VIRGINIA ELECTRIC AND POWER COMPANY (DOMINION ENERGY VIRGINIA)
SURRY POWER STATION UNITS 1 AND 2
UPDATED FINAL SAFETY ANALYSIS REPORT – REVISION 55

Pursuant to 10 CFR 50.71(e), Dominion Energy Virginia submits Revision 55 to the Updated Final Safety Analysis Report (UFSAR) for Surry Power Station (SPS).

The complete SPS UFSAR, Revision 55, is provided in Enclosure 1 and contains Security-Related Information that Dominion Energy Virginia requests be withheld from public disclosure in accordance with 10 CFR 2.390. A public version of the SPS UFSAR, Revision 55, is included in Enclosure 2.

A list and brief description of changes since the previous annual update is provided in the Revision Summary located in the Frontmatter of each enclosure. Third-party documents included by reference in the SPS UFSAR may not be text searchable.

If you have any questions or require additional information regarding this submittal, please contact Gary D. Miller at (804) 273-2771.

Sincerely,

James E. Holloway
Vice President – Nuclear Engineering & Fleet Support

COMMONWEALTH OF VIRGINIA)
)
COUNTY OF HENRICO)

The foregoing document was acknowledged before me, in and for the County and Commonwealth aforesaid, today by James E. Holloway, who is Vice President – Nuclear Engineering & Fleet Support of Dominion Energy Virginia. He has affirmed before me that he is duly authorized to execute and file the foregoing document in behalf of that Company, and that the statements in the document are true to the best of his knowledge and belief.

Acknowledged before me this 28th day of September 2023.
My Commission Expires: March 31, 2026

Revision 49—09/28/17 (continued)

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
Table 11.3-5 and Table 11.3-6 [SPS-UCR-2016-009]	Update reflects replacement of the Surry Radwaste Facility ventilation particulate and noble gas monitors.
3.5.2.1 [SPS-UCR-2016-008]	Modified to add description of use of demonstration or lead fuel assemblies.
9.1.3.1, Table 9.1-2, Figure 9.1-1, 9.10.1, 9.10.3.2 [SPS-UCR-2016-007]	Updated to reflect isolation of reactor coolant pump seal cooling and the charging cross-connect during fire events.
14.5.1.4, 14.5.1.7, Table 14.5-1, Table 14.5-6 [SPS-UCR-2016-010]	Updated peak cladding temperatures.
14B.5.1.6.1 [SPS-UCR-2016-011]	Modified high energy line inspection for consistency with technical requirements manual.

Revision 48—09/29/16

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
9.10.1, 9.10.2.1, 9.10.2.2.5, 9.10.2.2.8, 9.10.2.2.9, 9.10.2.8 [SPS-UCR-2016-005]	Update reflects code evaluations completed to address code deficiencies are included in the Appendix R report.
7.4.3.2 [SPS-UCR-2015-008]	Corrected source range pre-amplifier self test frequencies.
Figure 15.1-2 [SPS-UCR-2016-006]	Added note to Figure that refers the reader to the referenced drawing.
3.5.2.6.1 [SPS-UCR-2015-020]	Update reflects ASME revised stress criterion for optimized Zirlo^{TM} high performance fuel cladding
14.1, 14.2.7.2, 14.2.9.1.1, 14.4.1.2 [SPS-UCR-2016-003]	Update reflects increased statistical/deterministic Fdelta H limits
Table 4.1-5, 9.1.2.1 [SPS-UCR-2015-001]	Update reflects reactor coolant pump abeyance seal upgrade

Click on Change Package Number Highlighted in Red to View Change Request.

Revision 48—09/29/16 (continued)

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
9.10.4.8 [SPS-UCR-2015-009]	Update clarifies component cooling pump classification.
Table 5.2-1, Table 5.2-2, 6.2.2.1.4, 6.3.1.3.4, 9.1.2.1, 10.3.5.2 [SPS-UCR-2012-011]	Update reflects addition of FLEX mechanical connections to the AFW, CH, CS & SI systems to mitigate effects of a Beyond Design Basis Event.
9.10.2.6, 7.7.1 [SPS-UCR-2014-014]	Update reflects addition of communication equipment for offsite communication to mitigate effects of a Beyond Design Basis Event.
7.7.2, 7.10.2, 8.4.3, 9.1.2.1, 10.3.1.2, 14.3.1.5 [SPS-UCR-2015-010]	Update reflects addition of electrical and mechanical connections to the remote monitoring panels, CH, and backup IA systems to mitigate effects of a Beyond Design Basis Event.
8.4.5 [SPS-UCR-2015-017]	Reflects using LEDs for emergency lighting systems.
8.4.6 [FS-2008-005]	Updated to reflect the TSC Alternate Power Source - Final Package
6.2.2.2.4, 9.3.2.2.3 [SPS-UCR-2010-027]	Updated to reflect MOVs with the pressure locking modification
Table 14.5-6 [SPS-UCR-2015-011]	Reflects the Westinghouse LBLOCA error
10.3.3.1, 14b.5.1.6.1, 18.2.1 [SPS-UCR-2015-016]	Update reflects Relocation of TS augmented inspection requirements (except RCP flywheel) to the TRM
2.2.1.2, Table 2.2-8, Table 2.2-9, Table 11A-4, Table 11A-5, Table 11A-6, Table 11A-7 [SPS-UCR-2015-018]	Revised the Primary Met Tower Instrument Height

Click on Change Package Number Highlighted in Red to View Change Request.

Revision 47—09/30/15

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
6.2.2.2.4 [SPS-UCR-2011-001]	Reflects additional MOV pressure locking valve modifications.
3.5.2.1, 3.5.2.1.2, Table 3.5-3, Figure 3.5-9 [SPS-UCR-2015-006]	Reflects implementation of the Westinghouse integral nozzle design
9.8.1, 9.8.2, Table 9,8-1, 9.10.1, 10.3.9.3, Table 10.3-4, Figure 10.3-11 [SPS-UCR-2010-010]	Reflects the Compressed Air System Upgrade
9.10.1 [SPS-UCR-2013-014]	Update to include the Beyond Design Basis Storage Building
3.5.2.3 [SPS-UCR-2014-001]	Reflects Re-Insertion of Secondary Source Assemblies – Bounding Configuration
14.5.3.4.1, References 55, 56, 57, 58, 59, and 60, Table 14.5-18, 15.6.2.1, 15.6.2.2.1 [SPS-UCR-2015-014]	Update to include Beyond Design Basis Offsite Communications
3.6.1.1 [SPS-UCR-2015-005]	Revised Direct Power Distribution Measurements for Start-Up to be made at 50% RTP rather than 30% RTP
Figure 8.3-1 [SPS-UCR-2015-013]	Update to include the 500kV Switchyard Circuit Breaker CB58202 Tie-in Interim Package
8.3, Figure 8.3-1 [SPS-UCR-2014-003]	Reflects Removal of the 1G/2G 34.5KV Overhead Feeders
14.2 Refs, 14.3 Refs, 14B Refs [SPS-UCR-2015-003]	Incorporates Topical Report VEP-FRD-41, Rev. 02.
4.2.2.4, 9.1.2.6.9, 9.1.2.6.12, 9.1.2.6.13 [SPS-UCR-2015-004]	Reflects removal of the RCP Floating Ring Seal.
Table 5.4-17, Table 6.2-12, Figures 6.3-6 through 6.3-13, 8.5 [SPS-UCR-2015-002]	Update reflects the revised Surry Recirculation Spray Pump NPSH.
18.2.9 [SPS-UCR-2014-024]	License Renewal - update clarifies the responsibilities for General Condition Monitoring.

Click on Change Package Number Highlighted in Red to View Change Request.

Revision 47—09/30/15 (continued)

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
9.10.1, 9.10.4.14 [SPS-UCR-2014-010]	Update reflects Beyond Design Basis installation of spent fuel pool external make-up water source.
3.2.1, 3.5.2.6.2.1, 3.5 Refs [SPS-UCR-2014-019]	Update reflects Westinghouse revised clad corrosion model for ZIRLO and Optimized ZIRLO.
3.2.3.3, 3.2 Refs, Table 3.2-1, 3.3.2.3, 3.4.2.3, 3.4.3.2, 3.4 Refs, 4.2.9, 14.1, 14.1 Refs, 14.3.2.1, 14.3.2.3 [SPS-UCR-2014-021]	Update reflects discussion of the W-3 Alternate DNB correlations approved in Appendix D to DOM-NAF-2-P-A and increase to technical specification minimum temperature for criticality.
9.5.1 [SPS-UCR-2013-007]	Update reflects installation of wide range spent fuel pool instrumentation.
18.2.19, Table 18-1 [SPS-UCR-2014-012]	Update reflects that work control inspections for license renewal are required to be performed by a VT qualified individual.
5.5.3, 5.5.4, 5.5.6, 5.5.7 [SPS-UCR-2014-017]	Update replaces reference to Regulatory Guide 1.163 with NEI 94-01, Revision 3-A.
Figure 9.12-1 [SPS-UCR-2014-018]	Updated figure for Fuel Transfer System.
18.2.16, 18.5 Refs [SPS-UCR-2014-020]	Modify reflects program name change from Secondary Piping and Component Inspection program to Flow Accelerated Corrosion program.

Revision 46—Updated Online 09/30/14

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
Table 9.10-1 [SPS-UCR-2009-009]	Update corrects horsepower value for the replacement diesel-driven fire pump.
9.10.2.2.2, Table 9.10-1 [FS-2008-010]	Update reflects replacement of the diesel-driven fire pump.

Click on Change Package Number Highlighted in Red to View Change Request.

Revision 46—Updated Online 09/30/14 (continued)

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
9.10.2.6, 9.10.4.5, 9.10.4.6 [SPS-UCR-2014-008]	Clarified description of the Appendix R equipment located in Normal Switchgear and Cable Tray Rooms.
9.10.2.2.2, 9.10.4.24, Table 9.10-1 [SPS-UCR-2014-011]	Update reflects replacement of the diesel-driven fire pump fuel tank.
3.5.2.3, 9.1.2.3.1, 9.1.2.3.2.5 [SPS-UCR-2014-009]	Update reflects the re-insertion of secondary source assemblies for Unit 2.
11.2.3, 11.3.2.10, 11.3 Refs [SPS-UCR-2014-006]	Radiation protection description updated to include the Steam Generator Storage Facility.
Table 14.5-6 [SPS-UCR-2014-007]	Table updated to reflect a post analysis of record evaluation performed to assess the effect of an error in the HOTSPOT burst strain model on peak cladding temperature for the large break loss of coolant accident.
5.1, Table 5.4-11, Table 5.4-12, Table 5.4-13, Table 5.4-17, Figure 5.4-3, Figure 5.4-4, Figure 5.4-5, Table 6.2-4, Table 6.2-13, Figure 6.3-6, Figure 6.3-10 [SPS-UCR-2014-004]	Update implements revised LOCA containment safety analysis.
9.10.2.2.1 [SPS-UCR-2014-002]	Updated the Fire Protection System description to reflect backup water supply.
10.3.5.2 [SPS-UCR-2014-005]	Updated the Condensate System description to reflect use as backup water for the Fire Protection System in an emergency.
4.1.7.3, 4.1 Refs [SPS-UCR-2013-017]	Update reflects the Westinghouse documents related to MUR Uprate Fluence Evaluations.
Table 9.7-1 [SPS-UCR-2012-003]	Update reflects replacement of the last (4 of 4) containment sump pump.
Figure 8.3-1 [SPS-UCR-2013-013]	Update reflects final configuration of 34.5 kV switchyard modifications.

Click on Change Package Number Highlighted in Red to View Change Request.

Revision 46—Updated Online 09/30/14 (continued)

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
Table 14.5-6 [SPS-UCR-2013-011]	Update reflects post analysis of record evaluation performed to assess the effects of revised heat transfer coefficient multiplier distributions on peak cladding temperature for the large break loss of coolant accident.
9.10.2.1 [FS-2007-007]	Update reflects Fire Detection System replacement - final configuration.
14.5.1.6, 14.5.3.2, 14.5, 15A.3.3, 15.A.6, 15A, Table 15A-5, Table 15A-6, Table 15A-7, Table 15A-8, Table 15A-9 [SPS-UCR-2013-009]	Update reflects the updated reactor vessel lower radial key stiffness value.
3.5.2.1, 3.5.2.1.4, 3.5, Figure 3.5-10 [SPS-UCR-2013-010]	Update reflects incorporation of the Robust Protective Grid and modified Debris Filter Bottom Nozzle to the 15 x 15 upgrade fuel assemblies.
15.5.1.11.2 [SPS-UCR-2013-015]	Modify corrected the tornado missile velocity requirement.

Revision 45—09/30/13

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
14.3.3.2.3.1, 14.3.3.2.3.2, 14.3.3.2.3.3, 14.3.3.2.3.4, Table 14.3-6, Figure 14.3-25, Figure 14.3-27 [SPS-UCR-2013-008]	Reflects implementation of a revised rod ejection analysis (ETE-NAF-2013-0052, Rev. 0).
9.10.4.12 [SPS-UCR-2013-004]	Update reflects removal of the stator cooler oil collection trays from the reactor coolant pump oil collection system.
Table 9.7-1 [SPS-UCR-2013-001]	Update reflects replacement of 3 of 4 containment sump pumps.
9.8.1, 9.8.2, 9.8.3, Table 9.8-1, Figure 9.8-1, 9.10.1 [SPS-UCR-2013-002]	Update reflects interim configuration of the compressed air system upgrade.

Click on Change Package Number Highlighted in Red to View Change Request.

Revision 45—09/30/13 (continued)

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
Table 4.1-5, 9.1.2.1 [SPS-UCR-2011-026]	Update reflects all reactor coolant pumps now using Flowserve N-9000 seal.
10.3.1.4, 10.3.5.2, Figure 10.3-8 [SPS-UCR-2013-005]	Condensate System description updated to reflect installation of Unit 2 air in-leakage subsystem.
11.3.3, 11.3.3.14 [SPS-UCR-2011-009]	Updated description for new monitors on main steam lines and turbine driven auxiliary feedwater pump.
7.2.2.1.1, 8.2 [SPS-UCR-2011-019]	Station service transformers description updated to reflect replacement cables.
18.2.7 [SPS-UCR-2011-020]	License renewal section updated to correctly identify damper housings inspection requirements.
18.2.9, 18.2.19 [SPS-UCR-2011-032]	License renewal section updated to clarify commitments associated with general condition monitoring and work control process.
18.1.2, Table 18-1 [SPS-UCR-2012-006]	License renewal section updated to indicate commitment 9 is now complete.
18.2.15, Table 18-1 [SPS-UCR-2012-007]	License renewal section updated to indicate commitment 14 is now complete.
Figure 9.9-1 [SPS-UCR-2012-013]	Service Water System figure updated to reflect Unit 1 flash evaporation demineralizer assembly demolition.
2.5.3.1, Table 2.5-2 [SPS-UCR-2012-012]	Additional information clarifies earthquake history is based on a specific timeframe.
Table 14.5-6 [SPS-UCR-2012-005]	Table updated to reflect post analysis of record evaluation performed to assess the effects of fuel thermal conductivity degradation on peak cladding temperature for the large break loss of coolant accident.
Figure 3.5-9 [SPS-UCR-2012-010]	Figure modified to add fuel type descriptor that was previously omitted.

Click on Change Package Number Highlighted in Red to View Change Request.

Revision 44—09/27/12

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
9.10.2.1 [SPS-UCR-2012-008]	Fire Detection System updated to reflect replacement of some of the Robertshaw panels with SimplexGrinnell panels.
Table 9.5-3 [SPS-UCR-2010-028]	Table updated to reflect alternate power sources for the spent fuel pool pump motor.
10.3.1.2 [SPS-UCR-2012-001]	Steam generator blowdown discussion updated to reflect rerouting of piping.
Table 9.13-1 [SPS-UCR-2011-029]	Main control room and emergency switchgear and relay room ventilation data updated to reflect minimum air flow required to maintain design ambient conditions following a bounding event.
18.2.15 [SPS-UCR-2011-031]	License Renewal commitment on reactor vessel internals guide cards updated.
14.5.1.7, Table 14.5-5, Table 14.5-6 [SPS-UCR-2012-002]	Best estimate large break loss of coolant accident analysis description updated to reflect change to containment heat sink surface areas.
10.3.5.2, Figure 10.3-9 [SPS-UCR-2009-001]	Update reflects installation of the ultrasonic flowmeters in the feedwater lines.
9.1.2.6.5 [SPS-UCR-2010-024]	Deborating demineralizer discussion updated to reflect use of deborating vessel as cation demineralizer.
14.2.9.2.4.2, Table 14.2-2, Table 14.2-4, 14.4.1.2.1, 14.4.1.2.2, 14.4.1.3.1, 14.4.1.3.2, 14.4, Table 14.4-1, Table 14.4-2, Table 14.4-5 [SPS-UCR-2011-008]	Updated design basis accident radiological analyses for the fuel handling accident and locked rotor analysis.
11.1 [SPS-UCR-2011-023]	Updated radiation protection description to reflect an upgrade to the Station’s self contained breathing apparatus.
10.3.5.2 [SPS-UCR-2010-026]	Auxiliary feedwater discussion updated for use of Carbohydrazide for startup of Unit 1.

Click on Change Package Number Highlighted in Red to View Change Request.

Revision 44—09/27/12 (continued)

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
10.3.5.2 [SPS-UCR-2011-006]	Auxiliary feedwater discussion updated for use of Carbohydrazide for startup.
18.1.3, Table 18-1 [SPS-UCR-2011-014]	License Renewal commitment on tank inspections updated.
18.1.4 [SPS-UCR-2011-028]	License Renewal commitment on non-EQ cable inspections updated.
18.2.19 [SPS-UCR-2011-030]	License Renewal completion of work control audit commitment updated.
1.2.7, Figure 10.2-3, Figure 10.2-4, 10.3.3.1, 10.3 Refs, Figure 10.3-1, 14.2.13, 14.2.13.1, 14.2.13.2, 14.2.13.3, 14.2 Refs, Figure 14.2-72, Figure 14.2-73, Figure 14.2-74, Figure 14.2-75, Figure 14.2-76, Figure 14.2-77, Figure 14.2-78 [SPS-UCR-2009-017]	Updated descriptions and associated analyses to reflect Unit 1 turbine retrofit.

Revision 43—09/29/11

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
4.1.7.1, 4.1 Refs, Table 4.1-14, Table 4.1-15, 4.2.5, 4.3.3.2, 4.3.4, 4.3 Refs, Table 4.3-3, Table 4.3-4 [SPS-UCR-2010-007]	Update reflects increase to the cumulative core burnup applicability limit (effective full power years) for reactor coolant system pressure/temperature limits, low temperature overpressure protection system setpoints and low temperature overpressure protection system enabling temperature, to 48 effective full power years.
Table 3.2-1 [SPS-UCR-2011-025]	Modification reflects correction of departure from nucleate boiling ratio limit type on DNBR Limits Table.
6.2.2.2.4 [SPS-UCR-2010-017]	Update reflects current listing of motor operated valves that incorporate a pressure locking modification.

Click on Change Package Number Highlighted in Red to View Change Request.

Revision 43—09/29/11 (continued)

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
18.1.2, 18.2.6, Table 18-1 [SPS-UCR-2011-010]	License Renewal completion of concrete aging commitment updated.
18.3.5.3, Table 18-1 [SPS-UCR-2011-011]	License Renewal implementation of Alloy Management Program commitment updated.
18.2.7, Table 18-1 [SPS-UCR-2011-012]	License Renewal completion of fire protection piping aging effects commitment updated.
18.2.19 [SPS-UCR-2011-016]	License Renewal Work Control Process audits commitment updated.
18.2.7, Table 18-1 [SPS-UCR-2011-017]	License Renewal completion of fire protection sprinkler commitment updated.
18.3.2.4 [SPS-UCR-2011-021]	License Renewal added dates the inspection of the pressurizer surge lines was completed.
Table 18-1 [SPS-UCR-2011-022]	License Renewal completion of worker qualification commitment updated.
6.2.2.2.3, 9.1.2.6.21 [SPS-UCR-2010-015]	Globe valve description updated.
9.10.4.12 [SPS-UCR-2010-031]	Fire protection description updated to reflect addition of an oil collection assembly on each reactor coolant pump stator cooler.
8.2, 10.3.3.2, Table 10.3-4, Figure 10.3-11 [SPS-UCR-2010-032]	Update reflects upgrading the isolated phase bus duct for both Units.
3.5.2.2 [SPS-UCR-2010-014]	Updated section to reflect a replacement batch of enhanced performance control rod assemblies will be placed in service for cycle 24 operation.
4.1.7.1, 4.1 Refs, Table 4.1-12, Table 4.1-13 [SPS-UCR-2011-007]	Updated the reactor vessel surveillance capsule withdrawal schedule for 60-year operation.
2.3.1.2.2 [SPS-UCR-2010-008]	Updated emergency service water pump house discussion to reflect addition of missile shield.

Click on Change Package Number Highlighted in Red to View Change Request.

Revision 43—09/29/11 (continued)

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
9C.2 [SPS-UCR-2011-003]	Appendix on flooding updated to reflect the high level stop log roller removal.
14.2.9.2.4.3 [SPS-UCR-2011-005]	Modified locked rotor accident discussion to make it consistent with other sections.
1.1.5, 1.1.6, 3.2.2.1, 3.2.2.7, 3.2.3.3, 3.2 Refs, Table 3.2-1, Table 3.2-2, Table 3.2-3, 3.3.3.2.2, 3.4.1, 3.4.1.1.2, 3.4.1.1.4, 3.4.1.2, 3.4.1.3, 3.4.2, 3.4.2.1, 3.4.2.2, 3.4.2.3, 3.4.3.1, 3.4.3.2, 3.4.3.3, 3.4.3.4, 3.4.3.5, 3.4.3.6 (new), 3.4 Refs, Table 3.4-1, 3.5, 3.5.2.1, 3.5.2.1.2, 3.5.2.1.3, 3.5.2.1.4, 3.5.2.1.5, 3.5.2.6.1, 3.5 Refs, Table 3.5-3, Figure 3.5-9, Figure 3.5-17 (new), Table 4.3-1, Table 4.3-2, 9.1.2.3.2.1, 9.1.3.6, 9.1 Refs, 14.1, 14.1 Refs, 14.2.1.1, 14.2.1.2, 14.2.2.1, 14.2.2.2, 14.2.4.1, 14.2.7.2, 14.2.7.3.2, 14.2.7.4, 14.2.8.1, 14.2.9.1.1, 14.2.9.1.2, 14.2.9.1.7, 14.2.9.2.1, 14.2.9.2.2.2, 14.2.10.2, 14.2.10.3, 14.2 Refs, 14.3.2.1, 14.3.2.3, 14.3.3.2.1, 14.3 Refs, 14.4.1.1, 14.4 Refs, 14.5.1.5, 14.5.1.6, 14.5.1.7, 14.5.2.4.2, 14.5.2.5, 14.5.2.6, 14.5.3.4.1, 14.5.3.4.2, Table 14.5-1, Table 14.5-2, Table 14.5-3, Table 14.5-5, Table 14.5-6, Table 14.5-7, Table 14.5-13, Table 14.5-17, Table 14.5-18 (new), Figure 14.5-1, Figure 14.5-2, Figure 14.5-3, Figure 14.5-4, Figure 14.5-5, Figure 14.5-6, Figure 14.5-7, Figure 14.5-8, Figure 14.5-9, Figure 14.5-10, Figure 14.5-11, Figure 14.5-12, Figure 14.5-13, Figure 14.5-14, Figure 14.5-76, 15A.5, 15A.5.2.5, 15A.6 (new), 15A Refs, Table 15A-8 (new), Table 15A-9 (new) [SPS-UCR-2009-023]	Updated descriptions and associated analyses to reflect implementation of the Westinghouse 15 x 15 upgrade fuel design.

Revision 43—09/29/11 (continued)

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
1.2.7, Figure 10.2-1, 10.3.1.1, 10.3.3.1, 10.3 Refs, Figure 10.3-1, 14.2.13.1 (new), 14.2.13.2, 14.2.13.3, 14.2 Refs, Figure 14.2-81, Figure 14.2-82, Figure 14.2-83 (new), Figure 14.2-84 (new), Figure 14.2-85 (new), Figure 14.2-86 (new), Figure 14.2-87 (new) [SPS-UCR-2009-012]	Updated descriptions and associated analyses to reflect Unit 1 turbine retrofit.
1.1.6, 3.5 Refs [SPS-UCR-2011-004]	Discussion corrected to state that mid-grids are made of ZIRLO and NOT Optimized ZIRLO.
Table 9.7-1 [SPS-UCR-2009-024]	Updated pump data for Unit 1 containment sump pump replacements.
Table 4.1-5, 9.1.2.1 [SPS-UCR-2010-012]	Revised description of reactor coolant pump seal leakoff to reflect Flowserve N-9000 seals.
8.2, 10.3.3.2, Table 10.3-4, Figure 10.3-11 [SPS-UCR-2010-013]	Revised discussion on isolated phase bus duct coolers to reflect Unit 1 upgrade.
9.10.4.12 [SPS-UCR-2011-002]	Updated discussion to reflect addition of reactor coolant pump stator cooler outlet trough oil collection assemblies.
Table 18-1 [SPS-UCR-2010-018]	Updated license renewal commitment related to alloy 82/182 weld material.
18.2.15, 18.5 Refs [SPS-UCR-2010-022]	Updated license renewal commitment to perform enhanced inspections of reactor vessel internals in accordance with EPRI MRP-227.
3.5.2.2 [SPS-UCR-2010-025]	Reflects replacement of enhanced performance control rod assemblies for Unit 1 cycle 24 operation.
9.10.4.8, 9.10 Refs, 9.13.3.1 [SPS-UCR-2010-033]	Removed requirement to use 1-VS-F-58B after an Appendix R fire to ventilate the charging pump cubicles.

Click on Change Package Number Highlighted in Red to View Change Request.

Revision 43—09/29/11 (continued)

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
1.1, 1.1.2, 1.1 Refs, 3.2.1, 3.3.3.2.2, 3.4.1.3, Table 3.4-1, 4.1.7.1, 4.1.7.3, 4.1.7.4, 4.1 Refs, Table 4.1-2, Table 4.1-4, Table 4.1-5, Table 4.1-8, Table 4.1-14, Table 4.1-15, 4.2.5, 4.3.3.2, 4.3.4, 4.3 Refs, 5.3.1.1, 5.4.1.2, 5.4.3.1, 5.4.3.2.2, Table 5.4-1, Table 5.4-17, 6.2.1.1, 7.2.2.5, 7.3.2.6.1, 8.1, 9.1.2.2, 9.1.2.3.2.6, Table 9.1-4, Table 9.1-5, Table 9.1-6, Table 9.1-7, 9.4, 9.5, 9.9, 9.13.3.6, Figures 10.2-1 thru Figure 10.2-4, 10.3.1, 10.3.1.1, 10.3.1.2, 10.3.2, 10.3.3, 10.3.4, 10.3.5,10.3.5.2, 10.3.5.3, 10.3.9, Table 10.3-4, 11.2.5.1, Table 11.2-2, Table 11.2-3, 11.3.2.2, Table 11.3-3, Table 11A-1, 14.1, 14.1 Refs, 14.2.1.1, 14.2.1.2, 14.2.2, 14.2.2.1, 14.2.2.3, 14.2.4.1, 14.2.4.2, 14.2.4.3, 14.2.7.1, 14.2.7.2, 14.2.7.3.1, 14.2.7.3.2, 14.2.8, 14.2.8.1, 14.2.8.2, 14.2.8.3, 14.2.9.1, 14.2.9.1.1, 14.2.9.1.2, 14.2.9.1.6, 14.2.9.2.2.1, 14.2.9.2.2.2, 14.2.9.2.4.1, 14.2.9.2.4.3, 14.2.10.2, 14.2.10.3, 14.2.10.4.2, 14.2.10.5, 14.2.11.1, 14.2 Refs, Table 14.2-1, Table 14.2-2, Table 14.2-3, Table 14.2-4, Figure 14.2-1, Figure 14.2-2, Figure 14.2-3, Figure 14.2-4a, Figures 14.2-5 thru Figure 14.2-14, Figure 14.2-16, Figure 14.2-21, Figure 14.2-23, Figures 14.2-27 thru Figure 14.2-42, Figure 14.2-45, Figure 14.2-49, Figure 14.2-50, Figure 14.2-51, Figure 14.2-55, Figure 14.2-56, Figure 14.2-62, Figure 14.2-67, [SPS-UCR-2009-022]	Reflects the Measurement Uncertainty Recapture Power Uprate.

Click on Change Package Number Highlighted in Red to View Change Request.

Revision 43—09/29/11 (continued)

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
Figure 14.2-68, 14.3.1.2, 14.3.1.3, 14.3.1.4.3, 14.3.1.4.4, 14.3.2.1, 14.3.2.3, 14.3.2.4.2, 14.3.2.4.4, 14.3.2.5, 14.3.3.1.2, 14.3.3.2.2, 14.3.3.2.2.5, Tables 14.3-4 thru 14.3-11, Table 14.3-13, Table 14.3-15, Table 14.3-16, Figures 14.3-1 thru 14.3-9, Figure 14.3-14, Figure 14.3-19, Figure 14.3-24, Figure 14.3-26, 14.4.1.3.1, 14.4.2.1, Table 14.4-6, 14.5.2.3, 14.5.5, Table 14.5-1, Table 14.5-13, Appendix 14A, Table 14A-1, Table 14A-2 [SPS-UCR-2009-022]	(continued)
14.3.1.4.4, 14.3.2.4.4 [SPS-UCR-2010-030]	Removed discussion of 20 gpd primary to secondary leakage limit for Unit 1 B steam generator.
Table 9.7-1 [SPS-UCR-2010-034]	Updated pump data for Unit 2 containment sump pump replacements.
10.3.5.2, Figure 10.3-9 [SPS-UCR-2009-014]	Update reflects installation of the ultrasonic flowmeters in the feedwater lines.
10.3.1.2 [SPS-UCR-2010-020]	Description of the feedwater flow distribution removed to reflect new J-nozzle design, which provides even distribution.

Revision 42—09/30/10

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
14.2.9.1.6, Figure 14.2-49, Figure 14.2-50, Figure 14.2-55, Figure 14.2-56 [SPS-UCR-2010-019]	Loss of Reactor Coolant Flow Analysis updated to reflect the DNB transient for the underfrequency and undervoltage events in the LOFA reanalysis.
Table of Contents, List of Tables, List of Figures for following chapters: 9, 11, 14, & 15 [SPS-UCR-2010-021]	Table of Contents modified to include the Appendices Table of Content.

Click on Change Package Number Highlighted in Red to View Change Request.

Revision 42—09/30/10 (continued)

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
9.10.1, 9.10.2.2.5, 9.10.4.19 [SPS-UCR-2009-027]	Fire Protection discussions updated to include the addition of the Turbine Deck Security Office.
15A.3.2, 15A Refs [SPS-UCR-2010-009]	Modified references to reflect procedures updated.
9.9.2 [SPS-UCR-2010-011]	Modified the total flow for each intake structure to be consistent with the circulating water pump flow rate.
7.7.2, 11.3.6 [SPS-UCR-2010-003]	Removed discussion of the Main Control Room Bottled Air System.
11.2.3.2 [FS-2003-045]	Final configuration reflects portions of the blowdown water treatment subsystem that are no longer used at the station.
9.10.2.1 [SPS-UCR-2010-002]	Interim configuration reflects portions of the Surry Fire Detection System that have been replaced.
11.2.3.2 [SPS-UCR-2010-005]	Corrects FS 2003-045 to reflect portions of the blowdown water treatment subsystem that is no longer in use.
2.1.5.2, 2.1 Refs [SPS-UCR-2010-006]	Adds a new reference to Chapter 2.
6.2.2.2.13, 6.3.1.2.5 [SPS-UCR-2009-003]	Description of the containment strainer assembly seals was updated to reflect installation of the U2 seal closure frames.
7.2.1.1, Table 7.5-2, 7.7.2, 9.10.4.17, 9.13.2, 9.13.3.6, 9.13.4.1, 9.13.4.2, Table 9.13-1, 14.2.9.2.4.3, 14.3.1.4.4, 14.3.2.4.4, 14.4.1.2.1, 14.4.1.3.1, 14.5.5.2 [SPS-UCR-2009-026]	Discussion of the Main Control Room Bottled Air System was removed.
10.3.5.2 [SPS-UCR-2009-028]	A discussion was added describing the use of Carbohydrazide for startup of Unit 2 using Auxiliary Feedwater.
9.1, 9.1.2.6.23, Figure 9.1-1 [FS 2007-014]	Reflects installation of Zinc Injection System for Unit 1.
9.1, 9.1.2.6.23, Figure 9.1-1 [FS 2008-023]	Reflects final configuration of Zinc Injection System.

Click on Change Package Number Highlighted in Red to View Change Request.

Revision 42—09/30/10 (continued)

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
4.1.7.1, 4.1.7.3, Table 4.1-13 [SPS-UCR-2009-021]	Clarifies the capsule locations were original locations. Annotates Table to reflect relocation of Surry Unit 2 surveillance capsule U.
Table 9.7-1 [SPS-UCR-2009-025]	Corrected the containment sump pump data to reflect the current pumps.
18.3.5.6 [SPS-UCR-2009-011]	Updated discussion on reactor coolant pump and ASME code case N-481.
4.2.2.4, Table 4.1-5, 9.1.2.1 [SPS-UCR-2009-019]	Revised description of reactor coolant pump seal arrangement to reflect the Flowserve N-9000 seal.
14.5.2.1, 14.5.2.3, 14.5.2.4.1, 14.5.2.4.2, 14.5.2.5, 14.2.5.6, 14.5 Refs, Table 14.5-13, Table 14.5-14, Table 14.5-15, Table 14.5-16, Table 14.5-17, Figure 14.5-15 through Figure 14.5-76 [SPS-UCR-2009-008]	Revised to incorporate the reanalysis of the Westinghouse small break loss of coolant accident (SBLOCA).

Revision 41—09/30/09

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
Figure 10.2-1 (sh 2), 10.3.3.2 [FS 2008-011]	Reflects the Unit 2 main generator change in hydrogen pressure.
10.3.5.2, 10.3.5.3 [FS 2007-020]	Clarified description of AFW system alignments to ensure minimum AFW flow requirements are met for design basis accident with the RCS above 350 degrees for both Units.
KWI [SPS-UCR-2009-020]	Removed key word index.
8.3, Figure 8.3-1 [SPS-UCR-2009-010]	Reflects the redirection of the 531 transmission line to Suffolk substation.
14.3.1.4.4, 14.3.2.4.4 [SPS-UCR-2009-013]	Reflects a 20 gpd leakage limit for Unit 1 B steam generator for operating cycle 23.
6.2.2.2.13, 6.3.1.2.5 [FS 2008-024]	Added a description of Unit 1 seal closure frames installed over the containment sump strainer flexible metal seals.

Click on Change Package Number Highlighted in Red to View Change Request.

Revision 41—09/30/09 (continued)

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
9.4.3.5 [SPS-UCR-2009-005]	Raised the upper pH limit of the charging pump component cooling water system.
8.3, Figure 8.3-1, 8.5 [FS 2005-026]	Incorporates addition of Bus 7 and breakers in switchyard.
6.2.2.2.6, 6.2.4, 6.2.4.1.5, 6.2 Refs [SPS-UCR-2009-004]	Added new section, “Gas Accumulation in ECCS Piping” in response to Generic Letter 2008-01.
14.5.1.7, Table 14.5-5, Table 14.5-6 [SPS-UCR-2009-006]	Incorporates increase of carbon steel surface area in containment and the impact on the best estimate large break loss of coolant accident analysis.
9B.1.1, 9B.2.1, 9B.1 Refs, Table 9B.2-1 [FS 2008-021]	Updated the discussion on heavy loads to include reliance on a RV head drop analysis and revised the weight of the U1 RV head and lifting device.
5.4.2.1.7, Table 5.4-12, Table 5.4-13, Table 5.4-17, 6.1, 6.2.3.11, 6.3.1.3.2 [SPS-UCR-2009-002]	Implements changes to the Surry containment analysis using revised IRS/ORS pump flowrates.
9.4.3.3 [FS 2007-028]	Removed description of Chilled Water circulating pump low suction pressure trip.
5.4.2.1.7, Table 5.4-12, Table 5.4-13, Table 5.4-17, Figure 5.4-3, Figure 5.4-4, Figure 5.4-5, 6.3.1.4.3, 9.4.1.1, 9.4.3.3, 9.9.1 [FS 2008-017]	Incorporates increasing the SW inlet (river water) temperature to 100 degrees in accordance with Technical Specification change request 397.
14.5.1.6, 14.5.1.7, Table 14.5-1, Table 14.5-2, Table 14.5-3, Table 14.5-4, Table 14.5-5, Table 14.5-6, Figure 14.5-1, Figure 14.5-2, Figure 14.5-3, Figure 14.5-4, Figure 14.5-5, Figure 14.5-6, Figure 14.5-7, Figure 14.5-8, Figure 14.5-9, Figure 14.5-10, Figure 14.5-11, Figure 14.5-12, Figure 14.5-13, Figure 14.5-14 [FS 2008-022]	Incorporated the results of a reanalysis of the Westinghouse Best-Estimate Large Break Loss of Coolant Accident (BE-LOCA) analysis using the Automated Statistical Treatment of Uncertainty Method (ASTRUM).
18.5 Refs [FS 2008-025]	Editorial - Updated UFSAR references to reflect current revisions for the steam generator management program.

Click on Change Package Number Highlighted in Red to View Change Request.

Revision 41—09/30/09 (continued)

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
6.2.2.1.3, 6.2.2.2.13, 6.2.3.11.1, 6.2.3.3, 6.2.4.1.4, 6.2 Refs, Table 6.2-3, 6.3.1.2.5, 6.3.1.3.1, 6.3.1.3.2, 6.3.1.3.3, 6.3.1.3.4, 6.3.1.4.1, 6.3.1.4.3, 6.3.1.4.4, 6.3 Refs Table 6.3-3 [FS 2007-011]	Updated various sections to reflect compliance with GSI-191 for the strainer assembly.
Table 4.1-1 [FS 2008-013]	Revised Low-Pressure trip setpoint to be consistent with TSCR 318.
3.5 Refs, 14.4 Refs [FS 2008-020]	Updated reference placeholders with standard reference information.
18.2.11, Table 18-1 [FS 2008-018]	Updated to reflect license renewal commitments that have been completed.
12.3, 12.3 Refs, KWI [FS 2008-019]	Added NEI 99-01 as a reference.

Revision 40—09/30/08

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
2.1.5.2, Table 2.1-4 [FS 2007-022]	Adds limitation on dimethylamine to chemical section.
9.10.2.2.7 [FS 2008-008]	Modifies description on the actuation of the Low Pressure CO_2 Fire Protection System dampers.
9.10.4.8, 9.10 Refs [FS 2008-009]	Reflects that forced ventilation of the charging pump cubicles is not required after an Appendix R fire.
8.3, Figure 8.3-1, 8.5 [FS 2008-014]	Reflects changes associated with partial implementation of modification to 34.5 kV switchyard buses 5 and 7.
8.4.1 [FS 2007-019]	Incorporates the disconnect of the auto start circuitry for the high pressure heater drain pumps.
6.3.1.3 [FS 2008-006]	Reflects the installation of the entire sump strainer for Unit 2.

Click on Change Package Number Highlighted in Red to View Change Request.

Revision 40—09/30/08 (continued)

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
8.4.6 [FS 2008-012]	Incorporates changes associated with partial implementation of the modification of D transfer bus breaker to supply power to the TSC MCC and TSC UPS from the ACC diesel generator.
Table 9.4-1, Table 9.4-8 [FS 2008-007]	Corrected component cooling water pump design parameters.
5.4.1.2, 5.4.1.3.3, 5.4.1.3.5.4, 5.4.1.4, 5.4.2.1.6, 5.4.3, 5.4 Refs, Table 5.4-1, Table 5.4-2, Table 5.4-3, Table 5.4-4, Table 5.4-5, Table 5.4-6, Table 5.4-7, Table 5.4-8, Table 5.4-9, Table 5.4-13, Table 5.4-14, Table 5.4-15, Figure 5.4-1, Figure 5.4-2, Table 6.2-12, Table 6.2-13 [FS 2008-003]	Incorporates the containment response using new mass and energy data tables. Updates the minimum NPSH valves.
10.3.5.3 [FS 2007-024]	Updated the total accuracy value for the auxiliary feed flow loop.
10.3.5.2, 10.3.5.3 [FS 2008-001]	Incorporated changes associated with the modification of the operator selector switches for the AFW discharge MOVs.
9.10.4.23 [FS 2008-004]	Corrected the value of the concrete wall thickness separating the two fuel oil pump houses.
6.3.1.3, 11.3.2.1, Table 11.3-2, Figure 11.3-2 [FS 2006-024]	Modifies text associated with Incore Sump Room Drain Modifications.
3.5.2.6.1, 3.5 Refs, 14.4.1.1, 14.4 Refs [FS 2006-033]	Modifies lead rod average burnup limit for Surry fuel.
Figure 6.1-1, 6.2, 6.2.2.2.13, 6.2.3.11.3, Table 6.2-3,Table 6.2-13, 6.3, 6.3.1.2.5, 6.3.1.3, 6.3.1.4, Table 6.3-1, Table 6.3-3, Figure 6.3-2, Figure 6.3-5 [FS 2007-025]	Modifies text to reflect changes associated with Containment Sump Strainer Design.

Click on Change Package Number Highlighted in Red to View Change Request.

Revision 40—09/30/08 (continued)

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
1.1.8, 1.4.49, 5.3.4.1, 5.3.4.3, 5.3 Refs, Table 5.3-5, 5.4, 5.4.1.1, 5.4.1.3.1, 5.4.1.3.2, 5.4.1.3.3, 5.4.1.3.4, 5.4.1.3.5.2, 5.4.1.3.5.3, 5.4.1.3.5.4, 5.4.1.3.5.5, 5.4.1.3.6, 5.4.1.4, 5.4.2, 5.4.2.1, 5.4.2.1.1, 5.4.2.1.2, 5.4.2.1.3, 5.4.2.1.4, 5.4.1.2.5, 5.4.2.1.6, 5.4.2.1.7, 5.4 Refs, Tables 5.4-6, 5.4-7, 5.4-8, 5.4-9, 5.4-10, 5.4-11, 5.4-12, 5.4-13, 5.4-14, 5.4-15, 5.4-16, 5.4-17, 5.4-18, 5.4-19, 5.4-20, 5.4-21, 5.4-22, 5.4-23, 5.4-24, & 5.4-25, Figures 5.4-1, 5.4-2, 5.4-3, 5.4-4, 5.4-5, 5.4-6, 5.4-7, 5.4-8, 5.4-9, 5.4-10, 5.4-11, 5.4-12, & 5.4-13, 6.2.2.1.4, 6.2.3.11.1, 6.2 Refs, Tables 6.2-11, 6.2-12, & 6.2-13, Figures 6.2-3, 6.2-4, 6.2-5, 6.2-6, & 6.2-7, 6.3.1.3, 6.3.1.4, Figures 6.3-7, 6.3-8, 6.3-9, 6.3-10, 6.3-11, 6.3-12, 6.3-13, 6.3-14, 6.3-15, 6.3-16, & 6.3-17, 14.5.4, 14.5.5, 14.5.5.2, 14.5.5.3, 14.5 Refs, Tables 14.5-7, 14.5-8, & 14.5-11, 14B.2.3.3.1, 14B.2.3.3.2.1, 15.5.1.2 [FS 2005-027]	Performed containment analyses and LOCA alternate source term analyses to support GSI 191 modifications Unit 1.
7.6.2.1 [FS 2006-035]	Removed information that specifies which flux thimble locations are plugged.
6.3.1.3, 7.5.1.3, Figure 7.5-2, Figure 7.5-3 [FS 2007-002]	Modified the refueling water storage tank engineered safety features actuation system to support GSI 191 containment sump modifications for Unit 1.
7.2, 7.2.1.8.6 [FS 2007-021]	Added replacement of the Westinghouse process modules with NUS Scientech modules.
1.1.8, 1.4.49, 14.5.4, 14.5.5, 14.5.5.2, 14.5.5.3, Table 14.5-8, Table 14.5-9, Table 14.5-12, 15.5.1.2 [FS 2008-002]	Editorial changes; clarifies final markups for GSI-191 multiple packages.
5.4.2.1.6, 5.4 Refs [FS 2007-023]	Revised text to describe an alternate containment analysis method that can be used for the calculation of NPSHa for the recirculation spray pumps, and containment pressure and sump temperature response.

Click on Change Package Number Highlighted in Red to View Change Request.

Revision 40—09/30/08 (continued)

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
14.5.1.1, 14.5.1.2, 14.5.1.3, 14.5.1.4, 14.5.1.5, 14.5.1.6, 14.5.1.7, 14.5.2.5, 14.5 Refs, Tables 14.5-1, 14.5-2, 14.5-3, 14.5-4, 14.5-5, & 14.5-6, Figures 14.5-1, 14.5-2, 14.5-3, 14.5-4, 14.5-5, 14.5-6, 14.5-7, 14.5-8, 14.5-9, 14.5-10, 14.5-11, 14.5-12, 14.5-13, 14.5-14, 14.5-15, 14.5-16, 14.5-17, 14.5-18, 14.5-19, 14.5-20, 14.5-21, 14.5-22, 14.5-23, 14.5-24, 14.5-25, 14.5-26, 14.5-27, 14.5-28, 14.5-29, 14.5-30, 14.5-31, 14.5-32, 14.5-33, 14.5-34, 14.5-35, 14.5-36, & 14.5-37 [FS 2006-021]	Incorporated an analysis performed for LBLOCA using the Westinghouse Best-Estimate Large Break Loss of Coolant Accident (BE-LBLOCA) analysis methodology using the Automated Statistical Treatment of Uncertainty Method (ASTRUM). Revised text for consistency and removed unnecessary references.
14.5.1.6, 14.5.1.7, 14.5.2.5, Table 14.5-6 [FS 2007-026]	Revised table to incorporate a penalty to PCT for the analysis performed for the LBLOCA analysis using the Westinghouse BE-LBLOCA analysis methodology using ASTRUM.
4.3.4.2 [FS 2007-013]	Clarified the description of the pressurizer PORV backup air supply.
14.5.2.5, 14.5.2.6, 14.5 Refs, Table 14.5-15 [FS 2007-009]	Updated peak cladding temperature for small break LOCA analysis for Westinghouse fuel.
14.5 Refs, Table 14.5-5 [FS 2007-010]	Updated peak cladding temperature for large break LOCA analysis for Westinghouse fuel.
9.1, 9.1.2.6.23, Figure 9.1-1 [FS 2007-018]	Installed the Unit 2 zinc injection system.
14.2.9.2.4.2, 14.2.9.2.4.3, 14.3.1.4.4, 14.3.2.4.2, 14.3.2.4.4, 14.3 Refs, Tables 14.3-9, 14.3-10, & 14.3-15 [FS 2006-005 & FS 2006-020]	Revised the steam generator tube rupture and main steam line break accident analyses to reflect the change in the technical specification allowable primary-to-secondary leakage rate. [10 CFR 50.90 License Amendment]
18.2.11, 18.2.13, 18.2.15 [FS 2007-017]	Corrected the description of the Inservice Inspection Plan.

Click on Change Package Number Highlighted in Red to View Change Request.

Revision 39—09/27/07

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
KWI, 12.4 [FS 2007-016]	Reflected the audit and review functions contained in the Nuclear Facility Quality Assurance Program Description.
1.1.8, 1.4.49, 5.3.4.1, 5.3.4.3, 5.3 Refs, Table 5.3-5, 5.4, 5.4.1.1, 5.4.1.3.1, 5.4.1.3.2, 5.4.1.3.3, 5.4.1.3.4, 5.4.1.3.5.2, 5.4.1.3.5.3, 5.4.1.3.5.4, 5.4.1.3.5.5, 5.4.1.3.6, 5.4.1.4, 5.4.2, 5.4.2.1, 5.4.2.1.1, 5.4.2.1.2, 5.4.2.1.3, 5.4.2.1.4, 5.4.1.2.5, 5.4.2.1.6, 5.4.2.1.7, 5.4 Refs, Tables 5.4-6, 5.4-7, 5.4-8, 5.4-9, 5.4-10, 5.4-11, 5.4-12, 5.4-13, 5.4-14, 5.4-15, 5.4-16, 5.4-17, 5.4-18, 5.4-19, 5.4-20, 5.4-21, 5.4-22, 5.4-23, 5.4-24, & 5.4-25, Figures 5.4-1, 5.4-2, 5.4-3, 5.4-4, 5.4-5, 5.4-6, 5.4-7, 5.4-8, 5.4-9, 5.4-10, 5.4-11, 5.4-12, & 5.4-13, 6.2.2.1.4, 6.2.3.11.1, 6.2 Refs, Tables 6.2-11, 6.2-12, & 6.2-13, Figures 6.2-3, 6.2-4, 6.2-5, 6.2-6, & 6.2-7, 6.3.1.3, 6.3.1.4, Figures 6.3-7, 6.3-8, 6.3-9, 6.3-10, 6.3-11, 6.3-12, 6.3-13, 6.3-14, 6.3-15, 6.3-16, & 6.3-17, 14.5.4, 14.5.5, 14.5.5.2, 14.5.5.3, 14.5 Refs, Tables 14.5-7, 14.5-8, & 14.5-11, 14B.2.3.3.1, 14B.2.3.3.2.1, 15.5.1.2 [FS 2007-027]	Performed containment analyses and LOCA alternate source term analyses to support GSI 191 modifications Unit 2.
4.1.7.1, 4.1.7.3, 4.1.7.4, 4.1 Refs, Tables 4.1-14 & 4.1-15, 4.2.5, 4.3.3.2, 4.3 Refs, Tables 4.3-3 & 4.3-4 [FS 2006-015]	Incorporated the revised RT_{PTS} values provided for the Reactor Vessel Integrity Program. [10 CFR 50.61]
4.3.4.2 [FS 2006-022]	Changed the description of the pressurizer PORV backup air supply.
Figure 6.1-2, 6.2.2.2.13, 6.2.3.11.3, Tables 6.2-3 & 6.2-12, 6.3.1.2.5, 6.3.1.3, Tables 6.3-1 & 6.3-3, Figures 6.3-3 & 6.3-5 [FS 2006-029]	Completed partial installation of Unit 2 containment sump strainers to support GSI 191 modifications.
6.3.1.3, 6.3.1.4, 11.3.2.1, Table 11.3-2, Figure 11.3-3 [FS 2006-014]	Added the Unit 2 incore sump room drain to support GSI 191 containment sump modifications.

Click on Change Package Number Highlighted in Red to View Change Request.

Revision 39—09/27/07 (continued)

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
6.3.1.3, Figure 6.3-17, 7.5.1.3, 7.5.2.1, Figures 7.5-2 & 7.5-3 [FS 2006-007]	Modified the Unit 2 refueling water storage tank engineered safety features actuation system to support GSI 191 containment sump modifications.
Figures 6.3-2 & 6.3-3 [FS 2006-012]	Modified the Unit 2 outside recirculation spray pumps' test loops.
7.3.2.4 [FS 2007-001]	Revised the description of pressurizer pressure control.
7.7.1, 7.9.1, 7.9.3, 8.2, 8.4.4, Figure 8.4-1, 9.10.2.1. [FS 2005-015]	Replaced the intake structure supervisory system in the low level intake structure and in the main control room.
7.7.2, 7.11.2, 8.4.3 [FS 2005-009]	Updated the description of the power supply for the remote monitoring panels.
9.1.2.1, 9.1.3.5.3, 9.6.3.1, 9.6.3.2, 9.10.3.3, 9C.2, 10.3.1.5, 11.3.4.2, 11.3.4.3, 11.3.4.4 [FS 2007-004]	Replaced "operable" terminology with "functional" terminology in accordance with Regulatory Issue Summary 2005-20.
Table 9.7-1 [FS 2006-034]	Updated the description of the component cooling heat exchanger pit sump pump shaft material.
9.10.4.18 [FS 2007-005]	Provided additional fire hazard analysis discussion in order to address Mechanical Equipment Room No. 4.
9.12.9, 9.12.9.1, 9.12.9.2, 9.12.9.3, 19.2 Refs, 9B.1.5 [FS 2007-003]	Revised the description of handling ISFSI cask systems.
9.14.2, Table 9.14-1 [FS 2005-024]	Added the dry shielded canister drain and reflood pumps.
Table 9.14-1 [FS 2004-017]	Replaced the spent fuel storage cask vacuum pumps.
10.3.1.1, 14.2.13 [FS 2006-032]	Modified the turbine overspeed protection control permissive logic and circuitry.
10.3.5.2, 10.3.5.3 [FS 2006-030]	Defeated the auto-open function for auxiliary feedwater flow isolation motor-operated valves.
Figure 10.3-10 [FS 2005-025]	Replaced chemical feed system pumps.

Click on Change Package Number Highlighted in Red to View Change Request.

Revision 39—09/27/07 (continued)

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
11.2.6.2, 11.3.3, 11.3.3.1, 11.3.3.2, 11.3.3.13, 11.3.3.14, Tables 11.3-5, 11.3-6, & 11.3-8 [FS 2005-012]	Replaced ventilation system radiation monitors.
14.2.11.1, 14.2.11.1.1, 14.2.12, Figures 14.2-73, 14.2-74, 14.2-75, & 14.2-76 [FS 2006-031]	Revised the analysis description of auxiliary feedwater flow following loss of normal feedwater and loss of AC power events.
18.1.4, 18.2.6, 18.2.13, 18.2.19, Table 18-1 [FS 2006-025]	Reflected the completion of License Renewal Commitment Item Nos. 4, 12, 18, 26, and 27.
18.3.2.4, Table 18-1 [FS 2007-008]	Reflected the completion of License Renewal Commitment Item No. 24.

Revision 38—09/29/06

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
2.1.2.1 [FS 2006-023]	Revised the Exclusion Area Boundary to be the site boundary. [10 CFR 50.90]
2.2.1.2 [FS 2004-016]	Clarified the description of the applicability of Regulatory Guide 1.23 to meteorological equipment.
3.1, 3.1 Refs, 3.3.1, 3.3.2.3, 3.3.2.13, 3.3.3.2.2, 3.5.2.1.5, 3.5.2.5, 3.5.2.6.3, 3.5.2.6.4, Table 3.5-3, Figure 3.5-15, 3.6.3.13 [FS 2006-006]	Incorporated the use of integral fuel burnable absorber (IFBA) rods.
Figures 6.3-2 & 6.3-3 [FS 2006-004]	Modified the Unit 1 outside recirculation spray pumps' test loops.
7.6.2.1 [FS 2006-017]	Isolated the flux thimble tube at location 1-RC-TW-J3.
8.5 [FS 2004-023]	Modified the #1 and #3 emergency diesel generators' auto start circuits.
8.5 [FS 2006-009]	Aligned the description of engineered safeguards equipment powered by each emergency bus with the list contained in Technical Specification 3.16 Basis.
9.8 [FS 2006-016]	Corrected the description of the containment instrument air compressors' capacity.

Click on Change Package Number Highlighted in Red to View Change Request.

Revision 38—09/29/06 (continued)

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
9C.1.2 [FS 2005-013]	Augmented the description of the water level monitoring system to include the Amertap pit monitors and a description of the system power supply.
10.3.1.1 [FS 2005-008]	Clarified the description of the turbine-driven auxiliary feedwater pump design and operating conditions.
10.3.3.2 [FS 2005-022]	Added the new Unit 1 generator and exciter ratings and revised the cooling water flow value for the Unit 1 generator hydrogen coolers.
10.3.5.4 [FS 2006-010]	Revised the description of auxiliary feedwater pump surveillance test and inspections. [10 CFR 50.90]
11.2.3.1.7, 11.2.4.1.1, 11.2.4.1.5, 11.2.4.2.2 [FS 2005-016]	Corrected the description of Radwaste Facility reducing and processing functions.
14.3.3.2.1, 14.3.3.2.3.1, 14.3.3.2.3.2, 14.3.3.2.3.3, 14.3.3.2.3.4, 14.3 Refs, Table 14.3-6, Figures 14.3-24, 14.3-25, 14.3-26, and 14.3-27 [FS 2006-001]	Reanalyzed the control rod assembly ejection accident in support of the transition to Integral Fuel Burnable Poison (IFBA) fuel.
14.5.1.6, 14.5.2.5, 14.5.2.6, 14.5 Refs, Tables 14.5-5 & 14.5-15 [FS 2006-003]	Incorporated the peak clad temperature penalties and benefits for the large break and small break LOCA associated with implementation of IFBA fuel. [10 CFR 50.46]
14.5 Refs, Table 14.5-5 [FS 2005-007]	Incorporated the peak clad temperature penalties and benefits for the large break LOCA. [10 CFR 50.46]
14.5 Refs, Table 14.5-5 [FS 2006-002]	Incorporated the peak clad temperature penalties and benefits for the large break LOCA. [10 CFR 50.46]

Click on Change Package Number Highlighted in Red to View Change Request.

Revision 38—09/29/06 (continued)

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
Chapter 17 (all) [QA 2004-002]	Replaced Chapter 17 in its entirety with a brief description of and reference to the recently implemented Topical Report DOM-QA-1. The Dominion Nuclear Facility Quality Assurance Program Description is based on ANSI/ASME NQA-1-1994 and will be maintained as a separate, single document for Dominion facilities. [10 CFR 50.54(a)]
18.2.12 [FS 2005-023]	Removed the ASME XI edition and addenda reference for containment inservice inspection to allow periodic update as required by regulation.

Revision 37—09/30/05

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
1.1, 1.4.41, 2.1.3.5, 4.3.5, 5.1, 6.2.1.1, 6.2.2.1.3, 7.2.1.8.3, 14.1, 15.2.1 [FS 2004-031]	Corrected citations to regulation and regulatory guide dose limits for design basis accident analysis.
3.6.3.2 [FS 2004-029]	Indicated that ultrasonic or x-ray testing is no longer performed for burnable poison rods beginning with Cycle 20.
4.2.2.2, 4.2.6 [FS 2004-018]	Updated the estimated pressurizer heatup rate during startup for a reduced heater capacity of 1200 kW.
4.2.7.2, 7.5.2.2, 7.5.3.5, 7.6.2.2, 7.9.2 [FS 2004-027]	Replaced the emergency response facilities computer system.
4.3.3.1, 4.3 Refs [FS 2004-026]	Extended the inspection interval for reactor coolant pump flywheels from 10 to 20 years. [10 CFR 50.90]
Tables 4.3-2 & 4.3-4 [FS 2004-028]	Revised the stress intensity value for the Unit 2 reactor vessel flange.
4.4.1.7, 6.2.2.2.4, 6.2.2.2.10, 6.2.4, 6.3.1.5.1, 6.3.1.5.2, 9.3.4, 9.4.5 [FS 2004-033]	Changed the ASME Code reference for inservice testing activities from Section XI to a general reference to the ASME Code.

Click on Change Package Number Highlighted in Red to View Change Request.

Revision 37—09/30/05 (continued)

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
Tables 5.2-1 & 5.2-2 [FS 2005-011]	Reflected the removal of valves 1-MS-118 and 2-MS-118 as part of the decay heat subsystem removal.
5.3.5, 5.3 Refs, 6.2.3.3, 6.2.3.12.1, 6.2 Refs, Tables 6.2-14 & 6.2-15, Figures 6.2-3, 6.2-4, 6.2-5, 6.2-6, 6.2-7, & 6.2-8 [FS 2005-002]	Reflected that the Hydrogen analyzers and recombiners will continue to function and be periodically tested, but are no longer part of the plant design basis or credited in accident analyses.
6.3.1.3, Figure 6.3-16 [FS 2004-021]	Changed the refueling water storage tank low level alarm setpoint from 16.0% to 20.0%.
7.2.2.1.1 [FS 2000-006]	Increased the design temperature limit for power cable from 85°C to 90°C and described randomly spaced power cable having less than 1/4 diameter spacing.
7.2.3.2.7, Figure 8.4-1, 10.3.5.3 [FS 2003-030]	Changed electrical power feeds associated with replacement of the plant computer and the emergency response facilities computer system.
8.2 [FS 2003-060]	Provided clarification of the operating conditions and analysis required for electrical equipment and cables.
8.3, Figure 8.3-1 [FS 2004-006]	Installed redundant, underground feeder cables to the low level intake structure buses.
8.5 [FS 2003-037]	Corrected the description of the loads served by the emergency diesel generators. [10 CFR 50.90]
8.5 [FS 2004-025]	Clarified that three low head safety injection pump motors are analyzed to start at 72% of rated voltage.
8.5 [FS 2005-018]	Modified the #2 emergency diesel generator auto start circuit.
Table 9.4-2 [FS 2005-019]	Corrected the description of the capacity of the chilled water system chillers.
9.13.3.6, 9.13.4.2 [FS 2004-022]	Revised the description of the main control room and emergency switchgear and relay room ventilation system to rely on operating either one or two chillers.

Click on Change Package Number Highlighted in Red to View Change Request.

Revision 37—09/30/05 (continued)

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
9B.2.3, 9B.2.4.7, 9B.2 Refs, Table 9B.2-1 [FS 2004-038]	Replaced the 6-ton Auxiliary Building hoist with a 5-ton hoist.
10.3.5.2, Figure 10.3-9 [FS 2004-003]	Replaced Unit 2 auxiliary feedwater system isolation valves with stop-check valves.
10.3.5.2, Figure 10.3-9 [FS 2004-015]	Replaced Unit 1 auxiliary feedwater system isolation valves with stop-check valves.
Table 10.3-4 [FS 2004-004]	Revised the cooling water flow value for the Unit 2 generator hydrogen coolers.
Figure 10.3-11 [FS 2004-036]	Corrected tie-in locations between Sheets 1 & 2 describing the bearing cooling system.
Tables 11.3-5 & 11.3-7 [FS 2005-017]	Reflected consistent mark number format for the radiation monitoring system.
14.2 Refs, 14.3 Refs, 14B Refs [FS 2004-030]	Updated the references to the RETRAN Topical Report.
14.3.1.4.4, 14.3.2.4.2, Table 14.3-7, 14.3-8, 14.3-9, 14.3-10, 14.3-12, & 14.3-15 [FS 2005-010]	Corrected and clarified the description of the dose consequences of the main steam line break, locked rotor accident, and steam generator tube rupture based on the alternative source term methodology.
Table 14.3-8 [FS 2005-021]	Incorporated an editorial correction of the event time ranges.
14.5.1.6, 14.5 Refs, Table 14.5-5 [FS 2005-001]	Incorporated the peak clad temperature penalties and benefits for the large break LOCA. [10 CFR 50.46]
Figure 15.1-1 [FS 2004-032]	Provided the location of well-water supply system Well E and removed the incorrectly identified information center.
Figure 15.1-2 [FS 2004-010]	Added delay fencing in the Protected Area.
Figure 15.1-2 [FS 2004-012]	Added sally port fencing in the Protected Area.
15.6.2.1 [FS 2005-004]	Incorporated an editorial correction replacing “stem generator” with “steam generator.”
15.7, 15.7 Refs [FS 2004-034]	Clarified the scope of statistical information regarding the evaluation of masonry block walls in response to IE Bulletin 80-11.

Click on Change Package Number Highlighted in Red to View Change Request.

Revision 37—09/30/05 (continued)

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
18.1.1, 18.1.4, 18.2.1, 18.2.9, 18.2.19, Table 18-1 [FS 2004-037]	Reflected the completion of License Renewal Commitment Item Nos. 1, 2, 3, 7, 8, 19, and 29.

Revision 36—09/30/04

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
KWI [FS 2004-002]	Updated the Key Word Index to incorporate an editorial correction.
3.3.3.2.1, 3.3 Refs, 3.5 Refs [FS 2003-035]	Updated references to the topical report for reload design methodology. [10 CFR 50.90 License Amendment]
3.5.3.1, 3.5.3.1.6, 4.1.2.8, 4.1.6, 4.1 Refs, Tables 4.1-2, 4.1-8, & 4.1-15, 4.2.2.1, Table 4.2-1, 4.3.1.1, Tables 4.3-2, 4.3-4, 4.4-1, & 9B.2-1, 14.3.3.1.1.1, 14.5.3, 14.5.3.3.4, 14.5 Refs, 15.2 Refs, Table 15.2-2 [FS 2003-040 & FS 2003-052]	Replaced the Unit 2 reactor vessel closure head.
Table 4.1-2 [FS 2003-051]	Identified the replacement reactor vessel heads' dome insulation thickness.
4.2.2.1, 5.3.1.3.2, 9.12.5.2, 9.12.5.4, 9B.2.5, Table 9B.2-1, Table 11.3-2, Figures 11.3-2 & 11.3-3, 14.3.3.1.1.4.2, 15.5.1.1, 15.5.1.8, 15.5.1.11.1, 15A.3.5.2, 15A.3.5.2.4, 15A Refs [FS 2003-048]	Upgraded the Unit 2 reactor head assembly.
4.2.7.2 [FS 2003-042]	Completed the installation of the Unit 2 N-16 primary-to-secondary leakage detection system.
4.3.1.1, Table 4.3-1 & 4.3-2 [FS 2004-008]	Provided a text description of cumulative usage factors for reactor vessel components in lieu of a tabular format. Updated stresses for reactor vessel components.
Table 5.3-2, 9.4.1.3, 9.4.3.3, Table 9.4-2, Figure 9.9-1, Table 10.3-4, Figure 10.3-11 [FS 99-065]	Updated the description of the Unit 2 chilled water system to reflect equipment replacement and changing the system's source of cooling water.

Click on Change Package Number Highlighted in Red to View Change Request.

Revision 36—09/30/04 (continued)

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
5.5.3, 7.2.3.2.7, 7.3.2.3.2, 7.4.2.4, 7.4.3.2, 7.4.3.6, Tables 7.4-1, 7.4-2, & 7.4-3, 7.6.2.2, 7.7.2, Figure 7.7-1, 7.9.2, 7.9.2.2, 7.9.2.3, 7.9.2.5, 7.9.2.6, 7.9.3, 7.9.4, 9.10.4.1 [FS 2003-059]	Replaced the Unit 2 plant computer.
6.2.2.2.4 [FS 2003-053]	Replaced the Unit 2 charging pump discharge alternate header isolation valve, 2-CH-MOV-2287C.
7.2.1.2, 7.3.2.3.2, 14.2.4 [FS 2003-023]	Replaced the Unit 2 benchboard individual rod position indicators and the rod bottom lights with redundant flat panel displays.
7.5.2.2, 7.5.3.5, 7.6.2.2, 7.7.2, Figure 7.7-1, 7.9.2, 7.9.2.2, 7.9.2.5, 7.9.3 [FS 2002-019]	Replaced the Unit 1 plant computer.
7.6.2.1 [FS 2003-049]	Clarified the description of the Unit 2 incore instrumentation system.
8.5 [FS 2001-037]	Added provisions for inspection and repair of a buried fuel oil storage tank during plant operation. [10 CFR 50.90 License Amendment]
9.4.1.1 [FS 2004-014]	Added the vacuum priming system to the description of the component cooling heat exchangers.
9.4.1.3 [FS 2003-064]	Clarified the description of the chilled water used to cool the water in the refueling water storage tank.
9.4.1.3, Table 9.4-2 [FS 2003-050]	Updated the Unit 1 chilled water system capacity.
Table 9.6-1, 11.2.3.1.5, Table 11.2-1 [FS 2003-058]	Designated the waste disposal evaporator test tanks as “installed but no longer used.”
9.10.4.7 [FS 2004-011]	Removed the steam heating coils from the motor control center rooms’ ventilation units.
9.12.4.14, 9B.2.4.6, 9B.2.4.7, Table 9B.2-1 [FS 2003-011]	Uprated the Unit 2 polar crane capacity for each of the two hooks from 125 to 140 tons.
Figure 10.2-1, 10.3.3.2, Table 10.3-4 [FS 2003-012]	Replaced the Unit 2 main generator with an upgraded, refurbished generator.

Click on Change Package Number Highlighted in Red to View Change Request.

Revision 36—09/30/04 (continued)

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
10.3.1.2 [FS 2003-039]	Restored the automatic control mode for the Unit 2 steam header pressure controller.
10.3.3.2, Table 10.3-4 [FS 2003-009]	Replaced the Unit 2 main generator exciter.
10.3.5.1 [FS 2003-041]	Increased the Unit 2 feedwater recirculation flow from 2800 to 4300 gpm.
10.3.5.2, Figure 10.3-9 [FS 2003-038]	Modified the Unit 2 feedwater bypass regulating valve line to provide bypass flow indication during unit startup.
10.3.5.3 [FS 2003-054]	Incorporated editorial correction of punctuation errors.
11.2.4.1.6 [FS 2003-029]	Added the low-level waste storage facility and sea van storage pad to the description of the solid waste disposal system.
14.2.9.2.2.2, 14.2.9.2.3, 14.2.9.2.4.1, 14.2.9.2.4.2, 14.2.9.2.4.3, 14.2.9.2.4.4, 14.2 Refs, Tables 14.2-2, 14.2-4, & 14.3-14 [FS 2003-044]	Reflected the reanalyzed dose consequences of a locked rotor accident using alternate source term and methodologies described in Regulatory Guide 1.183.
14.2.10.3, 14.2.10.4.2, Figures 14.2-68, 14.2-69, 14.2-70, 14.2-71, & 14.2-72 [FS 2004-007]	Updated the reanalyzed information and figures for loss of external electrical load/turbine trip.
14.3.1.4, 14.3.1.4.1, 14.3.1.4.2, 14.3.1.4.3, 14.3.1.4.4, 14.3.1.4.5, 14.3.2.4, 14.3.2.4.2, 14.3.2.4.3, 14.3.2.4.4, 14.3.2.4.5, 14.3 Refs, Tables 14.3-9, 14.3-10, 14.3-11, 14.3-12, 14.3-14, & 14.3-16 [FS 2003-057]	Incorporated the reanalysis of the dose consequences of the steam generator tube rupture and main steam line break using the alternative source term methodology.
14.4.1.2.1, 14.4.1.2.2, 14.4.1.3.1, 14.4.1.3.2, 14.4 Refs, Table 14.4-5 [FS 2003-055]	Incorporated the reanalysis of the dose consequences of a fuel handling accident using the alternative source term methodology.
14.5.2.4.2, 14.5.2.5 [FS 2004-024]	Made editorial corrections to correctly refer to Tables 14.5-15 & 14.5-16.
14.5.2.6, 14.5 Refs, Table 14.5-16 [FS 2004-019]	Incorporated a change to the summary of peak clad temperature penalties and benefits for the small break LOCA. [10 CFR 50.46]

Click on Change Package Number Highlighted in Red to View Change Request.

Revision 36—09/30/04 (continued)

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
14.5.5.2, 14.5.5.3, 14.5 Refs, Table 14.5-12 [FS 2003-061]	Revised the discussion of dose consequences of the loss of coolant accident using 500 cfm instead of 10 cfm for the control room in-leakage and out-leakage parameters.
15.5.2, 15.5.2.1, 15.5.2.3, 15 Refs [FS 2003-031]	Completed the restoration of construction opening in the containment structure for the Unit 2 reactor pressure vessel head replacement.
17.2.1.2.D.3.c, Figure 17.2.1-3 [QA 2004-004]	Deleted the Manager Nuclear Engineering's responsibility for development of Improved Technical Specifications. Updated the title of and line of reporting for Supervisor Nuclear Records. [10 CFR 50.54(a)(3)]
17.2.2.8 [QA 2004-005]	Updated terminology to the current naming convention for inservice inspection personnel. [10 CFR 50.54(a)(3)]
17.2.10 [QA 2003-001]	Updated the description of qualification requirements for personnel performing non-destructive examinations. [10 CFR 50.54(a)(3)]
18.2.3 [FS 2004-001]	Established acceptance criteria for borated water leakage.
18.2.6, 18.2.10, Table 18-1 [FS 2004-005]	Described completion of commitments regarding inspection of inaccessible areas, groundwater monitoring, and internal inspections of containment polar crane girders.
18.2.19, Table 18-1 [FS 2004-009]	Described completion of commitments regarding procedures to assure consistent inspection of components for aging effects during work activities.
18.3.2.4, 18.5 Refs, Table 18-1 [FS 2003-062]	Completed detailed engineering evaluation for the potential effect of environmentally-assisted fatigue in safety injection accumulator nozzles and charging line nozzles.

Revision 35—09/30/03

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
1.1, 1.6.2.3, 2.1.3.1, 3.1, 4.1, 4.1.4, 4.1.5, Tables 4.1-8, 4.1-12, & 4.1-13, 4.3.1.1, 4.3.1.2, Tables 4.3-3 & 4.3-4, 5.0, 6.1, 6.3.1.2.1, 7.1, 7.5.3.5, 8.0, 9.0, Table 9.1-3, 10.1, 11.1, 11.3.2.9.1, 15.5.1.8, 18.0, 18.1, 18.1.1, 18.1.2, 18.1.3, 18.1.4, 18.2, 18.2.1, 18.2.2, 18.2.3, 18.2.4, 18.2.5, 18.2.6, 18.2.7, 18.2.8, 18.2.9, 18.2.10, 18.2.11, 18.2.12, 18.2.13, 18.2.14, 18.2.15, 18.2.16, 18.2.17, 18.2.18, 18.2.19, 18.2.20, 18.3, 18.3.1, 18.3.1.1, 18.3.1.2, 18.3.1.3, 18.3.2, 18.3.2.1, 18.3.2.2, 18.3.2.3, 18.3.2.4, 18.3.3, 18.3.4, 18.3.5, 18.3.5.1, 18.3.5.2, 18.3.5.3, 18.3.5.4, 18.3.5.5, 18.3.5.6, 18.3.6, 18.4, 18.4.1, 18.4.2, 18.5, Table 18-1 [FS 2002-016]	Reflected the increased operating life basis from 40 to 60 years and added Chapter 18 [10 CFR 54.21] to describe the programs and activities that manage the effects of aging materials during the extended operation period associated with license renewal.
Table 2.1-4, Figure 15.1-2 [FS 99-064]	Installed a tank farm and feed system for treating the circulating water system with sodium bromide and sodium hypochlorite.
2.2.1.2, 3.3.2.13, 6.2.2.1.2, 7.4.3.3.3, 7.4.3.5.2, 7.4.3.7.2, 7.4.3.7.4, 7.4.3.7.5, 11.3.3, 11.3.4.1, 11.3.4.5 [FS 2001-044]	Replaced paper strip chart recorders in the control room with video display recorders.
3.5.2.6.1, 3.5 Refs [FS 2002-034]	Identified the references for the design requirements for fuel assembly structural components.
3.5.3.1, 4.1.2.8, 4.1.6, 4.1 Refs, Tables 4.1-2, 4.1-9, & 4.1-14, 4.2.2.1, 4.2.5, 4.2 Refs, Table 4.2-1, 4.3.1.1, Tables 4.3-1, 4.3-2, 4.3-3, & 4.3-4, 4.4.1.3, Table 4.4-1, 15A.5.2, 15A.5.2.1, 15.A.5.2.2, 15A.5.2.3, 15A.5.2.4, 15A.5.2.5, 15A Refs [FS 2003-018 & FS 2003-026]	Replaced the Unit 1 reactor vessel closure head.
4.1 Refs, Table 4.1-14 [FS 2003-001]	Reflected a new reference nil ductility transition temperature for the Unit 1 reactor vessel closure head dome. [10 CFR 50.55a(a)(3)(ii) and 10 CFR 50.55a(g)(6)(i) Relief Requests]

Click on Change Package Number Highlighted in Red to View Change Request.

Revision 35—09/30/03 (continued)

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
Table 4.1-1, 7.5.1.4.1, 7.5.1.4.2 [FS 2001-022]	Changed the reactor coolant system low-pressure alarm from 2205 to 2210 psig.
4.2.2.1, Figures 4.2-2 & 4.2-3, 9B.2.4.4, 9B.2 Refs, Table 9B.2-1 [FS 2003-019]	Modified the service structure, cooling air shroud and shroud support, radiation shield, insulation, and intermediate lift ring for the Unit 1 reactor vessel head replacement.
4.2.2.1, 4.3.1.1, Table 4.3-1 [FS 2002-031]	Enhanced the description of repairs performed on the Unit 1 reactor vessel head and control rod drive mechanism nozzles.
4.2.2.6 [FS 2002-029]	Clarified the description of flanges used in the reactor coolant system.
4.2.7.2 [FS 2001-035]	Installed the Unit 1 N-16 primary-to-secondary leakage detection system.
4.2.7.2 [FS 2003-043]	Installed the initial phase of the Unit 2 N-16 primary-to-secondary leakage detection system.
4.2 Refs, Table 4.3-3 & 4.3-4 [FS 2003-014]	Corrected typographical errors.
4.3.3.2, 4.3 Refs, Table 4.3-4 [FS 2003-007]	Reflected the revised RT_{PTS} values provided for the Unit 2 Reactor Vessel Integrity Program.
Table 6.2-5 [FS 2002-028]	Replaced charging pump 1-CH-P-1B.
6.3.1.5.1, 6.3.1.5.2 [FS 2002-002]	Revised the frequency of inspection for the containment spray and recirculation spray nozzles. [10 CFR 50.90 License Amendment]
Figure 6.3-1 [FS 2000-021]	Removed the vent caps from the refueling water storage tanks.
7.2.1.2, 7.3.2.3.2, 14.2.4 [FS 2003-005]	Replaced the Unit 1 benchboard individual rod position indicators and the rod bottom lights with redundant flat panel displays.
7.2.2.1.6 [FS 99-062]	Removed the reactor protection system logic channel testing event recorder.
7.2.2.5, Table 7.2-3, 7.8, 7.8.1, Figure 7.8-1 [FS 2002-022]	Removed the load frequency recorder and the automatic load control system.

Click on Change Package Number Highlighted in Red to View Change Request.

Revision 35—09/30/03 (continued)

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
7.2.3.2.7, 7.9.4, 8.4.4, 8.4.5, 8.4.6, Figure 8.4-1, 9.10.2.7, 10.3.5.3 [FS 2002-017]	Provided power feed changes in preparation for plant computer replacement, installed a portion of the new computer for parallel testing, and permitted use of engineering-approved cable.
7.6.2.1, 7.6.3 [FS 2002-021]	Clarified the description of the incore instrumentation system.
8.4.4 [FS 2003-003]	Installed an additional 125V dc switchboard crosstie circuit breaker.
8.5 [FS 2003-013]	Modified the #3 emergency diesel generator breaker closure circuit.
9.4.3.5 [FS 2001-009]	Restored the original configuration of the charging pump component cooling water system.
9.10.2.2.2 [FS 2001-028]	Changed the pressure of the firewater system.
9.12.4.14, 9B.2.4.6, 9B.2.4.7, 9B.2 Refs, Table 9B.2-1 [FS 2003-010]	Uprated the Unit 1 polar crane capacity for each of the two hooks from 125 to 140 tons.
9.12.5.3 [FS 2003-017]	Provided an alternate method for monitoring subcriticality during fuel onload.
9.13.3.6 [FS 97-028]	Installed an alternate power feed to Mechanical Equipment Room-5 for use in the event of a fire.
9.13.3.6, 9.13.4.1 [FS 2000-019]	Provided shutdown of fans serving areas adjacent to the main control room (MCR) due to a safety injection signal or manual actuation in the MCR.
10.3.1.2 [FS 2003-028]	Restored the automatic control mode for the Unit 1 steam header pressure controller.
10.3.1.2, 10.3.8, 11.2.3, 11.2.3.2, 11.2.3.2.1, 11.2.3.2.2, Tables 11.2-4, 11.2-5, 11.2-6, & 11.2-7, Figures 11.2-2 & 11.2-3, 11.3.2.6, 11A.4, Tables 11A-10 & 11A-12 [FS 2003-047]	Reflected partial implementation of discontinued use of the steam generator blowdown treatment facility.
10.3.4.1, 10.3.4.2 [FS 98-045]	Increased the flow rate of the circulating water pumps from 210,000 gpm to 220,000 gpm.

Click on Change Package Number Highlighted in Red to View Change Request.

Revision 35—09/30/03 (continued)

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
10.3.5.1 [FS 2003-004]	Increased the Unit 1 feedwater recirculation flow from 2800 to 4300 gpm.
10.3.5.2, Figure 10.3-9 [FS 2003-024]	Modified the Unit 1 feedwater bypass regulating valve line to provide bypass flow indication during unit startup.
10.3.9, 10.3.9.2, Figure 10.3-11 [FS 2001-003 & FS 2003-046]	Added description of the bearing cooling normal makeup water supply and treatment system.
Figure 10.3-7 [FS 2001-030A]	Installed an additional cross-connect valve for isolation of the Unit 1 auxiliary steam header.
Figure 10.3-11 [FS 2000-029]	Replaced turbine lube oil coolers' temperature control valves with manual throttle valves.
Figure 10.3-11 [FS 2001-006]	Removed and capped dead-leg piping to the flash evaporators that are abandoned in place.
14.2.1.1, 14.2.1.2 [FS 2003-032]	Corrected the description of the reactor trip setpoint for the rod withdrawal from subcritical event.
14.4.1.2.1 [FS 2003-006]	Updated a cross-reference number.
14.5.3.2, 14.5 Refs [FS 2003-002]	Added text describing that it has been shown that the control rods will insert for cold leg breaks.
14.5 Refs, Table 14.5-5 [FS 2003-027]	Incorporated a change to the summary of peak clad temperature penalties and benefits for the large break LOCA. [10 CFR 50.46]
15.3.1, 15.3.2, 15.4, 15.4.1, 15.4.2, 15.4.3, 15.5.1.6, 15.5.1.8, 15.5.1.9, 15.5.1.9.1, 15.5.1.9.3, 15.5.1.9.4, 15.5.1.10, 15.5.2, 15.5.2.1, 15.5.2.2, 15.5.2.3, 15.5.2.4, 15.5.2.5, 15.5 Refs [FS 2003-020 & FS 2003-025]	Completed the restoration of construction opening in the containment structure for the Unit 1 reactor pressure vessel head replacement.
17.2.0.2, Table 17.2-0, 17.2.2.1, 17.2.2.5, 17.2.2.6, 17.2.10, 17.2.17 [FS 2003-021]	Made editorial corrections to correctly refer to Table 17.2-0.

Click on Change Package Number Highlighted in Red to View Change Request.

Revision 35—09/30/03 (continued)

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
17.2.1.1.A, 17.2.1.2.B, 17.2.1.2.B.1, 17.2.1.2.B.1.b.1.1, 17.2.1.2.C.1, 17.2.16.2.B.2, 17.2.16.2.C, 17.2.1.16.2.D, Figures 17.2.1-1 & 17.2.1-2, Table 17.2-0, App C A.8.e, B.6.e, B.6.i, B.7.c, & B.8 [FS 2003-015]	Revised organizational titles of the Senior Vice President Nuclear Operations, Shift Manager, and Unit Supervisor. [10 CFR 50.54(a)(3)]
17.2.1.2 [FS 2003-008]	Assigned responsibility for maintenance of plant equipment history to the Manager Nuclear Maintenance. [10 CFR 50.54(a)(3)]
17.2.1.2.A.2, Figure 17.2.1-1 [FS 2002-006]	Deleted the description of and reference to the Nuclear Oversight Board. [10 CFR 50.54(a)(4)]
Table 17.2-0 [FS 2002-033]	Provided for the repair and testing of a temporary opening in the containment due to reactor vessel head replacement. [10 CFR 50.54(a)(3)]

Revision 34—09/03/02

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
1.1.8, 1.4.11, 1.4.47, 2.1.2.1, Figure 2.1-3, 5.3.1.2, 5.3.1.3.4, 5.3.1.4, 5.3.1.4.1, 5.3.1.4.2, 5.4, 6.1, Table 6.2-6, 6.3.1.1, 7.7.1, 9.12.6, 9.12.6.1, 9.13.1, 9.13.2, 9.13.3.1, 9.13.3.2, 9.13.3.6, 9.13.3.7, 9.13.4.1, 11.3.1, 11.3.3.13, 11.3.4.2, 11.3.4.3, 11.3.4.4, 11.3.6, Table 11.3-1, 14.4.1.1, 14.4.1.2, 14.4.1.2.1, 14.4.1.2.2, 14.4.1.2.2.1, 14.4.1.2.2.2, 14.4.1.2.2.3, 14.4.1.2.2.4, 14.4.1.2.3, 14.4.1.3.1, 14.4.1.3.2, 14.4.1.3.3, 14.4.1.3.4, 14.4 Refs, Tables 14.4-1, 14.4-2, 14.4-3, 14.4-4, & 14.4-6, 14.5.4, 14.5.5, 14.5.5.1, 14.5.5.2, 14.5.5.3, 14.5.6, 14.5 Refs, Tables 14.5-7, 14.5-8, 14.5-10, 14.5-11, & 14.5-12 [FS 2000-005A]	Incorporated the reanalysis of the LOCA and Fuel Handling Accidents resulting from the implementation of alternative source term. [10 CFR 50.67]

Click on Change Package Number Highlighted in Red to View Change Request.

Revision 34—09/03/02 (continued)

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
3.4.1.1, 3.4.1.1.4, 3.4.1.2, 3.4 Refs, 3.5.2.1, 3.5.2.6.1, 3.5 Refs, Table 3.5-3 [FS 2002-003]	Reflected the physical description of Surry 2 Batch 20 and subsequent reload fuel batches for Units 1 and 2. Identified the fuel performance models for cycle-specific evaluations.
4.2.2.4 [FS 99-053]	Replaced reactor coolant pump main flange bolts with main flange fasteners.
4.3.1.1 [FS 2001-043]	Described the repairs performed on the Unit 1 reactor vessel head and control rod drive mechanism nozzles.
4.3.1.1, Figure 4.3-2 [FS 2001-046]	Clarified the stress analysis boundary conditions at the vessel head penetration shrink fit for the control rod drive mechanism housings. Showed the vessel head penetration welds in their correct orientation.
5.4.1.3.5.4, 8.4.4 [FS 2002-024]	Updated a reference document number and corrected a typographical error.
6.2.3.12.1, 6.2 Refs, Tables 6.2-14 & 6.2-15, Figures 6.2-3, 6.2-4, 6.2-5, 6.2-6, 6.2-7, & 6.2-8 [FS 2002-012]	Re-evaluated the hydrogen concentration in containment following a LOCA.
Table 6.2-13, 6.3.1.3, Table 14B-3 [FS 2001-026]	Changed the bleed flow contribution to outside recirculation spray pump NPSHa, clarified the function of the recirculation spray suction cross-connect line, and deleted the component cooling heat exchangers from the list of postulated targets in the auxiliary building.
7.6.2.1 [FS 2001-042]	Installed a plug in the high pressure seal at Unit 1 core location J5 (1-RC-TW-J5).
7.6.2.1, 7.6.2.2, 7.6.2.3.1, Figures 7.6-1 & 7.6-2 [FS 2000-049]	Provided the description of a second flux thimble tube and seal table seals design. Described the process for converting to the new design.
7.6.2.1, Figure 7.6-1 [FS 2002-013]	Installed a plug in the high pressure seal at Unit 2 core location N8 (2-RC-TW-N8).

Revision 34—09/03/02 (continued)

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
7.7.2, 9.10.3.5, 9.10.4.13, 10.3.1.2 [FS 99-034]	Incorporated changes to reflect that the decay heat release subsystem is no longer used and that decay heat release components have been removed on Unit 1.
Figure 8.3-1, 8.4.4 [FS 2002-004]	Installed an additional 125V dc switchboard crosstie circuit breaker.
8.5 [FS 2001-001]	Removed the diesel generator voltage and speed relay from the residual voltage time delay relay circuit and increased the time delay from 2.0 to 2.2 seconds.
8.5 [FS 2002-020]	Clarified the description of the analysis consideration of a loss of offsite power being sequenced with a loss of coolant accident.
8.5, Table 8.5-1 [FS 99-025]	Updated the setting of the emergency bus degraded voltage relays. [10 CFR 50.90 License Amendment]
9.1.2.1 [FS 2001-036]	Clarified auxiliary spray valve operation meeting the requirements of the Appendix R analysis.
9.4.3.1 [FS 2002-008]	Clarified component cooling system thermal relief requirements.
9.6.1.2, 9.6.2.2, 9.6.2.2.1, 9.6.2.2.3, 9.6.2.2.6, 9.6.3.2, 9.6.4.2, 9.6 Refs, Tables 9.6-3 & 9.6-7 [FS 2002-011]	Clarified the status of the High Radiation Sampling System—Post-Accident Operation. [10 CFR 50.90 License Amendment]
9.6.2.1 [FS 2001-024]	Reflected the abandonment of recorders from the secondary sampling system on-line chemistry monitoring panels.
9.10.1 [FS 2001-039]	Identified fire protection systems that are not required to satisfy regulatory criterion. [10 CFR 50.48]
9.10.1, 16.2, 17.2.1.2, 17.2.5 [FS 2001-034]	Removed terminology associated with the former 10 CFR 50.59 regulation and incorporated wording from the current rule.
9.13.1, 9.13.4.1 [FS 2002-009]	Clarified the description of auxiliary building ventilation fan performance.

Click on Change Package Number Highlighted in Red to View Change Request.

Revision 34—09/03/02 (continued)

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
9.13.3.3, 9.13.4.1 [FS 2002-015]	Enhanced the text description of the decontamination building ventilation system operation.
9B.2.4.4 [FS 2001-002]	Added the reactor vessel head stud racks to the description of special lifting devices.
9B.2.4.4, Table 9B.2-1 [FS 2001-017]	Removed the pneumatic reactor cavity seal ring and its lifting rig.
11.2.3, 11.2.3.1.7, 11.2.3.2, Tables 11.2-5 & 11.2-6 [FS 98-001]	Updated the description of steam generator blowdown to reflect system lineup and chemistry guidelines.
11.2.4.1.2 [FS 97-011]	Incorporated current methodology for handling and storing spent radioactive filters.
11.3.3.8, Tables 11.3-6 & 11.3-7 [FS 2001-025]	Changed the Unit 1 condenser air ejector radiation monitor to a more sensitive detector.
11.3.3.8, Tables 11.3-6 & 11.3-7 [FS 2001-038A]	Changed the Unit 2 condenser air ejector radiation monitor to a more sensitive detector.
14.2.10.3, 14.2.10.4, 14.2.10.4.1, 14.2.10.4.2, Figures 14.2-62, 14.2-63, 14.2-64, 14.2-65, 14.2-66, 14.2-67, 14.2-68, 14.2-69, 14.2-70, 14.2-71, & 14.2-62 [FS 2001-018]	Incorporated an improved analysis technique concerning loss of external electrical load.
Table 14.2-4 [FS 2001-031]	Cited the regulatory whole body dose limit. [10 CFR 100]
14.5 Refs, Table 14B-2, 15.5 Refs [FS 2001-041]	Corrected typographical errors.
14B.3.3, 14B.5.3.3 [FS 2001-045]	Provided discussion of the auxiliary building ambient temperature monitoring system for detection of a high energy line break and associated automatic/manual actions.
17.2.1.1, 17.2.1.2, 17.2.10, Figures 17.2.1-1, 17.2.1-2, & 17.2.1-3 [FS 2002-005]	Modified organizational titles and realigned certain reporting relationships within the Nuclear Business Unit. [10 CFR 50.54(a)(3)]
17.2.1.2, Figures 17.2.1-1 & 17.2.1-3 [FS 2001-040]	Relocated the Records Management Program organization from General Services to Nuclear Engineering. [10 CFR 50.54(a)(3)]

Click on Change Package Number Highlighted in Red to View Change Request.

Revision 34—09/03/02 (continued)

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
17.2.1.2, 17.2.3, 17.2.5, 17.2.6, 17.2.11, 17.2.15, 17.2.16, 17.2.18, 17.2 Refs, Table 17.2-0, Appendix C [FS 2001-023]	Relocated North Anna Power Station current technical specification requirements for the Management Safety Review Committee, Station Nuclear Safety and Operating Committee, and Station Nuclear Safety to the QA Topical Report. [10 CFR 50.90 License Amendment]
17.2.7 [FS 2002-023]	Updated the description of the organizational structure to reflect the responsibilities of the Vice President Nuclear Engineering and Vice President Nuclear Support Services with respect to procurement, vendor surveillance, and document reviews. [10 CFR 50.54(a)(3)]

Revision 33—09/04/01

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
1.1.6, 1.2.3, 3.3.2.12, 3.5, 3.5.1.3, 3.5.2.1, 3.5.2.1.1, 3.5.2.1.2, 3.5.2.1.4, 3.5.2.1.5, 3.5.2.2, 3.5.2.3, 3.5.2.4, 3.5.2.5, 3.5.2.6.1, 3.5.2.6.3, 3.5.2.6.4, 3.5.3.1, 3.5.3.1.1, 3.5.3.1.2, 3.5.3.2.1, 3.5.4, 3.5.4.1, 3.5 Refs, Tables 3.5-1 & 3.5-3, Figures 3.5-3, 3.5-4, 3.5-5, 3.5-7, 3.5-9, 3.5-11, 3.5-12, & 3.5-13 [FS 2000-027]	Incorporated technical and editorial corrections and clarifications resulting from the integration review of mechanical reactor design.
1.4.23, 7.5.1, 8.4.3 [FS 2001-011]	Provided clarification of the design and licensing basis for the power supplies to the vital bus systems.
2.4.1, Table 9.2-1, Table 15.2-1, 15.5.1.8 [FS 2000-051]	Corrected typographical, administrative, and format errors.
3.4.1.1.2, 3.4.1.1.3, 3.4.1.1.4, 3.4.1.1.5, 3.4.1.2, 3.4.1.3, 3.4.2, 3.4.2.1, 3.4.2.1.1, 3.4.2.1.2, 3.4.2.2, 3.4.2.2.1, 3.4.2.2.2, 3.4.2.2.3, 3.4.2.2.4, 3.4.2.3, 3.4.2.4, 3.4.2.5, 3.4.2.6, 3.4.3.1, 3.4.3.2, 3.4.3.2.1, 3.4.3.3, 3.4.3.5, 3.4.3.8, 3.4 Refs, Table 3.4-1, Figures 3.4-1, 3.4-4, 3.4-8, & 3.4-10, Table 4.2-1, 8.5, 10.3.5.3 [FS 2000-028]	Incorporated technical and editorial corrections and clarifications resulting from the integration review of thermal/hydraulic reactor design.

Click on Change Package Number Highlighted in Red to View Change Request.

Revision 33—09/04/01 (continued)

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
4.2.2.8, 14.2.6.2.2, 14.2.6.2.3 [FS 99-042A]	Established additional reactivity controls and surveillance for the vacuum-assisted backfill method of returning an RCS loop to service. [10 CFR 50.90 License Amendment]
Table 5.4-20 [FS 2001-013]	Revised the containment analysis results for depressurization time and subatmospheric peak pressure.
6.2.3.12.1, Table 6.2-14 [FS 2001-010]	Updated the description of the containment hydrogen generation analysis.
6.2.3.12.1, Table 6.2-14, 14.5.1.3, 14.5.1.4, Table 14.5-3, 15A References [FS 2001-027]	Corrected typographical, administrative, and format errors.
Figures 6.2-1 & 6.2-2 [FS 99-063]	Incorporated modifications to the Unit 1 safety injection system.
7.6.2.1, Figure 7.6-1 [FS 2000-046]	Installed a seal welded cap on the flux thimble tube at location 2-RC-TW-N8.
8.5 [FS 2000-037]	Added definition of loss of offsite power (LOOP) as a LOOP to both units to the introduction of the emergency power system.
8.5 [FS 2000-045]	Added a time delay relay to each filter exhaust fan start circuit to allow proper damper alignment.
9.4.4.3 [FS 2000-043]	Provided a description of the air lockup valve on the reactor coolant pump thermal barrier inside and outside containment component cooling trip valves.
9.6.1.2, 9.6.2.2.6, Table 9.6-7 [FS 2000-052]	Deleted time restraints for containment sump sampling or analysis with the high radiation sampling system.
9.8.1, Table 9.8-1 [FS 2001-007]	Deleted statement that the compressed air system air receivers are sized to provide ten minutes of breathing quality air and air to essential systems after shutdown of all compressors following a loss-of-power accident. Corrected compressed air system design data.

Click on Change Package Number Highlighted in Red to View Change Request.

Revision 33—09/04/01 (continued)

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
9.10.4.4 [FS 2000-048]	Included a description of the two-hour design basis discharge/recharge case for the station batteries.
9.10.4.4 [FS 99-043]	Revised the description of hydrogen generation and fire potential in the station battery rooms.
9.10.4.12 [FS 2000-041]	Incorporated modifications to the reactor coolant pump motor oil collection system.
9.10.6, 12.2.2.3, 17.2.1.1, 17.2.1.2, 17.2.2.1, 17.2.2.5, 17.2.3, 17.2.7, 17.2.10, 17.2.15, 17.2.16.2, 17.2.17, 17.2.18, Figures 17.2.1-1, 17.2.1-2, & 17.2.1-3, Table 17.2-0 [FS 2001-019]	Modified organizational titles and reporting relationships associated with the entire Nuclear Business Unit. [10 CFR 50.54(a)(3)]
9.12.3.1, 9.12.5.2 [FS 2000-017]	Changed the design of the reactor cavity seal from pneumatic to mechanical.
9.12.5.2 [FS 2000-044]	Corrected the description of lifting the reactor vessel head with the reactor containment polar crane.
9.13.1, 9.13.4.1, 14.3.2 [FS 2000-024]	Updated the description of feedwater isolation for the rupture of a main steam pipe accident and of auxiliary building ventilation system capability.
9.13.2 [FS 99-046A]	Clarified the design and testing of the safety-related charcoal filters installed in the auxiliary ventilation exhaust system. [10 CFR 50.90 License Amendment]
9.13.3.7, 9.13.4.1 [FS2000-053A]	Clarified auxiliary filtration requirements consistent with the Basis for Technical Specification 3.22.
9C.1.1, 9C.2 [FS 97-020]	Deleted “carbon steel” from the description of the flow restriction shields installed around circulating water system expansion joints.
10.3.1.2, 14.3.1.5 [FS 99-057]	Added the description of the backup bottled air system for the steam generator power operated relief valves.

Click on Change Package Number Highlighted in Red to View Change Request.

Revision 33—09/04/01 (continued)

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
11.2.3, 11.2.3.1.10, Table 11.2-1, Figures 11.2-2 & 11.2-5 [FS 2000-047]	Installed a cross-connect line between the Radwaste Facility building drain system and the laundry waste system. Installed a second laundry drain pre-filter.
Tables 11.2-2 & 11.2-3 [FS 2001-014]	Corrected typographical errors.
14.2.11.1, 14.2.12, Figures 14.2-73, 14.2-74, 14.2-75, 14.2-76, 14.2-77, 14.2-78, 14.2-79, & 14.2-80, 14B.5.1.7 [FS 2001-005]	Described the reanalysis of the loss of normal feedwater (LONF) and loss of ac power to the station auxiliaries (LOAC) events with 500 gpm auxiliary feedwater flow during the transient.
14.3.1.4.2, 14.3.1.4.4, 14.3.1.4.5, 14.3.2.4.2, 14.3.2.4.4, 14.3.2.4.5, 14.3 Refs, Tables 14.3-9, 14.3-10, 14.3-11, 14.3-12, & 14.3-16 [FS 2000-032]	Reflected the reanalysis of the dose consequences of the steam generator tube rupture and main steam line break events.
14.5.1.1, 14.5.1.2, 14.5.1.3, 14.5.1.4, 14.5.1.5, 14.5.1.7, 14.5.1.8, 14.5 Refs, Tables 14.5-2, 14.5-3, 14.5-4, 14.5-5, 14.5-6, 14.5-7, 14.5-8, & 14.5-9, Figures 14.5-2, 14.5-3, 14.5-4, 14.5-5, 14.5-6, 14.5-7, 14.5-8, 14.5-9, 14.5-10, 14.5-11, 14.5-12, 14.5-13, 14.5-14, 14.5-15, 14.5-16, 14.5-17, 14.5-18, 14.5-19, 14.5-20, 14.5-21, 14.5-22, 14.5-23, 14.5-24, 14.5-25, 14.5-26, 14.5-27, 14.5-28, 14.5-29, 14.5-30, 14.5-31, 14.5-32, 14.5-33, 14.5-34, 14.5-35, 14.5-36, 14.5-37 [FS 2001-008]	Updated the analysis of the large break loss-of-coolant accident.
Table 15.2-1 [FS 2000-054]	Restored the seismic Category I designation for the yard hydrant piping system.
15.5.1.8, 15.5 Refs. [FS 99-013]	Documented the evaluation of isolated containment penetration piping for susceptibility to thermal over-pressurization following a DBA. [NRC Generic Letter 96-06]
15A.3.2, 15A Refs [FS 2001-004]	Incorporated generic implementation procedure criteria and methodology for seismic verification of equipment.

Revision 33—09/04/01 (continued)

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
17.2.17, Table 17.2-0 [FS 99-067]	Updated the Quality Assurance Topical Report description of the retention of quality assurance records in electronic media. [10 CFR 50.54(a)(4)]
Table 17.2-0 [FS 2001-020]	Clarified the provision for substitution of experience for a bachelor's degree. [10 CFR 50.54(a)(3)]
Tables 17.2-0, 17.2-2, & 17.2-3 [FS 2000-003]	Reduced records retention requirements consistent with ANSI N45.2.9 or applicable regulations. [10 CFR 50.54(a)(4)]

Revision 32—09/01/00 (continued)

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
Table 4.1-2, 9.10.3.3, 9.10.4.2, 9.10.4.3, 9.10.4.13, 10.3.1.2, 10.3.1.5, 10.3.3.1, 11.3.3.14, 14.3.1.2, 14.3.1.3, 14B.2.3.2.3, 14B.4.2, 14B.4.3, 14B.5.1.1, 14B.5.1.4, 14B.5.1.5, 14B.5.1.6, 14B.5.1.6.1, 14B.5.1.6.2, 14B.5.1.6.3, 14B.5.1.6.4, 14B.5.1.6.4.2, 14B.5.1.6.4.3, 14B.5.1.6.4.5, 14B.5.2.1, 14B.5.2.5, 14B.5.3.3, 14B.5.4.2, 14B Refs, Tables 14B-2, 14B-3, & 14B-9, Figures 14B-1 & 14B-10 [FS 2000-007]	Incorporated technical and editorial corrections and clarifications resulting from the integration review of the high energy line break.
Table 4.1-4, 10.3.1.2, 10.3.4.2, 10.3.5.2, 10.3.6.2, Figure 10.3-2 [FS 99-038]	Incorporated technical and editorial corrections and clarifications resulting from the integration review of the feedwater, condensate, steam generator blowdown, and condensate polishing systems.
4.2.11, 4.2 Refs, 9.3.1, 9.6.2.1, 9.6.2.2.6, 9.6.3.2, Tables 9.6-7 & 9.7-1, Figure 9.7-1, 10.3.8.1 [FS 99-047]	Incorporated technical and editorial corrections and clarifications resulting from the integration review of the sampling and primary vents and drains systems.
5.2.2, 5.2 Refs [FS 2000-031]	Updated the discussion of acceptable closure time of a normally closed manual isolation valve.
Table 5.2-1 [FS 99-054]	Reflected the addition of a new inside containment isolation valve.
Tables 5.2-1 & 5.2-2 [FS 99-045]	Updated Table 5.2-1 to reflect changes to valves subject to Type C testing as defined in 10 CFR 50, Appendix J. [10 CFR 50, Appendix J]

Revision 32—09/01/00 (continued)

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
5.4.1.3.4, 6.2.2.1.4, 14.1, 14.1 Refs, 14.2.1, 14.2.2.2, 14.2.2.3, 14.2.4.2, 14.2.7.2, 14.2.7.3.1, 14.2.7.3.3, 14.2.7.4, 14.2.9.2.1, 14.2.9.2.2.2, 14.2.9.2.4.1, 14.2.9.2.4.3, 14.2.10.4.2, 14.2.13, 14.2 Refs, Figures 14.2-16 through 14.2-21, & 14.2-27, 14.3.1.1, 14.3.1.4.3, 14.3.1.4.4, 14.3.2.1, 14.3.2.2.1, 14.3.2.5, 14.3.3.1.1.2, 14.3.3.2.1, 14.3.3.2.1.2, 14.3 Refs, Tables 14.3-8, 14.3-11, & 14.3-12, 14.4.1.1, 14.4.1.2, 14.4.1.2.1, 14.4.1.2.2.2, 14.4.1.3.1, 14.4.2.1, 14.4.2.2.1, 14.5.1.2, 14.5.1.3, 14.5.1.8, 14.5.2.3, 14.5.2.4.2, 14.5.6, 14.5 Refs, Tables 14.5-2, 14.5-11, & 14.5-12, Figures 14.5-30 & 14.5-31 [FS 2000-016]	Incorporated technical and editorial corrections and clarifications resulting from the integration review of the plant safety analyses.
Table 6.2-6, Table 6.3-2, 14.5.5.3, 14.5 Refs [FS 2000-008]	Updated the allowable leakage from the safety injection and charging systems.
7.2.2.2.10, 7.3.2.2.3, 7.4.3.4, 7.4.3.6, 7.4.3.8, 7.4.4.1, 7.4.4.3, 7.4.4.4.2, 7.4.4.4.3, Table 7.4-3, Figure 7.4-2, 7.6.1, 7.6.2.1, 7.6.2.3.1, Figure 7.6-1, 7.11.1 [FS 99-035]	Incorporated technical and editorial corrections and clarifications resulting from the integration review of the nuclear instrumentation system.
7.3.1, 7.3.2.1, 7.3.2.2.1, 7.3.2.2.2, 7.3.2.3.1, 7.3.2.3.2, 7.3.3.2, 7.3.3.5, 7.3 RefDwgs, 7.7.2, 7.8.1, 7.8.2, 7.8.3, Figure 7.8-1 [FS 99-059]	Incorporated technical and editorial corrections and clarifications resulting from the integration review of the nuclear control system.
7.7.2, 9.10.3.5, 9.10.4.13, 10.3.1.2 [FS 99-033]	Incorporated changes to reflect that the decay heat release subsystem is no longer used and that decay heat release components have been removed on Unit 2.
7.12.1.1, 10.3.5.3 [FS 2000-022]	Incorporated technical and editorial corrections and clarifications resulting from the integration review of the electrical instrumentation and plant computer system.
9.4.4.3, 9.8.1, 9.8.2, 9.8.3, 9.8.4, Table 9.8-1, Figure 9.8-1, 10.3.9.3, Table 15.2-1 [FS 2000-011]	Incorporated technical and editorial corrections and clarifications resulting from the integration review of the instrumentation air system.

Revision 32—09/01/00 (continued)

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
Table 9.4-1 [FS 96-032]	Updated the design data for the component cooling water heat exchangers to describe the replacement heat exchangers.
9.7.2, 11.2.2, 11.2.5, 11.2.5.1, 11.2.5.2.3, 11.2.6.1, Tables 11.2-2 & 11.2-3 [FS 99-028]	Incorporated technical and editorial corrections and clarifications resulting from the integration review of the gaseous waste disposal system.
9.7.3 [FS 99-023]	Incorporated a modification to the level detector and controls for the auxiliary building sump pumps.
9.9.1.2 [FS 99-007]	Updated the description of emergency service water pump capacity associated with a design change to improve pump reliability.
9.9.1.3 [FS 2000-034]	Provided additional information concerning the response required for hurricane conditions that are less severe than those produced by the probable maximum hurricane.
9.10.2.2.9, 9.10 Refs [FS 99-021]	Added a description of the design basis for the halon system in the emergency switchgear rooms.
9.10.3.3, 10.3.1.2 [FS 99-019]	Added a description of the local operation of the atmospheric steam dump valves.
9.10.4.8 [FS 2000-010]	Incorporated terminology from new EPA regulation, 40 CFR 279.22(c)(1).
9.12.4.4, 9.12.4.5, 9.12.4.6, 9.12.4.9, 9.12.4.13, 9.12.4.14, 9.12.5.2, 9.12.5.4, 9.12.6.2, 9.12.8, 9.14.2, 9A.2 [FS 2000-014]	Incorporated technical and editorial corrections and clarifications resulting from the integration review of fuel handling and storage.
9.13.2, 14B.5.2.1 [FS 2000-004]	Incorporated the environmental impact of a turbine building high energy line break on the control room envelope, mechanical equipment room no. 5, and the emergency diesel generator room.
10.3.5.3, 14.2.11, 14.2.11.1, 14.2.11.1.1, 14.2.11.1.2, 14.2.11.1.3, 14.2.11.1.4, 14.2.11.2, 14.2.12, 14.2 Refs, Figures 14.2-79 through 14.2-89 [FS 2000-015]	Incorporated the description of the reanalysis of the loss of normal feedwater event and the loss of ac power to the station auxiliaries event.

Click on Change Package Number Highlighted in Red to View Change Request.

Revision 32—09/01/00 (continued)

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
11A.4.1, 11A.4.2, Table 11A-1 [FS 96-065]	Added descriptions of the application of the Offsite Dose Calculation Manual.
12.4 [FS 2000-026]	Corrected the reference to the personnel qualification requirements for SNSOC and station supervisory personnel. [10 CFR 50.90 License Amendment]
14.2.13 [FS 98-050]	Specified that the governor and main stop valves are exercised on a periodic basis in order to eliminate part of the transient experienced during turbine inlet valve freedom testing.
14.5.1.6, 14.5.1.7, 14.5.2.6, 14.5.2.7, 14.5 Refs, Tables 14.5-5 & 14.5-18 [FS 99-060]	Incorporated descriptions of the peak clad temperature penalties and benefits in the large and small break LOCA analyses.
16.2 [FS 99-052]	Revised the description of the administrative controls that apply to the Technical Requirements Manual.
17.2.1.2, 17.2.2.1, 17.2.17, Figure 17.2.1-1 [FS 2000-033]	Modified organizational titles and reporting relationships associated with information technology.
17.2.1.2, 17.2.2.6, Figure 17.2.2-1 [FS 2000-009]	Updated organizational description to reflect Supply Chain Management (Generation) titles.
17.2.1.2, Figure 17.2.1-2 [FS 2000-020]	Modified organizational titles and reporting relationships associated with records management.
17.2.1.2, Figure 17.2.1-2 [FS 2000-036]	Modified organizational titles and reporting relationships associated with the radwaste facility.

Revision 31—09/01/99

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
KWI, 1.4.9, 1.4.16, 4.1.3.1, 4.1.4, 4.1.7.1, 4.1.7.2, 4.1.7.4, 4.1 Refs, Tables 4.1-1, 4.1-5, 4.1-8, 4.1-10, & 4.1-11, 4.2.1, 4.2.2.1, 4.2.2.3, 4.2.2.3.1, 4.2.2.3.2, 4.2.2.3.3, 4.2.2.4, 4.2.2.7, 4.2.2.8, 4.2.3, 4.2.5, 4.2.6, 4.2.7.2, 4.2.9, 4.2.9.1, 4.2.9.2, 4.2.9.3, 4.2.9.4, 4.2.9.5, 4.2.9.6, 4.2.9.7, 4.2.10, 4.2.10.1, 4.2.10.2, 4.2 RefDwgs, Tables 4.2-3 & 4.2-4, Figures 4.2-8 & 4.2-11, 4.3.1.3, 4.3.2, 4.3.3.1, 4.3.3.2, 4.3.4.2, 4.3.6, 4.3 Refs, Tables 4.3-4 & 4.3-5, 4.4.1.4, 7.2.3.2.3, 7.3.2.4, 7.10.1, 7.10.2.3, Table 7.10-1, 9.10.3.2 [FS 99-001]	Incorporated technical and editorial corrections and clarifications resulting from the integration review of the reactor coolant system.
KWI, 4.2.2.2, 6.2.3.3, 6.3.2.1, Tables 6.3-1 & 3, 7.6.2.1, 7.6.3, 7.10 References, 8.4.1, 8.4.4, Tables 11.2-8 & 9, 11.3.3.10, 14.2.6, 14.5.1.1, 14.5.1.4, 14.5.2.3, Table 14.5-14 [FS 98-052]	Provided grammatical and editorial corrections.
KWI, Tables 5.2-1 & 5.2-2, 7.5 References, 9.1.2.3, Table 9.5-1, App 9B, 10.3.5.2, 10.3.5.3, 11.2.2, 11.2.3, 11.2.4, Tables 11.2-1 & 11.2-11, Figures 11.2-4 through 11.2-6, 11.3.3.1, 14.2.11, 14B.5.1.7, 16.2.2.1 [FS 99-004]	Revised key word references, corrected formatting, typing, and capitalization errors, updated reference lists and references in text, added a list of tables to App 9B, and replaced a non-standard drawing symbol.
KWI, 15.3.2 [FS 95-045]	Added references to the key word index and expanded the description of the containment reinforcing steel.
Ref Dwgs: 1.2, 1.4, 2.1, 2.3, 4.2, 5.3, 6.2, 7.2, 7.3, 7.7, 8.3, 8.4, 9.1, 9.2, 9.3, 9.4, 9.5, 9.6, 9.7, 9.8, 9.9, 9.10, 9.11, 9.12, 9.13, 9.14, 10.2, 10.3, 11.2, 11.3, 15.1, 15.5; Section 9.9 [FS 99-006]	Corrected reference drawing descriptions, eliminated duplicate entries, and added companion Unit 2 drawings, where appropriate, in the reference drawing list and revised drawing reference numbers in the text.
1.4.16, 1.4.17, 4.2.7.1, 7.7.2, 9.13.1, 9.13.4.1, 11.3.3, 11.3.3.1, 11.3.3.3, 11.3.3.7, 11.3.3.8, 11.3.3.10, 11.3.3.13, 11.3.3.14, 11.3.4.1, 11.3.4.2, 11.3.4.3, 11.3.4.4, 11.3.4.7, 11.3.6, 11.3 RefDwgs, Tables 11.3-6 through 11.3-9 [FS 99-002]	Incorporated technical and editorial corrections and clarifications resulting from the integration review of the radiation monitoring system.

Revision 31—09/01/99 (continued)

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
1.4.17, 6.3.1.2, Table 9.4-7, 9.9, Tables 9.9-1&2, Figure 9.9-1, 9.10.4.17 & 18 [FS 98-014]	Incorporated technical and editorial corrections and clarifications related to the Service Water (SW) System: deleted singular SW flow rate through recirculation spray heat exchangers, corrected the description of the emergency service water pumps, and enhanced the description of the high-level intake canal.
1.4.39, 8.5, Table 8.5-1, 9.10.2.4, & 9.10.4.19 [FS 98-022]	Incorporated technical and editorial corrections and clarifications related to the Emergency Diesel Generator (EDG) System: improved the description of testing, enhanced the description of the auto tap changer configuration, corrected the EDG day tank capacity, rewrote the description of the undervoltage setpoint scheme, and improved the description of load sequencing.
1.4.59, Table 5.4-20, 6.1, Figures 6.1-1 & 2, 6.2.3.3, 6.3.1.3, 6.3.1.5.1, 6.3.1.5.2, 6.3 References, Tables 6.3-1 & 3, Figure 6.3-1, 13.1, Table 13.1-1, 13.5, 13.5.1, 13.5.1.1, 13.5.1.2, 13.5.1.3, 13.5.1.3.1, 13.5.1.3.2, 13.5.1.3.3, 13.5.1.3.4, 13.5.1.3.5, 13.5.2, 13.5 References, Tables 13.5-1 & 13.5-2 [FS 98-027]	Incorporated technical and editorial corrections and clarifications related to the Containment Spray (CS) System: improved the description of testing; designated historical information; corrected a cross-reference; corrected the figure depiction of the RWST, CS pumps, and spray headers; reflected the analyzed amount of time of system operation; enhanced the description of electrical cables; reworded RWST welding requirements; changed the RWST material description; clarified the capacity, heat tracing, and insulation of the chemical addition tank (CAT); resolved discrepancy regarding the manifold drain line; clarified description of electrical equipment testing; corrected rated pump flow; corrected pump motor insulation class; corrected nominal RWST operating temperature; clarified CAT pump horsepower rating; clarified pump operating temperature and test pressure description; clarified the description of check valves; and changed the depressurization time and subatmospheric peak pressure.

Revision 31—09/01/99 (continued)

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
1.4.68, 1.4.69, 9.1.2.2, 11.2.2, 11.2.3, 11.3.2.1, 11.3.2.2, 11.3.2.6, 11.3.2.9, 11.3.5.8, Tables 11.3-3 & 11.3-4, 11A, Table 11A-1 [FS 99-016]	Incorporated technical and editorial corrections and clarifications resulting from the integration review of the radiation protection system.
1.5, 4.3.1.2, 6.2.2.2.7, 10.2 RefDwgs, Figure 10.2-1, 10.3.1, 10.3.1.1, 10.3.1.2, 10.3.1.3, 10.3.3, 10.3 RefDwgs, 14.3.2 [FS 99-012]	Incorporated technical and editorial corrections and clarifications resulting from the integration review of the main steam system.
Table 2.1-4, 10.3.1.4, 10.3.5.2 [FS 96-063]	Added ethanolamine to the list of chemicals used for pH control.
2.2.1.1, 2.2.1.2, 2.3.1.2.2, Table 9.4-9, 9.12.9.2, 11.3.4.5, Table 11A-1 [FS 99-024]	Updated text, table, and figure cross references; corrected typographical errors; revised non-standard number and unit formats; and sorted a table in alpha-numeric order.
2.3.1.1, 2.3.1.2.1, 2.3.2, 2.3 Refs, Tables 2.3-1 through 2.3-4 [FS 95-038]	Updated the mean monthly discharge and flood discharge rates, added new references, and revised the descriptions of on-site and off-site wells.
3.2.1 [FS 96-054]	Removed the description of boron injection via the safety injection system.
3.5.2.3 [FS 97-008]	Revised the description of secondary neutron sources to reflect that they are optional in reload cores.
4.1.2.6, 4.2.7.1 [FS 96-059]	Removed references to monitoring containment leakage by monitoring containment humidity.
4.1.7.4, 4.1 Refs, Tables 4.1-14 & 4.1-15 [FS 99-018]	Updated reactor pressure vessel toughness data associated with Technical Specification Basis change.
Table 4.2-2, 9.1.2.6.8 [FS 97-005]	Revised the reactor coolant dissolved hydrogen guidelines to include startup, shutdown, and off-normal conditions.
4.3.3.1 [FS 98-006]	Modified the description of inservice inspection requirements on the reactor coolant pump flywheel. [10 CFR 50.90 License Amendment]
4.3.4.2 [FS 96-053]	Clarified the function of the PORV backup-air spare bottles.

Revision 31—09/01/99 (continued)

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
Table 5.2-1, 5.3.1.3.1, 9.4.1.1, 9.4.4.7, 9.12.9.3, 9.13.4.2, 11.2.3.1.7 [FS 99-037]	Updated text cross references, corrected typographical errors, and improved grammatical usage.
Table 5.2-2 [FS 96-021]	Added the description of a new valve to containment penetration No. 24.
Table 5.3-2, 9.4.1.2, 9.4.3.2, Tables 9.4-2, 9.4-5, & 9.9-2, Figure 9.9-1, Table 10.3-4, Figure 10.3-11 [FS 98-030]	Updated the description of the Unit 1 chilled water system to reflect equipment replacement and changing the system's source of cooling water.
5.4.1.2 [FS 97-009]	Incorporated a description of the revised method of calculating core stored energy.
6.2.2.2.4 [FS 99-029]	Incorporated modifications to the safety injection system.
6.2.3.12, 6.2.3.13 [FS 99-020]	Added a description of the portable passive autocatalytic recombiner and its use.
Table 6.2-6, Table 6.3-2, & 14.5.5.2 [FS 96-030]	Improved consistency with the Technical Specifications' description of safety injection and recirculation spray loop leakage limits.
Figures 6.2-1 & 6.2-2 [FS 99-005]	Incorporated modifications to the Unit 2 safety injection system.
6.3.1.3 [FS 98-043]	Corrected typographical omission of a passage of recirculation spray pumps' cylindrical suction screens.
6.3.1.5.2 [FS 98-026]	Clarified the description of the initial testing of the recirculation spray system.
7.1, 7.1.1, 7.1.2, 7.2 Refs, 7.2.2.1.1, 7.2.2.1.4, 7.2.2.1.6, 7.2.2.4, 7.2.3.3, 7.2 RefDwgs, Tables 7.2-1 & 7.2-3, Figures 7.2-6, & 7.2-8 through 7.2-11, 7.5.1, 7.5.1.2, 7.5.1.3, 7.5.1.4.1, 7.5.1.4.2, 7.5.2.2, 7.5.2.3.2, 7.5.3.5, Tables 7.5-1 & 7.5-2, Figures 7.5-1, 7.5-2, 7.5-4, & 7.7-1, 10.3.5.3, Table 13.1-1 [FS 98-048]	Incorporated technical and editorial corrections and clarifications resulting from the integration review of the reactor protection system.

Click on Change Package Number Highlighted in Red to View Change Request.

Revision 31—09/01/99 (continued)

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
7.3.2.6, 8.1, 9.2, 9.4, 9.4.4.5, 9.5, 9.9, 9A.3.2.2.1, 9C.1, 9C.1.1, 10.3.1, 10.3.1.2, 10.3.2, 10.3.4, 10.3.5, 10.3.5.3, 10.3.9, 11.2.3.2, & Table 11.2-11 [FS 99-015]	Incorporated editorial changes and corrections to typographical errors.
7.4.3.2 [FS 97-030]	Added new type of cable to the description of the source range nuclear instrument channels.
8.4, 8.5 [FS 99-010]	Incorporated technical and editorial corrections and clarifications resulting from the integration review of the emergency power system.
8.4.4, 8.4.5 [FS 98-029]	Added descriptions of concurrent power supplies to the new Unit 1 main control room Hathaway annunciator.
8.4.4, 8.4.5 [FS 99-009]	Adds a description of the concurrent electrical supplies to the main control room Hathaway annunciators.
8.5 [FS 98-031]	Clarified the EDG start/load acceptance time and power rating.
9.1.2.4, 9.1.2.4.1, 9.1.2.4.2, 9.1.2.4.3 [FS 96-050]	Clarified the description of operation of the reactor makeup control.
9.1.2.6.22 [FS 97-003]	Correct the description of chemical and volume control system piping operation an inspection.
Table 9.1-6 & 14.4.2.1 [FS 98-046]	Revised the description of the volume control tank rupture accident analysis.
9.2 & 10.3 [FS 93-22]	Identified equipment described in the UFSAR that is installed but no longer used.
9.3.3.1 [FS 98-017]	Removed non-combustible from the description of the radiant energy shield between the RHR pump motors.
9.4.1.1, 9.4.3.1, 9.4.3.2, 9.4.4.1, 9.4.4.3, 9.4.4.5, 9.4.5, Table 9.4-2 [FS 97-006]	Incorporate changes to the description and operation of the component cooling system.
9.4.3.1 [FS 98-002]	Revises the component cooling water chemistry chromate concentration and pH limits.

Click on Change Package Number Highlighted in Red to View Change Request.

Revision 31—09/01/99 (continued)

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
9.4.3.2 [FS 96-008]	Incorporated a revised description of the modified chiller alarms.
9.4.3.4 [FS 97-018]	Added a description of the charging pump seal cooling system modification to a once-through cooling system.
9.4.4.1 [FS 96-025]	Removed the description of automatic closure of the primary drain cooler component cooling return line.
Table 9.4-8 [FS 97-023]	Deleted the table description of the condensate makeup line check valve.
9.5.1, 9.12.5.5, 9.12.9.1, 9.12.9.2, 9.12.9.3, Table 9.12-1 [FS 96-012]	Updated the description of spent fuel handling and the requirements for cask handling in and around the spent fuel pool.
9.5.3.4 [FS 97-016]	Deleted the reference to an assumed value for fuel assembly offload rate.
Table 9.5-3 [FS 97-029]	Added description that power to the spent fuel pool cooling pumps is supplied from emergency buses.
9.9 & 9.10.4.17 [FS 98-041]	Provided grammatical and editorial corrections.
9.9.1.3, 9.10.4.13, 10.3.1.5, 10.3.5.1, 10.3.5.2, 10.3.5.3, 10.3.5.4, Table 13.5-2, 14B.5.1.7, Figure 14B-20 [FS 98-037]	Incorporated technical and editorial corrections and clarifications resulting from the integration review of the Auxiliary Feedwater System.
9.9.2 [FS 98-018]	Added the description of a temporary service water supply path to the component cooling heat exchangers. [10 CFR 50.90 License Amendment]
9.12.3.4, 11.3.4.1, 11.3 References [FS 97-042]	Incorporated the exemption form criticality monitoring in the fuel storage and handling areas. [10 CFR 70.14 Exemption]
9.12.4 & App. 9B.1 [FS 97-002]	Enhanced the description of heavy loads and their handling.
9.12.5.4 [FS 97-022]	Revised the refueling reassembly sequence to reflect current practice.

Click on Change Package Number Highlighted in Red to View Change Request.

Revision 31—09/01/99 (continued)

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
9.12.5.4 [FS 98-040]	Improved the refueling procedure reassembly sequence.
9.12.9, 9.12.9.2, 9.12.9.3 [FS 99-030]	Incorporated technical and editorial corrections and clarifications resulting from the integration review of the Surry ISFSI.
9A.1, 9A.2, 9A.3.1.2, 9A.3.1.3.2, 9A.3.1.4, 9A.3.1.5, 14.4.1.3.2, 14.4.1.3.2.1, 14.4.1.3.2.2, 14.4.1.3.2.3, Table 14.4-3 [FS 97-017]	Revised the fuel assembly drop discussions using a 42 inch drop in lieu of a 24 inch drop and corrected typographical errors.
9B.2.4.4 [FS 97-001]	Added the SFP transfer canal gate lift rig to the list of special lifting devices.
9C.1, 10.3.4.2, 10.3.4.3 [FS 99-014]	Incorporated technical and editorial corrections and clarifications resulting from the integration review of the circulating water system.
10.3.1.2 [FS 94-040]	Added a description of the new condensate return divert line to the steam generator blowdown heat exchangers.
10.3.1.4 [FS 98-036]	Updated the description of the secondary plant chemistry monitoring and control.
10.3.5.1 [FS 95-017]	Removed extraneous detail from the description of the steam generator feedwater pumps.
10.3.7.3, 10.3.7.4 [FS 96-058]	Corrected the description of the function and testing of the dc motor-driven oil pump.
10.3.12 [FS 97-021]	Clarified the description of the main steam trip valve Appendix R solenoid operated valves.
11.2.3, 11.2.3.1.8, Figure 11.2-4 [FS 97-041]	Revised the description of the RF liquid waste reverse osmosis system.
11.2.3.1.7, 11.2.4.1.4, Table 11.2-1 [FS 96-039]	Added a description of the new RF liquid waste reverse osmosis system and revised liquid waste handling descriptions.
11.2.3.1.8, Figure 11.2-4 [FS 99-017]	Clarified the operation of the liquid waste reverse osmosis and demineralizer system.
11.2.5.3.4 [FS 95-036]	Incorporated a revised description of the modified waste gas decay tank oxygen analyzer.

Click on Change Package Number Highlighted in Red to View Change Request.

Revision 31—09/01/99 (continued)

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
11.3.4.3 [FS 96-007]	Corrected the nominal counting rates for limiting isotopes of the containment gas monitors.
11.3.5.1, 11.3.5.3, 11.3.5.5, 11.3.5.6, 11.3.5.7, 11.3.5.9 [FS 96-033]	Incorporated changes to the Radiological Environmental Monitoring Program
12.2.2.3, 12.2 References [FS 97-045]	Revised reactor operator training program references.
12.7 [FS 97-014]	Incorporated revised security plan references.
14.2.6, 14.2.6.1, 14.2.6.1.1, 14.2.6.1.2, 14.2.6.2, 14.2.6.2.1, 14.2.6.2.2, 14.2.6.2.3, 14.2.6.2.4, 14.2.6.2.5, & 14.2.6.3 [FS 95-041]	Revised the startup on an inactive loop accident analysis description.
14.2.11, 14.3.2, 14B.4.2, 14B.6, 14B.6.1, 14B.6.2, 14B Refs [FS 99-032]	Augmented the description of effects of piping system breaks outside containment with a transient analysis of a high-energy line break in the main steam valve house.
14.3.2 [FS 96-044]	Revised wording to clarify the main steam pipe break description.
14.5.5.3, 14.5 Refs [FS 99-036]	Incorporated the results of a sensitivity analysis performed to evaluate acceptable quantities of emergency core cooling system in conjunction with potentially unfiltered exhaust from the Auxiliary Building.
15.5.1.8 [FS 96-051]	Revised the description of containment electrical penetrations to address variations between manufacturers.
16, 16.1, 16.2, 16.2.1, 16.2.1.1, 16.2.1.2, 16.2.2, 16.2.2.1, 16.2.2.2, 16.2.2.3, Tables 16.2-1, 16.2-2, & 16.2-3 [FS 99-008]	Relocated requirements for plant operation and surveillance of systems to the Technical Requirements Manual (TRM). Explicitly incorporated the TRM into the UFSAR.
17.2.2.5 [FS 98-049]	Updated the qualification requirements for Oversight personnel.
17.2.16.2 [FS 98-051]	Incorporated a title change.

Click on Change Package Number Highlighted in Red to View Change Request.

Revision 31—09/01/99 (continued)

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
Table 17.2-0 [FS 98-038]	Revised the description to indicate the both Innsbrook record vaults meet ANSI requirements.

Revision 30—09/01/98

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
1.4, 6.1, 6.2, 6.3.1.5, 7.5.3.5, Tables 5.2-1&2, Tables 5.4-18, 19, & 20, Tables 6.2-2, 3, 4, 5, 6, 10, 11, 12, &13, Figs. 6.1-1 & 6.2-2 [FS 98-015]	Incorporated technical and editorial corrections and clarifications related to the Safety Injection System.
1.4.59, 5.3.3, 6.2.3, 6.3.1, 7.5.2.2, 11.3.3.10, Tables 6.3-1 & 3, Figs. 6.3-2, 3, & 5 [FS 98-019]	Incorporated technical and editorial corrections and clarifications related to the Recirculation Spray System.
2.2.1.1, Table 2.2-7, 2.5.3.2, 6.1, 6.2.2.1.2, Table 6.2-1, 6.2.3.12.1, 6.2.4.1.4, 6.2 References, 7.4.3.6, Figure 7.5-1, 8.3, 9.6, 9.8, 9.10, 9B.2.1, 9B.2.4.1, 9B.2.4.4, 9B.2.4.7, 9C, 11.2, Tables 11A-6, 7,9 & 10, Table 14.3-15, Table 14.5-11, 15.5.1.8 & Table 16.2-2 [FS 98-032]	Corrected references, typographical errors, and verb tense; clarified an abbreviated term and illegible text; and corrected format of numbers, upper/lower case usage, and text lists.
3.3.3.2.2, 3.5, App. 9A & Tables 3.3-1 & 9.12-1 [FS 97-043]	Increased the maximum fuel enrichment from 4.1 to 4.3 weight percent U-235. [10 CFR 50.90 License Amendment]
4.2.2.3.2 [FS 98-024]	Added a description of the removal of the steam generator channel head drain lines.
5.3.1 & 9.13 [FS 96-061]	Revised description of auxiliary ventilation and containment ventilation systems to reflect changes in these systems design and operation.
5.4 & Tables 5.4-17, 5.4-18, 5.4-19, 5.4-20, 6.2-11, 6.2-12 & 6.2-13 [FS 97-040]	Removed Containment concrete floor plugs and the Pressurizer cubicle roof plug.
6.2.2.1.1 & Table 6.2-2 [FS 96-047]	Updated the description of the Safety Injection control board indication.
6.2.2.1.3 [FS 96-027]	Changed to state that pressure-relieving devices discharge to the liquid waste disposal system.

Click on Change Package Number Highlighted in Red to View Change Request.

Revision 30—09/01/98 (continued)

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
6.2.2.2.1 [FS 97-039]	Clarified the tanks to which the accumulators may be drained.
6.2.2.2.4 & 6.2 References [FS 96-040]	Revised description of safety injection valves MOV-1890A/B and MOV-2890A/B to reflect addition of pressure equalization line. Added Reference to NRC Generic Letter 95-07.
6.2.3.3 [FS 98-007]	Changed containment spray and minimum recirculation spray pH ranges.
6.2.3.10, 6.2.4.1.4, 6.3.1.4, 15.5.1.3, 15.5.1.12 & Figure 15.5-1 [FS 97-007]	Revised the description of the Containment ground water control equipment, ground water protection methods, and liquid level alarms.
6.2.3.12 [FS 98-009]	Changed post-LOCA containment hydrogen concentration for new initial conditions.
6.2.3.12.1 [FS 96-052]	Revised valve stroke time for isolation of the volume control tank.
6.2.4.1.3, 6.2.4.1.4 [FS 96-046]	Changed to describe SI system testing as a series of tests during refueling, and to state that accumulator discharge check valves are tested during refueling.
6.3.1.2.1 [FS 97-004]	Removed the statement that sodium hydroxide solution was only present in the containment spray system during system operation.
6.3.1.4, Tables 6.2-12 & 13 [FS 98-021]	Revised description of NPSH to the recirculation spray pumps to include impact several minor phenomena with impact on post-LOCA sump level.
7.2.3.2.7 [FS 98-010]	Clarified the description of the AMSAC C-20 setpoint.
8.6 [FS 93-33]	Clarified preventive maintenance program requirements by deleting the statement which implies that insulation testing is performed on all electrical equipment.
9.9.1.2 & 9.9.3 [FS 96-011]	Updated the description of Emergency Service Water Pump, 1-SW-P-1A, to indicate the removal of the electric motor drive.

Click on Change Package Number Highlighted in Red to View Change Request.

Revision 30—09/01/98 (continued)

Section	**Changes** Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
9.9.1.3 & 9.10.4.18 [FS 96-055]	Clarified the description of actions taken prior to the arrival of a hurricane onsite and corrected the classification of the circulating water valves as safety related.
9.9.2 & Table 2.1-4 [FS 96-036]	Updated the description of service water chemical treatment and updated the list of onsite chemicals.
9.10.4.16 [FS 98-025]	Updated the description of Emergency Service Water Pump, 1-SW-P-1A, to indicate the removal of the electric motor drive.
10.3.1.2 [FS 98-013]	Removed the statement that the Main Steam Safety Valves temperature flow probes are required for compliance with Regulatory Guide 1.97.
10.3.5.3, 14.2.11.1.3 [FS 96-041]	Relocated the stated numerical value of auxiliary feedwater (AFW) flowrate from the section describing the AFW system to the section where event analysis is described.
11.2.2, 11.2.5, & Tbl. 11.2-11 [FS 97-035]	Modified descriptions of process vent system to remove implied wind speed limitations for system operation.
12.1.1.2.1, 17.2, & KWI [FS 98-003]	Updated Station Manager title to Site Vice President and Assistant Station Managers titles to Manager-Station O&M and Manager-Station S&L. [10 CFR 50.90 License Amendment]
14.2.7 [FS 98-11]	Updated the description of the feedwater temperature reduction event.
14.3.1 [FS 97-034]	Revised the steam generator tube rupture accident analysis to reflect the evaluation of the effect of steam generator tube bundle uncovery on radioiodine release.
17.2.1.2.B.1 [FS 98-028]	Identified the Site Vice President as the station position fulfilling the Plant Manager position identified in the ISFSI Technical Specifications.

Revision 30—09/01/98 (continued)

Section	Changes Made under the provisions of 10 CFR 50.59 except where indicated in brackets.
17.2.3 [FS 98-016]	Revised to reflect replacement of A/E Instruction Manual with an Engineering Standard.

Revision 29—3/1998

Section	Changes
17.2, 17.2.1.2, 17.2.2.1, 17.2.3, 17.2.4, 17.2.5, Figure 17.2.1-1, and Table 17.2-0 [FS 97-026]	Deleted reference to Nuclear Operations Department Standards and replaced with Nuclear Business Unit Standard. Added position of Project Manager (Configuration Management).
17.2.1.1 and 17.2.1.2 [FS 98-004]	Clarified organizational position descriptions by noting responsibilities for the ISFSI as they already exist.
17.2.1.2, Figure 17.2.1-2, and Figure 17.2.1-3 [FS 98-005]	Deleted the position of Supervisor Administrative Services in the Nuclear Management organization and assigned duties and responsibilities to other positions.
17.2.2.6 and 17.2.2.8 [FS 97-038]	Clarified Quality Inspection Coordinator qualifications.
17.2.17, Tables 17.2-2 and 17.2-3 [FS 97-048]	Added Generic Letter 88-18 commitment regarding storage of quality assurance records on optical disk media.
Table 17.2.0 [FS 96-049]	Added provision for storage of quality assurance records in an approved offsite facility.
Table 17.2-0 [FS 97-044]	Provided an additional alternative to ANSI/ANS 3.1.
Tables 17.2-2 and 17.2-3 [FS 98-012]	Clarified the description of onsite and offsite nuclear safety review committees.

Intentionally Blank

Revision 28—02/11/98

Section	Changes
Foreword	Updated to reflect recent NRC initiatives regarding UFSAR submittal requirements, and adequacy and consistency of design basis information; and to note Virginia Power's adoption of electronic methods to enhance UFSAR maintenance, and UFSAR distribution in both hardcopy and electronic media.
5.5 [FS 95-039]	Modified leak rate testing discussion to include 10 CFR 50, Appendix J, Option B performance-based leak rate testing rulemaking.
7.5.1.1 [FS 96-045]	Changed low-low pressurizer SI manual block setpoint from 2000 psia to 2000 psig.
9.6 [FS 95-043]	• Added introduction and revised subsection headings • Clarified the 3-hour requirement for PASS samples • Deleted references to sampling abandoned flash evaporators • Noted that condenser tube leakage monitoring may be by means other than chlorides monitoring • Deleted superfluous HRSS equipment brand names • Clarified operation of the HRSS waste tank • Clarified remote indication of HRSS parameters • Clarified SS valve isolation on an SI signal • Clarified environmental qualification of HRSS containment sump pump
9.10 & 17.2 [FS 96-042]	Deleted references to the Training Center records vault and associated features.
9.12 [FS 96-022 R1]	Updated to reflect current refueling practices.
14.5.2 [FS 96-057]	Updated to reflect reanalysis of small break loss of coolant accident (SBLOCA), including Tables 14.5-14 thru 16, and Figures 14.5-36, and 38 thru 68.

Click on Change Package Number Highlighted in Red to View Change Request.

Revision 28—02/11/98 (continued)

Section	Changes
Table 17.2-3 [FS 97-037]	Corrected typos.
All (no change bars) [FS 97-012] [FS 97-013]	• Consolidated 7 volumes to 4 volumes • Referenced Station Drawings previously included in UFSAR; inserted simplified diagrams • Removed notations associated with previously deleted material and renumbered sequentially • Renumbered previously inserted items that had suffixes (e.g., 4A, 4B) • Applied consistent typeface and page layouts • Improved consistency of measurement notation (e.g., time, mass, velocity), including abbreviations

FOREWORD

In the May 9, 1980, edition of the Federal Register (45 FR 30614), the NRC published a Final Rule requiring all licensed reactors to periodically update their Final Safety Analysis Reports. The purpose of the Rule was to establish baseline reference documents to be used in recurring safety analyses by licensees, the NRC, or other interested parties.

The “Supplementary Information” section of the Final Rule notice stated that submittal of an updated FSAR does not constitute a licensing action, but is only intended to provide information. The NRC Staff may review the material submitted, but does not intend to formally approve it. The NRC intends to use the updated FSAR in the future for appropriate applications such as reporting of deviations from conditions stated in the UFSAR.

The Rule became effective July 22, 1980, and established the following basic requirements for Vepco’s nuclear power stations:

- A complete Updated FSAR (UFSAR) was required as the initial submittal
- The UFSAR was to reflect information and analyses submitted to the NRC by Vepco, or prepared by Vepco pursuant to NRC requirements, since submission of the original FSAR (or, as appropriate, the last UFSAR)
- NOTE: The “Supplementary Information” section of the Final Rule notice clarifies this requirement by stating that no analyses other than those already prepared or submitted pursuant to NRC requirements are required because of the Rule: however, FSAR analyses that are known to be nonconservative based on new analyses must be updated. Other new analyses not previously included in the FSAR may be incorporated in the UFSAR at the option of the licensee. Furthermore, specialized studies provided in the original FSAR (e.g., seismology, meteorology) should include the latest information developed in response to NRC requirements when these studies are transferred to the UFSAR, and program type material referenced by the UFSAR (e.g., security plan, emergency plan, QA Program) should be referenced accurately. In addition, the level of detail in the UFSAR should be at least the same as but not necessarily greater than that provided in the original FSAR. Information on design changes should not be included until the changes are approved for use and operable.
- The initial UFSAR was due no later than July 22, 1982
- The initial UFSAR was required to be up-to-date as of a maximum of six months prior to the date of filing (January 31, 1982, was chosen by Vepco as the cutoff date)
- Subsequent updates are required at least annually and must reflect changes made up to a maximum of six months prior to the date of filing

- One original and 12 copies of the initial UFSAR and subsequent updates are required to be submitted to the NRC
- The updates are required to be certified by a duly authorized officer of Vepco
- The initial UFSAR should be a clean document without change bars and revision numbers. The subsequent annual revisions should include change indicators and page change identification

In response to the foregoing FSAR update requirements, Vepco and NUS Corporation executed an Agreement for FSAR update services in April 1981, and NUS began work on the project immediately. The project was accomplished in four basic phases:

1. Document Retrieval
2. Change Package Development
3. FSAR Revision
4. Printing

- During the initial document retrieval phase in the Spring of 1981, NUS engineers researched the licensing correspondence files at Vepco offices in Richmond and the design change files at the plant sites. All documents potentially affecting the FSAR were copied and taken to the NUS home office.

  Following the initial document review phase, NUS engineers periodically visited Richmond and the plant sites to acquire newly developed information. NUS was also placed on the distribution list for Vepco/NRC correspondence.

  The document retrieval phase continued until early 1982, at which time sufficient information was available to document changes up to the January 31, 1982, cutoff date.

- The documentation retrieved during the first phase was reviewed in detail during the second phase to determine the particular “two-digit” section or sections of the FSAR that should be revised, i.e., 1.1, 1.2, 1.3, etc. Copies of the document (or of the particular pages of the document that were of interest) were placed in separate files corresponding to the two-digit sections. These files were defined as “change packages.” Development of the change packages continued in parallel with the document retrieval phase, with new information being reviewed and assigned to appropriate change packages. The final change packages became a work product delivered to Vepco on conclusion of the update effort and are available for tracing the sources of changes to the original FSARs
- After development of the initial change packages the material filed therein was used in the third phase of the project to make the actual FSAR revisions. The revision process continued in parallel with the continuing development of the change packages.

The revision phase for most FSAR chapters included two cycles of Vepco review and comment. These comments became part of the change packages and were used in the development of the final draft UFSAR.

- Vepco reviewed and approved the final draft chapters of the UFSARs for printing. The printer prepared approximately 125 sets of the UFSARs. NUS delivered one original and 12 copies of the UFSAR directly to the NRC on July 20, 1982, for Surry and July 22, 1982, for North Anna. The original UFSARs were transmitted under cover letter supplied to NUS by Vepco (see the attachment to this foreword). The remaining copies were shipped to Richmond and the plant sites.

The following work products were also delivered to Vepco by NUS and are available for use in producing subsequent annual updates:

- Printer's copy of the UFSARs
- Annotated FSARs (2 copies)
- Final Change Packages (2 sets)
- Plant Drawing Indexes
- Key Word Indexes
- IBM Displaywriter Floppy Discs (2 sets each of the FSAR, Annotated FSAR, and Key Word Index)
- Update Procedures
- Introductory Volumes to the FSARs including this foreword, a list of effective pages, the key word indexes, the plant drawing indexes and a record of changes

Further 10 CFR 50.71(e) rulemaking pertaining to UFSAR requirements for nuclear power stations was promulgated as recently as July 29, 1996 [61 FR 39278]. In particular, the annual revision requirement has been relaxed to six months after each refueling outage provided the interval between successive updates does not exceed 24 months.

The NRC issued a letter to licensees dated October 9, 1996, entitled Request for Information Pursuant to 10 CFR 50.54(f) Regarding Adequacy and Availability of Design Basis Information. The letter required submittal of information that will provide the NRC added confidence and assurance that Virginia Electric and Power Company's nuclear plants are operated and maintained within their design bases and that any deviations are reconciled in a timely manner. The Company's response (Serial No. 96-535) dated February 7, 1997, described previously conducted programmatic reviews of the Updated Final Safety Analysis Report (UFSAR). The 1996 UFSAR Project Team examined the existing administrative controls for maintaining UFSAR content and usability. Process enhancements to simplify administrative controls, to increase accountability for technical content, and to improve UFSAR accessibility and usability are promoted by conversion to electronic media.

Under separate cover (Serial No. 97-108) dated May 23, 1997, Virginia Electric and Power Company notified the NRC about its project to address potential regulatory concerns involving the current design and licensing bases for the Surry and North Anna Power Stations. This project scope exceeds the level of scrutiny normally applied to the current licensing basis through routine surveillance and quality assurance activities. In order to facilitate thorough review, exhaustive validation, and a rigorous corrective action process, the recommended conversion to electronic media was implemented in Revision 28 of the Surry UFSAR. The entire text of the UFSAR was entered into electronic media. The conversion was accomplished by a process of augmenting recent UFSAR revision word processing packages with “scanned-in” optical character recognition documents for the balance of text, tables, and figures not previously stored electronically. A 100-percent word-for-word proofing was conducted by comparing a printed version of the entire electronic document with current controlled distribution copies. Thus, the electronic UFSAR was conveyed into service as the quality assurance document of record without introducing any substantive, technical, or non-editorial changes.

VIRGINIA ELECTRIC AND POWER COMPANY
RICHMOND, VIRGINIA 23261

R. H. LEASBURG
VICE PRESIDENT
NUCLEAR OPERATIONS

July 16, 1982

Mr. Harold R. Denton, Director
Office of Nuclear Reactor Regulation
U. S. Nuclear Regulatory Commission
Washington, D. C. 20555

Serial No. 424
NO/GSS:acm
Docket Nos. 50-280
50-281
License Nos. DPR-32
DPR-37

Gentlemen:

UPDATED FINAL SAFETY ANALYSIS REPORT
SURRY POWER STATION UNITS NO. 1 AND 2

Pursuant to 10 CFR 50.71(e), the Virginia Electric and Power Company hereby submits the Updated Final Safety Analysis Report (UFSAR) for the Surry Power Station Units No. 1 and 2. One signed original and twelve additional copies of the UFSAR are enclosed.

The UFSAR contains all the necessary changes since the submission of the original FSAR. This UFSAR is up to date as of February 1, 1982 which is within six months prior to the date of this letter.

The enclosed UFSAR is a completely new document without the pages from the original FSAR. It is not a revision of the original FSAR but retains all the applicable information from the original FSAR.

This initial UFSAR is a "clean" document without change bars and revision numbers. The subsequent revisions will have the change indicator and change identification.

Future revisions of the UFSAR will be submitted at least annually and will reflect all the changes up to six months prior to the date of submission.

As a duly authorized officer of Vepco, I hereby certify that the information given in the enclosed UFSAR accurately presents changes made since the previous submittal, necessary to reflect information and analyses submitted to the Commission or prepared pursuant to Commission requirement.

Very truly yours,

R. H. Leasburg

Enclosures:

CHAPTER 1 INTRODUCTION AND SUMMARY

1.1 INTRODUCTION

This FSAR supports the operation of two similar nuclear power units, designated as Surry Power Station Units 1 and 2, constructed on a site situated on Gravel Neck and adjacent to the James River in Surry County, Virginia, pursuant to the construction permit issued by the Commission.

Each unit includes a pressurized water reactor (PWR) nuclear steam supply system and turbine generator furnished by Westinghouse Electric Corporation, similar in design concept to several projects licensed by the Commission. The balance of each unit was designed by Vepco, with the assistance of its agent, Stone & Webster Engineering Corporation.

Each reactor unit was designed for a warranted power output of 2441 MWt, with an equivalent warranted gross electrical output of 822.6 MWe. However, the nominal core power rating for each unit is 2587 MWt. All steam and power conversion equipment, including the turbine generator, has been designed on the basis of this higher thermal output and has the capability to generate a maximum calculated gross output of 885 MWe. The engineered safeguards systems and the containment are designed and evaluated for operation at this higher power level, which is used in the analysis of all postulated incidents in this report that have offsite consequences.

Unit 1 achieved commercial operation in December 1972 and Unit 2 in May 1973. In 2010, both units were uprated to a core power output of 2587 MWt (corresponding to a nuclear steam supply system power rating of 2599 MWt).

The remainder of Chapter 1 of this report summarizes the principal design features and safety criteria of the nuclear units by emphasizing the similarities and differences with respect to other pressurized water nuclear power plants at other sites.

Chapter 2 contains a description and evaluation of the Surry site and its environs and demonstrates the suitability of the site for reactors of the size and type described. Chapters 3 and 4 describe the reactor and the reactor coolant system, and Chapters 5 and 15 describe the containment structure and related systems. Chapters 7 through 11 describe the other auxiliary systems. Chapters 5, 6, 7, 8, and 9 include descriptions of the various systems directly related to safeguards. Chapter 12 reviews Vepco's organization and technical competence, associated contractors and consultants, and information relating to station organization and personnel training. Chapter 13 describes Vepco's approach to initial tests and operation. Chapter 14 relates to safety evaluation; it summarizes the analyses that demonstrate the adequacy of the reactor protection system, the containment system, and the engineered safeguards system, and shows that the consequences of various postulated incidents are within the guidelines suggested in the Commission's regulation 10 CFR 100, 10 CFR 50.67, or Regulatory Guide 1.183 (RG 1.183).

Chapter 17 describes the quality assurance program for the operational phase of Vepco's nuclear power stations. Chapter 18 describes the existing and new aging management programs necessary to provide reasonable assurance that components within the scope of license renewal will continue to perform their intended functions consistent with the current licensing basis (CLB) through the subsequent period of extended operation and activities credited in support of the subsequent renewed operating licenses. The inclusion of Chapter 18 into the UFSAR is a condition of the subsequent renewed operating licenses. This final safety analysis report has been prepared using the AEC publication *A Guide for the Organization and Contents of Safety Analysis Reports* as a guide. Refinements may be made from time to time through amendments to this report.

With respect to the numbers, graphs, and drawings included within this report, it should be understood that normal tolerance permitted by good engineering practice is intended. Where operating parameters are unusually important, it is acknowledged that such items are included in the Technical Specifications, the adoption of which is a condition of the operating license.

1.1.1 Design Highlights

The design of the Surry Power Station is based upon concepts that have been developed and successfully applied in the construction of other PWR systems. In subsequent paragraphs, certain design features of the Surry Power Station are indicated that represent slight variations or extrapolations from other units approved for operation, such as H. B. Robinson 2 (Docket 50-261) and Indian Point 3 (Docket 50-286).

1.1.2 Power Level

The nominal power rating for each unit of the Surry Power Station is set at 2587 MWt. Site and engineered safeguards evaluation has been performed for a reactor thermal output of 2587 MWt, which corresponds to the maximum calculated nominal rating of the turbine generator. In 1995, a 2546-MWt power rating was achieved by about a 4.3% increase in the average reactor heat flux over the 2441-MWt rating established for initial operation. An additional 1.6% increase to 2587 MWt was included in a license amendment issued by the NRC in Reference 2 in response to Reference 1.

1.1.3 Reactor Coolant Loops

The reactor coolant system for each unit consists of three loops, each loop having components (steam generator, pumps, and piping) similar to those at Indian Point Unit 2, except that each of the Surry units has two reactor coolant loop stop valves and a bypass valve in each loop.

1.1.4 Peak Specific Power

The operation of the initial core cycle at 2441 MWt yielded a maximum steady-state peak specific power of 17.3 kW/ft and a corresponding peak power of 19.4 kW/ft for the 112% overpower condition. These values were justified by the results of incore experiments by Westinghouse and others at these and higher specific power ratings. These ratings were lower than the corresponding conditions for Indian Point Unit 2, which were 18.4 kW/ft steady-state and 20.6 kW/ft overpower, and which were a result of lower design hot-channel factors.

1.1.5 Fuel Clad

The fuel rod design for each unit uses Zircaloy-4, ZIRLO, or Optimized ZIRLO as a clad material. Zircaloy-4 was proven successful in the Carolinas-Virginia Tube Reactor (CVTR) and Saxon reactors, in Yankee (Rowe), test assemblies, and was subsequently used in many Westinghouse reactors. ZIRLO was later introduced and used in most Westinghouse PWR fuel. Optimized ZIRLO has been irradiated in lead assemblies which include Millstone Unit 3, V. C. Summer, and South Texas. Optimized ZIRLO has been introduced in reload batch quantities at Arkansas Nuclear One Unit 2 and Waterford Unit 3.

1.1.6 Fuel Assembly Design

The fuel assembly incorporated the rod cluster control concept in a canless 15 x 15 fuel and control rod array using grids to provide support for the fuel rods. Extensive out-of-pile tests have been performed on this concept, successful in-pile tests have been performed in the Saxton reactor, and operating experience is available from the San Onofre, Connecticut Yankee, and other similar plants. Prior to the introduction of Surry Improved Fuel (SIF) for both units, all grids were made of Inconel. Beginning with SIF, all intermediate spacer grids will be made of either Zircaloy or ZIRLO.

1.1.7 Moderator Temperature Coefficient of Reactivity

Burnable poison rods are used in the reactor unit to provide a negative moderator temperature coefficient at cycle start-up. As the fuel in the core is depleted and the boron shim concentration is decreased, the moderator temperature coefficient becomes more negative.

1.1.8 Containment

The reactor containment concept is based on the use of a reinforced-concrete container structure similar to that of the Connecticut Yankee Atomic Power Plant, but the containment is maintained at subatmospheric pressure during normal operation. Following the postulated loss-of-coolant accident (LOCA) described in Chapter 14, the containment peak pressure would be reduced to subatmospheric by the use of redundant chemical spray cooling systems, thereby positively terminating outleakage to the environment within 1 hour after the initiation of the accident assuming the most limiting single failure, i.e., loss of emergency power to one train of spray systems. These original design criteria were modified in conjunction with the analyses for implementation of the alternative source term. The modified criteria require that, following the

LOCA, the containment pressure be less than 2.0 psig within 1 hour and less than 0.0 psig within 6 hours. The radiological consequences analysis demonstrates acceptable results provided the containment pressure does not exceed 2.0 psig for the interval from 1 to 6 hours following the Design Basis Accident. Beyond 6 hours, containment pressure is assumed to be less than 0.0 psig, terminating leakage from containment.

1.1.9 Xenon Oscillations

Ex-core instrumentation is provided to obtain necessary information concerning power distribution. This instrumentation is adequate to enable the operator to monitor and control xenon-induced power oscillations. Extensive analysis, with confirmation of methods by special transient experiments at Haddam Neck, has shown that any induced radial or diametral xenon transients would die away naturally. A full discussion of xenon stability control can be found in WCAP 7208-L (1968), *Power Distribution Control of Westinghouse Pressurized Water Reactors*, Westinghouse proprietary.

SUMMARY

0.0.1 General

Each unit at the Surry Power Station incorporates a closed-cycle pressurized water nuclear steam supply system, a turbine generator, and their necessary auxiliaries. Radioactive waste disposal systems, a fuel handling system, and all auxiliaries, structures, and other onsite facilities required for a complete and operable nuclear power station are also provided. The general arrangement of the units is shown in the site plan, Figure 15.1-1, and the plot plan, Reference Drawing 1.

0.0.2 Structures

The major structures are the reactor containments, auxiliary building, fuel building, turbine building, and service building, which includes the main control area. General layouts of the reactor containment for Unit 1, the auxiliary building, and the fuel building, showing interior arrangements, are given on Reference Drawings 2 through 14.

Each reactor containment is a steel-lined, reinforced-concrete cylinder with a hemispherical dome and a flat, reinforced-concrete foundation mat. Each containment is designed to withstand the internal pressure accompanying the hypothetical design-basis incident, is virtually leaktight, and provides adequate radiation shielding for both normal operation and design-basis accident (DBA) conditions. Whenever at subatmospheric pressure, there is no outleakage of activity from the containment structure. The seismic criteria used in the design of the structures and equipment in the station are described in Section 2.5. The maximum horizontal ground acceleration for design purposes is 0.07g. The design-basis maximum horizontal ground acceleration is assumed to be 0.15g. Dampening at these accelerations has been assumed to be 5% and 10%, respectively. Vertical acceleration is two-thirds of the horizontal acceleration and is considered to act simultaneously with the horizontal acceleration.

0.0.3 Nuclear Steam Supply System

The nuclear steam supply system for each unit consists of a pressurized water reactor, a reactor coolant system, and associated auxiliary systems. The reactor coolant system is arranged as three closed reactor coolant loops connected in parallel to the reactor vessel, each containing a reactor coolant pump, isolation and bypass valves, piping, and a steam generator. An electrically heated pressurizer is connected to one of the loops.

Each reactor core includes uranium dioxide pellets, enclosed in zirconium alloy tubes with welded end plugs, as fuel. The tubes are supported in assemblies by structures of grids and there are suitable end pieces for the support of the assembled rods and restraint of abnormal axial movement. The mechanical control rod assemblies consist of clusters of stainless-steel-clad absorber rods that are guided by tubes located within the fuel assembly. The core consists of 157 of these fuel assemblies loaded in varying enrichments. Originally, an out-in fuel management approach was used in core design. Fresh, high-enrichment fuel was introduced into the core outer region. At the next refueling, it was moved to the core inner region where it was intermingled with fuel moved from the outer region during the previous refueling. Two refuelings later, the original high-enrichment fuel was discharged to spent-fuel storage. Currently a low leakage type of fuel management is employed which places burned fuel assemblies on the core periphery and intermingles the fresh fuel assemblies with previously burned assemblies in the core's interior regions.

The steam generators are vertical U-tube units containing Inconel tubes. Integral separating equipment reduces the moisture content of the steam at the turbine throttle to 0.25% or less.

The reactor coolant pumps are vertical, single-stage, centrifugal pumps equipped with controlled-leakage shaft seals.

The reactor coolant loop stop and bypass valves are motor-operated gate valves that are remotely controlled from the control room. These valves permit any loop to be isolated from the reactor vessel.

Nuclear auxiliary systems are provided to perform the following functions:

1. Accommodate reactor coolant system water makeup requirements.
2. Purify reactor coolant water.
3. Introduce chemicals for corrosion inhibition.
4. Introduce and remove chemicals for reactivity control.
5. Cool system components.
6. Remove residual heat during a portion of the reactor cooling period and also when the reactor is shut down.
7. Cool the spent-fuel pool water.
8. Permit the sampling of reactor coolant water.
9. Provide for emergency safety injection.
10. Vent and drain the reactor coolant system and the auxiliary systems.
11. Provide emergency containment spray.
12. Provide emergency chemical containment spray.
13. Maintain a subatmospheric containment pressure.
14. Provide containment ventilation and cooling.
15. Dispose of liquid and gaseous wastes, and provide for the disposal of solid wastes.

0.0.4 Reactor and Station Controls

The reactor is controlled by a coordinated combination of chemical shim and mechanical control rod assemblies. The control system permits the unit to accept step load increases of 10% and ramp load increases of 5% per minute over a load range of 15% to 100% power under normal operating conditions, subject to xenon limitations.

The control of both the reactor and turbine generator for each unit is accomplished from the control room and is supervised by licensed operators.

0.0.5 Waste Disposal System

The waste disposal system provides all equipment necessary to collect, process, and prepare for disposal of all radioactive liquid, gaseous, and solid waste produced as a result of station operation. The waste disposal system is capable of handling the wastes produced by both units as a result of station operation.

Liquid wastes are collected and processed by evaporation, reverse osmosis, and/or ion exchange. Processed liquid is analyzed before discharge into the river. Discharges are maintained below limits established by 10 CFR 20 or other appropriate regulations. Non-combustible and combustible solid wastes can be sorted, shredded, baled or drummed consistent with applicable offsite processing or disposal requirements. They are shipped from the site for ultimate disposal at an authorized location.

Gaseous wastes are diluted and discharged to the environment with a yearly average radioactivity level within the limits set forth in 10 CFR 20.

0.0.6 Fuel Handling Systems

The reactor is refueled with equipment designed to handle spent fuel under water from the time it leaves a reactor vessel until it is placed in a cask for shipment from the site. Spent fuel is transferred under water, which provides an optically transparent radiation shield and a reliable source of coolant for removal of residual heat.

0.0.7 Turbines and Auxiliaries

Each turbine is a tandem-compound, three-element, 1800-rpm unit having 57-inch, last-stage exhaust blading in the low-pressure elements. Four combination moisture separators-reheaters are employed to dry and superheat the steam between the high-pressure and low-pressure turbine cylinders for each unit. A single-pass, deaerating surface condenser installed in two sections, two 100%-capacity steam jet air ejectors, three 50%-capacity condensate pumps, two 50%-capacity steam generator feedwater pumps, three auxiliary feedwater pumps, and six stages of feedwater heating are provided.

0.0.8 Electrical Systems

The main generator for each unit is an 1800-rpm, 22-kV, three-phase, 60-cycle, hydrogen inner-cooled unit. A main step-up transformer delivers power to the high-voltage switchyard.

The station service power distribution system for each unit consists of station service transformers, 4160V and 480V switchgear and buses, and 480V motor control centers. The normal source of station service power is the main generator, while the reserve station service transformers provide an alternate source via the switchyard. The emergency power distribution system consists of 4160V and 480V switchgear and buses, 480V motor control centers, 120V ac vital buses, and 125V dc batteries and equipment. The emergency buses are normally powered from the switchyard via the three reserve station service transformers.

Emergency power is supplied by alternate sources, including one emergency diesel-driven generator for each unit and a third diesel-driven generator shared by both units. Each diesel-driven generator is capable of operating post-incident containment recirculation spray pumps as well as charging pumps and low-head safety injection pumps to ensure an acceptable containment pressure transient during the design-basis accident.

1.2 REFERENCE DRAWINGS

The list of Station Drawings below is provided for information only. The referenced drawings are not part of the UFSAR. This is not intended to be a complete listing of all Station Drawings referenced from this section of the UFSAR. The contents of Station Drawings are controlled by station procedure.

1.3 COMPARISON WITH OTHER STATIONS

Table 1.3-1 presents a summary of the design and operating parameters for the Surry Power Station nuclear steam supply systems. The table provides a comparison of these data with the data available from the FSAR of Turkey Point Units 3 and 4, and with the data available from the FSAR of H. B. Robinson Unit 2.

The Turkey Point and H. B. Robinson references were selected because both are closely related technically to the Surry units, and both were reviewed for operating licenses during the same general time frame as the Surry units.

The Surry Power Station units are also generally comparable with the pressurized water reactors at Pacific Gas and Electric Company, Duquesne Light Company, Rochester Gas and Electric Company, and the Tennessee Valley Authority (Sequoyah Units).

Table 1.3-1
COMPARISON OF INITIAL DESIGN PARAMETERS

Design Parameter	Surry Power Station	Turkey Point 3 or 4	H.B. Robinson
Thermal and Hydraulic Design Parameters			
Total core heat output	2441 MWt	2200 MWt	2200 MWt
Total core heat output	8331×10^6 Btu/hr	7479×10^6 Btu/hr	7479×10^6 Btu/hr
Heat generated in fuel	97.4%	97.4%	97.4%
Maximum thermal overpower	112%	112%	112%
System operating pressure, nominal	2250 psia	2250 psia	2250 psia
System operating pressure, minimum steady state	2200 psia	2200 psia	2200 psia
DNB ratio at nominal initial rating condition	1.97	1.81	1.81
Minimum DNB ratio for design transients	1.30	1.30	1.30
Coolant flow			
Total flow rate	100.7×10^6 lb/hr	101.5×10^6 lb/hr	101.5×10^6 lb/hr
Effective flow rate for heat transfer	96.2×10^6 lb/hr	97.0×10^6 lb/hr	97.0×10^6 lb/hr
Effective flow area for heat transfer	41.8 ft^2	41.8 ft^2	41.8 ft^2
Average velocity along fuel rods	14.2 ft/sec	14.3 ft/sec	14.3 ft/sec
Average mass velocity	2.31×10^6 lb/hr-ft^2	2.32×10^6 lb/hr-ft^2	2.32×106 lb/hr-ft^2
Coolant temperature (at 100% power)			
Nominal inlet	543°F	546.2°F	546.2°F
Minimum inlet due to instrumentation error and deadband	547°F	550.2°F	550.2°F

1.4 COMPLIANCE WITH CRITERIA

The design of the Surry Power Station meets the intent of the criteria as expressed within this section. Following the text of each criterion is a brief discussion specific to that criterion.

1.4.1 Quality Standards

Those systems and components of reactor facilities that are essential to the prevention of accidents that could affect the public health and safety or to the mitigation of their consequences are designed, fabricated, and erected in accordance with quality standards that reflect the importance of the safety function to be performed. Where generally recognized codes or standards on design, materials, fabrication, and inspection are used, they are identified. Where adherence to such codes or standards does not suffice to ensure a quality product in keeping with the safety function, they are supplemented or modified as necessary. A showing of sufficiency and applicability of codes, standards, quality assurance programs, test procedures, and inspection acceptance levels used is required.

Refer to the response to the criterion in Section 1.4.2.

1.4.2 Performance Standards

Those systems and components of reactor facilities that are essential to the prevention of accidents that could affect the public health and safety or to the mitigation of their consequences are designed, fabricated, and erected in accordance with performance standards that enable the facility to withstand, without loss of the capability to protect the public, the additional forces that might be imposed by natural phenomena such as earthquakes, tornadoes, flooding conditions, winds, ice, and other local site effects. The design bases so established reflect (a) appropriate consideration of the most severe of these natural phenomena that have been recorded for the site and the surrounding area, and (b) an appropriate margin for withstanding forces greater than those recorded, in view of uncertainties about the historical data and their suitability as a basis for design.

Those features of reactor facilities essential to the prevention of accidents that could affect the public health and safety or to the mitigation of their consequences are designed, fabricated, and erected in conformity with:

1. Quality standards that reflect the importance of the safety function to be performed. Approved design codes are used when appropriate to the nuclear application.
2. Performance standards that enable the facility to withstand, without loss of the capability to protect the public, the additional forces imposed by the most severe earthquake, flooding condition, wind, ice, or other natural phenomena characteristic of the site.

Features of the facility essential to accident prevention and the mitigation of accident consequences are the designs of the fuel, reactor coolant, and containment barriers; the controls and emergency cooling systems whose function is to maintain the integrity of these three barriers;

systems that depressurize the containment following a LOCA; a power supply and essential services; and the components employed to safely convey and store radioactive wastes and spent reactor fuel.

The fuel assembly rod design considers the effect on the zirconium alloy cladding of internal fission gas pressure buildup, thermal expansion, irradiation, and fabrication variations. Core design conditions and cladding material specifications are selected to limit hydrogen absorption during core life to levels that do not affect fuel cladding integrity. To ensure high quality, fuel rod materials are subjected to chemical analysis and tensile tests and the rods receive dimensional inspection, X-ray of welds, ultrasonic tests, and helium leak tests.

Quality standards of material selection, design, fabrication, and inspection governing the above features conform to the applicable provisions of recognized codes and good nuclear practice. The reinforced-concrete reactor containment structures conform to the applicable portions of ACI-318-63.

Further elaboration on quality standards of the reactor containment is given in Chapter 15. Vessels comply with Section III of the ASME Code under the specific classification dictated by their use. The principles of this Code, or equivalent guidelines, are employed where the Code is not strictly applicable but where the safety function calls for an equivalent assurance of quality. In the same manner, piping conforms to the requirements of USAS B31.1.

Particular emphasis is placed on the assurance of quality of each reactor vessel and hence on the acquisition of materials whose properties are uniformly within tolerances appropriate to the application of the design methods of the Code. The fatigue usage factor, derived from an assumed number of thermal cycles that is probably more than four times the number of such cycles actually expected, is less than that at which the propagation of material defects would occur.

The design margin and material surveillance ensure that each vessel is operated well within the ductile range of temperatures when the reactor vessel is operated within established operational limits. Further discussion of quality assurance for the reactor vessels, including the use of vessel irradiation test specimens, is given in Chapter 4.

All piping, components, and supporting structures of each reactor and the safety-related systems are designed to withstand a specified seismic disturbance in excess of that predicted for the site. Station design criteria specify that there is no loss of function of such equipment in the event of the DBA ground acceleration acting in the horizontal and vertical directions simultaneously. The dynamic response of Class I structures to ground acceleration, based on appropriate characteristics of the site foundation soils and on the critical damping of the foundations and structures, is included in the design analysis.

Each reactor containment is defined for seismic purposes as a Class I structure. Structural members have sufficient capacity to accept, without exceeding yield stresses, a combination of normal operating loads, functional loads due to a design-basis accident and the loadings imposed by the maximum wind velocity or the design-basis earthquake (DBE), whichever is larger. The emergency onsite power sources are not subject to interruption due to earthquakes, windstorms, floods, or disturbances in the external power transmission system. Power cabling, motors, and other equipment required for the operation of the engineered safeguards is suitably protected against the effects of the design-basis accident and other severe external environmental conditions, as applicable, to ensure a high degree of confidence in the operability of these systems should they be required.

Auxiliary and Emergency Systems	9
Radioactive Wastes and Radiation Protection	11
Structures and Construction	15

1.4.3 Fire Protection

The reactor facility is designed (1) to minimize the probability of events such as fires and explosions and (2) to minimize the potential effects of such events on safety. Non-combustible and fire-resistant materials are used whenever practical throughout the facility, particularly in areas containing critical portions of the facility such as the containment, the control room, and components of engineered safeguards.

Fire or explosions occurring within the reactor facility are avoided because of the inherent preventive features in the station design.

Waste hydrogen gas is collected in the waste gas decay tanks. The oxygen content of the tank is limited administratively to 2% by volume. The oxygen content by volume may be diluted to a concentration below its upper limit by the addition of nitrogen to the tank (preferred - to maximize radioactivity decay time of waste gases) or by performing a release. Systems processing hydrogen-oxygen mixtures that are potentially hazardous conform to the National Electrical Code for Areas of Class I, Division 2, Group B. All spark-producing devices near the waste hydrogen equipment are explosion-proof.

The containment and other structures containing safe-shutdown equipment are of fire resistive or non-combustible construction and contain mostly non-combustible equipment. Atmospheric conditions inside the containment are not of an explosive nature.

The control room is of non-combustible construction and is isolated from surrounding areas by heavy concrete shielding. The control room atmosphere is not explosive and is maintained under positive pressure by its air conditioning system.

The references chapters are as follows:

Reactor Coolant System	4
Containment System	5
Auxiliary and Emergency System	9
Radioactive Wastes and Radiation Protection	11

1.4.4 Sharing of Systems

Reactor facilities do not share systems or components unless it is shown that safety is not impaired by the sharing.

The facilities that have shared systems or components are tabulated in Section 1.5, with references to sections containing specific design details.

No impairment of the safety of the reactor facilities is caused by the sharing of any of these systems, and in certain instances such sharing enhances system reliability.

1.4.5 Records Requirements

Records of the design, fabrication, and construction of essential components of the plant are maintained by the reactor operator or are under Vepco’s control throughout the life of the reactor.

Records of the design, fabrication, and construction of essential components are maintained during the life of the unit and are available to Vepco. Chapter 17 includes a discussion of this matter. Records of all tests performed and test procedures used are kept by Vepco for the life of the unit.

The reference chapter is as follows:

Title	Chapter
Quality Assurance (Topical Report)	17

1.4.6 Reactor Core Design

The reactor core with its related controls and protection systems is designed to function throughout its design lifetime without exceeding acceptable fuel damage limits that have been stipulated and justified. The core and related auxiliary system designs provide this integrity under all expected conditions of normal operation with appropriate margins for uncertainties and for specified transient situations that can be anticipated.

The reactor core with its related control and protection system is designed to function throughout its design lifetime without exceeding acceptable fuel damage limits. The core design, together with reliable process and decay heat removal systems, provides for this capability under all expected conditions of normal operation with appropriate margins for uncertainties and anticipated transient situations, including the effects of the loss of reactor coolant flow, trip of the turbine generator, loss of normal feedwater, and loss of all offsite power.

The reactor control and protection instrumentation is designed to actuate a reactor trip for any anticipated combination of unit conditions when necessary to ensure a minimum departure from nucleate boiling ratio (DNBR) equal to or greater than the design DNBR limit (Section 3.2.3) and fuel center temperatures below the melting point of uranium dioxide.

The references chapters are as follows:

Title	Chapter
Reactor	3
Instrumentation and Control	7
Safety Analysis	14

1.4.7 Suppression of Power Oscillations

The design of the reactor core with its related controls and protection systems ensures that power oscillations, the magnitude of which could cause damage in excess of acceptable fuel damage limits, are not possible or can be readily suppressed.

The design of the reactor core and related protection systems ensures that power oscillations that could cause fuel damage in excess of acceptable limits are not possible or can be readily suppressed.

The potential for possible spatial oscillations of power distribution for this core are reviewed as part of the core stability evaluation described in Section 1.6. Ex-core instrumentation is provided to obtain necessary information concerning axial and azimuthal power distributions. This instrumentation is adequate to enable the operator to monitor and control xenon-induced oscillations. Based on the deviations detected by the long ion chambers, provisions in the reactor control and protection system reduce trip setpoints and if necessary initiate load runback to maintain margin to departure from nucleate boiling as a result of these potential oscillations in power distribution. Incore instrumentation is used to periodically calibrate and verify the information provided by the ex-core instrumentation.

The general conclusion based on experimental results from SENA and San Onofre is that the ex-core instruments do give an accurate indication of the fact that power redistribution is taking place. This has been confirmed by a comparison with incore instrumentation results.

The temperature coefficient in the power operating range was maintained zero or negative by the inclusion of burnable poison shims in the initial core loading. Burnable poison shims can also be used in subsequent core loadings if necessary.

The reference chapters are as follows:

Title	Chapter
Reactor	3
Instrumentation and Control	7

1.4.8 Overall Power Coefficient

The reactor is designed so that the overall power coefficient in the power operating range is not positive.

The overall power coefficient is negative under normal operating conditions throughout core life.

The reference chapter is as follows:

Title	Chapter
Reactor	3

1.4.9 Reactor Coolant Pressure Boundary

The reactor coolant pressure boundary is designed, fabricated, and constructed so as to have an exceedingly low probability of gross rupture or significant uncontrolled leakage throughout its design lifetime.

The reactor coolant system, in conjunction with its control and protective provisions, is designed to accommodate the system pressures and temperatures attained under all expected modes of unit operation or anticipated system interactions, and to remain within the applicable code stress limits.

The fabrication of the components that constitute the pressure-retaining boundary of the reactor coolant system is carried out in strict accordance with the applicable codes. In addition, there are areas where equipment specifications for reactor coolant system components are more restrictive than applicable codes.

The materials of construction of the pressure-retaining boundary of the reactor coolant system are protected by the control of coolant chemistry so as to prevent corrosion phenomena that might otherwise reduce the system structural integrity during its service lifetime.

The reference chapter is as follows:

Title	Chapter
Reactor Coolant System	4

1.4.10 Containment

Containment is provided. The containment structure is designed to sustain the initial effects of gross equipment failures, such as a large coolant boundary break, without loss of required integrity, and, together with other engineered safeguards as may be necessary, to retain for as long as the situation requires the functional capability to protect the public.

A reinforced-concrete, steel-lined containment structure operating at subatmospheric pressure encloses the entire reactor coolant system. It is designed to sustain, without loss of required integrity, all effects of gross equipment failures up to and including the rupture of the largest pipe in the reactor coolant system. Engineered safeguards, which consist of safety injection systems and containment depressurization systems, serve to cool the reactor core and return the containment to subatmospheric pressure and maintain it at subatmospheric pressure for as long as the situation requires. The containment and its associated engineered safeguards exceed the required functional capability of protecting the public from the consequences of gross equipment failures, since they provide for a rapid termination of the effects of the event.

The reference chapters are as follows:

Title	Chapter
Containment System	5
Engineered Safeguards	6

1.4.11 Control Room

The facility is provided with a control room from which actions to maintain the safe operation of the plant can be controlled.

Radiation protection is provided to permit access, even under accident conditions, to equipment in the control room or other areas as necessary to shut down and maintain safe control of the facility without radiation exposures of personnel in excess of 10 CFR 20 limits. It is possible to shut the reactor down and maintain it in a safe condition if access to the control room is lost through fire or other causes.

The control room is located at grade level in the service building. All safety-related switchgear, motor-generator sets, auxiliary instrument areas, battery rooms, and communications equipment are located in the basement of the service building. Sufficient shielding, distance, and containment integrity are provided to ensure that under postulated accident conditions during occupancy of the control room, control room personnel shall not be subjected to doses that, in the aggregate, would exceed the limits in 10 CFR 50.67. Emergency air-conditioning equipment is provided within the envelope of the shielded control room and associated portions of the basement, collectively called the control and relay room area. The control room is provided with the switchyard control panel, electrical recording panels, dc distribution panels, and a control panel for the operation of the diesel-generator system. The control panels contain those instruments and controls necessary for the operation of station and unit systems such as the reactor and its auxiliary systems, the turbine generator, and the steam and power conversion systems. Loading from the various station electrical distribution boards, such as the start-up boards, shutdown boards, and motor control centers, is accomplished from the station control panels.

The control room is common to the two units and is continuously occupied by qualified operating personnel under all operating and accident conditions.

In the event that access to the control room is restricted, either local control stations or the manual operation of critical components within the main control area can be used to effect hot shutdown from outside the control room.

The reference chapters are as follows:

Title	Chapter
Instrumentation and Control	7
Auxiliary and Emergency Systems	9

1.4.12 Instrumentation and Control Systems

Instrumentation and controls are provided as required to monitor and maintain within prescribed operating ranges essential reactor facility operating variables.

Instrumentation and controls essential to avoid undue risk to the health and safety of the public are provided to monitor and maintain neutron flux, primary coolant pressure and temperature, and control rod assembly positions within prescribed operating ranges.

The non-nuclear-regulating process and containment instrumentation measures temperatures, pressure, flow, and levels in the reactor coolant system, main steam system, containment, and auxiliary systems. Process variables required on a continuous basis for the start-up, operation, and shutdown of the unit are indicated, recorded, and controlled from the control room, into which access is supervised. The quantity and types of process instrumentation provided ensure the safe and orderly operation of all systems and processes over the full operating range of the station.

Reference chapters are as follows:

Title	Chapter
Engineered Safeguards	6
Instrumentation and Control	7

1.4.13 Fission Process Monitors and Controls

Means are provided for monitoring or otherwise measuring and maintaining control over the fission process throughout core life under all conditions that can reasonably be anticipated to cause variations in the reactivity of the core.

Nuclear instrumentation is provided to monitor reactor power from the source range through the intermediate range and power range up to 120% of full power. The system provides indication, control, and alarm signals for reactor operation and protection.

The operational status of the reactor is monitored from the control room. When the reactor is subcritical, the relative reactivity status is continuously monitored and indicated by proportional counters located in instrument wells in the neutron shield tank adjacent to the reactor vessel. Two source detector channels supply information on multiplication while the reactor is subcritical.

When the reactor is critical, means for showing the relative reactivity status of the reactor are provided by control rod assembly bank positions displayed in the control room. The position of the control rod assembly banks is directly related to the reactivity status of the reactor when at power, and any unexpected change in the position of the control rod assembly banks under automatic control or any change in the coolant temperature under manual control provides a direct and immediate indication of a change in the reactivity status of the reactor. Periodic sampling to determine the boric acid concentration provides a long-term means of following reactivity status.

The reference chapter is as follows:

Title	Chapter
Instrumentation and Control	7

1.4.14 Core Protection Systems

Core protection systems, together with associated equipment, are designed to prevent or to suppress conditions that can result in exceeding acceptable fuel damage limits.

The reactor protection system receives, from unit instrumentation, signals that are indicative of an approach to an unsafe operating condition. This system then actuates alarms, prevents control rod assembly motion, initiates load runback, and/or opens the trip breakers causing the insertion of the control rod assemblies, depending on the severity of the condition. The allowable operating range within reactor trip settings includes combinations of power, temperature, and pressure that do not result in the occurrence of a departure from nucleate boiling with all reactor coolant pumps in operation.

The reference chapter is as follows:

Title	Chapter
Instrumentation and Control	7

1.4.15 Engineered Safeguards Protection Systems

Protection systems are provided for sensing accident situations and initiating the operation of necessary engineered safeguards.

Instrumentation and controls provided for the protection systems are designed to trip the reactor when necessary to prevent or limit fission product release from the core and to limit energy release, to cause closure of containment isolation valves, and to control the operation of engineered safeguards equipment.

Additional tripping functions such as a high pressurizer pressure trip, low pressurizer pressure trip, high pressurizer water-level trip, loss-of-coolant-flow trip, steam and feedwater flow mismatch trip, steam generator low-low water-level trip, turbine trip, safety injection trip, neutron source and intermediate range trips, and manual trip are provided to back up the primary tripping functions for specific accident conditions and mechanical failures.

The passive accumulators of the safety injection system do not require signal or power sources to perform their function. The actuation of the active portion of this system is obtained from low-low pressurizer pressure, high containment pressure, steam header to steam line pressure differential, high steam flow coincident with a low T_{avg} or low steam line pressure signals, and manual actuation.

The containment isolation system provides the means for isolating various pipes passing through the containment walls as required to prevent the release of radioactivity to the outside environment in the event of a LOCA. The actuation of containment isolation is by coincident and redundant containment high-pressure signals.

Reference chapters are as follows:

Title	Chapter
Containment System	5
Engineered Safeguards	6
Instrumentation and Control	7

1.4.16 Monitoring Reactor Coolant Pressure Boundary

Means are provided for monitoring the reactor coolant pressure boundary to detect leakage.

Means of detecting leakage from the reactor coolant system are provided by measuring the airborne activity of the containment and indicating changes in makeup requirements and containment sump levels.

The sampling system for each unit contains two steam generator blowdown sample monitors in parallel. They are used for monitoring the liquid phase of the steam generators for radioactivity indicative of a primary-to-secondary system leak. Samples from each of the three steam generator bottoms are mixed in two common headers with each header going to a gamma scintillation counter mounted in an in-line liquid sampler. In general, both monitors are used continuously. Either monitor can be used to monitor any individual steam generator that is known to be leaking. In the event that one of the monitors becomes inoperative, or requires maintenance, the other monitor can be used to monitor any or all of the steam generators.

The output of the detectors is transmitted to the control room to provide indication, recording, and alarm functions. A high activity level is indicated by both audio and visual alarms.

The reference chapters are as follows:

Title	Chapter
Reactor Coolant System	4
Auxiliary and Emergency Systems	9
Radioactive Wastes and Radiation Protection	11

1.4.17 Monitoring Radioactive Releases

Means are provided for monitoring the containment atmosphere and the facility effluent discharge paths for radioactivity released from normal operations, from anticipated transients, and from accident conditions. An environmental monitoring program is maintained to confirm that radioactivity releases to the environs of the plant have not been excessive.

The containment atmosphere, the plant vent, and the waste disposal system liquid effluent discharge are monitored for radioactivity concentration during all normal operations, from anticipated transients, and from accident conditions.

All gaseous effluent from possible sources of accident releases of radioactivity external to the reactor containment (e.g., the spent-fuel pool and waste-handling equipment) are exhausted from monitored ventilation effluent pathways. Accident spills of liquids are maintained within the auxiliary building and collected in sumps. Any contaminated liquid effluent discharged to the condenser circulating water discharge canal is monitored. For the case of leakage from the reactor containment under accident conditions, the station radiation monitoring system, supplemented by portable survey equipment, will provide adequate monitoring of accident releases. The details of the procedures and equipment to be used in the event of an accident are specified in the station Emergency Plan Implementing Procedures (EPIPs).

The reference chapter is as follows:

Title	Chapter
Radioactive Wastes and Radiation Protection	11

1.4.18 Monitoring Fuel and Waste Storage

Monitoring and alarm instrumentation is provided for fuel and waste storage and handling areas for conditions that might contribute to a loss of continuity in decay heat removal and to radiation exposures.

The spent-fuel pool water temperature and level are continuously monitored. The temperature is displayed in the control room where an audible alarm sounds if the water temperature increases above a preset level. Audible alarms sound in the control room if the water level exceeds the high-level or low-level setpoints. The radiation level above the spent-fuel pool is continuously monitored by a radiation detector mounted on the fuel pool movable platform. A dose rate in excess of a preset level initiates an audible and visible alarm locally and in the control room. Continuous surveillance of radiation levels in the waste storage and handling areas is maintained by an appropriately mounted radiation detector. Radiation levels in excess of preset levels initiate audio and visual alarms locally and in the control room.

Auxiliary and Emergency Systems	9
Radioactive Wastes and Radiation Protection	11

1.4.19 Protection Systems Reliability

Protection systems are designed for high functional reliability and inservice testability necessary to avoid undue risk to the health and safety of the public.

The reactors use the Westinghouse magnetic-type control rod drive mechanisms that are similar to those used in the San Onofre, Indian Point, and Connecticut Yankee power stations. Upon a loss of power to the coils, the control rod assembly is released and falls by gravity into the core.

All reactor protection channels are supplied with sufficient redundancy to provide the capability for channel calibration and testing at power. The bypass removal of one trip circuit is accomplished by placing that circuit in a half-tripped mode; that is, a two-out-of-three circuit becomes a one-out-of-two circuit. Testing does not trip the system unless a trip condition exists in a concurrent channel. Reliability and independence are obtained by redundancy within each tripping function.

The reference chapters are as follows:

Title	Chapter
Reactor	3
Instrumentation and Control	7

1.4.20 Protection Systems Redundancy and Independence

Redundancy and independence designed into the protection systems are sufficient to ensure that no single failure or removal from service of any component or channel of such a system results in a loss of the protection function. The redundancy provided includes, as a minimum, two channels of protection for each protection function to be served.

The reactor protection system is designed in accordance with the IEEE *Standards for Nuclear Power Plant Protection Systems*.

Two reactor trip breakers are provided to interrupt power to the control rod drive mechanisms. The main breaker contacts are connected in series with the mechanism coils. Opening either breaker interrupts power to all mechanisms, causing them to release all control rod assemblies to fall by gravity into the core. Each breaker is opened through an undervoltage trip coil. A shunt trip relay is installed in parallel with the undervoltage attachment. Upon de-energization, contacts from the relay energize the reactor trip breaker shunt trip attachment and trips open the breaker. This provides a redundant/backup means to automatically trip the breakers upon the receipt of a trip signal from the reactor trip system. Each protection channel permits the actuation of one reactor trip breaker undervoltage trip coil. The protection system is thus inherently safe in the event of a loss of power to the control rod drive mechanisms.

The initiation of the engineered safeguards provided for the LOCA is accomplished from redundant signals derived from reactor coolant system and containment instrumentation. Channel independence is carried throughout the system from the sensors to the output relays, including the power supplies for the channels.

The reference chapter is as follows:

Title	Chapter
Instrumentation and Control	7

1.4.21 Single Failure Definition

Multiple failures resulting from a single event are treated as a single failure.

The requirements of this criterion are included in the criterion of Section 1.4.23.

1.4.22 Separation of Protection and Control Instrumentation Systems

Protection systems shall be separated from control instrumentation systems to the extent that the failure or removal from service of any control instrumentation system component or channel, or of those components or channels common to control instrumentation and protection circuitry, leaves intact a system satisfying all requirements for the protection channels.

The coincident trip philosophy is employed to prevent a single failure from causing a spurious trip or from defeating the function of any channel.

Each reactor trip circuit is designed so that the trip occurs upon the de-energization of the circuit; an open circuit or loss of power to a channel will, therefore, cause that channel to go into its trip mode. Redundancy within each channel provides reliability and independence of operation. Channel independence is carried throughout the system from the sensor to the relay providing the logic. In some cases, however, it is desirable to employ a common sensor for both a control and a protection channel. Both functions are fully isolated in the remainder of the channel, control being derived from the primary safety signal path through an isolation amplifier. Thus, a failure in the control circuitry does not adversely affect the safety channel.

The reference chapter is as follows:

Title	Chapter
Instrumentation and Control	7

1.4.23 Protection Against Multiple Disability for Protection Systems

The effects of adverse conditions to which redundant channels or protection systems might be exposed in common, either under normal or accident conditions, do not result in the loss of protection function or will be tolerable on some other basis.

The components of the reactor protection system are designed and arranged so that their environment in any emergency situation in which the components are required to function does not interfere with that function.

Each of the engineered safety features is designed to tolerate a single failure during the period of recovery following an incident, without loss of its protective function. This period of recovery consists of two segments, the short-term period and the long-term period. During the short-term period, the single failure is limited to a failure of an active component to complete its function as required. Should the single failure occur during the long-term rather than the short-term period, the safety-related system is designed to tolerate an active failure or a passive failure without loss of its protective function.

The following definitions pertain to the protection against multiple disability criteria:

Period of recovery - The time necessary to bring the plant to a cold shutdown and regain access to faulted equipment. The recovery period is the sum of the short- and long-term periods defined below.

Short term - The time from the initiation of the accident until the plant enters the recirculation phase of accident mitigation.

Long term - The time from when the plant enters the recirculation phase of the accident mitigation until the plant enters a cold shutdown mode and has the capability to access faulty equipment.

Active failure - The failure of a powered component, such as a piece of mechanical equipment, component of the electrical supply system, or instrumentation and control equipment, to act on command to perform its design function. Examples include the failure of a motor-operated valve to move to its correct position; the failure of an electrical breaker or relay to respond; the failure of a pump, fan, or diesel generator to start; etc.

Passive failure - The structural failure of a static component, which limits the component's effectiveness in carrying out its intended function. Examples include the failure of a battery or a cable.

Equipment moving spuriously from the proper safeguards position without signal, such as a motor-operated valve inadvertently shutting at the moment it is required, is not considered as an active failure.

The reference chapter is as follows:

Title	Chapter
Instrumentation and Control	7

1.4.24 Emergency Power for Protection Systems

In the event of loss of all offsite power, sufficient alternative sources of power are provided to permit the required functioning of the protection systems.

There are four separate 120V ac vital buses, each supplied by an independent 15 kVA inverter power supply. The inverter is housed within an electrical cabinet, which also contains a rectifier/charger, a static transfer switch, a manual bypass switch, and a voltage regulating line conditioner (RLC). This configuration is shown in Reference Drawing 1. The inverters are supplied in pairs by a common station battery. Each inverter pair and one battery form a safety train of uninterruptable power. There are two station batteries and inverter pairs per nuclear unit at Surry, which provide two independent redundant uninterruptable power supply (UPS) electrical trains. Normally, the inverter load is absorbed by the UPS rectifier/charger. The emergency onsite power required to operate safety related protection systems equipment is supplied by three 100%-capacity diesel generators for the two units.

The reference chapter is as follows:

Title	Chapter
Electrical Systems	8

1.4.25 Demonstration of Functional Operability of Protection Systems

Means shall be included for the suitable testing of the active components of protection systems while the reactor is in operation to determine if a failure or loss of redundancy has occurred.

Each protection channel in service at power is capable of being calibrated and tripped independently by simulated signals for test purposes to verify its operation. This includes a check through to the trip breakers that includes the trip logic. Thus, the operability of each trip channel is determined conveniently and without ambiguity.

The reference chapter is as follows:

Title	Chapter
Instrumentation and Control	7

1.4.26 Protection Systems Fail-Safe Design

The protection systems are designed to fail into the safe state or into a state established as tolerable on a defined basis if conditions such as a disconnection of the system, a loss of energy (e.g., electrical power, instrument air), or adverse environments (e.g., extreme heat or cold, fire, steam, or water) are experienced.

Each reactor trip circuit is designed so that trip occurs when the circuit is de-energized. An open circuit or loss of channel power therefore causes the system to go into its trip mode. In a two-out-of-three circuit, the three channels are equipped with separate primary sensors and each channel is energized from two independent electrical buses. Failure to de-energize when required is a mode of malfunction that affects only one channel. The trip signal furnished by the two remaining channels is unimpaired in this event.

The signal for containment isolation, except as initiated by safety injection, is developed from a three-out-of-four circuit in which each channel is separate and independent. The circuit signals for containment isolation upon high or high-high containment pressure. The failure of any one channel to energize when required does not interfere with the proper functioning of the isolation circuit. Each channel has provision for periodic tests to prove the ability to operate when energized.

Reactor trip is implemented by interrupting power to the magnetic latch mechanisms on each drive, allowing the control rod assemblies to insert by gravity. The protection system is thus inherently safe in the event of a loss of power.

The reference chapter is as follows:

Title	Chapter
Instrumentation and Control	7

1.4.27 Redundancy of Reactivity Control

Two independent control systems, preferably of different principles, are provided.

One of the two reactivity control systems employs control rod assemblies to regulate the position of neutron absorber within the reactor core. The other reactivity control system employs the chemical and volume control system to regulate the concentration of boron neutron absorber in the reactor coolant system.

The reference chapters are as follows:

Title	Chapter
Reactor	3
Instrumentation and Control	7
Auxiliary and Emergency Systems	9

1.4.28 Reactivity Hot Shutdown Capability

The reactivity control systems provided are capable of making and holding the core subcritical from any hot standby or hot operating condition.

The reactivity control systems are capable of making and holding the core subcritical from any hot standby or hot operating condition, including those resulting from power changes. The maximum excess reactivity expected for reload cores occurs at the beginning of life, no xenon conditions.

The control rod assemblies are divided into two categories, control groups and shutdown groups. The control groups, used in combination with soluble boron control, provide control of the reactivity changes of the core throughout the life of the core at power conditions. The control groups are used to compensate for short-term reactivity changes at power that might be produced by variations in reactor power requirements or in coolant temperature. The soluble boron control is used to compensate for the more slowly occurring changes in reactivity throughout core life as well as those attributable to fuel depletion and fission product buildup.

The reference chapters are as follows:

Title	Chapter
Reactor	3
Auxiliary and Emergency Systems	9

1.4.29 Reactivity Shutdown Capability

One of the reactivity control systems provided is capable of making the core subcritical under any anticipated operating condition (including anticipated operational transients) sufficiently fast to prevent exceeding acceptable fuel damage limits. The shutdown margin should ensure subcriticality with the most reactive control rod fully withdrawn.

The reactor core, together with the reactor control and protection system, is designed so that the minimum DNB ratio is at least the design DNBR limit (Section 3.2.3) and there is no fuel melting during normal operation, including periods of anticipated transients.

The shutdown groups of control rod assemblies are provided to supplement the control groups to make the reactor at least 1.77% delta k/k subcritical, following trip from any credible operating condition to the hot, zero-power condition, assuming the most reactive control rod assembly remains in the fully withdrawn position. Sufficient shutdown capability is also provided to ensure no DNB occurs for the most severe anticipated cooldown transient associated with a single active failure (i.e., the accidental opening of a steam bypass or relief valve). Thus, shutdown capability is achieved by a combination of control rod assemblies and automatic boron addition via the safety injection system with the most reactive control rod assembly assumed to be fully withdrawn. Manually controlled boron addition is used to supplement the control rod assemblies in maintaining the shutdown margin for the long-term conditions of xenon decay and unit cooldown.

The reference chapters are as follows:

Title	Chapter
Reactor	3
Engineered Safeguards	6
Auxiliary and Emergency Systems	9

1.4.30 Reactivity Holddown Capability

The reactivity control systems provided are capable of (1) making the core subcritical under credible accident conditions, with appropriate margins for contingencies, and (2) limiting any subsequent return to power such that there is no undue risk to the health and safety of the public.

The reactivity control systems provided are capable of making and holding the core subcritical under accident conditions in a timely fashion, with appropriate margins for contingencies. Normal reactivity shutdown capability by control rod assemblies is provided within 2.4 seconds after a trip signal and this is followed by boron injection to compensate for the long-term xenon decay transient and for unit cooldown. Any time that the reactor is at power, the quantity of boric acid retained in the boric acid tanks and ready for injection exceeds that quantity required for the normal cold shutdown. This quantity always exceeds the quantity of boron required to bring the reactor to hot shutdown and to compensate for subsequent xenon decay.

The reference chapters are as follows:

Title	Chapter
Reactor	3
Auxiliary and Emergency Systems	9

1.4.31 Reactivity Control System Malfunction

The reactor protection systems are capable of protecting against any single malfunction of the reactivity control system, such as the unplanned continuous withdrawal (not ejection or dropout) of a control rod, by limiting reactivity transients to avoid exceeding acceptable fuel damage limits.

Reactor shutdown with control rod assemblies is completely independent of the normal control functions, since the trip breakers completely interrupt the power to the control rod drive mechanisms regardless of existing control signals. The protection systems limit reactivity transients so that the DNBR is not less than the design DNBR limit (Section 3.2.3) for any single malfunction in the reactor control system or in the de-boration controls.

The reference chapters are as follows:

Title	Chapter
Reactor	3
Instrumentation and Control	7
Auxiliary and Emergency Systems	9

1.4.32 Maximum Reactivity Worth of Control Rods

Limits, which include reasonable margin, are placed on the maximum reactivity worth of control rods or elements and on the rates at which reactivity can be increased to ensure that the potential effects of a sudden or large change of reactivity cannot (1) rupture the reactor coolant pressure boundary, or (2) disrupt the core, its support structures, or other vessel internals sufficiently to lose the capability of cooling the core.

Limits, which include considerable margin, are placed on the maximum reactivity worth of control rod assemblies or elements and on the rates at which reactivity can be increased to ensure that the potential effects of a sudden or large change of reactivity cannot (1) rupture the reactor coolant pressure boundary or (2) disrupt the core, its support structures, or other vessel internals so as to lose the capability to cool the core.

The wiring arrangement for the control rod drive mechanisms prevents the withdrawal of control rod assemblies except as part of a select group of which each is part.

The maximum reactivity insertion rate is analyzed in a detailed unit analysis that assumes the two highest-worth sequential groups to be accidentally withdrawn at maximum speed, yielding reactivity insertion rates that are well within the capability of the overpower-overtemperature protection circuits to prevent core damage.

No credible mechanical or electrical control system malfunction can cause a control rod assembly to be withdrawn at a speed greater than its mechanical limit.

The reference chapters are as follows:

Title	Chapter
Reactor	3
Instrumentation and Control	7
Safety Analysis	14

1.4.33 Reactor Coolant Pressure Boundary Capability

The reactor coolant pressure boundary is capable of accommodating without rupture the static and dynamic loads imposed on any boundary component as a result of an inadvertent and sudden release of energy to the coolant. As a design reference, this sudden release is taken as that which would result from a sudden reactivity insertion such as rod ejection (unless prevented by positive mechanical means), rod drop, or cold water addition.

The reactor coolant pressure boundary is capable of accommodating without rupture the static and dynamic loads imposed as a result of a sudden reactivity insertion such as a control rod assembly ejection.

The operation of the reactor is such that the severity of an ejection accident is inherently limited. Since control rod assemblies are used to control load variations only and core depletion is followed with boron dilution, only the control rod assemblies in the controlling group are inserted in the core at power, and these assemblies are only partially inserted. A control rod assembly insertion limit monitor is provided as an administrative aid to the operator to ensure that this condition is met.

Through the arrangement of fuel assemblies, the design limits the maximum fuel temperature for the highest-worth ejected rod. This maximum temperature value precludes any resultant damage to the primary system pressure boundary such as gross fuel dispersion in the coolant and possible excessive pressure surges.

The failure of a rod mechanism housing causing a control rod to be rapidly ejected from the core is evaluated as a theoretical, though not a credible, accident. While limited fuel damage could result from this hypothetical event, the fission products are confined to the reactor coolant system and the reactor containment. The environmental consequences of rod ejection are less severe than those of the hypothetical loss of coolant, from which public health and safety are shown to be adequately protected.

The reference chapters are as follows:

Title	Chapter
Reactor	3
Reactor Coolant System	4
Safety Analysis	14

1.4.34 Reactor Coolant Pressure Boundary Rapid Propagation Failure Prevention

The reactor coolant pressure boundary is designed and operated to reduce to an acceptable level the probability of a rapidly propagating failure. Consideration is given to (1) the provisions for control over service temperature and irradiation effects that may require operational restrictions, (2) the design and construction of the reactor pressure vessel in accordance with applicable codes, including those that establish the requirements for the absorption of energy within the elastic strain energy range and for the absorption of energy by plastic deformation, and (3) the design and construction of reactor coolant pressure boundary piping and equipment in accordance with applicable codes.

The reactor coolant pressure boundary is designed to reduce the probability of a rapidly propagating failure to an acceptable level.

The fast neutron exposure of the core region of the reactor vessel changes the notch toughness of the vessel material. This change is indicated by the increase in the nil ductility transition temperature and allowance for it is made in the operating procedures by ensuring that the vessel is not subjected to full operating pressure until its temperature exceeds the design transition temperature, defined to be the nil ductility transition temperature plus a 60°F margin. The pressure during unit start-up and shutdown at temperatures below the nil ductility transition temperature are maintained below the threshold of concern for safe operation.

The design transition temperature dictates the procedures to be followed in hydrostatic testing and in station operations to avoid excessive cold stress. The value of the design transition temperature is increased during the life of the station as required by the expected shift in the nil ductility transition temperature, which is confirmed by the experimental data obtained from irradiated specimens of reactor vessel materials during the unit lifetime.

All pressure-containing components of the reactor coolant system are designed, fabricated, inspected, and tested in conformance with the applicable codes.

The reference chapter is as follows:

Title	Chapter
Reactor Coolant System	4

1.4.35 Reactor Coolant Pressure Boundary Brittle Fracture Prevention

For conditions under which reactor coolant pressure boundary system components constructed of ferritic materials may be subjected to potential loadings, such as a reactivity-induced loading, service temperatures shall be at least 120°F above the nil ductility transition temperature of the component material if the resulting energy release is expected to be absorbed by plastic deformation, or 60°F above the nil ductility temperature of the component material if the resulting energy release is expected to be absorbed within the elastic strain energy range.

Sufficient testing and analysis of materials used in reactor coolant system components are performed to ensure that the required nil ductility transition temperature limits specified in the criterion are met. Removable test capsules are installed in the reactor vessel and removed and tested at various times in the unit lifetime to determine the effects of the operation on system materials.

The reference chapter is as follows:

Title	Chapter
Reactor Coolant System	4

1.4.36 Reactor Coolant Pressure Boundary Surveillance

Reactor coolant pressure boundary components have provisions for the inspection, testing, and surveillance of critical areas by appropriate means to assess the structural and leaktight integrity of the boundary components during their service lifetime. For the reactor vessel, a material surveillance program conforming to current applicable codes is provided.

The design of the reactor vessel and its arrangement in the system permit accessibility during service life to all internal surfaces of the vessel and to certain external zones such as the areas of the nozzle-to-piping welds and the top and bottom heads. The reactor arrangement within the containment provides sufficient space for the inspection of the external surfaces of the reactor coolant piping, except for the area of pipe within the primary shielding concrete.

The monitoring of the nil ductility transition temperature properties of the core region plates, forgings, weldments, and associated heat-treated zones is performed in accordance with ASTM E 185, *Recommended Practice for Surveillance Tests on Structural Materials in Nuclear Reactors*. Samples of reactor vessel plate materials are retained and cataloged in case future engineering development shows the need for further testing.

The material properties surveillance program includes not only the conventional tensile tests, but also tests of fracture mechanics specimens. The fracture mechanics specimens are the wedge-opening-loading-type specimens. The observed irradiation shifts in the nil ductility transition temperature of the core region materials are used to confirm the calculated limits to start-up and shutdown transients.

To define permissible operating conditions below the design transition temperature, a pressure range is established. The range is bounded by a lower limit for pump operation and an upper limit that satisfies reactor vessel stress criteria. To allow for thermal stresses during the heat-up or cooldown of the reactor vessel, an equivalent pressure limit is defined to compensate for thermal stress as a function of the rate of change of coolant temperature. Since the normal operating temperature of the reactor vessel is well above the maximum expected design transition temperature, brittle fracture during normal operation is not considered to be a credible mode of failure.

The reference chapter is as follows:

Title	Chapter
Reactor Coolant System	4

1.4.37 Engineered Safeguards Basis for Design

Engineered safeguards are provided in the facility to back up the safety provided by the design of the core, the reactor coolant pressure boundary, and their protection systems. Such engineered safeguards are designed to cope with any size reactor coolant piping break up to and including the equivalent of a circumferential rupture of any pipe in that boundary and an unobstructed discharge from both ends.

Engineered safeguards are provided to cope with any size reactor coolant pipe break up to and including the circumferential rupture of any pipe in that boundary and an unobstructed discharge from both ends, and to separately cope with any steam or feedwater line break.

Limiting the release of fission products from the reactor fuel is accomplished by the safety injection system, which, by cooling the core, keeps the fuel in place and substantially intact and significantly limits the metal-water reaction.

A reinforced-concrete, steel-lined containment structure (Section 1.4.10), operating at subatmospheric pressure, is provided to enclose the entire reactor coolant system. It is designed to sustain, without loss of required integrity, all effects of gross equipment failures up to and including the rupture of the largest pipe in the reactor coolant system.

The reference chapter is as follows:

Title	Chapter
Engineered Safeguards	6

1.4.38 Reliability and Testability of Engineered Safeguards

All engineered safeguards are designed to provide such functional reliability and ready testability as is necessary to avoid undue risk to the health and safety of the public.

A comprehensive program of testing has been formulated for all equipment, systems, and system controls vital to the functioning of engineered safeguards. The program consists of performance tests of individual pieces of equipment in the manufacturer's shop, integrated tests of the system as a whole, and periodic tests of the activation circuitry and mechanical components to ensure reliable performance, upon demand, throughout the unit lifetime.

The engineered safeguards components are checked periodically and routinely. In the event that one of the components requires maintenance as a result of failure to perform according to prescribed limits during the test, the necessary corrections or minor maintenance are accomplished and the component is retested immediately.

The reference chapter is as follows:

Title	Chapter
Engineered Safeguards	6

1.4.39 Emergency Power for Engineered Safeguards

Alternative power systems are provided and designed with adequate independence, redundancy, capacity, and testability to permit the functioning required of the engineered safeguards. As a minimum, the onsite power system and the offsite power system each, independently, provide this capacity, assuming the failure of a single active component in each power system.

Two independent sections of emergency 4160V buses and switchgear are provided for each unit. Each section is sized to carry 100% of the emergency load and may be energized by either onsite or offsite power supplies. The onsite and offsite power supplies are both independently capable of supplying power to the engineered safeguards. This capability is maintained even in the event of a failure of any single active component in either system. In the unlikely event of total loss of offsite power, the emergency 4160V buses are energized by the emergency diesel generators. Three diesel generators are available for two units. One diesel is exclusively for Unit 1, the second is exclusively for Unit 2, and the third functions as a backup for either unit. Each diesel generator is connected to one of the emergency buses, and each bus is connected to one set of the duplicated engineered safeguards equipment, thus ensuring operations of safeguards equipment under all conditions, including the failure of a single component in each power system. Sections 8.4.1 and 8.5 discuss the alternate station power systems and emergency power system, respectively.

Tests of the automatic operation of the power source transfer system at the 4160V level are made during shutdown for refueling to ensure that station on-site power is supplied automatically when an offsite power source is out of service. The periodic starting and loading of each emergency diesel generator and its emergency bus ensures the operability of the emergency power supply in the event of loss of off-site power.

The reference chapter is as follows:

Title	Chapter
Electrical Systems	8

1.4.40 Missile Protection

Protection for engineered safeguards is provided against dynamic effects and missiles that might result from plant equipment failures.

Layout and structural design specifically protects the injection lines leading to unbroken reactor coolant loops against damage as a result of the maximum reactor coolant system pipe rupture. The separation of individual injection lines is provided to the maximum extent practicable. The movement of injection lines associated with the rupture of a reactor coolant loop is accommodated by line flexibility and by the design of the pipe supports, so that no damage beyond the missile barrier is credible.

The reference chapters are as follows:

Title	Chapter
Reactor Coolant System	4
Containment System	5
Engineered Safeguards	6

1.4.41 Engineered Safeguards Performance Capability

Engineered safeguards, such as the safety injection system and the containment heat removal system, provide sufficient performance capability to accommodate the failure of any single active component without any undue risk to the health and safety of the public.

The overall capability of the engineered safeguards meets the suggested requirements of 10 CFR 50.67 or RG 1.183, as applicable, for the occurrence of any rupture of a reactor coolant or main steam system pipe, including the double-ended rupture of a reactor coolant pipe, known as the design-basis accident.

The reference chapters are as follows:

Title	Chapter
Containment System	5
Engineered Safeguards	6
Safety Analysis	14

1.4.42 Engineered Safeguards Components Capability

Engineered safeguards are designed so that the capability of these features to perform their required function is not impaired by the effects of a LOCA to the extent of causing undue risk to the health and safety of the public.

Instrumentation, motors, cables, and penetrations inside the containment are selected to meet the most adverse accident conditions to which they may be subjected. These items are either protected from containment accident conditions or are designed to withstand, without failure, exposure to the worst combination of temperature, pressure, and humidity expected during the required operational period.

The safety injection system piping serving each loop is anchored at the missile barrier in each loop area to restrict potential accident damage to the portion of piping beyond this point. The anchorage is designed to withstand, without failure, the thrust force of any branch line served from the reactor coolant pipe and discharging fluid to the atmosphere, and to withstand a bending moment equivalent to that which produces failure of the piping under the action of free and unrestrained discharge to atmosphere or the motion of the broken reactor coolant pipe to which the safety injection system pipes are connected. This prevents possible failure at any point upstream from the support point, including the branch line connection into the piping header.

The containment spray and recirculation spray piping has been installed with sufficient anchors, constraints, and guides to withstand the effects of operating-basis and design-basis earthquakes. This piping has also been installed to withstand the effects of dead weight, thermal, and pressure forces in the piping. Redundant containment spray and recirculation spray piping systems have been installed to preclude the possibility of sprays being lost as a result of pipe failure.

The reference chapters are as follows:

Title	Chapter
Containment System	5
Engineered Safeguards	6

1.4.43 Accident Aggravation Prevention

Protection against any action of the engineered safeguards that accentuates significantly the adverse after effects of a loss of normal cooling is provided.

The reactor is maintained subcritical following a pipe rupture accident. The introduction of borated cooling water into the core does not result in a net positive reactivity addition. The control rod assemblies insert and remain inserted.

The supply of water by the safety injection system to cool hot core cladding does not produce significant metal-water reactions.

The delivery of cold emergency core cooling water to the reactor vessel following accidental expulsion of reactor coolant does not cause a further loss of integrity of the reactor coolant system boundary.

The reference chapter is as follows:

Title	Chapter
Engineered Safeguards	6

1.4.44 Safety Injection System Capability

A safety injection system with the capability for accomplishing adequate emergency core cooling is provided. This core cooling system and the core are designed to prevent fuel and clad damage that interferes with the emergency core cooling function and to keep the clad metal-water reaction within acceptable limits for all sizes of breaks in the reactor coolant piping up to the equivalent of a double-ended rupture of the largest pipe. The performance of such a safety injection system is evaluated conservatively in each area of uncertainty.

The safety injection system employs a passive system of accumulators that do not require any external signals or source of power for their operation to cope with the short-term cooling requirements of a large reactor coolant pipe break. The high-head and the low-head safety injection systems, each capable of supplying the required emergency cooling, are also provided for small-break protection and to keep the core submerged after the accumulators have discharged following a large break. These systems are arranged so that the single failure of any active component does not interfere with meeting the short-term cooling requirements.

The high-head and low-head safety injection systems are each capable of fulfilling long-term cooling requirements. The failure of any single active component or the development of excessive leakage during the long-term cooling period does not interfere with the ability to meet necessary long-term cooling objectives with one of the systems.

The primary purpose of the safety injection system is to automatically deliver cooling water to the reactor core in the event of a LOCA. This limits the fuel clad temperature and thereby ensures that the core remains intact and in place, with its essential heat transfer geometry preserved. This protection is afforded for:

1. All pipe break sizes up to and including the hypothetical instantaneous circumferential rupture of a reactor coolant loop, assuming unobstructed discharge from both ends.
2. A loss of coolant associated with the rod ejection accident.
3. A steam generator tube rupture.

The basic design criteria for LOCA evaluations are:

1. The cladding temperature is less than
   a. The melting temperature of zirconium alloy cladding material.
   b. The temperature at which gross core geometry distortion, including clad fragmentation, may be expected.
2. The total core metal-water reaction is limited to less than 1%.

Meeting these criteria ensures that the core geometry remains in place and substantially intact to such an extent that effective cooling of the core is not impaired.

For any rupture of a steam pipe and the associated uncontrolled heat removal from the core, the safety injection system adds shutdown reactivity so that with an assumed stuck control rod assembly, no offsite power, and minimum engineered safeguards, there is no consequential damage to the primary system, and the core remains in place and intact. When there is no stuck control rod assembly, offsite power is available, and all equipment is operating at design capacity, there is no significant cladding rupture.

The reference chapters are as follows:

Title	Chapter
Engineered Safeguards	6
Safety Analysis	14

1.4.45 Inspection of Safety Injection System

Design provisions, where practical, are made to facilitate the physical inspection of all critical parts of the safety injection system, including reactor vessel internals and water injection nozzles.

Design provisions are made for the inspection of all components of the safety injection system to the extent practical. An inspection is performed periodically to demonstrate system readiness.

The pressure containment boundaries can be inspected for leaks from pump seals, valve packing, flanged joints, and safety valves during system testing.

In addition, critical parts of the reactor vessel internals, injection nozzles, pipes, valves, and safety injection pumps can be inspected visually or by boroscopic examination for evidence of erosion, corrosion, and vibration wear, and non-destructive tests can be performed where such techniques desirable, practical, and appropriate.

The reference chapter is as follow:

Title	Chapter
Engineered Safeguards	6

1.4.46 Testing of Safety Injection System Components

Design provisions are made so that components of the safety injection system can be tested periodically for operability and functional performance.

The design provides for the periodic testing of active components of the safety injection system for operability and functional performance.

Preoperational performance tests of the components were performed in the manufacturer's shop. An initial system flow test, performed prior to initial criticality, demonstrated the proper functioning of the system. Thereafter, periodic tests demonstrate that components are functioning properly.

Each active component of the safety injection system may be individually actuated on the normal power source at any time during station operation to demonstrate operability. The test of the safety injection pumps, which perform as charging pumps during normal operation, employs a minimum-flow recirculation test line that connects back to the volume control tank. Remotely operated valves are exercised and actuation circuits tested. The automatic actuation circuitry, valves, and pump breakers also may be checked during integrated system test periods.

The reference chapters are as follows:

Title	Chapter
Engineered Safeguards	6
Instrumentation and Control	7

1.4.47 Testing of Safety Injection System

Capability is provided to test periodically the operability of the safety injection system up to a location as close to the core as is practical.

Design provisions include special instrumentation, testing, and sampling lines to perform the tests, and unit shutdown to demonstrate the proper automatic operation of the safety injection system. A test signal is supplied to initiate automatic action. The test demonstrates the operation of the valves, pump circuit breakers, and automatic circuitry. In addition, other tests are performed periodically to verify that the safety injection pumps attain required discharge heads.

The accumulator tank pressure and level are continuously monitored during unit operation, and flow from the tanks can be checked at any time using test lines.

The reference chapters are as follows:

Instrumentation and Control	7

1.4.48 Testing of Operational Sequence of Safety Injection System

Capability shall be provided to test, under conditions as close as practical to design, the full operational sequence that would bring the safety injection system into action, including the transfer to alternative power sources.

The design provides for the capability to test initially, to the extent practical, the full operational sequence up to the design conditions for the safety injection system to demonstrate the state of readiness and capability of the system. This functional test is performed with the reactor coolant system initially cold and at low pressure. The safety injection system valving is set to initially simulate the system alignment for power operation. This test may be conducted on the normal shutdown power system, and it may include transfer to the alternative power source.

During the initial system checkout, the functioning of the accumulators is checked by closing the stop valve, raising the pressure in the tank, and then opening the stop valve and observing the rising pressurizer level. The rising water level in the pressurizer provides an indication of system delivery.

The reference chapter is as follows:

Engineered Safeguards	6

1.4.49 Containment Design Basis

The containment structure, including access openings and penetrations and any necessary containment heat removal systems, is designed to accommodate, without exceeding the design leakage rate, the pressures and temperatures resulting from the largest credible energy release following a LOCA, including a considerable margin for the effects of metal-water or other chemical reactions that can occur as a consequence of the failure of safety injection systems.

The design of the containment structure is based on the design basis accident, discussed in Sections 5.4.1 and 5.4.2 which assumes a double-ended rupture of the largest pipe in the reactor coolant system, coupled with partial loss of the redundant engineered safeguards systems (minimum safeguards). The maximum containment pressure reached in a design basis accident is less than the 45-psig design limit. Further, the containment analyses performed assume a 2% metal-water reaction which is well above the less than 1% expected for all accidents considered.

The containment structure, including access openings and penetrations, is designed to withstand a pressure of 45 psig and the associated thermal effects without exceeding the design leakage rate of 0.1 weight percent of containment air per 24 hours.

The heat removal capacity of the containment spray systems for the minimum safeguards returns the containment pressure to a subatmospheric condition in less than 60 minutes after a design-basis accident. This original design criterion was modified in conjunction with the analyses for implementation of the alternative source term. The criteria were subsequently updated to support an increase in the containment depressurization profile for the alternative source term analyses. The updated criteria require that, following the LOCA, the containment pressure be less than 2.0 psig within 1 hour and less than 0.0 psig within 6 hours. The radiological consequences analysis demonstrates acceptable results provided the containment pressure does not exceed 2.0 psig for the interval from 1 to 6 hours following the Design Basis Accident. Beyond 6 hours, containment pressure is assumed to be less than 0.0 psig, terminating leakage from containment.

1.4.50 Nil Ductility Transition Temperature Requirement for Containment Material

Principal load-carrying components of ferritic materials exposed to the external environment are selected so that their temperatures under normal operating and testing conditions are not less than 30°F above nil ductility transition (NDT) temperature.

The containment liner is not exposed to the external environment. However, the containment liner has sufficient ductility to tolerate local deformations without rupture. The liner material has a nil ductility transition temperature of -20°F, which is 80°F below the normal minimum shutdown temperature of 60°F. The equipment and personnel hatches are made of steel with a nil ductility transition temperature of -20°F. Exposed hatch surfaces during station operation are not expected to be at a temperature below 10°F.

The reference chapter is as follows:

Title	Chapter
Containment System	5

1.4.51 Reactor Coolant Pressure Boundary Outside Containment

If part of the reactor coolant pressure boundary is outside the containment, appropriate features, as necessary, are provided to protect the health and safety of the public in case of an accidental rupture in that part. The determination of the appropriateness of features, such as isolation valves and additional containment, includes a consideration of the environmental and population conditions surrounding the site.

No portions of the reactor coolant pressure boundary extend beyond the containment barrier.

1.4.52 Containment Heat Removal Systems

Where active heat removal systems are needed under accident conditions to prevent exceeding containment design pressure, at least two systems, preferably of different principles, each with full capacity, are provided.

Four separate containment recirculation spray subsystems, each with approximately 50% capacity, serve to remove heat from the containment after a LOCA, as described in Section 6.3.1. Each subsystem contains one deepwell-type pump. In two subsystems, the recirculation spray pumps are located inside the containment. In the other two subsystems, the recirculation spray pumps are located in the containment auxiliary structures and are accessible for servicing at all times.

The reference chapters are as follows:

Title	Chapter
Containment System	5
Engineered Safeguards	6

1.4.53 Containment Isolation Valves

Penetrations that require closure for the containment function are protected by redundant valving and associated apparatuses.

All penetrations requiring valve closure for containment isolation have redundant valving so that the failure of one valve does not prevent the isolation of the containment. No manual operation or action is required to activate the valves to effect isolation. All remotely actuated valves have their positions indicated in the control room at group visual position indicators.

The reference chapter is as follows:

Title	Chapter
Containment System	5

1.4.54 Initial Containment Leakage Rate Testing

The containment is designed so that integrated leakage rate testing can be conducted at design pressure after the completion and installation of all penetrations, and the leakage rate can be measured over a sufficient period of time to verify its conformance with required performance.

Refer to the response to the criterion in Section 1.4.55.

1.4.55 Periodic Containment Leakage Rate Testing

The containment is designed so that integrated leakage rate testing can be done periodically at design pressure during the plant lifetime.

The test frequency, test pressure, and type of test used are in accordance with Technical Specifications.

The completed containment structure, with all necessary penetrations, is designed so that leakage does not exceed 0.1% of the contained volume per day at the design pressure of 45 psig. Upon completion of the construction of the containment structure and the installation of all penetrations, Type A tests of the containments were performed at 39.2 psig and 25 psig. The tests were performed using the leakage monitoring system described in Section 5.3.2. Since the normal operating pressure of the containment is subatmospheric, containment leakage is monitored continuously by means of the leakage monitoring system.

The periodic leakage rate retest is conducted at a single test pressure. During the interval between the periodic leakage rate retests, a series of periodic surveillance tests (Type B and C tests) are carried out to monitor the principal sources of leak development.

The reference chapter is as follows:

Title	Chapter
Containment System	5

1.4.56 Provision for Testing of Penetrations

Provisions are made for testing penetrations that have resilient seals or expansion bellows to permit leaktightness to be demonstrated at design pressure at any time.

All penetrations having resilient seals or expansion bellows are fitted with test connections to permit pressurization to 50 psig to demonstrate leaktightness.

The reference chapter is as follows:

Title	Chapter
Containment System	5

1.4.57 Provision for Testing of Isolation Valves

The capability is provided for testing the functional operability of valves and associated apparatuses essential to the containment function, for establishing that no failure has occurred, and for determining that valve leakage does not exceed acceptable limits.

Type C tests are performed on the isolation valves to verify their sealing capability and leaktightness as described in Section 5.5. The tests include valve closure and leakage tests. Isolation valves, which are normally closed, are exercised to verify closure and sealing capabilities. Valve leakage tests are performed in accordance with the requirements of the Type C test.

The reference chapter is as follows:

Title	Chapter
Containment System	5

1.4.58 Inspection of Containment Pressure-Reducing Systems

Design provisions are made to facilitate the periodic physical inspection of all important components of the containment pressure-reducing systems such as pumps, valves, spray nozzles, torus, and sumps.

Equipment composing the engineered safeguards systems is so situated that periodic physical inspections can be made. All equipment can be inspected during planned refueling shutdowns.

The reference chapters are as follows:

Title	Chapter
Containment System	5
Engineered Safeguards	6

1.4.59 Testing of Containment Pressure-Reducing Systems Components

The containment pressure-reducing systems are designed so that active components such as pumps and valves can be tested periodically for operability and required functional performance.

The containment recirculation spray pumps and valves are tested, periodically, by manually closing the required breakers in the control room to test actuation and component operation. Bypass lines on the recirculation spray pumps located outside the containment permit flow measurements to be made, which can then be compared to the results of preoperational tests. The recirculation spray pumps located inside the containment are periodically tested to ensure their operability.

Bypass lines to the refueling water storage tank permit brief operational tests of the containment spray pumps. Periodic tests of the CS pump discharge MOVs demonstrate that they are functioning properly. Test air connections on the containment spray discharge lines, installed prior to the nozzle air tests, ensure that these lines and the check valves are open.

The reference chapter is as follows:

Title	Chapter
Engineered Safeguards	6

1.4.60 Testing of Containment Spray Systems

A capability is provided to test periodically the delivery capability of the containment spray systems at a position as close to the spray nozzles as is practical.

Provision is made to permit the testing of the containment spray system and the containment recirculation spray system throughout the life of the unit to ensure that the systems are operational. For preoperational testing, the ends of the spray headers are fitted with blind flanges that allow the connection of temporary drain lines for full-flow testing up to the nozzles. Such testing allows for the testing of the spray systems over the full range of flow and starting conditions.

The reference chapter is as follows:

Title	Chapter
Engineered Safeguards	6

1.4.61 Testing of Operational Sequence of Containment Pressure-Reducing Systems

A capability is provided to test, under conditions as close to design considerations as practical, the full operational sequence that brings the containment pressure-reducing systems into action, including the transfer to alternative power sources.

The design of the control system for the containment spray system and the containment recirculation spray system includes manual test switches that provide for the individual testing of all the equipment in the systems and the testing of the operational sequence of the spray systems. These tests may be conducted on the normal shutdown power system or an alternative power source.

The reference chapters are as follows:

Title	Chapter
Containment System	5
Engineered Safeguards	6
Instrumentation and Control	7

1.4.62 Inspection of Air Cleanup Systems

Design provisions are made to facilitate the physical inspection of all critical parts of containment air cleanup systems, such as ducts, filters, fans, and dampers.

Refer to the response to the criterion in Section 1.4.65.

1.4.63 Testing of Air Cleanup Systems Components

Design provisions are made so that active components of the air cleanup systems, such as fans and dampers, can be tested periodically for operability and required functional performance.

Refer to the response to the criterion in Section 1.4.65.

1.4.64 Testing of Air Cleanup Systems

A capability is provided for the in situ periodic testing and surveillance of the air cleanup systems to ensure that (1) filter bypass paths have not developed and (2) filter and trapping materials have not deteriorated beyond acceptable limits.

Refer to the response to the criterion in Section 1.4.65.

1.4.65 Testing of Operational Sequence of Air Cleanup Systems

A capability is provided to test, under conditions as close to design conditions as practical, the full operational sequence that brings the air cleanup systems into action, including the transfer to alternative power sources and the design air flow delivery capability.

Engineered safeguards for the Surry Power Station do not include a postaccident air cleanup system. The containment ventilation system is normally in continuous service and is equipped to handle activity associated with normal station operation. No special tests or inspections of this system are performed.

1.4.66 Prevention of Fuel Storage Criticality

Criticality in the new-fuel and spent-fuel storage areas is prevented by physical systems or processes. Such means as geometrically safe configurations shall be emphasized over procedural controls.

During reactor vessel head removal and while loading and unloading fuel from the reactor, the boron concentration of the reactor coolant system and the fuel transfer canal, reactor cavity, and spent-fuel pool is maintained at not less than that required to shut down the core to a $k_{eff} = 0.95$ with all control rods inserted. This concentration is sufficient to ensure that $k_{eff} < 1.00$ even if all control rods are withdrawn.

The new-fuel storage racks are designed so that it is impossible to insert assemblies in violation of the design in other than the lattice spacing. The fuel is stored vertically in an array with sufficient center-to-center distance between assemblies to ensure an ever-safe geometry.

The spent-fuel storage racks are designed so that it is impossible to insert assemblies in violation of the design in other than the lattice spacing. Borated water is used to fill the spent-fuel pool at a concentration to match that used in the reactor cavity during refueling operations. The fuel is stored vertically in an array with sufficient center-to-center distance between assemblies to ensure $k_{eff} \leq 0.95$, even if unborated water is used to fill the pool.

The fuel transfer equipment is designed to handle one fuel assembly at a time. The new-fuel storage area cannot be flooded.

The reference chapter is as follows:

Title	Chapter
Auxiliary and Emergency Systems	9

1.4.67 Fuel and Waste Storage Decay Heat

Reliable decay heat removal systems are designed to prevent damage to the fuel in storage facilities that can result in radioactivity release to plant-operating areas or the public environs.

Decay heat from spent fuel is dissipated in the water of the spent-fuel pool and subsequently removed by a cooling system. Redundancy of system components is provided to ensure the maintenance of storage pool water cleanliness and level, and to remove heat from the water.

The reference chapter is as follows:

Title	Chapter
Auxiliary and Emergency Systems	9

1.4.68 Fuel and Waste Storage Radiation Shielding

Shielding for radiation protection is provided in the design of fuel and waste storage facilities as required to meet the requirements of 10 CFR 20.

The spent-fuel storage pool is designed to meet 10 CFR 20 requirements in providing radiation shielding for operating personnel during fuel transfer and during storage of spent fuel. Work areas adjacent to the canal wall are shielded; however, barricades are necessary to limit personnel access during actual fuel transfers.

Waste storage and processing facilities in the auxiliary building area have shielding meeting 10 CFR 20 requirements for operating personnel.

Periodic surveys by health physics personnel using portable radiation detectors ensure that radiation design levels are not degraded during unit lifetime.

The reference chapters are as follows:

Title	Chapter
Auxiliary and Emergency Systems	9
Radioactive Wastes and Radiation Protection	11

1.4.69 Protection Against Radioactivity Release From Spent Fuel

The containment of fuel and waste storage is provided if accidents could lead to the release of undue amounts of radioactivity to the public environs.

Spent fuel systems are designed to preclude gross mechanical failures that could lead to significant radioactivity releases. In addition, during refueling, fuel building ventilation air is passed through charcoal filters, containment ventilation air is monitored, and, if airborne radioactivity increases beyond a predetermined value, the containment ventilation system is isolated automatically.

Liquid waste storage facilities are designed so that any possible release of waste liquids is contained within the facility and does not result in an uncontrolled release to the environment. Any waste liquid leakage or release from components within the auxiliary building, fuel building, decontamination building, or radwaste facility flows directly to the vent and drain system or is collected in sumps and pumped to the liquid waste disposal system. The boron recovery tanks located in the station yard area are in separately diked, Class I structures, each of which is of sufficient capacity to retain the total liquid volume resulting from the rupture of one of these tanks. Radioactive gases are stripped from the liquid stored in the boron recovery tanks so that a tank failure does not constitute a significant gaseous release.

Waste gas inventories are carefully monitored and controlled so that no single component failure would result in a whole-body dose at the site boundary greater than 25 rem. All gaseous discharges from the station are continuously monitored for particulate and gaseous radioactivity during the release.

The reference chapters are as follows:

Title	Chapter
Containment System	5
Auxiliary and Emergency Systems	9
Radioactive Wastes and Radiation Protection	11
Safety Analysis	14

1.4.70 Control of Releases of Radioactivity to the Environment

The facility design includes those means necessary to maintain control over the plant radioactive effluents, whether gaseous, liquid, or solid. Appropriate holdup capacity is provided for the retention of gaseous, liquid, or solid effluents, particularly where unfavorable environmental conditions can be expected to require operational limitations upon the release of radioactive effluents to the environment. In all cases, the design for radioactivity control is justified (1) on the basis of 10 CFR 20 requirements for normal operations and for any transient situation that might reasonably be anticipated to occur and (2) on the basis of 10 CFR 100 dosage level guidelines for potential reactor accidents of exceedingly low probability of occurrence, except that reductions of the recommended dosage levels may be required where high population densities or very large cities can be affected by the radioactive effluents.

The control of waste gas effluents is accomplished by the holdup of waste gases in buried, double-wall decay tanks until the activity of tank contents and existing environmental conditions permit discharges within 10 CFR 20 requirements. In addition, waste gas effluents are monitored at the point of discharge for radioactivity and rate of flow. No decay tank failure results in an activity release greater than 10 CFR 100 limits.

The control of liquid waste effluents is maintained by batch processing all liquids, sampling them before discharge, and controlling their rate of release, and by preventing inadvertent tank discharges. Liquid effluents are monitored for radioactivity and rate of flow. Liquid waste disposal system collection and surge tank, and the evaporator, reverse osmosis, and ion exchange capacities are sufficient to handle any expected transient in the development of liquid waste volume.

Station solid wastes are prepared batchwise for offsite disposal by approved contractors. Solid wastes are prepared for shipment by placement in shielded and reinforced containers that meet regulatory requirements.

1.4 REFERENCE DRAWINGS

The list of Station Drawings below is provided for information only. The referenced drawings are not part of the UFSAR. This is not intended to be a complete listing of all Station Drawings referenced from this section of the UFSAR. The contents of Station Drawings are controlled by station procedure.

	Drawing Number	Description
1.	11448-FE-1A2	One Line Integrated Schematic, Electrical Power Distribution, Units 1 & 2

Intentionally Blank

1.5 COMMON FACILITIES

Separate and similar systems and equipment are provided for each unit, except as noted below. Where some components of a system are shared by both units, only those components that are shared are listed.

1. Electrical systems (Section 8.2)

   Standby station service transformer

   Backup emergency diesel generator

2. Chemical and volume control system (Section 9.1)

   Chemical-mixing tank

   Boric acid storage tanks (three)

   Boric acid pumps (four)

   Batching tank

   Resin fill tank

3. Boron recovery system (Section 9.2)

4. Component cooling water system (Section 9.4)

   Component-cooling surge tank

   Component-cooling pumps (four)

   Component-cooling heat exchangers (four)

5. Fuel pool cooling system (Section 9.5)

   Fuel pool circulation pumps (two)

   Fuel pool skimmer pumps (two)

   Fuel pool coolers (two)

   Fuel pool skimmer filters (two)

   Fuel pool purification filter (one)

   Fuel pool ion exchanger

   Fuel pool purification pumps (two)

6. Sampling system (Section 9.6)

7. Vent and drain system (Section 9.7)

   Auxiliary building sump pumps (two)

Fuel building sump pumps (two)

Liquid waste strainers (two)

8. Service water system (Section 9.9)
9. Fire protection system (Section 9.10)
10. Ventilation system (Section 9.13) (other than containment ventilation)
11. Heating boilers (Section 10.3.2)
12. Lubricating oil system (Section 10.3.7)

    Clean and dirty lube-oil storage tanks (two)

    Transfer pump

13. Radioactive waste systems (Section 11.2)
14. Structures, buildings, and miscellaneous

    Auxiliary building

    Fuel building

    Turbine building and turbine room crane

    Service building

    Main control area

    Decontamination building

    Office building

    General station services, nonelectrical

    Fuel-oil system

    Service water pump house

    Fire-pump house

    Intake and discharge canals

    Screenwell

    Laundry facility

    Radwaste facility

1.6 RESEARCH AND DEVELOPMENT REQUIREMENTS

(Note: This is the initial plant research and development. Any post research and development is described in the individual sections.)

The design is based on proven concepts that have been developed and successfully applied to the design of PWR systems. Results of work completed under the Nuclear Safety Research and Development Program conducted by the AEC were incorporated in the design and evaluation of applicable portions of the engineered safety features.

The term “research and development” as used in this section is the same as that used by the Commission in Section 5.2 of its regulations, as follows:

(n) “Research and development” means (1) theoretical analysis, exploration or experimentation; or (2) the extension of investigative findings and theories of the scientific nature into practical application for experimental and demonstration purposes including the experimental production and testing of models, devices, equipment, materials and processes.

The research and development discussed in the FSAR is to confirm the engineering and design values normally used to complete equipment and system designs. It does not involve the creation of new concepts or ideas.

The technical information generated is used either to demonstrate the safety of the design and more sharply define margins of conservatism, or to lead to design improvements.

The schedules for development of this technical information were compatible with the plant schedule such that definite results were made available before the plant design was complete.

The Westinghouse research and development programs under way during the FSAR stages of the Surry project are listed in WCAP-7498-L, *Topical Report, Safety Related Research and Development for Westinghouse Pressurized Water Reactors*, Spring 1970 (Reference 1). This topical report is upgraded periodically.

The specific areas in which additional information was developed and which were required for unit operation are as follows:

1. Core stability evaluation.
2. Fuel rod burst program.

Other areas of research and development are those that gave added confirmation that the overall design was conservative. These programs were carried out basically to provide technical information that could be applied to component or system optimization in future plants. These programs included the following:

1. Burnable poison program.

2. Blowdown forces program.
3. Reactor vessel thermal shock analysis program.
4. Containment spray program.
5. Fuel development program.
6. Incore detector program.
7. Empire States Atomic Development Associates DNB program.
8. Full Length Emergency Core Cooling Heat Transfer Test program.
9. Flashing heat transfer program.
10. Loss of coolant analysis program.

These programs are discussed extensively in WCAP-7498-L (Reference 1).

1.6.1 Required Research and Development

There are two programs which were required for plant operation: the core stability evaluation and fuel rod burst programs.

1.6.1.1 **Core Stability Evaluation Program (Item 1 of Reference 1)**

The purpose of this program was to establish means for the detection and control of potential xenon oscillations and for the shaping of the axial power distribution for improved core performance. This program was completed in two areas:

1. Confirmation of the ability of the ex-core detector system to indicate gross core power distribution sufficient to permit xenon oscillation within specified operating limits.
2. Development of a control system using the ex-core detector system and part-length control rods. (It should be noted that the part-length rods were removed by a design change initiated in 1978.)

The third part of this program, verification through start-up testing that the control system can control the core power distribution and that adequate margins exist to operate the Surry unit, was carried out on Westinghouse reactors that were placed in operation before Surry. These included H. B. Robinson Unit 2 (Docket 50-261) and Turkey Point Unit 3 (Docket 50-250).

1.6.1.2 **Fuel Rod Burst Program (Item 2 of Reference 1)**

The basic design criteria for LOCA evaluations are given in Section 14.5.

Satisfaction of these criteria ensures that the core geometry remains in place and substantially intact to such an extent that effective cooling of the core is not impaired.

The effect of rod bursting, swelling, or shattering must be considered in the loss-of-coolant evaluations. In the blowdown phase of the accident, core geometry distortion may result from clad bursting or swelling. The clad temperature may get sufficiently high (1200° to 2000°F) that a bursting or swelling of the clad would occur by virtue of the internal gas pressure and a significant reduction of clad strength. Clad bursting or swelling is of concern because of the possibility of blocking the flow channel so that coolant flow would be insufficient to meet the above LOCA design criteria.

A program to investigate the performance of fuel rods during a simulated LOCA was completed. It supplied empirical data on the above safety-related problems from which the amount and kinds of geometry distortion can be predicted over the range of conditions of interest. The effects of this geometry distortion on the ability of the emergency core cooling system to meet the LOCA design criteria were determined using analytical design techniques.

1.6.1.2.1 Single-Rod Burst Tests (SRBT)

The performance of the fuel rods during a simulated LOCA was evaluated in a test program that is described in WCAP-7379-L, Volume I and Volume II (Reference 2).

Volume I (Westinghouse Proprietary) describes burst, quench, and eutectic formation tests with unirradiated tubes and provides an evaluation of the data from both reports. An interpretation with regard to the postulated sequence during the LOCA is given.

Volume II (Non-proprietary) reports the results of work under AEC Contract AT-(30-1)-3017 and describes burst and quench tests on irradiated tubes.

The single-rod tests indicated that rod-to-rod interference might occur following rod burst and must be considered. The quantitative evaluation of the influence of adjacent rods in a fuel assembly would be difficult, if not impossible, to determine analytically. Therefore, the rod burst program was extended to include multi-rod burst tests. Multi-rod burst tests (MRBT) were performed to demonstrate that the rods in a PWR rod bundle burst randomly so that a minimal-flow channel area, for core-cooling purposes, is maintained.

1.6.1.2.2 Multi-Rod Burst Test

The results of this phase of the rod burst program are reported in WCAP-7495-L, Volume I and Volume II (Westinghouse Proprietary) (Reference 3).

Volume I describes the test apparatus and conditions and provides an evaluation of the test results. Volume II presents the application of the MRBT results to the LOCA core thermal analysis.

The MRBT results show that the burst locations are staggered axially along the fuel rods and that, to some degree, rod-to-rod contact does occur. However, the remaining flow area is always sufficient to ensure adequate core cooling. Analytical evaluations of a typical double-ended cold-leg break, considering flow redistribution due to the geometry distortion and rod-to-rod contact, have shown that the peak clad temperature increases approximately 70°F over the 2300°F peak temperature without geometry distortion.

The program was completed and results were satisfactory. No backup research and development measures were considered necessary.

1.6.2 Other Research and Development

Other areas of research and development included those described below.

1.6.2.1 Burnable Poison Program (Item 7 of Reference 1)

Burnable poison rod development is complete. The burnable poison rods are borosilicate glass encased in stainless steel tubes. The fixed rods are used to reduce the concentration of boric acid poison in the moderator, thus ensuring that the moderator coefficient of reactivity is always negative at operating temperature.

1.6.2.2 Blowdown Forces Program (Item 15 of Reference 1)

The objective of the program was to develop digital computer programs for the calculation of pressure, velocity, and force transients in the reactor coolant system during a LOCA, and to use these codes in the calculation of blowdown forces on the fuel assemblies and reactor internals to ensure that the stress and deflection criteria used in the design of these components are met.

Westinghouse completed the development of BLODWN-2, an improved digital computer program for the calculation of local fluid pressure, flow, and density transients in the primary coolant system.

Extensive comparisons were made between BLODWN-2 and test data, and the results are given in WCAP-7401 (Reference 4). Agreement between code predictions and data was good.

An analysis using the BLODWN-2 program was completed for the Indian Point Unit 2 reactor. It was concluded from the analysis that the design of this reactor met the established design criteria. Designs for subsequent Westinghouse pressurized water reactors included the use of the BLODWN-2 program.

1.6.2.3 Reactor Vessel Thermal Shock (Item 16 of Reference 1)

The effects of safety injection water on the integrity of the reactor vessel following a postulated LOCA were analyzed using data on the fracture toughness of heavy section steel, both at beginning of plant life and after irradiation, corresponding to approximately 40 years of equivalent plant life. The results showed that, under the postulated accident conditions, the integrity of the reactor vessel is maintained.

Fracture toughness data were obtained from a Westinghouse experimental program associated with the heavy section steel technology (HSST) program at the Oak Ridge National Laboratory and with the Euratom programs. Since results of the analyses were dependent on the fracture toughness of irradiated steel, efforts continued to obtain additional fracture toughness data. The HSST program was scheduled for completion by 1973.

A detailed analysis (Reference 5) of the linear elastic fracture mechanism method, along with various sensitivity studies, was submitted to the AEC staff and members of the Advisory Committee on Reactor Safety.

Revised material for this report, plus additional analytical and fracture toughness data, was presented at a meeting with the Containment and Component Technology Branch on August 9, 1968, and forwarded by letter for AEC review and comment on October 29, 1968.

It was not anticipated that the HSST program would lead to any new conclusions about the Surry reactor vessel integrity under LOCA conditions.

Several backup positions are available if vessel integrity cannot be ensured for the full plant life with the operating modes presently used. one solution would be to anneal the reactor vessel such that material properties approach their original values. This solution is feasible, in principle, and could be performed with the vessel in place.

Note: Refer to Section 18.3.2.3 regarding the operation beyond the original 40-year operating licenses.

1.6.2.4 **Containment Spray Program (Item 3 of Reference 1)**

In the unlikely event of a major LOCA, one of the radiological hazards could be the release into the containment of radioactive iodine from ruptured fuel. The absorption of this iodine by a suitable chemical spray has been investigated extensively by Vepco and Westinghouse. The research and development program is discussed in WCAP-7499-L (Reference 6).

1.6.2.5 **Fuels Development Program for Operation at High Power Densities (Item 8 of Reference 1)**

As part of the program to demonstrate the satisfactory operation of fuel at high burnup and power densities, fuel was tested in both the Saxton and Jose Cabrera (Zorita, Spain) reactors. The Saxton loose-lattice irradiation program was used to demonstrate fuel performance at conditions significantly in excess of 1970 PWR design limits, and to establish power burnup limits for the fuel. The Jose Cabrera reactor was the first PWR with a Zircaloy core to operate at similar core conditions to the 1970 design units. Because of the timely manner in which fuel could be irradiated in Jose Cabrera, four fuel assemblies were tested there to demonstrate the satisfactory operation of the fuel in a commercial PWR environment.

The sustained successful operation of special Jose Cabrera fuel rods at peak design power levels (in excess of those planned for these units) also increased the assurance that the fuel had adequate performance margins to accommodate transient overpower operation.

1.6.2.6 **Incore Detector Program (Item 9 of Reference 1)**

The purpose of this program was to develop fixed incore neutron detectors suitable for the continuous monitoring of the power distribution in a PWR core.

Testing at San Onofre, the Western New York Research Reactor, the Brookhaven high flux beam reactor, and the Union Carbide (Tuxedo) reactor were used to evaluate detector performance. Tests at the Tuxedo reactor were performed for detector linearity and the optimization of design. Cables for incore detectors were also tested. Cable reliability was greatly improved in this program.

This program permitted a fixed incore flux detector system to be installed in H. B. Robinson Unit 2 and showed the acceptability of installing a system in Indian Point Unit 2. These systems serve only as an operational convenience to the plant operator and as test vehicles to evaluate the need for and suitability of incore detectors for power distribution monitoring and control. The incore detector development program was continued in the early, large plants with the principal aims of demonstrating the design lifetime of a PWR and optimizing detector parameters. Since ex-core detectors, particularly long ion chambers, have been found effective for monitoring both axial and radial gross power distribution, there were no plans to install a fixed incore system in the Surry reactors. However, provision was made so that a fixed incore detector system could be installed in the Surry reactors.

1.6.2.7 **Empire States Atomic Development Associates DNB Program (Item 11 of Reference 1)**

This program provided experimental rod bundle DNB data with non-uniform rod axial flux distributions. The program was conducted at Columbia University under the direction of WNES, Pittsburgh, Pennsylvania. The results of this program are detailed in WCAP-7411-L (Reference 7), which was submitted in July 1970. The experimental rod bundle data with non-uniform rod axial flux distributions are directly applicable to the design of this unit. The results of the program show that the W-3 DNB correlation applied in the Surry design is conservative.

1.6.2.8 **Full Length Emergency Core Cooling Heat Transfer Test (FLECHT) (Item 12 of Reference 1)**

The purpose of the FLECHT program was to investigate experimentally the thermal behavior of a simulated PWR core during the core recovery period that follows a LOCA. The first series of tests are reported in WCAP-7435 (Reference 8).

The loss-of-coolant evaluation presented in the Surry application uses conservative design assumptions in the heat transfer models for analyses of the re-flooding phase of the accident. The FLECHT program assisted in developing new analytical models to describe the core recovery phenomena. The results were favorable in 1970, at which time the program was essentially complete.

1.6.2.9 **Flashing Heat Transfer Program (Item 13 of Reference 1)**

The program is completed. It proved that the present core thermal design analysis used for evaluating the LOCA results in a conservative prediction of the peak clad temperature. The results from the program were used in the initial loss-of-coolant analysis. The program and results are summarized in WCAP-7396-L (Reference 9).

1.6.2.10 **Loss-of-Coolant Analysis Program (Item 14 of Reference 1)**

The loss-of-coolant analysis program was intended to integrate, as appropriate, the more realistic heat transfer models obtained from experimental and analytical development programs into the core thermal design codes used to evaluate the LOCA (Reference 10).

This program was completed. An evaluation of the LOCA using the results of the flashing heat transfer program in the core thermal design code is presented in WCAP-7422-L (Reference 10).

1.6.3 Assurance for Completion of Research and Development

In 1970, assurance that the necessary information would be obtained was provided by the following facts:

1. The work being done did not require development of new concepts or ideas; only the normal engineering and design work was required to complete the design.
2. Vepco and Westinghouse Electric Corporation were capable of providing necessary information in sufficient time to obtain operating licenses for the units to permit scheduled commercial operation. The research and development program was compatible with the station schedule, in that definite results would be available before the station became operational.
3. Periodic reviews of this project and other similar Westinghouse PWR projects were held with the AEC staff, as information became available, to demonstrate that the required information was being developed in a satisfactory manner.

Significant results obtained in research and development programs were formally provided to the AEC, in as timely a manner as was reasonably practicable following program completion, by the following methods:

1. Preliminary safety analysis reports on new applications.
2. Final safety analysis report on this or other applications.
3. Topical reports applicable to this and certain other applications.
4. Topical reports applicable to all applications.

CHAPTER 2 SITE CHARACTERISTICS

This chapter primarily describes the site characteristics for the Surry Power Station as they existed when the facility was licensed. As such, current site characteristics may not agree with these descriptions. The site characteristics described here include geography, demographics, nearby facilities, meteorology, hydrology, geology, and seismology. This information was gathered to support or develop the original plant design bases. Chapter 2 also contains evaluations of these site characteristics demonstrating how applicable siting criteria were met at the time of original licensing of the facility. Because this information is not expected to be used to support current or future plant operations or regulatory activities, Chapter 2 does not need to be updated to reflect minor changes to these site characteristics. However, this does not preclude the need to update this chapter to reflect significant changes to this information.

In the past, minor changes to site characteristics have been incorporated into Chapter 2. While the updates were not required, these changes have not been removed. Therefore, some parts of this chapter reflect more recent information.

2.1 GEOGRAPHY, DEMOGRAPHY AND POTENTIAL EXTERNAL HAZARDS

2.1.1 Site Location and Description

2.1.1.1 Site Location

This section gives a general description of the region surrounding the Surry Power Station. Additional information can be found in the Surry Station Emergency Plan (Reference 1) and the safety analysis report (Reference 2) supporting the independent spent-fuel storage facility at for the Surry Power Station.

The Surry Power Station is located in Surry County, Virginia, on a point of land called Gravel Neck that juts into the James River from the south, as shown in Figure 2.1-1 and 2.1-16. The site is at the end of Route 650 and south of and adjacent to the Hog Island State Wildlife Management Area. It is bordered by the James River on either side of the peninsula. The site is 4.5 miles west-north-west of Fort Eustis, 7 miles south of Colonial Williamsburg, and 8 miles east north east of the town of Surry. Jamestown Island, part of the Colonial National Historical Park, is to the northwest on the northern shore of the James River.

The site coordinates are:

	Latitude	Longitude	Universal Transverse Mercator (UTM)		
Unit 1	37° 9' 58" N	76° 41' 55" W	4,114,460 mN	349,200 mE	zone 18s
Unit 2	37° 9' 57" N	76° 41' 53" W	4,114,415 mN	349,280 mE	zone 18s

The area within 10 miles of the site covers parts of Surry, Isle of Wight, York, and James City Counties, and parts of the cities of Newport News and Williamsburg. Surry and Isle of Wight Counties are predominantly rural and characterized by farmland, wood tracts of land, and marshy wetlands. York and James City Counties and the cities of Newport News and Williamsburg are more urban and are characterized by recreational areas and growing population centers. The Hog Island State Wildlife Management Area, immediately north of the site, is reached by a public access road running through the site. Public parking and viewing points are provided by the state within the refuge. The tip of the peninsula is very marshy and almost severed by many streams and creeks.

The region 10 to 30 miles east and southeast of the site is comprised of the Hampton, Newport News, Norfolk, and Portsmouth, Virginia urban areas. This general area is a major Atlantic Coast seaport and U.S. naval base, and the largest industry is shipbuilding. The site is 44 miles southeast of Richmond, Virginia. The Atlantic Ocean lies some 40 miles east of the site. Figure 2.1-2 shows the site and the general topography over an area to a radius of about 50 miles.

2.1.1.2 **Site Description**

The plant site comprises approximately 830 acres. The plant property lines, which are the same as the site boundary lines, are shown on Figure 2.1-3. Virginia Electric and Power Company (Virginia Power), owns, in fee simple, all of the land within the site boundary, both above and beneath the surface, with the exception of state route 650, which passes through the site to the Hog Island State Wildlife Management Area to the north.

The site boundary is clearly posted to ensure that it will not be transgressed by unauthorized individuals.

The ground surface at the site is generally flat, with steep banks sloping down to the river and to the low-level waterfowl refuge to the north. Station ground grade has been established at an elevation of 26.5 feet above the U. S. Coast & Geologic Survey mean sea level datum at Hampton Roads, Virginia.

Beyond the site boundaries, maximum land elevations within a 5-mile radius are generally in the range of 40 to 60 feet. Much of the region is characterized by marshes, extensive swamps, small streams, and pocosins. Water tables are very near to the surface throughout the entire area, accounting for the large amount of surface waters. Drainage throughout the area is toward Hampton Roads, on the Atlantic Ocean and near the mouth of Chesapeake Bay.

Control of law and order in Surry County is under the jurisdiction of the County Sheriff’s Department and the Virginia State Police.

Significant site structures are shown on Figure 2.1-3.

2.1.1.3 **Boundaries for Establishing Effluent Release Limits**

The release limits for liquid and gaseous effluents are based on the unrestricted areas as shown on Figure 2.1-4. For gaseous effluents, the unrestricted area is at or beyond the site boundary. For liquid effluents, the unrestricted area is at the discharge canal. Exposure of individuals to radiation in these areas will be within 10 CFR 20 limits. Since Vepco owns, in fee simple, the land within the site boundary, it has total control over access to this area. Access is controlled by the security guard force.

2.1.2 Exclusion Area Authority and Control

2.1.2.1 Authority

The Exclusion Area is the site boundary. The minimum distance from a reactor centerline to the site exclusion boundary as defined in 10 CFR 100 is 1650 ft. This is the distance for Unit 1, which is controlling and is sufficient, in conjunction with the plant design, to ensure that the dose limitations of 10 CFR 50.67 are met. Virginia Power has the authority to control activities within the Exclusion Area, including exclusion and removal of personnel and property. Virginia Power has total control over access to this area except for public access on State Route 650 to the Hog Island State Wildlife Management Area to the north of the site. A map of the site is shown in Figure 2.1-3.

2.1.2.2 Control of Activities Unrelated to Plant Operation

No activities unrelated to plant operations (other than transit through the area) are permitted in the Exclusion Area without Virginia Power approval.

2.1.2.3 Arrangements for Traffic Control

In the event of an emergency, local law enforcement officers will take control of traffic on State Route 650.

2.1.3 Population Distribution

2.1.3.1 Population Within 10 Miles

Figure 2.1-1 shows the general locations of the municipalities and other cultural features within 10 miles of the Surry site. As indicated on Figure 2.1-1, the municipalities which are wholly or partly within 10 miles of the site are:

	1990 Population[1]	Distance (miles) from Surry site	Direction from Surry site
City of Newport News	171,439	4.5 (closest point)[2]	ESE
City of Williamsburg	11,530	7	N
Town of Surry	190	8	WSW

The population distribution within 10 miles of the site was computed by overlaying 1990 census block data (Reference 3), (the smallest unit of census data), on the grid shown on Figure 2.1-1 and summing the population of the census blocks falling in each of the polar sectors comprising the grid. The population of census blocks shared by more than one polar sector was apportioned based on the fraction of the census block area in each sector.

1. Reference 3
2. Fort Eustis. This is a U. S. Army installation and not part of any local municipality.

The area of a census block is generally inversely proportional to the population of the census block. Thus, an urban census block may be geographically as small as a few city blocks. However, a sparsely populated rural census block could be several miles across, but include only several residents. As a result, any error from the allocating process should be very small. The 10 mile population distribution for 1990 is shown on Figure 2.1-5.

Population projections for the areas within 10 miles of the Surry site for the years 2000, 2010, 2020 and 2030 are given in Figures 2.1-6 through 2.1-9, even though the current license expiration dates for the two Surry units are 2052 and 2053 respectively. Population projections were based on Virginia Population Projections prepared by the Virginia Employment Commission (Reference 4). For conservatism, the projected population of polar sectors encompassing portions of more than one jurisdiction was escalated at the highest rate among the applicable jurisdictions.

The 1990 resident populations within 5 and 10 miles of Surry Power Station site were 3216 and 122,097 persons, respectively.

2.1.3.2 **Population Between 10 and 50 Miles**

Estimates of the 1990 resident population from 10 to 50 miles from the Surry site were computed using the same methodology used to develop the 10 mile population distribution. The population grid from 10 to 50 miles is shown on Figure 2.1-2 and the 50 mile population distribution for 1990 is shown on Figure 2.1-10.

Population projections for the areas between 10 and 50 miles for the years 2000, 2010, 2020 and 2030 were based on the same methodology as the 10 mile projections. These population projections are given in Figures 2.1-11 through 2.1-14.

The population contribution for the portion of northeastern North Carolina included in the 50 mile radius, which at its closest point is 42 miles from the site, was under 6000. The population growth projection was based on the adjacent Virginia jurisdictions. These jurisdictions are more urban than the included areas of North Carolina.

2.1.3.3 **Transient Population**

Information concerning transient population for the area was collected from several sources as this information is not available from the 1990 census data. The area within 10 miles of the site to the south and west is predominantly rural and characterized by farm land, wooded tracts of land, and marshy wetlands. Since there are no significant industrial or commercial facilities in these directions, and none are anticipated, the transient employment population is likely to be out of, rather than into, the area.

General transient employment population figures in the Williamsburg and Newport News areas within 10 miles of the plant are not available. However, large employers in these areas within 10 miles of the Surry site are listed in Table 2.1-1.

Transient population estimates for the tourist attractions, parks and recreational areas to the north, east and southeast are provided in Table 2.1-2. These figures were obtained from the individual attractions and the Virginia Division of Tourism (Reference 5). Total tourist figures in the Williamsburg area have not changed significantly over the last ten years. Ticket purchases at Colonial Williamsburg (Reference 6) and Jamestown and Yorktown National Historical Parks (Reference 7) have collectively decreased. Busch Gardens (Reference 8), located 5.4 miles NNE of the Surry site, and with an annual attendance of 2.1 million, is the largest single tourist attraction in the 10 mile area. Peak daily figures are estimated based on data provided by the Virginia Division of Tourism (Reference 5).

2.1.3.4 **Low Population Zone**

The Low Population Zone, as shown in Figure 2.1-1, is bounded by a 3 mile-radius circle centered at the Unit 1 reactor containment building. The Low Population Zone boundary was established to ensure that the dose limitation requirements of 10 CFR Part 100 are met.

The resident population distribution within the Low Population Zone is indicated in Figures 2.1-5 through 2.1-9 based on the 1990 census and projections every 10 years through to the year 2030. In summary, the Low Population Zone population for 1990, and the projected population through 2030, are as follows:

1990	145
2000	161
2010	174
2020	186
2030	199

The only significant sources of transient population within the Low Population Zone are noted on Table 2.1-2. Use of the Hog Island State Wildlife Management Area has remained essentially constant since the Surry Station began (Reference 9) operation. Peak annual use of the Chippoaks Plantation State Park dropped from 125,000 in 1989 to 98,000 in 1991 (Reference 10). Usage recovered to 115,552 in 1993. Future usage could be increased if additional camping facilities are added.

Considering the available road network leading from the Low Population Zone, together with the availability of private as well as public vehicles, there is reasonable assurance that these populations could be evacuated in a timely manner in the event of a design-basis accident.

2.1.3.5 **Population Center**

The nearest population center with more than 25,000 residents is the city of Newport News, which had a 1990 population of 171,439. Fort Eustis, a U. S. Army Base, which is geographically adjacent to Newport News, is within 4.5 miles of the Unit 1 reactor containment building. The closest point of Newport News proper is 7 miles east-south-east of the site. Either of these distances is greater than the population center distance, which is one and one-third times the Low

Population Zone boundary distance, as required by 10 CFR 100. In addition, the dose limitations of 10 CFR 50.67 or RG 1.183, as applicable, are met with considerable conservatism. There are no closer population centers whose population is likely to reach 25,000 by 2030.

2.1.3.6 **Population Density**

The cumulative resident population in 1990 to a distance of 50 miles in all directions from the plant is compared with the cumulative population resulting from a uniform population density of 500 people/sq. mile in Figure 2.1-15. Similarly, the projected cumulative resident population in 2030 to a distance of 50 miles in all directions from the plant is compared with the cumulative population resulting from a uniform population density of 1000 people/sq. mile.

2.1.4 Nearby Industrial, Transportation, and Military Facilities

This section evaluates the effects of potential accidents associated with present and projected nearby industrial, transportation, and military facilities.

2.1.4.1 **Location and Routes**

The James River shipping channel for ships and barges passes within 2.3 miles of the site, as shown on Figure 2.1-16. Route 650, a state secondary road, provides the only land access to the site. Portions of State Routes 10 and 31 pass within 10 miles of the site with the closest approach of State Route 10 being 4.5 miles from the site. The only railway within 10 miles is the CSXT Railway which is 6 miles to the northeast at its nearest approach to the site. The site is bordered on the east and west by the James River and is accessible by water craft at the east side pier. There are three airports within 10 miles of the site, Williamsburg-Jamestown Airport (5 miles NNW), Felker AAF (5 miles ESE), and Melville (Reference 11). There are no federal airways within 5 miles of the plant (Reference 11). There are no known mines or stone quarries within 5 miles of the site or commercial nuclear facilities within 50 miles of the site.

2.1.4.2 **Description of Facilities**

Lists of facilities and the hazardous materials they used or stored locally were obtained from local fire departments (Reference 12). There are no significant manufacturing facilities located within 5 miles of the Surry site. The closest industrial facility to the site is Anheuser-Busch, a brewery plant (5.5 miles NNE). There are no hazardous materials at the brewery that would pose a credible threat to the Surry site. BASF Corp., which operated the former Dow-Badische synthetic fibers factory 4.9 miles east-north-east, has closed the facility (Reference 13). Other significant facilities within 10 miles of the site are discussed in Table 2.1-1.

The only military installation within 5 miles of the site is the U. S. Army Transportation Center at Fort Eustis (4.5 miles east-south-east, at its closest point) (Reference 14). The U. S. Naval Reservation, including the U. S. Naval Supply Center, the U. S. Naval Weapons Station (Reference 15) and Camp Peary, occupies a large portion of the land area north and northeast of the site between the James and York Rivers. The U. S. Naval Reservation is bordered to the east-southeast by the Yorktown portion of the Colonial National Historical Park. The U. S. Naval

Weapons Station lies 6.2 miles northeast of the site. The nature of hazardous materials on these facilities is confidential. Increased activities at these facilities is not anticipated.

2.1.4.3 Pipelines

As shown on Figure 2.1-16, Columbia Gas Transmission Corporation and Colonial Pipeline Company own pipelines which cross the southeast corner of the site. A spur pipeline branches into the Surry Site from each of these lines to supply natural gas and No. 2 fuel oil, respectively, to the Gravel Neck Combustion Turbine Facility, which is located south of the intake canal. The Columbia Gas Transmission Corporation pipelines carry only natural gas and there are no plans to transport any other materials. The Colonial Pipeline Company pipeline carries No. 2 fuel oil. There are no other pipelines within 5 miles of the facility. The specifications of the pipelines are listed below (References 16 & 17).

Line	Year Built	Diameter	Max. Press.	Depth
Columbia Gas				
NW Line(1)	1960	8"	600 psi	>30"
SE Line (St. Rt. 626 to river)(1)	1971	10"	600 psi	>30"
SE Line (under river)(1)	1982	12"	600 psi	>30"
Spur to combustion turbines(2)	1969	12"	600 psi	>30"
Colonial Pipeline				
Main line(3)	1963	14" o.d.	1181 psi	>30" land >48" river
Spur to combustion turbines(4)	1990	12.75	150 psi	>30"

1. Line isolation is provided by manual gate valves at State Route 626 and both sides of the river.
2. Line isolation is provided by manual gate valves at the junction with the transmission pipelines.
3. Line isolation is provided by slab gate valves on each side of the river.
4. Line isolation is provided by a slab gate valve at the junction with the transmission pipeline.

2.1.4.4 Waterways

The James River, a major waterway with a 25-foot-deep channel, is navigable by seagoing vessels up to Richmond. A survey of dock facilities upstream of the Surry site was conducted to identify potentially hazardous materials transported past the site. Two categories of vessels use the river, closed container ships and bulk carriers. The container ships carry no Class 1[1] hazardous materials. Other hazardous materials are double contained and quantities are generally small. They are packed in drums or packages that are consolidated in large closed containers. Container ships pass the site about 80 times per year. Shipment frequency is not expected to increase in the near future (Reference 18).

The only potentially explosive hazardous material routinely shipped in bulk is “interface” which is a mixture of gasoline and diesel oil that represents the transition between batches of

1. International Maritime Dangerous Goods (IMDG) Code, Hazardous Materials Classification Section

gasoline and diesel oil in a pipeline. Interface is shipped in 30,000 bbl (1.3 million gallon barges). These shipments occur several times a month (Reference 19). Other materials, such as phenol, which is shipped in 5.5 million lb lots every few days, and occasional 2000-ton shipments of sulfuric acid are also transported past the site (Reference 20). Other flammable, non-explosive materials include asphalt and No. 6 fuel oil.

One facility shipped a number of barges containing up to 100,000 bbl (4.2 million gallons) of gasoline as recently as December 1991 before the dock was closed. The dock was reopened for one 100,000 bbl shipment in November 1993. However, the operator expects no future shipments and is considering closing the dock permanently (Reference 21).

Chemical compounds shipped along the James River are listed in Reference 22. Quantities and types of materials currently being shipped are similar.

The nearest point of the shipping channel is approximately 1.4 miles from the intake structure. In addition, the river depth at mean high tide for much of the distance between the intake structure and the channel is four feet or less. As a result, shipping on the James River does not constitute a hazard to the intake structure.

2.1.4.5 **Roads**

State secondary Route 650 is the only land access to the Surry site. It ends at the Hog Island State Wildlife Management Area, north of the site. No chemicals or cargo are expected to be transported on this portion of Route 650 unless the chemicals are used by the Surry Power Station. Chemicals stored onsite and evaluated for control room habitability are listed in Table 2.1-4.

Virginia Highway 10 is the only other primary state route that passes within 5 miles of the site. A list of chemical compounds transported on a regular basis by truck on Virginia Highway 10 in 1981 is also provided in Reference 22. This list was revalidated in 1994. This list does not include shipments of small amounts of chemical compounds shipped to and used by the local farmers and merchants in Surry and Isle of Wight Counties.

2.1.4.6 **Airports**

There are two airports that are just over 5 miles from the site which can be seen on Figure 2.1-17. Information on these airports was obtained from the Virginia Division of Aviation and the individual airports. Williamsburg-Jamestown Airport, 5 miles north-north-west, has a 3200-foot paved runway. There is no control tower. Operations primarily involve single engine light planes and a small number of business jets. The trend of operations over the past few years is essentially flat with approximately 17,000 operations per year. Forty-five planes were based at the airport in 1993. The traffic patterns at the airport are to the southwest and do not normally involve passing over the river (Reference 23).

Felker AAF at Fort Eustis is 5 miles east-south-east of the site. This facility maintains a control tower and has a 3000-foot paved runway. Traffic at Felker is primarily U. S. Army helicopters. There is also a flying club that operates light planes out of the facility. Helicopter operations are expected to decrease by 20% following transfer of certain training functions to another facility. Direct over flight of the station below 1500 feet is prohibited. Base legs and cross wind legs are three statute miles from the station (Reference 14).

Melville Airfield is a private grass strip about 6 miles west-south-west of the site. Only one plane is based there and the facility appears to see little use (Reference 24).

None of the airports expect significant facility changes that would affect use. No large commercial jets use any of these facilities. These and other airports potentially affecting the site are listed in Table 2.1-3.

2.1.4.7 **Projections of Facility Growth**

Given their rural nature, none of the facilities in Surry or Isle of Wight Counties are expected to change in the near future.

2.1.5 Evaluation of Potential Accidents

2.1.5.1 **Explosions and Flammable Vapor Clouds**

Possible sources of explosion and formation of flammable vapor clouds include the natural gas or No. 2 fuel oil carried by the pipelines passing near the site or explosive materials/chemicals used by nearby industrial facilities, carried by truck traffic on Virginia Highway 10, or carried by waterborne traffic on the James River.

2.1.5.1.1 Truck Traffic

As shown in Reference 22, the largest explosive load transported on Highway 10 contains 8500 gallons of gasoline. The explosive force of this quantity of gasoline is estimated to be equivalent to 50,700 lb of TNT using a simple TNT equivalent yield formula (Reference 25).

According to NRC Regulatory Guide 1.91 (Reference 26), if this amount of gasoline were to explode, a peak overpressure of 1 psi would be experienced about 1900 feet away from the point of explosion; whereas, the closest approach of Highway 10 to the site is 4.5 miles. The value of 1 psi is cited by Regulatory Guide 1.91 as a conservative value of peak positive incident overpressure below which no significant damage would be expected.

Flammable vapor clouds formed from a spill of gasoline on the highway do not present an explosive hazard because gasoline vapor clouds are not known to detonate in unconfined areas (References 27, 28 & 30).

2.1.5.1.2 Waterborne Traffic

Traffic on the James River is confined to a dredged ship channel which is approximately 2.3 miles distant from the Unit 1 containment. Interface product, carried by barge, is the only chemical transported on the river that would present a potential explosion hazard. These shipments are limited in frequency to several per month.

Since interface product is a mixture of gasoline and diesel fuel, it is less explosive than pure gasoline. Conservatively assuming the whole barge is filled with 1,300,000 gallons of gasoline, and is involved in an explosion, the explosive force generated by this quantity of gasoline is estimated to be equivalent to 7,760,000 pounds of TNT (Reference 25).

Regulatory Guide 1.91 (Reference 26) indicates an overpressure of 1 psi would be experienced about 8000 feet (1.6 miles) downwind of the explosion.

2.1.5.1.3 Industrial Facilities

As noted in Table 2.1-1, with the closure of the BASF fiber facility, the only offsite industrial facility within 5 miles of the Surry site using potentially explosive materials is the Propane Air Facility operated by Virginia Natural Gas which is 5 miles to the east-north-east. The propane is contained in buried tanks and does not represent a credible danger to the Surry Station (Reference 29).

The Gravel Neck Combustion Turbine Facility is located within the site boundary south of the intake canal. (See Figure 2.1-3.) The facility can burn either natural gas or No. 2 fuel oil which are fed into the facility through underground pipelines. The facility includes six (6) combustion turbines and has the capability to store approximately 6.5 million gallons of No. 2 fuel oil in three (3) above ground tanks. The facility is equipped with fire protection and fire suppression systems. The following features also help ensure that a fire at Gravel Neck will not adversely affect the Surry Power Station:

1. The Gravel Neck facility is located more than 2000 feet from the Surry Units with the intake canal separating them.
2. The fuel oil from a failed fuel oil storage tank would be contained by the dikes around the tanks.
3. The Gravel Neck facility is located more than 700 feet from the switchyard, over 200 feet from the transmission lines and over 1200 feet from the intake canal.

In addition, the flash point of the No. 2 fuel oil precludes the fuel from exploding under anticipated site conditions.

The combustion turbine casings are designed to contain the fragments of the rotor and associated blading should they fail. This eliminates external missile generation from the Gravel Neck site as a concern.

2.1.5.1.4 Pipelines

Pipeline locations are shown in Figure 2.1-16. An explosion of natural gas occurring in the pipelines is considered to be impossible due to the absence of oxygen. However, potential explosions may result from ruptured or leaking pipelines. As indicated in Regulatory Guide 1.91 (Reference 26), for an overpressure of about 1 psi to be experienced in the vicinity of the nuclear containments, in excess of the equivalent of 25,000 lb TNT of explosive material would be required.

The amount of natural gas, which would produce an explosive force equivalent to 25,000 lb TNT, corresponds to the contents of a 2.6-mile section of the pipe. In the case of a leaking pipeline, any potential explosion will not involve the whole quantity of the natural gas within the pipeline. This is because the natural gas will be dispersed and carried downwind by the ambient wind as soon as it leaks from the pipeline. For the case of a postulated ruptured pipeline, assuming the whole quantity is involved in an explosion and natural gas is escaping at sonic velocity, it will take more than 12 seconds to empty a 2.6-mile pipe section. The natural gas cloud will eventually occupy a volume of 450,000 ft^3 without wind advection. If the gas cloud is advected by a very low wind, i.e., 1 meter per second, the elongated gas cloud will have a diameter of 135 feet. Since an unconfined natural gas vapor cloud is not known to explode (References 27, 28 & 30), and the assumption of an explosion event involving the entire contents of a 2.6-mile section of a natural gas pipeline is a very conservative assumption, the pipelines are not considered a significant hazard to plant operation.

The pipeline carrying No. 2 fuel oil is not considered an explosion hazard due to its flashpoint as discussed in Section 2.1.5.1.3 above.

2.1.5.2 **Toxic Chemicals**

Potentially toxic chemicals associated with control room habitability and currently stored onsite are listed in Table 2.1-4. The list is comparable to that used for the Toxic Release Evaluation reported in Reference 31 and the chemical storage analysis in Reference 35. The effects of Halon release on control room habitability are discussed in Section 9.10.2.2.9 of the UFSAR. The quantity of dimethylamine is limited to 100 pounds (825 gallons of 2% solution) so as to not impact control room habitability as described in Regulatory Guide 1.78.

2.1.5.3 **Aircraft Accidents**

The crash probability due to the flights passing near the Surry site from either of the two airports 5 miles from the site, Felker AAF and Williamsburg-Jamestown Airport, was reported in NUREG/CR-4550 (Reference 32) as about 1×10^{-6} per year, based on an assumed combined operations of 126,500 per year. Based on current actual annual operations of 101,000, the revised crash probability is 8.2×10^{-7}. The majority of the general aviation operations from the two airports involve single engine light aircraft weighing less than 4000 lb, with 10% of the Williamsburg operations involving twins and small jets weighing less than 12,500 lb. Such small aircraft pose a minimal risk to the plant.

Melville, which lies 6 miles west-south-west of the site, is a private field with a 2900-foot unpaved runway. Use of the airfield is limited to a low volume of small aircraft. Any aircraft accident probability due to operation of Melville airfield will be less than the probability due to operation of the two airports analyzed. There are no other airfields within 10 miles of the site.

Newport News/Williamsburg International Airport (Formerly Patrick Henry), 11 miles east-southeast of the site, is an international airport with 172,000, 109,000 and 180,000 operations in 1983, 1988 and 1993, respectively. In 1993 approximately 37,000 involved commercial aircraft (Reference 33). Based on NUREG-0800 (Reference 34), the probability of a aircraft accident occurring at the Surry site from commercial traffic associated with this airport is estimated to be 1.3×10^{-7} per year. Airports/airfields further away from the site are not considered to be significant in the aircraft accident probability analysis.

Jamestown Settlement[b]	6.2 miles NW	373,000	1750	Open year round (Probably includes same peak daily visitors as Jamestown Colonial National Historical Park)
Colonial Williamsburg[b]	7.4 miles N	909,000	4000	Open year round. Only includes ticket purchases, i.e. does not include non-paying visitors to the area
Water Country[b]	7.5 miles NNE	460,000	5000	Open late May through Labor Day
Yorktown Colonial National Historical Park	9.2 miles ENE (Closest point)	310,000	1450	

a. 1993 unless otherwise noted

b. Substantial overlap in annual attendance very likely because of close proximity of attractions. Total annual visitors to the Williamsburg area, including shoppers who do purchase tickets to the attractions, are estimated at 5,000,000

Table 2.1-3
AIRPORTS WITHIN 20 MILES OF THE SITE

Airport	Type	Distance (miles)	Sector	No. of Operations: Comm. (1993)	No. of Operations: Total (1993)	kd^2 [a]	Longest Runway: Orient.	Longest Runway: Length (feet)	Comments
Felker AAF	Military	5	ESE	None	83,000	12,500	NW-SE	3000	72,000 rotary 11,000 light plane[b]
Williamsburg-Jamestown	Civil	5	NNW	None	18,000	12,500	NW-SE	3200	All small aircraft[c]
Melville	Private	6	WSW	None	Few	18,000	SSW-NNE	2900	Unpaved strip, no facilities, no planes based there
Newport News/ Williamsburg (was Patrick Henry)	Civil	11	ESE	37,000	180,000	121,000	SW-NE	8000	Nearest facility serving commercial jets
Langley AFB	Military	19	ESE	None	Not Avail.	361,000	WSW-ENE	10,000	Data on operations not available

a. 10 miles k = 500 < 10 miles k = 1000

b. Light aircraft are virtually all single engine aircraft weighing less than 4000 lb used by a local flying club. Helicopters currently use range in weight from 3200 lb to 55,000 lb. However, all but two types will be transferred to another facility. The combined annual operations for the two remaining types, UH-1, Huey at 9500 lb and UH-60, Blackhawk at 22,000 lb, are projected to be about 58,000.

c. Operations for 1991, 1992 and 1993 were 17,000, 18,000 and 15,600 respectively. The highest figure was entered in this table. 90% of the operations involve single engine aircraft typically weighing 2000 lbs. with some up to 4000 lb. The remaining operations involve twins and small jets weighing less than 12,500 lb, the runway limit.

2.2 METEOROLOGY AND CLIMATOLOGY

2.2.1 Meteorological Program

2.2.1.1 Local Meteorology

Data acquired by the National Weather Service (References 1 through 6) and summarized by the Environmental Data Service have been utilized to determine the normals, means, and extremes of temperature, precipitation, relative humidity, and fog applicable to the Surry Power Station site region. Site data have been obtained from meteorological instrumentation located at the plant site and summarized for the period March 3, 1974, to December 31, 1987.

Climatological data in this report, indicative of both long term expected values and extreme events, have been provided to represent a range of meteorological conditions that are considered typical for the Surry Power Station site region. Through the years it is expectd that some values may change slightly, however, the values presented in this report are stilel considered to be representative of climatic conditions typical to the site region. Climatological extremes for selected meteorological stations in the region are presented in Table 2.2-1. Normals and extremes of temperature, precipitation, relative humidity, and fog are presented for Richmond and Norfolk in Tables 2.2-2, 2.2-3, and 2.2-4. The closest available fog data for Surry site are from the National Weather Service observation stations at Richmond International Airport, Richmond, and Regional Airport, Norfolk, Virginia. The local climatological data (1980) for Richmond indicates an average of 25–30 days per year of heavy fog, and the local climatological data for Norfolk indicates an average of 20–25 days per year of heavy fog. Heavy fog is defined by the National Weather Service as fog which reduces visibility to 0.25 mile or less (Reference 1). The frequency of fog conditions reported at Surry is expected to be more similar to the annual average of heavy fog reported at Richmond than at Norfolk (References 1 & 2). Surry is in close proximity to the James River and has a rural environment (i.e., land-use characteristics favorable for rapid radiation cooling of the ambient air with high specific humidity due to the close proximity of the River). The occurrence of heavy fog in the Norfolk area is less than in the Richmond area due to the moderating influence of the Atlantic Ocean.

The distribution of wind direction and speed is an important consideration when evaluating transport conditions relevant to site diffusion climatology. There are no significant topographic features that would have any major influence on wind direction distribution.

Seasonal and annual distributions of wind direction recorded at the Surry site meteorological tower for both the upper and lower level are presented in Figures 2.2-1 through 2.2-10. On an annual basis the predominant wind direction at both levels is from the southwest and south-southwest direction. Seasonal variations in average wind speed are presented in Table 2.2-5.

Wind persistence is important when considering potential effects from any radiological release. Wind persistence is defined as a continuous flow from a given direction or range of directions. Periods of maximum wind persistence in 22.5 degree sectors recorded at the Surry site meteorological tower are presented in Figures 2.2-11 through 2.2-20. The maximum persistence period at the upper level was for 28 hours, once from the south and once from the north-northeast. At the lower level, the maximum persistence period was 30 hours from the west-southwest.

Atmospheric stability refers to the degree of wind turbulence. Stable conditions are associated with low turbulence and poor diffusion capability. Unstable conditions are associated with a high degree of turbulence and favorable diffusion characteristics. Atmospheric stability is classified into horizontal and vertical stability categories. The degree of wind variance or standard deviation of direction (sigma-theta) is used to determine horizontal stability. The vertical temperature differential (delta T) is used to determine vertical stability. The classification of sigma-theta data is presented in Table 2.2-6 and the classification of delta T data is presented in Table 2.2-7. The seasonal and annual frequency of horizontal (sigma-theta) stability classes and associated wind speeds for the Surry site are presented in Table 2.2-9. These distributions indicate that the wind is more stable at the upper level than at the lower level. Seasonal variations of the stability distribution presented are minor.

Table 2.2-1 lists some extremes of meteorological measurements for selected National Weather Service stations in the Surry region. The maximum amount of precipitation recorded at Norfolk for a 24-hour period was 11.4 inches which occurred in August of 1964. The maximum amount of precipitation recorded at Richmond for a 24-hour period was 8.79 inches during August 1955. The maximum monthly snowfall measured in the Norfolk area was 18.9 inches during February 1980, and the maximum monthly snowfall measured in Richmond was 28.5 inches during January 1940. The maximum 24-hour snowfalls observed were 21.6 inches at Richmond during January of 1940 and 12.4 inches at Norfolk in February 1980 (References 1 & 2). Once again, while these extreme values may change slightly through the years, they are still considered to be representative of extreme conditions typical to the site region.

2.2.1.2 **Onsite Meteorological Measurements Program**

There are two towers installed on the Surry site. Their locations are illustrated on Figure 2.2-21. The primary site monitors wind direction and wind speed at two levels of the tower, ambient air temperature at the lower tower level, differential air temperature between tower levels, horizontal wind direction fluctuation at both tower levels, dewpoint temperature at the lower tower level, and rainfall at the base of the tower. The backup site monitors wind direction, wind speed, and horizontal wind direction fluctuation.

The nearest structures are 500 feet north-northwest and 150 feet northwest of the primary and backup towers, respectively. At the primary site, the nearest continuous tree line is approximately 50 feet south of the tower. Tree heights are 40 to 50 feet. At the backup site, the nearest tree line, with trees 10 to 15-feet high, is located approximately 50 feet south-southwest of the tower.

The primary tower is a guyed, triaxial, open-latticed structure. On May 21, 2012, the primary tower wind and temperature instrument elevations were surveyed. Table 2.2-8 provides the survey and pre-survey above ground level (agl) instrument heights.

The backup tower is a freestanding, triaxial, open-latticed structure. The instrumentation on the backup tower is located at approximately 30.3 feet agl.

On the primary tower, the wind speed, wind direction, and sigma-theta sensors are mounted on booms longer than one-and-one-half times the tower face width. On the backup tower, the sensors are postmounted on top of the tower. The wind sensors are positioned such that the towers do not influence the prevailing south-southwest wind flow detected by the sensors. Temperature, differential temperature, and dewpoint temperature sensors are housed in motor-aspirated shields to insulate them from thermal radiation from the tower, solar, and terrestrial radiation.

Meteorological monitoring instrumentation is calibrated not less than semiannually. Inspection, service, and maintenance are performed as required to ensure adequate data recovery. Redundant recording systems are incorporated into the program to minimize data loss due to recorder failure. The data are listed, reviewed, and summarized into joint frequency distributions by using the atmospheric stability classification scheme shown in Table 1 of Regulatory Guide 1.23 (Proposed Revision 1).

Data from the site's primary and backup meteorological towers are transmitted to the control room and collected by the emergency response facility data acquisition system (ERFDAS). These parameters have been placed in the ERFDAS data base, thus making site meteorological field data available for display in the Technical Support Center (TSC), and the Corporate Emergency Response Center (CERC). Certain information is also hardwired for display on the control room meteorological panels. Table 2.2-10 identifies meteorological information transmitted and its display location. Additional information on emergency response facilities can be found in the Station Emergency Plan.

Temperature, differential temperature, wind speed, and wind direction from both the lower and upper primary tower level sensors are displayed on recorders in the control room, as are wind speed, wind direction, and sigma-theta from the backup tower.

A shelter is located at the base of each tower. The shelters have thermostatically-controlled heat and air conditioning to maintain an interior temperature within a range appropriate for proper equipment operation. The enclosures are located to minimize any micrometeorological effects on the tower instrumentation.

Inside the shelters, the signals are routed to the appropriate signal-conditioning equipment which go to (1) digital data recorders and (2) an interface with the intelligent remote multiplexer system.

Microprocessor-based data acquisition systems are the primary method of data collection for offsite historical files. In addition to being transmitted real-time to the control room recorders and to the ERFDAS, the data from the primary data collection system are telemetered daily to a computer in the corporate office. The data are then reviewed for representativeness and reasonability, including a comparison with data from other Company meteorological tower sites. Monthly, the data are transferred to the corporate mainframe computer for inclusion in the historical database. Backup collection consists of several remote data acquisition systems.

Meteorological instrumentation and data recording described above was upgraded to be consistent with Regulatory Guide 1.23, Onsite Meteorological Programs, Proposed Revision 1, and Regulatory Guide 1.97, Revision 3, Instrumentation for Light-water Cooled Nuclear Power Plants to Assess Plant and Environs Conditions During and Following an Accident, May 1983.

The meteorological sites and towers are consistent with Regulatory Guide 1.23, Onsite Meteorological Programs, February 1972.

2.2.2 Climate

Data acquired by the National Weather Service (NWS) and summarized by the Environmental Data Service (EDS) were used to determine the regional climatology pertinent to the Surry site. References 1 and 2 were used to determine the climatological characteristics of Richmond and Norfolk, Virginia, and Reference 7 for the climatological characteristics of the region.

The Surry site is situated in a humid subtropical climate which is characterized by warm, humid summers and mild winters. During the summer months, this region is dominated by tropical maritime air masses, while during the winter season this area is in a transitional zone between polar continental and tropical maritime air masses.

The climatic characteristics of the site region are influenced by the Atlantic Ocean, the Chesapeake Bay, and the Appalachian Mountains. The Atlantic Ocean has a moderating effect on the temperature for the Surry region, whereas the Appalachians act as a barrier to deflect midwest winter storms to the northeast of the Surry region. Winters are mild and short, spring and fall weather is usually very comfortable, and summers are long, hot, and humid, frequently tempered by cool periods associated with east and northeast winds off the Atlantic Ocean.

Snow is not common during winter in the Tidewater area of Virginia. (The Tidewater area is defined as the Coastal Plain area of Virginia extending west to the Fall Line.) A snowfall of 10 inches or more a month in the Tidewater area is expected to occur once every 4 years. In general, the total accumulated snow for the Tidewater is approximately 10 inches each year. Precipitation occurs mostly as rain in the site area. The summer months are usually associated with the greatest amount of precipitation. However, great amounts of rainfall have occurred during the fall season associated with the passages of tropical storms or hurricanes.

The Bermuda high that develops off the coast of the United States during the spring and summer seasons results in a moist, southerly flow of air from the Caribbean and South Atlantic to the Surry region. During the fall and winter seasons, a semipermanent high-pressure cell develops over the midwest region of the United States, resulting in a prevailing northwesterly flow of air into the Surry region. The mean annual wind speed for the Norfolk area is approximately 11 mph, and the mean annual wind speed for Richmond is approximately 8 mph.

Thunderstorms are frequent during the summer months with the greatest occurrence during the month of July. Only a small percentage of the thunderstorms can be classified as severe. Approximately four tornados are reported in Virginia each year, with the majority occurring east of the Blue Ridge Mountains.

An average of less than two hurricanes each year comes close enough to the coast to affect Virginia. These hurricanes can bring torrential rainfall to the Tidewater area, and high tides that result in flood conditions for low-lying areas along the coast. However, less than one hurricane per year actually crosses the state. A typical hurricane to affect the Tidewater area was Hurricane Dennis (August 1981), which brought 2.4 inches of rainfall to the Norfolk area and 0.25 inch to the Richmond area.

2.2.2.1 **Tornadoes**

During the period of January 1951 through December 1987, a total of 49 tornadoes on land have been reported within a 50-mile radius of the Surry site for an average of 1.3 tornadoes per year within this radius. As additional years of data are included in the analyses, it is expected that averages may change slightly. However, the averages presented in this report are still considered to be appropriate estimates of conditions typical to the site region.

The probability of a tornado striking a point within a given area may be estimated as follows (Reference 8):

$$P = \frac{zt}{A}$$

Where:

P = the mean probability per year

z = the geometric mean tornado path area

t = the mean number of tornadoes per year observed in the area of concern A

For the region surrounding the Surry site, the computed geometric mean tornado path length was about 1.6 miles and the computed geometric mean path width reported was about 118 yards, based on examination of reported tornado statistics (Reference 9). These values yield a z of 0.106 square miles based on tornado data for the period of January 1951 through December 1987. Using a 50-mile radius as a basis for A (excluding the Chesapeake Bay) and a value of

1.3 tornadoes per year for t, yields a probability of 1.73×10^{-5} per year, or a recurrence interval of about 58,000 years.

The Class 1 structures and systems, or parts thereof, whose failure might prevent the simultaneous cold shutdown of both reactor units during a loss-of-power incident will withstand by design a tornado with the following characteristics and associated effects:

1. Rotational wind velocity of 300 mph.
2. A pressure drop of 3 psi in 3 seconds.
3. Translational velocity of 60 mph.
4. Missile equivalent to a wooden utility pole 40-foot long, with 12-inch diameter, weighing 50 lb/ft^3, and traveling in a vertical or horizontal direction at 150 mph.
5. Missile equivalent to a 1-ton automobile traveling at 150 mph.

The pressure change and translational velocity above have been adopted from the license applications of others. The pressure change of 3.0 psi is considered conservative. The greatest officially observed pressure change near a tornado was 0.34 psi (which occurred in a 2-minute period) recorded at the Topeka Airport on June 8, 1966, as reported by Galway (Reference 10). The published work of Brooks (Reference 11) and Glaser (Reference 12) suggests that wind velocities of 220 to 300 mph would be produced by a central pressure difference of 1.1 to 1.5 psi.

Before adopting the tornado characteristics above, a tornado model was prepared to develop pressure and wind velocity criteria that were physically consistent. This tornado model was similar to the one suggested by Hoecker (Reference 13). The model included the following tornado specifications:

1. Overall diameter, 1000 ft.
2. Central pressure, 13.0 psia.
3. Central pressure difference, 1.5 psi.
4. Maximum pressure gradient, 0.02 psi/ft.
5. Radius of maximum winds, 200 ft.

Using this pressure structure and the cyclostrophic wind equation, an estimate of the maximum winds that would occur within such a tornado was obtained as follows (Reference 14):

$$V^2 = \frac{rg}{\rho}\ \frac{p}{r}$$

where:

p/ r = maximum pressure gradient, 2.88 $lb/ft^2/ft$ (0.02 psi/ft)

r = radius of maximum wind, 200 ft

ρ = density of air, 0.075 lb/ft^3

g = 32.2 ft/sec^2

V = maximum wind velocity, fps

The calculated maximum wind velocity of 338 mph compares with the design wind velocity of 300 mph, which is based on observed structural damage. Thus, the modeled tornado pressure distribution with a central pressure difference of 1.5 psi and a maximum pressure gradient of 0.02 psi/ft is physically consistent with accepted estimates of wind speeds associated with tornadoes. The model and derived estimates are also in agreement with the published works of Brooks, Glaser, and Hoecker. While the pressure difference of 1.5 psi is consistent with the other tornado characteristics chosen, the more conservative pressure difference of 3.0 psi has been used.

2.2.2.2 **Extreme Winds**

Extreme wind data were obtained from studies by Thom (Reference 15) and Huss (Reference 16). Severe weather data were obtained from a variety of sources. Severe storm, tornado, and hurricane data were obtained from References 8, 9, 17, 18 and 19.

According to Thom, the extreme 1-mile wind speed at 30 feet above the ground for a 100-year recurrence interval for the Surry region is 105 mph. Based on a gustiness factor of 1.3 according to Huss, the highest instantaneous gust expected once in 100 years is 137 mph.

The fastest mile wind recorded at Norfolk based on the 1953 to 1987 period of record was a southerly wind with a speed of 78 mph (Reference 2). The fastest mile wind recorded at Richmond based on the 1951 to 1987 period of record was a southeasterly wind with a speed of 68 mph (Reference 1). Both of these extreme wind speeds occurred during the passage of Hurricane Hazel in October 1954. While greater extreme wind speeds may occur in the future, these values are considered to be representative of extreme conditions typical to the site region.

2.2.2.3 **Tropical Storms and Hurricanes**

Since 1871 (when more complete weather recordkeeping began) through 1987, a total of 56 tropical storms or hurricane centers passed within 100 nautical miles of the Surry site (References 9 & 18). After 1885, weather records differentiated between tropical storms (less that 73 mph) and hurricanes (greater than 73 mph). From 1886 through 1987, there have been 34 passages of tropical storms, and 10 hurricanes have passed within 100 nautical miles of the site.

S0202021

2.3 HYDROLOGY

2.3.1 Surface Water Hydrology

2.3.1.1 General

Much of the region is characterized by marshes, extensive swamps, small streams, and pocosins. Water tables are very near the surface throughout the entire area, accounting for the large amount of surface waters. Drainage throughout the area is towards Hampton Roads, near the mouth of the Chesapeake Bay, and on to the Atlantic Ocean via the James River.

The James River is formed by the junction of the Cowpasture and Jackson Rivers in Botetourt County, Virginia, and flows easterly 340 miles before emptying into Hampton Roads at Newport News, Virginia.

The flow of water in the James River at the site consists of three components:

1. Fresh water discharge from the James River watershed.

2. Flow due to the oscillatory ebb and flood of the tide.

3. FLOW due to the circulation pattern caused by intrusion of saline water within the estuary.

The drainage area of the James River above the station site is 9517 square miles. The drainage area above the nearest gauge on the main stem of the James River near Richmond is 6757 square miles. An additional 1638 square miles of drainage area of tributaries between Richmond and the plant site is gauged, leaving 1122 square miles ungauged. Discharge records for the gauged tributaries below Richmond were used to estimate the discharge from the ungauged areas, and the total mean monthly discharge for each month for the period October 1934 to September 1993 was computed by summing the discharges from the gauged and ungauged watershed areas. These data are shown in Table 2.3-1 (References 1, 2, & 20).

In compiling the river discharge data, monthly mean flows have been used rather than daily mean flows. This choice was made because the cross-sectional area of the waterway in the 50 miles or so of tidal water between the station and Richmond increases significantly when compared with the stream above Richmond, and there is also a somewhat irregular, but significant, progressive increase in the cross-sectional area in this reach with distance downstream. The mean travel time for a flow of 14,000 cfs (a flow that is exceeded only 25% of the time) from Richmond to the site exceeds 20 days. Therefore, it can be assumed that short-period fluctuations in discharge at Richmond are considerably dampened at the station site. Further, within the estuary proper there is considerable inertia in the response of the salinity pattern and the net non-tidal circulation to rapid variations in river discharge, thereby providing additional damping.

The 85-mile stretch of the James River between Richmond and the mouth of the river is subjected to tidal motion and is hence a tidal estuary. The site is located in the transition region between the fresh water tidal river and the saline waters of the estuary proper. At a river discharge of about 10,000 cfs, the upstream portion of the site is in the fresh water river, and the salinity at the downstream side of the site is about 1 part/thousand. For river discharges less than 10,000 cfs (a condition occurring approximately 60% of the time), the water on both the upstream and downstream sides of the site will have varying concentrations of ocean-derived salts, depending on river discharge.

The tide in the James River is a semidiurnal tide, with two high waters and two low waters each lunar day of 24.84 hours. The oscillatory ebb and flood of this tide constitute the dominant motion in the waterway in the vicinity of the site. The net downstream flow required to discharge the fresh water seaward through any waterway cross section represents but a small fraction of the tidal flows.

The U. S. Coast and Geodetic Survey (USC&GS) tidal current tables (Reference 3) show that the ebb current is longer and stronger than the flood current at the site. The average of maximum ebb currents is 1.3 knots (2.2 ft/sec) and the average of maximum flood currents is 1.1 knots (1.9 ft/sec). During spring tides, the ebb currents reach a maximum of 1.9 knots (3.2 ft/sec) and the flood currents a maximum of 1.6 knots (2.8 ft/sec). During the typical tidal period of 12 hours, 25 minutes, the current, on the average, will ebb for 7 hours, 5 minutes, and flood for 5 hours, 20 minutes. It should be noted that the data used to compile the USC&GS tables are based on near surface observations, made during periods of normal river discharge, and therefore do not reflect meteorological effects. The predominance of ebb flow over flood flow will decrease with decreasing river discharge.

Within the estuary proper, the salinity decreases in a more or less uniform manner from the mouth toward the head, and at any location increases with depth. Superimposed upon the oscillatory tide, there is a net non-tidal circulation in which the upper, less saline layers of water move seaward, while the deeper, more saline layers of water move up the estuary. The net non-tidal seaward-directed flow is stronger and, in the vicinity of the site, extends to greater depths on the southern side of the estuary (looking downstream) than on the northern side. At times, the boundary between these two counterflows becomes strongly sloped so that the seaward flow extends to all depths on the south side of the estuary, and the flow directed up the estuary occurs from bottom to surface on the north side of the estuary.

The volume rate of flow associated with this net non-tidal circulation pattern, while small compared to the oscillatory tidal flows, is several-fold larger than the volume rate of river discharge. In general, the higher the salinity, the larger the ratio of the volume rate of seaward flow in the surface layers to the fresh water discharge. Consequently, since the salinity at any given location increases with decreasing river discharge, the volume rate of flow associated with the net non-tidal circulation does not decrease directly with respect to the river discharge.

There are no known or planned river control structures on the James River. Several small impoundments on tributaries in the upper reaches of the River do exist; however, their size and location would preclude any effect or danger to the safety-related structures at the station.

2.3.1.2 **Floods**

2.3.1.2.1 James River Flooding

The sources of flooding in the James River at the Surry site are flood discharges due to watershed runoff and surge due to severe storms.

As described in Reference 4, river discharge data for the period 1935 to 1993 have been collected, analyzed, and presented in Table 2.3-1. Statistical analysis of these data give the results shown in Table 2.3-2 (Reference 21). Flood discharges for the various recurrence intervals for the James River near Richmond, Virginia, are given in Table 2.3-3 (References 5 & 22). Similar data for the James River at the Surry site are given in Table 2.3-4 (References 6 & 23).

The peak flood discharge at Richmond, Virginia, during the period from 1935 to 1993 occurred in June 1972 due to the excessive rainfall during Hurricane Agnes. Flood levels reported for Richmond were 4 to 5 feet higher than those recorded during the previous flood of record. However, due to the wide flood plain at the site, the rise above normal water levels was relatively minor even during this severe flood.

It is highly unlikely that the formation of ice on the James River would obstruct the flow and cause flooding, due to the salinity of the river below the site. Thus, ice flooding is precluded as a source of flooding at the site.

An analysis of the probable rise in mean water level at the site associated with the flood discharges indicates that even for a flood discharge recurrence interval of only once in 50 years, the water level at the site would rise no more than 1 foot above normal mean river level, if not accompanied by unusual meteorological tides.

2.3.1.2.2 Hurricane Flooding

The site is located approximately 32 nautical miles upstream of the confluence of the James and York Rivers and approximately 40 nautical miles from the mouth of the Chesapeake Bay where it enters the Atlantic Ocean.

Table 2.3-5 shows the estimated tidal recurrence interval at Old Point Comfort, near the mouth of the James River. Based on a review of data compiled since 1971, there were no significant high-water levels due to storm surge in this area. The two most severe storms, Hurricane Agnes in 1972 and Hurricane David in 1979, had both been classified tropical storms by the time they reached Virginia. Neither of these two hurricanes produced a large storm surge at the Virginia coast. The highest water level recorded at Norfolk, Virginia, in 100 years of record occurred in August 1933 and reached 8.6 feet mean sea level (MSL).

The probable maximum hurricane (PMH) was chosen as the most severe meteorological event at the Surry site. The characteristics of a probable maximum hurricane at latitude 37 as shown in Reference 9, are:

Central pressure index	26.97 in. Hg
Radius of maximum winds	35 nautical miles
Forward speed of translation	22 knots
Maximum wind speed	135.4 mph

Open coast surge during the PMH was calculated at the entrance to the Chesapeake Bay using methods based on the Bathystropic Storm Tide theory as described in References 7 and 8. Theoretically, the highest open coast stillwater level consists of five components:

1. The highest astronomical tide.
2. An initial rise to account for short period anomalies.
3. The rise due to atmospheric pressure reduction.
4. The surge generated by the wind component acting perpendicular to the ocean bottom contours.
5. The surge generated by the wind component acting parallel to the ocean bottom contours.

Actual computation of the open coast surge was accomplished using two digital computer programs. The first program utilizes functions of wind speed, wind vector, and radial distance along the design axis and the traverse to compute the onshore and alongshore wind stress components, the rise in water level due to atmospheric pressure reduction for each time period at the beginning and end of each reach, and the average wind stress coefficient for each reach. The second program utilizes the output from the first program and the offshore bottom profile to compute the onshore and alongshore components of the open coast surge. The isovel field for probable maximum hurricane winds is shown in Figure 2.3-1.

The input data for the first program are shown in Figures 2.3-2 through 2.3-4. The Van Dorn wind stress coefficient was increased by 10%. The bottom friction factor used in the second program was calculated using the following equation, taken from Reference 8:

$$K = \frac{4.58 \times 10^{-6} \times W^{1.85}}{S^{1.3}}$$

where:

W = shelf width, nautical miles

S = shelf slope, minutes

For this case, the bottom friction factor was computed to be 0.00355.

The offshore bottom profile used in the second program is shown in Figure 2.3-5.

Table 2.3-6 lists components of the highest stillwater level at the open coast for the probable maximum hurricane. Once the open coast stillwater level was determined, the storm surge was routed through the Chesapeake Bay and up the James River to the power station using the methods presented in Reference 9.

The mathematical model presented in Reference 10 consists of the one-dimensional continuity and momentum equations applicable to variable area estuaries, embayments, or sea-level canals. The equations are solved simultaneously by means of an explicit finite-difference scheme to yield values of tidal elevation and flow along the longitudinal axis of the waterway. The model takes into account the effects of wind stress, river inflow, ocean tidal hydrography and non-conveyance river water storage.

The entire James River from the river mouth at Chesapeake Bay to the head of tide at Richmond, Virginia, was considered in the model. The first 75 miles of the river reach from the river mouth was divided into 25-mile segments. An adequate storage area was provided in the model to account for the total tidal area of the remaining upstream river reach.

The model was first calibrated and verified with mean tide and spring tide elevations along the James River based on Tide Tables and Nautical Charts published by the National Ocean Service (References 11 & 12, respectively). The Manning's roughness coefficients ranged from 0.018 to 0.033 for the river reaches depending on the depth and river bottom and overbank characteristics. Good agreements between the recorded tide levels and model results at various locations along the James River were found. The model was then used for storm surge routing by applying the open coast PMH storm surge hydrography at the river mouth. In addition, a conservative average wind speed of 91 mph along the PMH maximum wind axis covering the entire river reach was used to account for wind setup along the river.

The storm surge hydrography based on the mean sea level (MSL) datum at Surry Power Station and calculated in the manner described above, is shown in Figure 2.3-6. Also shown in the same figure is the wind speed versus time. For comparison purposes, the open coast storm surge which was transposed to the mouth of the James River without attenuation is shown in Figure 2.3-7. The PMH stillwater level at the Surry Station river intake is 22.7 feet (Reference 17) MSL. This surge level will result in reduced flow rates, due to reduced differential level driving head, in the gravity flow service water system. This is discussed in Section 9.9.1.3.

The size, period, and length of waves impinging on the east end of the site associated with the probable maximum hurricane were calculated using methods in Reference 13. These same methods were used to calculate run-up on slopes and the emergency pump house.

The maximum calculated wind speed acting over the 3-nautical-mile fetch affecting the station was 120.5 mph. The average depth of the fetch was 23 feet, plus the surge depth at the site, bringing the total depth to 46.6 feet.

Using Figure 1-28 and Equation 1-27 of Reference 13, these factors produced waves at the east end of the site with the following characteristics:

Wave height	9.7 ft
Wave length	159.0 ft
Period	5.6 sec

Using Figure 3-12 of Reference 13, assuming an average slope of bank of 1V to 5H, runup at the site was 8.24 feet for smooth slopes and 3.60 feet for rubble slopes. Since the slopes consist of material between the roughness of smooth and rubble slopes, these values were averaged, yielding a runup on slopes at the site of 5.9 feet. Consequently, the maximum runup elevation is approximately 28.6 feet MSL (22.7 feet MSL stillwater level at the site, plus 5.9-foot runup).

The maximum wind speed at the site was assumed to be 120.5 mph from the east. With the wind oriented in this direction, there would be no wave runup on the west side of the site. Waves would be generated and move in a westerly direction, impinging on the opposite shore.

In order to postulate waves on the west side of the site, it was assumed that waves would reflect off the opposite river bank and return to the west side of the site unattenuated. Wave runup elevations calculated in this manner will exceed those that can be reasonably expected at the west side of the site.

The average fetch was calculated in the manner described in Section 1.233b, Reference 13, and was found to be 3.2 nautical miles. The average depth of the river to the west of the site is 12.0 feet. When the river depth is added to the surge, the total water depth on the west side of the site is approximately 35 feet.

Using the methods outlined in Reference 13 and the above-mentioned data, wind-generated wave runup elevation was calculated for the west side of the site. The generated waves, impinging on the shoreline near Jamestown Island, possessed the following characteristics:

Wave height	8.5 ft
Wave length	171.0 ft
Period	6.2 sec

Assuming the shoreline around Jamestown Island approximates a smooth beach with a 10-degree slope, Reference 14 gives a reflection coefficient of 0.15 for wave H/L = 0.05. Trees and brush in the area will tend to further reduce this factor. Using this factor, the reflected wave height was calculated to be 1.3 feet. The unattenuated reflection of these waves was applied to the shore line on the west side of the station site.

Using Figure 3-12 of Reference 13, assuming the slopes in the area of the station discharge are approximately 1V to 2H, runup of waves on the west side of the site was calculated to be 1.3 feet above stillwater level in the vicinity of the discharge channel. The rock groins extending into the river and the topography between the river and the station will tend to minimize this calculated runup.

Maximum runup elevation for the west side of the site is 24.0 feet MSL. Critical equipment in this area is protected against flooding to Elevation 26.5 feet. The station grade of 26.5 feet MSL will accommodate a runup above stillwater level of 3.5 feet. In order to generate reflected waves of this magnitude, the reflection coefficient would have to be on the order of 0.4.

As shown in Reference Drawings 1 and 2, the emergency service water pumping equipment is housed in a reinforced-concrete structure above the deck of the circulating water intake structure. The floor and walls of the emergency pump room are watertight. A procedure requires the pump room entrance door to have a seal plate installed to limit water ingress into the pump house as discussed below before the arrival of the PMH to prevent inundation. Wave runup on the front of the structure is estimated to be well below the roof elevation of the structure (33.5 feet), therefore overtopping will not occur.

Breaking waves during the probable maximum hurricane could impinge on the superstructure of the emergency service water pump house, which is located on the deck of the intake structure. Using Minikin's method, as outlined on page 255 of Reference 13, the total resultant wave thrust on the wall is calculated to be approximately 29.3 kips/linear foot (Reference 19) acting at Elevation 22.7 feet MSL. The highly reinforced wall of the emergency service water pump house can withstand this loading.

The possibility of the river level being depressed below the suction level of the emergency service water pumps is extremely remote. The storm required to cause such a condition probably would be of the same magnitude as the probable maximum hurricane, and oriented in such a way that velocity components are downriver instead of upriver. For this to occur, the storm center must pass north of the river, and thus considerable filling by the storm would occur. Measurements of the probable maximum hurricane wind field indicate that downriver wind components could exist for about 24 hours, and these components would vary between zero and a maximum and back to zero during the period. Thus, it is safe to say that the suction of the pumps would not be exposed for more than 24 hours.

The emergency service water pump diesels are protected against flooding in the remotely possible event of a probable maximum hurricane.

The maximum stillwater level at the screen well is calculated to be Elevation 22.7 feet MSL. The sill of the pump room door and the air intake louver openings are located at

Elevation 21 ft. 2 in. MSL. The doors are equipped with removable seal plates which, when installed, limit water ingress into the ESW pump house such that continued emergency service water pump operation is not jeopardized through this pathway during the design basis hurricane. The air intake louver openings are protected against flooding to Elevation 24 feet MSL by watertight wells on the inside walls of the pump house. The openings are on the side of the building away from the surge.

In the unlikely event of a hurricane of postulated probable-maximum-hurricane magnitude at the Surry Power Station, there is a possibility of waves being generated, in the fetch formed between the circulating water intake structure and the east bank of the intake canal, of sufficient height and proper direction to cause intermittent surging of water into the emergency service water pump house through the air intake louvers located on the front of the structure.

To limit a buildup of water in the emergency service water pump house that could jeopardize emergency service water diesel operation, the air intake louvers are equipped with exterior covers which, when installed, limit water ingress into the ESW pump house. The exterior covers on these louvers prevent surging water from overtopping the watertight wells.

For both ESW pump house doors and the intake louver openings, the corresponding seal plates and exterior covers are required to be installed whenever hurricane conditions exist, or are forecast to exist, which would require their use to preclude significant water ingress.

With the normal air intake louvers covered, air for operation of the diesel-driven emergency service water pumps would be provided through the dampers located in the top of the pump house structure. The position of these dampers under the exhaust hood precludes any significant water entry into the pump house from wave overtopping or runup on the structure.

The elevation of the exhaust centerline is 36 ft. 6 in. MSL. This is sufficiently above the mean sea level to prevent flooding. It is possible that occasional waves may cause splash and spray up the walls of the structure to Elevation 36.2 feet MSL. These would not affect the integrity of the screen well, as the roof is watertight and the exhaust outlet is at an elevation above all wave generated splash, spray or flow and is configured to prevent any rainwater flow into the exhaust in such an event.

A minimum freeboard of greater than 4 feet is maintained between the canal water surface and the berm at Elevation +36 during hurricane flooding of the river (see Section 10.3.4.2).

In order to determine the maximum wave runup at the west end of the high-level intake canal, the wind at the station site was directed along the length of the canal. The following values were used in calculating the maximum wave runup, as described in Reference 15:

Canal depth range	20 – 25 ft
Wind speed	120.5 mph

Effective fetch	1500 ft

The waves generated possessed the following characteristics:

Wave height	1.7 ft
Wave length	41 ft
Period	1.6 sec

Using Figure 3-12 of Reference 15 and assuming a smooth canal liner sloping 1V to 1.5H, the wave runup was calculated (Reference 18) to be 4.0 feet.

Since a minimum freeboard of greater than 4 feet is maintained during a hurricane, no overtopping is anticipated, and there will be no effect on the station.

A list of maximum-probable-flood protection levels for Class I structures is contained in Table 2.3-7.

2.3.2 Ground-Water Hydrology

The hydrologic boundaries of the site proper are the James River on the east and west, Hog Island Creek to the north, and Chippokes and Hunnicut Creeks about 1 mile to the south.

Precipitation data pertaining to the site are contained in Section 2.2. A water budget analysis indicates that, of the total precipitation, 37% runs off and the remaining 63% is lost through evapotranspiration. Low soil permeabilities preclude significant ground-water recharge from local precipitation.

The soils in the site area, as described in Section 2.4, consist of a series (50 to 80 feet thick) of lenticularly interbedded fine sands, clays, and silts. These clay and silt members are essentially impermeable, and the sand member showed field permeabilities on the order of 1×10^{-4} cm/sec. Twenty shallow wells within a 3-mile radius of the site obtain small supplies of water for domestic purposes from these sands. The closest shallow well in use is located 1.6 miles south of Unit 1 and supplies domestic water to a private residence. There is an abandoned shallow well near the south property line.

The above deposits are underlain by 240 to 270 feet of tough impermeable clay containing only occasional and limited sand members. At a depth of about 320 feet below the surface, Eocene and older sediments are encountered. The sand members of these sediments are excellent aquifers; many domestic wells and some industrial wells in the area obtain water supplies from this source. In general, yields range from 15 to 50 gpm; however, a well 799 feet deep at Bacons Castle, about 5 miles to the south, yielded under test 940 gpm with only 20.25 feet of drawdown. The closest offsite deep wells are located on the State Waterfowl Refuge, about 1 mile north of the site; and at Drewry Point, approximately 0.6 mile southwest. Both wells are approximately

340 feet deep and have a yield of about 35 gpm. The well at Drewry Point is not in full-time use, since it serves a vacation cottage.

In addition to the 340-foot deep well on the State Waterfowl Refuge, which existed prior to station construction, there are nine operating water wells on the site property, which were constructed to serve several purposes. These wells are about 400 feet deep and obtain water from the Late Cretaceous sediments. Three of these wells yield 200 gpm each and are for makeup and domestic uses at the station. A separate well with a 100-gpm pump supplies the Training Center.

The hydraulic gradient is north, east, and west toward the James River. Both the deep well at Drewry Point and the shallow well south of the site up-gradient from the site. The deep well on the State Waterfowl Refuge is down-gradient from the site; however, it is not affected by water flow from the site. Based on the results of borings, the general geology of the area and the location of the site, the coefficient of permeability of the soil mass in a horizontal direction is estimated to be several orders of magnitude greater than in the vertical direction. Water that does not enter the soil will move laterally to the east, north, or west and discharge to the James River. There is no possibility of surface or near-surface water migrating downward to enter the aquifers in strata of Eocene or older ages which supply deep wells. The results of various ground-water hydrology studies indicate that no adverse effects will result to the water resources in the region because of the operation of the station.

The monitoring of various wells is incorporated in the environmental sampling program for the station. Water quality analyses at Surry Power Station Units 1 and 2 show a chloride concentration ranging from 33 to 49 ppm. In general, the quality of water from the lower aquifers is good except very near the coast or where the potentiometric levels have dropped significantly below MSL.

Due to the isolated location of the plant site (James River on the north, east, and west sides, and a game refuge on the south side), no substantial industrial or residential development is anticipated in the immediate vicinity of the plant site. Therefore, no additional demand of a substantial nature upon the ground-water supply is expected.

2.4 GEOLOGY

2.4.1 Geologic Investigations

Investigations of geologic foundation conditions at the Surry Power Station site have included the following:

1. Investigations and studies made under supervision of Dames & Moore, and reported on November 17, 1967 (Reference 1):
   a. Study and report on regional and local geology.
   b. Study of ground-water and surface hydrology.
   c. Borings - total number 55, maximum depth 200 feet.
   d. Laboratory tests of soil samples from borings to determine, under static and dynamic loads, shear strength, compressibility, permeability, and relative density of soils.
   e. Refraction seismic surveys to measure primary and shear wave velocities in near-surface soils.
   f. Micromotion studies.
2. Investigations and studies made under supervision of Stone & Webster Engineering Corporation:
   a. Ten borings by Penniman & Brown in the immediate area of the turbine building and reactor containment structures.
   b. In-place density tests of Sand A and Sand B as found during excavation of containment structure cofferdam.
   c. Lateral load test of two piles under the fuel building (report dated July 1968).
   d. Direct load test on seven piles (report dated June 28, 1967).
   e. Taking undisturbed block samples of Pleistocene clays for further testing by Hardin, and by Goldberg and Zoino.
   f. Installed system of piezometers to monitor ground-water levels in several aquifers.
3. Dr. R. V. Whitman, *Report on Foundation Dynamics for Proposed Nuclear Power Plant*, July 1967.
4. Dr. Boddy O. Hardin - Tests on undisturbed block samples of Pleistocene clays, and on a slightly disturbed sample of Miocene clay to determine static shearing strengths and shear

moduli for dynamic loadings (reported under dates of October 5, November 11, and December 1, 1967).

5. Goldberg and Zoino - October 18, 1967, and December 7, 1967, reports of tests on Pleistocene sands and undisturbed clays for determination of:

    a. Relative densities for sands.

    b. Consolidation characteristics of clays.

    c. Quick shear strength of clays.

    d. Shear strength characteristics of clays for triaxial tests with pore pressure measured, test type C. U.

Routine water samples have been taken from the James River in the area of the station where the river water is brackish. Basic sulfide and carbonate precipitation methods were used to analyze the water, instead of simply boiling the water to dryness and counting the residue. During mid-1968, a sample from Cobham Bay had a carbonate activity of 20 pCi/liter. This was greater than other samples taken from the river.

To investigate possible causes, the beaches along Cobham Bay were explored. There are numerous locations where the high banks along the river have been washed away, exposing outcroppings of the Yorktown formation which date from the Miocene Epoch (more than approximately 12 million years old). It seems wherever the outcroppings exist, a black, heavy, sand-like material is very abundant on the beaches, varying up to about 1-in. thick and several feet wide. Several samples of the black sand were taken and, in addition, numerous fossilized whale bones that were also found in the area were taken. Gamma spectral analysis by Vepco indicated a relatively high Thorium-232 content in the black sand, and a relatively high Uranium-238 content in the fossils.

In early 1969, a representative of Froehling and Robertson, Inc., of Richmond, Virginia, took six samples of the black sand and sent them to International Chemical and Nuclear Corporation for an analysis. The existence of Thorium-232 and its decay daughters was confirmed.

During the early part of 1969, a majority of the beaches along the James River were explored in an effort to determine the extent of the black sand deposits. Deposits were found scattered all along the southern shore of Cobham Bay. Locations were also found at outcroppings on Burwells Bay, south of Hog Island. In addition, deposits were found on the north shore of the James River, near Camp Wallace, which is northeast of the station site.

In June 1969, a representative of the Virginia State Radiation Health group was shown the deposits on Cobham Bay.

Since the sample of Cobham Bay water of 1968, other grab samples have varied from non-detectable limits up to 49 pCi/liter, with the majority below 10 pCi/liter.

2.4.2 Geology—Summary

2.4.2.1 Basic Geology

East of the Blue Ridge Mountains, Virginia may be divided into two broad physiographic units, the Piedmont Province and the Coastal Plain Province.

The Piedmont is essentially a bedrock plateau. Surface deposits are primarily residual soils derived from weathering of underlying bedrocks, which are basically a complex of meta-sediments of pre-Cambrian and early Paleozoic age, with some areas of sedimentary and igneous rocks of Triassic age.

The boundary between the Piedmont and Coastal Plain Provinces, termed the Fall Line, extends from New Jersey to Alabama and passes through Richmond and Petersburg. Slow regional downwarping along the axis of the Fall Line began in early Cretaceous time, about 120 million years ago, and continued through Tertiary time.

South and east of the Fall Line, the Piedmont surface was depressed to a gentle downward slope until, at Cape Henry, it is about 2800 feet below sea level. This downwarped surface formed a base on which Cretaceous and later sediments have been deposited in a general wedge-shaped mass, with individual members also being wedge-shaped and thickening toward the southeast. Based on regional data, these sediments are undeformed. They show no evidence of metamorphism and even the earliest are still essentially clays and sands. All available evidence indicates that, since early Cretaceous time, the crystalline basement beneath the Coastal Plain has been tectonically dormant. No faults are known or suspected at the site or in the vicinity of the site.

The Surry site is located on Gravel Neck, in Surry County, Virginia. The site is located in the Coastal Plain physiographic province approximately halfway between the Atlantic Ocean and the Fall Zone (see Figures 2.4-1 & 2.4-2).

In Virginia, the Coastal Plain has a stair-step character composed of a series of plains that are successively lower from west to east and are separated from one another by scarps. In the site vicinity, four plains are recognized. From the highest to the lowest they are the 120-foot plain, 90-foot plain, 70-foot plain, and 45-foot plain. Also, three prominent scarps are present. They are the Surry scarp, the Peary scarp, and the Chippokes scarp.

The surface of the Coastal Plain slopes gently in an east-to-southeast direction from about Elevation +200 at the Fall Line to sea level at the coast and thence out under the ocean. The slope is not uniform, but is characterized by essentially flat areas separated by gentle slopes of a few degrees, which are termed scarps. The average slope in the region of the site is about 1.5 ft/mile (Reference 4).

During the progressive downwarping of the crystalline basement of the Coastal Plain, various portions of the area were above, at, or below sea level, with alternating periods of marine and continental deposition occurring. A columnar geologic sections for the site area are shown on Figures 2.4-3 and 2.4-4.

The morphologic boundaries of Gravel Neck are the James River on the west, north, and east sides, and the Chippokes scarp to the south. This scarp is about 5 miles long, lies in a southeast-northwest direction, is 45 to 50 feet in height, and has a surface sloping downward toward the northeast at about 3 degrees. The site area is flat and featureless with an average Elevation of about 30 feet above mean sea level (MSL). In the immediate site area, there are no surface features indicative of actual or potential localized subsidence of landsliding. There is no history of surface mining, withdrawal of large quantities of fluids such as petroleum, or other activity by man which would cause settlement or ground disturbance. Heavy vegetation covers most of the site.

In the site area, surface deposits are sediments of the Norfolk Estuarine Formation of Pleistocene age, extending to depths of about 50 to 80 feet. The upper 20 to 35 feet of the Norfolk Formation consists of layers of brown and mottled brown sand, silty sand, and organic and inorganic silts and clays. Interspersed are thin lenses of iron-oxide cemented sands. The lower part of the formation consists of layers of gray sand, silty sand, and organic and inorganic silts and clays, many of which contain decayed vegetation and shell fragments. These most probably were deposited under estuarine, lagoonal, and swamp conditions. The Norfolk formation was deposited upon an erosional surface of the Yorktown formation during the late-Pleistocene age when the sea level rose to approximately Elevation 45 feet. At the end of the Pleistocene age the sea receded. Erosion of the Norfolk sediments is continuing today in the site area. It is accompanied by deposition of recent alluvial deposits in stream valleys, marshes, and lagoons.

The Norfolk Formation unconformably overlies the Chesapeake Group of Miocene age. Upper Miocene, Pliocene, and early Pleistocene deposits that may have existed have been removed by erosion. Within the site area, the surface of the Miocene sediments, estimated to be 240 feet thick, are found at elevations varying from -16 to -47 MSL. Consolidation tests made on samples from the Miocene deposits showed them to be overconsolidated by 4 to 5 tons/ft^2 in excess of existing overburden pressures. This suggests that from 150 feet to 200 feet of material previously lying above the present Miocene was removed by erosion before deposition of the Pleistocene deposits.

The Chesapeake Formation, of Miocene age, in the site area consists of compact, very stiff, tough clays, green to dark gray in color, with occasional compact sand and silt members. Shell fragments are common. These soils are strong and stable, with moderate to high shearing strengths. Underlying the Miocene sediments are Eocene, Paleocene, and Cretaceous sediments. These are estimated to be about 45, 55, and 800 feet thick, respectively, based on wells drilled in the general area. From seismic investigations about 2 miles southeast of the site, crystalline bedrock is estimated to be at a depth of about 1300 feet.

2.4.2.2 Geologic History

Although the complex evolutionary history of the Appalachian Highlands and that of the Coastal Plain is not completely understood, investigations by numerous geologists allow the following account of the basic geologic history of the central Appalachian region. Table 2.4-1 summarizes the major orogenic events, lists their area of influence, and comments on the character of the event.

Precambrian

Intense metamorphic deformation occurred in the Precambrian age from 1100 to 800 million years ago (Grenville orogeny). Sedimentary and igneous rocks were metamorphosed to form the metamorphic crystalline rocks now known as the basement. These basement rocks are exposed today in the Blue Ridge province and Baltimore gneiss domes.

The Grenville orogeny was followed by a period in late-Precambrian time characterized by subaerial erosion that apparently stripped away most superficial structures. This tectonically inactive period was followed by orogenic movements.

The Avalonian orogeny occurred in very late-Precambrian time, 580 to 600 million years ago. This period of deformation was marked by very large and thick accumulations of clastic sediment and volcanics accompanied, if not caused, by sharp local uplifts and downwarps. The nature of these uplifts, whether they were folds, fault blocks, or islands, remains obscure. This period of intense tectonic activity marks the beginning of the differentiation of the Appalachian region from the rest of North America.

Early-Paleozoic Era

The Avalonian orogeny was followed by the subaqueous deposition of thick carbonate and mud sequences, with some volcanics at the end of Cambrian and start of Ordovician time. In middle-Ordovician time, about 450 to 500 million years ago, the thick sequence of late-Precambrian and early-Paleozoic sediments was metamorphosed, deformed, and intruded by intense igneous activity. This period of deformation was called the Taconic orogeny and was the most intense tectonic event of the central Appalachian region.

A second orogeny, known as the Acadian orogeny, occurred during the Paleozoic age, about 360 to 400 million years ago. It was accompanied by regional metamorphism and granitic intrusion. Although very intense in the northern Appalachians, its effect in the central Appalachians is not well established.

Late Paleozoic Era

While the Piedmont and Blue Ridge provinces were undergoing metamorphism and igneous intrusion during the early- and mid-Paleozoic ages, the Valley and Ridge and Appalachian Plateau provinces were receiving sediments. At the end of the Paleozoic era, about 230 to 260 million years ago, the entire sedimentary sequence of the Valley and Ridge and Appalachian Plateau provinces were receiving sediments. At the end of the Paleozoic era, about 230 million years ago, the entire sedimentary sequence of the Valley and Ridge was folded and faulted producing the present mountainous terrain. This period of deformation is known as the Allegheny orogeny. It was long considered the main Appalachian orogeny; however, it is now evident that it was only one event at the end of a series of deformations throughout the Paleozoic. Its effect in the Piedmont and Coastal Plain must have been nominal. There is no evidence to date showing any marked tectonic activity in these provinces from the Appalachian events.

Early Mesozoic Era

The late-Triassic period, 190 to 200 million years ago, marked the last orogenic episode of the Appalachian region. Large regional arching was accompanied by development of downfaulted basins which were contemporaneously filled with Triassic continental sediments and lava flows. Accompanying the regional arching was the development of dike swarms. In the region of study, dikes trend mostly northwest which is transverse to regional structural trends. The dike activity may have lasted as late as the Jurassic period.

The eastern-most margin of the crystalline rocks of the Piedmont province was downwarped during Mesozoic time with accompanying uplift and arching of the western Piedmont and Blue Ridge provinces. The result was an accelerated erosion of the western areas and deposition of the eroded material on the downwarping eastern portion. Uplift and relative subsidence was most rapid during Cretaceous and Miocene times.

In the site area, the first sediments deposited on top of the crystalline bedrock were a mixture of terrestrial, deltaic, and shallow marine sediments of early-Cretaceous age. By late-Cretaceous time, a shallow sea covered the site area and stayed in the area until late-Miocene time. During this time interval, a thick sequence of marine sediments was deposited which are the Mattaponi, Aquia, Nanjemoy, Chickahominy, Calvert, St. Mary’s, and Yorktown formations.

The oldest unit encountered in the borings at the site is the Yorktown formation. Regionally it consists of a sand facies and silt-clay facies. The sand facies is the result of terrestrial stream deposits in a shallow marine environment. The silty and clayey sequences are the result of estuary and lagoon environments. In the borings at the site, only the silt-clay facies were encountered.

In late-Miocene and early-Pliocene time, 11 million years ago, the sea level receded which exposed the upper beds of the Yorktown formation to erosion. Extensive erosion occurred, followed by a period of deposition of the Sedley and Bacon’s Castle formation. They consist of Pliocene sediments of fluvial and estuarine origin.

During late-Pliocene and early-Pleistocene times, 2 million years ago, extensive erosion occurred which removed much, or in some places all, of the Bacon’s Castle and Sedley formations. Subsequently, the sea encroached on the land to about Elevation +100 and deposited estuarine and littoral (beach) sediments of the Windsor formation.

During mid-Pleistocene time, the sea receded in stages leaving step-like plains and scarps at each intermediate stage. Erosion was extensive and in the site area all of the Windsor formation and parts of the Yorktown formation were removed. The present valley of the James River was established during this time.

In late-Pleistocene time, the sea level rose for the last time to about Elevation +45 accompanied by the deposition of clayey sands of the Norfolk formation in marshes and nearshore marine environments.

From the end of the Pleistocene time to the present, the sea has receded and the erosion of Norfolk sediments is continuing today in the site area. It is accompanied by deposition of recent alluvial deposits in stream valleys, marshes, and lagoons.

2.4.2.3 **Structural Geology**

The site area lies on the southern flank of the Chesapeake-Delaware embayment, a depositional basin that has been downwarping and receiving sediments since late-Jurassic time, approximately 140 million years ago. Present regional subsidence in the site area has been measured to be about 1 to 5 mm per year (Reference 2). The resulting dip of the sedimentary units is oceanward, toward the east. The dip of the late Tertiary units (Yorktown) in the site area is 2 to 7 feet per mile, southeast (Reference 3).

For bedrock structural contours from the Cretaceous through the Pleistocene eras, no abrupt thickening nor asymmetric isopach contour patterns are present as would be expected for fault type subsidence (Reference 2). Rather, large gradually varying isopach patterns are evident. These may be formed by gradual regional downwarping, differential compaction, erosion or as a function of distance from the sediment source (deposition). The isopach centers vary in location with geological time and are not correlative with any localized structural effect.

Except for an area near Yorktown, Virginia, the site area and vicinity is devoid of any structural features indicative of folding or faulting. Southeast of Yorktown, Virginia, the beds of the Yorktown formation (Miocene age, 25 to 11 million years old) show a reversal of the regional dip. The beds dip 8 to 55 feet per mile, northwest. The reversal area was once believed to be of tectonic origin. However, as a result of more recent studies by Johnson, 1972 (Reference 3), the warping appears to be contemporaneous with Miocene deposition and the result of differential compaction of underlying units in response to surface loading. The northwest tilting had ceased prior to Pleistocene deposition, 2 million years ago. The overlying Pleistocene sediments show no dip reversal and conform with the regional trends.

In the immediate site area, surface inspection and subsurface investigations show no evidence of structural deformation. The borings indicate no offsets or folding of strata. There is no surface or subsurface evidence of prior landslides, cratering, or fissures that may be indicative of prior intense earthquake effects.

2.4.3 Soil Conditions

2.4.3.1 General

Original ground through the area of the station was at approximately Elevation +34, except for a few small shallow erosional depressions leading toward the river or north to the low marsh areas of the adjacent Hog Island Game Refuge.

Finished yard grade in the station area is Elevation +26.5. From ground surface to approximately Elevation -38 is a series of alternating strata of clay and sands of Pleistocene age. These lie unconformably on Miocene clays that have in their upper portion a series of thin sand lenses. These thin Miocene sand lenses were found intermittently between about Elevations -55 and -62, and were individually only a few inches to a foot or so in thickness.

The locations of borings in the station area are shown in Figure 2.4-5. Detailed subsurface profiles along two mutually perpendicular axes, one through the reactor centerline of the containment structures, and the other on a line midway between the two units, are shown in Figures 2.4-6 and 2.4-7, respectively. For convenience in descriptions and studies, the sand members shown in Figures 2.4-6 and 2.4-7 at about Elevation -5 have been called Sand A, those at about Elevation -35, Sand B, and the thin sands at about Elevation -55 in the upper portion of the Miocene clays, Sand C. Sand A was present in its natural state during the period of geological investigation, but was replaced by backfill in selected areas prior to construction.

Additional information on 1982 borings conducted in the vicinity of the Surry site can be found in Reference 2.

2.4.3.2 Pleistocene Clays

The Pleistocene clays are dark olive to dark gray, and of low to medium plasticity. Atterberg limits plot along or slightly above Casagrande's A Line, with liquid limits ranging from about 35% to 50%, and liquidity indices of about 30 to 40%. Quick shear strengths of these clays range from 1100 to 2900 lb/ft^2. These were obtained in tests on undisturbed block samples taken during excavation of the cofferdams for the reactor containment structures. Sensitivity of these clays was about 3 to 6, when sensitivity is defined as the ratio of shearing strengths in the undisturbed state to those after complete remolding, with no change in moisture. Shear moduli as determined in cyclic torsional shear tests (Reference 4) were found to be about 12,000 psi to 14,000 psi, using undisturbed samples reconsolidated to appropriate vertical effective stresses. These values agree satisfactorily with Hardin's proposed relations for computing shear moduli based on void ratio and effective stress. Damping in these tests was about 0.03 of critical at strains of about 2×10^5 radians. Consolidation tests on undisturbed samples showed preconsolidation of about 0.5 to 0.75 tons/ft^2 in excess of existing overburden.

2.4.3.3 Pleistocene Sands

Investigations of the Pleistocene sand made using borings during the initial site investigations (borings 7 through 44) were later supplemented by an additional series of borings

(45 through 50A), which were made after the station area had been excavated to about Elevation +7. A third group, designated by the suffix A or B, was then made adjoining and paralleling selected borings from the first two series. The purpose of this last series was to determine whether relatively low blow counts recorded for some of the samples taken in the sand were truly representative of conditions. Great care was taken with these last borings to ensure proper sampling techniques. The locations of all borings in the area of the structures are shown in Figure 2.4-5.

In the first series of borings, samples were taken using a 2.5-inch i.d. sampler, driven by a 300-lb weight falling 18 inches, or by hydraulic pull-down. In certain of the second series of borings, samples were taken alternatively with the above equipment and with a 1-3/8-inch i.d. sampler driven by a 140-lb weight falling 30 inches, commonly referred to as the standard penetration test.

Plotting of the results of the driving resistances against each other for the second series of borings indicated that, for soil requiring 10 blows for 12-inch penetration in the standard penetration test, the 2.5-inch sampler required from 7 to 8 blows.

In situ densities and relative densities of sand members A and B were established by direct measurements and by study of penetration resistances in borings.

Profiles of the soils as determined during the excavation of the cofferdams are shown in Figures 2.4-6 and 2.4-7. The two significant sand strata, A and B, are considered individually. Their density has been investigated by direct measurement of in situ density, as found in tests made as the cofferdams were excavated, and measurement of the density of undisturbed boring samples. The locations and elevations are shown in Figure 2.4-8. Shown also in this figure are locations where undisturbed block samples of the Pleistocene clays were recovered. Results of these in-place density tests are shown in Table 2.4-2, separated into Sand A and Sand B. In making these in situ tests, an attempt was made to select the cleaner sand members by visual examination. Despite this precaution, silty sands and some having significant dry strengths were included, especially in Sand B, which contained more silt and clay than did Sand A. Table 2.4-3 shows gradings for samples taken at 12-inch intervals vertically in Sand B between Elevations -26.5 and -36.5. It should be noted that only two of the samples were clean, and these were taken from a well-graded thin-gravel member.

Maximum densities obtained in the modified Proctor compaction tests by vibration were determined for comparison with the in situ density for each test. Minimum densities were determined for a number of the samples, which were sufficiently clean to make the minimum density test procedure valid. Relative densities are tabulated showing the values of in situ relative density, as compared with maximum density from both vibration and compaction. These data show Sand A in situ relative densities. Relative densities for Sand B were not established because of general excessive siltiness, which interfered with establishing minimum densities satisfactorily. In situ densities for these materials, in general, ranged from about 100 to 110 lb/ft^3, with one sample showing an in-place density of 94.2 lb/ft^3, equivalent to 88% of the maximum modified Proctor density for that soil.

Also shown in Table 2.4-2 are relative densities obtained by Dames & Moore from tests made on undisturbed samples of these soils. Undisturbed samples for this purpose were taken using the Dames & Moore thin-wall sampler, or with a Pitcher sampler forced down by hydraulic pressure. Their results are in close agreement with the in situ tests.

The soil within the cofferdams was excavated using a 3-yard clam shell bucket dropped freely. In both Sand A and Sand B, because of the projection of the wales, excavation by this equipment left an annulus of soil approximately 3 feet wide against the sheeting. This soil annulus stood intact with vertical faces of 12 to 16 feet in height until removed later.

Table 2.4-4 shows the blow counts for all samples in the upper sand from the borings. These are arranged in two groups, Group 1 being for the initial series of borings, and Group 2 for the second series of borings made within the area excavated to Elevation +7. The table also gives the amount of overburden for each sample above the elevation of the sample at the time the boring was made. A second column of "N" values headed "Adjusted Blow Count" is shown. In this column, the blow count for the 2.5-inch sampler has been increased by the ratio of 10:8 to correlate the results using this sampler with the standard penetration tests. Table 2.4-5 shows similar data for the lower sands.

As previously noted, supplementary borings, identified by the subscript A or B, were made adjacent to a number of the earlier borings that had shown relatively low blow counts, or "N" values. These supplementary borings were made about 3 feet from the original borings, under very careful supervision and sampling techniques to ensure results free of disturbance or error. Accordingly, where supplementary borings were made, data from the initial borings were omitted as being questionable.

These data are shown graphically in Figure 2.4-9 for Sand A and in Figure 2.4-10 for Sand B. On these graphs are shown the fraction of occurrences of different values of blow count for the Group 1 borings and Group 2 borings. In Sand A, particularly, the difference between the two groups of borings is quite marked. The overburden effective stress at the level where these samples were taken was of the order of 3500 to 4000 lb/ft^2.

After the area was excavated to Elevation +7, much less energy was required to drive the sampler, as indicated by the distribution of blow counts.

Relative densities of the sands from the penetration test results have been determined using the "Average Curve" of Gibbs and Holtz (Reference 5). These data, together with the relative densities as determined from the in situ tests and undisturbed samples, are plotted in Figure 2.4-11.

These data indicate that Sand A is of variable density, ranging from sand of medium density, having a minimum relative density of about 65%, to very dense sands with relative densities in excess of 95%. Sand B is more uniform. The loosest members again are of medium density, about 65 to 70% relative density, or possibly slightly greater, with the majority of the sand in the dense condition at about 80% or greater relative density. Also, it should be noted that Sand B contains considerable silt and clay, and is thus less susceptible to liquefaction than clean sands would be.

2.4.3.4 **Miocene Deposits**

Underlying Sand B is the Miocene clay. The contact is an unconformity, i.e., erosional surface, varying from about Elevation -34 to Elevation -40 in the station area. The Miocene clays are very stiff, and of a gray-green color. Boring 15, which was sampled continuously below Elevation -5, showed several thin sand members varying from a few inches to about a foot in thickness individually, and having a total thickness of about 4 or 5 feet below about Elevation -55. These sand members have been termed Sand C. This is a glauconitic, clayey, silty sand. It was definitely identified only in Boring 15, but sandy members were noted at about the same elevation in several of the other borings. It is believed to be of limited lateral extent.

The Miocene clay is heavily overconsolidated. Preconsolidation pressures as determined in consolidation tests are plotted in Figure 2.4-12. These show overconsolidation of about 4 to 5 tons/ft^2. Atterberg limits for this material plot somewhat above Casagrande's A Line in the region of low to medium plasticity. Quick shearing strengths are about 400 to 500 lb/ft^2. Shear moduli, as determined from torsional shear tests on a reconsolidated boring sample that may have been slightly disturbed, are about 16,000 psi. This is somewhat below the value computed after Hardin. Internal damping as measured in the torsional test is about 0.03 of critical at strains of about 2×10^{-5} radians.

2.4.3.5 **Site Settlement**

A site survey conducted in May 1975 indicated that site settlement was not a problem at the Surry Power Station (Reference 6). A follow-up survey program was continued over the next 2 years to further monitor site elevations. The results of the follow-up survey program are given in Table 2.4-6.

The follow-up survey program indicated that a small amount of heave had occurred in the vicinity of both containment structures; however, the differential movement between safety-related structures was below the allowable tolerance of 0.5 inches (0.042 feet). As shown by Table 2.4-6, the maximum differential movement had been about 0.2 inches (0.016 feet). Inspection of structural interfaces showed no visible evidence of differential displacements.

2.4.4 Ground-Water Level

As a portion of the original boring investigation, slotted plastic pipes were installed in a number of the borings to permit observations of ground-water levels in the area. These proved unsatisfactory. Accordingly, in September 1967, Casagrande-type piezometers were installed at five locations, as shown in Figure 2.4-5. These piezometers were installed after the start of excavation for the containment structures, and drainage incident to the construction was considered in locating the piezometers.

As previously discussed, the boring program indicated two principal sand strata under the proposed structures. Also, there is a thin sand member near the top of the Miocene clays. The piezometer program was designed to measure the water table elevations in these three strata.

There are five groups of piezometers. Groups P1 and P2 each contain three piezometers, one in Sand A and two in Sand B, with one near the top and one near the bottom. Groups P3 and P4 each contain two piezometers, one in Sand B and one in the thin stratum at about Elevation -55 in the underlying Miocene clays, Sand C. Group P5 contains two piezometers, one each in Sand A and Sand B.

All piezometers are bedded in clean sand and installed in permanent casings. Bentonite seals extend from the sand embedment up into the casings. Approximate tip elevations were selected from data obtained from nearby borings. This was refined with preliminary borings at the locations selected for each group of piezometers, and the final tip elevation adjusted as necessary to place each piezometer in the sand stratum selected for study.

Readings of the piezometers began on September 26, 1967, after they had been installed for at least a week, which provided time for stabilization. These readings were made at hourly intervals for a 24-hour period in order to include two tide cycles. No response to tides could be detected within the limits of accuracy of the read-out, which is estimated to be ±0.1 feet. Thereafter, readings on the piezometers were made once a day until October 6, 1967, when the read-out interval was changed to once a week.

On October 4, 1967, all piezometers were flushed, and the rate of fall noted. The rate of fall indicated that all piezometers were in good communication with the soils in which they were set.

Read-out of piezometers was continued at a weekly interval until June 1968, approximately 8 months, and then placed on a weekly to biweekly interval until October 1968, completing a year of observations. No significant variations were noted during this period. The range of piezometric level in the piezometers remote from the station was only about 1 foot throughout this period of observation. The highest ground-water level observed during this period in Groups P1 and P2, which are remote from the excavation, were as follows:

1. Group P-1

   Sand A +2.2 on September 26, 1968

   Sand B +2.8 on February 8, 1968

2. Group P-2

Sand A +4.3 on February 1, 1968

Sand B +3.8 on February 8, 1968

The range of fluctuation, high to low, through this period of observations was approximately as follows:

P-1-A (Sand A) 1.9 feet

P-1-C (Sand B) 2.0 feet

P-2-A (Sand A) 1.5 feet

P-2-C (Sand B) 1.6 feet

Additional piezometer data from 1967 and 1971 are shown for comparison purposes in Table 2.4-7 and Figures 2.4-14 through 2.4-19. The consistency of the readings over this period indicates that each stratum behaves as a continuous aquifer, rather than as a series of isolated lenses. Possible interconnection between Sands A and B was not established, but may exist. Should interconnection exist, communication should be small, since the vertical permeability of these sands is estimated to be about two orders of magnitude smaller than the horizontal permeability. Additional information on groundwater level at or near the Surry site can be found in References 7 and 8.

Moderate seepage occurred through the interlocks of the sheeting for the cofferdams for the containment structures. This drainage resulted in significant drawdown on the water table in Sands A and B at the cofferdam. In addition, six subsurface relief drains constructed with sand filters were provided into the Miocene clays under each containment structure. Two penetrate to Elevation -105, and four to Elevation -65. They discharge to the drainage system by means of a pervious layer provided under the containment structure. Seepage from Sand C through the cofferdam sheeting, and from under the structure, is collected in the sumps and removed by a system of permanent pumps. These pumps are set and controlled to maintain the water level around the containment structure at about Elevation -33 ±2 feet. The annular space between the cofferdam and walls of the containment structure was backfilled with select granular material that is pervious. This pervious backfill rests on pervious concrete, and is thus connected to and drained by the drainage system.

It is assumed that Sand A is continuous to the discharge canal, and thus would be exposed to inflow from the canal during high water levels in the river. The maximum flood on record in the James River is 234,000 cfs. This corresponds to about the flow in the average spring tide cycle at the site. A flood of this magnitude would raise the river water level at the site about 1 foot above normal level. As the installed piezometers indicated no response to tides, no response would be expected to a 1-foot increase in river water level.

The maximum recorded water level near the site was Elevation +7.7, which occurred as a hurricane surge in August 1933. Hurricane surges are of very short duration; the entire cycle from normal water level to maximum level to return to normal occurs in 24 hours or less.

The sharp gradient observed in the piezometric level in Sand A, proceeding away from the containment cofferdam observed during the construction period, indicates that short-duration exposure of Sand A to a high water level in the discharge canal would not affect the piezometric level in Sand A at the location of the structures because of the low permeability of the soils and the distance of the station site from the river and discharge canal.

Precipitation for the 12 months, September 1966 through August 1967, for several stations, is shown in Figure 2.4-20. It should be noted that total precipitation in this 12-month period was approximately equal to the mean precipitation for the area. Precipitation for the months of July and August was greater than normal, August having approximately double the recorded average for the month. Considering the geography of the site and the character of the near-surface deposits, it is reasonable to assume that precipitation in the immediate months preceding would have the greatest effect on water table conditions.

As indicated previously, the drainage system of the containment cofferdams is permanent. Observations showed piezometric levels during construction of about Elevation -5 in Sand A, and about Elevation -10 in Sand B near the containment structure cofferdams. Values approximating these levels may be anticipated during operations. However, piezometric levels in these sands have been assumed at Elevation +5 in studies of liquefaction potential. This is above values recorded remote from the units and is considered conservative.

2.4.5 Liquefaction Potential

2.4.5.1 Summary

Analyses of the potential for liquefaction of the sand underlying the Surry Power Station, based on piezometric data for the site, prove that liquefaction would not occur in any stratum for an earthquake having a maximum ground acceleration of 0.15g, the design-basis earthquake.

If the maximum earthquake acceleration were increased to a hypothetical value of 0.25g, the analyses indicate acceptable factors of safety against liquefaction, based on maintaining, in the future, present piezometric levels by means of the drainage provided. Even if it were assumed that drainage of Sand A or Sand B ceased to function and piezometric levels rose to a general site area value of Elevation +5, the analyses, which are based on conservative assumptions, give factors of safety greater than unity for the loosest zones found in either Sand A or Sand B. This would indicate that even momentary liquefaction will not occur in either sand. Since, however, Sand A immediately underlies the foundation mat of the auxiliary building and control area, where even local distortion might be significant, Sand A was removed from under the fuel building, auxiliary building, and control area, and replaced by dense-graded granular fill placed and compacted to such density equal to or exceeding 95% of that obtained in the Modified

Density Test-ASTM-1557-66. This effectively precludes any possibility of liquefaction in Sand A at any point under these structures. Since liquefaction of small pockets of Sand B could not result in any distortion of these auxiliary structures, Sand B was not replaced beneath the foundations of these structures.

The thin sand members in the upper portion of the Miocene deposits are permanently drained to the sump pumps exterior to the containment structure. This sand would not be subject to liquefaction under a hypothetical earthquake of 0.25g because of the weight of the overburden and the prevailing drainage, which results in depressed piezometric levels. The remaining strata are clays of types that are not subject to liquefaction.

Liquefaction will not occur at any location under yard areas adjacent to station structures, since the weight of the overburden is sufficient to preclude it.

2.4.5.2 **Analysis**

Stratigraphy, soil properties, and piezometric data for the site have been discussed in detail in Sections 2.4.3 and 2.4.4. Seven dynamic triaxial tests have been performed upon samples of these sands at their in situ densities. In none of the tests was a sudden, complete liquefaction experienced; rather, once the applied cyclic shear loads were made large enough, there was only a gradual increase in strain during each cycle of loading. Such behavior is consistent with the in situ relative densities and with the large content of fines in the sands, especially in Sand B. This program of dynamic triaxial tests is discussed in Reference 9. The procedures followed in the analysis to determine the factor of safety against liquefaction are given in Reference 10.

As discussed in Section 2.4.4, piezometric levels under the structures will be depressed below the general area piezometric level of Elevation +5 because of permanent drainage facilities provided within the cofferdams of the containment structures. Analysis indicates that, under any of the several structures considered, the highest future piezometric pressure level in Sand B will be at or below about Elevation -7. In the unlikely event that these drainage systems ceased to function, ground-water levels could rise to the general area piezometer level of Elevation +5.0. Analyses of liquefaction potential have been made for two different assumptions:

1. Ground-water level at Elevation -7.
2. Ground-water level at Elevation +5.

The factor of safety against liquefaction at any given depth within a soil can be estimated by comparing the average peak shear stress caused by an earthquake to the shear stresses required to cause liquefaction. The procedures used for estimating these two quantities have been verified by the experiences at Niigata and Anchorage.

Reference 11 presents curves used to establish the shear stress required to cause liquefaction. These curves were derived from tests upon a sand that is especially susceptible to liquefaction. Tests upon sands from Surry demonstrate that these curves give a conservative estimate for the resistance to liquefaction by the sands at Surry.

Reference 12 describes the basis for estimating the shear stresses caused by an earthquake. These estimates are based upon dynamic analyses giving the shear stresses developed near ground surface during actual earthquakes.

Typical calculations for safety factors are also presented in Reference 13. The safety factors presented are conservative, since:

1. A conservative (high) estimate has been used for the shear stresses caused by the assumed earthquake.
2. A conservative (high) estimate has been made for the number of cycles of motion during the assumed earthquake, thus leading to a conservative (low) estimate for the shear stress that will cause liquefaction.
3. The stresses required to cause liquefaction have been estimated using curves applicable to a sand (Sacramento River No. 3) that is especially susceptible to liquefaction. The characteristics of the sands at Surry indicate that they possess a greater resistance to liquefaction, especially Sand B, which is predominantly very silty, and, in places, clayey.

Factors of safety against liquefaction and cumulative strains of 5% for various structures and the several strata are tabulated in Reference 14 for 0.15g maximum ground acceleration, the design-basis earthquake, and in Tables 9.12D-l and 9.12D-2 of the FSAR (Reference 15) for an assumed hypothetical 0.25g ground acceleration.

The factor of safety against liquefaction of Sand A is of significance only for the yard areas, since this sand has been removed and replaced under the Class I structures. Analysis even for the hypothetical 0.25g acceleration shows an average factor of safety against initial liquefaction in the yard areas of 2.0 for Sand A for a ground-water table of Elevation +5. The factor of safety against the development of a cumulative strain of 5%, which may be used as a measure of the strain at which significant settlements may be expected to occur, would be about 2.1. Within isolated pockets, where the relative density may be only 60%, the safety factor against 5% strain would be about 1.6 for the conservative assumption of ground water at Elevation +5.0.

For Sand B, factors of safety at hypothetical 0.25g acceleration for average conditions at estimated future piezometer levels, considering drainage provided, would be about 1.8 under the auxiliary building for initial liquefaction, and 1.9 for 5% cumulative strain. If drainage were not considered, and a piezometric level of Elevation +5 was assumed, the values for average soil conditions for initial liquefaction would range from 1.4 under the auxiliary building to 1.8 under yard areas, and against 5% cumulative strain from 1.5 to 1.9.

Even if there were a few pockets where the relative density was only 60%, the safety factors against 5% strain would range from 1.2 to 1.5, based on the conservative assumption of a ground-water table at Elevation +5.

For Sand C, calculations indicate probable average factors of safety of about 1.9 against initial liquefaction, and 2.0 against a cumulative strain of 5% under the containment structure.

These are based on observed piezometric levels, considering the permanent drainage system. If there were isolated pockets of sand having a relative density of 60% within this member, the factor of safety would be 1.5 against a cumulative strain of 5%.

As a further check on shearing stresses, a modal dynamic analysis was made of the entire soil column using recently developed procedures by Dr. Whitman (Reference 16). For this purpose the record of the El Centro earthquake, normalized to give maximum particle velocities at the surface of about 6 in/sec and 8 in/sec, was used as input at the rock surface. Input data were normalized to surface particle velocity, since velocity is often considered a better measure of intensity than acceleration. Various relations between velocity and intensity have been enumerated in Neuman (Reference 17) and Medvedev (Reference 18). All possible interpretations of intensity VII, according to these published relations, were used in selecting velocity and intensity values used in the modal dynamic analysis.

Computed ground motion and intensity values are given in Table 2.4-8. The results of the modal dynamic analysis are given in Table 2.4-9. These results verify that a ground acceleration of 0.15g and a ground velocity of 9.0 in/sec are conservative for the Surry design-basis earthquake, which has intensity VII.

Comparable shear stress values for the yard area were used in the analysis of liquefaction potential, as shown in Table 2.4-10. The analysis was based on a surface acceleration of 0.15g and on piezometric data given in Section 2.4.4. The analysis further demonstrates that indicated shearing stresses used in the calculations and shown in Tables S9.12D-l and S9.12D-2 of the PSAR are conservative.

Considering the conservative nature of the calculations, such results are taken to imply that no liquefaction will occur at this site.

2.4.6 Piling

Unit loading under the turbine-generator foundation, the spent-fuel pit, the main steam shielding and safeguard area, and the refueling water storage tank are such that founding on the Pleistocene sediments would have resulted in undesirably large settlements. Accordingly, these structures are founded on piles. As an aid in selecting the pile type and appropriate loadings to be used, a series of seven piles of two different types and different lengths were driven and load-tested. A report on this test pile program is given in Reference 19. Onsite test pile data are also contained in Reference 20.

Based on the results of these tests, and considering structural arrangements and loadings, it was decided to use open-end steel pipe piles with an outside diameter of 12.75 inches by 5/16 wall thickness. Piles are driven into and derive their support from the overconsolidated Miocene clays. Tip grades for all piles are Elevation -70. To minimize disturbances of the Pleistocene clays, and to avoid lateral displacements of the soil and of structures on or buried in the soil due to driving the piles, a hole of 12-inch nominal diameter was prebored for each pile to Elevation -40.

Each pile was then cleaned out to Elevation -40 and the upper portion filled with concrete with a 28-day strength of 4000 psi.

Total lateral deflection of any given structure under dynamic loadings for clearance between structures and for design of piping, etc., is taken as the sum of shear deflections of the soil plus deflections of the piles relative to the soil. Lateral deflections of piles relative to the soil were computed using programs for lateral deflection of piles developed by Stone & Webster.

To verify these deflections, two piles driven under the spent-fuel pit were loaded laterally to shears associated with the operating-basis earthquake and the design-basis earthquake.

Test results were in excellent agreement with computed values. A report of this test is discussed in Reference 20. Stresses under vertical and lateral loadings are within normal working loads for these materials.

Allowable pile loadings for vertical loads are given in Table 2.4-11. Lateral loads are also given in Table 2.4-11. These loadings are conservative, as indicated by the results of the load tests conducted.

2.4.7 Foundation Design

A summary tabulation of the type of foundation under each of the principal plant structures is given in Table 2.4-12.

2.4.7.1 **Reactor Containment**

The reactor containment structures are founded directly on the highly preconsolidated Miocene clays, using 10-foot-thick reinforced-concrete mats. Founding grade is Elevation -41. A drainage layer consisting of 12 inches of compacted granular fill was placed directly on the clays. The six drains under the reactor containment (Section 2.4.4) connect with and drain to this drainage layer. This layer in turn connects with and is drained by a system of permanent sumps that maintain the water level in the annulus between the cofferdam and the reactor containment structure at about Elevation -33±2 feet.

To construct the containment structures, the general area was excavated from original ground surface, approximately Elevation +34, to Elevation +26.5. An area encompassing the entire power station, that is, from south of the south wall of the turbine room to about 35 feet north of the north side of the containment structures, was excavated to about Elevation +7. Local excavation was then performed as necessary to reach founding grades of the various structures. For the containment structures, this was done using two circular cofferdams consisting of steel sheet piling driven to tip grade Elevation -48. Each cofferdam is 150 feet in diameter. The sheeting was supported by reinforced-concrete ring wales. The annular space between the cofferdam and the structure is filled with porous concrete from Elevation -41 to Elevation -21.6, and above this level with carefully compacted granular fill. Both are pervious and connect with and form a portion of the drainage system around the structure. The granular fill is blanketed with 2 feet of impervious material near the top of the cofferdam to exclude water from above.

A detailed analysis of the settlement of the containment structures, including effects of heave or rebound, which is an upward movement that usually occurs in the soils under excavations as an elastic response to the removal of the weight of the soil, is presented in Reference 18. Computations of rebound for the containment structures indicated a total rebound of about 0.21 feet, of which 0.09 feet was from excavation from Elevation +26 to Elevation +7, and 0.12 feet. from excavation within the cofferdams. Four reference points for measuring heave were installed at Elevation -41 within each cofferdam before starting excavation. Observation showed good agreement between predicted and observed rebounds. Rebounds for excavation from Elevation +7 to Elevation -41 near the center of each cofferdam after completion of excavation were measured at 0.12 feet in the cofferdam for Unit 1, and 0.15 feet in the cofferdam for Unit 2. This compares with the prediction of 0.12 feet. Rebound is largely an elastic response, and is recovered quickly as load is reapplied by construction.

Deadweight load of the containment structure is approximately 7300 lb/ft^2, and is symmetrical. The actual weight of soil removed in excavating to Elevation -41 is about 8600 lb/ft^2. However, the drainage provided under these structures results in an increase in effective stresses in the underlying soil. When these factors are evaluated, a small net increase in effective stress in the soil of about 0.75 tons/ft^2 in excess of that which existed before construction is indicated, assuming the drainage to be fully effective. This is discussed in detail in Reference 21. This net added load is small compared with the overconsolidation of 4 to 5 tons/ft^2 in excess of effective stresses in these soils before start of excavation. Long-term settlements from this net loading are estimated to be less than 0.5 inch. Settlements of approximately the same magnitude are estimated for adjoining structures. Thus differential settlement between the containment structure and adjoining structures will be small.

Under the design-basis earthquake contact, the pressure under the containment is increased to 10,000 lb/ft^2. Since the founding level is 66 feet below surrounding grade, the effective stress in the soil adjoining is approximately 6950 lb/ft^2 considering drawdown of piezometric levels. Shearing strength of the Miocene clays is about 4500 lb/ft^2, and in the overlying Pleisocene clays about 1100 to 2900 lb/ft^2, 1500 lb/ft^2 being a conservative value for use as an average. The factor of safety against shear failure under the edge of the mat is in excess of 3.0, based on Terzaghi's procedure for computing bearing values for shallow foundations. This approach is conservative, since it is based on a load over the entire foundation area, whereas for the rocking mode under the design-basis earthquake the highest contact pressure occurs only under a limited portion near the edge of the foundation.

Additional settlement under these earthquake-induced loadings will be negligible, since they are well within the preconsolidation of the clay, and, further, are of such short duration that no consolidation can occur.

2.4.7.2 Spent-Fuel Building

Foundations for this structure consist of a continuous reinforced-concrete mat at Elevation 0 ft. 10 in., which is in turn supported on pipe piles into the Miocene clays with tip grades at Elevation -70. For a complete discussion of loadings on the piles, see Section 2.4.6. Sand A was excavated from beneath this structure and replaced with dense, select, granular fill. Estimated long-term settlements of this structure will be on the order of 0.5 inches.

2.4.7.3 Auxiliary Building and Control Area

These structures are founded on continuous reinforced-concrete mat foundations at Elevation -2. The mats were placed on dense, select, granular fills that replaced Sand A.

The deadload weights of these structures are less than the weight of soil removed. Soil loadings are, therefore, appreciably less than preconsolidation loadings of the Pleistocene deposits remaining. There will be small elastic settlement as loads are applied, and long-term settlements will be less than 0.5 inches. Average bearing weights are about 2.2 to 2.5 kips/ft^2. Factors of safety against edge failure exceed 3.0.

2.4.7.4 Turbine Room

The turbine generators are founded on continuous reinforced-concrete mats supported by open-ended pipe piles driven to tip grades of Elevation -70. These units average about 5000 lb/ft^2 load over the area of the mats. Estimated long-term settlements will be on the order of 0.5 inches.

The remainder of the structure is isolated from the turbine-generator foundation, and is founded on a system of continuous-strip spread footings, except for some internal columns, which are founded on spread footings. Net founding contact pressures were kept at or below 2 tons/ft^2 at Elevation +4. Where foundations were carried deeper, contact pressures were increased at the rate of 120 lb/ft^2 per foot of depth below Elevation +4.0. This recognizes the increase in bearing value allowable as footing depth below surrounding grade is increased. Bearing values are conservative, and were established considering shear strength and preconsolidation of the Pleistocene clays.

The average load of this structure is less than half the weight of soil removed. Accordingly, long-term settlements will be small.

2.4.7.5 Miscellaneous Yard Structures

The excavation for the station is backfilled to yard grade with dense, compacted granular fill. Miscellaneous small structures such as pipe enclosures, tanks, etc., are founded on or in this structural fill.

2.4.7.6 Screen Well

The river intake structure is founded on fine, clean Pleistocene sands with some interbedded clays at Elevation -27. Foundation is a reinforced-concrete mat.

The area was investigated by borings 51 through 55. These sands are quite dense, with N values in the Pleistocene formations ranging from 23 to 115. The median N value for samples from the five borings is 45 blows per foot.

Considering their density, there is no possibility of liquefaction under this structure.

The river intake structure was constructed within a steel sheet pile cofferdam, and the sheeting anchored to the structure and left in place. Tip grade of the sheeting is Elevation -51. Since the area behind the screenwell is at Elevation +11, and in front is dredged to Elevation -27, it is subject to imbalanced lateral earth loads. Its stability was analyzed and found to be satisfactory; values were as follows:

1. General slide failure through dike of intake canal:
   a. Static FS = 2.24
   b. For DBE FS = 1.53
2. Friction factors coefficient-of-sliding at foundation level (passive pressure from sheeting not considered):
   a. Static (one cell empty) 0.4
   b. DBE (operating condition) 0.4

2.4.8 Relative Earthquake Displacements

Considering the varying types of foundations used, determination of relative motion or displacements between the several structures for design of piping and rattle space was necessary.

In these analyses, displacements due to vibration and to ground movement during earthquake have been considered as follows:

1. Translation, both horizontal and vertical, and rotation of the building relative to the static position of the soil-structure interface.
2. In addition, for the auxiliary building and fuel building, lateral deflection from shear of a column of soil extending from Elevation -40 to founding grade, in accordance with the procedures outlined in a report by Dr. R. V. Whitman (Reference 22).
3. For pile-supported structures, deflection of the piles relative to the soil in which they are embedded.
4. Flexure and shear distortions of the several structures in estimating movements above the founding grades.

Vertical motions are given at the exterior of each structure. These motions include vertical translation and vertical motion of the exterior of the structure due to rocking assumed to be coincident with the vertical translation.

For the containment structure, values shown are the root mean square of the sum of the displacement for four modes of vibration, using a model with four degrees of freedom. For other structures, displacements for the fundamental periods were used, since these are relatively low, simple structures. Values of various elevations for the several structures are tabulated in Table 2.4-13.

Displacements of the piles relative to the ground were computed using a computer program developed for laterally-loaded piles and using values of the coefficient of subgrade reaction based upon physical properties of the several soil strata. Computed deflections for the 12.75-inch-diameter concrete-filled pipe piles are shown on Table 2.4-14.

To verify these displacements, a cyclic lateral load test was made on two piles located in the compacted fill area under the fuel building where Sand A was removed. These tests are discussed in Section 2.4.6. Computed and test deflections were in good agreement.

Maximum relative motions between structures were computed as the sum of the vibratory displacements of both structures at a given elevation, plus relative ground motion from Figure 2.4-21. The values so obtained are considered to be extremely conservative. They assume relative motions of the several structures to be perfectly opposed and coincident with simultaneous maximum earthquake motion displacement of appropriate direction.

To allow for these relative motions between structures, the following is provided:

1. A space of 6 inches is provided between the pile-supported fuel building and the auxiliary building, and between the fuel building and the containment structures. For other structures, the clearance is 3 inches. Intrusion of foreign material into these clearance spaces is prevented by compressible filler material.
2. Maximum relative motion between adjoining structures is included in the stress analyses of all piping that must extend from one building to another.

Adequate slack was left in electrical cables.

In addition to the movements resulting from structural vibration, there will be movements of the structures relative to each other, resulting from ground displacements from orbital earthquake motion. These have been estimated from the ground movement spectrum at periods corresponding to one-half wave length for the type of motion considered; that is, shear in the horizontal and vertical planes, and compression-rarefaction for push-pull motion, with relative motion taken as twice the spectral displacement.

Vertical motion has been assumed as two-thirds of the horizontal. These data are shown on Figure 2.4-21. This figure provides quantitative values for that portion of relative displacements between structures that is due to orbital particle motion under earthquake excitation. The relative displacement due to orbital motion is assumed to be twice the maximum single amplitude of ground displacement for a wavelength equal to twice the distance between the centroids of the structures considered. Periods are computed from these wavelengths using primary and shear wave velocities as appropriate to the orientation or relative motion and for the soil at about founding elevation. Using these periods, the amplitudes of displacement can then be computed for maximum ground acceleration and velocity.

2.4.9 Slope and Bank Stability

The site is essentially flat, except immediately at the river banks and along the north property line, where it slopes gently down to the lowlands of the game preserve. The nearest river bank is approximately 1800 feet west of the station, where the banks are about 5 feet to 25 feet high above the beach. The beach has very gentle slopes, and the river bottom offshore is nearly flat, reaching 6-foot depth about 1000 feet offshore.

The station is about 8800 feet west of the bank along the east side of the peninsula, and about 1800 feet south of the north property line. Prior to excavation, the ground surface in the station site area was generally level at about Elevation +34, except for a minor erosional channel with gentle side slopes which entered the area from the west. Adjacent to the station, the bottom of this depression was at about Elevation +24. The discharge canal follows this depression, to minimize excavation and disturbance of vegetation.

The site was excavated to a generally level grade at Elevation +26.5. Temporary excavation for the buildings and containment structures was made to about Elevation +7. After completion of construction, the area was backfilled with compacted soils to Elevation +26.5.

The discharge canal lies to the north of the station. Its centerline is approximately 380 feet from the centerline of the containment structures, and about 350 feet from the north wall of the fuel building. The cross section of the discharge canal and its relation to the station is shown in Figure 2.4-22.

The river banks and the open channel sections of the discharge canal are sufficiently distant from the station that these free-sloping surfaces will not affect the dynamic shear stresses at the station resulting from earthquake motions.

Along the river front, rather steep banks have developed because of the undercutting during heavy storm wave conditions; however, these banks are otherwise stable. Local slumping might develop under heavy earthquake conditions, but migration of such disturbance back to the station, a distance of about 1800 feet, could not occur. As indicated in Section 2.4.5, the sands underlying the site are not subject to liquefaction, and a flow slide could not develop in them.

The banks of the discharge canal at Surry have been investigated for stability. They have a factor of safety under static conditions of about 2.0.

Analyses of the stability of these banks under earthquake conditions have been made, following the basic concepts outlined by Newmark (Reference 23). In these studies, effects of increased pore pressure in the sand members under earthquake conditions have been considered.

Slide analyses have been considered for two different modes of failure: a rotational slide in a perpendicular vertical plane, where it was assumed that the lower sands had adequate friction to establish the slip plane in the medium clays at about Elevation -20 to -25; and a block slide analysis in which it was assumed that failure would develop in the lower sands because of excess pore pressures developed in these members under earthquake vibration. Tests on these sands have shown that a significant number of cycles of loading are required between the cycle when pore pressures first became equal to the overburden stresses, and the cycle when cumulative strains reach 5%.

A conservative value for the residual strength was used for the first mode of analysis by assuming zero shear strength in the sand members; that is, pore pressures in these sands were assumed to be equal to the overburden pressures along the plane of shear, although this condition holds only for a portion of the time in each pulse. N/A for these assumptions was about 1.8 for an assumed earthquake of 0.5g horizontal and 0.10g vertical acting simultaneously, indicating an adequate factor of safety and no distortion of the bank for this mode.

N/A is the ratio of acceleration applied as a static force that the bank could withstand to the maximum single-pulse ground acceleration.

For analysis of the second mode, excess pore pressures developing in about 12 cycles of loading for varying ratios of $\tau/\sigma v$ (where τ is shear stress and σv is vertical effective stress in soil mass) were determined from the results of the dynamic triaxial tests. Approximate shearing stresses and effective stresses were then evaluated at various points along the assumed plane of shear. From these data, excess pore pressures under dynamic loadings were determined. Since the excess pore pressures, as shown by the test results, ranged from a maximum to a minimum value in each cycle of loading, the mean value in each cycle was used in evaluating the excess pore pressure. These were then added to initial static-state pore pressure, assuming a 5-foot drawdown of the piezometric surface near the discharge canal to permit evaluating residual shearing strengths in the soil mass at various points under the slide block.

"N" was then determined from the ratio of the total residual shear strength to the total mass in the sliding block.

This analysis is conservative because of several factors. Excess pore pressures are zero at the start of earthquake motion, and several cycles of such motion are required, especially when the overburden effective stresses are high, before excess pore pressure becomes significant. Therefore, there could be only a few cycles of motion, rather than the 12 used where the residual shearing strength would be of the minimal values assumed. It is assumed that the excess pore pressure peaks coincide with the peak of velocity in the sliding mass. The test data from which the pore pressure was established were conservative, since initial pore pressures that may have existed at the beginning of each series of loading cycles at a given stress level were ignored in plotting the values of $\tau/\sigma v$.

N/A values on this method of analysis were in excess of 0.5 for an earthquake having a horizontal acceleration of 0.15g and vertical acceleration of 0.10g.

These studies, therefore, indicate that for the design-basis earthquake at 0.15g horizontal earthquake acceleration, there would be no significant slides or movements of the discharge canal banks.

Stability analyses made of the banks of the intake canal, based on the assumption that a combined horizontal ground motion of 0.15g and vertical ground motion of 0.10g would act simultaneously to produce maximum shearing stresses, indicated a factor of safety of 1.5 corresponding to Newmark's N/A of approximately 2.0, which indicates no displacement. Analysis was by the method of slices and assumed no loss of shear strength in sand members. If it is assumed that sand members suffered a complete loss of shear strength because of increased pore pressures under vibratory loadings, the factor of safety is reduced to 1.34. These values indicate the banks of the intake canal would be stable under earthquake conditions.

The intake canal is lined with mesh-reinforced concrete for its entire length. Since such a lining could be cracked or otherwise damaged in the event of earthquakes, an analysis was made of the rate of seepage loss. In this study, it was assumed the lining did not exist. The study was based on tests of permeability made during site investigations, described by Dames & Moore in *Revised Report - Environmental Studies, Proposed Nuclear Power Plant, Surry, Virginia,* November 17, 1967, and showed that seepage loss from the canal would be insignificant with respect to the volume of water stored. Further, the emergency service water pumps are sized with adequate margins to accommodate expected leakage from the canal. Therefore, the net loss of water from the canal, even in the event of severe damage to the lining, would be zero.

Because of the large depth and generous freeboard of the intake canal, as described in Section 10.3.4.2, settlement developing from an earthquake would not interfere with the effectiveness of the canal in providing emergency cooling.

No information was obtained after construction of the canal that would necessitate alteration of the analysis of the potential for settlement of, leakage from, or stability of the intake canal.

The estimated seepage rate from the intake canal is 40 gpm. The seepage rate can also be stated as. 00476% of the circulating water flow in the canal, with one unit operating. With two units operating, the percentage is halved. The quoted seepage rate of 40 gpm could vary by a factor of 20 or more without adversely affecting the safe-shutdown requirements for the plant. The 40 gpm represents 0.027% of the minimum capacity of one service water pump. More detailed information on the service water system is contained in Section 9.9.

Table 2.4-1
OROGENIC MOVEMENTS IN THE CENTRAL APPALACHIAN REGION

Orogenic Episode and Approximate Time Interval	Known Area of Influence	Maximum Manifestation
APPALACHIAN MOVEMENTS		
Palisadian		
Late Triassic (Carnian-Norian) 190 to 200 million years	Belt along central axis of already completed mountain chain	Fault troughs, broad warping, basaltic lava, dike swarms
Allegheny		
Pennsylvania and/or Permian (Westphalian and later) 230 to 260 million years	West side of central and southern Appalachians, south-east side of northern Appalachians; perhaps also in Carolinian Piedmont	Strong folding, also middle-grade metamorphism and granite intrusion at least in southern New England
Acadian		
Devonian, mainly Middle but Episodic into Mississippian (Emsian-Givetian 360 to 400 million years)	Whole of northern Appalachians, except along northwest edge; as far southwest as Pennsylvania	Medium-to high-grade metamorphism, granite intrusion
Taconic		
Middle (and late) Ordovician (Caradocian, locally probably older) 450 to 500 million years	General on northwest side of northern Appalachians, local elsewhere; an early phase in Carolinas and Virginia, perhaps general in Piedmont province	Strong angular unconformity, gravity slides, at least low-grade metamorphism, granodmafic intrusion
Avalonian		
Latest Precambrian 580 to 600 million years	Southeastern Newfoundland, Cape Breton Island, southern New Brunswick; probably also central and southern Appalachians	Probably some deformation uplift of sources of coarse arkosic debris, gravity slides
GREENVILLE (PRE-APPALACHIAN) MOVEMENTS		
Late Precambrian 800 to 1100 million years	Eastern North America, including western part of Appalachian region	High-grade metamorphism, granitic and other intrusion

DENSITY DATA FOR SAND MEMBERS, FROM ONSITE TESTS IN COFFERDAM

Sample No.	Percent Passing No. 200	Field Density	Minimum Density, lb/ft	Modified Proctor, F&R	Percent Compaction of Modified Proctor	Maximum Density, lb/ft, Dry Vibratory Compaction		Relative Density	
						A	B	Vibration,%	Ramming,%

Notes: Minimum Density - Minimum of three trials, tests give excellent reproducibility - ASTM-D20-49-64T.

Vibratory compaction A - Placed oven dry in six layers under surcharge of 1 psi - tapped firmly for 3 minutes after each layer was placed.

B - Same as above except sample saturated with excess water on surface.

Where relative density is computed using vibratory test data, the higher of the two test values was used.

For samples marked “NA” under Minimum Density, there was significant dry strength, making the test procedure not applicable.

At roof (Elevation +66)	0.5	0.5	0.25	0.9	0.9	0.5

a. Basic procedures used to compute values shown in this table, values that essentially represent motions of structures relative to the static position of ground, are given in Section 2.4.8. Soil values and computational procedures used in making these computations are given in Reference 16. The fuel building is supported on fixed end piles, and pile deflections, as indicated, are added to computed soil deflections for this structure in arriving at values shown in this table.

b. Clearance between structures: Fuel building to vapor containment and auxiliary building - 6-in. minimum at all levels.
Auxiliary building to vapor containment - 3-in. minimum at all levels.
Auxiliary building to control room and battery area - 3-in. minimum at all levels.

Figure 2.4-2
REGIONAL GEOLOGY

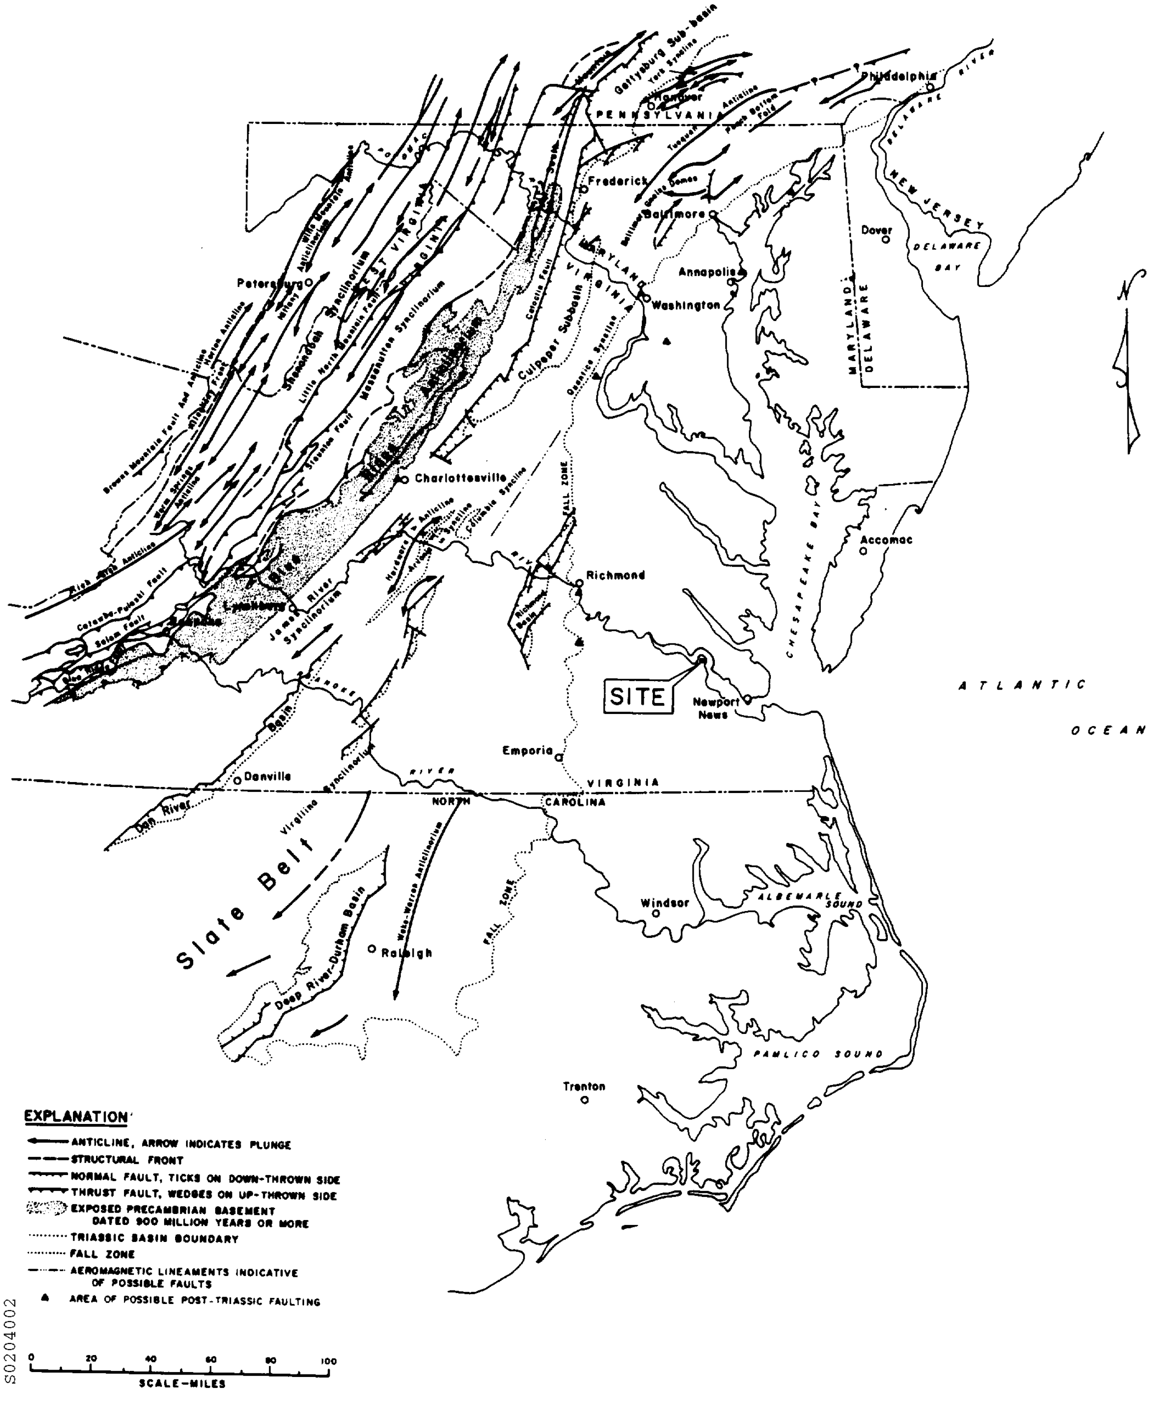

Figure 2.4-3
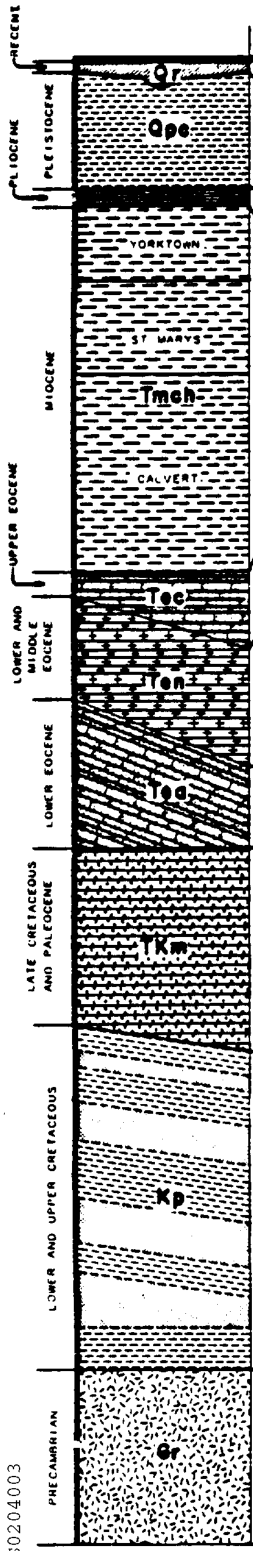
COLUMNAR GEOLOGIC SECTION



GEOLOGIC AGE AND DESCRIPTION	ORIGIN	DISTRIBUTION	WATER-BEARING PROPERTIES
Recent alluvium, beach and organic sediments such as found on Hog Island Waterfowl Refuge.	Deposited by ocean currents.	Thick deposits present only at Hampton	May yield a little water to shallow wells.
Pleistocene Columbia group. Consists of clays and sands that make up the surficial terraces. Marly strata are present in easternmost terraces only.	The higher westerly terraces are of continental origin, but the lower easterly terraces are of marine origin.	Exposed at the surface throughout the area.	Excellent water-bearing formation for domestic and small industrial supplies.
Bacon's Castle formation and Sedley formation of Pliocene age.	Sediments of Bacon's Castle formation are of fluvial origin. Sedley formation is of marine origin.		
The Chesapeake group of Miocene age consists of shell marl, dark-blue or gray clay, and subordinate sandy strata. The Yorktown formation is sandy and very fossiliferous. The St. Marys formation consists of tough blue or gray clays. The Calvert formation is diatomaceous and sandy but is less fossiliferous than the Yorktown formation.	Deposited in marine waters but may have extended inland some distance west of the present Fall Line.	Exposed in stream beds except at Hampton and lower Warwick, where it is concealed by younger sediments. The Yorktown and St. Marys formations crop out throughout the central and western area and the Calvert formation crops out along the Fall Line.	Yorktown formation yields small quantities of hard water to wells. St. Marys formation is not water-bearing. Calvert formation yields small to moderate supplies of water in many places. At Yorktown and in the lower peninsula area the water may be somewhat brackish.
Upper Eocene Chickahominy formation. Consists of gray marl beds containing glauconite and pyrite. Highly foraminiferal.	Deposited in marine waters.	Known from well cuttings at Yorktown, Camp Peary, Jamestown, Fort Eustis, Newport News, and Fort Monroe. Thins to a vanishing point before approaching the Fall Line.	Not a water-bearing formation at Yorktown. Some thin water-bearing sand beds in central part of the peninsula are probably Chickahominy formation.
Lower and Middle Eocene Nanjemoy formation. Consists of gray marl glauconite and quartz sand, and thin limestone beds.	Deposited in marine waters.	Typical exposure from the Fall Line to Williamsburg, but may be thinner or absent east of Williamsburg. Lower Eocene part of the formation thins to a vanishing point about 20 miles east of the Fall Line. Middle Eocene part may be quite thin in vicinity of Newport News.	Yields ample water for domestic supplies along the lower Chickahominy River and at the head of the York River. Water for industrial use is pumped at West Point.
Lower Eocene Aquia formation. Consists of glauconitic marl and basal quartz sand beds. Maximum thickness about 125 feet.	Deposited in marine waters.	Occurs along the Fall Line. Formation is exposed at the surface near Richmond. No unconformity with underlying Mattaponi formation.	Basal sands yield moderate supplies of water to wells in Hanover, Henrico, and western King William Counties.
Late Cretaceous and Paleocene Mattaponi formation. Consists of mottled clay, glauconitic sand and marl, and thick basal quartz sand.	Deposited in estuaries and bays.	Occurs at depth in central and eastern parts of the Coastal Plain as far west as the Fall Line.	A prolific water-bearing formation tapped by many domestic and a few industrial wells, notable at West Point and Newport News. The formation constitutes a vast reserve of fresh water in the central Coastal Plain. East of Williamsburg, the formation yields brackish water.
Potomac group of lower and Upper Cretaceous sands and clay beds.	Deltaic sediments deposited in fresh to slightly brackish waters.	The formation crops out in the vicinity of Richmond but lies beyond the reach of most wells a short distance east of the Fall Line (See plate 1).	The formation yields water to a few wells near the Fall Line but elsewhere it is not yet reached by wells.
Pre-Cambrian metamorphosed igneous and sedimentary rock. Granite.	Igneous intrusive rocks.	Crops out along the Fall Line except where Triassic units are present. Underlies entire Coastal Plain.	Yields small to moderate supplies of water to wells along or near the Fall Line.

2.5 SEISMOLOGY

2.5.1 General

Site engineering seismology studies were performed to:

1. Evaluate the seismicity of the area.
2. Select the operating-basis earthquake (OBE) and design-basis earthquake (DBE) conditions.

A comprehensive description of the region seismicity (Reference 1) has been prepared, and a brief description of the seismic history of the region is included herein to assist in reviewing the seismicity of the site area.

2.5.2 Tectonics

The tectonics of the region are largely dependent on the study of the Appalachian Highlands, especially that of the Blue Ridge and Piedmont provinces. The appearance of the Coastal Plain is a relatively recent event and is related to the late tectonic history of the Piedmont. Coastal Plain tectonics will be introduced after a basic discussion of the early tectonics of the Appalachian Highlands which form the structural basis for the region. The tectonic features of the region are shown on Figure 2.5-1.

The Appalachian Highlands form a continuous mountain chain extending the length of the eastern North American shoreline from central Alabama to Newfoundland. The tectonic trends (fold axis, faults, foliation, structural pattern, igneous intrusives, etc.) or the Highlands, though locally irregular, generally are remarkably even. They are parallel to one another, and parallel to the general northeast-southwest trend of the mountain chain. Taken broadly, the chain is a series of arcs convex to the northwest. The central arc extends from New York City to southern Virginia (approximately 400 miles), and delineates the region known as the central Appalachians. Most of the site region is within this area. To the south is another arc which extends from southern Virginia to central Alabama (approximately 500 miles), and delineates the region known as southern Appalachians. It includes the most southern parts of the site region.

One of the most prominent structural features of the region is the western edge of the Blue Ridge province, known as the tectonic front (Reference 2). It marks the boundary between the highly deformed and metamorphosed crystalline rocks of the Blue Ridge and Piedmont provinces to the east and unmetamorphosed sedimentary rocks of the Valley and Ridge and Appalachian Plateau provinces to the west. Through most of central and northern Virginia there is no marked evidence of major faulting along the front. South of about latitude 36 degrees North the front is continuously faulted for the entire length of the southern Appalachians, 500 miles. From latitude 36 degrees to the Roanoke area the faulting is high-angle reverse. South of Roanoke it abruptly changes character to systems or low-angle thrust sheets. Some of these thrust faults have throws as great as 10 miles to the northwest. The closest approach of this faulted front to the site is 130 miles to the west.

Immediately northwest of the tectonic front is the Valley and Ridge province and the Appalachian Plateau. These are separated by the Allegheny front, which marks the sharp transition between the intensely folded and faulted, rocks of the Valley and Ridge and the gently folded, and only locally-faulted, plateau rocks. The Allegheny front is approximately 200 miles from the site area.

Within the central Appalachian region, the Valley and Ridge province is structurally dominated by large, parallel, northeast-southwest trending fold systems rather than by faults as in the southern Appalachians. The main fold belts are the Massanutten synclinorium, Shenandoah synclinorium, and Nittany anticlinorium, approximately 140, 165 and 180 miles northwest of the site area, respectively. Two major fault zones also traverse the Valley and Ridge province in this area, the Staunton fault and the Little North Mountain fault. The Staunton fault is approximately 145 miles west-northwest of the site area and trends northeast to southwest, parallel with the regional structural fabric. It is a high-angle reverse fault along its 95-mile length through the central Appalachians. Near Roanoke, it joins the Catawba-Pulaski fault system which are low-angle thrust faults. Further northwest, about 150 miles from the site, is the Little North Mountain fault zone. This zone trends parallel to regional structure for a total length of about 190 miles and is a high-angle reverse fault, dipping southeast at its surface exposures.

All of the above mentioned tectonic features of the Valley and Ridge Province, regardless of their tectonic origin, date back to Paleozoic age with the most intense activity during the Allegheny orogeny, 230 to 260 million years ago. No active surface faulting is known in this area.

East of the tectonic front are the Blue Ridge and Piedmont provinces. The Blue Ridge province has been structurally folded and faulted into a complex anticlinorium. Through the area of study it is composed of metamorphosed Precambrian age, 1100 million-year-old gneiss with some small areas of younger Precambrian or Cambrian schists. Small faults are common throughout the anticlinorium. However, as shown on Figure 2.5-1, there is one large fault zone about 55 miles long trending northeast, parallel with the regional structure, just west of Charlottesville, Virginia. The faulting is high-angle reverse. It is about 120 miles northwest of the site. All of the above-mentioned tectonic features of the Blue Ridge are of Paleozoic age, with the most intense activity during the Taconic orogeny, 450 to 500 million years ago. No active surface faulting is known in this area.

Further east is the Piedmont province. It is primarily composed of early-to mid-Paleozoic sedimentary and igneous rocks that have been metamorphosed into schist, gneiss, and granitic gneisses. Within the older crystalline rocks are basins of unmetamorphosed sediments of Triassic age, 180+ million years old.

The boundary between the older Precambrian rocks of the Blue Ridge and the Piedmont does not appear to contain major faulting within the study area. In southern Virginia this transition is marked by a major fold belt known as the James River synclinorium which is faulted along the northwest. The synclinorium is 110 miles west of the site.

In Northern Virginia, the eastern Blue Ridge boundary is slowly approached by the western fault system of the Culpeper Triassic Basin until, near the Maryland border, it intersects the Blue Ridge basement rock complex. This Triassic basin border fault, as well as all other known Triassic basin border faults, is a high-angle normal fault.

It is downfaulted on the east side with a vertical displacement of about 10,000 feet, a magnitude common to most large Triassic fault basins. The fault is part of a system that extends a distance of about 125 miles to the northeast and joints the Gettysburg and Newark-Delaware basin system, which are out of the area of study. It is about 110 miles northwest of the site. Other Triassic faults and associated sedimentary basins, which are of common origin and character, located within the study area are:

1. A Triassic basin just south of Charlottesville, Virginia, approximately 110 miles west of the site. It is about 25 miles long and faulted on both the east and west sides.
2. Dan River basin, approximately 120 miles west of the site. It is about 110 miles long and faulted on the west side.
3. Central Triassic faulting, located south of Arvonia syncline approximately 95 miles west of the site. The faulting extends intermittently for 70 miles along a northeast trend. The small basins formed are faulted on the west side.
4. Richmond basin, approximately 55 miles west of the site. It is the closest known faulting to the site area. The basin trends north-northeast and away from the site area. It appears to be about 65 miles long and faulted on both the east and west sides.
5. Deep River-Durham basin approximately 120 miles southwest of the site area. It is faulted primarily on the east side for about 160 miles.
6. Recent aeromagnetic data indicate the possibility of additional Triassic basin faulting east of the Baltimore area as shown on Figure 2.5-1.

Other Piedmont tectonic structures are of Paleozoic age, most of which are contemporaneous with the intense metamorphic and tectonic activity related to the Taconic and Acadian orogenies of 450 and 360 million years ago. The major fold belts include the James River synclinorium, previously mentioned, the Hardware anticline, the Arvonia-Columbia-Quantico syncline trend, the Virginia synclinorium and the Wake-Warren anticlinorium, about 110 miles west, 105 miles northwest, 90 miles northwest, and 80 miles southwest of the site, respectively. Faulting, though common on a localized scale throughout the Piedmont, is not prominent on a regional scale. Aeromagnetic data (Reference 3) indicate a major Paleozoic age lineament through central Virginia. It trends northeast across the State of Virginia and is about 100 miles northwest of the site. The lineament has not been identified by field mapping, but is inferred to be a metamorphosed and recrystallized fault trend (Reference 4).

Additional Paleozoic faulting is associated with the northwest side of the James River synclinorium, about 12 miles west of the site, and two faults associated with the Baltimore, Maryland, area 140 miles north of the site. The James River synclinorium faults are westerly thrust faults, about 50 miles long, trending northeast. The Baltimore area faults trend northeast to north, are normal faults, and extend for a length of about 10 miles.

East of the Piedmont is the Atlantic Coastal Plain. The Coastal Plain is essentially an irregular, thick, dissected, eastward-facing wedge of unconsolidated to semi-consolidated sediments. The basement of this wedge consists of Paleozoic-age Piedmont-type rocks. They are largely igneous and low- to high-grade metamorphic rocks.

The site is located in the Coastal Plain, Physiographic Province. In Virginia, the province is bounded on the east by the Atlantic Ocean and on the west by the Fall Line and the Piedmont Physiographic Province. The crystalline basement rock crops out near the Fall Zone about 50 miles west of the site. From the Fall Zone, the basement surface slopes gently to the southeast, and is overlain by Cretaceous and Tertiary sediments that are about 1300 feet thick at the site.

The Coastal Plain sediments effectively mask the crystalline basement rock so that no faulting can be identified in the area. However, the available regional data and the geologic studies at the site indicate that the overlying Cretaceous and Tertiary sediments are essentially underformed in the site area. The absence of folding and faulting in the exposed sedimentary strata of the Coastal Plain in the vicinity of the site indicates that any displacements along possible unknown faults have been negligible.

2.5.3 Seismicity

2.5.3.1 **Earthquake History**

The site is situated in a region that has experienced only infrequent minor earthquake activity. The closest major earthquakes to the site, the Charleston earthquakes of 1886, had their epicenters about 350 miles southwest of the site. No shock within 50 miles of the site has been large enough to cause structural damage. Since the region has been populated for over 300 years, it is probable that any earthquake of moderate intensity, VI or greater, would have been reported during this period. It is very likely that all earthquakes with intensities of V or greater within the last 200 years have been reported.

The first record of earthquake occurrence in the vicinity of the site was made in the late Eighteenth century. Since then, only about eight earthquakes with epicentral intensities of Modified Mercalli V or greater have been reported within 100 miles of the site. All intensity values in this report refer to the Modified Mercalli Scale as abridged in 1956 by Richter (Table 2.5-1). The intensity scale is a means of indicating the relative size of an earthquake in terms of its perceptible effects. Modified Mercalli intensity, where abbreviated, is designated as "MM."

Forty-four earthquakes of intensity V (MM) or greater have been reported within 200 miles of the site from 1774 through September 1995. The largest of these are of epicentral intensity VIII

(MM). There has been no resultant structural damage at the site and the associated acceleration is estimated to have been less than 0.05g.

Listed in Table 2.5-2 and shown in Figure 2.5-2 are all known earthquakes from 1774 through September 1995 with epicentral locations within a 50-mile radius of the site and all earthquakes of intensity V (MM) or greater with epicentral locations within 200 miles of the site. There are no known epicentral locations within a 30-mile radius of the site. The historical earthquakes of the region that are believed to have been felt at the site (Reference 5) are discussed in greater detail in Reference 6.

Most of the nearest recorded earthquakes in the region have occurred in the Piedmont Province, west of the Fall Zone. The closest approach of the Fall Zone to the site is about 50 miles. These shocks are generally related to known faults in the Piedmont rocks. Several shocks have occurred in the Richmond, Virginia, area, which is on the Fall Zone. This activity along the Fall Zone is consistent with similar occurrences both to the north and south of the site area.

2.5.3.2 Correlation of Epicenters with Geologic Structures

Relative to the site, the most significant earthquakes and associated seismotectonic zones are believed to be the following:

1. 1897 Giles County, Virginia; intensity VIII (MM) - associated with the Appalachian seismic zone.
2. 1875 Richmond, Virginia; intensity VII (MM) - associated with the central Virginia seismic zone.
3. 1866 Charleston, South Carolina; intensity X (MM) - associated with the Charleston seismic area.

Giles County, Virginia

The 1887 earthquake of Giles County, Virginia, of epicentral intensity VIII (MM), is part of what has been described by Bollinger (Reference 7) as the southern Appalachian seismic zone, and its northern extension the northern Virginia-Maryland seismic zone. The zone is characterized by a general northeast-southwest alignment of the epicenters of the larger shocks in the site region. The zone is roughly coincident with tectonic features of the Blue Ridge and the eastern side of the Valley and Ridge provinces. It is indicative of continued deep-seated crustal adjustments along zones of intense ancient tectonic deformations. The latest intense period of major deformation was the Allegheny orogeny, approximately 230 to 260 million years ago. There is no evidence of active surface faulting along this trend today.

Richmond, Virginia

The Richmond area is the eastern-most extension of the central Virginia seismic zone described by Bollinger (References 8 & 9).

The central Virginia seismic zone is a relatively narrow, isolated zone of activity, offset from the Appalachian seismic zone and located in the Piedmont province, oblique to the northeast-southwest structural grain. This zone includes an east-west elongate cluster of low to moderate seismic activity. It extends from Richmond, Virginia, to the edge of the Blue Ridge province. It covers a relatively small area of about 16,500 square miles (Reference 9) and appears to be related to deep seismic activity in the vicinity of Triassic faulting.

The historical record of the region attests to the areal extent of the zone as described above. The historical record is over 200 years old within a relatively well populated area. Therefore, shocks of intensity V (MM) and greater would have been recorded by the local populace. Bollinger (Reference 9) has worked out the theoretical earthquake recurrence ratio for different levels of earthquake intensity for the eastern United States. For the large earthquake intensities the recurrence rates are VIII (MM) (51 years), and VII (MM) (13 years) and much less for the lower intensities.

Charleston, South Carolina

The seismic history of the southeastern United States is dominated by earthquake activity in the Charleston area. Charleston is about 350 miles south of the site and represents the closest zone of major earthquake activity. Of the 850 earthquakes reported for the southeastern United States in the period of 1754 to 1971, 402 have been in the Charleston area. All of these shocks have been localized to a very limited area around Charleston. Based on the character of the epicentral record and the high frequency of shocks consistently within a small area, the Charleston area is treated as a seismotectonic province by itself. The largest shock that occurred here was the shock of epicentral intensity X (MM) on August 31, 1886. It was felt at the site with an intensity V (MM).

Other Events

Another significant series of earthquakes in the Coastal Plain occurred near the northern New Jersey coast about 250 miles northwest of the Surry site, in 1927. The maximum reported epicentral intensity of these earthquakes was VII. Three shocks were felt over an area of about 3000 square miles, from Sandy Hook to Toms River, New Jersey. Highest intensities were felt from Asbury Park to Long Branch, where several chimneys fell, plaster cracked, and articles were thrown from shelves. This shock has not been related to any known geologic feature, although there is some suggestion that it could be related to possible geologic structures associated with the Hudson River Valley to the north.

There have been small shocks in the Coastal Plain closer to the site. Few of these earthquakes caused any structural damage, and they are of interest only in that they indicate the possible presence of unidentified faulting in the basement rock beneath the Coastal Plain.

The closest reported earthquakes to the site were two small shocks felt only at Suffolk, Virginia, on April 19, 1918. It is possible that these shocks were not of tectonic origin; however, if they were valid earthquakes, they could indicate the presence of minor faulting in the basement rock close to the site.

2.5.3.3 **Identification of Active Faults**

Based on the studies listed below, there is no known evidence for active faulting in the vicinity of the site (Reference 6).

1. Photo interpretation - Airphotos, topographic maps, and Earth Resources Observing Satellite (EROS) photos of the site area were examined. No evidence of surface rupture, surface warping, or offset of geomorphic features possibly indicative of faulting was found.
2. Aeromagnetic studies - Aeromagnetic mapping of the site and region was examined. There was no aeromagnetic feature indicative of faulting in the vicinity of the site. Some distant, regional features indicative of bedrock faulting were found. They are shown on Figure 2.5-1.
3. No macroseismic activity has been detected in the site area. The closest epicentral location is about 30 miles southeast of the site. It is of intensity III (MM) and not correlative with any known surface feature.
4. Detailed geologic mapping of the site area and vicinity in References 10, 11 and 12 show no evidence of surface or active faulting.
5. Borings drilled at the site indicate continuity of strata and are indicative of no significant (5 feet) fault displacements, dating back at least 2 million years as shown by the top of the erosional Micocene surface.

Regionally, there is no known active surface faulting. Surface expression in the form of active fault scarps have not been observed. Seismic activity within the region is believed to be due to deep-seated crustal adjustments along previous zones of structural deformation and weakness.

2.5.4 Seismic Design

2.5.4.1 **Operating-Basis Earthquake (OBE)**

The number of cycles of significant motion in a number of earthquake records has been analyzed. Observation indicates maximum acceleration occurs as a single peak (Reference 13) (never appears more than once). Table 2.5-3 shows the number of cycles of motion in which an acceleration of half the peak is equalled or exceeded in a number of earthquake records. These were taken from accelerograms of the earthquakes listed. A decrease in acceleration to one-half the peak value corresponds approximately to a decrease of one order of intensity on the Modified Mercalli scale and, as a result, conservatively defines the number of cycles of significant motion.

For this site, the operating-basis earthquake is most probably characterized as a sharp, short local earthquake of Intensity VI or less. As indicated on Table 2.5-3, small, sharp earthquakes of this type, such as Golden Gate '57 or Hollister, showed only a few cycles of significant motion. For the design-basis earthquake, longer duration as well as larger accelerations would be expected. Even for great earthquakes such as El Centro '40 and Taft '52, which were much more intense than anticipated for the design-basis earthquake at Surry, there are only about 10 cycles of significant motion. Use of eight to ten cycles in analyses for the design-basis earthquake is reasonable and conservative.

The number of cycles of significant motion is important in demonstrating that fatigue failure due to stress reversals is not a critical consideration in designing the containment structure. The number of loading cycles is also considered when evaluating the hazard of liquefaction for the design-basis earthquake.

The maximum estimated earthquake intensity at the Surry site is VI (MM). Based on correlations between intensity and peak acceleration (Reference 14), the peak acceleration values for intensity VI would be 0.0425g vertical and 0.066g horizontal. Also, monitoring sites are differentiated by geological classification (soft, intermediate, and hard). The Surry site most closely resembles the soft site condition (i.e., shallow and deep alluvium) as opposed to intermediate (sedimentary rock) or hard (igneous and metamorphic rock). The interpretation of their graph, of acceleration and intensity (Reference 14) indicates that the mean peak ground acceleration in the maximum direction (horizontal) on a soft site is about 65 cm/sec (Reference 2) or less than 0.07g.

On the basis of the seismic history of the area, it does not appear likely that the site will experience earthquake ground motion of more than a few percent of gravity during the economic life of the facility. However, Class I structures and equipment are designed to withstand a maximum horizontal ground acceleration of 7% of gravity. Vertical acceleration is taken as being two-thirds of horizontal, assumed acting simultaneously and in proper phase to be additive to loads or stresses from horizontal motions. It is believed that this magnitude of ground motion would not be exceeded at the site during an earthquake similar to any previously experienced in the area.

2.5.4.2 **Design-Basis Earthquake (DBE)**

For the safe and orderly shutdown of the station, all Class I structures and equipment are designed using a seismic factor equal to the ground acceleration at foundation level that might occur due to the maximum credible earthquake. The design-basis earthquake for this site would be a shock similar to one of the following:

1. The eastern Virginia earthquake of 1875 occurred as close to the site as its related geologic structure. It is estimated that the magnitude, m, of this earthquake was about 5 on the Richter Scale. It is probable that this earthquake was related to Piedmont structure, near the Fall Zone. However, it is impossible to locate precisely the epicenter of this shock from the limited data available. Since the earthquake and a subsequent aftershock were felt in Williamsburg, the epicenter of this shock may have been located east of the Fall Zone, in the

basement rock of the Coastal Plain. Thus, the conservative assumption is made that an epicentral intensity-VI earthquake could conceivably occur in the basement rock associated with some hypothetical geologic structure. The possibility of such an occurrence is believed to be quite remote.

2. The northern New Jersey earthquake of 1927 occurred close to the site. Since this shock occurred in the Coastal Plain and has not been related to any known geologic structure, the conservative assumption is made that it could be related to a hypothetical geological structure in the basement rock near the site. The magnitude, m, of this epicentral intensity-VII earthquake is estimated to have been about 5. Again, the possibility of such an occurrence is quite remote.

Based on the foregoing evaluation, the design-basis earthquake magnitude is very conservatively assumed to be as large as 5 to 5.5 (epicentral intensity-VII shock), originating in the basement rock close to the site. An occurrence of a shock of the same size as the largest of the 1886 Charleston shocks at a distance of 200 miles or so would result in significantly lower accelerations at the site.

2.5.4.3 **Seismicity Measurement**

A seismic sensing and recording system, incorporating three remote triaxial accelerometers, is installed at the Surry Power Station. The system provides data on the frequency, amplitude, and phase relationship of the seismic response of the Unit 1 reactor containment structure, and provides data on the input vibratory ground motion at the site.

System calibration, testing, recording, and playback are accomplished at the recorder unit located in the control room. Two triaxial accelerometers are installed in the Unit 1 reactor containment structure. One instrument is located on the basement floor (Elevation -27 ft. 7 in.) and the other instrument is located on the uppermost floor (Elevation 47 ft. 4 in.). The instruments are oriented so that the corresponding axes of each accelerometer are aligned in the same direction, and are located approximately above each other. They are mounted rigidly to the containment structure, so that the accelerometer records can be related to the containment structure movement, as required by Safety Guide 12, dated March 10, 1971.

The third triaxial accelerometer is installed in the free field accelerometer enclosure, located approximately 8 feet west of the security fence and 8 feet south of the sally port. The instrument enclosure is located on a 24-inch concrete foundation, and will record data on the free-field ground motion.

The system is capable of performing its required functions over the appropriate range of environmental conditions. A maintenance program is provided in accordance with the supplier’s instruction manual.

The recorder unit will begin recording and initiate an alarm in the control room when actuated by the seismic trigger unit located with the free-field accelerometer. Recording will continue until several seconds after the strong motion ground accelerations have decreased below the trigger setting, and this information will be available to the control room operator.

2.5.5 Estimated Ground Acceleration for Design-Basis Earthquake

2.5.5.1 **General**

It is estimated that the maximum horizontal particle acceleration at planned foundation levels at the site, due to the design-basis earthquake, would be no more than about 15% of gravity. The vertical motion is taken to be two-thirds of the horizontal motion, acting simultaneously with it.

This estimate has been arrived at by several procedures. One procedure was to compare the physical characteristics of the Surry site with those at sites where strong motion records are available (for example, Taft and El Centro, California). If the propagation of earthquake wave motion through the soil strata at the Surry site is comparable to other locations, and there is no unusual amplification of motion, especially in the frequency regions of significance to structures, then the available strong motion records can be used in estimating maximum ground acceleration at Surry. This comparison of site conditions was based upon the amplification spectrum.

Another procedure was based upon empirical formulas developed from a study of world earthquake occurrence by Japanese seismologists.

2.5.5.2 **Amplification Spectrum**

The amplification spectrum was developed by computing wave motion through a layered model of the earth's material, from basement rock up through any desired elevation within the overlying soil. In the model, vertically traveling waves were assumed to propagate through a medium in accordance with wave propagation theory for that medium, assuming any desired degree of damping. Thus, it was possible to model the subsurface conditions on the basis of the following physical properties for each stratum:

1. Thickness.
2. Shear wave velocity.
3. Density.
4. Damping.

A complete description of the procedure is presented in the Duke, Leeds, Matthieson, and Frazer paper (Reference 15).

Amplification spectra for the Surry site and the Taft and El Centro strong motion stations were compared using 10% of critical damping in the overlying soil strata. This damping value is considered conservative under the fairly large earthquake motion assumed for the design-basis earthquake.

This comparison indicates that the amplification spectrum at the Surry site is approximately the same as that at the Taft, California, strong motion site, and appears to be lower than that at the El Centro, California, strong motion site.

The maximum expected amplification at the Surry site is about 2, and occurs at longer periods, about 0.75 seconds or more.

Amplification at long periods has been observed in other areas of deep soil strata (Mexico City, San Francisco, etc.). Available records on rocks and earthquake motion indicate that maximum acceleration and dominant frequencies occur at relatively short periods when the amplification ratio for the site is less than 2, and that at periods on the order of 0.75 seconds and longer, accelerations are much smaller. Since the motion at the ground surface is the product of the rock motion times the amplification ratio, it is apparent that, for an amplification spectrum as described here, the maximum acceleration at or near ground surface will be less than twice the maximum accelerations at the rock surface. Orbital particle velocities and displacements at the ground surface would be larger than at the rock surface, since these are larger for the longer periods.

In discussions with consultants of the Atomic Energy Commission, it was agreed that a maximum rock acceleration of 0.07g was appropriate at this site. If it were assumed that the amplification ratio was 2.0 even in the short period portions of the spectrum, a very conservative assumption, the maximum acceleration at the ground surface would be about 0.14g. It is pertinent to compare these theoretical studies with observations. Some recent observations have indicated amplification or soil ground motion over that of bedrock motion on the order of 3 to 4, and increased amplification as the soil thickness increases. These possibilities have been investigated by the use of the amplification spectrum. Figure 2.5-3 presents the results of varying layer thickness. Under small earthquake motions, the soil layers would act essentially as elastic media, and with small amounts of damping, amplification of 3 to 6 would be expected. As the earthquake motion increases in magnitude, damping would increase, thereby reducing the amplification of basement motion for larger earthquakes.

The computed amplification of 3 to 4 is consistent with observed amplification in small earthquakes and moderate soil thickness. Apparently, though, if the properties of the various strata remain essentially similar, the greater the thickness of overburden material, the lower the amplification as a result of damping in the soil.

This fact of decreasing amplification with increasing depth can be more easily visualized for the one-layer system as presented in Reference 16.

Thus these studies indicate:

1. On the basis of computed amplification ratios for the design-basis earthquake, a maximum horizontal ground acceleration of 0.15g is conservative.

2. The amplification spectra for the site compare closely with those at other overburden sites for which instrumental records are available. No unusual amplifications would be expected because of the deep overburden. Accordingly, it is possible to evaluate the expected ground motion at Surry by comparison with available instrumental records from other overburden sites.

2.5.5.3 **Available Strong Motion Data**

The magnitude 5 to 5.5 earthquake selected for the design-basis earthquake corresponds to a maximum epicentral intensity of about VII. The maximum intensity reported during any historical earthquake is referenced to the worst conditions at a particular location; i.e., the maximum amplitude of ground motion, adverse subsurface soil conditions, and poor construction.

These conditions may well have existed near the epicenters of the 1875 shock and the 1927 shock, and may have contributed to the maximum intensity reported. It is probable that similar earthquakes near the Surry Power Station site would result in a much lower maximum intensity for structures founded upon the firmer soils of the site. Therefore, the use of an intensity-VII shock as the design-basis earthquake is a conservative assumption. But, given the importance of the proposed facility, it has been assumed that the maximum expected ground motions, based on a historical evaluation of recorded ground motions, will occur at the Surry site.

Since the east coast of the United States has in general been seismically quiet, little data are available for the region around the site. However, a reasonable amount of instrument data is available for California earthquakes in the range of magnitudes from 5 to 5.5 at sites with subsurface conditions similar to the Surry site. Much of these data were originally presented by Gutenberg and Richter (Reference 17), and an attempt was made to develop an empirical relationship between epicentral intensity and maximum ground acceleration. The ground acceleration indicated for a maximum intensity of VII according to the Gutenberg and Richter formula is about 7% of gravity. This work was later continued by Hershberger (Reference 18). Hershberger used these additional data to refine the Gutenberg and Richter formulas. The ground acceleration indicated for a maximum intensity of VII, according to Hershberger's data, is about 13% of gravity.

Several other investigators have also compiled instrumental data regarding earthquakes in the range of magnitudes being considered in the current study William K. Cloud (Reference 19), in a paper reporting maximum accelerations during earthquakes, gives instrumental data for several shocks with magnitudes between 5 and 6. All but one of these records correspond to sites on soil. The maximum accelerations recorded during these shocks ranged between 10.2% and 17.3% of gravity, at epicentral distances of less than 13 miles. The average of these accelerations is about 14.5% of gravity.

John H. Wiggins, Jr. (Reference 20), reports maximum ground accelerations at epicentral distances of less than 20 miles for six California earthquakes with magnitudes between 5.2 and

5.6. The maximum recorded acceleration for any of these shocks was 15.9% of gravity for a magnitude 5.2 shock at a distance of 12 miles. The epicentral intensity of the shock was VII.

2.5.5.4 **Theoretical Studies**

The possible ground accelerations at the site have also been analyzed on the basis of empirical formulas developed by Dr. Kiyoshi Kanai of Japan.

Using data from Japanese earthquakes, Dr. Kanai (Reference 21) has developed formulas relating earthquake magnitude to maximum particle acceleration in basement rock. According to the Kanai formulas, acceleration in the basement rock at Surry would be about 4 to 7% of gravity, and the maximum ground acceleration at foundation level would be about 10 to 13% of gravity.

2.5.5.5 **Summary**

The preceding studies have evaluated the probable maximum acceleration for the design-basis earthquake at or near the ground surface by three different approaches. All three have indicated that a maximum horizontal ground acceleration of 0.15g at foundation levels is a conservative and reasonable value.

2.5.6 Conclusions

It is concluded that the site will not experience any significant earthquake ground motion during the estimated useful life of the nuclear facility. Historically, there is no basis for expecting more than very minor ground motion at the site. However, to provide protection against the remote contingency of an earthquake, the Class I structures and equipment are designed to withstand and remain operating at an earthquake ground motion producing accelerations as high as 7% of gravity. For a safe and orderly shutdown of the station, a maximum horizontal ground acceleration of 15% of gravity is used. This ground acceleration might result from a magnitude 5 to 5.5 earthquake in the basement rock near the site. The seismic history and the known tectonics of the region indicate that the possibility of such an occurrence is quite remote. Vertical accelerations are taken as two-thirds the appropriate maximum ground accelerations acting simultaneously and in phase to produce maximum loads or stresses.

Design is based on the use of response spectra.

Dr. N. M. Newmark has indicated that the primary influence on the response of structures with varying natural frequencies results from:

1. The maximum ground acceleration for structures having a frequency of more than 2 cycles per second.
2. The maximum ground velocity for structures with natural frequencies between 0.3 cycles and 2 cycles per second.
3. The maximum ground displacement for structures with natural frequencies less than about 0.3 cycles per second.

As previously indicated, the greatest amplification of the bedrock motion occurs for the longer periods. To allow for this, the spectra have been adjusted in the longer-period portions by normalizing these portions to somewhat higher values than the standard Housner spectra.

For frequencies higher than about 2 cycles per second, the Housner spectra have been followed, normalized to a horizontal ground acceleration of 7% of gravity for the operating-basis earthquake, and 15% of gravity for the design basis earthquake.

In the frequency range between 0.3 cycles per second and 2 cycles per second, Housner's average spectra have been normalized to a maximum ground velocity of about 4 in/sec for the operating-basis earthquake, and 9 in/sec for the design-basis earthquake.

For frequencies lower than about 0.3 cycles per second, the spectra were prepared using data suggested by Drs. Newmark and Hall in a recent paper (Reference 22).

Although a relatively high degree of conservatism is introduced into the intermediate frequency range through this approach, the basic principal of average response spectra recorded for sites on deep overburden is adhered to. The resulting spectra used in design are shown on Figures 2.5-5 and 2.5-6 for the operating-basis earthquake and the design-basis earthquake, respectively.

Table 2.5-1
MODIFIED MERCALLI INTENSITY (DAMAGE) SCALE OF 1931
(ABRIDGED)

I. Not felt except by a very few under especially favorable circumstances. (I Rossi-Forel Scale).

II. Felt only by a few persons at rest, especially on upper floors of buildings. Delicately suspended objects may swing. (I to II Rossi-Forel Scale.)

III. Felt quite noticeably indoors, especially on upper floors of buildings, but many people do not recognize it as an earthquake. Standing motorcars may rock slightly. Vibration like passing of truck. Duration estimated. (III Rossi-Forel Scale.)

IV. During the day felt indoors by many, outdoors by few. At night some awakened. Dishes, windows, doors disturbed. Walls make creaking sound. Sensation like heavy truck striking building. Standing motorcars rocked noticeably. (IV to V Rossi-Forel Scale.)

V. Felt by nearly everyone, many awakened. Some dishes, windows, ect., broken. A few instances of cracked plaster. Unstable objects overturned. Disturbance of trees, poles, and other tall objects sometimes noticed. Pendulum clocks may stop. (V to VI Rossi-Forel Scale.)

VI. Felt by all. Many frightened and run outdoors. Some heavy furniture moved. A few instances of fallen plaster or damaged chimneys. Damage slight. (VI to VIII Rossi-Forel Scale.)

VII. Everybody runs outdoors. Damage negligible in buildings of good design and construction. Slight to moderate in well-built ordinary structures. Considerably in poorly-built or badly-designed structures. Some chimneys broken. Noticed by persons driving motorcars. (VIII Rossi-Forel Scale.)

VIII. Damage slight in specially-designed structures. Considerable in ordinary substantial buildings with partial collapse. Great in poorly-built structures. Panel walls thrown out of frame structures. Fall of chimneys, factory stacks, columns, monuments, walls. Heavy furniture overturned. Sand and mud ejected in small amounts. Changes in well water. Persons driving motorcars disturbed. (VIII+ to IX Rossi-Forel Scale.)

IX. Damage considerable in specially-designed structures. Well-designed frame structures thrown out of plumb. Great in substantial buildings, with partial collapse. Buildings shifted off foundations. Ground cracked conspicuously. Underground pipes broken. (IX+ Rossi-Forel Scale.)

X. Some well-built wooden structures destroyed. Most masonry and frame structures destroyed with foundations. Ground badly cracked. Rails bent. Landslides considerable from river banks and steep slopes. Shifted sand and mud. Water splashed (slopped) over banks. (X Rossi-Forel Scale.)

XI. Few, if any, (masonry) structures remain standing. Bridges destroyed. Broad fissures in ground. Underground pipelines completely out of service. Earth slumps and land slips in soft ground. Rails bent greatly.

XII. Damage total. Waves seen on ground surface. Lines of sight and level distorted. Objects thrown into the air.

CHAPTER 3 REACTOR

3.1 GENERAL

Note: As required by the Subsequent Renewed Operating Licenses for Surry Units 1 and 2, issued May 4, 2021, various systems, structures, and components discussed within this chapter are subject to aging management. The programs and activities necessary to manage the aging of these systems, structures, and components are discussed in Chapter 18.

The reactor core is a multi-region cycled core. The fuel rods are coldworked, partially annealed zirconium alloy tubes containing slightly enriched uranium dioxide fuel. All fuel rods are pressurized with helium during fabrication to reduce stresses and strains and to increase fatigue life. Beginning in Cycle 21, some fuel rods contain fuel with a thin layer of boride coating on the outer surface to act as integral fuel burnable absorber (IFBA, References 1 & 2).

The fuel assembly is a canless type with the basic assembly consisting of the control rod guide thimbles joined to the grids and the top and bottom nozzles. The fuel rods are supported at several points along their length by the grids.

Control rod assemblies, flux suppression inserts (Unit 1 only, Cycles 13 through 20), and burnable poison rods are inserted into the guide thimbles of the fuel assemblies. Flux suppression inserts were removed after Cycle 20 of Unit 1. Beginning in Cycle 21, cores may use IFBA and/or discrete (fixed) burnable absorber rods. The absorber sections of the control rods are fabricated of silver-indium-cadmium alloy sealed in stainless steel tubes. The absorber material in the fixed burnable poison rods is in the form of either borosilicate glass sealed in stainless steel tubes, or Al_2O_3 - B_4C pellets in Zircaloy-4 tubes. The flux suppression inserts in Unit 1 consist of hafnium bar encapsulated in Zircaloy-4 tubing.

The control rod drive mechanisms are of the magnetic latch type. The latches are controlled by three magnetic coils. They are so designed that upon a loss of power to the coils, the control rod assembly is released and falls by gravity to shut down the reactor.

3.2 DESIGN BASES

3.2.1 Performance Objectives

The reactor core average thermal power is 2587 MWt. The nuclear steam supply system power rating is 2599 MWt, which includes 12 MWt pump heat. This is the maximum thermal power rating for which the plant heat removal systems are designed.

The reactor core fuel loading and incore fuel management are designed to yield prespecified cycle average and core average burn-up values. Data for successive reload cycles can be found in the respective reload safety evaluations prepared by Vepco. Typical nuclear design data (representative of the initial core) can be found in Table 3.3-1.

The fuel rod cladding is designed to maintain its integrity for the anticipated rod life. The effects of fission gas release, fuel dimensional changes, and corrosion-induced and irradiation-induced changes in the mechanical properties of cladding are considered in the design of the fuel assemblies.

The control rods, being long and slender, are relatively free to conform to any small misalignments. Tests have shown that the rods are very easily inserted and not subject to binding even under conditions of severe misalignment.

The control rods provide sufficient reactivity control to terminate any credible power transient before reaching the departure from nucleate boiling ratio (DNBR) design limit (Section 3.2.3). This is accomplished by ensuring sufficient control rod worth to shut the reactor down by at least 1.77% in the hot condition with the most reactive control rod stuck in the fully withdrawn position. Redundant equipment is provided to add soluble poison to the reactor coolant to maintain shutdown margin when the reactor coolant is cooled to ambient temperatures.

During initial core design, experimental measurements from critical experiments or operating reactors, or both, were used to validate the methods employed in the design. Nuclear parameters were calculated for every critical phase of operation and, where applicable, were compared with design limits to show that an adequate margin of safety exists. This same general design procedure has been employed for all the subsequent reload cycles.

In the thermal/hydraulic design of reload cores, the maximum fuel and clad temperatures during normal reactor operation and at thermal overpower conditions are conservatively evaluated and verified to be consistent with safe operating limitations.

3.2.2 Design Criteria

3.2.2.1 Reactor Core Design

The reactor core, together with reliable process and decay heat removal systems and control and protection instrumentation, is designed to function throughout its design life without exceeding the following limits, which preclude fuel damage with appropriate margins for transients:

1. Minimum DNBR not less than the applicable DNBR safety analysis limit (Section 3.2.3).
2. Fuel Rod Design criteria limits defined in Section 3.5.2.6.1.

Additional information on nuclear design can be found in Section 3.3.

3.2.2.2 **Suppression of Power Oscillations**

The design of the reactor core and related protection systems ensures that power oscillations that could cause fuel damage in excess of acceptable limits are not possible. Any tendency toward oscillation is readily suppressed.

The potential for possible spatial oscillations of power distribution for this core was reviewed as part of the core stability evaluation effort described in Section 1.6.1. Ex-core instrumentation is provided to obtain necessary information concerning axial and azimuthal power distributions. This instrumentation is adequate to enable the operator to monitor and control xenon-induced oscillations. Based on the deviations detected by the long ion chambers, provisions in the reactor control and reactor protection systems reduce trip setpoints and, if necessary, initiate load cutback to maintain DNBR margin as a result of these potential oscillations in power distribution. Incore instrumentation is used to periodically calibrate and verify the information provided by the ex-core instrumentation.

3.2.2.3 **Redundancy of Reactivity Control**

Control rods and soluble boron in the reactor coolant are the two independent reactivity control systems that are provided to ensure compliance with General Design Criterion 27, as discussed in Section 1.4.

3.2.2.4 **Reactivity Hot Shutdown Capability**

The control rods and soluble boron in the reactor coolant are designed so that the core can be made and held subcritical from any hot standby or operating condition, thus complying with General Design Criterion 28 as discussed in Section 1.4.

3.2.2.5 **Reactivity Shutdown Capability**

The worth of the control rods is designed to ensure a 1.77% delta k/k shutdown margin under any operating condition with the most reactive rod stuck in the fully withdrawn position. The control rods and dissolved boron from the safety injection system also ensures no DNB occurs for the most severe cooldown transient caused by a single active failure, as discussed in Section 1.4.

3.2.2.6 **Reactivity Holddown Capability**

The reactor is normally shut down within 2 seconds of a reactor trip signal with the control rods. Sufficient soluble boron is continually available for injection to maintain the core subcritical during approach to, and at, cold shutdown.

3.2.2.7 **Reactivity Control Systems Malfunction**

The reactor protection system is capable of protecting against any single malfunction of the reactivity control system, as discussed in response to General Design Criterion 31 in Section 1.4. Reactor shutdown with control rod assemblies is completely independent of normal control functions, as discussed in Chapter 7. The protection system limits reactivity transients so that the DNBR is not less than the applicable DNBR safety analysis limit (Section 3.2.3) for any single malfunction in either the reactor coolant system or in the de-boration control system.

3.2.2.8 **Maximum Reactivity Worth of Control Rods**

Limits that include considerable margin are placed on the rates at which reactivity can be increased to ensure that the potential effects of a sudden or large change of reactivity cannot rupture the reactor coolant boundary or disrupt the core, its support structures, or other vessel internals so as to lose the capability to cool the core.

3.2.3 Safety Limits

The reactor is capable of meeting the performance objectives described in Section 3.2.1 throughout the core life under both steady-state and transient conditions without compromising the integrity of the fuel elements. Thus, the release of unacceptable amounts of fission products to the coolant is prevented.

Design parameters pertaining to safety limits are given below for the nuclear, thermal/hydraulic, and mechanical aspects of the design. This information can be considered as the basis for the identification of Technical Specification limits and setpoints. These limits and setpoints are subject to change after each reload, or if the operating strategy during a given cycle is altered for some reason.

3.2.3.1 **Nuclear Limits**

As required by Technical Specifications, the nuclear heat flux hot channel factors, $F_q(Z)$, do not exceed the limits assumed in the safety analysis.

The nuclear axial peaking factor, F_Z^N, and the nuclear enthalpy rise hot channel factor, $F_{\Delta H}^N$, are limited in their combined relationship so as not to exceed the F_q^N or DNBR limits.

The limiting nuclear hot-channel factors are higher than those calculated at full power for the range from all control rod assemblies fully withdrawn to maximum allowable control rod assembly insertion. Control rod assembly insertion limits as a function of power are delineated in the Technical Specifications to ensure that somewhat worse hot-channel factors do not occur at lower power levels due to control rod insertion, and that the DNBR is always greater at partial power than at full power.

The reactor protection system ensures that the reactor core nuclear limits are not exceeded.

3.2.3.2 **Reactivity Control Limits**

The control system and operating procedures provide adequate control of core reactivity and power distribution. The following control limits are met:

1. Sufficient control is available to produce a minimum hot shutdown margin of 1.77% delta k/k.
2. The shutdown margin is maintained with the most reactive control rod assembly stuck in the fully withdrawn position.
3. The shutdown margin is maintained at ambient temperature by the use of soluble poison.
4. There will be no DNB following a trip as a result of any single active failure in the steam system (e.g., safety valve, relief valve, or bypass valve sticking open), even if the most reactive control rod remains fully withdrawn.

3.2.3.3 **Thermal/Hydraulic Limits**

The reactor core is designed to meet the following limiting thermal/ hydraulic criteria:

1. The minimum DNBR during normal operation, including anticipated transients, will not be less than the applicable DNBR safety analysis limits. The DNBR limits are listed in Table 3.2-1.
2. No fuel melting during Condition I and II operation.

To maintain fuel rod integrity and prevent fission product release, it is necessary to prevent clad overheating under all anticipated operating conditions. This is accomplished by preventing departure from nucleate boiling (DNB), which, if it were to occur, would cause a large decrease in the heat transfer coefficient between the fuel rods and the reactor coolant, resulting in high clad temperatures.

The ratio of the heat flux causing DNB at a particular core location, as predicted by the applicable correlation, to the existing heat flux at the same core location is the DNBR. DNB is not, however, an observable parameter during reactor operation. Therefore, the observable parameters, reactor power, reactor coolant temperature and pressure have been related to DNB through the applicable DNBR correlation. Reactor Core Safety Limit curves provided in the Core Operating Limits Report (COLR) show the loci of points of thermal power, reactor coolant system average temperature, and reactor coolant system pressure for which the minimum DNBR is not less than the safety analysis limit, that fuel centerline temperature remains below melting, that the average enthalpy at the exit of the vessel is less than or equal to the enthalpy of saturated liquid, or that the core exit quality is within limits defined by the DNBR correlation.

The core thermal and hydraulic design basis requires that departure from nucleate boiling (DNB) be avoided with a 95% probability at a 95% confidence level during normal operation and operational transients. This is one of the key analysis criteria in many of the Chapter 14 safety analyses. Historically, demonstration of compliance with this design basis has been accomplished by (1) deterministic application of key DNBR analysis uncertainties in transient analysis and (2) comparing the resultant departure from nucleate boiling ratio (DNBR) to the applicable DNBR correlation limit. The correlation DNBR limit is established to ensure that there is a 95% probability with 95% confidence that DNB will not occur when the calculated DNBR is at the DNBR limit. For normal operation, operational transients, and during transients which experience minor variations in power, temperature, and pressure near hot-full-power (HFP) conditions, a statistical application of key DNBR analysis uncertainties to the correlation DNBR limit may be employed as described below and in Section 3.4.3.2.

The Statistical DNBR Evaluation Methodology (Reference 1) is employed to determine a revised DNBR limit. This new limit combines the correlation uncertainty with the uncertainties of key DNBR analysis input parameters. Transient analysis with the revised methodology does not require that the uncertainties be applied in the initial conditions. Instead, nominal values may be used.

The Statistical DNBR Limit is developed by means of a Monte Carlo process. The variation of actual operating conditions about nominal statepoints due to parameter measurement and other key DNB uncertainties is modeled with a random number generator-based algorithm. This algorithm produces thousands of statepoints at each nominal statepoint. The random statepoints are then supplied to the core thermal-hydraulic code, COBRA or VIPRE-D, which calculates the minimum DNBR. Each DNBR is randomized by a correlation factor as described in the topical report (Reference 1). The standard deviation of the resultant DNBR distribution is increased by a small sample correction factor to obtain its 95% upper confidence limit, thereafter being combined Root-Sum-Square with code and model uncertainties to obtain the total DNBR standard deviation, σ_{total}. The Statistical DNBR Limit (SDL) is then:

$$SDL = 1 + 1.645 \text{ x } \sigma_{total}$$

in which the 1.645 multiplier is the z-value for one-sided 95% probability of a normal distribution. Thus, this SDL is consistent with the design basis that departure from nucleate boiling (DNB) will not occur on at least 95% of the limiting fuel rods during normal operation and operational transients, and any transient conditions arising from faults of moderate frequency (Conditions I and II events) at a 95% confidence level. As an additional criterion, the SDL ensures that at least 99.9% of the core avoids DNB for these conditions.

The Statistical DNBR Evaluation Methodology is employed on a transient specific basis (References 4 & 6) as indicated in Table 3.2-2 and in the transient analysis summaries in Chapter 14.

In the evaluation of DNB thermal-hydraulic performance, the design limit is conservatively increased to a safety analysis limit to provide DNB margin to offset the effect of rod bow (see Section 3.4.3.5), and any other DNB penalties that may occur and to provide flexibility in design and operation of the plant. For non-statistical (deterministic) DNB analyses, the deterministic design limit (DDL) is set equal to the applicable code/correlation limit. For statistical DNB analyses, the design DNBR limit is set equal to the applicable statistical design limit (SDL). The DNBR limits are presented in Table 3.2-1. The difference between the safety analysis limit and the design limit is the available retained DNBR margin, against which penalties may be assessed to account for the DNB effect of changes in the fuel product, plant operating conditions, or analysis methodology (e.g., fuel rod bowing).

The DNB analysis of the Westinghouse 15 x 15 SIF is based on the Statistical DNBR Evaluation Methodology (Reference 1), the COBRA-IIIC/MIT code (Reference 2), and the WRB-l DNB correlation (Reference 3) as submitted to the NRC in Reference 4, and approved by the NRC in Reference 5. The W-3 DNB correlation and a deterministic treatment of key DNBR analysis uncertainties are used when any of the conditions are outside the range of the WRB-l DNB correlation and Statistical DNBR Evaluation Methodology. (See Section 3.4.3.2.) The DNB limits applicable for use in the COBRA code with the W-3 and WRB-l correlations are listed in Table 3.2-1 for application with the deterministic and statistical DNB methodologies.

The DNB analysis of the Westinghouse 15 x 15 Upgrade is based on the Statistical DNBR Evaluation Methodology (Reference 1), the VIPRE-D code (Reference 6), and the WRB-1 DNB correlation (Reference 6) as submitted to the NRC in Reference 7, and approved by the NRC in References 8 and 9. The W-3, ABB-NV, or WLOP DNB correlations and a deterministic treatment of key DNBR analysis uncertainties are used when any of the conditions are outside the range of the WRB-l DNB correlation and Statistical DNBR Evaluation Methodology. (See Section 3.4.3.2.) The DNB limits applicable for use in the VIPRE-D code with the WRB-1, W-3, ABB-NV, and WLOP correlations are listed in Table 3.2-1 for application with the deterministic and statistical DNB methodologies.

Additional information on thermal/hydraulic design can be found in Section 3.4.

3.2.3.4 **Mechanical Limits**

3.2.3.4.1 Reactor Internals

The reactor internal components are designed to withstand the stresses resulting from start-up, steady-state operation with any number of pumps running, and shutdown conditions. No damage to the reactor internals occurs as a result of loss of pumping power.

Lateral deflection and torsional rotation of the lower end of the core barrel are limited to prevent excessive movements resulting from seismic disturbances, thus preventing interference with control rod assemblies. Core drop in the event of failure of the normal supports is limited so that the control rod assemblies do not disengage from the fuel assembly guide thimbles.

The structural components are designed to maintain their functional integrity in the event of a major loss-of-coolant accident (LOCA). The dynamic loading resulting from the pressure oscillations because of a LOCA does not prevent insertion of the control rod assemblies.

Seismic design criteria for the reactor internals are discussed in Appendix 15A. Additional information on mechanical design can be found in Section 3.5.

3.2.3.4.2 Fuel Assemblies

The fuel assemblies are designed to perform satisfactorily throughout their required lifetime. The loads, stresses, and strains resulting from the combined effects of flow-induced vibrations, earthquakes, reactor pressure, fission gas pressure, fuel growth, thermal strain, and differential expansion during both steady-state and transient reactor operating conditions have been considered in the design of the fuel rods and fuel assembly. The assembly is also structurally designed to withstand handling and shipping loads prior to irradiation, and to maintain sufficient integrity at the completion of design burnup to permit safe removal from the core, handling, shipment, and fuel reprocessing.

The fuel rods are supported at several locations along their length within the fuel assemblies by brazed or welded grid assemblies, which are designed to maintain control of the lateral spacing between the rods throughout the design life of the assemblies. The magnitude of the support loads provided by the grids is established to minimize possible fretting without overstressing the cladding at the points of contact between the grids and fuel rods, and without imposing restraints of sufficient magnitude to result in buckling or distortion of the rods.

The fuel rod cladding is designed to withstand operating pressure loads without rupture, and to maintain encapsulation of the fuel throughout its design life.

3.2.3.4.3 Control Rod Assemblies

The criteria used for the design of the cladding on the individual control rods in the control rod assemblies are similar to those used for the fuel rod cladding. The cladding is designed to be free-standing under all operating conditions and to maintain encapsulation of the absorber material throughout the control rod design life. Allowance for wear during operation is included for the control rod cladding thickness.

Adequate clearance is provided between the control rods and the guide thimbles that position the rods within the fuel assemblies so that coolant flow along the length of the control rods is sufficient to remove the heat generated without overheating of the absorber cladding. The clearance is also sufficient to compensate for any misalignment between the control rods and guide thimbles and to prevent mechanical interference between the rods and guide thimbles under any operating condition.

3.2.3.4.4 Control Rod Drive Mechanisms

Each control rod drive mechanism is designed as a hermetically sealed unit to prevent leakage of reactor coolant water. All pressure-containing components are designed to meet the requirements of ASME Code Section III for Class A vessels.

The control rod drive mechanisms for the control rod assemblies provide control rod assembly insertion and withdrawal rates consistent with the required reactivity changes for reactor operational load changes. This rate is based on the worths of the various rod groups, which are established to limit power-peaking flux patterns. The maximum reactivity addition rate is specified to limit the magnitude of a possible nuclear excursion resulting from a control system or operator malfunction. Also, the control rod drive mechanisms provide a fast insertion rate during a trip of the control rod assemblies, which results in a rapid shutdown of the reactor for conditions that cannot be handled by the reactor control system.

1. DET-DNB means that deterministic DNBR methods are used for this event.
2. STAT-DNB means that statistical DNBR methods are used for this event.
3. Non-DNB means that this DNB is not a limiting criterion for this event.

3.3 NUCLEAR DESIGN

This section discusses the nuclear characteristics of the core, and evaluates the characteristics and design parameters that are significant with respect to the design objectives (Section 3.2.1). These evaluations demonstrate the capability of the reactor to achieve these objectives while performing safely under all steady-state and transient operational modes.

3.3.1 Reactivity Control Aspects

Reactivity control is provided by boron dissolved in the reactor coolant, movable neutron-absorbing control rod assemblies, fixed burnable poison rods, and/or integral fuel burnable absorber (IFBA).

The concentration of soluble boron is varied as necessary during the life of the core to compensate for changes in reactivity that occur with changes in temperature of the reactor coolant from cold shutdown to hot operating conditions, changes in reactivity associated with inventory changes in the fission product poisons xenon and samarium, reactivity losses associated with the depletion of fissile inventory and buildup of long-lived fission product poisons, and changes in reactivity due to burnable poison burnup.

The control rod assemblies provide reactivity control for: fast shutdown, reactivity changes associated with changes in the average coolant temperature above hot-zero-power temperature (since core average coolant temperature is increased with power level), reactivity associated with any void formation, and reactivity changes associated with the power coefficient of reactivity.

The control rod assemblies are divided into two categories according to their function. Thirty-two control rod assemblies compensate for changes in reactivity due to variations in operating conditions of the reactor, such as power or temperature. They are divided into four control groups or banks, each consisting of eight assemblies. Sixteen control rod assemblies provide additional shutdown reactivity, and are termed shutdown assemblies. The total shutdown worth of all the control rod assemblies is specified to provide adequate shutdown with the most reactive assembly stuck out of the core.

Burnable poison (fixed burnable poison rods and/or IFBA) provides control of part of the excess reactivity available during the core cycle. The primary function of burnable poison is to prevent the moderator temperature coefficient from being positive, under normal operating conditions, by reducing the soluble boron content of the reactor coolant at the beginning of life, as described in WCAP-7113 (Reference 1). The number and location of fixed burnable poison rods for the first core cycle is shown in Figure 3.3-1. The use of burnable poison in subsequent cycles is discussed in Section 3.3.3.2.2.

Since the presence of control rod assemblies and burnable poison influences flux shape in the core, it is pertinent to summarize some typical fission power density distributions. Figures 3.3-2 and 3.3-3 illustrate X-Y power density distributions for rodded and unrodded conditions. The value of F_{xy} shown on each figure indicates the ratio of maximum power density to average power density.

3.3.2 Nuclear Design Data

The values of design parameters cited in this section and in Tables 3.3-1 through 3.3-3 generally pertain to the first Surry core cycle. The pertinent nuclear design data for each subsequent cycle of operation are contained in a reload safety evaluation prepared by Vepco prior to cycle start-up. The reload safety evaluation process involves an evaluation of the reload core during which the values of kinetics parameters, fuel temperatures, peaking factors, and core limits used in the currently applicable safety analysis are compared with corresponding values for the planned reload cycle. Where the evaluation shows parametric values for the planned cycle that are outside the bounds of the previous safety analysis, the specific accident analyses sensitive to these parameters are reevaluated or reanalyzed. If a reanalysis leads to Technical Specification changes, these are obtained from the NRC, also prior to cycle start-up.

3.3.2.1 **Core Reactivity Characteristics**

A summary of nuclear design data for the first cycle only, including core reactivity characteristics, is presented in Table 3.3-1. Discussion of the table is facilitated by use of line numbers. A summary of reactivity requirements and control rod worth is given in Tables 3.3-2 and 3.3-3, which may be used in conjunction with Table 3.3-1.

General structural characteristics are given in lines 1 through 10 of Table 3.3-1, while performance characteristics are listed in lines 11 through 22. Typical values of effective neutron multiplication constants and estimated critical boron (chemical shim) concentrations are listed for specified conditions in lines 23 through 41. Several of these items, such as soluble boron control, are discussed in greater detail below.

Adequate control to render the reactor subcritical at temperatures below the operating range is provided by the soluble boron concentration. The boron concentration during refueling, reported in line 32 of Table 3.3-1, based on all the control rod assemblies being inserted, provides approximately 10% delta k/k shutdown margin.[1] This concentration is also sufficient to maintain the core subcritical with no control rod assemblies inserted in the core. This is consistent with General Design Criteria No. 26 (GDC-26), which states that one of two independent reactivity control systems "shall be capable of holding the reactor core subcritical under cold conditions." For cold shutdown at the beginning of core life, the concentration shown in Table 3.3-1, line 40, is sufficient for 1% delta k/k shutdown with all but the maximum-worth control rod assembly inserted.

The boron concentration for refueling is equivalent to less than 2% by weight boric acid (H_3BO_3), and is well within solubility limits at ambient temperature. This concentration is also

1. The text applies to the initial core cycle; see Technical Specifications for current shutdown requirements.

maintained in the spent-fuel pool, since it is directly connected with the refueling canal during refueling operations.

The initial full-power boron concentration without equilibrium xenon and samarium is shown in line 37 of Table 3.3-1. As these fission product poisons are built up, the boron concentration is reduced. This initial boron concentration assumes no full-length rod insertion. The xenon-free, zero-power shutdown, k = 0.99[1] or less, with all but the maximum-worth control rod assembly inserted, is maintained with the boron concentrations shown in lines 40 and 41, for the cold and hot conditions, respectively.

The boron concentrations given above are representative of those during the first operating cycle where burnable poison rods and the associated worth listed in lines 42, 43, and 44 were present. Core kinetic characteristics are dependent on boron concentrations, and the presence of burnable poison rods and control rods. A discussion of these factors follows.

3.3.2.2 **Kinetic Characteristics**

The response of the reactor core to unit conditions or operator adjustments during normal operation, as well as the response during abnormal or accidental transients, is determined by means of a detailed simulation. In these calculations, reactivity coefficients are required to couple the response of the core neutron multiplication to the variables that are set by conditions external to the core. Since the reactivity coefficients change during the life of the core, a range of coefficients is established to determine the response of the unit throughout life and to establish the design of the reactor control and protection system.

3.3.2.3 **Moderator Temperature Coefficient**

The moderator temperature coefficient in a core controlled by soluble boron is less negative than the coefficient in an equivalent rodded core. One reason is that control rods contribute a negative increment to the coefficient, and in a core using soluble boron, the control rods are only partially inserted. Also, the boron concentration is decreased with the decrease in water density upon an increase in temperature. This gives rise to a positive component of the moderator temperature coefficient due to the removal of boron from the core. This effect is directly proportional to the amount of reactivity controlled by the dissolved boron.

To reduce the soluble boron requirement for control of excess reactivity, burnable poison rods and/or IFBA rods are incorporated in the core design. The effect of reducing the soluble boron concentration is to make the moderator temperature coefficient more negative. This is caused by a reduction of the effect that coolant temperature and density changes have on the boron number density in the core.

The burnable poison rods for the initial core were borated glass tubes clad in stainless steel. Clusters of these rods were distributed throughout the core in vacant control rod guide thimbles.

1. The text applies to the initial core cycle; see Technical Specifications for current shutdown requirements.

The initial core pattern is shown in Figures 3.3-1 and 3.3-4 on a gross core and an assembly-wise basis, respectively. Information regarding research, development, and nuclear evaluation results of the burnable poison rods can be found in WCAP-7113 (Reference 1) and WCAP-9000 (Reference 2). The number of rods and the corresponding reactivity worth at beginning of life of the initial cycle are indicated in lines 42, 43, and 44 of Table 3.3-1.

Typically, the moderator temperature coefficient is negative at operating temperatures. The coefficient becomes more negative with increasing burnup, as a result of build-up of plutonium and fission products and reduction of the boron concentration. The reactivity loss due to equilibrium xenon is controlled by reduction of boron concentration. As xenon builds up, the boron concentration is reduced. The calculated range of the moderator temperature coefficient from beginning of life to end of life of the initial cycle is shown in line 45.

The control rods provide a negative contribution to the moderator coefficient. This is indicated in Figure 3.3-5, which shows a typical relationship between moderator temperature and moderator temperature coefficient, both with and without rods.

Design calculations for Surry reload cycles subsequent to cycle 1 have shown that the moderator temperature coefficient may be positive at the beginning of a cycle, with hot zero-power conditions and all rods out. Although control rod insertion can be used to bring the coefficient negative, this would lengthen the plant start-up after a refueling and would make the start-up more complex by requiring restrictions on boron concentration and control rod movement. Therefore, to facilitate start-up, it is desirable to allow a slightly positive moderator temperature coefficient at lower power levels. As the power level is raised, the average core water temperature becomes higher, as allowed by the programmed average temperature for the plant, tending to bring the moderator coefficient more negative. Also, the boron concentration can be reduced as xenon builds into the core. Thus, there is less need to allow a positive coefficient as full power is approached. As fuel burnup is achieved, boron is further reduced and the moderator coefficient becomes negative over the entire operating power range.

The impact of a positive moderator temperature coefficient on the accident analyses presented in Chapter 14 has been assessed. Any incident which was found to be sensitive to minimum or near-zero moderator coefficients was reanalyzed. In general, reanalysis was based on the assumptions and methods employed in the original accident analysis, with exceptions noted in the discussion of each incident in Chapter 14. Accidents not reanalyzed included those resulting in excessive heat removal from the reactor coolant system for which a large negative moderator coefficient is conservative, and those for which the moderator coefficient is assumed to be negative due to control rod insertion resulting from reactor trip.

The Technical Specifications allow a constant positive moderator temperature coefficient below 50% of rated power, decreasing linearly to zero at 100% of rated power. This provides ample operating flexibility and allows a reasonable degree of flexibility in core design and plant operation for future cycles.

A requirement that the reactor is not to be made critical with a reactor coolant temperature below 538°F is imposed to provide added assurance that the assumptions made in the safety analysis remain bounding by maintaining the moderator temperature within the range of those analyses.

The positive moderator temperature coefficient will exist for only a short time at beginning of cycle, and the Technical Specifications require the maximum upper limit of the MTC coefficient to be zero at full power. Operating with a positive moderator temperature coefficient is acceptable as long as plant operation is limited in accordance with the values of cycle-specific parameter limits that are established using NRC-approved methodologies.

3.3.2.4 **Moderator Pressure Coefficient**

The moderator pressure coefficient has a sign opposite to the moderator temperature coefficient. The net effect of the moderator pressure coefficient on the total coefficient is small because of the small magnitude of the pressure coefficient, since a change of 50 psi in pressure has no more effect on reactivity than a half-degree change in moderator temperature. The calculated initial-core beginning-of-life and end-of-life pressure coefficients are shown in Table 3.3-1, line 46.

3.3.2.5 **Moderator Density Coefficient**

A uniform moderator density coefficient is defined as a change in the neutron multiplication per unit change in moderator density. The range of the moderator density coefficient from beginning to end of life of the initial core is specified in Table 3.3-1, line 47.

3.3.2.6 **Doppler and Power Coefficients**

The calculation of power coefficients in a large, slightly enriched core is complex. As fuel pellet temperature increases with power density, the resonance absorption in U-238 increases as a result of Doppler broadening of the resonances. The relationship between effective fuel temperature and resonance absorption in a fuel rod is sufficiently complex in itself. An additional degree of complexity is introduced in relating these resonance-broadening effects to actual operation of the core, in which non-uniform power and fuel temperature distributions are subject to continual change with control rod movements, fuel burnup, and varying heat transfer characteristics of the fuel rods.

The Doppler reactivity coefficient is defined as the change in neutron multiplication per degree change in the effective fuel temperature, delta k/k/°F. The variation in this quantity with effective fuel temperature is shown in Figure 3.3-6, as computed by the LEOPARD code (Reference 3). It may be observed that the Doppler coefficient is non-linear and becomes less negative as temperature increases. The integral under the curve between the effective fuel temperature associated with the hot-zero-power condition and that associated with full power represents the Doppler reactivity defect.

To obtain the integral or differential change in core reactivity with power, it is necessary to know the change in effective fuel temperature with power, delta T/delta P, as well as the Doppler coefficient, delta k/k/°F. An empirical approach is taken to calculate the behavior of delta T/delta P with power, based on operating experience of Westinghouse cores. Results obtained with this approach are illustrated in Figure 3.3-7, which shows reactivity effects associated with Doppler broadening only. (The results presented do not include any moderator coefficient, even though the moderator temperature changes with core power level.)

In the empirical model used above, a large temperature drop is assumed to occur across the fuel pellet-clad gap. Under conditions where this gap may be essentially "closed," the fuel temperature for a given power level, and the quantity delta T/delta P, may be significantly reduced. At a lower effective fuel temperature, the Doppler reactivity defect is reduced; however, the Doppler coefficient is more negative. The net effect of using a closed-gap model is a power coefficient that shows much less variation with power than that shown with a gap model. Results obtained using this model are shown in Figure 3.3-8, where it may be observed that the power coefficient at full power is similar to that obtained with the gap model.

The above discussion relates primarily to reactivity characteristics on a core basis. A similar situation exists with regard to local Doppler reactivity feedback characteristics, which are important in determination of the stability of the reactor to xenon oscillations. Calculations indicate that local reactivity feedback in the range of interest for stability (50% to 150% of core average power density) is relatively insensitive to the thermal model.

3.3.2.7 **Summary of Control Rod Requirements**

Figure 3.3-9 depicts the functional grouping and designation of the control rod assemblies.

Reactivity requirements of control rods at beginning and end of life are summarized in Table 3.3-2. The requirements, discussed below, include those that are associated with shutdown conditions.

3.3.2.8 **Total Power Defect**

Control rods must be available to compensate for the reactivity change incurred with a change in power level due to the Doppler effect. The magnitude of this change has been established by correlating the experimental results of numerous operating cores.

The average temperature of the reactor coolant increases with power level in the reactor. Since this increase in coolant temperature is actually a part of the power-dependent reactivity change, along with the Doppler effect and void formation, the associated reactivity change must be controlled by rods. The largest amount of reactivity that must be controlled is at the end of life, when the moderator temperature coefficient has its most negative value. The moderator temperature coefficient range for the initial cycle is given in Table 3.3-1, line 45, while the cumulative reactivity change is shown in the first line of Table 3.3-2. By the end of each fuel cycle, the non-uniform axial depletion causes a severe power peak at lower power. The reactivity associated with this peak is part of the power defect.

3.3.2.9 **Operational Maneuvering Band**

Each control rod assembly control group is operated at power within a prescribed band of travel in the core to compensate for periodic changes in boron concentration, temperature, and pressure. The band has been defined as the operational maneuvering band. When the control rod assemblies reach either limit of the band, a change in boron concentration must be made to compensate for any additional change in reactivity.

3.3.2.10 **Control Rod Bite**

For good response to rapid changes in load, the control groups of control rod assemblies were originally positioned at a location that maintained a design minimum reactivity insertion rate. The partial control group insertion that was specified to provide the specified reactivity insertion rate is called control rod bite. The current analyses and design basis are met even when the unit is operated with all rods out of the core.

3.3.2.11 **Excess Reactivity Insertion Upon Reactor Trip**

Current control requirements are nominally based on providing 1.77% delta k/k shutdown at hot zero-power conditions, with the highest-worth control rod assembly assumed to be stuck in its fully withdrawn position.

3.3.2.12 **Calculated Rod Worths**

The control rod assemblies are arranged in a symmetric pattern as shown in Figure 3.3-9. Calculations are made to verify that the control rod worths are sufficient to meet the shutdown requirements. These worths are established assuming that the highest-worth control rod assembly is stuck in the fully withdrawn position. Table 3.3-3 lists the calculated worths for the beginning and end of the first cycle.

To be sure of maintaining a margin between calculated and required control rod worths, the calculated reactivity worths are decreased by 10% to account for any errors or uncertainties in the calculation.

A comparison between calculated and measured control rod worth shows the calculations to be well within the allowed uncertainty of 10%.

3.3.2.13 **Reactor Core Power Distribution**

In order to meet the performance objectives without violating safety limits, the peak to average power density must be within the limits set by the nuclear hot-channel factors. For the peak power point in the core at rated power, the nuclear heat flux hot-channel factor, F_q^N was established as specified in Table 3.3-1, line 21. For the hottest channel at rated power, the nuclear enthalpy rise hot-channel factors, $F^N_{\Delta H}$ was established as specified in Table 3.3-1, line 22. These values are specific to the initial cycle.

Power capability of a PWR core is determined largely by consideration of the power distribution and its interrelationship to limiting conditions involving:

1. The linear power density.
2. The fuel cladding integrity.
3. The enthalpy rise of the coolant.

To determine the core power capability, local as well as gross core neutron flux distributions have been determined for various operating conditions at different times in core life.

The presence of control rods, burnable poison, flux suppression inserts (Unit 1 only, Cycles 13 through 20) and chemical shim concentration all play significant roles in establishing the fission power distribution, in addition to the influence of thermal/hydraulic and temperature feedback considerations. The computer programs used to determine neutron flux distributions include a model to simulate non-uniform water (and chemical shim) density distributions.

Thermal/hydraulic feedback considerations are especially important late in cycle life, when the magnitude of the flux redistribution and reactivity change with change in core power or control rod assembly movement are strongly influenced by enthalpy rise up the core and by the fuel burnup distribution. Consequently, extensive X-Y and Z power distribution analyses are performed to evaluate fission power distributions. Typical X-Y power distributions are presented in Figures 3.3-2 and 3.3-3 to illustrate the combined effect of a control rod assembly group upon assembly average power density. Incore instrumentation is employed to evaluate the core power distributions throughout core lifetime to ensure that the thermal design criteria are met.

The Ex-Core Nuclear Instrumentation System supplies the necessary information for the operator to control the core power distribution within the limits established for the protection system design. This information consists of a multipen recorder, which displays the upper and lower ion chamber signals, and an indicator that gives the difference in these two signals for each long ion chamber. These ion chamber signals to the recorders and indicators are calibrated against incore power distribution obtained from the movable detector system generated in the adjacent section of the core. This essentially divides the core into eight sections, four in the upper half and four in the lower half.

The relationship between core power distribution and ex-core nuclear instrumentation readings was established during the start-up testing program (Chapter 13). Incore flux measurements were made for reactor power in the range of 25 to 100%. These measurements, together with long ion chamber currents, were processed to yield the relationships between core average axial power generation, axial peaking factor, and axial offset as indicated by the ex-core nuclear instrumentation. These relationships can be checked during operation to assess the effect of core burnup on the sensitivity between incore power distribution and ex-core readings.

The reactor core may be subject to axial xenon oscillations at the end of a fuel cycle life. The axial instability is due principally to the negative moderator temperature coefficient of reactivity that exists at end of life. Since the moderator coefficient at beginning of life is small, stability against axial oscillations is greatly increased at beginning of life. Consequently, stability margin experiments would not be informative at beginning of life.

A more detailed discussion of the background, analytical, and experimental data which form the basis for this approach is given in WCAP-7208 (Reference 4).

Ex-core neutron flux detectors were added to meet Regulatory Guide 1.97 and Appendix R requirements. These are discussed in Section 7.10.

3.3.3 Analytic Methods and Supporting Experimental Data

3.3.3.1 **Introduction**

The confidence in procedures and design methods for the initial core cycles was based on comparison of these methods with experimental results. The experiments included critical experiments performed at the Westinghouse Reactor Evaluation Center and other facilities, and also measured data from operating power reactors. Extensive descriptions of these analytic methods and the supporting experiment theory correlations are given in References 5 through 16. Discussion of these items may be found in other safety analysis reports on similar stations (e.g., the FSAR for Carolina Power and Light Company’s H. B. Robinson Unit No. 2, Docket No. 50-261).

The current core analysis methodology is described in the following section.

3.3.3.2 **Reload Methodology**

3.3.3.2.1 Introduction

Each reload core is evaluated to demonstrate that it will not adversely affect the safety of the plant. The evaluation is accomplished utilizing the methodology described in VEP-FRD-42-A, Rev. 2, MRev. 2 (Reference 17).

3.3.3.2.2 Core Description

The Surry cores consist of 157 fuel assemblies surrounded by a core baffle, barrel, and thermal shield, and enclosed in a steel pressure vessel. The pressure inside the vessel is maintained at a nominal 2250 psia. The coolant (and moderator) is pressurized water, which enters the bottom of the core at a nominal 540°F and undergoes a nominal average rise in temperature of 66°F before exiting the vessel. The average coolant temperature is 573.0°F and the average linear power density of the core is 6.6 kW/ft.

Each of the 157 fuel assemblies consists of 204 fuel rods (except fuel assemblies which have been reconstituted, see Section 3.5.2.1) arranged in a 15 x 15 square array. The fuel used in the Surry cores consists of slightly enriched uranium dioxide fuel pellets contained within a

Zircaloy-4, ZIRLO, or Optimized ZIRLO clad. A small gap containing pressurized helium exists between the pellets and the inner diameter of the clad. For the positions in the 15 x 15 array not occupied by fuel rods, there are 20 guide tube locations for fixed burnable poison rods, flux suppression inserts (Unit 1 only, Cycles 13 through 20), or control rods and one centrally located instrumentation tube. The fuel rods in each fuel assembly are supported by seven grids located along the length of the assembly. In the original Surry fuel design, all of these grids were fabricated from Inconel-718. In the Surry Improved Fuel (SIF) design, which was introduced in Cycle 10 (Batch 12) at each unit, the five middle grids on the assembly are made from zirconium-based alloy (Zircaloy-4 or ZIRLO). Inconel continues to be used for the top and bottom grids on the SIF fuel assemblies. These grids are mechanically attached to the guide tubes, which are, in turn, fastened to the upper and lower nozzles, and thus provide for assembly structural support. Beginning with the feed for Cycle 13 (Region 15), the Surry fuel assemblies also include an additional protective bottom Inconel grid, located directly above the bottom nozzle. This protective grid is a debris resistance feature, and is not considered an assembly structural component. Beginning in Cycle 21, each fuel assembly may contain from 0 to 148 integral fuel burnable absorber (IFBA) rods. The IFBA fuel rod design includes a thin layer of boride coating on the outer surface of the majority of the fuel pellets in the fuel rod, as well as axial blankets. The axial blanket is a six-inch (approximate) stack of slightly enriched annular fuel pellets without boride coating located at the top and bottom of the fuel stack in each IFBA rod. Cores may continue to use a limited number of discrete (fixed) burnable poison rod assemblies in conjunction with IFBA fuel assemblies, or may use IFBA fuel assemblies exclusively.

Beginning in Surry Unit 2 Cycle 31, all fuel rods in each new fuel batch may contain axial blankets. The axial blanket is a six-inch (approximate) stack of natural or slightly enriched fuel pellets (solid or annular) located at the top and bottom of the fuel stack in each fuel rod.

The 15 x 15 Upgrade fuel assembly design incorporates the following additional features vs. SIF fuel:

- three intermediate flow mixing grids (IFMs), made of ZIRLO, which improve flow mixing (IFMs are not credited for assembly structural support)
- balanced vane mid-grids, also made of ZIRLO, which reduce assembly vibration thus improving grid-to-rod fretting margin
- “tube-in-tube” guide thimble tubes which enhance dimensional stability against guide tube and assembly bowing and incomplete rod insertion
- Optimized ZIRLO fuel clad for improved corrosion resistance
- oxidation of the bottom portion of the fuel outer clad, including the bottom end plug and bottom end plug weldment, to improve debris resistance.

There are 48 rod cluster control assemblies (referred to as control rods) used to control core reactivity. The absorber material of the control rods is an alloy consisting of 80% silver, 15% indium, and 5% cadmium. The various control rods are arranged in and move in symmetrically located groups, or banks. Banks A, B, C, and D are denoted as the control banks and are moved in a fixed sequential pattern to control the reactor over the power range of operation. The remaining rods are denoted as shutdown banks and are used to provide shutdown margin.

In addition to the control rods, a chemical (boric acid) shim is used to control excess core reactivity and to facilitate operational flexibility. Above certain concentrations of chemical shim, burnable poison rods and/or integral fuel burnable absorber rods are also used to control excess reactivity. Burnable poison can also be used to shape (i.e., improve) the core power distribution. Discrete burnable poison rods contain borosilicate in the form of Pyrex glass clad in a stainless steel tube, or Al_2O_3 pellets in Zircaloy-4 tubes. Burnable poison rod assemblies, which may be used in any fuel assembly not under a control rod bank location, typically consist of clusters of either 8, 12, 16, or 20 rods that are inserted into the Zirconium-based alloy control rod guide tubes. IFBA fuel assemblies typically contain up to 148 IFBA rods symmetrically distributed throughout each assembly.

Flux suppression insert (FSI) assemblies were used in peripheral core locations in Unit 1 from Cycle 13 to Cycle 20 to suppress the neutron leakage flux in the radial and axial vicinity of reactor vessel weld locations. Each FSI contained twenty neutron absorber rods which were inserted into the fuel assembly guide thimble tubes. Each neutron absorber rod contained a hafnium stack encapsulated in thick walled Zircaloy cladding. The fast and thermal neutron flux in each fuel assembly with an FSI was reduced by reducing power through the insertion of negative reactivity. The active absorber region of the FSI assemblies was preferentially loaded toward the bottom of the active fuel region. By itself, this tended to skew the core average axial power distribution. To minimize this impact, some burnable poison rods with absorber removed from the bottom of the rodlets were used in Surry 1 cores with FSIs. Removal of the absorber had the effect of a positive reactivity insertion, which offset some of the axial impact of the FSIs. Other than the use of less absorber material and biasing the location of the poison stack toward the top of the fuel stack, these short burnable poison assemblies were mechanically identical to other current burnable poison assemblies.

Flux suppression inserts were removed from the Unit 1 core following operation of Cycle 20 and after approval of a revised methodology to assess the impact of fluence on vessel welds. When the FSIs were removed from the core, the use of shorter burnable poison assemblies was eliminated.

3.3.3.2.3 Conclusions

The effect of a given reload on previously acceptable safety limits is documented in a reload safety evaluation report. The report addresses the mechanical, nuclear, and thermal/hydraulic design of the reload core, and provides references wherein more detailed supporting information can be found.

3.4 THERMAL/HYDRAULIC DESIGN AND EVALUATION

3.4.1 Thermal/Hydraulic Characteristics of the Design

The capability of the reload core design to meet thermal-hydraulic safety limits and fuel thermal-hydraulic design criteria is evaluated as part of the reload safety evaluation process. The cycle specific reload safety evaluation addresses the thermal-hydraulic design of the reload core and confirms that the thermal-hydraulic limits are met for each fuel assembly. The thermal/hydraulic evaluation is performed to confirm Departure from Nucleate Boiling Ratio (DNBR) results for applicable UFSAR Chapter 14 accidents and transients. This is accomplished by determining if the key DNBR analysis parameters for the reload core are conservatively bounded by the values used in the applicable safety analyses of record.

The thermal-hydraulic performance of the core is projected based on assumed operating conditions and the core loading pattern which sets the type, number, and location of fresh and re-inserted fuel assemblies. The assumed operating conditions include operation within the core operating limits of the COLR.

Table 3.4-1 presents a typical set of values used in the thermal-hydraulic analyses. Thermal-hydraulic design parameter values used for the actual reload core analyses may differ slightly from the values listed in Table 3.4-1.

3.4.1.1 Fuel and Cladding Temperatures

Consistent with the thermal-hydraulic design bases, the following discussion pertains mainly to fuel pellet temperature evaluation. The thermal-hydraulic design assures that the maximum fuel temperature is below the melting point of UO_2 (melting point of 5080°F unirradiated and decreasing by 9°F per 10,000 MWD/MTU (Reference 41)). The basis for the PAD5 fuel melt limit is consistent with the descriptions in Reference 42. The temperature distribution within the fuel pellet is predominantly a function of the local power density and the UO_2 thermal conductivity. However, the computation of radial fuel temperature distributions combines crud, oxide, cladding gap and pellet conductances. The factors which influence these conductances, such as gap size (or contact pressure), internal gas pressure, gas composition, pellet density, fuel relocation, and radial power distribution within the pellet, etc., have been combined into a semi-empirical thermal model with the model modifications for time dependent fuel densification given in References 1 and 42. This thermal model enables the determination of these factors and their net effects on temperature profiles. The temperature predictions have been compared to inpile fuel temperature measurements and/or melt radius data as part of the generic approval of the fuel performance model (References 1 and 42).

As described in References 1 and 42, fuel rod thermal evaluations (fuel centerline, average and surface temperatures) are determined throughout the fuel rod lifetime with consideration of time dependent densification. To determine the maximum fuel temperatures, various burnup rods, including the highest burnup rod, are analyzed over the rod linear power range of interest.

The principle factors which are employed in the determination of the fuel temperature are consistent with the methods described in Reference 42.

3.4.1.2 Westinghouse Experience with High-Power Fuel Rods

Westinghouse experience (through 1969) with non-pressurized fuel rods operating at high power ratings has been summarized in the Indian Point Unit 2 Preliminary Safety Analysis Report (Docket 50-247) and in the Preliminary Safeguards Report for the Saxton Reactor operating at 35 MWt (Docket 50-146). These reports present considerable statistical evidence of successful operation of 1368 high-performance Zircaloy-clad fuel rods in the Carolina-Virginia Test Reactor (CVTR) and 94,920 rods in the Shippingport Core I Blanket. After the date of these reports, a significant amount of additional information was developed relating to the integrity of free-standing Zircaloy-clad oxide fuel rods at high power ratings. In addition, a comprehensive experimental program was performed to extend the operating experience to higher power and to higher exposures. This information is summarized in Figure 3.4-2.

Figure 3.4-2 shows that 30 Saxton Plutonium Project non-pressurized fuel rods operated at a design peak power level of up to 18.5 kW/ft to a peak exposure of approximately 30,000 MWD/MTU (megawatt days per metric ton of metal (U + Pu)). No failures occurred with this fuel. In the Saxton overpower test, two selected fuel rods from the Saxton Plutonium Project assemblies were removed after peak exposure of 18,000 MWD and inserted in a subassembly for short-time irradiation at a design rating of 25 kW/ft. Results of this program indicated satisfactory performance of the fuel in every respect. The Saxton Plutonium Project was extended by irradiating approximately 250 rods to peak burnups of about 50,000 MWD/MTU at design linear power levels ranging from 9.5 to 23.6 kW/ft.

In the above tests (performed on non-pressurized rods), the strain fatigue experienced by the cladding was more severe than that expected to occur for pressurized rods, which would be placed under identical operating conditions.

Internally pressurized fuel rods have been investigated at Westinghouse. These investigations included ex-core and incore experimental programs and analytical studies. Fuel rods internally pressurized with various gases were irradiated in the Saxton reactor. Test results showed that initial pressurization was effective in substantially reducing the rate of cladding-creep onto the UO_2 fuel. The Saxton test results confirmed the results of analyses that predict fuel-cladding mechanical interaction early in life for non-pressurized fuel rods, and delayed interaction for initially pressurized fuel rods.

To verify the substantial design margin that exists with regard to excessive internal pressures in a fuel rod, several highly pressurized Zircaloy-clad fuel rods were irradiated for several months in the Saxton reactor, then removed for examination. At an internal pressure of approximately 3500 psia (as compared to the design value of 2250 psia), the fuel rods operated satisfactorily for the period of the test without any indication of failure. Two fuel rods, deliberately tested at unrealistically high internal pressures, experienced clad cracking but operated satisfactorily for the period of the test.

Westinghouse irradiated many internally pressurized fuel rods in Saxton and also at the Jose Cabrera plant in Spain. Approximately 150 fuel rods were subjected to long-term irradiation testing. These tests provided additional confirmation of the suitability of internally pressurized fuel rods. This long-term testing program was continued at Saxton until 1971 and at Jose Cabrera until 1972, and provided verification of core life performance data with the fuel rod design bases.

The initial Surry fuel was intended to operate to a peak fuel exposure of 49,000 MWD/MTU. The change in fuel characteristics as a function of exposure had been investigated in certain cases, but the exact nature and extent of such changes to the planned exposures had not been investigated in great detail. However, based upon work at lower exposures (References 2 & 3-5), such property changes were not considered of major significance and tended to saturate at relatively low exposures. The models used to predict the thermal performance of the fuel in the initial Surry cores were combined in an integrated computer program to enable consideration of the several effects arising due to irradiation. These thermal models were compared to data in the literature, with generally good correlation. The thermal performance of current fuel is similarly evaluated using an overall fuel design code that has been shown to provide good agreement with a variety of published and proprietary data (References 1 and 42).

3.4.1.3 **Pressure Drop and Hydraulic Forces**

The total pressure loss across the reactor vessel, including the inlet and outlet nozzles, and the pressure drop across the core are listed in Table 3.4-1. The design values are presented as nominal values.

3.4.2 Departure from Nucleate Boiling Technology

Departure from nucleate boiling (DNB) is predicted by analysis of hydrodynamic and heat transfer phenomena and is affected by the local and upstream conditions, including the flux distribution.

In reactor design, the heat flux associated with departure from nucleate boiling and the location of departure from nucleate boiling are both important. The magnitude of the local fuel rod temperature after departure from nucleate boiling occurs depends upon the axial location of the occurrence. The W-3 DNB correlation and its modification for the “L”-grid (References 6 & 31), which have been utilized in the analysis of 15 x 15 LOPAR assemblies (all assemblies prior to Region 12 on both units), incorporate both local and system parameters in predicting the local DNB heat flux. These correlations include the non-uniform flux effect and the upstream effect, which includes inlet enthalpy and distance. The local DNB heat flux ratio, defined as the ratio of the DNB heat flux to the local heat flux, is indicative of the margin available in the local heat flux to the onset of departure from nucleate boiling. The WRB-1 DNB correlation

(Reference 29), which is used in the analysis of 15 x 15 Surry Improved Fuel (SIF) and 15 x 15 Upgrade assemblies, is based on local fluid conditions and represents the rod bundle data with better accuracy over a wide range of variables than previous correlations (W-3 based) used in design. Validation of the WRB-1 DNB correlation applicability to the 15 x 15 Upgrade fuel assembly design is provided in Reference 37.

3.4.2.1 **W-3 Correlation**

The W-3 DNB correlation was developed to predict the DNB flux and the location of departure from nucleate boiling equally well for uniform and axially non-uniform heat flux distributions. This correlation replaced the preceding WAPD W-2 correlations (published in *Nucleonics* (Reference 7), May 1963), in order to eliminate the discontinuity of the latter at the saturation temperature, and to provide a single unambiguous criterion of the design margin.

The sources of the data used in developing this correlation were:

WAPD-188 (1958)	CU-TR-No. 1 (NW-208) (1964)
ASME Paper 62-WA-297 (1962)	CISE-R-90 (1964)
CISE-R-63 (1962)	DP-895 (1964)
ANL-6675 (1962)	AEEW-R-356 (1964)
GEAP-3766 (1962)	BAW-3238-7 (1965)
AEEW-R-213 and 309 (1963)	AE-RTL-778 (1965)
CISE-R-74 (1963)	AEEW-355 (1965)
CU-MPR-XIII (1963)	EUR-2490.e (1965)

The comparison of the measured to predicted DNB flux of this correlation is given in Figure 3.4-3. The local flux DNBR versus the probability of not reaching departure from nucleate boiling is plotted in Figure 3.4-4. This plot indicates that with a DNBR equal to the correlation DNBR limit (of 1.30), the probability of not reaching departure from nucleate boiling is 95% at a 95% confidence level.

Rod bundle data without mixing vanes agree very well with the predicted DNB flux, as shown in Figure 3.4-5. The rod bundle data with mixing vanes, shown in Figure 3.4-6, show on the average an 8% higher value of DNB heat flux than predicted by the W-3 DNB correlation.

It should be emphasized that the inlet subcooling effect of the W-3 correlation was obtained from both uniform and non-uniform data. The existence of an inlet subcooling effect has been demonstrated to be real, and hence the actual subcooling was used in the calculations. The W-3 correlation was developed from tests with flow in tubes and rectangular channels. Good agreement was obtained when the correlation was applied to test data for rod bundles.

The form of the W-3 correlation was presented by Tong in Reference 32. The W-3 predicted heat flux at DNB is calculated as follows:

$$q'' = \frac{q''_{DNB,\,EU,\,Dh}}{F}(CWF)(F'_s)$$

where:

$q''_{DNB,EU,Dh}$ = W-3 Equivalent Uniform Heat Flux with all flow cell walls heated

F = Nonuniform Heat Flux Factor (F-factor)

CWF = W-3 Cold Wall Factor

F'_s = W-3 Modified Spacing Factor

Subsequent to Reference 32, an extensive experimental program was performed to investigate the behavior of DNB due to non-uniform axial heat flux distribution, heater rod lengths, axial grid spacing, and grids with and without mixing vanes. The results of these tests are documented in References 31, 33, 34, and 35.

3.4.2.1.1 W-3 Equivalent Uniform Flux DNB Correlation

The equivalent uniform DNB flux $q'_{DNB,EU}$ is calculated from the W-3 equivalent uniform flux DNB correlation as follows (Reference 6):

$$\begin{aligned}\frac{q'_{DNB,EU}}{10^6} = {} & [(2.022 - 0.0004302p) \\ & + (0.1722 - 0.0000984p)e^{(18.177 - 0.004129p)X}] \\ & \times\left[1.037 + \frac{G}{10^6}(0.1484 - 1.596X + 0.1729X|X|)\right] \times [1.157 - 0.869X] \\ & \times [0.2664 + 0.8357e^{-3.151D_e}] \times [0.8258 + 0.000794(H_{sat} - H_{in})]\end{aligned}$$

The ranges of the parameters in the data used to develop the correlation are:

System pressure	p = 1000 to 2300 psia
Mass velocity	$G = 1.0 \times 10^6$ to 5.0×10^6 lb/hr-ft^2
Equivalent diameter	D_e = 0.2 to 0.7 in.
Quality	X = -0.25 to +0.15
Inlet enthalpy	H_{in}, no limit, Btu/lb
Length	L = 10 to 144 in.
Heated perimeter/Wetted perimeter	D_h/D_e = 0.88 to 1.00

Geometries - circular tube, rectangular channel, and rod bundles

Flux - uniform and equivalent uniform flux converted from non-uniform data by using the F-factor (See Section 3.4.2.1.2).

3.4.2.1.2 Nonuniform Heat Flux Factor (F-factor)

The F-factor relates DNB data for axially non-uniform power distributions to DNB data for axially uniform power distributions (Reference 32). Reference 33 documented the experimental program to investigate the effects on DNB due to non-uniform axial heat flux distributions. It was concluded therein that the use of the F-factor was an acceptable means of accounting for axially non-uniform power distributions.

The local non-uniform $q''_{DNB,N}$ is calculated as follows:

$$q''_{DNB,\,N} = \frac{q''_{DNB,\,EU}}{F}$$

where:

$$F = \frac{C}{q''_{local\ at\ l_{DNB}}(1 - e^{-Cl_{DNB}})}\int_0^{l_{DNB}} q''(z)e^{-C(l_{DNB} - z)}dz$$

l_{DNB} = distance from the inception of local boiling to the point of DNB

z = distance from the inception of local boiling, measured in the direction of the flow

The empirical constant, C, as presented in Reference 6, was revised in Reference 32 through the use of more recent non-uniform DNB data. However, the revised expression (showing less than 1% deviation from that of Reference 6) does not significantly influence the value of the F-factor and the DNBR. It does provide a better prediction of the location of departure from nucleate boiling.

The new expression is:

$$C = 0.15\frac{(1 - \chi_{DNB})^{4.31}}{(G/10^6)^{0.478}}in^{-1}$$

where:

G = mass velocity lb/hr-ft^2

χ_{DNB} = quality of the coolant at the location where DNB flux is calculated

In determining the F-factor, the value of q''_{local} at l_{DNB} was measured at $z = l_{DNB}$, the location where the DNB flux is calculated. For a uniform flux, F becomes unity, so that $q''_{DNB,N}$ reduces to $q''_{DNB,EU}$. The comparisons of predictions by using W-3 correlations and the non-uniform DNB data obtained by B&W (Reference 9), Lee (References 10 & 11), and Obertelli (Reference 10) are given in Figures 3.4-8 and 3.4-9. To determine the predicted location of departure from nucleate boiling, the ratio of the predicted DNB flux to the local heat flux along the length of the channel must be evaluated. The location of the minimum DNBR is considered to be the location of departure from nucleate boiling.

3.4.2.1.3 W-3 Cold Wall Factor

The W-3 equivalent uniform flux DNB correlation is used for predicting DNB in channels which are entirely, or almost entirely, surrounded by heated walls (i.e., typical cells). The W-3 Cold Water Factor (CWF) accounts for the presence of unheated surfaces due to thimble or instrument tubes (i.e., thimble cells) (Reference 32). References 34 and 35 documented the experimental program to investigate the effect on DNB due to thimble cold wall cells. It was concluded that the cold wall factor is appropriate for rod bundles with mixing vane grids.

The W-3 Cold Wall Factor from Reference 32 is:

$$CWF = 1.0 - R_u[13.76 - 1.372e^{(1.78X)} - 4.732(G/10^6)^{-0.0535} - 0.0619(P/10^3)^{0.14} - 8.509(D_h)^{0.107}]$$

where:

$R_u = 1 - (D_e/D_h)$

X = local quality, fraction

G = local mass velocity, lb/hr-ft^2

P = primary system pressure, psia

D_h = equivalent diameter based on heated perimeter, inches

3.4.2.1.4 Modified Spacer Factor, R-Grid and L-Grid Correlations

To account for mixing between subchannels due to spacer grids, Tong (Reference 32) developed a spacer grid factor for use with the W-3 equivalent uniform flux correlation. However, the use of the W-3 equivalent uniform flux correlation with this spacer factor yielded conservative predictions, particularly in rod bundles with mixing vane grid spacers. Hence, a correlation factor was developed to adapt the W-3 correlation (which was developed based on single-channel data) to rod bundles with mixing vane spacer grids. This correction factor, termed the “Modified Spacer Factor,” was developed as a multiplier on the W-3 correlation.

The Modified Spacer Factor (F'_s) was developed from rod bundle DNB test results conducted in the Westinghouse high-pressure water loop at Columbia University. These tests were conducted on non-uniform axial heat flux test sections to determine the DNB performance of a low parasitic, top-split mixing-vane grid design, referred to as the “R” grid. A description of this test program and a summary of the results are given in References 35 and 36. This Modified Spacer Factor for the “R” grid is:

$$F'_{S,R} = (1.445 - 0.0371L)(P/225.896)^{0.5}(e^{(X+0.2)^2} - 0.73) + K_S(G/10^6)(TDC/0.019)^{0.35}$$

where:

L = total heated core length, ft

P = primary system pressure, psia

X = local quality, fraction

K_S = axial grid spacing coefficient

G = local mass velocity, lb/hr-ft^2

TDC = thermal diffusion coefficient

Additional DNB testing was conducted with an “L” type grid. A description of this test program and a summary of the results are given in Reference 35. The Modified Spacer Factor for the “L” grid is simply:

$F'_{S,L} = F'_{S,R} \times 0.986$

3.4.2.2 **WRB-1 Correlation**

The details of the proprietary WRB-1 correlation are provided in Reference 29. The WRB-1 correlation was developed exclusively from Westinghouse rod mixing vane grid bundle data (over 1100 points) based on local fluid conditions. This correlation accounts directly for cold wall effects, and variations in rod heated length and grid spacing. The F-factor (Section 3.4.2.1.2) is employed for axially non-uniform heat flux profiles.

The applicable range of variables is:

Pressure	$1440 \leq P \leq 2490$ psia
Local Mass Velocity	$0.9 \leq G_{loc} / 10^6 \leq 3.7$ lb/ft^2-hr
Local Quality	$-0.2 \leq X_{loc} \leq 0.3$
Heated Length, Inlet to CHF Location	$L_h \leq 14$ ft
Grid Spacing	$13 \leq g_{sp} \leq 32$ in.
Equivalent Hydraulic Diameter	$0.37 \leq d_e \leq 0.60$ in.
Equivalent Heated Hydraulic Diameter	$0.46 \leq d_h \leq 0.59$ in.

Figure 3.4-7 shows measured critical heat flux plotted against predicted critical heat flux using the WRB-1 correlation (Reference 29).

3.4.2.3 **ABB-NV and WLOP Correlations**

The ABB-NV and WLOP correlations (Reference 38), were developed exclusively from non-mixing vane grid bundle data based on local fluid conditions. The ABB-NV and WLOP correlations are meant to be used as a replacement for the W-3 correlation. The applicable range of variables for the ABB-NV correlation is:

Pressure	$1750 \leq P \leq 2415$ psia

Local Mass Velocity	$0.8 \leq G_{loc} / 10^6 \leq 3.16$ lb/ft^2 - hr
Local Quality	$X_{loc} \leq 0.22$
Heated Length, Inlet to CHF Location	48 in* $\leq L_h \leq$ 150 in
Heated Hydraulic Diameter Ratio	$0.679 \leq d_h \leq 1.08$
Grid Distance	$7.3 \leq g_d \leq 24$ in

*For heated lengths less than 48 inches, a minimum value of 48 is used.

The applicable range of variables for the WLOP correlation is:

Pressure	$185 \leq P \leq 1800$ psia
Local Mass Velocity	$0.23 \leq G_{loc} / 10^6 \leq 3.07$ lb/ft^2 - hr
Local Quality	$X_{loc} \leq 0.75$
Heated Length, Inlet to CHF Location	48 in* $\leq L_h \leq$ 168 in
Grid Spacing Term	$27 \leq g_{st} \leq 115$
Heated Hydraulic Diameter Ratio	$0.679 \leq d_h \leq 1.00$
Matrix Heated Hydraulic Diameter	$0.4635 \leq g_d \leq 0.5334$ in

*For heated lengths less than 48 inches, a minimum value of 48 is used.

3.4.2.4 Definition of Departure from Nucleate Boiling Ratio

In predicting the local DNB flux in a non-uniform heat flux channel, the following two steps are required:

1. The uniform DNB heat flux, $q''_{DNB,\ EU}$, is computed with the W-3 or WRB-1 correlation using the specified local reactor conditions.

2. This equivalent uniform heat flux is converted into corresponding non-uniform DNB heat flux, $q''_{DNB,N}$, for the non-uniform flux distribution in the reactor. The non-uniform DNB heat flux, $q''_{DNB,N}$, is given by:

$$q''_{DNB,\ N} = \frac{q''_{DNB,\ EU}}{F}$$

The DNB heat flux ratio is defined as:

$$DNBR = \frac{q''_{DNB,\ N}}{q''_{loc}}$$

where q''_{loc} is the actual local heat flux.

To calculate the minimum DNBR of a reactor coolant flow channel, the values of $(q''_{DNB,N})/(q''_{loc})$ along the channel are evaluated and the minimum value is selected as the minimum DNBR in that channel.

The W-3 and WRB-1 correlations depend on both local conditions and inlet enthalpies of the actual system fluid. Thus, the minimum DNBRs calculated with the correlations provide a measure of the margin on heat flux when compared to the DNBR design limits.

3.4.3 Thermal/Hydraulic Evaluation

3.4.3.1 Core Analysis

The basic objective of core thermal-hydraulic analysis is to verify that safety limits established by departure from nucleate boiling (DNB) concerns are met. Thermal-hydraulic design parameters are presented in Table 3.4-1. DNB, which could occur on the heating surface of the fuel rod, is characterized by sudden decrease in the heat transfer coefficient with corresponding increase in the surface temperature. DNB is of concern in reactor design because of the possibility of fuel cladding rod failure resulting from the increased temperature.

In order to preclude potential DNB related fuel damage, a design basis is established and is expressed in terms of a minimum departure from nucleate boiling ratio (MDNBR). DNBR is the ratio of the predicted heat flux at which DNB occurs (i.e., the critical heat flux, CHF) and the local heat flux of the fuel rod. By imposing a design DNBR limit, adequate heat transfer between the fuel cladding and the reactor coolant is assured. DNBRs greater than the design limit indicate the existence of thermal margin within the nuclear core. Thus, the purpose of core thermal-hydraulic analysis, or DNB analysis, is the accurate calculation of DNBRs in order to assess and quantify core thermal margin.

In performing DNB analysis, a subchannel approach is commonly used wherein a section of the core is modeled as an array of adjoining subchannels. Each subchannel is defined as the flow channel formed by four fuel rods, or by three fuel rods and a guide thimble tube. When the fuel rods are given design radial and axial power distributions, the array represents the region of maximum design power generation. Within this array, the hottest subchannel (hot channel) is identified with the fuel rod which has the highest integrated power (hot fuel rod). Engineering uncertainties are applied to the hot channel and the hot fuel rod in order to conservatively account for manufacturing tolerances. A detailed thermal analysis of the core is then performed to determine the flows and enthalpies at each axial position within the hot channel.

When performing the thermal analysis, it is necessary to consider the effect that the surrounding core region has on the subchannel flows. The problem is basically one of integrating the relatively small subchannel geometry into a larger geometry which is representative of the entire core. Traditionally, the problem has been solved by using a multistage method involving at least two analyses. A core analysis is first performed to provide crossflow boundary conditions which are used in the subsequent subchannel analysis. In the core analysis, each fuel assembly is modeled as a single, lumped flow channel. In the subchannel analysis, the hot assembly is modeled separately as an array of subchannels. Hot assembly crossflows determined in the first analysis are used as boundary conditions in the second analysis in order to simulate the effects of the core on the subchannel flows. The original Surry thermal-hydraulics design code, THINC (Reference 8), is a multistage code.

An alternate, more direct approach for performing the thermal analysis is a single stage method. Using this method, a single analysis is performed in which an array of subchannels representing the hot assembly is combined with an array of lumped channels which represent the remaining assemblies within a core segment. Using this single geometry, boundary conditions are not required since the effect of the core is inherently included when computing the subchannel flows. Although single stage analyses have been performed previously, the thermal-hydraulic codes then in existence were capable of handling only a limited number of channels. This necessitated coarse simulations of the core consisting of only a few subchannels together with very large lumped channels representing many assemblies. However, the development of the COBRA IIIC/MIT computer code (Reference 24) has provided the capability to analyze geometries consisting of up to 200 channels. Thus, it is now possible to perform single stage thermal analyses using the same radial nodalization as used in the traditional multistage analyses.

This concept has been applied by Virginia Electric and Power Company (Vepco) in the development of a core thermal-hydraulics analysis capability. This capability is based upon a single stage analysis which incorporates the geometries and methodologies used in multistage analyses. The accuracy of this approach has been verified through comparisons with analyses which were used in the design and licensing of the Surry Nuclear Power Station.

The COBRA IIIC/MIT computer code calculates the flow and enthalpy within interconnected flow channels by solving finite difference equations of continuity, energy, and momentum. The mathematical model is applicable to both steady state and transient conditions, and the model considers both turbulent mixing and diversion crossflow. In formulating the mathematical model, one-dimensional, two-phase, separated slip-flow was assumed to exist during boiling. The two-phase flow structure was assumed to be fine enough to allow specification of void fraction as a function of enthalpy, flow rate, heat flux, pressure, position and time. Sonic velocity propagation effects were not included. Within a channel, the diversion crossflow velocity was assumed to be small compared to the axial velocity. This assumption allowed the use of a simplified equation for the conservation of transverse momentum.

The equations are solved as a boundary value problem by using a semi-explicit finite difference scheme. The boundary conditions for the problem are in the inlet enthalpy, inlet mass velocity and exit pressure. The boundary value solution is obtained by assuming a uniform exit pressure distribution. (The equations do not require actual pressures since only pressure differences are used.) When performing a computation, the code iterates over the length of the core until convergence of the flow solution is obtained. Convergence is achieved when the change in any channel flow is less than a user specified fraction of the flow from the previous iteration.

The same finite difference equations are used for both steady state and transient computations. For steady state calculations, the time step, Δt, is set equal to an arbitrarily large value thereby negating the time dependent terms. For transient calculations, the time step is set equal to a user specified value. When performing a transient calculation, a steady state calculation is first performed to obtain initial conditions. Time dependent forcing functions consisting of inlet temperature, inlet flow, system pressure, and core average heat flux are used to establish boundary conditions at succeeding times. The calculation iterates over the first time step until the flow solution converges. The converged solution is then used as the initial conditions for the new time, and the procedure continues for all of the subsequent time steps.

Although the equations of continuity, energy and momentum form the basic structure of the mathematical model, their solution is still dependent upon the use of empirical correlations. Of major importance are the correlations used in calculating the pressure gradient and those used in calculating turbulent mixing. Once the flow solution is obtained, additional correlations are used in calculating the DNBR distribution. The COBRA IIIC/MIT computer code allows user specification of the appropriate correlations.

VIPRE-D (Reference 38) is the Dominion version of the computer code VIPRE (Versatile Internals and Components Program for Reactors - EPRI), developed for EPRI (Electric Power Research Institute) by Battelle Pacific Northwest Laboratories in order to perform detailed thermal-hydraulic, subchannel analyses to predict CHF and DNBR of reactor cores. VIPRE-01 has been approved by the U.S. Nuclear Regulatory Commission (USNRC). VIPRE-D, which is based upon VIPRE-01, was developed by Dominion to fit the specific needs of Dominion's nuclear plants and fuel products by adding vendor specific CHF correlations and customizing its input and output. Dominion, however, has not made any modifications to the NRC-approved constitutive models and algorithms in VIPRE-01.

The NRC has approved the use of the Vepco version of the COBRA-IIIC/MIT code (Reference 24) and the VIPRE-D code (Reference 38) as alternative approaches for performing reactor core thermal-hydraulic analysis.

3.4.3.2 **Application of DNB Correlations in Design**

The WRB-1 and W-3 CHF correlations are used for the calculation of DNBRs in Westinghouse 15 x 15 SIF fuel assemblies. The WRB-1 CHF correlation is applicable to the operating conditions for which the Statistical DNBR Evaluation Methodology applies. The W-3 correlation is only used below the first mixing grid or when the operating conditions are outside of the range of validity of the WRB-1 CHF correlation, such as the main steam-line break evaluation, where there are reduced temperature and pressure. The W-3 CHF correlation is always used deterministically. COBRA IIIC/MIT is used to determine the local conditions for the DNB evaluation of the 15 x15 SIF. Table 3.2-1 list the DNBR limits for application of WRB-1 and W-3 correlations with COBRA IIIC/MIT.

The WRB-1, W-3, ABB-NV, and WLOP CHF correlations are used for the calculation of DNBRs in Westinghouse 15 x15 Upgrade fuel assemblies. The WRB-1 CHF correlation is applicable to the operating conditions for which the Statistical DNBR Evaluation Methodology applies. The W-3 or ABB-NV correlation is used below the first mixing grid. The W-3 or WLOP correlation is used when the operating conditions are outside of the range of validity of the WRB-1 CHF correlation, such as the main steam-line break evaluation, where there are reduced temperature and pressure. The W-3, ABB-NV and WLOP CHF correlations are always used deterministically. VIPRE-D is used to determine the local conditions for the DNB evaluation of the Westinghouse 15 15 Upgrade fuel. Table 3.2-1 list the DNBR limits for application of WRB-1, W-3, ABB-NV, and WLOP correlations with VIPRE-D.

During steady-state operation at the nominal design conditions, the values of the DNBR are determined. Under adverse operating conditions, particularly overpower transients, more limiting conditions develop than those existing during steady-state operation.

For transients which are analyzed with a deterministic treatment of key DNBR analysis uncertainties, initial conditions are obtained by combining maximum steady-state errors with nominal values. The following steady-state errors are considered:

1. Core Power +2 percent calorimetric error allowance
2. Average Reactor Coolant System (RCS) temperature +4°F controller deadband and measurement error allowance
3. Pressurizer pressure ±30 psi steady-state fluctuations and measurement error allowance
4. Reactor flow Thermal design flow

Initial values for core power, average reactor coolant system temperature, and pressurizer pressure are selected to minimize the initial DNBR unless otherwise stated in the sections describing specific accidents (See Chapter 14).

The ranges of permissible initial reactor operating conditions of core flow rate, system temperatures and system pressure are stated in the Technical Specifications for Surry Power Station.

For transients which are analyzed under the Virginia Power *Statistical DNBR Evaluation Methodology* (Reference 30), nominal values are used for the initial conditions in the transient analysis. The use of the Statistical DNBR Evaluation Methodology does not require that the uncertainties be applied in the initial conditions since these uncertainties are statistically incorporated in the statistical design limit (see Section 3.2.3.3). The Statistical DNBR Evaluation Methodology is employed on a transient specific basis (See Section 3.2.3.3) as indicated in the transient analysis summaries in Chapter 14.

3.4.3.3 **Effects of Departure From Nucleate Boiling on Neighboring Rods**

DNB propagation would occur when a rod in DNB which is above system pressure is assumed to balloon at the location of DNB and contact an adjacent rod which would then experience DNB due to local flow blockage. The design basis precludes extensive DNB propagation and associated fuel failures. The design basis for this criterion is that no increase in fuel failures due to DNB propagation will occur in cores that have fuel rods operating with rod internal pressure in excess of system pressure. The design limit for Condition II events is that DNB propagation is not extensive, that is, the process is shown to be self-limiting and the number of rods in DNB and above system pressure is less than 1 rod. For Condition III/IV events, it is shown that the best estimate total fraction of rods in the core that are in DNB, including the effects of DNB propagation, for a specific event is less than the calculated fraction of rods violating the DNBR for that event.

3.4.3.3.1 Departure From Nucleate Boiling With Physical Burnout

Westinghouse (Reference 12) has conducted DNB tests in a 25-rod bundle where physical burnout occurred with one rod. After this occurrence, the 25-rod test section was used for several days to obtain more DNB data from the other rods in the bundle. The burnout and deformation of the rod did not affect the performance of neighboring rods in the test section during the burnout, or the validity of the subsequent DNB data points as predicted by the W-3 correlation. No occurrences of flow instability or other abnormal operation were observed.

3.4.3.3.2 Departure From Nucleate Boiling With Return to Nucleate Boiling

Additional DNB tests were conducted by Westinghouse (Reference 13) in 19-rod and 21-rod bundles. In these tests, departure from nucleate boiling without physical burnout was experienced more than once on single rods in the bundles for short periods of time. Each time, a reduction in power of approximately 10% was sufficient to reestablish nucleate boiling on the surface of the rod. During these and subsequent tests, no adverse effects were observed on this rod or any other rod in the bundle as a consequence of operating in departure from nucleate boiling.

3.4.3.4 **Hydrodynamic and Flow Power Coupled Instability**

Boiling flows may be susceptible to thermal-hydraulic instabilities (Reference 14). These instabilities are undesirable in reactors because they may cause a change in thermal-hydraulic conditions that may lead to a reduction in the DNB heat flux relative to that observed during a steady flow condition or to undesired forced vibrations of core components. Therefore; a thermal-hydraulic design criterion was developed which states that modes of operation under Condition I and II events will not lead to thermal-hydrodynamic instabilities.

Two specific types of flow instabilities are considered for Westinghouse PWR operation. These are the Ledinegg or flow excursion type of static instability and the density wave type of dynamic instability.

A Ledinegg instability involves a sudden change in flow rate from one steady state to another. This instability occurs when the slope of the Reactor Coolant System pressure drop-flow rate curve ($d\Delta P/dG$ internal) becomes algebraically smaller than the loop supply (pump head) pressure drop-flow rate curve ($d\Delta P/dG$ external). The criterion for stability is $d\Delta P/dG$ internal > $d\Delta P/dG$ external. The Westinghouse pump head curve has a negative slope ($d\Delta P/dG$ external < 0), whereas the Reactor Coolant System pressure drop-flow curve has a positive slope

($d\Delta P/dG$ internal > 0) over the Condition I and Condition II operational ranges. Thus, the Ledinegg instability will not occur.

The mechanism of density wave oscillations in a heated channel has been described by Lahey and Moody (Reference 15). Briefly, an inlet flow fluctuation produces an enthalpy perturbation. This perturbs the length and the pressure drop of the single-phase region and causes quality or void perturbations in the two-phase regions which travel up the channel with the flow. The quality and length perturbations in the two-phase region create two-phase pressure drop perturbations. However, because the total pressure drop across the core is maintained by the characteristics of the fluid system external to the core, the two-phase pressure drop perturbation feeds back to the single phase region. These resulting perturbations can be either attenuated or self-sustained. A simple method has been developed by Ishii (Reference 16) for parallel closed channel systems to evaluate whether a given condition is stable with respect to the density wave type of dynamic instability. This method has been used to assess the stability of typical Westinghouse reactor designs under Condition I and II operation. The results indicate that a large margin to density wave instability exists; for example, increases on the order 150 to 200 percent of rated reactor power would be required for the predicted inception of this type of instability.

The application of Ishii's method (Reference 16) to Westinghouse reactor designs is conservative because of the parallel open channel feature of Westinghouse PWR cores. For such cores, there is little resistance to lateral flow leaving the flow channels of high power density. There is also energy transfer from high power density channels to lower power density channels. This coupling with cooler channels causes an open channel configuration to be more stable than the above closed channel configuration under the same boundary conditions. Flow stability tests (References 17 and 39) have been conducted in which the closed channel systems were shown to be less stable than when the same channels were cross-connected at several locations. The cross-connections were such that the resistance to channel-to-channel crossflow and enthalpy perturbations would be greater than that which would exist in a PWR core which has a relatively low resistance to crossflow.

Flow instabilities, which have been observed, have occurred almost exclusively in closed channel systems operating at low pressures relative to the Westinghouse PWR operating pressures. Kao, Morgan and Parker (Reference 18) analyzed parallel closed channel stability experiments simulating a reactor core flow. These experiments were conducted at pressures up to 2200 psia. The results showed that for flow and power levels typical of power reactor conditions, no flow oscillations could be induced above 1200 psia. Additional evidence that flow instabilities do not adversely affect thermal margin is provided by the data from the rod bundle DNB tests. Many Westinghouse rod bundles have been tested over wide ranges of operating conditions with no evidence of premature DNB or of inconsistent data which might indicate flow instabilities in the rod bundle.

In summary, it is concluded that thermal-hydrodynamic instabilities will not occur under Condition I and II modes of operation for Westinghouse PWR reactor designs. A large power margin exists to predicted inception of such instabilities. Analysis has been performed which shows that minor plant-to-plant differences in Westinghouse reactor designs - such as fuel assembly arrays, core power to flow ratios, and fuel assembly length - will not result in gross deterioration of the above power margins.

3.4.3.5 **Fuel Rod Bow**

Rod bowing in excess of that originally expected was observed in Westinghouse 15 x 15 low parasitic (LOPAR) fuel assemblies. Based on these observations, Westinghouse developed an empirical model to conservatively predict rod bow. Westinghouse used the model to analyze the impact of increased rod bow on the DNBR. The conclusion was that the impact of rod bow could be accommodated by existing design margins, and reactor safety was not affected. This information was formally submitted for NRC generic review in January 1976 (Reference 19).

Several inherent design margins were generically associated with Westinghouse DNBR analyses of LOPAR fuel, and were used to accommodate the increased rod bowing as discussed in Reference 19. The LOPAR conservatisms include:

1. Axial heat flux spikes.
2. Better data correlation resulting in a 95 × 95 confidence level DNBR limit of 1.24 versus the original limit of 1.30.
3. Pitch reduction modeling.
4. Assumed thermal diffusion coefficient (TDC) values.

Further testing by Westinghouse of selected rods (for a thimble cell) bowed into contact indicated that the inherent design margins identified above could not offset the DNBR reduction being seen. As a result, penalties on $F\Delta H$ were required by the NRC (Reference 20).

Based on more recent test data obtained and evaluated by Westinghouse, the appropriate reductions in $F\Delta H$ (or DNBR) resulting from fuel rod bow during irradiation were determined to be significantly less than those accommodated in the Technical Specifications as a result of Reference 20. The more recent tests were concerned with the determination of the DNBR reduction due to rod bow when selected rods (forming a thimble cell) were bowed to 85% channel closure. As documented in References 19, 20, and 21, the 85% channel closure would not be exceeded, on a 95 × 95 basis, for a region of fuel up to 33,000 MWD/MTU (the nominal region average discharge burnup). The DNBR reduction associated with the 85% channel closure tests was found to be 11.7% for 15 x 15 LOPAR fuel (Reference 21). The 11.7% DNBR reduction was more than completely offset by existing thermal margins in the core design. The inherent thermal margins previously delineated for the 15 x 15 LOPAR fuel provided thermal margins in excess of 18%. Therefore, the appropriate reduction in $F\Delta H$ due to rod bow was determined to be zero at all operating conditions for the Surry Power Stations (Reference 22). The NRC subsequently approved this position (Reference 23).

More recently, Westinghouse employed a revised rod bow evaluation methodology (Reference 25) to significantly reduce the required rod bow penalty. NRC approval (Reference 26) of Reference 25 permitted Virginia Electric and Power Company to apply the reduced penalty in DNBR evaluation, thus freeing most of the available retained DNBR margin for other uses. No Technical Specification changes were required, but the NRC was notified (Reference 27) in an information letter of Virginia Power's use of the reduced penalty. The NRC, subsequently, approved a further reduction in the maximum applicable burnup from 33,000 to 24,000 MWD/MTU (Reference 28).

The rod bow behavior of the 15 x 15 SIF assemblies and the mixing vane grid spans of the 15 x 15 Upgrade assemblies is predicted to be within the bounds of existing 15 x 15 LOPAR assembly rod bow data (Reference 36). The most probable causes of significant rod bow are rod-grid and pellet-clad interaction forces and wall thickness variation (WTV). The SIF assembly will have reduced grid forces (due to the greater irradiation-induced relaxation of the zirconium alloy grids) and the same fuel tube thickness-to-diameter ration (t/d) as the LOPAR assembly, which should tend to decrease SIF rod bow compared to LOPAR fuel. For a given burn-up, the magnitude of rod bow gap closure for the SIF assembly is conservatively taken to be the same as that applied to the 15 x 15 LOPAR fuel assembly.

In the upper spans of the 15 x 15 Upgrade fuel assemblies, additional restraint is provided with the intermediate flow mixer grids (IFMs) such that the grid-to-grid spacing in those spans with IFMs is approximately 13 inches compared to the approximately 26 inches in the other spans. Using the NRC approved scaling factor (References 25 and 28), results in predicted channel closure in the limiting 13 inch spans of less than 50 percent closure. Therefore, no rod bow penalty is required in the 13 inch spans in safety analysis.

The available retained DNBR margin (see Section 3.2.3.3) is used to accommodate DNB penalties due to fuel rod bowing.

3.4.3.6 **Transition Core DNB Methodology**

The Westinghouse transition core DNB methodology is given in Reference 40. Using this methodology, transition cores are analyzed as if the entire core consisted of one assembly type. The resultant DNBRs are then reduced by the appropriate transition core penalty.

The 15 x 15 SIF fuel assembly has a higher mixing vane grid loss coefficient relative to the Upgrade mixing vane grid loss coefficient. The 15 x 15 Upgrade fuel assembly has Integral Flow Mixer (IFM) grids located in spans between mixing vane grids, where no grid exists in the 15 x 15 SIF assembly. The higher loss coefficients and the additional grids introduce localized flow redistribution between the fuel assemblies at various axial zones in a transition core. Because the localized flow redistribution results in reduced flows to both fuel types at various axial locations, transition core penalties are applied to both fuel types. The transition core DNBR penalties are functions of the number of each fuel assembly type in the core, Reference 40. Sufficient DNBR margin (see Section 3.2.3.3) is maintained in the safety analysis to offset the transition core penalties.

Table 3.4-1
THERMAL/HYDRAULIC DESIGN PARAMETERS

	Current Operation
Total core heat output	2587 MWt
Total core heat output	8829×10^6 Btu/hr
Heat generated in fuel	97.4%
Maximum thermal overpower	118%
Nominal system pressure	2250 psia
Coolant flow	
Total flow rate	265,500 gpm
Total flow rate at inlet	101.2×10^6 lb/hr
Average velocity along fuel rods	13.3 ft/sec
Average mass flux	2.27×10^6 lb/hr-ft^2
Core bypass flow	6% (Unit 2), 6.7% (Unit 1) (3)
Coolant temperature	
Nominal inlet, °F	539.9
Average rise in vessel	66.2
Average rise in core	70.0
Average in core	576.6
Average in vessel	573.0
Average core discharge	609.9
Average vessel discharge	606.1
Heat transfer	
Active heat transfer surface area	42,460 ft^2
Average heat flux	202,500 Btu/hr-ft^2
Average linear power	6.56 kW/ft
Peak linear power for normal operation	16.4 kW/ft (1)
Pressure drop	
Across core	22.8 psi (2)
Across vessel, including nozzles	43.4 psi (2)
DNBR Correlation	WRB -1 (SIF, Upgrade)

1. Based on FQ of 2.50.
2. These are nominal pressure drops for 15 x 15 Upgrade Fuel and are based on a best estimate flow of 294,900 gpm. The pressure drops for 15 x 15 SIF are 23.8 psi (core) and 44.4 psi (vessel).
3. Unit 1 core bypass flow from Reference 43.

3.5 MECHANICAL DESIGN

The reactor core cross section and reactor vessel internals are shown in Figures 3.5-1 and 3.5-2, respectively. The core, consisting of the fuel assemblies, control rods, source rods, and guide thimble plugging devices, provides and controls the heat source for reactor operation. The internals, consisting of the upper and lower core support structure, are designed to support and orient the fuel assemblies and control rod assemblies, direct the coolant flow to and from the core components, and support and guide the incore instrumentation. A listing of the mechanical design parameters of the initial cores is given in Table 3.5-1.

The fuel assemblies are arranged in a roughly circular cross-sectional pattern. The assemblies within a region are identical in configuration, but contain fuel of different enrichments depending on the location of the assembly within the core. Small differences may exist between different regions of fuel, as new design features are incorporated into reload fuel assemblies. The fuel is in the form of slightly enriched uranium dioxide ceramic pellets. The pellets are stacked to an active height of 144 inches within Zircaloy-4, ZIRLO, or Optimized ZIRLO tubular cladding, which is then plugged and seal-welded at the ends to encapsulate the fuel.

The core is divided into regions of several different enrichments. The loading arrangement for the initial cycle is indicated on Figure 3.5-3. Refueling generally takes place in accordance with an in-out movement schedule. The enrichments of the fuel for the three fuel regions in the first core cycle are given in Table 3.5-1. Limitations on the enrichment of reload fuel are provided in the Technical Specifications.

The fuel rods of all regions are internally pressurized with helium during fabrication. Heat generated by the fuel is removed by demineralized borated light water, which flows upward through the fuel assemblies and acts as both moderator and coolant.

The control rod assemblies consist of groups of individual control rods supported by a spider at the top end and thereby actuated as a group. In the inserted position, the control rods fit within hollow guide thimbles in the fuel assemblies. The guide thimbles are an integral part of the fuel assemblies and occupy locations within the regular fuel assembly pattern where fuel rods have been deleted. In the withdrawn position, the control rods are guided and supported laterally by guide tubes forming an integral part of the upper core support structure. Figure 3.5-4 shows the typical fuel assembly structural components and a control rod assembly. The relative positions of the control rods in a fuel assembly are shown in Figure 3.5-5.

As shown in Figure 3.5-2, the fuel assemblies are positioned and supported vertically in the core between the upper and lower core plates. The core plates are provided with pins that index into closely fitting mating holes in the fuel assembly top and bottom nozzles. The pins maintain the fuel assembly alignment, permitting free movement of the control rods.

Operational or seismic loads imposed on the fuel assemblies are transmitted through the core plates to the upper and lower core support structures. Vertical loads are transmitted to the internals support ledge at the pressure vessel flange. Horizontal loads are transmitted to the lower radial support and internals support ledge. The internals also provide a form-fitting baffle surrounding the fuel assemblies, confining the upward flow of most of the coolant in the core area to the fuel-bearing region.

3.5.1 Reactor Internals

The reactor internals are designed to support and orient the fuel assemblies and control rod assemblies. The internals also absorb the control rod assembly dynamic loads and transmit these and other loads to the reactor vessel flange, provide a passageway for the reactor coolant, and support incore instrumentation. The reactor internals are shown in Figure 3.5-2. The internals are designed to withstand the combination of forces due to weight, preload of fuel assemblies, differential hydraulic pressure, control rod assembly dynamic loading, vibration, and earthquake acceleration. The internals were analyzed similarly to those of Connecticut Yankee (Haddam Neck), San Onofre, Jose Cabrera (Spain), Saxton, and Yankee (Rowe). The structure satisfies stress values prescribed in the ASME Code, Section III, Nuclear Vessels. The dynamic criteria for design and the stress levels of the internals in each unit are similar to those used for Connecticut Yankee.

The Surry Unit 1 reactor internals have been modified to change the flow path of the reactor coolant from downflow between the core barrel and baffle plates to an upflow direction. This was accomplished by plugging the core barrel flow holes and creating new flow holes in the top former plate.

The internals are designed to the criteria stated in Chapter 15, including Appendix 15A.

The reactor internals are equipped with bottom-mounted incore instrumentation supports. These supports are designed to sustain the applicable loads outlined above.

In a hypothesized downward vertical displacement of the internals, energy-absorbing devices would limit the displacement by contacting the vessel bottom head. The load is transferred through the energy-absorbing devices to the vessel. The cylindrically shaped energy absorbers are contoured on their bottom surface to the reactor vessel bottom head geometry. Their number (four) and design are determined so as to limit the forces imposed to a safe fraction of yield strength. Assuming a downward vertical displacement, the potential energy of the system is absorbed mostly by the strain energy of the energy-absorbing devices.

In the unlikely event that the normal core support structure fails, the energy-absorbing devices would limit the fall of the core as well as absorb the energy of the drop which would otherwise be imparted to the vessel. The energy of fall was calculated assuming a complete and instantaneous failure of the primary core support and would be absorbed during the plastic deformation of a controlled volume of stainless steel, loaded in tension, in each device. The maximum deformation of this austenitic stainless piece would be limited to approximately 15%, after which a positive stop is provided to ensure support. Standard textbook calculations were used to derive the amount of strain.

The displacement in the hot condition is on the order of 0.5 inch, and there is an additional strain displacement in the energy-absorbing devices of approximately 0.75 inch. Alignment features in the internals prevent cocking of the internals structure during this postulated displacement so that the control rod assemblies are able to be inserted upon trip. The displacement distance of about 1.25 inches is not enough to cause the tip of any of the control rods to come out of the guide thimbles.

The components of the reactor internals are divided into three parts, consisting of the lower core support structure, including the entire core barrel and thermal shield, the upper core support structure, and the incore instrumentation support structure.

3.5.1.1 **Lower Core Support Structure**

The major containment and support member of the reactor internals is the lower core support structure, shown in Figure 3.5-6. This support structure assembly consists of the core barrel, the core baffle, the lower core plate and support columns, the thermal shield, the intermediate diffuser plate, and the bottom support plate, which are welded to the core barrel. All the major material for this structure is type 304 stainless steel. The core support structure is supported at its upper flange from a ledge in the reactor vessel head flange, and its lower end is restrained in the transverse direction by a radial support system attached to the vessel wall. Within the core barrel are axial baffle and former plates, which are attached to the core barrel wall and form the enclosure of the assembled core. The lower core plate is positioned at the bottom level of the core below the baffle plates, and provides support and orientation for the fuel assemblies.

The lower core plate is perforated for flow purposes, and contains the lower locating pins for the fuel assemblies. Columns are placed between this plate and the bottom support plate of the core barrel in order to stiffen this plate and transmit the core load to the bottom support plate.

An intermediate perforated diffuser plate is placed between the bottom support plate and the lower core plate to uniformly diffuse coolant flowing into the core.

The one-piece thermal shield is fixed to the core barrel at the top with rigid bolted connections. The bottom of the thermal shield is connected to the core barrel by means of six axial flexures. This number is consistent with the number of flexures used on other three-loop plants. This bottom support allows for differential axial growth of the shield with respect to the core barrel, but restricts radial or horizontal movement of the bottom of the shield.

The adequacy of the flexures has been evaluated and verified utilizing the information gained from the instrumentation of the thermal shield during the hot-functional test of the three-loop H. B. Robinson Unit 2 reactor. This study was performed by correlating the hot-functional data with tests performed on thermal shields in the manufacturing facilities (determination of normal modes, natural frequency and flexure stresses). The result of these analyses indicates an adequate margin based on the criteria of Section III of the ASME Code.

In the event of a failure of the flexures, the thermal shield will remain fixed at the top and will become free at the bottom. Mechanical shaker tests performed on actual thermal shields indicate that the vibration effects will not affect the structural adequacy of the thermal shield support, with stress levels remaining within the limits of Section III of the ASME Code.

Irradiation baskets in which encapsulated materials samples can be inserted and irradiated during reactor operation are attached to the outer side of the thermal shield (Section 4.1.7).

The lower core support structure, consisting principally of the core barrel, serves to provide passageways and control for the coolant flow. Inlet coolant flow from the vessel inlet nozzles proceeds down the annulus between the core barrel and the vessel wall, on both sides of the thermal shield, and into a plenum at the bottom of the vessel. It then turns and flows up through the bottom support plate, passes through the intermediate diffuser plate and then through the lower core plate. The flow holes in the diffuser plate are arranged to prevent gross inlet flow maldistribution to the core. After passing through the core, the coolant enters the area of the upper support structure and then generally flows radially to the core barrel outlet nozzles and directly through the vessel outlet nozzles.

A small amount of water also flows between the baffle plates and core barrel to provide additional cooling of the barrel. Similarly, a small amount of the entering flow is directed into the vessel head plenum and exits through the vessel outlet nozzles.

Downward-directed loads from weight, fuel assembly preload, control rod assembly dynamic loading, and earthquake acceleration are carried by the lower core plate partially into the lower core plate support flange on the core barrel and partially through the lower support columns into the bottom support plate. Finally, the load enters through the core barrel and ends in the core barrel flange supported by the vessel head flange. Transverse loads are carried by the core barrel to be shared by the lower radial support and the vessel head flange. Loads resulting from transverse acceleration of the fuel assemblies are transmitted to the core barrel by connections of the lower core support plate and a radial support-type connection of the upper core plate, as shown in Figure 3.5-7.

The main radial support system for the lower end of the core barrel is accomplished by “key” and “keyway” joints to the reactor vessel wall. At four equally spaced points around the circumference, Inconel blocks are welded to the vessel inside wall. Each of these blocks has a “keyway” geometry. Opposite each of these is a “key” that is attached to the barrel. During assembly, as the internals are lowered into the vessel, the keys engage the keyways in the axial direction. With this design, the internals are provided with a support at their extremities, and may be viewed as a beam fixed at the top and simply supported at the bottom.

Radial and axial expansions of the core barrel are accommodated, but transverse movement of the core barrel is restricted by this design. Cycle stresses in the internal structures are within the limits of ASME Code Section III, thus eliminating any possibility of failure of the core support.

3.5.1.2 **Upper Core Support Assembly**

The upper core support assembly, shown in Figure 3.5-7, consists of the top support plate, deep beam sections, upper core plate, support columns, and guide tube assemblies. The support columns establish the spacing between the top support plate, deep beam sections, and the upper core plate, and are fastened at top and bottom to these plates and beams. The support columns transmit the mechanical loadings between the two plates. The guide tube assemblies, shown on Figure 3.5-8, sheath and guide the control rod assembly drive shafts and control rod assembly, and provide no other mechanical functions. They are fastened to the top support plate and are guided by pins in the upper core plate for proper orientation and support. Additional guidance for the control rod assembly drive shafts is provided by the control rod assembly shroud tube, which is attached to the upper support plate and guide tube.

The upper core support assembly, which is removed as a unit during the refueling operation, is positioned in its proper orientation with respect to the lower support structure by flat-sided pins pressed into the core barrel, which in turn engage in slots in the upper core plate. At an elevation in the core barrel where the upper core plate is positioned, the flat-sided pins are located at equal angular positions. Slots are milled into the core plate at the same positions. As the upper support structure is lowered into the main internals, the slots in the plate engage the flat-sided pins in the axial direction. Lateral displacement of the plate and of the upper support assembly is restricted by this design.

Fuel assembly locating pins protrude from the bottom of the upper core plate and engage the fuel assemblies as the upper core support assembly is lowered into place. Proper alignment of the lower core support structure, the upper core support assembly, and the fuel and control rod assemblies is ensured by this guidance arrangement. The upper core support assembly is restrained from any axial movements by a large circumferential spring located between the upper barrel flange and the upper core support assembly. This spring is compressed by the reactor vessel head flange when the closure bolts are tightened.

Vertical loads from hydraulic loads, earthquake acceleration, and fuel assembly preload are transmitted through the upper core plate via the support columns to the deep beams and top support plate to the reactor vessel head. Transverse loads from coolant cross flow, earthquake acceleration, and possible vibrations are distributed by the support columns to the top support plate and upper core plate. The top support plate is particularly stiffened to minimize deflection.

3.5.1.3 **Incore Instrumentation Support Structures**

The incore instrumentation support structure consists of bottom mounted instrumentation thimble guides that carry the retractable flux thimble thermocouples through the bottom of the vessel. The flux thimble thermocouples consist of a detector path to allow measurement of neutron flux and thermocouples to measure core exit temperature.

Conduits extend from the bottom of the reactor vessel down through the primary concrete shield area and up to a thimble seal table. The trailing ends of the thimbles at the seal table are extracted approximately 15 feet during refueling of the reactor in order to avoid interference within the core. The thimbles are closed at the leading ends and serve as the pressure barrier between the reactor pressurized water and the containment atmosphere.

Mechanical seals between the retractable thimbles and the conduits are provided at the seal table. During normal operation, the retractable thimbles are stationary and are retracted only during refueling or for maintenance. Chapter 7 contains more information on the layout of the incore instrumentation system.

The incore instrumentation support structure is designed for adequate support of instrumentation during reactor operation, and for resisting damage or distortion during refueling.

3.5.1.4 **Evaluation of Core Barrel and Thermal Shield**

The core internals design is based on the experience gained from previous analyses, tests, and operational results. Data from previous Westinghouse pressurized water reactors was evaluated, and information derived was considered in the Surry design. For example, Westinghouse used a one-piece thermal shield that is attached rigidly to the core barrel at one end and permitted to flex at the other. The earlier designs were multi-piece thermal shields that rested on vessel lugs and were not rigidly attached to the top.

Early core barrel designs employed threaded connections, such as tie rods, that joined the bottom support to the bottom of the core barrel, and a bolted connection that attached the core barrel to the upper barrel. Such designs were associated with thermal shield oscillation, which created forces on the core barrel. Other forces were induced by unbalanced flow in the lower plenum of the reactor. In subsequent control rod assembly designs, fuel followers and a large bottom plenum in the reactor have not been required.

The reactor core barrel incorporates improvements based on the Connecticut Yankee (Haddam Neck) and the Jose Cabrera (Spain) reactor core barrels. Deflection-measuring devices employed in the Connecticut Yankee and the Jose Cabrera reactors during hot-functional testing, and strain gauges employed in the Jose Cabrera reactor, provided important information for use in the design of the internals. Careful inspections of Connecticut Yankee and Jose Cabrera reactor internals such as structural welds, nozzle interfaces, upper core plate supports, and thermal shield attachments uncovered no defects.

Substantial scale model testing was performed by Westinghouse. These tests included a complete full-scale fuel assembly operating at reactor flow, temperature, and pressure conditions. Tests were also run on a one-seventh scale model of the Indian Point Unit 2 reactor. Results of these tests indicated movement of only a few mils at full scale. Strain gauge measurements taken on the core barrel also indicated very low stresses. Testing to determine thermal shield excitation due to inlet flow disturbances was also performed. Information gathered from these tests was then used in the design of the thermal shield and core barrel.

3.5.2 Core Components

3.5.2.1 Fuel Assembly

All of the fuel assemblies prior to Batch 12 (also referred to as Region 12) of both Surry units were of the 15 x 15 LOPAR design. Fuel assemblies from Batches 12 through 26 (Unit 1) and Batches 12 through 25 (Unit 2) are of the 15 x 15 SIF design. Fuel assemblies from Unit 1 Batch 27 and Unit 2 Batch 26 and subsequent Batches are of the 15 x 15 Upgrade design. The LOPAR, SIF, and 15 x 15 Upgrade assemblies are of similar design, and their overall configurations are shown in Figure 3.5-9. A comparison of nominal design features of the 15 x 15 LOPAR, 15 x 15 SIF, and 15 x 15 Upgrade assemblies is found in Table 3.5-3. The assemblies are square in cross section, nominally 8.426 inches on a side, and have a fuel column nominal height of 144 inches. The overall height of the 15 x 15 LOPAR assembly is 159.71 inches, while the overall height of the Zircaloy SIF and 15 x 15 Upgrade assemblies is 159.975 inches. The overall height of the ZIRLO SIF ranges from 159.775 inches to 159.975 inches.

Beginning with Batch 16 at both units, the Surry fuel assemblies include fuel rod cladding, guide thimbles, instrumentation tubes and mixing vane grids fabricated from ZIRLO (Reference 8). This advanced zirconium alloy was incorporated to improve the corrosion resistance of the fuel. ZIRLO is also dimensionally more stable than Zircaloy under irradiation, but most other properties (e.g., yield strength) are very similar to Zircaloy-4. Minor changes to some as-built dimensions (e.g., fuel rod length) were made to reflect the different behavior of the ZIRLO alloy. The as-built fuel assembly length was decreased slightly (to approximately 159.8 inches, between the LOPAR and Zircaloy-4 SIF assembly lengths) to allow for assembly growth to higher burnups. The fuel assembly envelope dimensions remained unchanged.

Additional changes to the fuel design introduced with 15 x 15 Upgrade include guide thimble tube-in-tube dashpots, balanced vane structural mid-grids, three non-structural Intermediate Flow Mixing grids (IFMs), shorter fuel rod end plugs than those used in later batches of SIF fuel (discussed below), and an oxide coating on the lower portion of the fuel rod cladding. A comparison of the 15 x 15 Upgrade and SIF designs (Figure 3.5-17) shows the addition of the IFMs and the relative grid heights.

The 15 x 15 Upgrade fuel rod cladding is fabricated of Optimized ZIRLO. (The 15 x 15 Upgrade guide thimbles, instrumentation tubes, mixing vane grids, and Intermediate Flow Mixing grids are fabricated of ZIRLO.) Optimized ZIRLO is incorporated to further reduce the fuel clad corrosion rate while maintaining the composition and physical properties, such as mechanical strength, similar to standard ZIRLO.

The fuel rods in a LOPAR, SIF, and 15 x 15 Upgrade fuel assembly are arranged in a square array with 15 rod locations per side and a nominal centerline-to-centerline pitch of 0.563 inch between rods. Of the total possible 225 rod locations per assembly, 20 are occupied by guide thimbles for the control rods and burnable poison rods, and one central thimble is reserved for incore instrumentation. The remaining 204 locations contain fuel rods. In addition to fuel rods, a fuel assembly also includes a top nozzle, a bottom nozzle, and seven structural grid assemblies. The five structural (mixing vane) mid-grids on the SIF assemblies are Zircaloy or ZIRLO and on the 15 x 15 Upgrade assemblies are ZIRLO, while the two end grids are Inconel. The 15 x 15 Upgrade assemblies also add three IFMs, fabricated of ZIRLO, located in the hottest spans between structural grids. The IFM region is located between the third and sixth mid-grids, where each IFM is located between mid-grids as shown in Figure 3.5-17. The IFMs do not provide structural support for the assembly. All seven grids on the LOPAR assembly are made of Inconel.

Beginning with Region 15, a protective Inconel grid was added directly above the bottom nozzle to enhance debris resistance. Some minor changes to the fuel rod were also made in conjunction with use of the protective grid.

These include: use of a slightly longer bottom end plug which, together with repositioning the rods to directly above the bottom nozzle, ensures a solid metal interface between the protective grid and the fuel rod; and use of an external grip top end plug to facilitate rod positioning during manufacturing of assemblies with protective grids.

Further small dimensional changes were made to the fuel starting with Surry 2 Batch 20. The fuel assembly length was increased to match the Zircaloy-4 SIF design (159.975 inches) and the fuel rod length was increased by a comparable amount, as indicated in Table 3.5-3, to take advantage of the low growth rate of ZIRLO. The external grip feature was also removed from the fuel rod top end plug, slightly decreasing its length. These changes allowed use of a slightly longer bottom end plug on the fuel rods, to enhance debris resistance, as well as a minor increase in the fuel rod plenum volume, providing a small benefit for rod internal pressure analyses.

The 15 x 15 Upgrade design also incorporates these features, except it is equipped with the slightly shorter bottom end plug design that SIF fuel had prior to Surry Unit 1 Batch 21 and Surry Unit 2 Batch 20. The shorter bottom end plug increases the upper plenum length while retaining the overall fuel rod length and the active fuel length. However, this end plug design still ensures a solid metal interface between the protective grid and the fuel rod. Also, the outer part of the bottom end plug and weldment, and the bottom portion of the outer fuel cladding on the 15 x 15 Upgrade are oxidized to improve debris resistance.

Beginning with Batch 28, the Robust Protective Grid and modified Debris Filter Bottom Nozzle were incorporated into the 15 x 15 Upgrade assemblies. The Robust Protective Grid and modified debris Filter Bottom Nozzle provide enhanced debris filtering capabilities and improved resistance to fatigue failure.

Beginning with Batch 29, the Westinghouse Integral Nozzle (WIN) top nozzle design has been introduced in new Westinghouse fuel batches. This nozzle design eliminates threaded fasteners from the nozzle to reduce the risk of loose parts.

Beginning with Batch 33 for both units, the Westinghouse Conventional Manufactured Advanced Debris Filter Bottom Nozzle (ADFBN) replaced the modified Debris Filter Bottom Nozzle (mDFBN) on the 15x15 Upgrade fuel assembly design. The ADFBN design is similar to the mDFBN design as it has the same adapter plate flow hole design and flow hole pattern and thus has the same loss coefficient. The ADFBN design, however, lowered the side skirts to help improve the debris filtering capability of the bottom nozzle by eliminating the large lateral flow path between the bottom nozzle legs in the mDFBN design. Small flow holes were added to the new skirt to maintain flow to the baffle-former region while still reducing the overall lateral flow path available to debris.

The 21 guide thimbles, in conjunction with the grid assemblies and the top and bottom nozzles, comprise the basic structure of the fuel assembly. The top and bottom ends of the guide thimbles are fastened to the top and bottom nozzles, respectively. The grid assemblies are fastened to the guide thimbles at each location along the height of the fuel assembly at which lateral support for the fuel rods is required. The fuel rods are contained and supported, and the rod-to-rod centerline spacing is maintained along the assembly within this skeletal framework.

Fuel assemblies shall be limited to those fuel designs that have been analyzed with applicable NRC staff approved codes and methods and shown by tests or analyses to comply with all fuel safety design bases. Small numbers of demonstration or lead fuel assemblies which differ from the fuel described in Chapter 3 or that have not completed representative testing may be used in the Unit 1 or Unit 2 cores in non-limiting locations. These assemblies will be substantially the same as the fuel described in Chapter 3, but may incorporate some dimensional, material, or mechanical differences which would be described in the appropriate supporting licensing documentation (e.g. license amendment, exemption request, or 10 CFR 50.59 evaluation). The effects of operation with demonstration or lead assemblies will be assessed for each reload core in which they are irradiated to demonstrate that all reload safety requirements are satisfied. Demonstration assemblies with 17 rod locations per side in a square array have been used in the past in the Surry reactors. The assemblies were used to demonstrate the feasibility of extended discharge burn-ups. WCAP 8362 (Reference 1) concludes that the presence of 17 x 17 demonstration assemblies does not adversely affect reactor performance relative to an all 15 x 15 assembly core.

Reconstituted fuel assemblies, which contain small numbers of non-fueled solid zircaloy or stainless steel rods in the place of failed fuel rods, may be used in Surry reload cores. Assemblies which have low burnup and have been determined to contain failed rods may be reconstituted to allow for the continued utilization of the energy remaining in the fuel assembly. The non-fueled rods are manufactured from solid zircaloy or stainless steel, may be slightly oversize in diameter to compensate for grid spring relaxation and any grid degradation that may occur during failed rod removal, and have a tapered end to ease insertion and prevent grid damage. In Reference 5, NRC concurred that the presence of reconstituted assemblies does not adversely affect reactor performance or safety relative to a core containing no reconstituted assemblies.

3.5.2.1.1 Bottom Nozzle

The bottom nozzle is a square pedestal structure which controls the coolant flow distribution to the fuel assembly and functions as the bottom structural element of the fuel assembly. The nozzle is fabricated from stainless steel similar to type 304, and it consists of a perforated plate joined to four angle legs with pads or feet and side skirts which help support the legs and also help preclude debris from traveling around the bottom nozzle. The plate, legs and side skirts form a plenum space for the inlet coolant flow into the fuel assembly. The perforated plate serves as the bottom end support for the fuel rods. The bottom support surface for the fuel assembly is formed under the plenum space by the four pads at the bottom of the angle legs.

The guide thimbles, which carry axial loads imposed on the assembly, are fastened to the bottom nozzle plate. These loads, as well as the weight of the assembly, are distributed through the nozzle to the lower core support plate. Indexing and positioning of the fuel assembly in the core is fixed by two holes in diagonally opposite pads, which mate with two locating pins in the lower core plate. Lateral loads imposed on the fuel assembly are also transferred to the core support structures through the locating pins.

3.5.2.1.2 Top Nozzle

The top nozzle is a square box-like structure that functions as the fuel assembly upper structural element and forms a plenum space where the heated reactor coolant mixes and is directed toward the flow holes in the upper core plate. The nozzle is comprised of an adaptor plate, nozzle enclosure, top plate, two clamps, holddown springs, and assorted hardware. The LOPAR assemblies had single- or double-leaf holddown springs, while the SIF and 15 x 15 Upgrade assemblies have a three-leaf spring. All parts with the exception of the springs and their holddown bolts are constructed of stainless steel similar to type 304. The springs are made from age-hardenable Inconel 718, and the bolts from Inconel 600 or Inconel 718. Beginning with Batch 29, the Westinghouse Integral Nozzle (WIN) top nozzle design has been implemented on all new Westinghouse fuel assemblies. Holddown bolts were eliminated from the WIN design and replaced with retaining pins. The top nozzle and pins are also constructed of stainless steel similar to type 304. The WIN design uses a three-leaf spring made of the same material used in previous nozzle designs. The WIN is mechanically attached to the fuel assembly in the same way as the original SIF and 15 x 15 Upgrade removable top nozzle design.

The adaptor plate is square in cross-section, and is perforated by machined slots to provide for coolant flow through the plate. On LOPAR fuel assemblies, the top ends of the guide thimble adaptors are welded to the adaptor plate. In the original SIF and 15 x 15 Upgrade assembly removable top nozzle design, the guide thimble adaptors are mechanically attached to the adaptor plate as described in Reference 6. Thus, the adaptor plate, which acts as the fuel assembly top end plate, provides a means of distributing evenly among the guide thimbles any axial loads imposed on the fuel assemblies, and limits any excessive axial movement of fuel rods.

The nozzle enclosure is a square thin-walled shell that forms the plenum section of the top nozzle. The bottom end of the enclosure is welded to the periphery of the adaptor plate, and the top end joins the periphery of the top plate.

The top plate is square in cross-section, with a large central opening. The opening allows clearance for the control rods to pass into the guide thimbles in the fuel assembly, and provides for coolant exit from the fuel assembly into the upper internals area. Two pads containing axial through-holes, located on diametrically opposite corners of the top plate, provide a means of positioning and aligning the top of the fuel assembly. Like the bottom nozzle, alignment pins in the upper core plate mate with the holes in the top nozzle plate.

Holddown forces of sufficient magnitude to oppose the hydraulic lifting forces on the fuel assembly are obtained by means of the leaf springs, which are mounted on the top plate. The springs are fastened in pairs to the top plate at the two corners where alignment holes are not located, and extend out from the corners parallel to the sides of the plate. On LOPAR fuel assemblies, each pair of springs is fastened with a clamp that fits over the ends of the springs. Each clamp is secured with two bolts, which pass through the clamp and springs and thread into the top plate. At assembly, the spring-mounting bolts are torqued sufficiently to preload against the maximum spring load, and then are lock-welded to the clamp, which is counter-bored to receive the bolt head. On the SIF and 15 x 15 Upgrade fuel assemblies, attachment of the holddown springs was modified. The counterbore was eliminated from the clamp design, allowing the holddown spring screws to bear directly on the springs. The clamp, which is tack welded to the top nozzle, continues to fit over the end of the springs, and acts as a cover for the screw heads. A lock wire that is welded to the clamp ensures that the spring screws remain in position during operation. On 15 x 15 Upgrade fuel assemblies with the WIN top nozzle design, attachment of the holddown springs was modified. The holddown springs screws were eliminated entirely. Instead, the tail end of the holddown spring pack slides into a blind pocket machined into the top nozzle casting. The spring pack is held in place by a retaining pin pushed vertically through the pocket and springs. The pin is tack welded to the top nozzle to secure it in position. The WIN spring design has a rounded tail and the tang and tang windows are centered, creating a same-hand spring.

The spring load is obtained through deflection of the spring by the upper core plate. The spring projects above the fuel assembly and is depressed by the core plate when the internals are loaded into the reactor. The free end of the spring is bent downward and is captured in a slot in the top plate. This is done to guard against release of loose parts in the reactor in the event (however remote) of spring fracture.

In addition, the fit between the upper spring and slot and between the spring set and the mating slot in the clamp is sized to prevent rotation of either end of the spring set into the control rod path in the event of spring fracture.

In addition to its plenum and structural functions, the nozzle provides a protective housing for components that mate with the fuel assembly. In handling a fuel assembly with a control rod assembly inserted, the control rod assembly spider is protected by the nozzle. During operation in the reactor, the top nozzle protects the control rods from coolant cross flows in the unsupported span between the top nozzle adaptor plate and the end of the guide tube in the upper internals package. Other fuel insert components that mate with the fuel assembly thimble tubes, such as plugging devices, source assemblies, flux suppression inserts and burnable poison assemblies, are similarly protected by the top nozzle of the fuel assembly.

3.5.2.1.3 Guide Thimbles

The control rod guide thimbles in the fuel assembly provide guide channels for the control rods during insertion and withdrawal. The guide thimbles are fabricated from a single piece of Zircaloy-4 or ZIRLO tubing, which is drawn to two different diameters. The larger inside diameter at the top provides a relatively large annular area for rapid insertion during a reactor trip. It also accommodates a small amount of upward cooling flow during normal operations. The bottom portion of the guide thimble has a smaller diameter to cause a dashpot action when the control rods approach the end of travel in the guide thimbles. The transition zone at the dashpot section is conical in shape so that there are no rapid changes in diameter in the tube.

Flow holes are provided just above the transition of the two diameters to permit the entrance of cooling water during normal operation, and to accommodate the outflow of water from the dashpot action during reactor trip.

The control rod guide thimbles are closed at the bottom by means of a welded end plug. The end plugs are subsequently fastened to the bottom nozzle during fuel assembly fabrication. Flow holes are provided in the end plugs to permit entrance of cooling water during normal operation and to regulate dashpot action during control rod trip. The instrumentation thimble is left open at the bottom to receive the incore instrumentation.

The 15 x 15 Upgrade guide thimble incorporates the tube-in-tube dashpot design. The tube-in-tube design utilizes a separate dashpot tube assembly that is inserted into the guide thimble assembly and bulged into place. This design enhances stability thus providing more margin to guide thimble and assembly bowing, and more margin to incomplete rod insertion.

3.5.2.1.4 Grids

The grid assemblies consist of individual slotted straps that are interlocked in an “egg-crate” arrangement. The Inconel grids (all grids in LOPAR fuel assemblies and end grids in SIF and 15 x 15 Upgrade assemblies) are furnace-brazed to permanently join the straps at their points of intersection. The SIF Zircaloy or ZIRLO grid straps (all mid-grids), the 15 x 15 Upgrade

ZIRLO grip straps (all mid-grids and IFMs) and both designs' Inconel protective grids are permanently joined by welding. Details such as springs, support dimples, mixing vanes, and tabs are punched and formed in the individual straps prior to assembly.

Two types of grid assemblies are used in the 15 x 15 LOPAR fuel assembly. Grids with mixing vanes that project from the upper edges of the straps into the coolant stream are used in the high-heat region of the fuel assemblies to promote mixing of the coolant. A grid of this type is shown in Figure 3.5-11. The grids located at the bottom and top ends of the assembly are of the non-mixing type. They are similar to the mixing type but do not have mixing vanes on the internal straps. Inconel 718 is used for the grid material because of its corrosion resistance and high strength properties. After the combined brazing and solution annealing temperature cycle, the grid material is age-hardened to obtain the material strength necessary to develop the required grid spring forces.

Two types of structural grid assemblies are used in the 15 x 15 SIF and 15 x 15 Upgrade assemblies. The top and bottom grids are the same non-mixing vane grids used in the LOPAR assemblies. The middle mixing vane grids are similar to the mixing vane grids used on the LOPAR assemblies with the exception that they are made of Zircaloy (SIF) or ZIRLO (SIF and 15 x 15 Upgrade). The 15 x 15 Upgrade structural mixing vane mid-grids are slightly shorter than the SIF mixing vane mid-grids to maintain assembly pressure drop similar to the other fuel designs. The shorter mixing vane mid-grids compensate for the IFMs. There are also some dimensional differences between the Inconel and zirconium alloy grid straps to compensate for differences in material strength properties. The Inconel is used for the end grids primarily for its high strength and corrosion resistance. Zirconium-based alloys are now used for the mid-grids primarily for their low neutron absorption properties.

The outside straps on all structural grids contain mixing vanes on their upper edges that also aid in guiding the grids and fuel assemblies past projecting surfaces during handling or core loading and unloading. In addition, there are small tabs projecting downward from the lower edge of the outside straps; the irregular contour of the straps is also for guiding.

On the Batch 15 fuel only (fresh feed to Cycle 13), the orientation of the mixing vane grids was slightly modified, with every other mixing vane grid being rotated 90 degrees in the clockwise direction. The purpose for the rotation was to minimize the susceptibility of the fuel assembly to flow induced vibration. There were no physical or material changes to the grids or their axial positions, and this change did not impact the pressure drops, DNB performance, or other thermal-hydraulic performance of the Surry fuel assembly. However, subsequent testing showed that this change could affect the DNB performance of some (other) fuel designs, so grid rotation was not applied to later batches of Surry fuel.

Starting with Batch 15 of the Surry Units 1 and 2, the fuel assemblies incorporate an additional protective bottom Inconel grid (P-grid), located directly above the bottom nozzle. The straps of the P-grid subdivide the flow holes in the bottom nozzle, reducing the amount and size of debris that can enter the fuel assembly. The P-grid inner grid straps contain paired horizontal dimples that provide coplanar four-point contact within each grid cell. (To accommodate the coplanar dimples, alternating cells have the dimples at alternating elevations.) The P-grid is designed to have its dimples on the full diameter of the fuel rod's solid bottom end plug throughout the design life of the fuel assembly.

The protective grid is fabricated from Inconel-718. The straps are welded at the intersects and to the outer grid strap, similar to the Zircaloy and ZIRLO grids. The top of the P-grid outer grid strap retains the anti-snag features used in the top and bottom Inconel grids. The bottom portion of the outer grid strap is bent inward toward the top of the bottom nozzle to minimize potential for hang-up. In addition, the protective grid has a slightly smaller envelope than the bottom non-mixing vane grid and the bottom nozzle to minimize the potential for interaction with other fuel assemblies during handling. The interface between the P-grid, the bottom nozzle, and the fuel rod is illustrated in Figure 3.5-10.

Hydraulic tests showed that the impact of incorporating the protective grids into the fuel assemblies was effectively offset by positioning the fuel rods on the bottom nozzle. The magnitude of the effect on the pressure drop loss coefficients was negligible, so the presence of the protective grid does not change the DNB performance of the fuel.

IFMs are present in the 15 x 15 Upgrade design. IFM grids are considered nonstructural upper assembly grids which contain mixing vanes similar to the structural mid-grids. Specifically, the IFM grids are located in the top three mixing vane grid spans. The IFM grids are neutronically insignificant.

The addition of IFM grids increases pressure drop across the fuel assembly. To alleviate this impact 15 x 15 Upgrade mid-grids utilize an I-spring design that permits a reduced grid height. The inner strap thickness was also decreased to reduce the pressure drop of the grids and thus allow adding IFM grids with minimal impact.

3.5.2.1.5 Fuel Rods

The fuel rods consist of uranium dioxide ceramic pellets contained in slightly cold-worked and partially annealed Zircaloy-4, ZIRLO, or Optimized ZIRLO tubing, which is plugged and seal-welded at the ends to encapsulate the fuel. Sufficient void volume and clearances are provided within the rod to accommodate fission gases released from the fuel, differential thermal expansion between the cladding and the fuel, and fuel swelling due to accumulated fission products without overstressing of the cladding or seal welds. Shifting of the fuel within the cladding is prevented during handling or shipping prior to core loading by a carbon steel or stainless steel helical compression spring that bears on the top of the fuel pellet column. The holddown force to prevent fuel shifting is obtained by compression of the spring between the top end plug and the top of the fuel pellet stack.

Beginning in Cycle 21, each fuel assembly may contain from 0 to 148 integral fuel burnable absorber (IFBA) rods. The IFBA fuel rod design includes a thin layer of boride coating on the outer surface of the majority of the fuel pellets in the fuel rod, as well as axial blankets. The axial blanket is a six-inch (approximate) stack of slightly enriched annular fuel pellets without boride coating located at the top and bottom of the fuel stack in each IFBA rod. Cores may continue to use discrete (fixed) burnable poison rod assemblies in conjunction with IFBA fuel assemblies.

Beginning in Surry Unit 2 Cycle 31, all fuel rods in each new fuel batch may contain axial blankets. The axial blanket is a six-inch (approximate) stack of natural or slightly enriched fuel pellets (solid or annular) located at the top and bottom of the fuel stack in each fuel rod. Axial blankets reduce neutron leakage and improve fuel utilization.

All fuel rods are internally pressurized with helium during fabrication. The fuel rod void space is sized to ensure adherence to the pressure criteria. The rod internal pressure is evaluated for the limiting fuel rod, assuming a conservative operating history. The evaluation is based on expected operating conditions at the peak steady-state power, and also considers the fission gas release from normal operating transients. The model used to predict the quantity of fission gas in the gap is based on an extensive comparison with both published and proprietary data covering a variety of conditions. The internal pressure of the lead rod in the reactor is limited to a value that does not cause the diametral gap to increase due to outward cladding creep during steady state operation, and does not cause extensive DNB propagation to occur.

Additional information on the rod internal pressure design basis can be found in WCAP-17642-P-A (Reference 14).

The fuel pellets are right circular cylinders consisting of slightly enriched uranium dioxide powder, which is compacted by cold pressing and sintering to the required density. The ends of each pellet are dished slightly to allow the greater axial expansion at the center of the pellets to be taken up within the pellets themselves and not in the overall fuel length. Some pellets may have a thin coating of boride material applied to the circumferential surface as discussed in Section 3.5.2.1.5.

A lower pellet density was used in the outer fuel regions of the first core to compensate for the anticipated effects of the higher burn-up experienced in these regions. Reload cores have a uniform nominal pellet density that is slightly higher than those used in the initial core.

The fuel enrichments listed in Table 3.5-1 were used for the three regions in the first core loading. Enrichments used in reload fuel regions are discussed in the reload safety evaluation prepared for each subsequent core cycle.

Each fuel assembly is identified by a serial number engraved on the top nozzle. The fuel pellets are fabricated by a batch process so that only one enrichment region is processed at any given time. The serial numbers of the assemblies and corresponding enrichment are documented and verified by the manufacturer prior to shipment.

Each assembly is assigned a specific core loading position prior to insertion. A record is then made of the core loading position, serial number, and enrichment. Before core loading, two independent reviews are made to ensure that the loading assignment is correct. The serial number is checked before an assembly is loaded into the core. After the core is completely loaded, each serial number is checked again for agreement with the core loading drawing.

Any error in enrichment, beyond the normal manufacturing tolerances, can cause power shapes which are more peaked than those calculated with the correct enrichments. There is an 8% uncertainty margin between the calculated worst value and the design value of $F\Delta h$ assumed for the analysis of normal steady-state operation and anticipated transients. The incore system of movable flux detectors, which is used to verify power distribution limits, is capable of detecting anomalies (such as fuel enrichment errors, core loading errors, or misaligned control rods) that cause peaking factors or core tilts in excess of design values. Power distribution measurements are taken at low power when extremely adverse power distribution can be tolerated. The analysis described below shows that the power increase due to any combination of misplaced fuel assemblies would significantly raise peaking factors and would be readily observable with the incore flux monitors. In addition, thermocouples located in the flux thimbles monitor the outlet of about one-third of the fuel assemblies in the core. There is a high probability that the thermocouples would also indicate any abnormally high coolant temperature rise.

An analysis of the effect of misplacing a fuel assembly was performed on a core very similar to the initial Surry core. The power distribution in the X-Y plane of the core was calculated using a “full core” description with the PDQ-07 code. A discrete representation was used wherein each individual fuel rod was described by a mesh point. The radial power-peaking factor for the reference case (Case 1) was 1.370.

In Case 2, the central fuel assembly which would normally be of 2.15 weight percent enrichment, was assumed to be interchanged with an outer fuel assembly of 3.3 weight percent enrichment. The radial power-peaking factor for this case was 2.538 and occurred in the central fuel assembly. The power distribution was badly skewed with a tilt of approximately 15% across the core. Incore instrumentation would easily detect a misplacement of this nature.

In Case 3, the central 2.15 weight percent enrichment fuel assembly in the core was assumed to be interchanged with a neighboring 2.70 weight percent enrichment fuel assembly. The radial power-peaking factor for this case was 1.625. A power distribution tilt of approximately 10% results in the two rows of fuel adjacent to the interchanged fuel assemblies, which would be detected by the incore instrumentation. The interchange of 2.15 and 2.70 weight percent enrichment fuel assemblies not at the core center would introduce more pronounced power distribution tilts than Case 3.

The possibility of having an assembly in which all the fuel is of the wrong enrichment was also considered. In this case there was no interchange of assemblies, but there was one assembly in the core that departed from the nominal enrichment.

An analysis of the effect of an inadvertent loading of an assembly with an enrichment increased by 20% over the nominal value showed that the error was detectable at many of the detector locations in the core. In the case of a centrally placed assembly with this enrichment error, five flux detectors would show a signal more than 5% above the expected value. If the assembly bearing the enrichment error was placed off-center and as far from a flux detector as possible, the tilt caused by a 20% error in enrichment would be detectable in more than half of the detector locations in the core, either as a flux increase over expected symmetric values or as a flux decrease on the opposite side of the core.

If the movable detector system failed to detect an assembly enrichment error, the peaking factors would still show margin to the design conditions through the inclusion of measurement uncertainties, and normal plant operation could be safely continued. It is not credible that any positive indication of power distribution anomalies that are sufficiently large to cause a significant departure from design conditions would be ignored. These measurements are an integral part of the physics start-up tests where considerable emphasis is placed on obtaining good power distribution measurements.

In the event that a single fuel pin or a single fuel pellet had a higher enrichment than the nominal value, then the local power generation would be increased approximately by the percentage of the enrichment error. In the case of an enrichment error greater than 8% there exists a possibility, depending on location, that design limits on fuel rating would be violated for that pin or pellet. The consequences of such a local reduction of DNBR and increase in clad and fuel temperatures would be limited to the incorrectly loaded pin or pins.

During initial core loading and subsequent refueling operations, detailed written handling and checkoff procedures are utilized throughout the loading sequence. The initial cores were loaded in accordance with a core loading plan similar to that illustrated in Figure 3.5-3, which shows the locations of the different enrichment fuel assemblies typically used in initial cores. The actual core loading plans for both initial and reload cores show the identification number for the fuel assembly used in each core location.

During subsequent refueling operations, reconstituted fuel assemblies (see Section 3.5.2.1) may be included among the fuel assemblies used for reloading the core.

3.5.2.2 **Control Rod Assemblies**

The control rod assemblies each consist of a group of individual control rods fastened at the top end to a common spider assembly. These assemblies, one of which is shown in Figures 3.5-4 and 3.5-12, are provided to control the reactivity of the core under operating conditions. These assemblies contain absorber material for 142 inches of their length. The number of control rod assemblies for the initial cores is specified in Table 3.5-1. Part length rods have since been removed.

The absorber material used in the control rods is silver-indium-cadmium alloy, which is essentially “black” to thermal neutrons and has sufficient additional resonance absorption to significantly increase its worth. The alloy is in the form of rods, which are sealed in stainless steel tubes to prevent the rods from coming in direct contact with the coolant.

When the control rod assembly has been fully withdrawn, the tip of the control rods remains engaged in the guide thimbles so that alignment between control rods and thimbles is maintained. Since the control rods are long and slender, they are relatively free to conform to any small misalignments encountered with the guide thimble.

The spider assembly is in the form of a center hub with radial vanes containing cylindrical fingers from which the control rods are suspended. Handling detents and detents for connection to the drive shaft are machined into the upper end of the hub. A spring pack is assembled into a skirt integral to the bottom of the hub to stop the control rod assembly and absorb the impact energy at the end of an insertion. The radial vanes are joined to the hub and the fingers joined to the vanes by furnace brazing. A centerpost that holds the spring pack and its retainer is threaded into the hub within the skirt and welded to prevent loosening in service. All components of the spider assembly are made from type 304 stainless steel except for the springs, which are Inconel X-750 alloy, and the retainer, which is 17-4 PH stainless in the H 1100 condition.

The control rods are fastened securely to the spider. The rods are first threaded into the spider fingers, pinned to maintain joint tightness, and the pins are then welded in place. The end plug below the pin position is designed with a reduced section to permit flexing of the rods to correct for small operating or assembly misalignments.

In construction, the silver-indium-cadmium rods are inserted into cold-worked stainless steel tubing which is then sealed at the bottom and the top by welded end plugs. Sufficient diametral and end clearance is provided to accommodate relative thermal expansions and to limit the internal pressure to acceptable levels.

The bottom plugs are made bullet-nosed to reduce the hydraulic drag during a reactor trip and to guide smoothly into the dashpot section of the fuel assembly guide thimbles. The upper plug is threaded for assembly to the spider and has a reduced end section to make the joint more flexible.

The original control rod assembly design was replaced prior to Surry 1 & 2 Cycle 11 and Cycle 24 with an “enhanced performance” control rod assembly design. The enhanced design is essentially the same as the original with the exception of the cladding tubes which are hard chrome plated to increase both wear resistance and the life of the control rods. The ends of the cladding tubes are not plated, however, to preclude weld contamination of the end plug. Trace element impurities in the cladding were also restricted to lower values than previously allowed to reduce corrosion in the cladding. In addition, the absorber rodlet diameter in the lower twelve inches of the absorber rods was reduced to decrease cladding strain due to swelling induced by irradiation of the absorber.

The chrome plated stainless steel clad silver-indium-cadmium alloy absorber rods are resistant to radiation and thermal damage. thereby ensuring their effectiveness under all operating conditions.

3.5.2.3 **Neutron Source Assemblies**

Two neutron source assemblies were utilized in the initial cores. These assemblies consisted of three secondary source rods and one primary source rod, twelve burnable poison rods and four thimble plugs each. The primary source rods contained capsules of Plutonium-Beryllium source material 24 inches long. The secondary source rods contained Antimony-Beryllium pellets stacked to a height of 121.754 inches. The primary source, secondary source and burnable poison rods utilized 304 SS cladding materials. The rods were fastened to a spider at the top end similar to the control rod spiders. The neutron source rods were inserted, as part of two burnable poison rod assemblies, into the control rod guide thimbles in fuel assemblies at unrodded locations in the core.

For the initial Unit 1 and Unit 2 cores following the steam generator replacement outages (Unit 1 Cycle 6 and Unit 2 Cycle 5), each core contained two new primary source assemblies containing one primary source rod and 12 burnable poison rods each. Each core also contained three secondary source assemblies containing four secondary source rods and sixteen thimble plugs each. The primary source rods contained a 1.5-inch length of Californium-252. Aluminum oxide spacers were used to maintain the source material position in the rod. The secondary source rods contained Sb-Be pellets stacked to a height of 67.87 inches. The primary source, secondary source and burnable poison rods all utilized 304 SS cladding material. The rods on the primary source assemblies were attached to a base plate similar to the standard burnable poison assemblies. The secondary source rods were fastened to a spider at the top end similar to the control rod spiders. The rods in the neutron source assemblies were inserted into the control rod guide thimbles in fuel assemblies at unrodded locations in the core.

The primary sources were used in the initial cycles (and in the first cycles following steam generator replacement) to ensure adequate count rate for the source range detectors at the beginning of cycle. No primary sources are currently placed in reload cycles. Secondary sources were loaded in reload cores through Cycle 14 at each unit, but were removed until Cycle 26 at Unit 2 and Cycle 27 at Unit 1.

Beginning with the aforementioned cycles, secondary source assemblies were re-inserted into the Surry reactor cores. The assemblies have slightly different design than the secondary sources used in prior cycles. Each core holds two secondary source assemblies containing six secondary source rods without thimble plugs. The secondary source rods contain Sb-Be pellets stacked to a height of 88.0 inches and are attached to a base plate similar to standard burnable poison assemblies. All rods utilize a double-encapsulated design with 304 SS cladding material. The neutron sources assemblies will be inserted into the control rod guide thimbles in fuel assemblies at unrodded locations in the core.

Source range detector minimum count rate can be provided by the fuel assemblies on the periphery of the core, and secondary sources are not normally required for this purpose. Secondary sources may be loaded into reload cores to charge them for possible future use.

Design criteria similar to those for the fuel rods were used for the design of the source rods. The requirements for the source rods included that the cladding be free-standing, internal pressures remain less than reactor operating pressure, and sufficient internal gaps and clearances be provided to allow for differential expansions between the source material and cladding.

3.5.2.4 **Plugging Devices**

It is permissible to limit bypass flow through the guide thimbles in fuel assemblies that do not contain insert components such as control rod assemblies, source assemblies, or burnable poison rods, by fitting the fuel assemblies at those locations with plugging devices. The plugging devices consist of a flat retaining plate with short rods suspended from the bottom surface of the plate and a spring pack assembly attached to the top surface. During installation in the core, the plugging devices fit within the fuel assembly top nozzles and rest on the top nozzle adaptor plate. The short rods project into the upper ends of the guide thimbles to reduce the bypass flow area. The spring pack is compressed by the upper core support assembly when it is lowered into place.

All components in the plugging devices, except for the springs, are constructed from type 304 stainless steel. The springs used in each plugging device are wound from an age-hardenable Inconel X-750 to obtain higher strength.

Beginning with Cycle 10 of each unit, all plugging devices were removed from the core (Reference 7).

3.5.2.5 **Burnable Poison Rod Assemblies**

Burnable poison rod assemblies (BPRA) may be incorporated into the core design to reduce the soluble boron requirement for control of excess reactivity, and to shape the core power distribution. The number of BPRA or BPRA poison rods may vary from one operating cycle to the next, and may be used in any fuel assembly not under a control rod bank location. BPRA burnable poison rods are commonly referred to as fixed, discrete, and/or removable burnable poison rods. This type of burnable poison is “fixed” and “discrete” in the sense that the neutron absorber is contained in solid form (not soluble) in discrete rods (separate from the fuel). BPRA burnable poison is removable because the BPRA itself may be removed from the fuel assembly.

The BPRA burnable poison rods consist of $A1_20_3$-B_4C pellets contained within Zircaloy-4 tubular cladding that is plugged and seal-welded at the ends to encapsulate the pellets. The pellets are supported by the bottom end plug and, depending on pellet stack length, spacers may also be employed. A typical BPRA burnable poison rod is shown in Figure 3.5-13.

The BPRA burnable poison rods in each fuel assembly are grouped and attached together at the top end of the rods by a flat retaining plate that fits inside the fuel assembly top nozzle and rests on the top nozzle adaptor plate. The retaining plate and the poison rods are held down and restrained against vertical motion through a spring pack attached to the plate. This spring is compressed by the upper core plate when the reactor upper internals package is lowered into the reactor, and this ensures that the poison rods cannot be lifted out of the core by flow forces. Each rod is attached to the retaining plate.

The clad in the poison rod assemblies is cold-worked Zircaloy-4 seamless tubing. The upper and lower end plugs, nuts and solid spacers are fabricated from Zircaloy-4. The spring spacers are 302 or 304 stainless steel. The hold-down assembly is fabricated from stainless steel similar to type 304, except for the hold-down springs which are wound from Inconel 718 wire.

3.5.2.6 **Evaluation of Core Components**

3.5.2.6.1 Fuel Evaluation

The integrity of the fuel rods is ensured by proper fuel rod design. This is achieved by designing the fuel rods so that specific design criteria are satisfied. The design process must consider the effects of variations and fluctuations in core and local power, and in reactor coolant temperature, pressure and flow which occur during normal operation and Anticipated Operational Occurrences (AOOs).

To ensure reliable operation, established fuel rod design criteria must be satisfied for all operating conditions consistent with normal operation and AOOs. The fuel rod design is judged to have met these criteria when it is demonstrated that the performance of a fuel region is within the limits specified by the criteria for these events. This is generally accomplished by demonstrating that the limiting fuel rod performance with appropriate allowance for uncertainties is within the limits specified by each criterion. These evaluations are performed using the Performance Analysis and Design (PAD5) code and models (Reference 14) which is licensed up to a fuel rod average burn up of the design (i.e., 62,000 MWD/MTU for Surry Improved Fuel Assemblies with ZIRLO High Performance Cladding Material and 15x15 Upgrade assemblies with Optimized ZIRLO High Performance Cladding Material that is consistent with the burnup extension included in References 17 and 20). Note that the older Surry fuel assemblies with Zicaloy-4 cladding remain limited to 60,000 MWD/MTU (Reference 2).

- Clad Stress
  - Design Basis - The fuel system will not be damaged due to excessive fuel clad stress.
  - Acceptance Limit - Maximum cladding stress intensities excluding Pellet-Cladding Interaction (PCI) induced stress shall be evaluated based on American Society of Mechanical Engineers (ASME) Boiler and Pressure Vessel Code guidelines. Stresses in the cladding are combined to calculate a maximum stress intensity which is then compared to the criteria described in Reference 14.
- Clad Strain

- Design Basis - The fuel rod will not fail due to excessive fuel clad strain.
- Acceptance Limit - The design limit for the fuel rod clad strain is that the total tensile strain, elastic plus plastic, due to uniform cylindrical fuel pellet deformation during any single Condition I or II transient shall be less than 1% from the pre-transient value.

- Rod Internal Pressure
  - Design Basis - The fuel system will not be damaged due to excessive fuel rod internal pressure.
  - Acceptance Limit - The internal pressure of the lead fuel rod in the reactor will (1) be limited to a value below that which could cause the diameter gap to increase (cladding liftoff) due to outward cladding creep during normal operation; (2) be limited to a value below that which could result in cladding hydride reorientation in the radial direction; and (3) be limited to preclude extensive Departure from Nucleate Boiling (DNB) propagation.
- Clad Fatigue
  - Design Basis - The fuel system will not be damaged due to fatigue.
  - Acceptance Limit - The fatigue life usage factor is limited to prevent reaching the material fatigue limit.
- Clad Oxidation
  - Design Basis - The fuel system will not be damaged due to excessive fuel clad oxidation.
  - Acceptance Limit - The predicted oxide thickness shall be no greater than 100 microns.
- Clad Hydrogen Pickup
  - Design Basis - The fuel system will be operated to prevent significant degradation of mechanical properties of the clad at low temperatures as a result of hydrogen embrittlement caused by the formation of zirconium hydride platelets.
  - Acceptance Limit - The best estimate hydrogen pickup in the cladding shall not exceed 600 ppm on a volume-average basis at end of life through the entire clad wall.
- Fuel Rod Axial Growth
  - Design Basis - The fuel system will not be damaged due to excessive axial interference between the fuel rods and the fuel assembly structure.
  - Acceptance Limit - The fuel rods shall be designed with adequate clearance between the fuel rod and the top and bottom nozzles to accommodate the differences in the growth of fuel rods and the growth of the assembly without interference.

- Clad Flattening
  - Design Basis - Fuel rod failures will not occur due to clad flattening.
  - Acceptance Limit - The fuel rod design shall preclude clad flattening during projected exposure.
- Clad Free Standing
  - Design Basis - The fuel system will not be damaged due to excessive fuel clad stress.
  - Acceptance Limit - The cladding shall be short-term free standing at beginning of life, at power, and during hot hydrostatic testing.
- Fuel Pellet Overheating (Power-to-Melt)
  - Design Basis - The fuel rods will not fail due to fuel centerline melting for normal operation or AOOs.
  - Acceptance Limit - The fuel rod centerline temperature shall not exceed the fuel melt temperature during Condition I and II operation, accounting for degradation of the melt temperature due to burn up and the addition of integral burnable absorbers.
  - The PAD5 melting temperature model uses the following equation based on an unirradiated UO2 fuel melting point of 5080 °F and burnup.

$$T_{melt} = 5080°F - \frac{9}{10,000}(BU)$$

Where,

T_{melt} = UO_2 melting temperature, °F

BU = UO_2 burnup, MWD/MTU

- Pellet/Clad interaction (PCI)
  - Design Basis - The fuel rod will not fail due to pellet clad interaction.
  - Acceptance Limit -Two related criteria, the one percent clad strain criterion and the fuel overheating criterion, must be met.

Reference 14 is the basis for these fuel performance criteria, which are evaluated on a cycle-specific basis as part of each fuel reload.

The following information is HISTORICAL and is not intended or expected to be updated for the life of the plant.

The Region 1 fuel was initially expected to be irradiated for only the first cycle of reactor operation, so an initial density of 94% was used for this fuel. Since the Region 2 and 3 fuel was expected to be retained through two and three cycles of operation, respectively, lower fuel pellet densities were specified for these regions to accommodate the anticipated effects of the higher burnups this fuel would reach. The specified initial density was 93% for Region 2, and 92% for Region 3. Reload cores have utilized a slightly higher nominal pellet density. The operation of this fuel to approved burnup levels is supported by the current fuel densification and swelling model, and by operating experience with higher density fuel.

There are no Technical Specification restrictions on fuel residence time. The high-density prepressurized fuel is typically used for two to four cycles of operation. Current Westinghouse fuel is stable with respect to densification, so significant axial pellet column gaps and clad flattening do not occur (Reference 3).

The design bases and functional requirements for the fuel assembly structural components are discussed in References 6, 8, 9, 11, and 14.

3.5.2.6.2 Evaluation of Control Rods

Time of control rod assembly trip and control rod cooling were evaluated as follows:

1. Analytical techniques were used to predict the trip behavior of a control rod assembly. Tests were also performed under an experimental program conducted in the Westinghouse Reactor Evaluation Center, and the results verified these analytical techniques.

   The calculated control rod insertion trip to the dashpot entry at full flow rate and operating temperature is less than the design value.

2. Control rod guide thimble and dashpot flow analyses have been performed to determine the adequacy of thimble design to meet cooling requirements. Results indicated that adequate cooling flow is provided in the dashpot and the thimble to prevent boiling.

3.5.2.6.3 Evaluation of Burnable Poison Rods

The BPRA burnable poison rods are positively positioned in the core inside fuel assembly guide thimbles, and held in place by attachments to an upper structure assembly compressed beneath the upper core plate. In order to maintain encapsulation of the absorber material throughout the design lifetime, the BPRA burnable poison rod design incorporates sufficient margin to accommodate the anticipated effects of gas release, absorber material swelling, clad growth and creep, stress, strain, and corrosion.

The BPRA burnable poison rods consist mainly of a column of poison pellets encapsulated within cold-worked, Zircaloy-4 seamless tubing. The individual pellets are a sintered ceramic of relatively low density $A1_20_3$-B_4C and are in the form of a solid, right circular cylinder with flat ends. Rod fabrication is initiated by loading a spring spacer into the tubing, followed by the poison pellets. The spring spacer is loaded into the plenum gap region of the rod to support the pellet stack for shipping, handling and operation. For operation, the spring preload ensures a bearing load on the pellet stack and individual pellets, such that no axial gaps are available in he rod to allow clad creep collapse. A solid spacer may also be employed depending on the length of the pellet stack.

The assembled BPRA burnable poison rods are prepressurized with dry, high purity helium gas. During operation, the pressurized helium gas provides good heat transfer across the pellet-to-clad diametral gap and reduces the pressure differential across the clad wall thickness which contributes to clad creep ovality. Sufficient volume is provided in the rod plenum gap region, accounting for the reduction in available volume due to the spring spacer, to accommodate the prepressurization gas plus the gas released from the poison due to the neutronic reaction between the B^{10} isotope and thermal neutrons.

Fuel rods containing integral burnable absorber (IFBA) are evaluated as described in Section 3.5.2.6.1. The evaluation also considers the effects of gas that accumulates inside the rod as a result of neutron absorption by the boride burnable absorber material. The same design limits apply to all fuel rods, whether or not the rod contains integral poison.

3.5.2.6.4 Effects of Vibration and Thermal Cycling on Fuel Assemblies

Reactor coolant flow can induce fuel rod vibration. The effect of the vibration on the fuel assembly and individual fuel rods is minimal. The cyclic stress range associated with deflections of such small magnitude is insignificant and has no effect on the structural integrity of the fuel rod.

The fuel assembly grids provide sufficient fuel rod support to limit fuel rod vibration and to maintain cladding wear to within acceptable limits. Significant operating experience exists with Westinghouse fuel using the grid designs found in the LOPAR and SIF assemblies. Significant wear of the cladding or grid supports is not expected during the life of the assembly, nor have grid or fuel rod abnormalities been observed on this fuel.

The effect of thermal cycling of the fuel on the grid to rod support is a slight relative movement between the grid contact surfaces and the clad. This movement is gradual during heatup and cooldown, and the grid assemblies allow thermal expansion of the rods without imposing restraint sufficient to develop buckling or distortion of the fuel rods. The number of such thermal cycles is small over the life of a fuel assembly, so this motion is a negligible contribution to wear of the contacting parts.

The deflection of the control rods, or rods of fuel insert components such as burnable poison rods, flux suppression inserts (Unit 1 only, Cycles 13 through 20), thimble plugs or source rods, is limited by the fit within the fuel assembly guide thimbles. Analyses performed for the original core insert components indicate that cyclic deflections within the limited range allowed by the guide thimbles results in an insignificantly low stress in either the insert rodlets or in the joint of the rodlet to a spider or retainer plate.

3.5.3 Control Rod Drive Mechanism

3.5.3.1 Control Rod Assembly Design Description

The control rod drive mechanisms are used for withdrawal and insertion of the control rod assemblies in the reactor core, and to provide sufficient holding power for stationary support.

Fast total insertion, or reactor trip, is obtained by simply removing the electrical power to allow the control rod assemblies to fall by gravity.

The complete drive mechanism, shown in Figure 3.5-14, consists of the internal latch assembly, the pressure vessel, the operating coil stack, and the drive shaft assembly.

Each assembly is an independent unit that can be dismantled, removed, or installed separately. Each drive mechanism is threaded and seal-welded onto an adaptor located on top of the reactor pressure vessel, and is connected to the control rod assembly directly below by means of a grooved drive shaft. The upper section of the drive shaft is suspended from the working components of the drive mechanism. The drive shaft and control rod assembly remain connected during all reactor operations, including trip of the control rod assemblies.

Reactor coolant fills the pressure-containing parts of the drive mechanism. All working components and the shaft are immersed in the reactor coolant, and utilize it for cooling and lubrication of sliding parts.

Three magnetic coils, which form a removable electrical unit and surround the control rod drive mechanism pressure housing, induce magnetic flux through the housing wall to operate the working components. They move two sets of latches that lift or lower the grooved drive shaft.

The three magnets are turned on and off in a fixed sequence by solid-state switches. The sequencing of the magnets produces step motion over the 144 inches of normal control rod travel.

The mechanism is capable of handling a 360-lb load, including the drive rod weight, at a rate of 45 inches per minute. Lift capacity is available for overcoming mechanical friction between the moving and the stationary parts. Gravity provides the drive force for control rod assembly insertion and the weight of the whole control rod assembly is available to overcome any resistance.

The mechanisms are designed to operate in water at 650°F and 2485 psig. The temperature at the mechanism head adaptor is much less than 650°F because it is located in a region of limited water flow from the reactor core.

A multiconductor cable connects the mechanism operating coils to the dc power supply through the power programmer. The power supply is described in Section 7.3.

All part-length control rod assemblies have been removed. On Unit 1, the part-length control rod drive mechanisms have been removed from all core locations except H04. The mechanism housing at location H04 is used for the reactor vessel head vent system. On Unit 2 all the part-length control rod drive mechanisms have been removed and a direct penetration in the reactor vessel head is used for the reactor vessel head vent system. To maintain the pressure boundary function, adapter plugs were threaded on the part-length locations and then seal welded with a canopy weld. To maintain cooling airflow characteristics, dummy cans were attached to the adapter plugs to occupy the volume of the removed part-length control rod drive mechanisms.

3.5.3.1.1 Latch Assembly

The latch assembly contains the working components that withdraw and insert the drive shaft and attached control rod assembly. It is located within the pressure housing and consists of the pole pieces of three electromagnets. They actuate two sets of latches that engage the grooved section of the drive shaft.

The upper set of latches move up or down to raise or lower the drive rod by 0.625 inch. The lower set of latches have a 0.047-inch axial movement to shift the weight of the control rod assembly from the upper to the lower latches.

3.5.3.1.2 Pressure Vessel

The pressure vessel consists of the latch housing and the rod travel housing. The latch housing is the lower portion of the vessel, and contains the latch assembly. The rod travel housing is the upper portion of the vessel. It provides spaces for the drive shaft during its movement.

The housings are designed in accordance with the requirements for Class A vessels of ASME Code Section III, Nuclear Vessels.

3.5.3.1.3 Operating Coil Stack

The operating coil stack is an independent unit that is installed on the drive mechanism by sliding it over the outside of the pressure housing. It rests on a pressure housing flange without any mechanical attachment, and may be removed and installed while the reactor is pressurized.

The three operating coils (A, B, and C) are made of round copper wire insulated with a double layer of filament-type glass yarn.

The design operating temperature of the coils is 450°F. Coil temperature can be determined by resistance measurement. Forced air cooling along the outside of the coil stack maintains a coil temperature of approximately 390°F.

3.5.3.1.4 Drive Shaft Assembly

The main function of the drive shaft is to connect the control rod assembly to the mechanism latches. Grooves for engagement and lifting by the latches are located throughout the 144 inches of control rod travel. The grooves are spaced 0.625 inch apart to coincide with the mechanism step length, and have a 45-degree slot angle.

The drive shaft is attached to the control rod assembly by a coupling. The coupling has two flexible arms that engage the grooves in the spider assembly.

A 0.25-inch-diameter disconnect rod runs down the inside of the drive shaft. It utilizes a locking button at its lower end to lock the coupling and control rod assembly. At its upper end, there is a disconnect assembly for remote disconnection of the drive shaft assembly from the control rod assembly.

During unit operation, the drive shaft assembly remains connected to the control rod assembly at all times.

3.5.3.1.5 Position Indicator Coil Stack

The position indicator coil stack slides over the rod travel housing section of the pressure vessel. It detects drive shaft position by means of a cylindrically wound differential transformer that spans the normal length of control rod travel (144 inches).

3.5.3.1.6 Drive Mechanism Materials

All parts exposed to reactor coolant, such as the pressure vessel, latch assembly, and drive rod, are made of metals that resist the corrosive action of the water.

Three types of metals are used exclusively: stainless steel, Inconel X, and cobalt-based alloys. Wherever magnetic flux is carried by parts exposed to the main coolant, stainless steel is used. Cobalt-based alloys are used for the pins, latch arm tips, and pin shoe facing in the latch arms.

Inconel X is used for the springs of both latch assemblies, and type 304 (Unit 1) and type 316 (Unit 2) stainless steel is used for all pressure containment. Hard chrome plating provides wear-resistant surfaces on the sliding parts, and prevents galling between mating parts during assembly.

Outside of the pressure vessel, where the metals are exposed only to the reactor containment environment and cannot contaminate the reactor coolant, carbon and stainless steels are used.

Carbon steel, because of its high permeability, is used for magnetic flux return paths around the operating coils, and is zinc-plated 0.001-inch thick to prevent corrosion.

3.5.3.2 Principles of Operation

The drive mechanism shown schematically in Figure 3.5-14 withdraws and inserts its control rod assembly as electrical pulses are received by the operator coils.

An ON and OFF sequence that is repeated by a silicon-controlled rectifier in the power programmer causes either withdrawal or insertion of the control rod assembly. Position of the control rod assembly is indicated by the differential transformer action of the position indicator coil stack surrounding the rod travel housing. The differential transformer output changes as the top of the ferromagnetic drive shaft assembly moves up within the rod travel housing.

In normal operation, the stationary gripper coil of the drive mechanism holds the control rod assembly withdrawn from the core in a static position until the movable gripper coil is energized.

3.5.3.2.1 Control Rod Assembly Withdrawal

The control rod assembly is withdrawn by repetition of the following sequence of events:

1. Movable Gripper - ON

   The movable gripper armature raises and swings the movable gripper latches into the drive shaft groove.

2. Stationary Gripper Coil - OFF

   Gravity causes the stationary gripper latches and armature to move downward until the load of the drive shaft is transferred to the movable gripper latches. Simultaneously, the stationary gripper latches swing out of the shaft groove.

3. Lift Coil - ON

   The 0.625-inch gap between the lift armature and the lift magnet pole closes, and the drive rod raises one step length.

4. Stationary Gripper Coil - ON

   The stationary gripper raises and closes the gap below the stationary gripper magnetic pole, and swings the stationary gripper latches into a drive shaft groove. The latches contact the shaft and lift it 0.047 inch. The load is thus transferred from the movable to the stationary gripper latches.

5. Movable Gripper Coil - OFF

   The movable gripper armature separates from the lift armature under the force of one spring and gravity. Three links, pinned to the movable gripper armature, swing the three movable gripper latches out of the groove.

6. Lift Coil - OFF

   The gap between the lift armature and the lift magnet pole opens. The movable gripper latches drop 0.625 inch to a position adjacent to the next groove.

3.5.3.2.2 Control Rod Assembly Insertion

The sequence for control rod assembly insertion is similar to that for control rod assembly withdrawal:

1. Lift Coil - ON

   The movable gripper latches are raised to a position adjacent to a shaft groove.

2. Movable Gripper Coil - ON

   The movable gripper armature raises and swings the movable gripper latches into a groove.

3. Stationary Gripper Coil - OFF

   The stationary gripper armature moves downward and swings the stationary gripper latches out of the groove.

4. Lift Coil - OFF

   Gravity separates the lift armature from the lift magnet pole, and the control rod assembly drops down 0.625 inch.

5. Stationary Gripper Coil - ON

   See Section 3.5.3.2.1, event number 4.

6. Movable Gripper Coil - OFF

   See Section 3.5.3.2.1, event number 5.

The sequences described above are considered to be one step or one cycle, and the control rod moves 0.625 inch for each cycle. Each sequence can be repeated at a rate of up to 72 steps per minute, and the control rods can therefore be withdrawn or inserted at a rate of up to 45 in/min. Tripping by gravity is not subject to the rate limit of 45 in/min.

3.5.3.2.3 Control Rod Assembly Tripping

If power to the stationary gripper coil is cut off, as it is for tripping, the combined weight of the drive shaft and the control rod assembly is sufficient to move the latches out of the shaft groove. The control rod assembly falls by gravity into the core. The tripping occurs as the magnetic field, holding the stationary gripper armature against the stationary magnet, collapses, and the stationary gripper armature is forced down by the weight acting upon the latches.

3.5.4 Fuel Assembly and Control Rod Assembly Mechanical Tests

To prove the mechanical adequacy of the fuel assembly and control rod assembly, functional test programs were conducted on three test assemblies representative of the Surry LOPAR design. One test was run on a full-scale San Onofre (Reference 4) mock-up version of the fuel assembly and control rod assembly, and the other two on two full-scale assemblies for a 12-foot active core. One of the 12-foot assemblies incorporated stainless steel guide tubes, and the other incorporated Zircaloy-4 guide tubes. These tests were performed with silver-indium-cadmium control rods.

The test assemblies were tested under simulated reactor operating conditions at 1800 psig, 575°F, and flow velocities up to 16.5 ft/sec in the Westinghouse Reactor Evaluation Center for a total of more than 6400 hours.

Each test assembly was subjected to trip cycling equivalent to one or more station lifetimes. The test history for each prototype is summarized in Table 3.5-2.

Each of three test fuel assemblies remained in excellent mechanical condition. No measurable signs of wear on the fuel tubes or control rod guide thimbles were found.

The control rods were also found to be in excellent condition, with maximum wear on absorber cladding measuring approximately 0.001 inch.

3.5.4.1 **Loading and Handling Tests**

Tests simulating the loading of the test fuel assemblies into a core location were conducted to determine that proper provisions were made for guidance of a fuel assembly during refueling operations. A dummy fuel assembly is still used to test operability of fuel movement equipment.

3.5.4.2 **Lateral and Axial Bending Tests**

3.5.4.2.1 Lateral Bending Tests

A prototype fuel assembly was subjected to lateral bending tests in order to determine the mechanical characteristics of the assembly, and to verify that it was capable of withstanding the loads and deflections that would be encountered during shipping, handling, and core operation. The lateral bending tests showed than an assembly is capable of withstanding lateral deflections in excess of 0.25 inch at mid-height when supported as in the core, and in excess of 0.5 inch at the top nozzle when standing free, without evidence of damage. Deflections encountered during shipment and core operation, and specified allowable (and normally expected) deflections during handling and storage, do not exceed these limits.

3.5.4.2.2 Axial Load Test

In axial tests, the prototype assembly was successfully loaded to 2200 lb or more with no resulting damage. The maximum column load expected to be experienced in service is 1000 lb.

The test results have been used as a reference in the design of fuel-handling equipment to establish the limits for inadvertent axial loads during refueling.

a. ZIRLO was introduced on Batch 16 fuel (Cycle 14). The increased ZIRLO fuel assembly and fuel rod lengths were introduced with Surry 2 Batch 20 fuel.
b. Original SIF fuel rods (Batch 12, introduced in Cycle 10) were 152.185 inches long. Length was decreased slightly starting with Batch 13 (Cycle 11) as part of Westinghouse standardization of 15 x 15 fuel products.
c. Reconstituted fuel assemblies may contain some solid metal filler rods in place of fuel rods.
d. Debris filter bottom nozzles were introduced on Batch 13 fuel. P-grids were introduced on Batch 15 fuel (Cycle 13).
e. Starting with Batch 23 (Cycle 21) annular pellets may be used in the top and bottom of fuel rods containing IFBA. The specified diameter does not include the thickness of any IFBA coating that may be used.
f. Fuel assemblies from Surry 1 Batch 27 and Surry 2 Batch 26 and subsequent batches are of the 15 x 15 Upgrade design with Optimized ZIRLO and IFMs.
g. Dimension is for outer tube in tube-in-tube design.
h. Westinghouse Integral Nozzle (WIN) design was introduced on Batch 29 fuel.
i. Advanced Debris Filter Bottom Nozzles (ADFBN) were introduced on Batch 33 fuel.
j. Starting in Surry Unit 2 Batch 33 (Cycle 31), all fuel rods may contain natural or slightly enriched fuel pellets in the top and bottom.

a. ZIRLO was introduced on Batch 16 fuel (Cycle 14). The increased ZIRLO fuel assembly and fuel rod lengths were introduced with Surry 2 Batch 20 fuel.
b. Original SIF fuel rods (Batch 12, introduced in Cycle 10) were 152.185 inches long. Length was decreased slightly starting with Batch 13 (Cycle 11) as part of Westinghouse standardization of 15 x 15 fuel products.
c. Reconstituted fuel assemblies may contain some solid metal filler rods in place of fuel rods.
d. Debris filter bottom nozzles were introduced on Batch 13 fuel. P-grids were introduced on Batch 15 fuel (Cycle 13).
e. Starting with Batch 23 (Cycle 21) annular pellets may be used in the top and bottom of fuel rods containing IFBA. The specified diameter does not include the thickness of any IFBA coating that may be used.
f. Fuel assemblies from Surry 1 Batch 27 and Surry 2 Batch 26 and subsequent batches are of the 15 x 15 Upgrade design with Optimized ZIRLO and IFMs.
g. Dimension is for outer tube in tube-in-tube design.
h. Westinghouse Integral Nozzle (WIN) design was introduced on Batch 29 fuel.
i. Advanced Debris Filter Bottom Nozzles (ADFBN) were introduced on Batch 33 fuel.
j. Starting in Surry Unit 2 Batch 33 (Cycle 31), all fuel rods may contain natural or slightly enriched fuel pellets in the top and bottom.

3.6 TESTS AND INSPECTIONS

3.6.1 Physics Tests

3.6.1.1 Tests to Confirm Reactor Core Characteristics

A detailed series of start-up physics tests are performed each cycle from zero power up to and including 100% power. As part of these tests, a series of core power distribution measurements are made from at or below 50% power to 100% power by means of the core movable detector system. These measurements are analyzed and the results compared with the analytical predictions upon which safety analyses were based.

3.6.1.2 Tests Performed During Operation

To detect and eliminate possible errors in the calculations of the initial reactivity of the core and the reactivity depletion rate, the predicted relation between fuel burnup and the boron concentration necessary to maintain adequate control characteristics is normalized to accurately reflect actual core conditions. When full power is reached initially during each cycle, and with the control groups in the desired positions, the boron concentration is measured and the predicted curve is adjusted to this point. As power operation continues, the measured boron concentration is compared with the predicted concentration, and the slope of the curve relating burnup and reactivity is compared with that predicted. This normalization should be completed after about 10% of the cycle burnup has occurred. Thereafter, actual boron concentration can be compared with the predicted concentration, and the reactivity prediction of the core can be continuously evaluated.

Any reactivity anomaly greater than 1% would be unexpected, and its occurrence would be thoroughly investigated and evaluated.

3.6.2 Thermal/Hydraulic Tests and Inspections

General hydraulic tests on models have been used to confirm the design flow distributions and pressure drops (References 1 & 2). Fuel assemblies and control and drive mechanisms are also tested in this manner. Appropriate onsite measurements are made to confirm the design flow rates.

Vessel and internals inspections were reviewed prior to initial startup to confirm such thermal and hydraulic design values as bypass flow. A reactor coolant flow test, as noted in Table 13.3-1, was performed following fuel loading but before initial criticality to verify that proper coolant flow rates had been used in the core thermal and hydraulic analysis. Periodic testing is performed to verify the RCS flow rates used in design calculations are met.

3.6.3 Core Component Tests and Inspections

To ensure that all materials, components, and assemblies conformed to the design requirements, a release point program was established with the manufacturer. This program required surveillance of all raw materials, special processes (i.e., welding, heat treating, non-destructive testing, etc.), and those characteristics of parts that directly affected the assembly and alignment of the reactor internals. The surveillance was accomplished by the issuance of an Inspection Release by the quality control organization after conformance had been verified.

A resident quality control representative performed a surveillance/audit program at the manufacturer's facility, witnessed the required tests and inspections, and issued the inspection releases. An example would be the radiographic examination of the welds joining core barrel shell courses.

Components and materials supplied by Westinghouse to the assembly manufacturer were subjected to a similar program. Quality control engineers developed inspection plans for all raw materials, components, and assemblies. Each level of manufacturing was evaluated by a qualified inspection for conformance, e.g., witnessing the ultrasonic testing of core plate raw material. Upon completion of specified events, all documentation was audited prior to releasing the material or component for further manufacturing. All documentation and inspection releases are maintained in the quality control central records section. All materials are traceable to the mill heat number.

In conclusion, a set of "as built" dimensions were taken to verify conformance to the design requirements and ensure proper fitup between the reactor internals and the reactor pressure vessel.

3.6.3.1 **Fuel Product Assurance**

Fuel product assurance philosophy is generally based on the performance of inspections by the supplier to a 95% confidence that at least 95% of the product meets specification, unless otherwise noted. This confidence level is based on past experience gained during the manufacturing of over 10,000 metric tons of uranium cores. The following inspections are included:

1. Component parts - Parts received are generally inspected to a 95×95 confidence level. The characteristics inspected depend upon the component parts, and include dimensional and visual inspections, and check audits of test reports, material certifications, and non-destructive examinations such as X-ray and ultrasonic tests. Supplier material processes and component specifications specify in detail the inspections to be performed. All material used in the manufacture of the core is accepted and released by Quality Control.

2. Pellets - Inspection is performed to a 95×95 confidence level for the dimensional characteristics such as diameter, length, and squareness of ends. Additional visual inspections are performed for cracks, chips, and pores according to standards established at the beginning of production. These standards are based upon standards used in previous cores that have in turn served as standards for millions of pellets manufactured and used in operating cores. Density is determined in terms of weight per unit length. Chemical analyses are performed on each blend of pellets throughout pellet production. The hydrogen content of pellets loaded into fuel tubing is also tested and controlled.

Pellets that are coated with a boride material for use in integral fuel burnable absorber (IFBA) rods undergo additional inspections to determine the linear boron concentration on the pellet and the adherence of the coating.

3. Rod Inspection - Fuel rod inspection consists of the following non-destructive examination techniques and methods associated with the parameters or characteristics identified:

   a. *Leak testing* - Each rod is tested, using a calibrated mass spectrometer, with helium being the detectable gas.

   b. *Enclosure welds* - Rod welds are inspected by ultrasonic test or x-ray as an alternative method in accordance with a qualified technique and the applicable specification.

   c. *Dimensional* - All rods are dimensionally inspected prior to final release. The requirements include such items as camber and visual appearance. A sample of rods is evaluated for length.

   d. *Plenum dimensions* - All fuel rods are inspected by gamma scanning radiography or other approved methods to ensure proper plenum dimensions.

   e. *Pellet-to-pellet-gaps* - All fuel rods are inspected by gamma scanning or other approved methods to ensure that no significant gaps exist between pellets.

   f. *Gamma scanning* - Non-IFBA fuel rods are active gamma scanned to verify enrichment control prior to acceptance for assembly loading. IFBA fuel rods are passive gamma scanned to verify enrichment control and zone lengths prior to acceptance for assembly loading.

   Traceability of rods and associated rod components is maintained throughout manufacture and Quality Control release.

4. Final QC Release - The rods, upon final inspection, are released and available for fuel assembly loading.

5. Assembly - Inspection consists of 100% inspection for drawing and specification requirements.

6. Other inspections - The following inspections are performed as part of the routine inspection operation:

   a. Measurements, other than those specified above, that are critical to thermal/hydraulic analyses are obtained to enable evaluation of manufacturing variations to a 99.5% confidence level.

   b. Tool and gauge inspection and control is performed, including standardization to primary and secondary working standards. Tool inspection is performed at prescribed intervals on all serialized tools. Complete records are kept of the calibration and condition of tools.

c. Check audit inspection of all inspection activities and records to ensure that prescribed methods are followed and that all records are correct and properly maintained.

d. Surveillance of outside contractors, including approval of standards and methods, is performed where necessary.

To prevent the possibility of mixing enrichments during fuel manufacture and assembly, meticulous process control is exercised.

The UF_6 gas is normally received from the enrichment plant in sealed containers, the contents of which are fully identified.

Upon receipt by the supplier, an additional identification tag completely describing the contents is affixed to the containers before transfer to UF_6 storage.

The UF_6 is converted to UO_2. After conversion the UO_2 is normally milled and then blended. The blended powder is inspected by Quality Control and released for pelleting based on a chemical analysis.

Pellet production lines are physically separated from each other, and pellets of only a single enrichment and design are produced in a given production line or a segregated part of the line.

Finished pellets are placed on trays which are identified as to enrichment and transferred to closed storage carts.

If the storage carts are moved out of the established control area, the carts are locked and sealed to prevent mixing of pellets of different designs and enrichments. Unused powder and substandard pellets are returned to storage.

Loading of the pellets into the cladding is again accomplished in separated production lines, and again only one design and enrichment at a time is loaded on a line.

A bar code that provides traceability information is laser etched on each fuel tube. The bar code provides a reference of the fuel pellets contained in the fuel rods. Other approved methods of identification may be used.

At the time of installation into an assembly, an inspector verifies that all fuel rods in an assembly have the same contract identification, and that the top nozzle to be used on the assembly carries the correct identification information. The top nozzle identification is then used by manufacturing and station fuel handling personnel to maintain fuel assembly traceability. All fabrication plant personnel handling fuel materials should have thorough medical examinations and should be checked for color blindness.

3.6.3.2 **Control Rod, Burnable Poison Rod and Source Rod Tests and Inspections**

All clad/end plug and/or seal welds in control rods, burnable poison rods, flux suppression insert rods, and source rods are checked for integrity by visual inspection; ultrasonic test or, alternatively, may also be inspected by x-ray; and helium leakage in accordance with qualified techniques and supplier specifications. Beginning with Cycle 20 at both units, the feed burnable poison rods are fabricated with a new end plug welding process, and the vendor no longer performs ultrasonic testing or x-ray on these components.

CHAPTER 4 REACTOR COOLANT SYSTEM

4.1 DESIGN BASES

Note: As required by the Subsequent Renewed Operating Licenses for Surry Units 1 and 2, issued May 4, 2021, various systems, structures, and components discussed within this chapter are subject to aging management. The programs and activities necessary to manage the aging of these systems, structures, and components are discussed in Chapter 18.

4.1.1 Performance Objectives

The reactor coolant system transfers the heat produced by the nuclear reaction in the core to the steam generators, where steam is generated to drive the turbine generator. Borated demineralized light water is circulated at the flow rate and temperature consistent with achieving the reactor core thermal-hydraulic performance presented in Section 3.4. The water also acts as a neutron moderator, a reflector, and a solvent for the neutron absorber.

The reactor coolant system provides a boundary for containing the primary coolant under operating temperature and pressure conditions. It serves to confine radioactive material and limits its uncontrolled release to the secondary system and to the other parts of the unit. During transient operation, the system heat capacity attenuates thermal transients generated by the core or extracted by the steam generators. The reactor coolant system accommodates coolant volume changes within the protection system criteria both during normal operation and during anticipated transient conditions.

The thermal-hydraulic effects resulting from loss of power to the reactor coolant pumps are reduced to acceptable levels by appropriate selection of the inertia of the reactor coolant pumps so that core damage does not result. The layout of the system ensures natural circulation capability following a loss-of-flow incident to permit cooldown without overheating the core.

A portion of the reactor coolant system piping is used by the safety injection system to deliver cooling water to the core for emergency core cooling during a loss-of-coolant accident (LOCA).

4.1.2 Design Criteria

4.1.2.1 Quality Standards

Quality standards of material selection, design, fabrication, and inspection conform to the applicable provisions of recognized codes and good nuclear practice (Section 4.1.6). Details of the quality assurance test procedures and inspection acceptance levels are given in Sections 4.3.1 and 4.4. Particular emphasis is placed on the quality assurance of the reactor vessel

4.1.2.2 **Performance Standards**

All piping, components, and supporting structures are designated and designed as Seismic Class I components, and are designed to withstand the jet thrust forces of a pipe rupture[1]. Details are given in Section 4.1.3.

4.1.2.3 **Records Requirements**

Records of the design, fabrication, quality control, and construction of the major reactor coolant system components and the related engineered safety features components are maintained by or are available to Vepco throughout the station life.

4.1.2.4 **Missile Protection**

The dynamic effects of a pipe rupture accident[1] and other postulated accidents have been evaluated in the detailed layout and design of the high-pressure equipment and missile barriers. The design ensures the missile protection necessary to maintain functional capability.

4.1.2.5 **Reactor Coolant Pressure Boundary**

The reactor coolant system, with its control and protective provisions, accommodates the pressures and temperatures attained under all expected modes of station operation or anticipated system interactions, and maintains the stresses within applicable code stress limits (Section 4.3.1).

4.1.2.6 **Monitoring Reactor Coolant Leakage**

Positive indications in the control room of leakage of coolant from the reactor coolant system to the containment are provided by equipment that permits continuous monitoring of the containment internal pressure, temperature, and gaseous and particulate activity; of containment sump water level; of makeup water to the primary system; and of the temperature of water leaking from the reactor vessel through its head flange. This equipment provides information that is indicative of a basic level of leakage from primary systems and components. Any increase observed may be indicative of an increase in the leakage rate from the reactor coolant system. The equipment provided is capable of monitoring such a change. Refer to Section 4.2.7.

4.1.2.7 **Reactor Coolant Pressure Boundary Capability**

The reactor coolant pressure boundary is capable of accommodating, without rupture, the loads resulting from a sudden reactivity insertion such as results from rod ejection. Details of this analysis are provided in Section 14.3.3.

The operation of the reactor is such that the severity of an ejection accident is inherently limited. Since control rod assemblies are used to control load variations only, and core depletion is followed with boron dilution, only the control rod assemblies in the controlling groups are

1. As discussed in Section 4.1.3 and Section 15.6.2, it is no longer necessary to consider the dynamic effects of postulated rupture of the primary reactor coolant loop piping. However, other pipe ruptures as discussed in Section 15.6.2 must still be considered.

inserted in the core at power, and at full power these rods are only partially inserted. A rod insertion limit monitor is provided as an administrative aid to the operator to ensure that this condition is met.

The reactor design is such that the maximum fuel temperature for the highest-worth ejected rod is below the threshold for resultant damage to the primary system pressure boundary.

The failure of a rod mechanism housing, causing a control rod assembly to be rapidly ejected from the core, is evaluated as a theoretical but not credible accident. While limited fuel damage could result from this hypothetical event, the fission products would be confined to the reactor coolant system and the reactor containment. The environmental consequences of rod ejection would be less severe than from the hypothetical LOCA, for which public health and safety is shown to be adequately protected.

4.1.2.8 **Reactor Coolant Pressure Boundary Rapid Propagation Failure Prevention**

The probability of a rapid propagation type failure is remote. The reactor coolant pressure boundary is designed to reduce to an acceptable level the probability of this type of failure.

In the core region of the reactor vessel it is expected that the notch toughness of the material will change as a result of fast neutron exposure. This change is evidenced as a shift in the reference temperature for the nil ductility transition (RT_{NDT}) which is factored into the operating procedures. The RT_{NDT} shift of the vessel material and welds, due to radiation effects, is monitored by an integrated surveillance program that conforms with the requirements of 10 CFR 50, Appendix H and ASTM E 185, and is described in Section 4.1.7.

All pressure-containing components of the reactor coolant system are designed, fabricated, inspected, and tested in conformance with the applicable codes. Further details are given in Section 4.1.6.

The reactor vessel closure heads were replaced with closure heads with impact properties that exceed the original head requirements. The low alloy steels of the replacement closure head flanges have an RTNDT of -67°F for Unit 1 and -60°F for Unit 2. 10 CFR 50 Appendix G requires the minimum temperature for the pressure-temperature limit curves be greater than or equal to the RTNDT of the limiting flange-region material. These replacement closure head flange RTNDT values are less limiting than that assumed in the development of the Technical Specification pressure/temperature limit curves. Therefore, the Technical Specification pressure/temperature limit curves will not change.

4.1.2.9 **Reactor Coolant Pressure Boundary Surveillance**

The design of the reactor vessel and its arrangement in the system provides the capability for accessibility during service life to all the internal surfaces of the vessel and to certain external zones of the vessel, including the nozzle to reactor coolant piping welds and the top and bottom heads. The reactor arrangement within the containment provides sufficient space for inspection of the external surfaces of the reactor coolant piping, except for the area of pipe within the primary shielding concrete.

4.1.3 Design Characteristics

4.1.3.1 Design Pressure

The reactor coolant system design and operating pressure, the safety, power relief, and pressurizer spray valve design setpoints, and the protection system pressure setpoints are listed in Table 4.1-1. The design pressure allows for operating transient pressure changes. The selected design margin considers core thermal lag, coolant transport times and pressure drops, instrumentation and control response characteristics, and system relief valve characteristics. The design pressures and data for the respective system components are listed in Tables 4.1-2 through 4.1-7.

4.1.3.2 Design Temperature

The design temperature for each component is selected to be above the maximum coolant temperature in that component under all normal and anticipated transient load conditions. The design and operating temperatures of the respective system components are listed in Tables 4.1-2 through 4.1-7.

4.1.3.3 Seismic Loads

The seismic loading conditions are established by the operating-basis earthquake (OBE) and design-basis earthquake (DBE). The ground acceleration values and the basis for their selection are presented in Section 2.5. The seismic analysis of the reactor coolant system is described in more detail in Appendix 15A.

For the OBE loading condition, the nuclear steam supply system is capable of continued safe operation. Therefore, for this loading condition, critical structures and equipment are required to operate within allowable code stress limits. The seismic design for the design-basis earthquake provides a margin that ensures the capability to shutdown and maintain the nuclear facility in a safe condition. In this case, it is only necessary to ensure that the reactor coolant system components are able to perform their safety function. This has come to be referred to as the “no-loss-of-function” criterion and the loading condition as the “no-loss-of-function earthquake” loading condition.

The criteria adopted for allowable stresses and stress intensities in vessels and piping subjected to normal loads plus seismic loads are defined in Section 15A.

To further ensure against accident aggravation, the reactor coolant system has been checked for the combination of stresses associated with the design-basis earthquake and the most severe pipe rupture loadings on the reactor coolant system.[1] These stress loadings are designed to be below the limits assumed to cause rupture, as illustrated in Section 15A.

For the combination of normal and operating-basis earthquake loadings, the stresses in the support structures are designed to be within the limits of the applicable codes as discussed in Section 15A.

For the combination of normal and operating-basis earthquake loadings, and for the combination of these loads plus the most severe on the primary reactor coolant system due to postulated pipe rupture loadings[1], the stresses in the support structures are limited to values that ensure structural integrity and maintain the component stresses within the limit previously established.

4.1.4 Cyclic Loads

All components in the reactor coolant system are designed to withstand the effects of cyclic loads due to reactor coolant system temperature and pressure changes. These cyclic loads are introduced by normal power changes and reactor trip, start-up, and shutdown operations. The number of thermal and loading cycles used for design purposes are given in Table 4.1-8. Heatup and cooldown rates are limited as indicated in Section 4.2.6.

The number of cycles for unit heatup and cooldown at 100°F/hr was selected as a conservative estimate based on an evaluation of the expected requirements. The resulting number, which averages five heatup and cooldown cycles per year and was based on the original license period of 40 years, could be increased significantly; however, it is intended to represent a conservative realistic number rather than the maximum allowed by the design. This estimate has been retained for the 80-year renewed operating license period.

Although loss-of-flow and loss-of-load transients are not included in the tabulation, since the tabulation is intended to represent only normal design transients, the effects of these transients have been analytically evaluated and are included in the fatigue analysis for primary system components.

The reactor coolant system and its components are designed to accommodate 10% of full-power step changes in station load and 5% of full-power-per-minute ramp changes over the range from 15% full power up to and including, but not exceeding, 100% of full power without reactor trip. Automatic rod withdrawal is disabled. The station loading from 15% to 100% is accomplished by manual control rod withdrawal. Operator action will be needed to restore the station parameters to the reference values on design basis load increase transients. The reactor coolant system accepts a complete loss of load from full power with reactor trip. In addition, the steam dump system makes it possible to accept a 50% load rejection from full power without reactor trip.

1. As discussed in Section 15.6.2, it is no longer necessary to consider the dynamic effects of postulated rupture of the primary reactor coolant loop piping. However, other pipe ruptures as discussed in Section 15.6.2 must still be considered.

4.1.5 Service Life

The service life of reactor coolant system pressure components depends upon the material irradiation, unit operational thermal cycles, quality manufacturing standards, environmental protection, and adherence to established operating procedures.

The reactor vessel is the only component of the reactor coolant system that is exposed to a significant level of neutron irradiation. It is therefore the only component that is subject to any appreciable material irradiation effects. These effects are discussed in Section 4.1.7.

Reactor vessel design is based on the transition temperature method of evaluating the possibility of brittle fracture of the vessel material as a result of operations. The service life of the reactor coolant system components, as required by the ASME Code, Section III, for Class “A” vessels, is established for the 80-year design life. These operating conditions include the cyclic application of pressure loadings and thermal transients listed in Table 4.1-8.

4.1.6 Codes And Classifications

All pressure-containing components of the reactor coolant system are designed, fabricated, inspected, and tested in conformance with the applicable codes listed in Table 4.1-9.

The reactor coolant system is classified as Class I for seismic design. The load combinations for Class I design are described in Chapter 15.

The Westinghouse Equipment Specification for the reactor vessel contains many requirements that are supplemental to those specified in ASME Code, Section III. These requirements include the following:

1. Design
   a. Design pressures and temperatures have been selected to be above pressures and temperatures that would be expected to occur under all normal and transient conditions.
   b. A complete fatigue analysis was performed on the entire vessel.
2. Inspection and Quality Assurance
   a. In addition to the normal straight-beam ultrasonic examination required by the ASME Code, all pressure boundary plate material was examined by the angle-beam ultrasonic method.
   b. All weld deposit overlay cladding used for the vessel corrosion resistant lining was 100% ultrasonically inspected to verify that the cladding is bonded to the base metal.
   c. After the vessel hydrostatic test, all vessel and head internal surfaces were liquid penetrant inspected, and all external surfaces were magnetic particle inspected.

d. Prior to placing the vessel in service, an ultrasonic examination of pressure boundary welds was performed in accordance with the ASME Code for inservice inspection of nuclear reactor coolant systems.

e. In addition to the ASME Code-required third-party inspector, Westinghouse provided full-time quality assurance coverage in the Babcock & Wilcox Co. shop, and also in the Rotterdam Dockyard (RDM) shop during the fabrication of the Surry vessels.

f. In addition to the quality assurance coverage provided by Westinghouse, Vepco and the architect-engineer, Stone & Webster, performed regular quality assurance audits of reactor vessel fabrication as performed by RDM.

Unit 1 Reactor Vessel Closure Head was replaced with a closure head fabricated and manufactured in accordance with the French Construction Code (R-CCM) 1993 Edition with 1st Addenda June 1994, 2nd Addenda June 1995, 3rd Addenda June 1996 and Modification Sheets FM 797, 798, 801, 802, 803, 804, 805, 806, and 807. The sizing calculations and the stress and fatigue analysis were performed to ASME B&PV Code, Section III, 1995 Edition 1996 Addenda. The Design Report (Reference 14) certified that the closure head meets the design requirements and stress limits for the ASME B&PV Code, Section III, 1995 Edition addenda through 1996, except as noted below.

Exception: The CRDM Adapter Tube Assembly includes a friction weld at the bimetallic joint between the housing flange and the tube. The use of friction welds in the fabrication of vessels and piping is not in accordance with the requirements of Section III of the ASME Boiler and Pressure Vessel Code. Consideration of this weld as a Category B full penetration weld in the stress analysis is justified in the Report of Reconciliation (Reference 15) for the Surry Unit 1 replacement reactor vessel closure head.

The Unit 2 reactor vessel closure head was replaced with a closure head fabricated and manufactured by Mitsubishi Heavy Industries (MHI). The replacement reactor vessel closure head was designed and fabricated in accordance with ASME B&PV Code, Section III, 1995 Edition with 1996 Addenda. The stress and fatigue analyses were performed to ASME B&PV Code, Section III, 1995 Edition with 1996 Addenda. The Mitsubishi Heavy Industries Design Specification, Reference 16, for the Unit 2 reactor vessel head contains many requirements that are supplemental to those specified in ASME Code, Section III. These requirements include the following:

1. Design

   a. Design pressures and temperatures have been selected to be above the pressures and temperatures that would be expected to occur under all normal and transient conditions.

   b. A complete fatigue analysis was performed on the entire head.

2. Inspection and Quality Assurance

a. All weld deposit overlay cladding used for head corrosion resistant lining was 100% ultrasonically inspected to verify that the cladding is bonded to base metal.

b. The final non-destructive examination of the pressure boundary materials was conducted in the following:

(1) Low alloy materials were magnetic particle examined after final machining of the reactor vessel head.

(2) Surfaces that are clad were magnetic particle examined prior to cladding.

(3) Surfaces were magnetic particle examined after removal of temporary attachments.

4.1.7 Irradiation Surveillance Program

4.1.7.1 General Description

In the surveillance program (References 4 & 5) the evaluation of the radiation damage is based on pre-irradiation testing of Charpy V-notch and tensile specimens, and post-irradiation testing of Charpy V-notch and tensile specimens. Wedge opening loading (WOL) fracture mechanics test specimens are also irradiated for potential supplemental testing. This program is directed toward evaluation of the effect of radiation on the fracture toughness of reactor vessel steels based on the transition temperature approach and the fracture mechanics approach, and is in accordance with ASTM-E-185, *Recommended Practice for Surveillance Tests on Structural Materials in Nuclear Reactors*. Low melting point alloys are included as thermal control specimens. They provide indication if the area of surveillance has exceeded a given temperature.

The reactor vessel surveillance program uses eight specimen capsules, more than the minimum number recommended by ASTM-E-185. The capsules are located about 3 inches from the vessel wall, directly opposite the center portion of the core. Elevation and plan views showing the location and dimensional spacing of the capsules with relation to the core, thermal shield, and vessel and weld seams are shown in Figures 4.1-1 and 4.1-2, respectively. The capsules can be removed or relocated when the vessel head and upper internals are removed. The capsules contain specimens of some of the materials found in the Surry reactor vessel. These specimens include material from the shell plates located in the core region of the reactor and associated weld metal and heat-affected-zone metal. (As part of the surveillance program, a report of the residual elements in weight percent to the nearest 0.01% will be made for surveillance material base metals and as deposited weld metal.) In addition, 8 Charpy specimens in each of the surveillance capsules are made from fully documented specimens of SA533 Grade B correlation monitor material obtained through Subcommittee II of ASTM Committee E10, Radioisotopes and Radiation Effects. The eight Unit 1 capsules contain approximately 32 tensile specimens, 240 Charpy V-notch specimens (which include weld metal and heat-affected-zone material), and 40 WOL specimens. The eight Unit 2 capsules contain a total of 32 tensile specimens, 352 Charpy V-notch specimens (which include weld metal and heat-affected-zone material), and 32 WOL specimens.

The dosimeters permit evaluation of the flux seen by the specimens and vessel wall. In addition, thermal monitors made of low-melting alloys are included to monitor temperature of the specimens. The specimens are enclosed in a tight-fitting stainless steel sheath to prevent corrosion and ensure good thermal conductivity. The complete capsule is helium leak tested. Vessel material sufficient for additional capsules is kept in storage should the need arise for additional replacement test capsules in the program.

The anticipated degree to which the specimens will perturb the fast neutron flux and energy distribution will be considered in the evaluation of the surveillance specimen data. Verification and possible readjustment of the calculated wall exposure will be made by use of data on all capsules withdrawn.

Specimen data for Unit 1 capsules are given in Table 4.1-10. Specimen data for Unit 2 capsules are given in Table 4.1-11. The schedule for removal and reinsertion of capsules is shown on Table 4.1-12 (Unit 1) and Table 4.1-13 (Unit 2). Irradiated surveillance capsules which do not require testing to satisfy ASTM E-185 are designated as standby capsules. There currently is no detailed regulatory guidance regarding the treatment of standby capsules that are removed but not tested. To address this concern, all surveillance capsules placed in storage will be maintained for possible future insertion. If one or more capsules will not be maintained in such a way as to permit future insertion, then the NRC staff will be notified of this change.

Irradiation of the specimens is higher than the irradiation of the adjacent vessel wall because they are closer to the core than the vessel itself. Since these specimens experience higher irradiation and are actual samples from the materials used in the vessel, the RT_{NDT} measurements are representative of the vessel at a later time in life. Data from fracture toughness samples (WOL) are expected to provide additional information for use in determining allowable stresses for irradiated material, if required.

The reactor vessel surveillance capsule holders are located at 15, 25, 35, and 45 degrees relative to the core symmetry, as shown in Figure 4.1-2.

The unirradiated reference temperature for the nil ductility transition (RT_{NDT}) for a material may be determined either by large specimen drop weight tests or by Charpy V-notch impact tests. The unirradiated RT_{NDT} is the higher of (a) the nil ductility transition temperature as determined by drop weight test, or (b) the temperature at which Charpy test specimens oriented normal to the major working direction exhibit at least 50 ft-lb of absorbed energy and 35 mils of lateral expansion, minus 60°F. RT_{NDT} values for irradiated materials are calculated in the manner prescribed by Regulatory Guide 1.99, Revision 2, *Radiation Embrittlement of Reactor Vessel Materials* using data from the rector vessel material surveillance program.

Tables 4.1-14 and 4.1-15 provide the unirradiated RTNDT values as determined by NB-2331 of Section III of the ASME B&PV Code or one of the 3 alternative methods for determining the RTNDT described below.

- Topical Report BAW-2308
- Branch Technical Position (BTP) 5-3, Revision 2
- EPRI Report BWRVIP-173-A, Appendix B, Alternative Approach 2 (GE Method)

Framatome ANP Topical Report BAW-2308, Revision 1-A (Reference 17) provides an alternate method for determining the adjusted RT_{NDT} (reference nil-ductility temperature) of the Linde 80 weld materials present in the beltline region of the reactor pressure vessels at Surry Power Stations Unit 1 and 2. Topical Report BAW-2308, Revision 1-A, also provides revised initial (unirradiated) RT_{NDT} values and initial (unirradiated) uncertainty terms for the Linde 80 weld materials present in the reactor pressure vessels of Surry Units 1 and 2. Topical Report BAW-2308, Revision 1-A was approved by the NRC in August 2005.

The alternative initial reference temperature values provided in Topical Report BAW-2308, Revision 1-A are obtained by using the B&W Owners Group Master Curve reference temperature database and ASME Code Case N-629. As described in Topical Report BAW-2308, Revision 1-A, previous initial RT_{NDT} values for Linde 80 class of weld materials were determined by the 50 ft-lb Charpy impact energy according to NB-2331 of Section III of the ASME B&PV Code, which gave overly conservative initial RT_{NDT} values.

The Master Curve methodology permits establishment of a reference temperature, T_0, using direct fracture toughness testing of compact tension (CT) specimens ranging in size from 0.5-inch thickness CTs (0.5T-CTs) to 2.0T-CTs, and precracked Charpy-sized bend specimens, based on ASTM standard Test Method E 1921. The value of T_0 is statistically related to the temperature at which fracture toughness specimens from a given weld wire heat exhibited a median fracture toughness of 100 $MPa\sqrt{m}$, which is equivalent to 90 $ksi\sqrt{in}$. The Master Curve method therefore represents an alternative to the “indirect” tests of fracture toughness using drop weight and Charpy V-notch testing per ASME Code Section III, Paragraph NB-2331, which are used to establish values of RT_{NDT}.

Topical Report BAW-2308, Revision 1-A concludes that the use of initial (unirradiated) reference temperature values and appropriate uncertainty terms for certain Linde 80 weld materials, based on Master Curve method and ASME Code Case N-629, provide an acceptable alternate means of predicting irradiation induced shift in fracture toughness when the RT_{NDT}-based irradiation induced shift models of Regulatory Guide 1.99, Revision 2 are employed.

NRC approved use of Topical Report BAW-2308, Revision 1-A subject to certain conditions and limitations delineated in the final safety evaluation attached to Reference 17.

By letter dated February 5, 2007, the PWROG submitted Topical Report BAW-2308, Revision 2, “Initial RT_{NDT} of Linde 80 Weld Materials,” to NRC for review. The intent of Topical Report BAW-2308, Revision 2, was to supplement Topical Report BAW-2308, Revision 1-A, by addressing two of the NRC imposed conditions. NRC has determined that Topical Report BAW-2308, Revision 2 is acceptable for referencing in licensing applications to the extent specified in the final safety evaluation attached to Reference 23.

Branch Technical Position (BTP) 5-3 (Reference 37), formerly known as MTEB 5-2, provides the NRC guidance on Appendices A, G, and H to 10 CFR Part 50 and in 10 CFR 50.61, specifically for older plants designed and built before certain requirements were in force. BTP 5-3 can be used to determine initial RTNDT when insufficient fracture toughness testing data is available to use ASME Code Section III, Paragraph NB-2331, by using the following:

1. If dropweight tests were not performed, but full Charpy V-notch curves were obtained, the nil ductility transition temperature (NDTT) for SA-533 Grade B, Class 1 plate and weld material may be assumed to be the temperature at which 30 ft-lbs was obtained in Charpy Vnotch tests, or 0°F, whichever was higher.
2. If dropweight tests were not performed on SA-508-2 forgings, the NDTT may be estimated as the lowest of the following temperatures:
   a. 60°F,
   b. The temperature of the Charpy V-notch upper shelf
   c. The temperature at which 100 ft-lbs was obtained on Charpy V-notch tests if the upper shelf energy values were above 100 ft-lbs.
3. If transversely-oriented Charpy V-notch specimens were not tested, the temperature at which 50 ft-lbs and 35 mils lateral expansion would have been obtained on transverse specimens may be estimated by one of the following criteria:
   a. Test results from longitudinally-oriented specimens reduced to 65% of their value to provide conservative estimates of values expected from transversely oriented specimens.
   b. Temperatures at which 50 ft-lbs and 35 mils lateral expansion (LE) were obtained on longitudinally-oriented specimens increased 20°F to provide a conservative estimate of the temperature that would have been necessary to obtain the same values on transversely-oriented specimens.
4. If limited Charpy V-notch tests were performed at a single temperature to confirm that at least 41 J (30 ft-lbs) was obtained, that temperature may be used as an estimate of the RTNDT provided that at least 61 J (45 ft-lbs) was obtained if the specimens were longitudinally oriented. If the minimum value obtained was less than 61 J (45 ft-lbs), the RTNDT may be estimated as 11°C (20°F) above the test temperature.

BWRVIP-173-A, Appendix B, Alternative Approach 2 was developed by General Electric (GE) to address SA508, Class 2 forgings when data is scarce or incomplete (Reference 34). It includes a method for determining the initial RTNDT for plates and forgings with limited measured data. The approach for vessel plate and forging materials is as follows:

(1) Derive a nil-ductility transition temperature (NDTT) value as equal to the longitudinal Charpy V-notch 35 ft-lb transition temperature.

(2) Operate on the lowest longitudinal Charpy V-notch data point (ft-lbs) to obtain at least 50 ft-lbs transition temperature by adding 2°F per ft-lb, or by plotting a curve (ft-lbs vs. temperature) where possible. If no transverse Charpy V-notch data are available, an adjustment must be made to convert from longitudinal to the transverse 50 ft-lbs transition temperature. BTP 5-3 suggests a 20°F shift, whereas GE recommends a 30°F shift. The NRC has accepted both longitudinal to transverse temperature shift methods as being conservative.

(3) RTNDT is the higher of the NDTT from (1), or the transverse Charpy V-notch 50 ft-lbs transition temperature value from (2) minus 60°F.

NRC has determined that BWRVIP-173-A, Appendix B, Alternative Approach 2 is acceptable for referencing in licensing applications to the extent specified in the final safety evaluation attached to Reference 34.

ASME Section XI Appendix G provides guidance for translating the value of RT_{NDT} into a K value, representative of the material's resistance to fracture. Normal operation and hydrostatic test pressure/temperature operating limits which satisfy the requirements of 10 CFR 50 Appendix G are established on the basis of linear-elastic fracture mechanics theory, such that thermal and pressure stresses will not result in combined stresses in excess of the material's resistance to fracture (K). Because the normal operating temperature of the reactor vessel is well above the RT_{NDT} of the limiting reactor vessel beltline material, brittle fracture during normal operation is not considered to be a credible mode of failure.

The allowable pressures are revised periodically according to the schedule in the reactor vessel surveillance program. The revised curves are based upon the experimentally determined fluence from the last analyzed capsule, and a conservative fluence projection for the next scheduled capsule withdrawal. The use of an RT_{NDT} which includes the projected change in RT_{NDT} due to irradiation provides additional conservatism for the non-irradiated components of the reactor coolant system.

Virginia Power has been a member of the Babcock and Wilcox Owner's Group (B&WOG) Reactor Vessel Working Group (RVWG). Surry Units 1 and 2 are participants in the RVWG's Master Integrated Reactor Vessel Surveillance Program (MIRVSP) (Reference 8). The program integrates (a) the plant specific reactor vessel surveillance programs of the participants, (b) the existing supplemental B&W Owners Group irradiation capsules, (c) additional supplemental irradiation capsules to assure the availability of high fluence and thermal annealing data for the participants' reactor vessels, (d) existing test reactor irradiation data sources, and (e) provisions for additional test reactor irradiation data sources. The objectives of the MIRVSP are as follows:

1. Provide a unified power reactor data base for Linde 80 welds necessary to perform the analysis required by 10 CFR 50, Appendix G for materials that may exhibit < 50 ft-lb Charpy upper-shelf energy.
2. Maximize the effectiveness of data sharing among participants to assure that required data is available to all participants for current and extended plant operation.
3. Provide the materials, specimens, irradiation capsules, and power reactor irradiation sites required to obtain data that can be used to evaluate the thermal annealing process.
4. Minimize testing of redundant capsules (those which do not provide useful information) in existing plant-specific RVSP's to ensure optimum utilization of data sources.
5. Simplify the licensing process by providing a single document that covers the RVSP integration and capsule withdrawal schedules and which can be referenced in each utility's design documentation.

The MIRVSP does not reduce the number of required capsules in the plant-specific programs, nor does it eliminate the requirement that an acceptable reactor vessel fluence monitoring program be maintained. An integrated program must meet the criteria enumerated in 10 CFR 50, Appendix H, Paragraph III.C.

These criteria and considerations are satisfied by the MIRVSP approach (Reference 9). The Surry 1 and 2 plant-specific surveillance capsule withdrawal schedules presented in Tables 4.1-12 and 4.1-13 are consistent with the guidelines of the MIRVSP as described above. Standby Capsules U, S, and Y (Unit 1) and T and Z (Unit 2) are available to satisfy potential fluence monitoring requirements during the 20-year license renewal and subsequent license renewal (SLR) periods.

4.1.7.2 Flux Activation Measurements in the Irradiation Samples

The Surry Units 1 & 2 surveillance program capsules contain passive neutron flux monitors made of U-238, Np-237, Co-Al, Cu, Ni, Cadmium-shielded Co-Al, and Fe. The iron (for Surry Unit 2), nickel, copper, and cobalt-aluminum monitors, in wire form, are placed in holes drilled in spacers at several axial levels within the capsules. For Surry Unit 1, the test specimens also serve as iron dosimeters. Cadmium-shielded neptunium and uranium fission monitors are accommodated within a dosimeter block located near the center of the capsule.

The use of passive monitors does not yield a direct measure of the energy dependent flux level at the point of interest. Rather, the activation or fission process is a measure of the integrated effect that the time- and energy-dependent neutron flux has on the target material over the course of the irradiation period. An accurate assessment of the average neutron flux level incident on the various monitors may be derived from the activation measurements only if the irradiation parameters are well known. In particular, the following variables are of interest:

- The operating history of the reactor
- The energy response of the monitor
- The neutron energy spectrum at the monitor location
- The physical characteristics of the monitor

The specific activity of each of the monitors is determined using established ASTM procedures. Following sample preparation, the activity of each monitor is determined using contemporary gamma-ray spectroscopy techniques. The overall standard deviation of the measured data is a function of the precision of sample weighing, the uncertainty in counting, and the acceptable error in detector calibration.

Having the measured specific activities, the operating history of the reactor, and the physical characteristics of the sensors, reaction rates referenced to full power operation are determined from the following equation::

$$R = \frac{A}{N_0 F Y \sum_{j=1}^{n} \frac{P_j}{P_{ref}} C_j (1 - e^{-\lambda t_j}) e^{-\lambda t_d}}$$

where:

R	=	sensor reaction rate averaged over the irradiation period and referenced to operation at a core power level of Pref (rps/atom)
No	=	number of target element atoms per gram of sensor (atom/gram)
A	=	measured specific activity
F	=	weight fraction of the target isotope in the target material
Y	=	number of product atoms produced per reaction
n	=	total number of monthly intervals comprising the irradiation period
Pj	=	average core power level during irradiation period j (MW)
Pref	=	maximum or reference core power level of the reactor (MW)
l	=	decay constant of the product isotope (s-1)
tj	=	length of irradiation period j (s)
td	=	decay time following irradiation period j (s)

C_j = Calculated ratio of ø(E > 1.0 MeV) during irradiation period j to the time-weighted average ø(E > 1.0 MeV) over the total irradiation period.

The computed full power reaction rates form a suitable basis for comparison with the results of neutron transport calculations described in Section 4.1.7.3

4.1.7.3 Calculation of Integrated Fast Neutron (E Greater than 1.0 Mev) Flux at the Irradiation Samples

Knowledge of the neutron environment within the pressure vessel-surveillance capsule geometry is required as an integral part of LWR pressure vessel surveillance programs for two reasons. First, in the interpretation of radiation-induced property changes observed in materials test specimens, the neutron environment (fluence, flux) to which the test specimens were exposed must be known. Second, in relating the changes observed in the test specimens to the present and future condition of the reactor pressure vessel, a relationship between the environment at various positions within the reactor vessel and that experienced by the test specimens must be established. The former requirement is normally met by employing a combination of rigorous analytical techniques and measurements obtained with passive neutron flux monitors contained in each of the surveillance capsules. The latter information, on the other hand, is derived solely from analysis.

This section describes a discrete ordinates Sn transport analysis performed for the Surry Units 1 & 2 reactor to determine the fast neutron (E > 1.0 Mev) flux and fluence as well as the neutron energy spectra within the reactor vessel and surveillance capsules; and, in turn, to develop data for use in relating neutron exposure of the pressure vessel to that of the surveillance capsules.

A plan view of the Surry reactor geometry at the core midplane is shown in Figure 4.1-2. Eight irradiation capsule holders attached to the thermal shield are included in the design to support the reactor vessel surveillance program (References 4 & 5). The capsules were originally located at 45°, 55°, 65°, 165°, 245°, 285°, 295°, and 305° relative to the major axis at 0°.

An axial and plan view of a single surveillance capsule attached to the thermal shield is shown in Figure 4.1-1. The stainless steel specimen container is 1-inch square and approximately 3 feet in height. The containers are positioned axially such that the specimens are centered on the core midplane, thus spanning the central 3 feet of the 12-foot high reactor core.

From a neutronic standpoint, the surveillance capsule structures are significant. In fact, they have a marked impact on the distributions of neutron flux and energy spectra in the water annulus between the thermal shield and the reactor vessel. Thus, in order to properly ascertain the neutron environment at the test specimen locations, the capsules themselves must be included in the analytical model. Use of at least a two-dimensional computation is, therefore, mandatory.

Fast neutron fluence (E > 1.0 MeV) analyses (References 18 & 19) were performed in support of the transition to integral fuel burnable absorber (IFBA) for Surry Units 1 and 2, and the removal of flux suppression inserts for Unit 1. The neutron fluence analyses are valid to a cumulative core exposure of 48 Effective Full Power Years for both units. Core power distributions for use in the plant specific fluence evaluations for Surry Units 1 and 2 are derived from measured assembly and cycle burnups for operating cycles 1 through 19 for Unit 1, and cycles 1 through 18 for Unit 2. The fluence evaluations reflect the low leakage fuel management strategies employed in previous operating cycles, and also include the rated thermal power uprate from 2441 MWt to 2546 MWt. Future operating cycles were assumed to be representative of reload core designs with integral fuel burnable absorber and without flux suppression inserts. A capacity factor of 95% was assumed to be representative of future operation.

The primary tool used in the determination of the flux and fluence exposure to the reactor vessel and surveillance capsules is the two-dimensional discrete ordinates transport code DORT (Reference 2). The neutron fluence analysis is divided into seven tasks: (1) generation of the neutron source, (2) development of the DORT geometry models, (3) calculation of the macroscopic material cross sections, (4) synthesis of the results, and (5-7) estimation of the calculational bias, the calculational uncertainty, and the final fluence.

The time-averaged space and energy-dependent neutron sources were calculated for the previous cycles explicitly modeled in the fluence evaluations. The effects of burnup on the spatial distribution of the neutron source were accounted for by calculating the cycle average fission spectrum for each fissile isotope on an assembly-by-assembly basis, and by determining the cycle-average specific neutron emission rate. This data was then used with the normalized time weighted average pin-by-pin relative power density (RPD) distribution to determine the space and energy-dependent neutron source. The azimuthally averaged, time averaged axial power shape in the peripheral assemblies was used with the fission spectrum of the peripheral assemblies to determine the neutron source for the DORT analyses.

The BUGLE-93 (Reference 3) cross section library was used for the neutron fluence analyses. The BUGLE-93 library is an ENDF/B-VI based data set produced specifically for light water reactor applications.

The system geometry is approximated using a combination of two-dimensional DORT models. The radial plane DORT model, (R,θ), encompasses a plane bounded radially by the center of the core and extending through the reactor vessel wall and into the concrete shield, and azimuthally by the major axis at 0° and the adjacent 45° radius. The vertical plane DORT model, (R, Z), encompasses a plane bounded axially by the upper and lower grid plates, and radially by the center of the core and a vertical line within the concrete shield. For the Unit 1 cycles where flux suppression inserts were modeled, the DORT models were further refined into multiple axial regions due to the asymmetric flux distribution.

The cross sections, geometry, and appropriate neutron sources were combined to create a set of DORT neutron transport models (R,θ) and (R, Z) for the analysis. Each (R,θ) and (R, Z) DORT run utilized a cross section Legendre expansion of three (P_3), at least forty-eight directions (S_8), with the appropriate boundary conditions. The DORT analyses produce two sets of two-dimensional flux distributions, one for a vertical plane (R, Z), and one for the radial plane (R,θ), for each set of dosimetry.

Under the assumption that the three-dimensional neutron flux is a separable function, both two-dimensional data sets were mathematically combined to estimate the flux at all three-dimensional points (R,θ,Z) of interest.

The neutron fluence evaluations documented in References 18 and 19 were performed by Framatome ANP with acceptable methods that are in compliance with NRC Regulatory Guide 1.190, *Calculational and Dosimetry Methods for Determining Pressure Vessel Neutron Fluence.* Compliance with NRC Regulatory Guide 1.190 requires that fluence values must be unbiased best-estimate calculations with a well-defined uncertainty. The neutron fluence analyses of References 18 and 19 meet these conditions, with a calculational uncertainty (1σ) of less than or equal to 15 percent.

The fluence values used in References 18 and 19 have been determined to conservatively bound the more recently developed fluence analyses that explicitly consider the effects of a Measurement Uncertainty Recapture (MUR) uprated core power level (2597 MWth).

The neutron fluence evaluations documented in References 32 and 33 were performed by Westinghouse Electric Company. The fluence projections from Framatome ANP are more conservative than the Westinghouse fluence projections.

The most recent pressure vessel fluence calculation for Surry Units 1 and 2 is documented in Reference 38, where a discrete ordinates Sn transport calculation was performed for the Surry Units 1 and 2 reactors to determine the neutron radiation environment within the traditional and extended beltline region of the reactor pressure vessel. The neutron transport methodology followed the guidance of the NRC Regulatory Guide 1.190, “Calculational and Dosimetry Methods for Determining Pressure Vessel Neutron Fluence” (March 2001). The methods used to develop the calculated pressure vessel fluence are consistent with the NRC-approved methodology described in Westinghouse Report WCAP-14040-A, Revision 4 (Reference 39).

In performing the fast neutron (E > 1.0 MeV) exposure calculations for the Surry Units 1 and 2 reactor vessels, a series of fuel-cycle-specific forward transport calculations were carried out using the two-dimensional/one-dimensional flux synthesis technique to obtain synthesized three-dimensional neutron flux distributions in Reference 38. All of the transport calculations supporting the analyses were carried out using the DORT discrete ordinates code (Reference 40) and the BUGLE-96 cross-section library (Reference 41). The BUGLE-96 library provides a coupled 47-neutron, 20-gamma-ray group cross-section data set based on ENDF/B-VI, produced specifically for light-water reactor applications. In these analyses, anisotropic scattering was treated with a P5 Legendre expansion and angular discretization was modeled with an S16 order of angular quadrature. Energy- and space-dependent core power distributions, as well as system operating temperatures, were treated on a fuel-cycle-specific basis. In Reference 38, fast neutron

(E > 1.0 MeV) fluence projections at 54, 68, and 72 Effective Full Power Years are provided for the pressure vessel materials at the traditional and extended beltline regions.

4.1.7.4 Measurement of the Initial RT_{NDT} of the Reactor Pressure Vessel Baseplate and Forgings Material

The temperature at which a material transitions from failure by ductile tearing to failure by brittle fracture is known as the Reference Temperature for the Nil Ductility Transition (RT_{NDT}). The unirradiated RT_{NDT} is the higher of (a) the nil-ductility transition temperature (NDTT or T_{NDT}) as determined by drop weight test, or (b) the temperature at which Charpy test specimens oriented normal to the major working direction exhibit at least 50 ft-lb of absorbed energy and 35 mils of lateral expansion, minus 60°F. The unirradiated (or initial) NDTT for the pressure vessel baseplate and forged materials was determined in accordance with ASTM requirements in place at the time of the original design and licensing of Surry Units 1 and 2. Drop weight and Charpy V-notch testing was performed in accordance with the then-applicable versions of ASTM E208 and ASTM E23, respectively.

The quantity identified as T_{NDT} in Tables 4.1-14 and 4.1-15 is defined in the version of ASTM E208 applicable at the original design and licensing of Surry Units 1 and 2 as “the temperature at which a specimen is broken in a series of tests in which duplicate no-break performance occurs at 10°F higher temperature.”

Tables 4.1-14 and 4.1-15 also provide the unirradiated RTNDT values as determined by NB-2331 of Section III of the ASME B&PV Code or one of the 3 alternative methods for determining the RTNDT listed below.

- Topical Report BAW-2308
- Branch Technical Position (BTP) 5-3, Revision 2
- EPRI Report BWRVIP-173-A, Appendix B, Alternative Approach 2 (GE Method)

As part of the Westinghouse surveillance program referred to above, Charpy V-notch impact tests, tensile tests, and fracture mechanics specimens are taken from the core region plates and forgings, and core region weldments including heat-affected-zone material. The test locations are similar to those used in the tests by the fabricator at the plate mill.

The uncertainties of measurement of the baseplate NDTT are:

1. Differences in Charpy V-notch ft-lb values at a given temperature between specimens.
2. Variation of impact properties through plate thickness.

The fracture toughness technology for pressure vessels and correlation with service failures based on Charpy V-notch impact data is based on the minimum data points. The Charpy V-notch data consists of multiple tests by the material supplier, the fabricator, and by Westinghouse as part of the surveillance program. In accordance with ASME Code Section III, Subarticle NB-2331, Paragraph (a)(4), only the minimum data points at each Charpy V-notch test temperature were used as input.

There are quantitative differences between the NDTT measurements at the surface, one-quarter thickness (1/4-T), or center of a plate. The NDTT from 1/4-T to the center in heavy plates is observed to vary from improvement in the NDTT to increases up to 85°F. The NDTT at the surface is measured to be as much as 85°F lower than at 1/4-T.

The 1/4-T location is considered conservative since the enhanced metallurgical properties of the surface are not used for the determination of NDTT. In addition, the limiting NDTT for the reactor vessel after operation is based on the NDTT shift due to irradiation. The design value of NDTT after irradiation is assessed at the tip of an assumed quarter-thickness flaw for purposes of establishing Reactor Coolant System (RCS) pressure/temperature operating limits.

Data have been accumulated on the variation of NDTT across heavy section steels at Westinghouse, Nuclear Energy Systems. Similarly, an evaluation of properties of pressure vessel steels in plates 6 to 12 inches thick has been sponsored by the Pressure Vessel Research Committee. Data show NDTT differences between 1/4-T and center of less than 20°F. The criterion of using NDTT + 60°F at the 1/4-T location without taking advantage of the enhanced properties at the surface of reactor vessel plates is conservative.

To assess any possible uncertainties in the consideration of NDTT shift for welds, heat-affected zones, and base metals, test specimens of these three material types are included in the reactor vessel surveillance program.

Additional information on the surveillance programs is available in References 4 and 5, which were submitted to the NRC by Vepco letter dated January 23, 1978. The results of the surveillance programs are documented in References 6 and 20 for Unit 1 Capsules V and X respectively, and References 7 and 21 for Unit 2 Capsules V and Y respectively. Additional information concerning upper shelf energy and chemical composition is reported in References 10, 11, 12, 35, and 36. Although Reference 12 considered higher cumulative core burnups (effective full power years, EFPY) than the values assumed in the pressure/temperature limits and the low temperature overpressure protection system (LTOPS) enable temperature, the then-existing Technical Specification bases were considered conservative, and were not revised to take credit for the additional margin. References 24 and 25 extended the cumulative core burnup applicability limit for the pressure/temperature limits and low temperature overpressure protection system (LTOPS) enabling temperature to 48 EFPY, and included consideration of Measurement Uncertainty Recapture (MUR) uprate. Reference 44 extended the cumulative core burnup applicability limit for the pressure/temperature limits and low temperature overpressure protection system (LTOPS) enabling temperature to 68 EFPY.

Table 4.1-1
REACTOR COOLANT SYSTEM PRESSURES

	Pressure (psig)
Hydrostatic test pressure	3107
Design pressure	2485
Safety valves (open)	2485
High-pressure trip setpoint	2370
Power relief valves (open)	2335
High-pressure alarm	2310
Pressurizer spray valves (open)	2260
Operating pressure (at pressurizer)	2235
Low-pressure alarm	2210
Low-pressure trip setpoint	1885

Table 4.1-2
REACTOR VESSEL DESIGN DATA

Design pressure	2485 psig
Operating pressure	2235 psig
Hydrostatic test pressure	3107 psig
Design temperature	650°F
Overall height of vessel and closure head	40 ft. 5 in.
Water volume, with core and internals in place	Approximately 3720 ft^3
Thickness of insulation, vessel & flange	3 in. (nominal)
Thickness of insulation, reactor closure head dome	5 in.[a] (nominal)
Number of reactor closure head studs	58
Diameter of reactor closure head studs	6 in.
I.d. of flange	149.7205 in. (Unit 1) 149.563 in. (Unit 2)
O.d. of flange	184 in.
I.d. at shell	157 in.
Inlet nozzle i.d.	Tapered 27.437 to 35.406 in.
Outlet nozzle i.d.	28.97 in. straight
Clad thickness, minimum	0.1968 in. (Unit 1) 0.125 in. (Unit 2)
Lower head thickness, minimum	5 in.[b]
Vessel belt-line thickness, minimum	7.875 in.[b]
Closure head thickness, minimum	6.286 in.[c] (Unit 1) 6.188 in.[b] (Unit 2)
Reactor coolant inlet temperature (100% power)	536.7 - 542.9°F
Reactor coolant outlet temperature (100% power)	603.3 - 609.1°F
Reactor coolant flow	(100.8 - 101.6) x 10^6 lb/hr

a. Some areas at tangent points are less than 5 in.
b. Not including 0.125-inch minimum thickness of cladding.
c. Not including 0.1968 minimum thickness of cladding.

Table 4.1-3
PRESSURIZER AND PRESSURIZER RELIEF TANK DESIGN DATA

Pressurizer	
Design pressure	2485 psig
Operating pressure	2235 psig
Hydrostatic test pressure	3107 psig
Design/operating temperature	680/653°F
Water volume, 100% power	780 ft^3 [a]
Steam volume, 100% power	520 ft^3
Surge line nozzle diameter	14 in.
Shell i.d.	84 in.
Minimum shell thickness	4.1 in.
Minimum clad thickness	3/16 in.
Electric heaters capacity (total)	1300 kW
Heatup rate of pressurizer using heaters only	55 °F/hr
Power-operated pressurizer relief valves	
Number	2
Opening pressure	2335 psig
Capacity, saturated steam/valve	
(maximum)	210,000 lb/hr
(nominal)	179,000 lb/hr
Pressurizer safety valves	
Number	3
Opening pressure	2485 psig
ASME rated flow	293,330 lb/hr
Pressurizer Relief Tank	
Design pressure	100 psig
Rupture disk (or safety head) relief pressure	100 psig
Design temperature	340°F
Normal water temperature	120°F
Standby water volume	900 ft^3
Total volume	1300 ft^3
Rupture disk (or safety head) total relief capacity	900,000 lb/hr
Number of rupture disks	2

a. Contents at 60% of net internal volume = 100% power.

Table 4.1-4
STEAM GENERATOR DESIGN DATA (PER STEAM GENERATOR)

Number of steam generators per unit	3	
Design pressure, reactor coolant/steam	2485/1085 psig	
Reactor coolant hydrostatic tested pressure (tube side)	3107 psig	
Hydrostatic test pressure (shell side)	1356 psig	
Design temperature, reactor coolant/steam	650/600°F	
Reactor coolant flow	(33.6 - 33.9) $\times 10^6$ lb/hr	
Total heat transfer surface area	51,500 ft^2	
Heat transferred at 100% load	2968 $\times 10^6$ Btu/hr	
Steam conditions at 100% load, outlet nozzle		
Steam flow	(3.86 - 3.87) $\times 10^6$ lb/hr	
Steam temperature	(509.2 - 518.3)°F	
Steam pressure	738.9 - 800.3 psia	
Feedwater temperature at 100% load	452.0°F	
Overall height	67 ft. 8 in.	
Shell o.d., upper/lower	178/135 in.	
Shell thickness	2.9 in.	
Number of U-tubes	3342	
U-tube o.d.	0.875 in.	
Tube wall thickness (average)	0.050 in.	
Number of manways/i.d.	6/16 in.	
Number of handholes/i.d.	6/6 + 2/2 in.	
	At 2652 MWt [a, b]	At Zero Power [b]
Reactor coolant water volume	1077 ft^3	1077 ft^3
Primary-side fluid heat content	28.4 $\times 10^6$ Btu	27.5 $\times 10^6$ Btu
Secondary-side water volume	1688.5 ft^3	3581.8 ft^3
Secondary-side steam volume	3870 ft^3	1976.7 ft^3
Secondary-side fluid heat content	45.53 $\times 10^6$ Btu	95.0 $\times 10^6$ Btu

a. 2652 MWt represents the steam generator design performance capability and is not intended to indicate reactor thermal power rating.

b. The parameter values listed in this section of the table represent initial plant design and operating information. These values are not intended to be updated in the future.

Table 4.1-5
REACTOR COOLANT PUMP DESIGN DATA

Number of pumps	3
Design pressure/operating pressure	2485/2235 psig
Hydrostatic test pressure	3107 psig
Design temperature (casing)	650°F
Revolutions per min at nameplate rating	1170
Design head	280 ft
Design capacity/pump	88,500 gpm
Flow at 542.9°F/pump	33.6×10^6 lb/hr
Seal-water injection/pump	8 gpm
Seal-water return/pump	2.5 gpm
Pump discharge nozzle i.d.	27.5 in.
Pump suction nozzle i.d.	31 in.
Overall pump assembly height	25 ft. 5 in.
Pump casing water volume/pump	56 ft^3
Thermal barrier water volume/pump	25 ft^3
Approximate pump-motor moment of inertia	70,000 lb/ft^2

	North Anna Motors	Original Surry Motors
Motor data Type	ac induction single speed, air cooled	ac induction single speed, air cooled
Voltage	4000V	4000V
Insulation class	B thermolastic epoxy	B thermolastic epoxy
Phase	3	3
Frequency	60 Hz	60 Hz
Starting		
Input (hot reactor coolant)	5163 kW	4375 kW
Input (cold reactor coolant)	6839 kW	5740 kW
Power (nameplate)	7000 hp	6000 hp

Table 4.1-6
REACTOR COOLANT PIPING DESIGN DATA

Design/operating pressure	2485/2235 psig
Hydrostatic test pressure (cold)	3107 psig
Design temperature (except pressurizer surge line)	650°F
Design temperature (pressurizer surge line)[b]	680°F
Reactor inlet piping i.d.	27.5 in.
Reactor inlet piping, nominal thickness	2.375 in.
Reactor outlet piping, i.d.	29 in.
Reactor outlet piping, nominal thickness	2.50 in.
Coolant pump suction piping, i.d.	31 in.
Coolant pump suction piping, nominal thickness	2.625 in.
Pressurizer surge line piping, nominal diameter[a]	12 in.
Pressurizer surge line piping, nominal thickness	1.125 in.
Water volume (all three loops)	1041 ft^3

a. Surge line fitted with a 14 in./12 in. adapter at the pressurizer.

b. Pressurizer surge line is also evaluated for the effect of thermal stratification and stripping per NRC Bulletin 88-11, dated December 20, 1988 (Appendix 15A, References 37 & 38).

Table 4.1-7
LOOP STOP VALVES

Design/normal operating pressure	2485/2235 psig
Hydrostatic test pressure shop/loop	5400/3107 psig
Design temperature	650°F
Hot-leg valve size, nominal	29 in.
Cold-leg valve size, nominal	27.50 in.
Open/close travel time	210 sec

Table 4.1-8
THERMAL AND LOADING CYCLES

Transient Conditions	Design Cycle[a]
Heatup at 100°F/hr	200
Cooldown at 100°F/hr	200
Loading at 5% of full power per min (15 to 100% equals one cycle)	18,300
Unloading at 5% of full power per min (100 to 15% equals one cycle)	18,300
Step load increase of 10% full power (but not to exceed full power)	2000
Step load decrease of 10% of full power	2000
Step load reduction from 100 to 50% load	200
Reactor trip from full power	400
Hydrostatic test pressure, 3107 psig at 100°F	5
Hydrostatic test pressure, 2485 psig at 400°F	40

Steady-state fluctuations - the reactor coolant average temperature for purposes of design will be assumed to increase and decrease a maximum of 6°F in 1 minute. The corresponding reactor coolant pressure variation will be less than 100 psig. It is assumed that an infinite number of such fluctuations will occur.

a. Estimated for equipment design purposes (using the original license period of 40 years as a basis) and not intended to be an accurate representation of actual transients, or to reflect actual operating experience. These estimates have been retained for the 80-year subsequent renewed operating license period.

Table 4.1-9
REACTOR COOLANT SYSTEM - CODE REQUIREMENTS

Component	Codes
Reactor vessel [a]	ASME III[b]Class A
Control rod drive mechanism housing	ASME III[b] Class A
Unit 1 control rod drive mechanism head adapter plugs	ASME III[b] Class 1
Steam generators	
Tube side	ASME III[b] Class A
Shell side[c]	ASME III[b] Class C
Reactor coolant pump casing	No code (design per ASME III - Article 4)
Pressurizer	ASME III[b] Class A
Pressurizer relief tank	ASME III[b] Class C
Pressurizer safety valves	ASME III[b]
Reactor coolant piping	USAS B31.1[d]
System valves, fittings, and piping	USAS B31.1d,e

a. Unit 1 Reactor Vessel Closure Head replaced with closure head designed to French Construction Code (R-CCM) 1993 Edition with 1st Addenda June 1994, 2nd Addenda June 1995, 3rd Addenda June 1996, and Modification Sheets FM 797, 798, 801, 803, 804, 805, 806, and 807. The sizing calculations and the stress and fatigue analysis were performed to ASME B&PV Code, Section III, 1995 Edition 1996 Addenda. The Design Report certified that the Unit 1 closure head meets the design requirements and stress limits for the ASME B&PV Code, Section III, 1968 Edition through Winter 1968 Addenda

b. ASME Boiler and Pressure Vessel Code, Section III, Nuclear Vessels.

c. The shell side of the steam generator conforms to the requirements for Class A vessels and is so stamped as permitted under the rules of Section III.

d. USAS B31.1 Code for Pressure Piping.

e. A reanalysis of the pressurizer surge line to account for the effect of thermal stratification and striping was performed in accordance with the requirements of ASME Boiler and Pressure Vessel Code, Section III 1986 with addenda thru 1987 incorporating high cycle fatigue as required by NRC Bulletin 88-11, dated December 20, 1988.

a. Withdrawal schedule meets requirements of ASTM E 185-82, *Standard Practice for Conducting Surveillance Tests for Light - Water Cooled Nuclear Power Reactor Vessels*, dated July 1, 1982.

b. 48.0 EFPY corresponds to the estimated cumulative core burnup at the end of the 60-year license period. 68.0 EFPY corresponds to the estimated cumulative core burnup at the end of the 80-year license period. Fluence values for withdrawn capsules are obtained from capsule test reports.

c. These capsules are required to satisfy the requirements of ASTM E 185-82 during the initial period of extended operation.

d. This capsule will be removed during the subsequent period of extended operation.

e. Standby Capsules S and U are available to satisfy potential fluence monitoring requirements during the subsequent license renewal period. Future projected capsule fluence values are related to asset management objectives.

4.2 SYSTEM DESIGN AND OPERATION

4.2.1 General Description

The reactor coolant system consists of three similar heat transfer loops connected in parallel to the reactor vessel. Each loop contains a steam generator, a pump, two loop-stop valves, loop piping, and instrumentation. The pressurizer surge line is connected to one of the loops on the reactor side of a stop valve. Auxiliary system piping connections into the reactor coolant piping are provided as necessary. A flow diagram of the system is shown in Figure 4.2-1 and Reference Drawings 1 and 2. All of the major components of the reactor coolant system are located inside containment.

Reactor coolant system and component design data are listed in Tables 4.1-1 through 4.1-7.

Pressure in the system is controlled by the pressurizer, where water and steam pressure are maintained through the use of sprays and electrical heaters. Steam can be formed by the heaters or condensed by pressurizer spray to minimize pressure variations due to contraction and expansion of the coolant. Instrumentation to be used in the pressure control system is described in Chapter 7. Spring-loaded code safety valves and power-operated relief valves are connected to the pressurizer and discharge to the pressurizer relief tank, where the discharged steam is condensed and cooled by mixing with water. To ensure degassification and decay heat removal under certain accident conditions without relying on main coolant pump operation the reactor coolant vent system provides remote venting capability of the reactor vessel head and pressurizer steam space.

4.2.2 Components

4.2.2.1 Reactor Vessel

The reactor vessel is a cylinder with a hemispherical bottom and a flanged and gasketed removable upper head. Figure 4.2-2 is a schematic of the reactor vessel. The materials of construction of the reactor vessel are given in Table 4.2-1. Provision is made for removal of reactor internals if required during reactor life.

Coolant enters the reactor vessel through inlet nozzles in a plane just below the vessel flange and above the core. The coolant flows downward through the annular space between the vessel wall and the core barrel into a plenum at the bottom of the vessel, where it reverses direction. Approximately 95% of the total coolant flow is effective for heat removal from the core. The remainder of the flow includes the flow through the control rod assembly guide thimbles, the leakage across the fuel assembly outlet nozzles, and the flow deflected into the head of the vessel for cooling the upper flange. All the coolant is united and mixed in the upper plenum, and the mixed coolant stream then flows out of the vessel through exit nozzles located on the same plane as the inlet nozzles.

The reactor vessel contains the core support assembly, upper plenum assembly, fuel assemblies, control rod assemblies, surveillance specimens, and incore instrumentation. The reactor vessel internals are designed to direct the coolant flow, support the reactor core, and guide the control rod assemblies in the withdrawn position.

The reactor internals are described in detail in Section 3.5, and the general arrangement of the reactor vessel and internals is shown in Figure 3.5-2. Design data are listed in Table 4.1-2.

A one-piece thermal shield, concentric with the reactor core, is located between the core barrel and the reactor vessel. The thermal shield is bolted and welded to the top of the lower core barrel. The thermal shield, which is cooled by the coolant on its downward pass, protects the vessel by attenuating much of the gamma radiation and some of the fast neutrons that escape from the core. This reduces thermal stresses in the vessel that result from heat generated by the absorption of gamma energy. The thermal shield is illustrated in Figure 3.5-6 and described in Section 3.5.1.1.

Fifty incore instrumentation nozzles are located on the lower head. The reactor vessel closure head and the reactor vessel flange are joined by 58 6-inch-diameter studs. Two concentric metallic o-rings seal the reactor vessel when the reactor closure head is bolted in place. A leakoff connection is provided between the two o-rings to monitor leakage across the inner o-ring. In addition, a leakoff connection is also provided beyond the outer o-ring seal.

The reactor vessel insulation is of the reflective type, supported from the nozzles, and consisting of inner and outer sheets of stainless steel spaced 3 inches apart with multilayer aluminum foil as the insulating agent. The clearance between the reactor vessel and insulation is 0.5 inch. Insulation sheets are also provided for the reactor closure head and are supported on the refueling seal ledge and vent shroud support rings.

For Unit 1, to reduce radiation exposure to personnel during reactor vessel head removal and during maintenance operations in the vicinity of the head a permanent reactor vessel head shield has been installed. This shielding consists primarily of cylindrical steel plate (ASTM A36) that is permanently attached to the intermediate lift ring. The shielding is comprised of three sections, each spanning 120 inches. Each section is approximately one inch thick, six feet tall and weighs 3500 pounds. To allow ease of maintenance activities a cutout is provided in the shield for access to the Reactor Vessel Level Indication System. Cutouts are also provided for cooling shroud ventilation nozzles, which are covered by swing doors.

For Unit 2, to reduce exposure to personnel during reactor vessel head removal and during maintenance operations in the vicinity of the head a permanent reactor vessel head shield has been incorporated as an integral part of the CRDM cooling shroud. The shield consists of upper and lower sections. The lower section consists primarily of cylindrical stainless steel plate that is permanently attached to the reactor vessel head lifting rig lugs by special mounting devices. The lower shield/cooling shroud is comprised of four curved segments bolted together to encircle the RV head. These segments are constructed of 3/8 inch ASTM A240, TP304 stainless steel plate that is 40 inches high welded to the inside of one inch ASTM A240, TP304 stainless steel that is 43 inches high and weighs approximately 4500 lb. Three of the segments each have an opening through which air is drawn from the containment as part of the CRDM cooling system. There are holes in two of the segments, such that the RV head vent line passes through one without contacting the shield/shroud and the RVLIS line passes through the other one without contacting the shield/shroud. To accomplish the radiation shielding function, a sliding door is provided to cover each opening when work is being performed in the head area. The doors slide on wheels on a rail mounted above each opening. Door restraints are mounted on the lower shield/shroud to keep the door from moving radially away from the lower shield/shroud. The upper shield/cooling shroud is square in design. The upper shield/cooling shroud consists of four flat side panels and four corner panels. The side and corner panels are constructed of one inch ASTM A240, TP304 stainless steel that is approximately 50 inches high and weighs approximately 7000 lb.

The head lifting rig is classified as QA Category II and since the addition of the shielding to the reactor vessel head does not modify or change the operation, function, or design of the Reactor Coolant System (RCS) or any of its components, this design change is classified as QA Category II. The head shielding is seismically designed in order to protect safety-related equipment in the area following a postulated seismic event.

Protective coating of the Unit 1 shielding was performed in accordance with ANSI N101.4, *Quality Assurance for Protective Coatings Applied to Nuclear Facilities*, prior to receipt on site. All material installed by this design is environmentally qualified for pressure, temperature, relative humidity, and radiation conditions inside the containment during normal operation and following accident conditions. There are no protective coatings on the Unit 2 shielding.

Manufacture of the original Surry vessels was begun by the Babcock & Wilcox Company at Mt. Vernon, Indiana. However, due to scheduling problems, it was necessary to transfer these vessels in a partially fabricated state to the Rotterdam Dockyard Company, Rotterdam, The Netherlands, for completion of fabrication.

The basic construction of the Surry vessels consists of the following:

1. Vessel assembly

   a. Vessel flange - Machined forging.

   b. Nozzle shell - Machined forging, penetrated by six primary coolant nozzles.

   c. Intermediate and lower shells - Each fabricated from two formed cylindrical plates. Two longitudinal weld seams.

   d. Lower head transition ring - Machined forging.

   e. Lower head - Formed from single plate, penetrated by 50 instrumentation tubes.

2. Closure head assembly

   Unit 1 Dome section - Hemispherical dished segment plate (one piece), penetrated by 65 control rod drive mechanism housings.

Unit 2 closure head assembly is a single forging (one piece), penetrated by 71 total penetrations as follows:

a. 48 penetrations for Control Rod Drive Mechanism (CRDM) head adapters with threaded housings,

b. 17 penetrations for spare CRDM head adapters with threaded capped housings,

c. 4 penetrations with cap,

d. 1 penetration for reactor vessel head venting,

e. 1 penetration for Reactor Vessel Level Indication System (RVLIS).

The replacement RVCH was originally intended for NAPS Unit 2. Some fabrication was performed before it was redesigned for Surry Unit 2. Therefore there are 4 penetrations with cap on the Surry Unit 2 head.

Inside surfaces of both closure head and vessel assembly that contact primary coolant are clad with corrosion-resistant material.

At the time of their transfer from Babcock & Wilcox to Rotterdam, the original vessels were at the following stages of completion:

1. Surry Unit 1

   a. Closure head

      Original closure head has been replaced with a closure head fabricated by Framatome ANP for a French utility power plant and purchased by Dominion for Surry Unit 1.

   b. Vessel

      Flange welded to nozzle shell, six nozzles welded in nozzle shell, inside surfaces clad.

      Intermediate shell welded to lower shell, not clad.

      Lower head dome welded to transition ring, inside surfaces clad.

2. Surry Unit 2

   a. Closure head

      The replacement Unit 2 closure head was fabricated by Mitsubishi Heavy Industries, LTD at the Kobi Shipyard and Machinery Work, Japan.

   b. Vessel

      Flange welded to nozzle shell, three of six primary nozzles welded.

      Intermediate and lower shells formed and welded but not welded together, no clad.

Lower head dome welded to transition ring, not clad.

Four solenoid operated globe valves initiate and terminate venting in two redundant flow paths at each vent location. These isolation valves are powered by vital dc power supplies and are fail-closed active valves. A 3/8-inch orifice is installed in each flow path to minimize the reactor coolant pressure boundary extension and to maintain the venting rate at an acceptable value. System operation is conducted from the control room of each unit.

4.2.2.2 **Pressurizer**

The general arrangement of the pressurizer is shown in Figure 4.2-4, and the design data are listed in Table 4.1-3.

The pressurizer maintains the required reactor coolant pressure during steady-state operation, limits the pressure changes caused by coolant thermal expansion and contraction during normal load transients, and prevents the pressure in the reactor coolant system from exceeding the design pressure.

The pressurizer contains replaceable direct immersion heaters, safety and relief valves, a spray nozzle, a vent system, and interconnecting piping, valves, and instrumentation. The electric heaters are located in the lower section of the vessel, and maintain the pressure of the reactor coolant system by keeping the water and steam in the pressurizer at system saturation temperature. Table 4.1-3 indicates initial design capacity for pressurizer heaters. The initial heater design capacity allows for operation with some heaters out of service. With all heaters in service, the heaters are capable of raising the temperature of the pressurizer and contents at approximately 55°F/hr during reactor start-up. Acceptable operation has been evaluated with 1200 kW of heater capacity, which would be capable of raising the temperature of the pressurizer and contents at approximately 52°F/hr during reactor start-up.

The pressurizer is designed to accommodate positive and negative surges caused by load transients. The surge line attached to the bottom of the pressurizer connects the pressurizer to the hot leg of a reactor coolant loop. During a positive surge, caused by a decrease in load, the spray system, which is fed from the cold leg of a coolant loop, condenses steam in the vessel to prevent the pressurizer pressure from reaching the operating point of the power-operated relief valves. Power-operated spray valves on the pressurizer limit the pressure during load transients. In addition, the spray valves can be operated remote manually from the control room. A small continuous spray flow is provided to ensure that the pressurizer liquid is homogeneous with the coolant and to prevent excess cooling of the spray and surge line piping.

During a negative pressure surge, caused by an increase in load, flashing of water to steam and generation of steam by automatic actuation of the heaters keep the pressure above the minimum allowable limit. Heaters are also energized on high water level during positive surges to heat the subcooled surge water entering the pressurizer from the reactor coolant loop.

A Westinghouse Owners Group analysis has determined that the minimum requirement to maintain natural circulation in a three-loop plant with a pressurizer volume of 1300 ft^3 is 125 kW of heater capacity. Two backup heater groups rated at 250 and 200 kW and their associated controls are energized from redundant emergency buses H and J, which are capable of being fed from either offsite power or emergency power. The Class 1E interfaces for motive and control power are protected by safety grade circuit breakers.

The pressurizer heaters are not automatically shed from the emergency power sources upon the occurrence of a safety injection actuation signal. The pressurizer heaters will, however, be automatically shed from the Emergency Bus with a Loss of Offsite Power (LOOP). Once the Emergency Bus has been reenergized, the pressurizer heaters are sequenced onto the bus after a 180-second time delay. Refer to Section 8.5 for a more detailed description of the Emergency Power System. Procedures have been implemented to instruct the operator in the use of pressurizer heaters in establishing and maintaining natural circulation. This is the preferred method of controlling the RCS pressure during a cooldown.

The pressurizer is constructed of carbon steel, with internal surfaces clad with austenitic stainless steel. The heaters are sheathed in austenitic stainless steel.

The pressurizer vessel surge nozzle is protected from thermal shock by a thermal sleeve. A thermal sleeve also protects the pressurizer spray nozzle connection. A manway is provided in the top portion of the pressurizer.

The pressurizer vent system is provided to remove non-condensable gasses from the pressurizer steam space. The pressurizer vent is designed and operated like the reactor head vent system discussed in Section 4.2.2.1. The pressurizer vent system does not provide a means of pressure control.

4.2.2.3 **Steam Generators**

A steam generator repair program was completed at the Surry Power Station in 1980 and 1981 for Units 2 and 1, respectively. The purpose of the program was to repair degradation caused by corrosion-related phenomena and to restore the integrity of the steam generators to a level equivalent to new equipment. The repair program basically consisted of replacing the steam generator lower assembly and refurbishing the upper assembly. This program is described in Reference 1. The following description pertains to the as-modified system. Principal design data are given in Table 4.1-4; a general sectional view is given in Figure 10.3-2.

4.2.2.3.1 General System Description

Each loop of the reactor coolant system contains a vertically mounted U-tube steam generator. These generators consist of two integral sections: an evaporator section and a steam drum section. The evaporator section consists of a U-tube heat exchanger, while the steam drum section houses moisture-separating equipment. The steam drum section is located in the upper part of the steam generator. The lower assembly of each steam generator is designed and manufactured in accordance with Sections III and XI of the 1974 edition of the ASME Boiler and Pressure Vessel Code, including addenda through Winter 1976. The steam generator lower assemblies bear the applicable ASME Code stamp. The original upper shell was reanalyzed based on the above referenced version of the Code (excluding the Appendix G fracture mechanics analysis).

High pressure and high temperature reactor coolant flows into the channel head, through the Inconel U-tubes, and back to the channel head. A partition plate divides the channel head into inlet and outlet sections. An access opening for inspection and maintenance is provided in each section of the channel head. Welding of the U-tubes to the tube support plate ensures zero leakage across the tube joints. The tubes are supported at intervals by horizontal support plates.

4.2.2.3.2 Steam Generator Design Features

The current steam generators include many design improvements over the original steam generators. These features improve the flow distribution, improve bundle access, reduce secondary-side corrosion, facilitate maintenance and inservice inspection activities, and ultimately ensure the integrity of the steam generators. The replacement lower assembly includes the following features:

1. A cast channel head is used to meet current inservice inspection (ISI) requirements. Improvements incorporated affect the tube-to-tubesheet weld and the ends of the primary nozzles.
2. Primary nozzle closure rings are welded inside the channel head at the base of each primary nozzle so that closure plates can be installed during primary chamber maintenance. This design allows the plates to be bolted to the rings for quick installation and removal. Closure plates allow maintenance or inspection to be conducted in the channel head while other operations are conducted with the reactor cavity flooded.
3. The steam generators were originally equipped with a channel head drain that allowed the steam generator to be completely drained before performing inspection and maintenance activities. The channel head drains have since been removed and capped due to transgrannular stress corrosion cracking.
4. Recessed tube-to-tubesheet welds were used in conjunction with full-depth tube roll for all tubes (see Figure 4.2-5). Absence of the protruding tube stub in the present design results in lower entry losses and therefore a lower pressure drop in the primary loop. In addition, a possible point of crud buildup is avoided with this design.
5. The primary manways and all handholes are designed to receive either welded diaphragms, gaskets, or both, without any modifications. In addition, bolt-on trunnions are provided for two handholes to facilitate installation.

6. All pressure-containing parts, with the exception of the Inconel tubes, are made of carbon or low-alloy steel. All surfaces in contact with the reactor coolant are made of, or clad with, stainless steel or Inconel.

7. The locations of each tube are marked in accordance with an established grid system, i.e., row and column number. The marking of the tubes facilitates identification of tubes for plugging or inspection, thereby minimizing radiation exposure and time required for the activity.

8. The insulation for the steam generators and associated piping is reflective type, stainless steel jacket, fabricated in removable sections where access to welds is required for inservice inspection.

   Reflective insulation was chosen for the following reasons:

   a. Chloride and fluoride free.

   b. Quickly removed and replaced for inservice inspection.

   c. All metal, will not absorb water.

   d. Easy to decontaminate.

   Areas covered with this insulation are as follows:

   a. Steam generators - the entire steam generator.

   b. Reactor coolant piping - reactor coolant piping in each loop from just beyond the hot-leg loop stop valve to the steam generator, and from the bottom of the loop at the pipe restraint on the cold leg to the steam generator.

   c. Main steam piping - from just beyond the crane wall penetration back to the steam generator.

   d. Feedwater piping - from just beyond the crane wall penetration back to the steam generator.

   The insulation was cleaned, tested, and/or inspected, and protected against contamination prior to shipping to the site. During installation, handling was performed in a manner that prevented contamination by chlorides, halogens, and other contaminants as described in the specification for steam generator insulation. All surfaces over which the insulation was placed were cleaned and decontaminated of corrosion-forming residues. Cleaning of stainless steel piping met the criteria described in Regulatory Guides 1.37 and 1.44.

9. Each steam generator was constructed with 3342 Inconel-600 thermally treated tubes. The tube dimensions are 7/8-inch o.d. with 0.05-inch wall thickness.

Extensive research has determined that significant improvement in the stress corrosion resistance of Inconel-600 tubing can be achieved by modification of the metallurgical structure through thermal treatment. The primary objective of this treatment is to develop an improved metallurgical structure, associated with the grain boundary precipitate morphology, which provides increased margin with respect to stress corrosion performance. Several benefits result from this treatment: improved resistance to stress corrosion cracking in NaOH, resistance to intergranular attack in oxygenated environments and in sulfur-containing species, and reduction of residual stress imparted by tube processing.

Certain heat treatments can improve caustic stress corrosion resistance but result in a chromium-depleted grain boundary layer (sensitization) that is not as resistant to off-chemistry environments, should they be experienced. Analysis of available data indicates that there is a broad band of temperature and time within the typical sensitization range for Inconel-600 which provides improved resistance to stress corrosion cracking in both caustic and pure water environments. The thermal treatment used was within this time-temperature band.

The thermal treatment was designed to improve the corrosion resistance against secondary-side attack, specifically caustic stress corrosion. The treatment also results in resistance to primary-side stress corrosion cracking. The thermal treatment was performed as a final operation on the straight-length tubing, after the straightening and polishing. It consisted of heat-treating the tubing in a vacuum at a nominal temperature of 1300°F for about 15 hours. This treatment results in a microstructure consisting of semi-continuous grain boundary precipitates, but with little or no chromium depletion adjacent to the boundaries. In addition, the eight inner rows (smallest diameter) of tubes were stress-relieved following bending at a temperature of about 1300°F for several hours. This microstructure change in conjunction with the relief of most residual stresses provides the corrosion resistance to both primary-side and secondary-side environments.

Intergranular attack in environments containing oxygen and/or sulfur has been evaluated. The special thermal heat treatment was established to ensure that the grain boundary morphology is not conducive to intergranular attack. It is known that grain boundary carbide precipitation, while beneficial in caustic and other species, may be detrimental in certain oxygenated and sulfur-bearing environments if the material is “sensitized,” i.e., there is a chromium-depleted region adjacent to the boundaries. The time and temperature of the special heat treatment have been established to ensure that the microstructure is “desensitized” toward intergranular attack in environments containing oxygen and sulfur.

Test results obtained during the development of the special heat-treating process validated the above. Desensitization of the material was routinely monitored during production.

4.2.2.4 **Reactor Coolant Pumps**

Each reactor coolant loop contains a vertical single stage centrifugal pump using a controlled leakage seal assembly. A view of a controlled leakage pump is shown in Figure 4.2-6.

The principal design parameters for the pumps are listed in Table 4.1-5. The reactor coolant pump estimated performance and NPSH characteristics are shown in Figure 4.2-7. The performance characteristic is common to all of the higher specific speed centrifugal pumps, and the “knee” at about 45% design flow introduces no operational restrictions since the pumps operate at full speed.

Reactor coolant is pumped by the impeller attached to the bottom of the rotor shaft. The coolant is drawn up through the impeller, discharged through the passages in the diffuser, and out through a discharge nozzle in the side of the casing. The motor-impeller is removed from the casing for maintenance or inspection without removing the casing from the piping. All parts of the pumps in contact with the reactor coolant are austenitic stainless steel or equivalent corrosion-resistant materials.

The pump uses a three-stage seal arrangement. The seals control leakage, used as seal lubrication and cooling, along the pump shaft. The number 1 and 2 seals divert the majority of seal leakage to the VCT. The number 3 seal minimizes the leakage of water and vapor from the pump into the containment atmosphere. Leakage past the number 3 seal is directed to the suction of the PDTT pump.

High-pressure water flow from the charging pumps is injected into the reactor coolant pump, where a portion of the flow goes down the pump shaft past the thermal barrier to the reactor coolant system, and a portion travels up the shaft past the lower radial bearing to the number 1 seal cavity. The thermal barrier functions to cool hot reactor coolant flowing to the seal package, in the event seal injection flow is lost.

Component cooling water is supplied to the motor bearing lube oil coolers, air coolers, and the thermal barrier cooling coil. On loss-of-offsite power, the reactor coolant pumps and the component cooling pumps are de-energized due to the loss of station service and emergency stub buses. Component cooling water flow to the thermal barrier can be manually reinitiated following the restoration of the emergency stub bus after the automatic start of the diesel generators.

The squirrel cage induction motor driving the pump is air-cooled, and has oil-lubricated thrust and radial bearings. A water-lubricated bearing provides radial support for the pump shaft.

A flywheel on the shaft above the motor provides additional inertia to extend flow coastdown. Each pump contains a ratchet mechanism to prevent reverse rotation.

The original RCP motors can be replaced with motors from the North Anna plant, with appropriate compensatory measures taken. An oil collection system attaches to the original RCP motors to reduce the potential for fire in the Containment Building (see Section 9.10.4.12 for further information).

All the pressure-bearing parts of the reactor coolant pump are analyzed in accordance with Article 4 of the ASME Code, Section III. This includes the casing, the main flange, and the main flange fasteners. The analysis includes pressure, thermal, and cyclic stresses; and these are compared with the code allowable stresses.

Mathematical methodologies are prepared and used in the analysis, which proceeds in two phases:

1. In the first phase, the design is checked against the design criteria of the ASME Code, with pressure stress calculations, although thermal effects are included implicitly with the experience factors. By this procedure, the shells are profiled to attain optimum metal distribution, with stress levels adequate to meet the more limiting requirements of the second phase.
2. In the second phase, the interactivity forces needed to maintain geometric capability between the various components are determined at design pressure and temperature, and applied to the components along with the external loads, to determine the final stress state of the components. These are finally compared with the code allowable values.

There are no other sections of the code that are specified as areas of compliance, but where code methods, allowable stresses, fabrication methods, etc., are applicable to a particular component, these are used to give a rigorous analysis and conservative design.

4.2.2.5 **Pressurizer Relief Tank**

Principal design parameters of the pressurizer relief tank are given in Table 4.1-3.

Steam discharged from the power-operated relief valves or from the safety valves passes to the pressurizer relief tank, which is partially filled with water at or near containment ambient temperature, under a predominantly nitrogen atmosphere. Steam is discharged under the water level to condense and cool by mixing with the water. The tank is equipped with a spray, and a drain to the vent and drain system (Section 9.7), which is operated to cool the tank following a discharge.

The tank size is based on the requirement to condense and cool a discharge equivalent to 110% of volume between zero-power pressurizer water level setpoint and the high water level reactor trip setpoint.

Rupture disks protect the tank from overpressurization caused by a discharge exceeding the design value. The rupture disks, which discharge into the reactor containment, have a relief capacity in excess of the combined capacity of the pressurizer safety valves. The tank design pressure (and the rupture disk setting) is twice the calculated pressure resulting from the maximum safety valve discharge described above. This margin is to prevent deformation of the disks. The tank and rupture disk holders are also designed for full vacuum to prevent tank collapse if the tank contents cool without nitrogen being added.

The discharge piping from the safety and relief valves to the relief tank is sufficiently large to prevent backpressure at the valves from exceeding 20% of the setpoint pressure at full flow.

The pressurizer relief tank, by means of its connection to the vent and drain system (Section 9.7), provides a way for removing any non-condensable gases from the reactor coolant system that might collect in the pressurizer vessel.

The tank is constructed of carbon steel with a corrosion-resistant coating on the internal surface.

4.2.2.6 **Piping**

The general arrangement of the reactor coolant system piping is shown on the station layout drawings in Section 15.1. Piping design data are presented in Table 4.1-6.

The reactor coolant piping layout is designed on the basis of providing floating supports for the steam generators and reactor coolant pumps to absorb the thermal expansion from the fixed or anchored reactor vessel.

The austenitic stainless steel reactor coolant piping and fittings that make up the loops are 29-inch i.d. in the hot legs, 27.5-inch i.d. in the cold legs, and 31-inch i.d. between each loop's steam generator outlet and its reactor coolant pump suction.

Smaller piping, including the pressurizer surge relief and spray lines, as well as drains and connections to other systems, are austenitic stainless steel. Joints and connections are welded except for stainless steel flanges such as the connections to the carbon steel pressurizer relief tank and the connections at the relief and safety valves, the MOV relief header drains, the loop flow elements, the reactor head vent piping spectacle flanges, and the reactor head vent valve pipe flanges.

Three resistance temperature detectors are installed in the hot leg of each loop near the inlet to the steam generator. One resistance temperature detector is installed in the cold leg of each loop at the discharge of the reactor coolant pump. These detectors are mounted in thermowells and provide reactor protection and control. A resistance temperature detector is also provided on each hot and cold leg to provide information when the loop is shut down.

As a result of IE Bulletin 79-27, the power supplies to each reactor coolant system loop wide-range T_H-T_C combination have been diversified. The associated hot-leg and cold-leg temperature loops in each reactor coolant system loop are supplied by the same vital power source, which is different from the other two T_H-T_C combinations. Also, the associated T_H and T_C instruments of each reactor coolant system loop input to their own recorder on the main control board. This modification of the wide-range temperature loops ensures that indication of differential temperature between T_H and T_C in at least two reactor coolant loops will be available in the event of the loss of reactor coolant pumps and any vital bus.

Thermal sleeves are installed at the following locations where high thermal stresses could otherwise develop due to rapid changes in fluid temperature during normal operational transients:

1. Return line from the residual heat removal loop.

2. Both ends of the pressurizer surge line.
3. Pressurizer spray line connection to the pressurizer.
4. Charging line connection.
5. Loop fill header connections to each loop.

4.2.2.7 Small Valves

All valve surfaces in contact with reactor coolant are austenitic stainless steel or equivalent corrosion-resistant materials. Connections to stainless steel piping are welded.

Valves that perform a modulating function are equipped with two sets of packing and an intermediate leakoff connection.

4.2.2.8 Loop Stop Valves

The reactor coolant loop stop valves, one of which is shown on Figure 4.2-8, are remotely controlled, motor-operated gate valves that permit any loop to be isolated from the reactor vessel during cold or refueling shutdowns. A stop valve is installed on each hot leg and in each cold leg. During return to service of an isolated filled loop, coolant is circulated through a bypass line, which contains a remotely controlled, motor-operated stop valve. This bypass valve is closed during normal loop operation. A valve pump interlock circuit prevents the starting of the reactor coolant pump in a given loop unless either (a) both hot leg and cold leg loop stop valves are open or (b) the cold leg loop stop valve is closed and the bypass valve is open. The interlock also prevents pump operation if the bypass valve and either of the stop valves are closed.

To ensure against an accidental start-up of an unborated and/or cold isolated loop, an additional valve interlock system is provided that meets the IEEE-279 *Criteria for Nuclear Power Plant Protection Systems,* August 1968. This is shown on Reference Drawing 1, which indicates a relief line and bypass around the cold-leg stop valve. These additional valve temperature and flow interlocks require that a controlled flow of reactor coolant is circulated through the relief line of the inactive loop insuring that boron concentration and temperature of the isolated loop are brought to equilibrium with the remainder of the reactor coolant system, prior to opening the cold leg loop stop valve. This controlled flow will minimize the possibility of a sudden reactivity addition from cold water or boron dilution.

The valve-temperature and valve-flow relief line interlocks are provided to:

1. Prevent opening of a hot-leg loop stop valve unless the cold-leg loop stop valve is closed.
2. Prevent opening of a cold-leg loop stop valve unless:
    a. The hot-leg loop stop valve has been opened a specified time.
    b. The loop bypass valve has been opened a specified time.
    c. Flow has existed through the relief line for a specified time.

d. The cold-leg temperature is within 20°F of the highest cold-leg temperature in other loops and the hot-leg temperature is within 20°F of the highest hot-leg temperature in the other loops.

Returning an isolated loop to service requires that the above interlocks be satisfied, a minimum temperature exists in the loop, and that core reactivity be monitored using a source range nuclear instrument channel.

If a loop was initially drained, the above interlocks can be bypassed. The initially isolated and drained loop may be returned to service by partially opening a loop stop valve and filling the loop in a controlled manner from the reactor coolant system. If using the Volume Control Tank (VCT) as the makeup source, the charging flow from the VCT is periodically sampled during the backfill evolution to ensure its boron concentration meets the minimum refueling water boron concentration requirement established by Technical Specification 3.10.A.9. Makeup to the Reactor Coolant System solely through auxiliary spray during the backfill evolution is prohibited to ensure that a sufficient fraction of makeup flow is mixed with coolant in the active Reactor Coolant System volume and flows through the core, where the source range instrumentation is available to provide secondary indication of improperly blended makeup flow. The vacuum-assisted backfill evolution involves initiation of reactor coolant pump seal injection in the isolated and drained loop to allow establishment of a partial vacuum prior to partially opening the cold leg loop stop valve. The following controls are required to assure that no sudden positive reactivity addition or loss of reactor coolant system inventory occurs during the backfill evolution:

1. Only one loop should be filled at a time.
2. The isolated loop must be verified to be drained.
3. Adequate reactor coolant inventory exists to assure that, during the fill operation, decay heat removal is maintained. This minimum inventory level should not be violated during the fill operation.

If this method is used to fill a loop, then the loop is no longer considered to be isolated and the requirements for returning the isolated loop to service are not applicable as long as the loop stop valves are opened within a specified time.

The parameters of each reactor coolant loop stop valve are shown in Table 4.1-7.

4.2.3 Pressure-Relieving Devices

The reactor coolant system is protected automatically against overpressure by control and protective circuits such as the high-pressure trip, and by code safety valves connected to the top head of the pressurizer. The code safety and power-operated relief valves discharge into the pressurizer relief tank, which condenses and collects the valve effluent. The schematic arrangement of the relief devices is shown in Reference Drawing 2, and the valve design parameters are given in Table 4.1-3. Valve sizes are determined as indicated in Section 4.3.4.

Power-operated relief valves and code safety valves are provided to protect against pressure surges which are beyond the pressure limiting capacity of the pressurizer spray. The self-actuated code safety valves provide ultimate overpressure protection; these valves are completely independent of all control and protective circuits.

The 6-in. pipes connecting the pressurizer nozzles to their respective code safety valves are shaped in the form of a loop seal. As a result of normal heat loss to the ambient, steam continually condenses in the loops. The 1-inch drain lines on the bottom of each PSV loop seal join to form a common line which connects to the pressurizer at a point approximately 30 feet below the loops. This allows the condensate to continuously drain back to the pressurizer and prevents the accumulation of water in the loop seals.

The pressurizer code safety valves are provided with an indirect indication of valve position located in the control room. This indication is derived from temperature detectors installed in the discharge piping of each safety valve. A high temperature annunciator is provided to warn of a leaking/lifting valve.

The power-operated relief valves are also equipped with a single temperature detector downstream. A high temperature annunciator is provided to warn of a leaking/lifting valve. This system is common to both power-operated relief valves. The power-operated relief valves are equipped with redundant limit switches that provide indication of the valves being fully closed, fully open, or some intermediate position.

In addition to the above methods of monitoring valve position, the code safety valves have been equipped with acoustic sensors. Two sensors are attached to the discharge piping of each valve. One of the sensors provides active indication of flow through the valve while the other sensor is used in a passive backup capacity, capable of being utilized if necessary. The operator is alerted to a detection of flow through a valve via a flashing annunciator. The specific valve causing the annunciator alarm can be determined by an indication on the acoustic monitoring panel located in the cable spreading room. The system is powered from either Unit 1 or Unit 2 semi-vital bus with automatic transfer on loss of either unit’s power via voltage monitoring relays.

One relief valve in the discharge piping of the RHR pumps provides a small degree of relief capacity in the event of an overpressure transient during RHR operation. The water relief capacity of the valve is 750 gpm at a backpressure of 5 psig. The RHR system relief valve is set at 600 psig and has no automatic isolation.

The pressurizer relief tank is protected against a steam discharge exceeding the design pressure value by rupture disks that discharge into the reactor containment. The rupture disk relief conditions are given in Table 4.1-3. The rupture disks are also designated as safety heads.

4.2.4 Protection Against Proliferation of Dynamic Effects

Essential operating and protective systems are protected from loss of function due to dynamic effects and missiles that might result from a pipe rupture[1]. Protection is provided by missile shielding and/or segregation of redundant components.

The reactor coolant system is surrounded by concrete shield walls. These walls provide shielding to permit access into the containment during full-power operation for inspection and maintenance of selected equipment. These shielding walls also provide missile protection for the containment liner plate.

The concrete covering over the reactor coolant system and the concrete floor under the reactor coolant system also provides for shielding and missile protection.

Steam generator restraints are provided at the upper support ring to resist lateral loads resulting from seismic and main steam line pipe rupture forces.

Missile protection afforded by the arrangement of the reactor coolant system is illustrated in the containment structure drawings given in Section 15.1. As can be seen from these drawings, protection against dynamic effects results from separation of loops by compartment walls.

4.2.5 Materials of Construction

Each of the materials used in the reactor coolant system was selected for the expected environmental and service conditions. The major component materials are listed in Table 4.2-1.

All materials that are exposed to the reactor coolant are corrosion-resistant. They were chosen for specific purposes at various locations within the system and for their superior compatibility with the reactor coolant. The chemical composition of the reactor coolant is maintained within the specification given in Table 4.2-2. Reactor coolant chemistry is further discussed in Section 4.2.8. Secondary chemistry is discussed in Section 10.3.5.

The phenomena of stress-corrosion cracking and corrosion fatigue are not encountered in these materials unless a specific combination of conditions is present. The necessary conditions are a metallurgically susceptible alloy, an aggressive environment, stress, and time.

Unit 1 reactor vessel closure head has been replaced with a closure head designed for a French nuclear power plant of similar design. The code for the replacement closure head materials was the French R-CCM Code. Equivalence documents were prepared to identify equivalent ASME Code materials. Table 4.2-1 summarizes the major component materials for the closure head and provides ASME equivalent materials where appropriate. RCCM/ASME Equivalency Report - Base Materials (Reference 11) provides ASME equivalent base materials used for the

1. As discussed in Section 15.6.2, it is no longer necessary to consider the dynamic effects of a postulated rupture of the primary reactor coolant loop piping or select reactor coolant system branch piping sections for the 80 year period of extended plant operations. However, other pipe ruptures as discussed in Section 15.6.2 must still be considered.

pressure boundary (including structural attachments). RCCM/ASME Equivalency Report - Filler Materials (Reference 12) provides ASME equivalent of the filler materials used for pressure boundary and attachments welded on the closure head. RCCM/ASME Equivalency Reports - Base Materials and RCCM/ASME Equivalency Reports for Filler Metals provides analysis and justification for deviations identified in the base materials and filler materials equivalency reports (References 11 & 12).

It is characteristic of stress corrosion that combinations of alloy and environment that result in cracking are usually quite specific. Environments that have been shown to cause stress-corrosion cracking of stainless steels are free alkalinity in the presence of a concentrating mechanism, and the presence of chlorides and free oxygen. With regard to the former, experience has shown that deposition of chemicals on tube surfaces can occur in a steam-blanketed area within a steam generator. In the presence of this environment, stress-corrosion cracking can occur in stainless steels having only the nominal residual stresses resulting from normal manufacturing procedures. However, the steam generator contains Inconel tubes. Testing to investigate the susceptibility of heat exchanger construction materials to stress corrosion in caustic and chloride aqueous solutions indicates that the Inconel alloy used has excellent resistance to general and pitting-type corrosion in severe operating water conditions.

The use of lead in the materials of the secondary side of the station is minimized except for that occurring as an insignificant trace element in metallurgical alloys.

All external insulation of reactor coolant system components is compatible with the component materials. The cylindrical shell exterior and closure flanges to the reactor vessel are insulated with metallic reflective insulation. The closure head is insulated with low halide-content insulating material. All other external corrosion-resistant surfaces in the reactor coolant system are insulated with inhibited low-halide or halide-free insulating material as required.

The stress limits established for the reactor vessel are dependent upon the temperatures at which the stresses are applied. As a result of fast neutron irradiation in the region of the core, the material properties change, including an increase in the NDTT. This was discussed in Section 4.1.7. An NDTT no greater than 40°F was set as the design limit. The material was tested to verify conformity to specified requirements and to determine the actual NDTT value. In addition, this plate was 100% volumetrically inspected by ultrasonic test using both longitudinal and shear wave methods.

The remaining material in the reactor vessel and other reactor coolant system components meets the appropriate design code requirements and specific component function.

The reactor vessel material was heat-treated specifically to obtain good notch-ductility. This ensured a low NDTT, and thereby gave assurance that the finished vessel could be initially hydrostatically tested and operated as near to room temperature as possible without restrictions.

The techniques used to measure and predict the integrated fast neutron (E greater than 1 MeV) fluxes at the sample locations are described in Section 4.1.7. The calculation method used to obtain the maximum neutron (E greater than 1 MeV) exposure of the reactor vessel is identical to that described for the irradiation samples. Since the neutron spectra at the samples are applied with confidence to the adjacent section of reactor vessel, the maximum vessel exposure is obtained from the measured sample exposure by appropriate application of the calculated azimuthal neutron flux variation.

The calculated maximum fast neutron fluence to the reactor vessel beltline (E greater than 1 MeV) after 80 years of operation (68 EFPY) is 6.35 × 1019 n/cm2 and 7.26 × 1019 n/cm2 for Units 1 and 2, respectively. When calculated in the manner prescribed by Regulatory Guide 1.99, Revision 2, Topical Report BAW-2308, Revision 1-A and Topical Report BAW-2308, Revision 2-A, the limiting values of RTNDT are predicted to occur in the Unit 1 lower shell longitudinal weld L2 at the 1/4-T location and the Unit 2 intermediate to lower shell circumferential weld at the 3/4-T location. For the purposes of pressure-temperature limit curve development, conservative bounding 1/4T and 3/4T RTNDT values of 228.4°F and 189.5°F, respectively, were utilized corresponding to a prior analysis of the Surry Unit 1 Intermediate to Lower Shell Circumferential Weld. Unirradiated RT_{NDT} values for reactor vessel materials are presented in Tables 4.1-14 and 4.1-15. Data used in the original design assessment of radiation-induced transition temperature increases is presented in Table 4.2-3 and Figure 4.2-9.

To evaluate the RT_{NDT} shift of welds, heat-affected zones, and base material for the vessel, test coupons of these material types are included in the reactor vessel surveillance program described in Section 4.1.7.

4.2.6 Maximum Heat-Up and Cooldown Rates

The reactor coolant system operating cycles used for design purposes are given in Table 4.1-8 and described in Section 4.1.4. During unit heat-up and cooldown, the rates of temperature and pressure changes are limited. The system design heat-up and cooldown rate of 100°F/hr satisfies stress limits for cyclic operation (ASME Vessel Code, Section III) and is consistent with the expected number of cycles. However, the normal system heat-up and cooldown rates are conservatively set at 50°F/hr. Sufficient electrical heaters are installed in the pressurizer to permit an adequate pressurizer heat-up rate of 55°F/hr when starting with a minimum water level and all pressurizer heaters in service. This rate takes into account the small continuous spray flow provided to maintain the pressurizer liquid homogeneous with the coolant.

The heat-up and cooldown rate for the pressurizer should not exceed 100°F/hr and 200°F/hr, respectively. A maximum temperature difference of 303°F between the pressurizer and reactor coolant hot leg is specified to maintain thermal stresses and fatigue in the surge line below design limits. Pressurizer spray should not be used if the temperature difference between the pressurizer and the spray fluid is greater than 320°F.

The fastest cooldown rates, which result from the hypothetical case of a break of a main steam line, are discussed in Section 14.3.2.

4.2.7 Leakage

4.2.7.1 Leakage Detection

Coolant leakage from the reactor coolant system to the containment is indicated in the control room by one or more of the following methods:

1. The containment air particulate monitoring system - A system is provided to monitor particulate activity from the areas enclosing the reactor coolant system components so that any leakage from them can be easily detected. Experience has shown that the containment air particulate monitoring system responds rapidly to primary system leakage and will provide a sensitive indication of such leakage. The curves in Figure 4.2-10 indicate the air particulate monitor response times as a function of percentage of failed fuel and rate of coolant leakage. For example, the curves indicate, for 1% failed fuel, monitor response times of approximately 20 minutes, 6 minutes, and 2 minutes for assumed leakage rates of 10, 100, and 1000 cm^3/min, respectively. Lesser quantities of failed fuel will, of course, result in increasingly longer response times.

   In the range of percent failed fuel covered by Figure 4.2-10, the effect of activated corrosion products is negligible. If there is no failed fuel, the containment air particulate monitor will still detect a leak, if there are sufficient activated corrosion products present in the reactor coolant. With equilibrium activated corrosion products present in the reactor coolant, a leak of 1000 cm^3/min would be detected in less than 4 hours. Lesser quantities of activated corrosion products will result in increasingly longer response times.

   The containment air particulate monitor is indicated, recorded, and alarmed in the control room.

2. The containment gas monitor - A system is provided to monitor gaseous activity from areas enclosing the reactor coolant system. Even though the gas monitor itself is less sensitive than the particulate monitor, the gaseous activity from any leakage is expected to be higher than the particulate activity, so that the gas monitor will also be sensitive to a leak. The containment gas monitor is indicated, recorded, and alarmed in the control room.

   The capability and sensitivity of the containment gas monitor to detect primary coolant system leakage is highly dependent on the operating condition of the plant. The following three cases illustrate this:

   Case 1. If there is no prior leakage into the containment and the primary coolant gaseous activity is a maximum (about 200 $\mu Ci/cm^3$), a leak of 0.1 gpm can be easily detected in less than 30 minutes.

Case 2. If there is no prior leakage into the containment and the primary coolant gaseous activity is 0.6 $\mu Ci/cm^3$ (typical of operating pressurized-water reactors), a 1-gpm leak should be detected within 2 hours.

Case 3. If there is prior continuing leakage of 0.5 gpm into the containment and the containment gas monitor high radiation alarm setting is twice the existing steady state activity in the containment, it will take about 60 hours to detect a 2-gpm leak and 1 hour to detect a 100-gpm leak, as shown in Figure 4.2-11.

3. Abnormal makeup water requirements - Any leakage will cause an increase in the amount of makeup water required to maintain normal level in the pressurizer. The primary-grade water and concentrated boric acid makeup flow rate are both recorded and alarmed in the control room.

4. Containment instrumentation - The reactor containment sump level instrumentation and the containment pressure and temperature instrumentation could all indicate leakage in the containment, but not necessarily from the primary coolant system. These measurements are also subject to variations unrelated to leakage from ruptured fluid systems. The instruments all indicate in the control room; however, it is not the primary purpose of the containment sump level and containment pressure or temperature instrumentation to detect primary coolant system leakage. Primary coolant system leakage can be most readily detected by increased makeup requirements to the primary coolant system and by the containment gas monitors.

   The containment pressure and temperature are recorded by the data logger. The containment pressure also alarms in the control room.

5. Reactor vessel leakoff - Leakage through the reactor vessel head flange will leak off between the double o-ring seal to the leakoff provided. Leakage into this leakoff will cause high temperature in this line, which will actuate an alarm in the control room.

Methods 1 and 2 can only be used for leakage detection if there are sufficient activated products in the reactor coolant. If there are no such activated products in the reactor coolant, the other methods can be used to detect a leak.

In accordance with the information provided in Reference 2, and the safety evaluation of Reference 3, it was concluded that the reactor coolant leakage detection capability meets the staff guidelines of 1 gpm in 4 hours.

4.2.7.2 **N-16 Primary to Secondary Leakage Detection System**

There are three N-16 leak detection channels per unit. The detectors are located adjacent to each of the main steam lines in the Mechanical Equipment Room (MER). They continuously monitor main steam and provide indication locally via Local Processing Display Units (LPDUs). The LPDUs provide a leakrate signal to a recorder remotely in the control room for each unit. The N-16 recorder is located in the main control board vertical section. They provide a digital indication up to 1000 gallons per day of primary to secondary leakage as well as trending information. Alarm inputs are provided to the control room annunciator cabinet to alert operators of steam generator leakage and also provide an operational fault alarm in case of an internal malfunction in an N-16 channel. All LPDUs are mounted in the cable spreading rooms.

The N-16 leak detection systems are designed for continuous operation. Continuous, as used to describe the operation of the N-16 leak detection systems, means that the monitors provide the required information at all times except when the system is out of service for testing or maintenance and approved alternate monitoring methods are in place.

The N-16 leak detection system is an indicating system and does not interact with any plant controlling system. Each steam generator N-16 channel provides an input to the ERF data acquisition system. The N-16 channel information is displayed on the plant computer system.

4.2.7.3 **Leakage Prevention**

Reactor coolant system components are manufactured to normal code requirements as outlined in Section 4.1.6. Leakage through metal surfaces or welded joints is unlikely because of the welded construction of the reactor coolant system and the extensive non-destructive testing to which it is subjected.

Some leakage from the reactor coolant system is permitted by the reactor coolant pump seals. Also, all sealed joints are potential sources of leakage even though the most appropriate sealing device is selected in each case. Because of the large number of joints and the difficulty of ensuring complete freedom from leakage in each case, a small integrated leakage is considered acceptable.

All valves 3 inches or larger in lines connecting to the reactor coolant system which are normally subjected to reactor coolant system operating conditions are provided with leakoff connections. Some of these valves are equipped with backseats which limit leakage.

4.2.7.4 **Locating Leaks**

Experience has shown that hydrostatic testing is successful in locating leaks in a pressure-containing system.

Methods of locating leaks during a station shutdown include visual observation for escaping steam or water, or of boric acid crystals near the leak. The boric acid crystals are transported outside the reactor coolant system in the leaking fluid and deposited by the evaporation process.

4.2.8 Water Chemistry

The reactor coolant system water chemistry is selected to provide the necessary boron content for reactivity control and to minimize corrosion of reactor coolant system surfaces.

All materials exposed to reactor coolant are corrosion-resistant. Periodic analyses of the coolant chemical composition monitor the adherence of the system to the reactor coolant water quality listed in Table 4.2-2. Maintenance of the reactor coolant system water quality to minimize corrosion is accomplished using the chemical and volume control system and the sampling system, which are described in Sections 9.1 and 9.6, respectively.

4.2.9 Reactor Coolant Flow Measurements

Both the calculated system pressure drop and the pump design head contain sufficient margin to ensure a system flow rate equal to or greater than design flow rate. Straightforward hydraulics techniques are employed, together with detailed model tests using scaling techniques in accordance with Hydraulic Institute standards. This design approach has been substantiated by measurements in operating Westinghouse-designed plants.

Core safety limits are not particularly sensitive to the absolute value of reactor coolant system flow. In the course of the initial unit start-up, data pertinent to determining coolant flow, both directly and indirectly, were obtained to verify that flow was not less than design. A definite exact measurement of flow is not necessary for unit operation or for protection system purposes. Further, there are no design provisions to vary flow, e.g. throttling devices; thus variations in absolute flow are not of concern during operation. Protection in the event of a loss of flow resulting from loss of power to one or more pumps is analyzed in Section 14.2.9.

Two methods are used in the station to measure reactor coolant system flow rate. These methods supplement each other to confirm that system flow is equal to or greater than design flow.

The methods discussed below consist of (1) a secondary heat balance coupled with coolant temperatures, and (2) elbow tap differential pressure measurements.

4.2.9.1 **Secondary Heat Balance**

Reactor coolant system flow rate is calculated by accurately measuring the secondary system power generation together with the corresponding measured hot-leg to cold-leg temperature differential in the reactor coolant system (loop delta T). Flow is equal to power divided by the reactor coolant enthalpy decrease.

4.2.9.2 **Elbow Tap Differential Pressure**

Measurement of the elbow tap flow meter differential pressure provides a highly repeatable measure of flow rate. The flow rate is determined from the measured 90-degree elbow differential pressure by documented (Reference 4) standard elbow characteristics.

4.2.9.3 **Experience**

Each of the above methods is employed to obtain an independent assessment of flow. Both are evaluated in terms of consistency, one with another, as well as between loops. Possible error allowances are established on the basis of various in-plant calibrations, e.g., loop temperature. Experience has shown that all methods used indicate greater than design flow, with good agreement between loops and reasonable agreement between methods sufficient to validate greater than design flow.

4.2.9.4 **Low-Flow Trip Setpoint**

Elbow taps are used in the reactor coolant system as an instrument device that indicates the status of reactor coolant flow. The basic function of this device is to provide information as to whether a reduction in flow rate has occurred. The correlation between flow reduction and elbow tap readout has been well established by the following equation (Reference 4):

$$\frac{\Delta P}{\Delta P_o} = \left(\frac{\omega}{\omega_o}\right)^2$$

Where:

ΔP_o = referenced pressure differential

ω_o = referenced flow rate

ΔP = pressure differential

ω = flow rate

The full-flow reference point was established during initial unit start-up. The low-flow trip point was then established by extrapolating along the correlation curve. The technique has been used in providing core protection against low coolant flow in Westinghouse PWR plants. The expected absolute accuracy of the channel is within ±10%. Field results have shown the repeatability of the trip point to be within ±1%. The analysis of the loss-of-flow transient presented in Section 14.2.9 assumes an instrumentation error of ±3%.

4.2.10 Loose Parts Monitoring System

The undetected presence of loose parts or other solid objects circulating in the primary system or secondary, side of the steam generators represents an undesirable situation with regard to potential safety concerns such as flow blockage, core reactivity control, fuel damage, and degradation of the primary system pressure boundary. In addition, there is a concern over possible component damage and degradation of service life due to the impact and abrasion of the loose parts. For this reason, a loose parts monitoring system has been installed to provide the ability to monitor the primary system and secondary side of the steam generators for the presence of loose circulating parts and other foreign objects.

4.2.10.1 **Design Criteria**

The loose parts monitoring system was designed and installed in accordance with the requirements of the appropriate edition of the ASME Code, Section III or XI, as applicable. All attachment clamps have been seismically analyzed to prevent possible damage to safety-related equipment in the event of a seismic event. The loose parts monitoring system cabinet has also been seismically analyzed and seismically mounted and supported.

The loose parts monitoring system is a non-safety-related system. The system has been reviewed for environmental qualification, and it has been determined that the requirements of IE Bulletin 79-01B, NUREG-0588, and IEEE 323-1974 are not applicable. Redundancy requirements are not applicable to the loose parts monitoring system but spare channels are provided in case of instrument channel failure.

With the exception of the hard-line cable, which is Category III, the cable in the loose parts monitoring system is Category I, Class 1E, nuclear grade, flame retardant, and qualified for its intended service conditions. The hard-line cable from the reactor vessel head is routed so that it does not endanger the seismic requirements of other devices located on the reactor vessel head.

4.2.10.2 **System Description**

The loose parts monitoring system provides the operator a means to detect and monitor the presence of a loose part or other solid object circulating freely in the primary or secondary system.

The loose parts monitoring system installed on each unit consists of 10 accelerometers, an amplifier cabinet with associated electronics, and remote alarm annunciators located in the control room. Two accelerometers are located on the reactor vessel head, two on the reactor vessel thimble tubes, one on the primary side of each of the steam generators and one on the secondary side of each steam generator.

Each accelerometer is routed to a line driver, via hardline cable, with the output of the line driver connected to twisted pair cable. The twisted pair cable is routed to the containment penetration and then to the cabinet input terminal block.

The output of each accelerometer and signal conditioner is monitored by a master alarm module. If an accelerometer detects a loose part, an alarm contact is actuated which alerts the operator to a potential loose part.

4.2.11 Loss of Decay Heat Removal

Generic Letter 88-17, *Loss of Decay Heat Removal,* concerns the difficulties and potential consequences involved in preventing, and in recovering from, a loss of cooling to the core while the unit is shut down (References 5 though 10). The concern resulted in several initiatives to ensure adequate protection from a loss of shutdown cooling, especially during reduced inventory conditions. Reduced inventory is defined to be a RCS level lower than three feet below the reactor vessel flange. This corresponds to an inventory level of 15.7 feet elevation.

Adequate indication of RCS level and temperature, and of RHR system performance, is provided in the control room. A permanent RCS standpipe and an ultrasonic level detector are installed to ensure that at least two independent, continuous RCS level indications are monitored in the control room during reduced inventory conditions. Both level monitors provide indication, trending, and low-level alarms in the control room. Whenever the reactor vessel head is located on the reactor vessel, prior to draining the RCS to a reduced inventory condition, at least two core exit thermocouple (CET) temperature indicators are demonstrated to be operable. The CETs continuously indicate in the control room and are periodically recorded on the control room shutdown logs. When the CETs are disconnected due to vessel disassembly, the RHR system temperature indication remains operable and available in the control room. Continuous monitoring of the RHR system performance is provided in the control room by these instruments: suction and discharge temperature indication and trend recording, system flow indication, MOV position indication when energized, pump current indication, pump breaker status indication, system low-flow alarm, pump auto-trip alarm, pump discharge high-pressure alarm, pump cooling water low flow alarm and component cooling status (e.g. temperature, flow and pump current).

Controls are in place to implement specific actions to be taken when draining the RCS. Those actions are based on the Westinghouse Owners Group reduced inventory project guidance and additional plant-specific analyses. The analyses consider the variables affecting time to core boiling, including RCS inventory, RCS temperature, time since shutdown, and total decay heat inventory. The analyses provide the necessary information to determine equipment and operation requirements or limitations, including:

1. Prior to entering a reduced inventory condition, controls are established to provide reasonable assurance containment closure can be achieved prior to the time core boiling could result from a loss of decay heat removal. During reduced inventory conditions, at least one boundary on each containment penetration is maintained intact, with the exception of penetrations in use or undergoing maintenance which are under administrative control. In the event of a loss of decay heat removal, a containment closure team is responsible for closing the administratively controlled penetrations.

2. Prior to entering a reduced inventory condition, one charging pump and one low head safety injection pump are maintained available with a specified flowpath to the core. Administrative controls ensure that additional means of shutdown cooling or inventory make-up are also available.

3. Whenever possible in a reduced inventory condition, activities are avoided that could disrupt stable conditions in the RCS or RHR system, or compensatory actions are taken. Maintenance activities are assessed prior to implementation for their potential to cause a loss of RCS inventory. Procedures include measures to prevent a loss of RHR and to enhance monitoring for early diagnosis of a loss of RHR.

4. To ensure that pressurization of the reactor vessel upper plenum does not occur upon a loss of cooling, procedures require that the cold leg isolation valve shall be closed first when isolating an RCS loop. When returning an RCS loop to service, the hot leg isolation valve shall be opened first. Whenever maintenance requires an opening on the cold leg during

reduced inventory operation, procedural controls are in place to ensure a sufficient vent path is available.

These actions are adequate to ensure that decay heat removal capability is maintained.

4.3 SYSTEM DESIGN EVALUATION

4.3.1 Safety Factors

The safety of the reactor vessel and all other reactor coolant system pressure-containing components and piping is dependent on several major factors, including design and stress analysis, material selection and fabrication, quality control, and operations controls.

4.3.1.1 Reactor Vessel

A stress evaluation of the reactor vessel was carried out in accordance with the rules of Section III of the ASME Code. The evaluation demonstrated that stress levels are within the limits of the code. Tables 4.3-1 and 4.3-2 presents a summary of the estimated stress evaluation.

Fatigue evaluations of the components having the highest cumulative usage factors including head, control rod housing, head flange, vessel flange, primary nozzles, closure studs, core support pad, bottom head to shell, and bottom instrumentation, were also performed. The evaluations show that the cumulative usage factors for these components are less than 1.0 as required by Section III of the ASME Boiler and Pressure Vessel Code, Nuclear Vessels.

The cycles specified for the fatigue analysis result from an evaluation of the expected unit operation, coupled with experience from nuclear power plants, such as Yankee-Rowe. These cycles include five heatup and cooldown cycles per year, a conservative selection and were based on the original 40-year operating license period.

The vessel design pressure is 2485 psig, while the normal operating pressure is 2235 psig. The resulting operating membrane stress is therefore amply below the code allowable membrane stress to account for operating pressure transients.

To preclude the possibility of brittle failure, the combined pressure and thermal stresses in the reactor vessel are limited in accordance with the requirements of ASME Section XI Appendix G, which is cited in 10 CFR 50 Appendix G (Reference 1).

These stress limits are maintained by operating procedures that rely upon administrative pressure and temperature control during heatup and cooldown.

The shift in Reference Temperature for the Nil Ductility Transition (RT_{NDT}) is established periodically during operation by testing of vessel material samples which are irradiated cumulatively by securing them near the inside wall of the vessel in the core area. To compensate for any increase in the RT_{NDT} caused by irradiation, the limits given in the station operating manual on the pressure-temperature relationship are periodically changed to stay within the stress limits, which are stated above during heatup and cooldown. Refer to Section 4.1.7.

The vessel closure contains 58 6-inch studs. The stud material is SA-540 with a minimum yield strength of 104,400 psi at design temperature. The membrane stress in the studs at the steady-state operational condition is approximately 37,500 psi.

The normal operating temperature always exceeds even the highest anticipated DTT during the life of the station. Thus, the emphasis of conservative operation is placed on heatup and cooldown because long-term irradiation of the vessel raises the DTT and thereby limits the heatup or cooldown rates. The conservatism in setting up the temperature-pressure relationship limits stated above consists of:

1. Use of a stress concentration factor of four on assumed flaws in calculating the stresses.
2. Use of nominal yield of material instead of actual yield.
3. Neglecting the increase in yield strength resulting from radiation effects.

As part of the initial station operator training program, Westinghouse instructed supervisory and operating personnel in reactor vessel design, fabrication, and testing, as well as present and future precautions necessary for pressure testing and operating modes. The need for record-keeping was stressed. Such records are helpful in determining the number of operating hours at various power levels and temperatures. These data are used to determine the effects of irradiation on the materials in the core region. These instructions are incorporated in the operating manuals.

The allowable stress criteria for the reactor internals indicate that for the bending state of stress, an outer fiber strain of 40% of ultimate strain is specified. This limit is equal to the average absolute strain (20% of the ultimate strain) in the cross section. If the loading is pure bending, this will give a maximum outer fiber strain of 40%. The 20% average fiber strain is 8% of the actual strain at ultimate.

The geometric shape factor does not enter directly into these strain considerations. The normal geometric shape factor that is used is 1.27 for circular piping.

The following structural elements of the reactor pressure vessel are analyzed in detail (refer to Figures 4.3-1 and 4.3-2):

A. Main closure, including adjacent shells, flange rings, and studs.

B. Inlet and outlet nozzles.

C. Core support pads and adjacent shell.

D. Transition in the cylindrical shell and transition from the cylindrical shell to bottom head.

E. Control rod drive housings.

F. Instrumentation tubes.

A description of the method of analysis for each of the above items is given below:

A. Main Closure

An analytical model is used in which the cylindrical and the spherical shell courses are treated according to the thin-shell theory.

The hubs, if present, are treated as either stiff rings or as a general shell. The flanges are treated as stiff rings or, when possible, partly as a shell, and the studs are treated as cantilever beams.

The deformations at the junctures between the elements are expressed in terms of thermal load, mechanical load, and redundant forces. Then the interaction analysis is performed by solving the set of equations, which is obtained by application of the equilibrium and compatibility conditions.

Once the redundant forces and displacements are known, the stresses are easily calculated.

This is done for all possible load combinations, so a complete analysis is made in which the stresses are compared with the stress and fatigue limits given by the ASME Boiler and Pressure Vessel Code, Section III.

The thermal analysis is performed by calculation of a three-dimensional model using a finite difference technique.

B. Inlet and Outlet Nozzles Including Adjacent Shell

These items are analyzed by methods depending on the loads considered.

The stresses caused by internal pressure and non-uniform temperature distribution are found by means of finite element technique.

The stresses in the shell due to external forces induced by its own weight, earthquake, pipe break, etc., are calculated using the revised Bijlaard curves (Reference 2), while the stresses in the nozzle are found by treating the nozzles as cantilever beams.

The non-uniform temperature distribution due to the main thermal transient is calculated with a finite difference technique.

Finally, the stresses due to all possible load combinations are calculated for various cross sections, and compared with the applicable stress and fatigue limits.

C. Core Support Pads and Adjacent Shell

The stresses in the pads due to mechanical loads are found by treating the pads as clamped cantilever beams, while the stresses in the shell are calculated with the Bijlaard curves (Reference 2).

The stresses due to steady-state temperature fluctuations are determined by means of the skin stress method.

At the end, the stresses due to the various specified load combinations are compared with the applicable stress and fatigue limits.

D. Vessel Wall Transition

The stresses in the vessel wall transition are found by treating the wall according to the thin-shell theory, with respect to the pressure stresses as well as to the temperature-induced stresses.

It is assumed that the worst temperature distribution occurs at the end of the heatup. This temperature is hand calculated. Stresses due to fast thermal transients are calculated with the formulas for skin effect stresses. The total stresses due to the possible load combinations are compared with the applicable stress and fatigue limits.

E. Control Rod Drive Housing

The following paragraphs apply to Surry Unit 1 only.

The analysis of the control rod drive housing and the adjacent shell is performed in two steps.

The first step is to calculate the temperature distribution due to thermal transients using the finite difference method. The boundary condition in the thermal analysis is that in all cases the shrink fit remains, i.e., there is always conduction between the housing and the shell.

The second step is to calculate the stresses due to internal pressure, shrink fit, and temperature distribution for all load conditions. The effects due to a difference in coefficient of thermal expansion are also considered. The relative radial displacement of both housing and hole in the vessel wall is checked for all conditions to be sure that the assumed boundary condition holds. After combining the calculated stresses, the results are compared with the applicable stress and fatigue limits.

The following paragraphs apply to Surry Unit 2 only.

The analysis of the control rod drive housing and adjacent shell is performed in two steps.

The first step is to calculate the applicable thermal boundary conditions based on the design transient conditions. This is done using classical heat transfer methods. The thermal boundary conditions are applied to a finite element analysis to determine temperatures in the structure. Conduction between the adjacent shell and housing is applied in the shrink-fit region.

The second step is to calculate stresses in the housing and adjacent shell due to internal pressure and temperature distribution for all load conditions. This is also done using a finite element analysis. The effects due to a difference in coefficient of thermal expansion are considered. Shrink fit is considered in this evaluation. After combining the calculated stresses, the results are compared with the applicable stress and fatigue limits.

F. Flux Monitor Housing

The analysis of the flux monitor housing is performed in the same way as for item 5. The only difference is that there exists a clearance fit between housing and shell that will remain at all load conditions.

4.3.1.2 **Steam Generators**

A stress evaluation of the steam generators was performed in accordance with Section III of the ASME Boiler and Pressure Vessel Code. Based on the stress evaluation, the critical steam generator components meet the required stress and fatigue limits of ASME Section III (1974 Edition through Winter 1976 Addendum).

The steam generator is designed to withstand a maximum primary-to-secondary pressure differential of 2485 psig coincident with a maximum temperature of 650°F. This faulted condition is postulated to result from a steam-line-break accident.

Faulted conditions are defined in paragraph N-412(t)5 of Section III of the ASME Code. Stress limitations, based on the lower bound theorem of limit analysis for this condition, are stated in paragraph N-417.11(a & b).

The steam generator is also designed for a loss-of-coolant accident (LOCA) wherein a secondary-to-primary pressure differential of 1100 psid at 600°F can occur. This faulted condition is postulated to result from a reactor-coolant-pipe-break accident[1]. The above code reference is applicable.

The 1100-psid pressure differential resulting from the LOCA is less than the normal operating pressure differential of 1465 psid (2250 psia primary minus approximately 785 psia secondary). Therefore, this accident condition does not result in any stresses in the tubesheet in excess of those determined for the normal operating condition.

No significant corrosion of the Inconel tubing is expected during the lifetime of the station. The corrosion rate reported in Reference 3 shows worst-case rates 15.9 mg/dm^2 in the 2000-hour test under steam generator operating conditions. Conversion of this rate to a 60-year unit life gives a corrosion loss of less than 2.3×10^{-3} inch, which is insignificant compared to the nominal tube wall thickness of 0.050 inch. It has been shown that, to increase the 60-year unit life to 80 years, it can be concluded that the calculated uprate tube wear at 60 years of operation (<2 mils) will not result in unacceptably large rates of tube wear if extended to 80 years of operation.

Collapse tests of 7/8-.050 wall straight tubes at room temperature indicate that actual tube strengths are significantly higher than specification, and a collapse pressure of 6000 psi is recorded for the straight tube. The ASME Code charts indicate a collapse pressure of 2740 psi for this tube. The difference is attributed to the fact that the yield strength of the tube tested was 44,000 psi, and the code charts are based on a yield strength of approximately 29,000 psi at room temperature.

---

1. As discussed in Section 15.6.2, "leak-before-break" analyses have demonstrated that the probability of rupture of the primary reactor coolant loop piping and select branch reactor coolant piping sections is extremely small, and it is no longer necessary to consider the dynamic effects of such an accident for the 80 year period of extended plant operations. However, this does not alter the primary loop LOCA as the design basis for the steam generators.

Consideration is given to the superimposed effects of secondary-side pressure loss and the design-basis earthquake loading. The fluid dynamic forces on the internal components affecting the primary-secondary boundary (tubes) is considered as well. For this condition the criterion is that no rupture of primary-to-secondary boundary (tubes and tubesheet) occurs.

The fluid dynamic forces on the internals under secondary-steam-break accident conditions indicate, in the most severe case, that the tubes are adequate to constrain the motion of the baffle plates. There is some plastic deformation, but boundary integrity is maintained.

4.3.1.3 **Steam Generator Tube Vibration Considerations**

In the design of power system steam generators, it has been recognized that an inadequately supported tube can give rise to the serious consequences of flow-induced vibration, which may lead to primary/secondary tube leakage. Historically, it has been noted that many tube vibratory failures have been due to local design configuration weaknesses such as impingement of fluid on the bundle through nozzles without protective baffle plates.

Flow induced vibration at the tubesheet caused by turbulence, fluidelastic excitation, and vortex shedding has been evaluated. These analyses have revealed that at the maximum alternating bending stress in the tube, the code allowable number of cycles is infinite and the fatigue factor is zero.

For the tube supports, the wear coefficient of the type 405 stainless steel supports is low enough to effectively maintain initial tube clearances. Although tests and calculations show that the tube support conditions will not change noticeably during the vessel life, analyses have been performed assuming loss of support at various elevations, and the alternating tube bending stress did not exceed allowed values.

The propensity for a steam generator tube rupture due to flow-induced vibration was specifically evaluated for the steam generators at the uprated conditions. The use of stainless steel essentially eliminates the potential for tube denting in the support plates. Since tube denting is a prerequisite for flow-induced vibration that can lead to tube failure, the likelihood for this type of tube degradation is not significant.

4.3.1.4 **Piping Quality Assurance**

Quality control techniques used in the fabrication of the reactor coolant system are equivalent to those used in manufacture of the reactor vessel which conforms to Section III of the ASME Code.

The Nuclear Piping Code B31.7 is derived from ASME Section III criteria. Thus, the quality assurance requirements added by Westinghouse to USAS B31.1.0-1955 procured reactor coolant piping ensure that the quality level of a Westinghouse plant is comparable to that of Nuclear Piping Code USAS B31.7 itemized below:

1. The material specifications are ASTM specifications approved for nuclear use in the various code cases.
2. The reactor system materials are non-destructively examined to levels required of Class A vessels.
3. Welding procedures and welders must be qualified to the requirements of Section IX of the ASME Code. The same requirement prevails in USAS B31.7.
4. All main primary coolant butt welds, 29, 31, and 27.5-inch o.d. are examined to the same standards required in USAS B31.7. All other butt welds are examined as required by USAS B31.1.
5. All nozzle welds must be radiographically examined when the branch weld is in excess of 2-inch pipe size.
6. All nozzle, girth, and longitudinal welds must be liquid penetrant examined. This requirement is equivalent to USAS B31.7.
7. Hydrostatic testing is performed in completed systems. This requirement is equivalent to USAS B31.7.

Field erection and welding procedures are governed by Westinghouse specifications, which, upon implementation, ensure that the field fabrication results in the same quality as that resulting from the shop fabrication of the same piping. In these specifications for shop fabrication and field erection are references to portions of the ASME Code.

4.3.2 Reliance on Interconnected Systems

The principal heat removal systems that are interconnected with the reactor coolant system are the steam and power conversion, safety injection, and residual heat removal systems. The reactor coolant system is dependent upon the steam generators, the main steam system (Section 10.3.1), and the condensate and feedwater systems (Section 10.3.5) for stored and residual heat removal from normal operating conditions down to a reactor coolant temperature of approximately 350°F. The layout of the reactor coolant system ensures the natural circulation capability to permit unit cooldown following a loss of power to all reactor coolant pumps. The auxiliary steam generator feedwater pumps (Section 10.3.5) supply water to the steam generators in the event that the main feedwater pumps are inoperative. The safety injection system is described in Section 6.2. The residual heat removal system is described in Section 9.3.

4.3.3 System Integrity

A complete stress analysis that reflects consideration of all design loadings detailed in the design specification is prepared by the manufacturer to ensure compliance with the stress limits on Section III of the ASME Boiler and Pressure Vessel Code for the reactor vessel, steam generator, reactor coolant pump casing, and pressurizer. A similar analysis of the piping is prepared by a qualified piping analyst to show compliance with the stress limits of the applicable USA Standard.

As part of the design control on materials, Charpy V-notch toughness test curves are run on all ferritic material used in fabricating pressure parts of the reactor vessel, steam generator, and pressurizer to provide assurance for hydrotesting and operation in the ductile region at all times. In addition, drop-weight tests are performed on the reactor vessel plate material.

As an assurance of system integrity, all pressure-containing components in the system were hydrotested at 3107 psig prior to initial operation.

4.3.3.1 **Reactor Coolant Pump Flywheel Integrity**

Precautionary measures, taken to preclude missile formation from reactor coolant pump components, ensure that the pumps will not produce missiles under any anticipated accident condition.

The reactor coolant pumps run at 1189 rpm, and the controlled leakage pump assembly is capable of operation without mechanical damage with overspeeds up to and including 125% of nominal speed.

Each component of the pumps has been analyzed for missile generation. Any motor rotor fragments would be contained by the heavy stator. The same conclusion applies to the impeller, because the small fragments that might be ejected would be contained by the pump casing.

The reactor coolant pump flywheel dimensions are shown in Figure 4.3-3. As for the pump motors, the most adverse operating condition of the flywheels is considered to be the loss-of-load situation. The following conservative design-operation conditions preclude missile production by the pump flywheels. The flywheels are fabricated from rolled, vacuum-degassed, ASTM A-533 steel plates. Flywheel blanks are flame-cut from the plate, with allowance for exclusion of flame-affected metal. A minimum of three Charpy tests are made from each plate parallel and normal to the rolling direction, to determine that each blank satisfies design requirements. An NDTT less than +10°F is specified. The finished flywheels are subjected to 100% volumetric ultrasonic inspection. The finished machined bores are also subjected to magnetic particle or liquid penetrant examination. These design-fabrication techniques result in flywheels with primary stress at operating speed (shown in Figure 4.3-4) less than 50% of the minimum specified material yield strength at room temperature (100° to 150°F). A detailed evaluation has been performed to determine the critical speed for the reactor coolant pump flywheel from the standpoint of fracture and subsequent missile production. Ductile failure and brittle fracture of the flywheel were considered individually. Limiting speeds were established for each. The ductile failure limit of 3485 rpm (290% overspeed) is governing for crack sizes less than 1.15 inches, and the brittle fracture limit becomes governing for larger crack sizes. Because this crack size is very large in comparison to that which is detectable under current procedures, it is conservatively concluded that 3485 rpm is the limiting speed for the design (Reference 4).

An ultrasonic inspection capable of detecting at least 0.5-inch-deep cracks from the ends of the flywheel, and a dye penetrant or magnetic particle test of the bore, both at the end of 10 years, were more than adequate as part of a unit surveillance program. These inspections were applicable to the first two inspection intervals.

The design specifications for the reactor coolant pumps include as a design condition the stresses generated by a design-basis earthquake ground acceleration of 0.15g. The pump would continue to run unaffected by such conditions. In no case does any bearing stress in the pump exceed or even approach a value that the bearing could not carry.

In order to preclude undetected flywheel deterioration during plant life, even though such deterioration is not expected, the flywheel will be inspected once every twenty years (Reference 14). The inspection shall be a qualified inplace UT examination over the volume from the inner bore of the flywheel to the circle of one-half the outer radius or a surface examination (MT and/or PT) of exposed surfaces defined by the volume of the disassembled flywheels.

Following a hypothetical bearing seizure, the flywheel is not expected to twist off. Therefore, the reactor coolant pumps are not considered sources of missiles and the engineered safeguards are not in jeopardy.

4.3.3.2 **Pressurized Thermal Shock**

The Pressurized Thermal Shock (PTS) Rule was approved by the U. S. Nuclear Regulatory Commissioners on June 20, 1985, and appeared in the Federal Register on July 23, 1985. The Code of Federal Regulations (10 CFR 50.61) contains the applicable requirements and screening criteria.

The Rule outlines regulations to address the potential for PTS events on reactor vessels in nuclear power plants. PTS events have been shown from operating experience to be transients that result in a period of severe cooldown in the primary system coincident with a high or increasing primary system pressure. The PTS concern arises if one of these transients acts on the beltline or extended beltline regions of a reactor vessel where a reduced fracture resistance exists because of neutron irradiation. Such an event may produce the propagation of flaws postulated to exist near the inner wall surface, thereby potentially affecting the integrity of the vessel.

As part of the calculations which support Surry 1 and 2 subsequent license renewal limits (Reference 20) RT_{PTS} values were generated for each Surry 1 and 2 beltline or extended beltline material using the prescribed PTS Rule Methodology. These calculations utilized initial (unirradiated) RT_{NDT} and end of 80-year license fluence. Compliance with 10 CFR 50.61 for the original 40-year license period was transmitted by References 6, 12, and 13. Reference 16 provided the RT_{PTS} values to the NRC, applicable to the 60-year operating licenses. The results for the 80-year RT_{PTS} are presented in Tables 4.3-3 and 4.3-4 for Units 1 and 2, respectively. As these tables demonstrate, all RT_{PTS} values remain below the PTS screening criteria throughout the currently licensed life of the Surry Units 1 and 2. It has been determined that all Surry Units 1 and 2 reactor vessel beltline and extended beltline materials meet the 10 CFR 50.61 PTS screening criteria for operation through the end of the 80-year license period.

4.3.4 Overpressure Protection

The reactor coolant system is protected against overpressure by code safety valves and power-operated relief valves located on the top of the pressurizer. The safety valves on the pressurizer are sized to prevent system pressure from exceeding the design pressure by more than 10%, in accordance with Section III of the ASME Code. The capacity of the pressurizer code safety valves and power-operated relief valves is determined from considerations of the reactor protection system, and accident or transient conditions that may cause overpressure.

Mass input and heat input pressure transients were assumed, and calculations were performed to determine the low pressure overpressure protection setpoint for the power-operated relief valves (References 9 & 10).

The setpoint was chosen to ensure that 110% of the ASME Section XI Appendix G isothermal limit curve will not be exceeded during a limiting pressure transient (References 9, 10 & 11). Sufficient safety margin is provided by this setpoint, since the transient analysis shows that only one power-operated relief valve, set to open at 390 psig, is required to prevent exceeding 110% the Appendix G isothermal limit. The power-operated relief valves are set to operate as discussed above whenever the reactor coolant system is less than 350°F and the reactor head is bolted.

For subsequent license renewal (SLR), Reference 21 extended the cumulative core burnup applicability limit for the pressure/temperature limits and low temperature overpressure protection system (LTOPS) enabling temperature to 68 EFPY, and included consideration of the Measurement Uncertainty Recapture (MUR) uprate.

Vepco has submitted plant specific data to the NRC for safety and relief valve testing and for the power-operated relief valve block valve testing required by NUREG-0737, Item II.D.I. This information is provided in References 7 and 8, respectively.

In Reference 7 it was concluded that the Surry Units 1 and 2 safety and relief valves, piping arrangement, and fluid inlet conditions were bounded by the valve and test parameters of the EPRI safety and relief valve test program and that the EPRI tests confirmed the ability of the safety and relief valves to open and close under the expected operating fluid conditions. In Reference 8 it was concluded that the block valve tested by EPRI was similar in design to the Surry block valves and that the valve successfully completed the evaluation and test program, fully opening and closing on demand.

4.3.4.1 **Operational Conditions**

The operational conditions requiring overpressure protection are controlled by administrative procedures as follows:

1. While water-solid, only one charging pump is permitted to be operational.
2. The safety injection accumulators must be isolated so that they do not discharge into the reactor coolant system while water-solid.
3. The safety injection logic must be blocked while water-solid.
4. The temperature of the reactor coolant system must not be more than 50°F cooler than the bulk water in the steam generators before starting the first reactor coolant pump.

4.3.4.2 **Air Supply**

A backup air supply is provided to ensure power-operated relief valve operability in the event of a loss of the primary air supply and/or a loss of offsite power. The sizing of the redundant air supply considered both power-operated relief valve response times with the above setpoints, and assumed that operator action does not occur for 10 minutes. Annunciators are provided to alert operators of low air pressure supply. Four high-pressure air bottles are provided for each valve. Two bottles are normally aligned to the manifold, the other two are initially fully charged and used as installed spare bottle capacity. The intent is to reduce the time required to reestablish bottle pressure when a low pressure alarm occurs. Alternatively, the spare bottles may be valved in to increase the air supply available during certain modes of plant operation.

The capacity of available bottles is a function of valve stroke time and air regulator setpoint. Valve stroke time is dependent upon the valve condition and air regulator setpoint. The air bottle volumes are each 1.74 ft^3 and contain a nominal pressure of 2200 psig. The minimum pressure required to fully stroke the valve is 85 psig without assistance from Reactor Coolant System pressure. The minimum pressures required at the power operated relief valve (PORV) diaphragm to full stroke the valve at Reactor Coolant pressure of 365 psig and 2335 psig are 79 psig and 37 psig, respectively. This includes the effects of RCS pressure assistance on the required minimum backup air pressure. The following formula is used with current plant parameters and setpoints to determine required bottle capacity:

$$P_{INITIAL} = P_{FINAL} + [P_{CYCLE} * V_{CYCLE} *N]/V_{ACCUM}$$

where:

$P_{INITIAL}$	=	Initial pressure in the accumulator, psig
P_{FINAL}	=	Final pressure in the accumulator, 100 psig
P_{CYCLE}	=	Air regulator setpoint, psia
V_{CYCLE}	=	Volume of air required to complete a PORV cycle, 0.126 ft^3
N	=	Number of PORV cycles as analyzed for power operations or LTOPS operation

V_{ACCUM} = Total volume of the air accumulator, (total volume of bottles aligned to system, 1.74 ft^3 per bottle)

The containment instrument air system header to the power-operated relief valves contains two solenoid valves in series and a backup high-pressure air supply in the line to each relief valve. Two reactor coolant system transmitters are used to provide high-pressure alarms and to control the valves. Two key-lock switches are installed in the main control board (vertical section) to permit administrative control of the system at the appropriate point during cooldown or heatup.

4.3.5 System Accident Potential

The potential of the reactor coolant system as a cause of accidents was evaluated by investigating the consequences of certain credible types of component and control failures, as discussed in Sections 14.2 and 14.3. Reactor coolant pipe rupture is evaluated in Section 14.5.

As evaluated in Section 14.2, no credible component or control failure results in a DNBR less than the design DNBR limit (Section 3.2.3). Sections 14.3 and 14.5 show that for breach of the reactor coolant system boundary resulting from a steam generator tube rupture, a rod-ejection accident, or a pipe break up to and including the double-ended rupture of a reactor coolant pipe, the consequences in terms of activity releases are within the guidelines of 10 CFR 50.67 or RG 1.183, as applicable.

4.3.6 Redundancy

Each loop of the reactor coolant system contains a steam generator and a reactor coolant pump. The normal power supply to the reactor coolant pumps is from electrically separate buses, as shown in Figure 8.3-1.

Table 4.3-1
SUMMARY OF ESTIMATED PRIMARY-PLUS-SECONDARY STRESS INTENSITY FOR COMPONENTS OF THE REACTOR VESSEL - UNIT 1

Area	Total Stress Intensity, psi	Allowable Total Stress at Operating Temperature, psi
Control rod housing	69,800	69,900
Head flange	71,700	80,000
Vessel flange	69,500	80,000
Primary nozzles	53,757	80,100
Closure studs	85,600	109,740
Core support pad	40,800	69,900
Bottom head to shell	32,736	80,100
Bottom instrumentation	56,531	69,900

Table 4.3-2
SUMMARY OF ESTIMATED PRIMARY-PLUS-SECONDARY STRESS INTENSITY FOR COMPONENTS OF THE REACTOR VESSEL - UNIT 2

Area	Total Stress Intensity, psi	Allowable Total Stress at Operating Temperature, psi
Control rod housing	77,500	a
Head	47,900	80,100
Vessel flange	57,700	80,100
Primary nozzles	53,757	80,100
Closure studs	87,100	110,400
Core support pad	40,800	69,900
Bottom head to shell	32,736	80,100
Bottom instrumentation	56,531	69,900

a. The stresses in the control rod housing were determined to be acceptable using simplified elastic-plastic analysis in accordance with Paragraph NB-3228.5 of Section III of the ASME B&PV Code.

4.4 TESTS AND INSPECTIONS

4.4.1 Reactor Coolant System Inspection

4.4.1.1 Non-destructive Inspection of Materials and Components

Table 4.4-1 summarizes the quality assurance program for all reactor coolant system components. In this table all of the non-destructive tests and inspections required by Westinghouse specifications on reactor coolant system components and materials are specified for each component. All tests required by the applicable codes are included in this table. Westinghouse requirements, which were more stringent in some areas than those requirements specified in the applicable codes, are also included. The fabrication and quality control techniques used in the fabrication of the reactor coolant system were equivalent to those used for the reactor vessel.

Westinghouse required, as part of its reactor vessel specification, that certain special tests, which were not specified by the applicable codes, be performed. These tests are listed below:

1. Ultrasonic testing—Westinghouse required that a 100% volumetric ultrasonic test of reactor vessel plate for shear wave be performed in addition to code requirements. A 100% volumetric ultrasonic test is a severe requirement, but it ensures that the plate is of the highest quality.
2. Irradiation surveillance testing—The cumulative effects of neutron and gamma irradiation on the reactor vessel material, including weld metal and the heat-affected zones, are monitored as described in Section 4.1.7.

Table 4.4-1 summarizes the quality assurance program with regard to inspections performed on primary system components. In addition to the inspections shown in Table 4.4-1, there were those which the equipment supplier performed to confirm the adequacy of material he received, and those performed by the material manufacturer in producing the basic material. The inspections of reactor vessel, pressurizer, and steam generator were governed by ASME Code requirements. The inspection procedures and acceptance standards required on pipe materials and piping fabrication were governed by USAS B31.1 and Westinghouse requirements, and are equivalent to those performed on ASME-coded vessels.

Procedures for performing the examinations were consistent with those established in ASME Code Section III and were reviewed by qualified engineers. These procedures were developed to provide the highest assurance of quality material and fabrication. They considered not only the size of the flaws, but, of equal importance, how the material was fabricated, the orientation and type of possible flaws, and the areas of most severe service conditions. In addition, the accessible external surfaces of the primary reactor coolant system pressure-containing segments receive a 100% surface inspection by magnetic particle or liquid penetrant testing after hydrostatic test (see Table 4.4-1). All reactor coolant system plate material was subjected to shear as well as longitudinal ultrasonic testing to give maximum assurance of quality. All forgings received the same inspection. In addition, 100% of the material volume was covered in these tests as an added assurance over the grid basis required in the code.

Quality control engineers monitored the supplier's work, witnessing key inspections not only in the supplier's shop but in the shops of subvendors of the major forgings and plate material. Normal surveillance included verification of records of material, physical and chemical properties, review of radiographs, performance of required tests, and qualification of supplier personnel.

Equipment specification for fabrication required that suppliers submit the manufacturing procedures (welding, heat treating, etc.) which were reviewed by qualified Westinghouse, Vepco, and Stone & Webster engineers. Field fabrication procedures were also reviewed to ensure that installation field welds were of equal quality.

Section III of the ASME Code requires that nozzles carrying significant external loads be attached to the shell by full-penetration welds. This requirement was carried out in the reactor coolant piping, where all auxiliary pipe connections to the reactor coolant loop were made using full-penetration welds.

The reactor coolant system components were welded under procedures that required the use of both pre-heat and post-heat. Pre-heat requirements, not mandatory under code rules, were performed on all weldments, including P1 and P3 materials, which are the materials of construction in the reactor vessel, pressurizer, and steam generators. Pre-heating and post-heating of weldments both served a common purpose: the production of tough, ductile metallurgical structures in the completed weldment. Pre-heating produces tough ductile welds by minimizing the formation of hard zones, whereas post-heating achieves this by tempering any hard zones which may have formed due to rapid cooling.

4.4.1.2 **Electroslag Weld Quality Assurance**

4.4.1.2.1 Piping Elbows

The 90-degree elbows were electroslag-welded. The following were performed for quality assurance of the welding procedures:

1. The electroslag welding procedure employing one-wire technique was qualified in accordance with the requirements of ASME Code Section IX and Code Case 1355, plus supplementary evaluations as requested by Westinghouse. The following test specimens were removed from a 5-inch-thick weldment and successfully tested:

    a. Six transverse tensile bars - as welded.

    b. Six transverse tensile bars - 2050°F, H_2O quench.

    c. Six transverse tensile bars - 2050°F, H_2O + 750°F stress relief heat treatment.

    d. Six transverse tensile bars - 2050°F, H_2O quench, tested at 650°F.

   e. Twelve guided side bend test bars.

2. The casting segments were surface-conditioned for 100% radiographic and penetrant inspections. The acceptance standards were ASTM-E-186 severity level 2, except that no category D or E defectiveness was permitted, and USAS Code Case N-10, respectively.

3. The edges of the electroslag weld preparations were machined. These surfaces were penetrant-inspected prior to welding. The acceptance standard was USAS Code Case N-10.

4. The completed electroslag weld surfaces were ground flush with the casting surface. Then, the electroslag weld and adjacent base material were 100% radiographed in accordance with ASME Code Case 1355. Also, the electroslag weld surfaces and adjacent base material were penetrant-inspected in accordance with USAS Code Case N-10.

5. Weld metal and base metal chemical and physical analyses were determined and certified.

6. Heat treatment furnace charts were recorded and certified.

4.4.1.2.2 Reactor Coolant Pump Casings

The reactor coolant pump casings are electroslag-welded. The following were performed for quality assurance of the components:

1. The electroslag welding procedure employing two- and three-wire technique was qualified in accordance with the requirements of the ASME Code Section TX and Code Case 1355, plus supplementary evaluations as requested by Westinghouse. The following test specimens were removed from an 8-inch-thick and from a 12-inch-thick weldment and successfully tested for both the two-wire and the three-wire techniques, respectively:

   a. Two-wire electroslag process, 8-inch-thick weldment.

      (1) Six transverse tensile bars, 750°F post-weld stress relief.

      (2) Twelve guided side bend test bars.

   b. Three-wire electroslag process, 12-inch-thick weldment.

      (1) Six transverse tensile bar, 750°F post-weld stress relief.

      (2) Seventeen guided side bend test bars.

      (3) Twenty-one Charpy V-notch specimens.

      (4) Full section macroexamination of weld- and heat-affected zones.

      (5) Numerous microscopic examinations of specimens removed from the weld- and heat-affected zone regions.

      (6) Hardness survey across weld- and heat-affected zones.

2. A separate weld test was made using the two-wire electroslag technique to evaluate the effects of a stop and restart of welding by this process. This evaluation was performed to

establish proper procedures and techniques, as such an occurrence was anticipated during production applications due to potential equipment malfunction, power outages, etc. The following test specimens were removed from an 8-inch-thick weldment in the stop-restart-repaired region and successfully tested:

a. Two transverse tensile bars - as welded.

b. Four guided side bend test bars.

c. Full section macroexamination of weld- and heat-affected zone.

3. All of the weld test blocks in 1 and 2 above were radiographed using a 24-MeV Betatron. The radiographic quality level (ASTM-E-94) obtained was between 0.5 to 1%. There were no discontinuities evident in any of the electroslag welds.

   a. The casting segments were surface-conditioned for 100% radiographic and penetrant inspections. The radiographic acceptance standards were ASTM-E-186 severity level 2, except that no category D or E defectiveness was permitted, for section thickness up to 4.5 inch, and ASTM-E-280 severity level 2 for section thicknesses greater than 4.5 inch. The penetrant acceptance standards were ASME Code Section III, paragraph N-627.

   b. The edges of the electroslag weld preparations were machined. These surfaces were penetrant-inspected prior to welding. The acceptance standards were ASME Code Section III, paragraph N-627.

   c. The completed electroslag weld surfaces were ground flush with the casting surface. Then, the electroslag weld and adjacent base material were 100% radiographed in accordance with ASME Code Case 1355. Also, the electroslag weld surfaces and adjacent base material were penetrant-inspected in accordance with ASME Code Section III, paragraph N-627.

   d. Weld metal and base metal chemical and physical analyses were determined and certified.

   e. Heat treatment furnace charts were recorded and certified.

4.4.1.3 **Continuous Drive Friction Weld Process**

Unit 1 CRDM nozzle to adapter welds were performed by the Continuous Drive Friction process. This process is not permitted by the ASME Code Section III, but is approved by the R-CCM Code and has been used extensively for this application in non-U.S. nuclear plants. The Welding Procedure Specification (WPS), the supporting Procedure Qualification Record (PQR) and Welding Operator Performance Qualification (WPQ) were reconciled to ASME Section IX requirements for the CRDM welds. The destructive tests of the supporting PQR were compared with the required tests and criteria of the ASME Code for an equivalent full penetration weld. These welds are deemed acceptable for this application for Surry Unit 1.

4.4.1.4 Reactor Coolant System Field Erection and Welding

Field erection and field welding of the reactor coolant system was performed so as to permit exact fit-up of the 31-inch i.d. closure pipe subassemblies between the steam generator and the reactor coolant pump. After installation of the pump casing and the steam generator, measurements were taken of the pipe length required to close the loop. Based on the measurements, the 31-inch i.d. closure pipe subassembly was properly machined and then erected and field-welded to the pump suction nozzle and to the steam generator exit nozzle. Thus, upon completion of the installation, the system was essentially of zero stress in the installed position.

4.4.1.5 Reactor Coolant System Cleanliness

Cleaning of the reactor coolant system and associated equipment was accomplished before and/or during erection of various equipment. Stainless steel piping was cleaned in sections as specific portions of the systems were erected. Pipe and units large enough to permit entry by personnel were cleaned by locally applying approved solvents (Stoddart solvent, acetone, and alcohol) and demineralized water, and by using a rotary disk sander or 18-8 wire brush to remove all trapped foreign particles.

4.4.1.6 Reactor Coolant System Testing Following Opening

For normal opening, the integrity of the system in terms of strength is unchanged. Prior to normal operation, even though it was not required, the system was pressurized to 2335 psig (operating pressure + 100 psi) to ensure leaktightness during normal operation.

For repairs on components greater than 2 inches in diameter, the thorough non-destructive testing gives a very high degree of confidence in the integrity of the system, and will detect any significant defects in and near the new welds.

Repairs on components 2 inches in diameter or smaller are relatively minor in comparison, and surface examination ensures a similar standard of integrity. In all cases, the leak test ensures leak tightness during normal operation.

4.4.1.7 Inservice Inspection Capability

During the design phase of the reactor coolant system, careful consideration was given to providing access for both visual and/or non-destructive inspection. To facilitate this program, critical areas of the reactor vessel were mapped during the fabrication phase. This map serves as a reference base for subsequent ultrasonic tests.

The inservice inspection and inservice testing of ASME Code Class 1, 2, and 3 components and supports are performed in accordance with a periodically updated version of the ASME Code and Addenda, as required by 10 CFR 50.55(a). Relief from specific requirements of the Code is provided by written request for approval to the NRC.

CHAPTER 5 CONTAINMENT SYSTEM

This section describes the containment system for either unit. The containment systems for the two units are similar and completely independent.

Note: As required by the Subsequent Renewed Operating Licenses for Surry Units 1 and 2, issued May 4, 2021, various systems, structures, and components discussed within this chapter are subject to aging management. The programs and activities necessary to manage the aging of these systems, structures, and components are discussed in Chapter 18.

5.1 GENERAL DESCRIPTION

The containment system, together with the engineered safeguards (Chapter 6), is designed to limit radiation doses under conditions resulting from design-basis accident (Chapter 14) to less than or equal to the limits specified in 10 CFR 50.67 at the site boundary and beyond.

The steel-lined, reinforced-concrete containment structure, including foundations, access openings, and penetrations are designed and constructed to maintain full containment integrity when subjected to the temperatures, pressures, potential missiles resulting from the design-basis accident, and the earthquake conditions and tornados described in Chapter 2. Systems are provided to remove heat from the containment and to ensure against breaching containment integrity at the time of, or following, the design-basis accident, or any lesser accident.

The original containment concept includes provisions for routine operation at a reduced internal pressure in which the air partial pressure varies between about 9.0 and 10.3 psia, and for the return to subatmospheric pressure within 60 minutes after the design-basis accident through the use of multiple spray systems. This concept provides for positive termination of outleakage of fission products from the containment, since the containment is maintained at subatmospheric pressure after depressurization. The pressure following depressurization is maintained at less than 14.7 psia. The current concept for the design basis accident containment internal pressure reduction, consistent with alternate source term (AST) analysis, is discussed in Section 5.4.

Provisions have been made for the leak testing of liner seams during construction; for air pressure and leak testing of the containment structure at the completion of construction; for leak testing of the penetrations and access openings at any time; for continuous leak monitoring of the containment structure while at subatmospheric pressure; and for periodic pressure testing of the containment structure throughout station life.

Leak tightness testing of liner welds during construction was performed by welding a structural steel gas test channel over each weld. The test channels of the dome of the containment are located outside the liner plate, with test holes tapped and plugged from the inside. Test channels of the floor liner are piped through the concrete, which covers the floor, to test port panels, and are plugged. Test channels on the straight side walls of the containment are located inside the liner plate, and are tapped and plugged from the inside.

The containment weld test channels used for leak testing of the containment liner welds as described in Section 5.5 were left in place at the completion of construction. Therefore, the test channel welds are tested as an integral part of the containment liner plate welds during the operational phase leak rate testing.

Although the leak test channels were not designed as structural elements, nor as a pressure boundary, they do provide additional leak protection. The test channels are capable of withstanding all loads that might be imposed on them during normal, test, and design basis accident conditions without any loss of function, and the presence of the test channels does not in any way impair the performance of the containment liner itself.

Details of containment structural design are given in Chapter 15, and details related to performance during postulated accident situations are given in Section 5.4 and Chapter 14.

5.2 CONTAINMENT ISOLATION

5.2.1 Design Bases

The containment isolation system has the following design bases:

1. During incident conditions, at least two barriers exist between the atmosphere outside the containment structure and:
   a. The atmosphere inside the containment structure.
   b. The reactor coolant and connecting systems.
2. The design pressure of all piping and connecting components within the isolation boundary is greater than the design pressure of the containment, 45 psig.
3. The failure of one valve or barrier does not prevent isolation.
4. The operation of the containment isolation system is automatic.
5. All isolation valves and equipment are protected from missiles and water jets originating from the reactor coolant system.
6. All remotely actuated and automatically operated isolation valves have their positions indicated in, and can be operated from, the control room.
7. Containment isolation system valves are located so as to require a minimum length of piping between the isolation valves and their penetrations.
8. Special consideration is given to the design of the low-head safety injection and recirculation spray pump inlet lines, in that highly reliable components are used in a single valve arrangement, which is enclosed in a special valve pit.

For isolation, the two-barrier valving arrangements consist of the following:

1. Two automatic isolation valves one on each side of the containment wall.
2. Two automatic isolation valves located outside the containment wall.
3. An automatic isolation valve and a membrane barrier. A membrane barrier consists of either pipe, tubing, or a component wall.
4. An administratively-controlled, manually-operated valve outside the containment, and a closed system inside the containment.
5. Two administratively-controlled, manually-operated valves, one on each side of the containment wall.

6. A sump recirculation pipe and valve arrangement, conservatively designed and fabricated, and enclosed by a special valve pit. The suction lines for the low-head safety injection pumps and the recirculation-spray pumps are designed to prevent gross system leakage. The major portion of this piping is buried in the reinforced-concrete base mat, and only a short length of piping exists between the mat and the isolation valve. This valve is equipped with a reliable remote operator. The design of this portion of the installation is compatible with letters from the Advisory Committee on Reactor Safeguards to the U.S. Atomic Energy Commission (References 1 & 2). Provisions for detecting leaks in these suction lines are described in Chapter 6.

The criteria applied to the various functional classes of piping to implement the design bases are as follows:

1. Class I piping is open to the outside atmosphere and is connected to the reactor coolant system, or a connecting system, or is open to the containment atmosphere. An example is the line from the containment sump pumps to the waste drain tanks. For Class I piping, the following is provided for isolation subsequent to a LOCA:
    a. Incoming lines with one check valve inside the containment wall and an automatic isolation valve outside the containment.
    b. Outgoing lines with one automatic isolation valve inside and one automatic isolation valve outside the containment wall or two automatic isolation valves outside the containment wall.
2. Class II piping is connected to a closed system outside the containment and is connected to the reactor coolant system, or a connecting system, or is open to the containment atmosphere. An example is the excess letdown line. For Class II piping, the following is provided for isolation subsequent to a LOCA:
    a. Incoming lines with one check valve inside the containment wall and one automatic isolation valve outside the containment wall.
    b. Outgoing lines with one automatic isolation valve.
3. Class III piping is connected to open systems outside the containment and is separated from the reactor coolant system, or a connecting system, and the containment atmosphere by a valve under administrative control or by a membrane barrier. Examples are the component cooling-water lines. For Class III piping, the following is provided for isolation subsequent to a LOCA:
    a. Incoming lines with one check valve inside the containment wall and a valve under administrative control outside the containment wall.
    b. Outgoing lines with one automatic isolation valve or a valve under administrative control outside the containment wall.

In the case of the main feedwater and auxiliary feedwater systems, isolation of the Class III lines is provided by one check valve inside and one check valve outside the containment wall. Isolation of the steam supply to the turbine driven auxiliary feedwater pump is provided by a normally open manual valve under procedural control. Isolation of the service water lines to the Recirculation Spray Heat Exchangers is provided by the closed membrane system inside of the containment wall and a remote manual isolation valve outside the containment wall in each line.

4. Class IV piping must remain open after a LOCA. An example is the high-head safety injection/charging pump header to the reactor coolant system. For Class IV piping, the following is provided for isolation subsequent to a LOCA:

   a. Incoming lines with one check valve inside the containment wall and one remote manual valve outside the containment wall.

   b. Outgoing lines with one automatic isolation valve outside the containment wall.

   Isolation for the seal water supply to the Reactor Coolant Pumps (RCP) is provided by two check valves inside the containment wall and one administratively controlled manual valve outside the containment. Isolation barriers are provided by the check valves inside containment and the closed portion of the chemical and volume control system on the discharge of the charging pumps. These lines remain open after a safety injection signal, and the flow contributes to the total injection flow while cooling the RCP seals.

5. Class V piping is connected to systems outside the containment wall, which are normally not in service and are isolated by a normally closed isolation valve under administrative control. A Class V line is separated from the reactor coolant system, connecting systems, and the containment atmosphere by a closed valve and/or by a membrane barrier. An example is the service air line.

The isolation valve configuration for each penetration is provided in Tables 5.2-1 and 5.2-2 for Units 1 and 2, respectively.

Where check valves are used as isolation valves, consideration has been given to the ability of these check valves to prevent the leakage of air into the containment when the containment atmospheric pressure is negative.

Check valves in the containment spray and recirculation spray systems are positive-closure check valves. These valves have an external, adjustable counterweight, set to maintain the disk tightly sealed during certain phases of accident conditions when the containment atmospheric pressure is slightly negative. These types of check valves are provided in these systems because they are open to the containment atmosphere through the spray nozzles when the systems are isolated after an accident.

Check valves used for isolation purposes in other pipelines, normally those containing water, are ordinary check valves. They do not have the positive closure feature because they are in series with an automatic trip valve or a valve under administrative control. This arrangement would require a double failure; that is, a failure of the automatic trip valve to close and a rupture in the line downstream from the check valve, which would cause the water leg normally holding the check valve closed and sealed to be drained. This allows outward leakage past the check valve if the check valve fails to seal tightly with a small differential air pressure.

A monitoring arrangement is provided to test the leaktightness of each automatically actuated trip valve and check valve. Examples of valve arrangements for each class of penetration are depicted in Figure 5.2-1.

Instrumentation and adjunct control circuits associated with automatic isolation valve closure are fail-safe (initiate closure) upon loss of voltage and/or control air. Most isolation valves are air-to-open/spring-return-closure diaphragm-operated, piston-operated or direct acting electric solenoid valves thus providing a fail-safe design. The automatic isolation valves inside the containment will function properly under all containment atmospheric pressures.

Under accident conditions, the containment pressure is positive and the solenoid valve vents the control air to the containment atmosphere. Because both sides of the isolation valve diaphragm are vented, balanced forces on either side of the diaphragm result, allowing the spring to close the automatic isolation valve. Circuits that control redundant automatic valves are redundant in the sense that no single failure will preclude isolation. Means are provided to periodically test the functioning of the automatic isolation equipment such as the setpoint of sensors, the speed of response, and the operability of fail-safe features. The containment isolation instrumentation is discussed in Section 7.5.

It should be noted that isolation valves actuated by electric motors upon electrical failure fail in the as-is position.

The trip valves in the reactor coolant sample system and the residual heat removal sample systems are direct acting electric solenoid valves. This ensures that the valves could be reopened to draw a sample under single failure criteria, after an accident.

The steam generator blowdown trip valves are 2-inch, double disk, pressure seal-type gate valves. The valves are of sufficient size to meet the maximum allowable pressure-drop requirement at the design flow rate and will minimize the occurrence of cavitation.

5.2.2 Isolation Design

The general criteria covering the number and location of isolation valves required to ensure containment integrity during LOCA conditions are provided in Section 5.2.1. Tables 5.2-1 and 5.2-2 for Units 1 and 2, respectively, summarizes the major piping penetrations through the containment for each fluid system as to the type of valves that are provided, their position under various plant conditions, the fluid they contain and the systems they connect. The tables also identify if the system is essential or non-essential and the isolation actuation signals. In addition, the tables identify those valves that are required to be leak tested in accordance with 10 CFR 50 Appendix J.

The isolation valves tested in accordance with 10 CFR 50 Appendix J provide containment integrity during LOCA conditions. The remaining isolation valves, which are not required to be tested in accordance with 10 CFR 50 Appendix J, provide isolation to mitigate the consequences of other accident conditions (e.g., mainsteam, feedwater and blowdown valves are not tested, but provide isolation in the event of a steam generator tube rupture).

Containment isolation is accomplished under the following conditions:

1. Phase-1 isolation is initiated by a safety injection actuation signal. Safety injection is actuated by any one of the following input signals (Section 7.5):

    a. High steam-line flow with low steam-line pressure or low-low T_{avg}.

    b. High steam-line differential pressure.

    c. Low-low pressurizer pressure.

    d. High containment pressure.

    e. Manual initiation.

    These input signals provide the diversity required by Section 6.2.4 of the Standard Review Plan (Reference 3).

2. Phase 2 - Isolation is initiated by a high containment pressure signal, and closes the automatic trip valves in all normally open lines penetrating the containment that are not required to be open to control containment pressure to perform an orderly shutdown without actuation of the consequence limiting safeguards in case of a small reactor coolant system leak.

3. Phase 3 - Isolation is initiated by a high-high containment pressure signal, which is indicative of a major LOCA. Remaining automatic trip valves normally open lines that penetrate the containment which have not been shut by 2. above are shut by this signal.

Plant systems with containment penetrations have been categorized as essential or non-essential. There are, in turn, two levels of essential systems:

Level 1 - Systems required to mitigate the consequences of an accident.

Level 2 - Systems required to maintain the operability of critical systems or functions.

Level 1 essential systems (Tables 5.2-1 & 5.2-2) include the engineered safety features (such as containment spray, recirculation spray, and the safety injection system) and the service-water system used to cool the recirculation-spray heat exchangers. Level 2 essential systems (Tables 5.2-1 & 5.2-2) include the auxiliary feedwater system, the component cooling-water system associated with reactor coolant pump operation, containment air cooling, and residual heat removal. Non-essential systems (Tables 5.2-1 & 5.2-2) include the other systems not required for the Level 1 and Level 2 functions described above.

Level 1 essential systems are required to operate after a LOCA. Level 2 essential systems remain unisolated from containment unless they are not required, or until a LOCA is indicated by Phase 2 isolation. Non-essential systems are either isolated during normal operation or they are isolated by a Phase 1 isolation signal. Some non-essential systems may be operated manually following a LOCA if conditions warrant their use.

Once Phase 1 containment isolation has been initiated by a safety injection actuation signal, the automatic isolation valves can be opened only after the manual reset of the actuating signal and the deliberate remote manual operation of the individual valve (an exception is the condenser air ejector containment isolation valve described in the next paragraph). There are no valve control switches that control the reopening of more than one valve.

Under normal conditions, the condenser air ejector discharge is vented to the atmosphere and the containment discharge divert valve is closed. When high radioactivity is detected by the condenser air ejector radiation monitors, the normal condenser air ejector discharge flow path to atmosphere is isolated and the containment divert valve opens to divert the condenser air ejector discharge to containment. If a containment isolation (safety injection) signal occurs, the condenser air ejector containment isolation trip valve will close. When the containment isolation signal resets, the condenser air ejector containment isolation trip valve will open and divert the condenser air ejector discharge back to the containment if the high radioactivity signal is still present. The isolation valve has an electrical interlock, however, that prevents reset until containment pressure is subatmospheric. Normal flow to the atmosphere is not restored until the high radiation signal is cleared. See Sections 10.3.8.2 and 11.3.3.8 for further information.

Diverse isolation signals are provided for the automatic containment isolation valves in non-essential systems. However, some non-essential systems are not automatically isolated by a containment isolation signal. But the staff of the Nuclear Regulatory Commission has agreed that sufficient isolation provisions have been provided at Surry for all non-essential penetrations (Reference 4). Penetrations with normally closed manual isolation valves are locked closed and administratively controlled such that, if a valve is required to be opened during plant operation, a dedicated person is assigned to close it after the evolution requiring it to be open has been completed, or to close it within 60 seconds after the receipt of a containment isolation signal.

The basis for the 60-second limit is that no fuel cladding is expected to melt or fail until after 60 seconds following a loss-of-coolant accident (LOCA). This is verified for PWRs by the FLECHT experimental results (Reference 7). Thus, fission product release from the core to the containment atmosphere or to other portions of the Reactor Coolant System (RCS) could not occur until at least one minute after the event.

If any of the automatic signals fail to actuate the containment isolation trip valves or the remote manual valves, isolation can be accomplished manually from the control room. The solenoid valves that operate the automatic trip valves can be actuated by an electric signal that is produced in the control room.

For lines coming into the containment, check valves are used wherever an additional barrier is provided by either a membrane or an automatic isolation valve. The use of check valves in this service is confined to either liquid lines or lines that are closed outside the containment. These check valves shut under a differential pressure when the higher pressure is on the containment side of the check valve.

The monitoring arrangement provided to test the leaktightness of each automatic trip valve and check valve consists of a monitoring tap on the main line upstream from each isolation valve. To test for valve tightness, the main piping section upstream from each valve is pressurized and evidence of fluid leakage is checked using the makeup air method. When not in use, the monitoring lines are plugged at the open end. As described in Section 5.5, containment isolation valves are tested to verify their sealing capability and leaktightness.

Several spare containment pipe penetrations of various sizes are provided. All pipes in these spare penetrations are sealed at both ends.

All isolation valves and equipment are protected from missiles and water jets originating from the reactor coolant system. Missile protection for isolation valves, actuators, and controls is provided by locating isolation valves between the steam generator cubicle wall, crane wall, and the containment wall or locating isolation valves outside the containment structure. The pressure-sensing devices that detect high containment pressure are located outside the containment on the leakage-monitoring tubing that is open to the containment. The location of the pressure-sensing devices outside the containment protects them from missiles developed by a LOCA. Details regarding the probability of missile damage and design features to prevent the formation of missiles are given in Section 15.5.1.11.

The fuel transfer penetration between the refueling canal inside the containment and the spent-fuel pit is fitted with a blind flange inside the containment and a normally closed gate valve in the transfer canal outside the containment to prevent leakage through the transfer tube during accident conditions.

The following precautions, which apply to all lines penetrating the containment, are intended to prevent the inadvertent opening of these lines to the atmosphere outside the containment:

1. Automatic isolation valves can be opened only upon the cessation of the actuating signal and the manual reset of controls.
2. Automatic isolation valves are capable of manual actuation from the control room, with the limitations on the opening of the valve discussed in item 1. above.
3. Remote manual valves are closed and opened only under administrative control.

4. Local manual valves are closed and opened under administrative control.
5. Check valves open only when the fluid pressure is higher on the side outside the containment.
6. The design pressure of piping and connecting components within the isolation boundary is greater than the design pressure of the containment (45 psig).
7. Remote manual valves, once opened by a high-containment-pressure isolation signal, can only be closed upon the cessation of the actuating signal and the manual reset of controls.

For items 1, 2, 3, and 4 above, and for flanged closures, specific plant procedures define the positioning of these closures in the containment isolation system during normal operation, shutdown, and accident conditions.

Tables 5.2-1 and 5.2-2 Notes

1. Component Cooling Containment Penetration Isolation:

   Penetration #'s: 1, 2, 4, 5, 9, 10, 11, 12, 13, 14, 16, 17, 18, 25, 26, 27, 110

   These penetrations are in closed systems. Containment penetration check valves and trip valves are leak tested, but the leakage is not included in the 10 CFR 50 App. J Type B and C total leakage. During the associated penetration check valve test, the containment penetration manual isolation valve is leak tested in the reverse direction. The valve is tested with system pressure on the upstream side and the downstream side vented.

   Reference: T. S. Amendment 72/73 dated September 29, 1981.

2. Safety Injection Inside Containment Penetration Isolation:

   Penetration #'s: 7, 21, 23, 35, 36, 37, 60, 61, 62, 113

   Inside containment penetration check valves are not Type C tested. A single valve is acceptable because the system is closed outside of containment and a single active failure does not prevent isolation.

   Penetration numbers 7 and 113 have locked closed outside containment isolation valves under administrative control.

3. General Design Criteria (GDC) Compliance:

   Penetration #'s: 20, 24, 46, 106

   Containment isolation for the above penetrations is consistent with the original design basis of the UFSAR for applicable class 5 lines. GDC 55 & 56 were not promulgated when these containment isolation configurations were designed. These penetrations are considered to meet the requirements of GDC 53 (July 1967). Type C testing is performed on the outside isolation valve only.

4. Locked Closed Containment Penetration Isolation Valves:

   The following Penetrations have either one or two Containment Penetration Isolation Manual Valves locked closed. These valves are maintained under administrative control. The valves outside containment are verified locked closed periodically. The valves inside containment are verified prior to exceeding Refueling shutdown conditions.

   Penetration #'s:

   <u>Outside/Inside Locked</u>: 22, 51, 54, 96, 103, 104, 114

   <u>Outside Locked</u>: 7, 20, 24, 42, 47, 55, 57, 58, 66, 67, 68, 69, 94, 97, 101, 105, 106, 113

The following penetrations have the containment penetration Isolation MOV Breaker locked open with the valve in the closed position. The containment isolation MOVs also have their handwheel locked. The valves and breakers are verified locked closed periodically.

Penetration #'s: 90, 91

5. Seal Water To RCP's:

   Penetration #'s: 35, 36, 37

   Needle valves are throttled open and administratively controlled. These lines remain open after a safety injection signal and contribute to the total injection flow while cooling the RCP seals. The incoming lines have a check valve inside containment and a local manual valve (throttle valve) outside containment combined with both a closed system and continuous water seal at a pressure sufficient to preclude containment atmospheric leakage.

6. Open Containment Penetration Isolation Valves:

   Penetration #'s: 61,74,75,76

   Penetration 61 has its breaker de-energized with the valve in the open position. This penetration is for Low Head Safety Injection Discharge to the Reactor Coolant System Cold Legs. The Safety Injection System outside containment has an external leakage Technical Specification requirement which provides limits to ensure acceptable leakage during accidents.

   Penetrations 74, 75, & 76 are the normal steam supply to the turbine driven auxiliary feedwater pump and are normally open. These valves are closed in accordance with emergency procedures to provide steam generator isolation in the event of a steam generator tube rupture.

7. Main Steam Containment Penetration Isolation:

   Penetration #'s: 39, 40, 41, 73, 74, 75, 76, 77, 78, 87, 88, 102

   No testing required - per App. J.

   These penetrations are in systems directly connected to the steam generator secondary side and, therefore, are considered a closed system (an extension of the primary containment). In addition, the steam generator remains at a pressure greater than peak accident pressure for at least the first hour and is not considered a credible leakage path from containment.

   Reference: T. S. Amendment 72/73 dated September 29, 1981.

   An air test is performed prior to a Type A Test. If a Type A Test is not performed, station procedures verify that no external leakage exists.

8. Service Water To Recirculation Spray Heat Exchanger Containment Penetration Isolation:

   Penetration #'s: 79, 80, 81, 82, 83, 84, 85, 86

These penetrations are in closed systems. Each train is leak tested but the leakage is not included in the 10 CFR 50 App. J Type B and C total leakage. The valves in these lines remain open during a design basis accident.

Reference: T. S. Amendment 72/73 dated September 29, 1981.

9. Water Filled Penetrations:

   Penetration #'s: 7, 15, 21, 23, 46, 60, 61, 62, 66, 67, 68, 69, 113

   These penetrations are in systems that are water filled and/or normally operating under accident conditions at a pressure greater than peak accident pressure. Therefore, these penetrations are not considered credible leakage paths from containment.

   Reference: NRC SER dated November 21, 1988.

10. Type C Reverse Direction Tests:

    Penetration #'s: 90, 91, 103

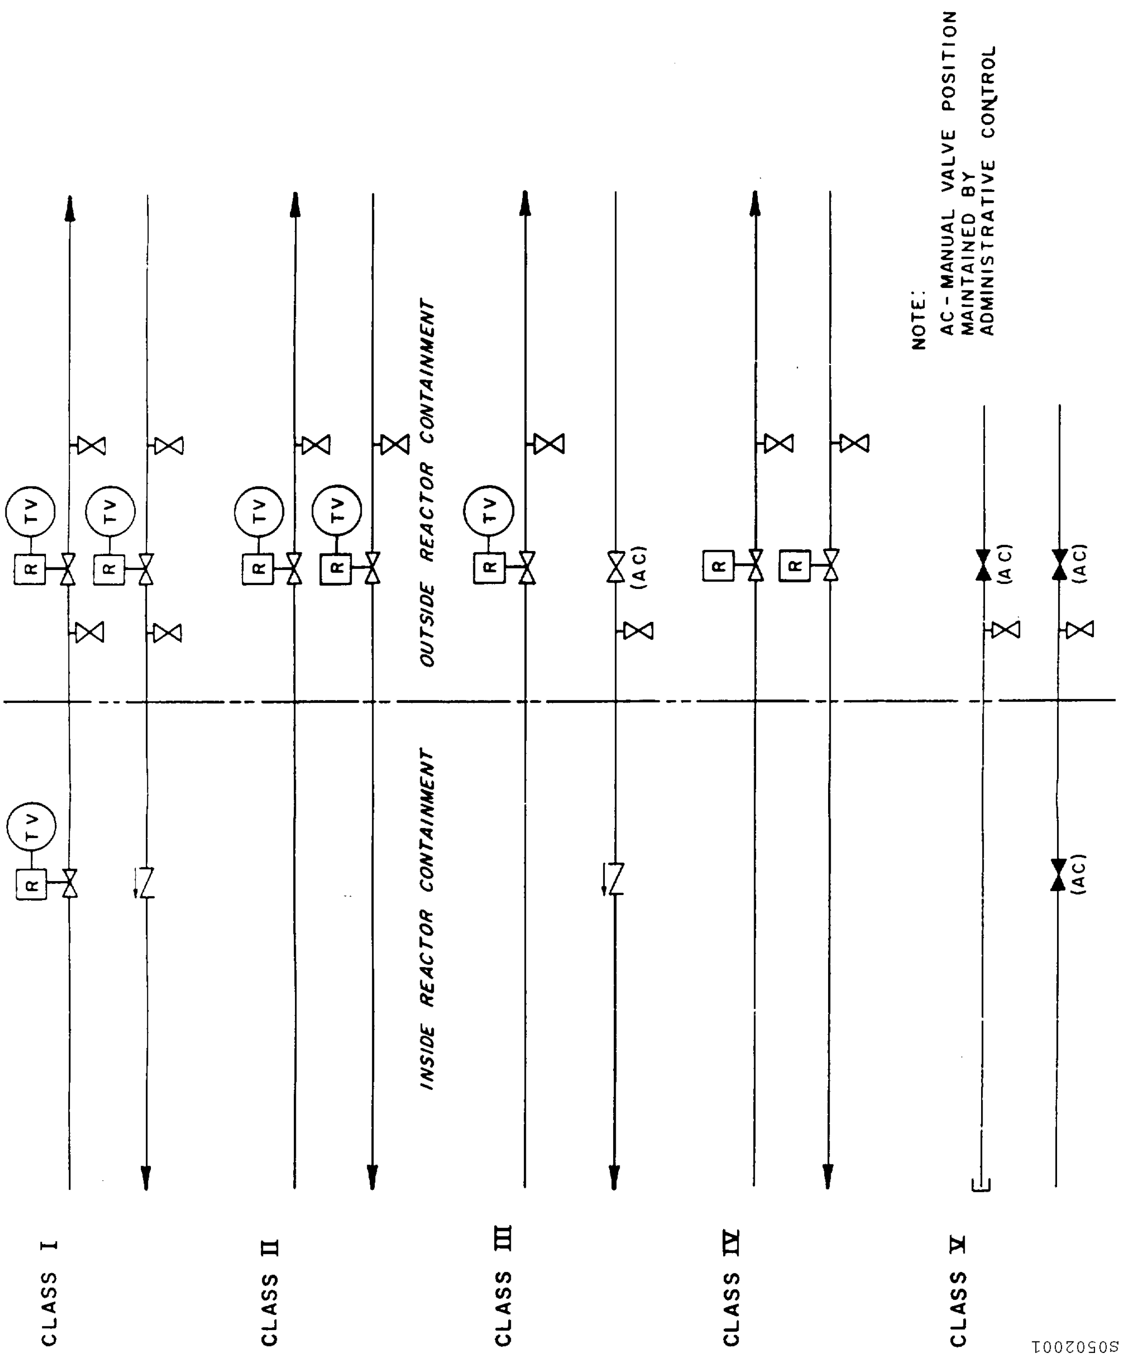
    Type C testing of the inboard isolation valve for penetration 90, 91, and 103 is performed in the reverse direction due to the existing piping configuration. For the type of inboard isolation valves used (diaphragm and butterfly), leakage is the same in either direction.

11. Steam Generator Recirc. And Transfer System:

    Penetration #'s: 22, 96, 114

    Due to the piping configuration inside containment, the above penetrations were added to the Type C testing program to ensure that any leakage through these valves is identified and corrected.

Figure 5.2-1
EXAMPLE OF VALVE ARRANGEMENT CONTAINMENT ISOLATION SYSTEM



5.3 CONTAINMENT SYSTEMS

5.3.1 Ventilation Systems

5.3.1.1 General Description

Containment ventilation consists of an air cooling recirculation system, an air cooling control rod drive mechanism (CRDM) system, a filter system, and a purge system. They are shown on Reference Drawing 1. A review of the effects of the power uprate to a core power of 2587 MWt was conducted and the containment air recirculation system was found to be adequate. The reactor coolant pump motors (Section 4.2.2.4) are cooled with an integral component cooling water system. The air-cooling recirculation system, air-cooling control rod drive mechanism system, and reactor pump motor coolers provide the total cooling required to limit the bulk air temperature to 125°F during normal summer operations. The minimum temperature allowed is 75°F.

5.3.1.2 Design Basis

The ventilation systems were originally designed to limit the containment bulk air temperature to below 105°F when three of the recirculating fans are running, three CRDM-cooling systems are running, and the cooling systems for the reactor coolant pump motors are functioning. Operating experience has demonstrated that the heat load in containment exceeds the original design estimates but that the ventilation systems are adequate to maintain the containment bulk air temperatures less than 125°F. The value of 125°F is the maximum containment initial temperature assumed in the design basis accident containment response evaluations.

The recirculation fan and cooling coil systems are designed to remove their portion of the heat load, under subatmospheric operating conditions, when supplied with 680 gpm of 70°F water. The relative humidity during both summer and winter operations is about 40%, with 70°F cooling water entering the recirculation coolers and 105°F bulk air temperature.

The control rod drive mechanism cooling system is designed to meet the required heat removal load when three fan cooling coil units are operating.

The two inside containment iodine filtration units are designed to remove airborne activity that may be released by nominal operational reactor coolant system leakage during subatmospheric operations.

The purge system is designed to purge the containment after the pressure has been raised to within 1-inch water gauge of atmospheric. The purging rate can be varied in steps from approximately one change per day to one change per hour. The purge exhaust is charcoal filtered for airborne radioactivity removal. If fuel is being handled within containment, the purge exhaust air flow may be directed through one or two safety related filters depending on the purge flow rate, or it may be routed through a non-safety related charcoal filter. Without fuel handling inside containment, the purge exhaust air may be routed through a nonsafety related charcoal filter. The purge system design also provides ventilation and space heating for cold weather refueling and maintenance.

Principal component data are given in Table 5.3-1.

5.3.1.3 System Descriptions

5.3.1.3.1 Air-Cooling Recirculation System

The air-cooling recirculation system consists of three 75,000-cfm (at subatmospheric conditions) fan and cooling coil banks discharging into a common ring duct from which cool supply air is ducted to the various compartments.

A vane-axial fan is installed in ductwork routed from a recirculation system discharge plenum at Elevation -27 ft. 7 in. to the containment dome area. The fan supplies approximately 10,000 cfm at subatmospheric conditions to the containment dome area to prevent warm air stratification.

Return-air transfer ducting is provided to prevent the short-circuiting of return-air flow paths, and thereby ensure cooling-air flow to the area above the operating floor. Three 36-inch-diameter ducts, each with a vane-axial fan, take suction from approximately 30 feet above the operating floor and discharge below Elevation -3 ft. Each duct has an air flow capacity of approximately 25,000 cfm. The vane-axial fans are operated with normal station power.

The recirculation system cooling coils are served primarily by the component cooling water system (Section 9.4.3.1), with backup cooling available from the chilled component cooling water system (Section 9.4.3.3).

Containment cooling design heat loads are given in Table 5.3-2.

5.3.1.3.2 Control-Rod Drive Mechanisms

The control-rod drive mechanisms are cooled by three 24,000-cfm (at subatmospheric conditions) fan and coil banks. All three units are required to provide the essential heat removal during normal operation. On Unit 1, air is drawn through the top of the shroud down over the CRDM coil stacks. On Unit 2, air is drawn through the sides of the shroud and up over the CRDM coil stacks. The air then circulates through the mechanisms, and discharges back to the containment through the cooling coils. Each fan and coil unit has two 100% flow capacity fans for redundancy.

5.3.1.3.3 Iodine Filtration Units

The inside containment iodine filtration units are self-contained packages installed on the lower level of each containment. Each consists of a 2000-cfm fan with roughing, high efficiency particulate air (HEPA), and charcoal filters installed within concrete shielding. The units are remotely operable from the control room.

5.3.1.3.4 Purge System

The containment purge supply and exhaust subsystems consist of supply and exhaust ducting arranged to ventilate either containment when the pressure has been raised to within 1-inch of water gauge of atmospheric pressure. The normal station powered supply fans are not operated to assure that the containments are negatively pressurized. The exhaust fan(s) draw outside air through low efficiency filters and a winter heating coil into containment through two isolation butterfly valves. The purge exhaust air is drawn through low-level ducts within the containment. This air flows through two isolation butterfly valves that may connect to one or both safety related filter trains or one non-safety-related filter train (Section 9.13) through two isolation dampers installed in series. The outer exhaust valve is fitted with an 8-inch bypass valve to permit reduced purge flow if required. An 18-inch pressure-equalizing valve is installed on the outside of the containment structure between the supply system penetration valves to bring the containment up to atmospheric pressure on shutdown.

The motor-operated butterfly valves are located on either side of the containment penetrations for pressure integrity. The two isolation trip dampers in series connecting the purge exhaust ducting to the safety-related filter inlet header are air operated and are designed to fail in the closed position on loss of air. The air is supplied from either the station compressed air system or through an air accumulator sized to store sufficient air to keep the dampers open for 2 hours. The butterfly valves, air-operated isolation trip dampers, and ducting leading to the safety-related filter inlet header, including the safety-related filter system, are constructed to meet seismic qualification requirements. The valves are normally kept closed except during unit shutdown when they are opened for ventilation, heating, and purging.

The purge system fans, isolation valves, and bypass and pressure equalizing valves are remote manually operated from the control room for system alignments. If a safety-injection signal is received, the purge supply fans will trip off and the isolation valves and dampers will automatically shut to isolate the containment and allow the safety-related filters to treat the air exhausted from the emergency core cooling equipment areas.

Since the Surry units have subatmospheric containments, containment purging operations are not allowed unless the unit is in cold shutdown or refueling conditions. Technical Specifications require that containment integrity be established before increasing reactor coolant temperature above 200°F, and that containment air partial pressure be within specifications before exceeding 350°F. Technical Specifications also require that the containment vacuum be maintained for all plant conditions under which the engineered safeguards systems are required to be operational. Purging is precluded under these conditions because physical limitations prohibit containment purging unless the containment vacuum is broken.

The connection to the non-safety-related charcoal filter is located between the isolation valves and isolation dampers. Although seismically supported, the connection is isolated seismically via a flexible joint from the seismic duct. When not in use, the connection is closed by installing the closed side of a spectacle flange. The maximum purge rate through this path is limited to 20,000 cfm as the filter also serves the Auxiliary Building General Exhaust.

5.3.1.4 **Design Evaluation**

Whenever the three main recirculation fan and coil units, the three CRDM fan and coil units, and the main coolant pump cooling systems are operating, the containment bulk air temperature will be maintained below 125°F. Two of the three fans in the recirculation system will continue to operate under limited main coolant leakage conditions that result in containment pressures up to but not exceeding the Consequence Limiting Safeguards (CLS) high-high containment pressure actuation setpoint (Section 7.5.1.2). The third fan will continue to operate, if normal station power is available, until stopped either manually or by actuation of an electrical fault protection device. This may provide sufficient heat removal to permit reactor shutdown under limited leakage conditions without resorting to spray injection.

The inside containment filter units will remove the airborne iodine and particulate radioactivity that could result from nominal operational leakage during subatmospheric operations.

The purge system provides the capability to change the containment air and remove radioactivity, if required, before entry for refueling and maintenance. The purge system is designed for one air change per hour and to maintain a minimum of 60°F inside the containment.

5.3.1.4.1 Incident Control

During normal operation of the plant, the containment purge system is not in use.

After unit shutdown and cooldown, purging of the containment can take place. The purge exhaust air may be directed to either the non-safety-related or safety-related ventilation filters in the auxiliary building if fuel is being handled inside containment, but no filtration is credited in the analysis. The analysis of the fuel handling accident in containment does not require that containment integrity be established prior to fuel movement. The purge design flow through the non-safety-related filter is 20,000 cfm with a limit of 30,000 cfm through the safety-related filters when containment integrity is established. If containment integrity is not established, the maximum purge exhaust rate equals the maximum safety-related fan flow limit of 39,600 cfm. The physical design and installation of the duct systems preclude exceeding these limits. The discharge of the safety-related filters and non-safety-related filter are monitored by the same system for radioactivity prior to release. Should a LOCA signal from the other unit be received, the air-operated isolation dampers will fail closed and allow the safety-related filters to treat the air exhausted from the ECCS areas. As described in Section 9.13.4.1, if a safety injection actuation occurs and auto alignment of the ventilation system is defeated, manual action is required to realign the system to the ECCS filtration mode. An alarm is received in the main control room if the purge is not realigned following a safety injection signal. This condition is not expected however, since defeating the automatic realignment is no longer credited in the fuel handling accident analysis and procedural controls have been established to eliminate operating with automatic alignment defeated.

5.3.1.4.2 Malfunction Analysis

The three air-cooling recirculating subsystems are required to maintain the containment bulk air design temperature during warm weather.

The three CRDM ventilation systems are required to provide the essential cooling.

The two inside containment self-contained particulate and iodine filter packages provide redundancy for small leakage rates.

During refueling, a high-radiation signal from the containment gas or particulate monitors or the manipulator crane area monitor will automatically trip the containment purge supply fans and close the containment isolation control valves. This automatic function is not credited in the fuel handling accident nor is it required to be operable. The operability of the containment gas and particulate monitors and the manipulator crane area monitor is relied upon in conjunction with communications to provide a timely and valid indication of a fuel handling accident in the containment.

5.3.1.5 **Tests and Inspections**

The systems are inspected, tested, and pneumatically balanced upon installation. Particulate and charcoal filters are individually tested before shipment. The filters in the purge exhaust flowpath are tested after installation and can be periodically tested for leakage and dioctylphthalate smoke test efficiency as described in Section 9.13.5.

5.3.2 Leakage-Monitoring System

The containment leakage-monitoring system was used for the preoperational integrated test of the containment and is used for the periodic measurement of leakage into the containment during normal unit operation. Section 5.3.2.2 describes two methods that can be used to monitor containment leakage: the reference volume method and the absolute method. The absolute method of leakage rate testing is the preferred method of testing due to overall test measurement accuracy. The reference volume method is not used but could be if necessary.

5.3.2.1 **Design Basis**

The leakage-monitoring system is not operational since the reference volume method is no longer used in containment leakage rate testing. The system can be made operational if necessary; however, the connections to the manometers would have to be reestablished since these are not used in the absolute system. In addition, the system would require necessary maintenance prior to use.

The absolute method applies the perfect gas law to measured changes in the containment pressure, temperature, and relative humidity, and reduces the data by means of a mathematical least-squares linear regression calculation.

Design data for the leakage-monitoring system components are given in Table 5.3-3. The system was designed in accordance with an Atomic Energy Commission Safety Guide entitled. *Reactor Containment Leakage Testing and Surveillance Requirements.*

5.3.2.2 **Description**

The absolute system consists of instruments to measure and record containment pressure, temperature, and relative humidity. These measurements are recorded at different times and the air mass in the containment is determined by the perfect gas law. Data compiled in this fashion are fitted to a linear regression equation relating time and the mass of air in the containment to leakage. Statistical methods are used to compute the variance in the results and thereby evaluate the error.

The reference volume method is based on determining the change in the pressure differential between the sealed reference system and the open-ended system of containment as caused by containment leakage. This method is limited by the difficulty in ensuring and validating the system integrity. Thus it is difficult to obtain accurate results. For this reason, the absolute method is the method of choice.

The accuracy of the test used to monitor containment leakage (ILRT) is verified by a supplemental test (superimposed method). The supplemental test is conducted for sufficient duration to accurately establish the change in leakage rates between the ILRT and the supplemental test. The results from the supplemental test are acceptable if the difference between the supplemental test data and the data obtained from either the reference volume test method or the absolute test method is within 0.25 L_a, where L_a is the maximum allowable leakage rate at the calculated peak accident pressure.

5.3.2.3 **Design Evaluation**

Periodic leakage monitoring is performed as required by Appendix J by the absolute method. This method is verified by a supplemental test (superimposed method). The absolute method is sufficiently accurate to establish that the containment leakage rate is less than the Technical Specification required leakage limit.

As part of the containment isolation system (Section 5.2), each open leakage-monitoring line penetrating the containment structure is provided with two automatic trip valves. In the event of an incident, these lines are closed and no leakage to the environment occurs. The containment leakage-monitoring system tubing, as an extension of the containment, is designed to withstand the pressure and temperature expected during an incident.

5.3.2.4 Tests and Inspections

The temporary instruments used to perform the Type A test are calibrated before each test as required by Appendix J.

5.3.3 Spray Systems

The containment-spray systems, which consist of containment-spray subsystems and recirculation-spray subsystems, are described in detail in Section 6.3.1.

The containment-spray subsystems operate during the depressurization period after a LOCA.

The containment-spray subsystems transfer chilled water from the refueling-water storage tank to the containment through the containment-spray headers. The chilled water removes sensible heat from the containment, resulting in a decrease in containment temperature and pressure. The containment-spray pumps and recirculation-spray pumps are driven by electric motors powered from either normal or emergency power sources as described in Chapter 8. The recirculation-spray subsystems recirculate water from the containment sumps through heat exchangers to the recirculation-spray headers. These subsystems provide a net heat removal from the containment. They are designed to aid in lowering the temperature and pressure within the containment and to maintain the containment subatmospheric once it is depressurized.

5.3.4 Vacuum System

The containment vacuum system is used to obtain the initial subatmospheric pressure in containment and to maintain that pressure during unit operation. It consists of a steam jet air ejector, two mechanical vacuum pumps, and the required piping, valves, and instrumentation.

Many of the containments currently in use operate at approximately atmospheric pressure. Following a LOCA, the containment pressure rises. Although the pressure can be reduced rapidly at first, the pressure-time transient curve is asymptotic to atmospheric pressure and the outleakage of fission products may continue for some time.

The subatmospheric containment concept is based on the normal operation of the containment below atmospheric pressure. Following a LOCA, the pressure will rise to above atmospheric pressure with subsequent outleakage. However, the containment temperature and pressure can be reduced rapidly, returning the containment to subatmospheric pressure and thus terminating outleakage. This is because the pressure-time curve crosses atmospheric pressure rapidly, being asymptotic to the initial subatmospheric pressure. The engineered safeguards used for pressure reduction are designed to limit the outleakage of fission products to an acceptable quantity.

Before unit operation, the containment pressure is at atmospheric pressure. During the reactor system heat-up, the pressure is reduced with a steam ejector so that containment operating pressure is reached before reactor power operation.

A subatmospheric containment pressure is maintained whenever the reactor is operating at or near design pressure and temperature. During operation, inleakage occurs and the vacuum system maintains the containment subatmospheric. The air pumped out is metered to provide a constant indication of containment system integrity. After reactor shutdown and reactor coolant system depressurization and before refueling or extended maintenance, the containment pressure is returned to atmospheric.

The initial operating temperatures for the subatmospheric and atmospheric containment are approximately equal. However, the subatmospheric containment has a lower initial air pressure.

It follows that for any containment pressure, the subatmospheric containment must have a higher steam partial pressure, which results in a higher containment temperature. The atmospheric containment would have an initial temperature of about 105°F and a temperature of approximately 273°F if allowed to rise to 50 psig following a LOCA. The subatmospheric containment starting at 10.0 psia would have an initial temperature of about 105°F and a temperature of approximately 285°F if allowed to rise to 50 psig following a LOCA.

The higher temperature for the subatmospheric containment results in the more effective operation of both static heat sinks and engineered heat removal systems. This higher temperature makes it possible to use reasonably sized water spray systems to return the containment to subatmospheric pressure and then to hold the containment subatmospheric.

The subatmospheric containment is based on known technology; 10 psia corresponds to a pressure altitude of about 10,000 feet. No difficulties have been encountered in the design and procurement of equipment for operation at this sub-atmospheric pressure. The containment is designed to resist the external pressure without new technology. The concept provides for an increase in unit safety through the reduction in possible activity release. The need for charcoal air recirculation filters and fans operating in a steam environment is eliminated and dependence is placed on a redundancy of simple spray systems.

The advantages of the subatmospheric containment are best realized if pressure is reduced rapidly to a subatmospheric level. A review of various heat removal systems indicates that the injection of cold water into the containment is the most rapid and dependable means of depressurization. This water must be borated when used in conjunction with shim-controlled reactors, since it will ultimately be recirculated to the reactor for core cooling. Depressurization is accomplished through the combined operation of the containment spray, which provides a cold-water heat sink, and the recirculation spray, which removes heat from the containment.

Transient heat transfer calculations required to size the spray systems and consider the effect of static heat sinks are well understood.

Figure 5.3-1 shows typical pressure transient curves for comparable atmospheric and subatmospheric containments following a LOCA. As shown, the pressure in the atmospheric type of containment design drops to a low value, but outleakage continues indefinitely, while outleakage is terminated in the subatmospheric containment type as soon as pressure is reduced below atmospheric.

5.3.4.1 **Design Bases**

The containment vacuum system is designed to perform the following three functions:

1. Evacuation of the containment from atmospheric pressure and maintenance of the subatmospheric pressure used for normal operation.
2. Removal of air from the containment to compensate for containment inleakage during normal operation.
3. Removal of steam and air from the containment to compensate for leakage following a design-basis accident.

The system is designed to reduce the containment pressure from atmospheric to within the Technical Specification air partial pressure limits in a time period compatible with the station start-up schedule by using the containment vacuum steam jet air ejector. To compensate for inleakage, each vacuum pump is capable of removing 5 cfm. The containment will be at a variable subatmospheric operating air partial pressure of between 10.1 and 11.3 psia whenever the reactor coolant system is at or exceeds hot standby pressure and temperature (450 psig and 350°F, minimum).

5.3.4.2 **Description**

The containment vacuum system consists of a steam jet air ejector and two mechanical vacuum pumps, with the required piping, valves, and instrumentation, as shown in Figure 5.3-2. Pump control and system instrumentation are discussed in Section 7.5. Containment vacuum system component data are given in Table 5.3-4.

The steam jet air ejector removes air from the containment to create the initial vacuum before operations, and operates on 150-psig steam provided by the auxiliary steam system, as discussed in Section 10.3.2. The air ejector is sized to draw down the containment pressure to 9.5 psia within 4 hours.

There are two five-cfm mechanical vacuum pumps, each of which can provide more than 100% of the required pumping capacity. The pumps are capable of being operated from the emergency diesel generators discussed in Section 8.5 and discharge to the process vent through the charcoal filters of the gaseous waste disposal system (Section 11.2.5).

Each containment vacuum pump is located inside a leaktight containment vacuum pump tank. A pipe running from the containment to the containment vacuum pump tank transports air from the containment to the containment vacuum pump inside the tank. The leaktight tank prevents seal leakage from the containment vacuum pump from escaping to the atmosphere.

5.3.4.3 **Evaluation**

The steam jet air ejector which is used only for initial reduction of the pressure in the containment and the vacuum pumps which are normally used during plant operations are not part of the engineered safeguards. The system is only operated when the reactor coolant system is below a temperature of 200°F. Each of the mechanical vacuum pumps is capable of removing containment inleakage and maintaining the required vacuum. The pumps are sized for intermittent and automatic operation so that, on a continual operational basis, they have the capacity for removing inleakage at a rate of about four times the design value.

The operation of the containment vacuum system is not required for several months after the design-basis accident. The containment is designed and demonstrated to have a leak rate not exceeding 0.1% per day at the design pressure. It is therefore reasonable to assume that the leakage rate, under normal plant operation and during the postaccident period, when the containment has been returned to subatmospheric pressure, will be considerably less. However, assuming the leakage rate to be independent of containment pressure, the rate of 0.1% per day would correspond to a leakage flow of 1.2 scfm and would increase containment pressure approximately 0.01 psi per day (i.e., 100 days are required to increase pressure 1 psi).

Offsetting the tendency for the containment pressure to rise as a result of the inleakage of air after the design-basis accident is the reduction in the containment pressure effected by the recirculation spray subsystem's ability to cool down the containment atmosphere further, since decay heat evolution decreases with time.

The effect of long-term leakage must be considered. Ultimately, air inleakage could result in the containment pressure increasing to atmospheric, with temperature fluctuations possibly raising the pressure to slightly above atmospheric. When the vacuum system resumes operation, it discharges through charcoal filters, which are part of the gaseous waste disposal system. Therefore, the amount of activity released to the environment is minimal.

Excess depressurization of the containment is not considered credible, since the vacuum pumps have such a small capacity when compared to the containment free volume. It requires a vacuum control system signal failure and uninterrupted operation of the vacuum pumps for approximately 17 days to result in a 1-psi decrease in containment pressure with the required capacity of 5 cfm. Alarms are provided in the control room to indicate that the containment pressure has dropped below the normal operating level. The alarm points are set at values above the design loading of the containment. This allows sufficient time for the operator to take corrective action before the pressure drops below the design loading of the containment. Administrative procedures require that the steam ejector be isolated to prevent its operation at any time other than that required during start-up of the unit. The steam ejectors are secured during normal operation by administrative control to preclude the possibility of excessive depressurization.

The minimum credible pressure expected for this containment design is caused by inadvertent operation of the containment spray system.

An evaluation of this event is performed using Charles' Law and the following initial conditions.

Minimum air partial pressure (P_1)	9.85 psia	TS limit of 10.1 psia – 0.25 psi uncertainty
Maximum bulk air temperature (T_1)	125.5°F	TS limit of 125°F + 0.5°F uncertainty
Minimum RWST temperature (T_2)	32°F	Bounding minimum value
Saturation pressure at T_2 (P_{sat})	0.09 psia	ASME Steam Tables at 32°F

Using Charles' Law for the air partial pressure (temperatures converted to Rankine), the final pressure in containment is calculated:

$$P_{total} = P_{air} + P_{vapor} = \frac{T_2}{T_1}P_1 + P_{sat}(T_2) = \frac{(460 + 32)(10.1 - 0.25)}{(460 + 125.5)} + 0.09 = 8.37 \text{ psia}$$

For an inadvertent CS actuation starting at the TS minimum air partial pressure of 10.1 psia and TS maximum air temperature of 125°F, the containment liner meets the following criteria without operator action to terminate CS.

1. Minimum containment pressure is greater than the bottom mat liner internal design pressure of 8.0 psia.
2. Minimum containment pressure is greater than the containment shell and dome internal design pressure of 3.0 psia.

5.3.4.4 Tests and Inspections

The steam jet air ejector and the mechanical vacuum pumps are not part of the engineered safeguards. Therefore, preoperational inspection of this simple mechanical device is satisfactory. The mechanical vacuum pumps were operated during the initial containment leakage rate test described in Section 5.3.2 and demonstrated adequate capacity to remove inleakage. During normal unit operation, they are alternated in service periodically, so their performance status is continually available.

5.3.5 Hydrogen Analyzer System

The requirements of TMI-2 Short Term Lessons Learned, NUREG 0578 and subsequent clarifications contained in the NRC letter dated October 30, 1979, required that there be a continuous indication of hydrogen concentration in the containment atmosphere provided in the control room. As a result, redundant hydrogen analyzers qualified to IEEE 323-1974 and IEEE 344-1975 were added with the capability of measuring over the range of 0 to 10% hydrogen concentration with containment conditions of 9 psia to 60 psia and 100% humidity. The redundant qualified hydrogen analyzers are shared by Units 1 and 2—a transfer switch with control circuitry provides for the capability of Unit 1 to utilize both analyzers or for Unit 2 to utilize both analyzers. This same circuitry allows for the operation of the direct operating electric solenoid containment isolation valves to the hydrogen analyzers.

Hydrogen analyzer H_2A-GW-104-1 has the capability of being powered from the Orange Train of Unit 1 or Unit 2 vital power and hydrogen analyzer H_2A-GW-204-1 has the capability of being powered from the Purple Train of the Unit 1 or Unit 2 vital power via switchable power sources.

Each analyzer has the capability to obtain an accurate sample within 90 minutes of the initiation of safety injection. Hydrogen concentration measurements will be indicated and recorded in the control room. The 90-minute timeframe is based upon the functional requirements provided in RG 1.7, Revision 3. Compliance with RG 1.7 ensures that indication of hydrogen concentration in the containment atmosphere is available in a timely manner to support the Emergency Plan (and related procedures) and related activities such as guidance for the severe accident management plan (References 1 & 2).

A qualified heat tracing system was added to the sample lines to each hydrogen analyzer in order to maintain a truly representative sample of containment atmosphere. The heat tracing system will be initiated on a safety injection signal.

A supply of oxygen gas is available to the hydrogen analyzer for use as the reagent gas for hydrogen recombining and a supply of hydrogen gas is available as the calibration gas.

5.4 CONTAINMENT DESIGN EVALUATION

The reactor containment is maintained at a subatmospheric pressure in which the air partial pressure varies between approximately 10.1 and 11.3 psia. The containment shell and dome are designed to withstand an internal pressure as low as 3 psia, and the containment bottom mat liner is designed to withstand an internal pressure as low as 8 psia. The Technical Specifications specify the partial pressure limitations as a function of service-water temperature. The allowable variation is based on the ability of the containment heat removal systems to depressurize the containment and depends on seasonal temperature changes in the service water and thermal recirculation effects. The containment design pressure is 45 psig, which is greater than the peak post-LOCA pressure, based on a double-ended hot-leg rupture. The containment returns to subatmospheric pressure within 60 minutes of the occurrence of the accident, thus terminating outleakage from the containment (Section 14.5.5). This original design criterion was modified in conjunction with the analyses for implementation of the alternative source term. The criteria were subsequently updated to support an increase in the containment depressurization profile for the alternative source term analyses. The updated criteria require that, following the LOCA, the containment pressure be less than 2.0 psig within 1 hour and less than 0.0 psig within 6 hours. The radiological consequences analysis demonstrates acceptable results provided the containment pressure does not exceed 2.0 psig for the interval from 1 to 6 hours following the Design Basis Accident. Beyond 6 hours, containment pressure is assumed to be less than 0.0 psig, terminating leakage from containment.

A subatmospheric containment limits the outleakage of fission products to meet 10 CFR 50.67 criteria for the design-basis accident as discussed in Section 14.5.6, using conventional spray cooling as described in Section 6.3.1.

At the design containment leak rate of 0.1% of contained volume per day, air inleakage is not significant for a considerable length of time after a LOCA. Ultimately, air inleakage, combined with ambient barometric pressure fluctuations, could result in a containment pressure slightly above atmospheric. To prevent this, the vacuum system maintains the containment pressure at several inches of mercury below the lowest expected atmospheric pressure during normal operation. The vacuum cannot be lost rapidly because of the inherent low-leakage design features of the containment.

The containment isolation features, such as penetrations, access hatches, and isolation valves, have been designed so that double barriers or seals exist between the interior of the containment and the environment. Hence, there are no direct leakage paths between the containment and the environment.

The seismological design bases for the reactor containment are described in Sections 2.5 and 15.2.4.

The containment structural design was in accordance with then current design practices for steel-lined, reinforced-concrete reactor containment structures. The design was based on accepted analytical methods and does not vary in any significant feature from structures then being licensed or approved for construction. Rigid controls were maintained for all the materials, and the construction practices were as indicated in Chapter 15. Subatmospheric pressure operation results in no significant effect on the structural design.

The subatmospheric containment system does not depart in any significant way from good engineering design practices as used for atmospheric containments, yet it provides a substantial increase in public safety.

The following sections provide descriptions of the analytical models used to calculate the containment pressure and temperature responses to the design basis loss of coolant accident.

5.4.1 LOCA Mass and Energy Release Analysis

5.4.1.1 **Purpose of Analysis**

The analysis documented in this section involves calculations of the long term Loss of Coolant Accident (LOCA) mass and energy releases for the double-ended pump suction guillotine (DEPSG) and double-ended hot leg guillotine (DEHLG) break cases with the proposed uprated conditions. This documentation provides the analytical basis with respect to the LOCA containment mass and energy release for the operation of the Surry Power Station Unit 1 and 2 at the described conditions.

Rupture of any of the piping carrying pressurized high temperature reactor coolant, termed a LOCA, will result in release of steam and water into the containment. This, in turn, will result in an increase in the containment pressure and temperature. The mass and energy release rates described in this section are used in further computations to evaluate the containment heat removal systems capability and containment structural integrity following a postulated loss of coolant accident. These analyses are performed to demonstrate compliance with General Design Criteria 38 and 50 of 10 CFR 50, Appendix A. Section 5.4.1.2 presents the long term mass and energy release analysis for containment pressurization evaluations. Section 5.4.1.3 presents the post-blowdown mass and energy releases for use in evaluation of recirculation spray pump available NPSH.

5.4.1.2 **System Characteristics and Modeling Assumptions**

The mass and energy release analysis is sensitive to the assumed characteristics of various plant systems, in addition to other key modeling assumptions. Some of the most critical items are: RCS initial conditions, core decay heat, safety injection flow, and metal and steam generator heat release modeling. Specific assumptions concerning each of these items are discussed below. Tables 5.4-1 through 5.4-5 present key data assumed in the analysis.

For the long term mass and energy release calculations, operating temperatures which bound the highest full power average coolant temperature were used as initial conditions. A core rated power of 2587 MWt (adjusted for calorimetric error of +0.38% of power) was assumed. The use of higher temperatures is conservative because the initial fluid energy is based on coolant temperatures which are at the maximum levels attained in steady state operation. Additionally, an allowance of +4.0°F is reflected in the temperatures in order to account for instrument error and deadband. The initial Reactor Coolant System (RCS) pressure in this analysis is based on a nominal value of 2250 psia. Also included is an allowance of +30 psi, which accounts for the measurement uncertainty on pressurizer pressure. The selection of 2250 psia as the limiting pressure is considered to affect the blowdown phase results only, since this represents the initial pressure of the RCS. The RCS rapidly depressurizes from this value until the point at which it equilibrates with containment pressure.

The rate at which the RCS blows down is initially more severe at the higher RCS pressure. Additionally, the RCS has a higher fluid density at the higher pressure (assuming a constant temperature) and subsequently has a higher RC mass available for releases. Thus, 2280 psia initial pressure was selected as the limiting case for the long term mass and energy release calculations. A 3% increase in the nominal RCS volume (which is composed of 1.6% allowance for thermal expansion and 1.4% for uncertainty) is also modeled. These assumptions conservatively maximize the mass and energy contained in the RCS.

The selection of the core model for the long term mass and energy calculation is based on the need to conservatively maximize the core stored energy. To maximize the core stored energy used in the analysis, an upper bound value is used which addresses the effect of uncertainties in the fuel temperature models and the material properties. The fuel design features and conditions used in the calculation of fuel temperatures for the core stored energy are selected to be bounding for the Surry reload cores. The core stored energy is calculated following the methodology of WCAP-17642-P-A.

Regarding safety injection flow, the mass and energy calculation considered configurations to conservatively bound potential alignments. The spectrum of cases included: Minimum SI - Single Train (conservatively low ECCS flowrates); Maximum SI - Single Train (conservative early depletion of refueling water storage tank); and Maximum SI - Two Train (nominal configuration).

The following assumptions were employed to ensure that the mass and energy releases are conservatively calculated, thereby maximizing energy release to containment:

1. Maximum expected operating temperature of the Reactor Coolant System (100% power conditions).
2. An allowance in temperature for instrument error and dead band (+4.0°F).
3. Margin in RCS volume of 3% (which is composed of 1.6% allowance for thermal expansion and 1.4% for uncertainty).
4. Core rated power of 2587 MWt.

5. Allowance for calorimetric error (+0.38% power).
6. Conservative coefficient of heat transfer (i.e., steam generator primary/secondary heat transfer and Reactor Coolant System metal heat transfer).
7. Allowance in core stored energy for effect of fuel densification.
8. An upper bound calculation of core stored energy which addresses the effect of uncertainties in the fuel temperature models and the material properties.
9. An allowance for RCS initial pressure uncertainty (+30 psi).
10. A maximum containment backpressure equal to design pressure.
11. The steam generator (SG) metal mass was modeled to include only the portion of the SG which is in contact with the fluid on the secondary side (i.e., 474,000 lbm/SG out of a possible 691,000 lbm). Portions of the SGs such as the elliptical head, upper shell, and miscellaneous internals have poor heat transfer due to their location with respect to the secondary side water level. The energy stored in these areas available for release to the primary side break flow will not be able to effectively transfer energy to the RCS, thus the energy will be removed at a much slower rate and time period (i.e., >10,000 seconds).
12. A provision for modeling steam flow from the secondary side to the turbine through the turbine isolation valve was conservatively addressed with the control systems and setpoints in the modeling code. The valve isolation time was modeled as occurring at 1.5 seconds after the low pressurizer pressure reactor trip setpoint was reached.
13. As noted in Section 2.4 of Reference 2, the option to provide more specific modeling pertaining to decay heat has been exercised to specifically reflect the Surry Unit 1 and 2 core heat generation, while retaining the two sigma uncertainty to assure conservatism.
14. Steam generator tube plugging level (0% uniform).
    - Maximizes reactor coolant volume and fluid release.
    - Maximizes heat transfer area across the SG tubes.
    - Reduces coolant loop resistance, which reduces Δp upstream of break and increases break flow.
15. The main feedwater flow was modeled as a linear coastdown over a duration of ten seconds. The coastdown was modeled as occurring after the low pressurizer pressure-SI trip setpoint was reached plus a signal processing time.

Use of the above conditions and assumptions result in a bounding analysis of the release of mass and energy from the RCS in the event of a LOCA. This analysis is applicable for operation of Surry Unit 1 and 2 at a core rated power of 2587 MWt.

5.4.1.3 **Long Term LOCA Mass and Energy Release Analysis**

5.4.1.3.1 Introduction

The evaluation model used to the long term LOCA mass and energy release calculations was the March 1979 model described in Reference 2. This evaluation model has been reviewed and approved by the NRC, and has been used in the analysis of other dry containment plants. These mass and energy releases are used in the containment response analysis described in Section 5.4.2. A discrepancy between volumetric heat capacities used in WCAP-10325-P-A (Reference 2) and those documented in more recent ASME Code documents was identified. This condition was addressed in PWROG-17034-P-A (Reference 13), where the NRC determined, with various generic methodology issues addressed, the continued use of WCAP-10325-P-A is acceptable for performing LOCA mass and energy release analysis for plants with large dry and sub-atmospheric containments.

5.4.1.3.2 LOCA Mass and Energy Release Phases

The containment system receives mass and energy releases following a postulated rupture in the RCS. These releases continue over a time period, which, for the LOCA mass and energy analysis, is typically divided into four phases:

1. Blowdown—the period of time from accident initiation (when the reactor is at steady state operation) to the time that the RCS and containment reach an equilibrium state.
2. Refill—the period of time when the lower plenum is being filled by accumulator and ECCS water. At the end of blowdown, a large amount of water remains in the cold legs, downcomer and lower plenum. To conservatively consider the refill period for the purpose of containment mass and energy releases, it is assumed that this water is instantaneously transferred to the lower plenum along with sufficient accumulator water to completely fill the lower plenum. This allows an uninterrupted release of mass and energy to containment. Thus, the refill period is conservatively neglected in the mass and energy release calculation.
3. Reflood—begins when the water from the lower plenum enters the core and ends when the core is completely quenched.
4. Post-reflood (GOTHIC)—describes the period following the reflood transient. For the pump suction break, a two-phase mixture exits the core, passes through the hot legs and is superheated in the steam generators. After the broken loop steam generator cools, the break flow becomes two phase.

Computer Codes

The Reference 2 mass and energy release evaluation model is comprised of mass and energy release versions of the following codes: SATAN VI and WREFLOOD. These codes were used to calculate the long term LOCA mass and energy releases through the end of reflood for the Surry Power Station Unit 1 and 2. GOTHIC calculates the post reflood mass and energy releases in accordance with Topical Report DOM-NAF-3 (Reference 8).

SATAN calculates blowdown, the first portion of the thermal-hydraulic transient following break initiation, including pressure, enthalpy, density, mass and energy flowrates, and energy transfer between primary and secondary systems as a function of time.

The WREFLOOD code addresses the portion of the LOCA transient where the core reflooding phase occurs after the primary coolant system has depressurized (blowdown) due to the loss of water through the break and when water supplied by the Emergency Core Cooling refills the reactor vessel and provides cooling to the core. The most important feature is the steam/water mixing model. (See Section 5.4.1.3.5.2.)

GOTHIC models the post-reflood portion of the transient. The GOTHIC code is used for the transfer of decay heat and the stored energy in the primary and secondary systems to the containment.

5.4.1.3.3 Break Size and Location

Generic studies have been performed with respect to the effect of postulated break size on the LOCA mass and energy releases. The double ended guillotine break has been found to be limiting due to larger mass flow rates during the blowdown phase of the transient. During the reflood and froth phases, the break size has little effect on the releases.

Three distinct locations in the reactor coolant system loop can be postulated for pipe rupture:

1. Hot leg (between vessel and steam generator)
2. Cold leg (between pump and vessel)
3. Pump suction (between steam generator and pump)

The break locations analyzed for this program are the double-ended pump suction guillotine, DEPSG (10.48 ft^2) and the double-ended hot leg guillotine, DEHLG (9.18 ft^2). Break mass and energy releases have been calculated for the blowdown, reflood and post-reflood phases of the LOCA for each case analyzed. The following information provides a discussion on each break location.

The DEHLG has been shown in previous studies to result in the highest blowdown mass and energy release rates. Although the core flooding rate would be the highest for this break location, the amount of energy released from the steam generator secondary is minimal because the majority of the fluid which exits the core bypasses the steam generators venting directly to containment. As a result, the reflood mass and energy releases are reduced significantly as compared to either the pump suction or cold leg break locations where the core exit mixture must pass through the steam generators before venting through the break. For the hot leg break, generic studies have confirmed that there is not reflood peak (i.e., from the end of the blowdown period the containment pressure would continually decrease). The DEHLG reflood and post-reflood phase calculations are not required to determine peak containment pressure, but were calculated for use in the calculation for the recirculation spray pump available NPSH. Further details about the hot leg mass and energy analysis are contained in Section 5.4.1.4. The mass and energy releases for the hot leg break blowdown phase are included in the present section.

The cold leg break location has also been found in previous studies to be much less limiting in terms of the overall containment energy releases. The cold leg blowdown is faster than that of the pump suction break, and more mass is released into the containment. However, the core heat transfer is greatly reduced, and this results in a considerably lower energy release into containment. Studies have determined that the blowdown transient for the cold leg is, in general, less limiting than for the pump suction break. During reflood, the reflooding rate is greatly reduced and the energy release rate into the containment is reduced. Since the DEPSG case provides bounding results, the cold leg break location is not explicitly analyzed.

The pump suction break combines the effects of the relatively high core flooding rate, as in the hot leg break, and a break flow path through which the stored energy in the steam generators can be transferred to the containment. As a result, the pump suction break yields the highest energy flow rates during the post-blowdown period since all of the Reactor Coolant System available energy contributes to the calculated mass and energy releases.

5.4.1.3.4 Assessment of Single Failure Effects

An analysis of the effects from various single failures has been performed on the mass and energy release rates for each break analyzed. An inherent assumption in the generation of the mass and energy release is that offsite power is lost. This results in the actuation of the emergency diesel generators, required to power the safety injection system. This is not an issue for the blowdown period which is limited by the DEHLG break.

Three cases have been analyzed for the effects of a single failure. In the case of minimum safeguards, the single failure postulated to occur is the loss of an emergency diesel generator. This results in the loss of one pumped safety injection train. Two variations on the minimum safeguards scenario were addressed. The first case was a maximum safety injection (SI) flow, single train case. This case will result in low flow rates, but an early refueling water storage tank depletion. The second configuration is the minimum SI flow, single train case. As compared to the first case the SI flow would be minimized, although the time of RWST depletion would be later. Sensitivities indicate that containment depressurization time is more limiting for the minimum SI-single train case. Containment depressurization peak pressure and LHSI pump NPSH are more limiting for the maximum SI-single train scenario. For the case of maximum safeguards, no failure is postulated to occur. Sensitivity cases using mass and energy data for the pump suction, maximum safeguards case indicated that this configuration is not limiting for any analysis acceptance criteria. Therefore, no detailed data or containment analysis results are presented for this case. The analysis of the cases described ensures that the effect of all credible single failures is bounded.

5.4.1.3.5 Mass and Energy Release Data

5.4.1.3.5.1 *Blowdown Mass and Energy Release Data*

A version of the SATAN-VI code, which is the code used for the Emergency Core Cooling System (ECCS) calculation in Reference 3 is used for computing the blowdown transient. The code utilizes the control volume (element) approach with the capability for modeling a large variety of thermal fluid system configurations. The fluid properties are considered uniform and thermodynamic equilibrium is assumed in each element. A point kinetic model is used with weighted feedback effects. The major feedback effects include moderator density, moderator temperature and Doppler broadening. A critical flow calculation for subcooled (modified Zaloudek), two-phase (Moody) or superheated break flow is incorporated into the analysis. The methodology for the use of this model is described in Reference 2.

5.4.1.3.5.2 *Reflood Mass and Energy Release Data*

The WREFLOOD code used for computing the reflood transient is a modified version of that used in the 1981 ECCS evaluation model (Reference 3).

The WREFLOOD code consists of two basic hydraulic models—one for the contents of the reactor vessel, and one for the coolant loops. The two models are coupled through the interchange of the boundary conditions applied at the vessel outlet nozzles and at the top of the downcomer. Additional transient phenomena, such as pumped safety injection and accumulators, reactor coolant pump performance and steam generator release, are included as auxiliary equations which interact with the basic models as required. The WREFLOOD code permits the capability to calculate variations during the core reflooding transient of basic parameters, such as core flooding rate, core and downcomer water levels, fluid thermodynamic conditions (pressure, enthalpy, density) throughout the primary system, and mass flow rates through the primary system. The code permits hydraulic modeling of the two flow paths available for discharging steam and entrained water from the core to the break, i.e., the path through the broken loop and the path through the unbroken loops.

A complete thermal equilibrium mixing condition for the steam and emergency core cooling injection water during the reflood phase has been assumed for each loop receiving ECCS water. This is consistent with the usage and application of the Reference 2 mass and energy release evaluation model in recent analyses, e.g., D. C. Cook Docket (Reference 4). Even though the Reference 2 model credits steam/mixing only in the intact loop and not in the broken loop, justification, applicability and NRC approval for using the mixing model in the broken loop has been documented (Reference 4). This assumption is justified and supported by test data, and is summarized as follows:

The model assumed a complete mixing condition (i.e., thermal equilibrium) for the steam/water interaction. The complete mixing process, however, is made up of two distinct physical processes. The first is a two phase interaction with condensation of steam by cold ECCS water. The second is a single phase mixing of condensate and ECCS water. Since the steam release is the most important influence to the containment pressure transient, the steam condensation part of the mixing process is the only part that need be considered. (Any spillage directly heats only the sump.)

The most applicable steam/water mixing test data has been reviewed for validation of the containment integrity reflood steam/water mixing model. This data is that generated in 1/3 scale tests (Reference 5), which are the largest scale data available and thus most clearly simulates the flow regimes and gravitational effects that would occur in a PWR. These tests were designed specifically to study the steam/water interaction for PWR reflood conditions.

From the entire series of 1/3 scale tests, a group corresponds almost directly to containment integrity reflood conditions. The injection flowrates for this group cover all phases and mixing conditions calculated during the reflood transient. The data from these tests were reviewed and discussed in detail in Reference 2. For all of these tests, the data clearly indicate the occurrence of very effective mixing with rapid steam condensation. The mixing model used in the containment integrity reflood calculation is therefore wholly supported by the 1/3 scale steam/water mixing data.

Additionally, the following justification is noted. The post-blowdown limiting break for the containment integrity peak pressure analysis is the double-ended pump suction guillotine. For this break, there are two flowpaths available in the RCS by which mass and energy may be released to containment. One is through the outlet of the steam generator, the other via reverse flow through the reactor coolant pump. Steam which is not condensed by ECCS injection in the intact RCS loops passes around the downcomer and through the broken loop cold leg and pump in venting to containment. This steam also encounters ECCS injection water as it passes through the broken loop cold leg, complete mixing occurs and a portion of it is condensed. It is this portion of steam which is condensed that is taken credit for in this analysis. This assumption is justified based upon the postulated break location, and the actual physical presence of the ECCS injection nozzle. A description of the test and test results is contained in References 2 and 5.

The methodology previously discussed in Reference 2 has been utilized and approved on the Dockets for numerous dry containment plants such as Beaver Valley Unit 2, Millstone Unit 3 and Indian Point Unit 2.

The blowdown and reflood mass and energy release data (including the transients of principal parameters during reflood) are provided in Section 5.4.2 as composite tables of data used in the containment response analysis. Section 5.4.2 describes the usage of these data in the GOTHIC code.

5.4.1.3.5.3 *Post-Reflood Mass and Energy Release Data*

The GOTHIC code (Reference 8) is used for computing the post-reflood transient. GOTHIC calculates the transfer of decay heat and the stored energy in the primary and secondary systems to the containment. The mass and energy releases that occur during this phase are typically superheated due to the depressurization and equilibration of the broken loop and intact loop steam generators. During this phase of the transient, the RCS has equilibrated with the containment pressure, but the steam generators contain a secondary inventory at an enthalpy that is much higher than the primary side. Therefore, there is a significant amount of reverse heat transfer that occurs. Steam is produced in the core due to core decay heat. For a pump suction break, a two phase fluid exits the core, flows through the hot legs and becomes superheated as it passes through the steam generator. Once the broken loop cools, the break flow becomes two phase.

The mass and energy release rates calculated by GOTHIC are processed as described in Section 5.4.2.1 for use in the containment response analysis.

5.4.1.3.5.4 *Decay Heat Model*

As part of the Surry Core Uprating effort a detailed DEHLG mass and energy release analysis (Section 5.4.1.4) was completed for use in the evaluation of recirculation spray pump available NPSH. The 1975 mass and energy release evaluation model (Reference 6) was used for this calculation. The decay heat standard available and incorporated into the Reference 6 evaluation model was adopted by the ANS Standards Subcommittee in October 1971.

The NRC staff Safety Evaluation Report (SER) for the March 1979 evaluation model approved use of the November 1979 ANS Standard-5.1 decay heat model for the calculation of mass and energy releases to the containment following a loss-of-coolant accident. Therefore, to more realistically model the RCS, the Reference 7 decay heat model was utilized for this core uprating effort in conjunction with the 1975 evaluation model. The Reference 7 decay heat model is utilized in the GOTHIC containment analysis. This standard was used in the mass and energy release model with the following input specific for the Surry Power Station Unit 1 and 2. The primary assumptions which make this calculation specific for the Surry Power Station are the enrichment factor, minimum/maximum number of the new fuel assemblies per cycle and fuel cycle length. A conservative lower bound for enrichment of 3% was used. Table 5.4-2 lists the decay heat values used in this analysis.

Significant assumptions in the generation of the decay heat values:

1. Decay heat sources considered are fission product decay and heavy element decay of U-239 and Np-239.

2. Decay heat power from fissioning isotopes other than U-235 is assumed to be identical to that of U-235.

3. Fission rate is constant over the operating history of maximum power level.

4. The factor accounting for neutron capture in fission products has been taken from Equation 11 of Reference 7 up to 10,000 seconds, and Table 10 of Reference 7 beyond 10,000 seconds.

5. The fuel has been assumed to be at full power for 10^8 seconds.
6. The number of atoms of U-239 produced per second has been assumed to be equal to 70% of the fission rate.
7. The total recoverable energy associated with one fission has been assumed to be 200 MeV/fission.
8. Two sigma uncertainty (two times the standard deviation) has been applied to the fission product decay.
9. End of cycle core average burnup that is less than or equal to 40,000 MWD/MTU.
10. Core fresh fuel loading that is greater than or equal to 72.5 MTU.
11. Core average fuel enrichment that is greater than or equal to 3.0%.

5.4.1.3.6 Sources of Mass and Energy

The sources of mass considered in the LOCA mass and energy release analysis are the reactor coolant system, accumulators and pumped safety injection.

The energy inventories considered in the LOCA mass and energy release analysis include:

1. Reactor Coolant System Water
2. Accumulator Water
3. Pumped Injection Water
4. Decay Heat
5. Core Stored Energy
6. Primary Metal
7. Steam Generator Metal (includes transition cone, shell, wrapper, and other internals)
8. Steam Generator Secondary Energy (includes fluid mass and steam mass)
9. Secondary Transfer of Energy (feedwater into and steam out of the steam generator secondary)
10. SG tubes

In the mass and energy release data presented, no Zirc-water reaction heat was considered because the clad temperature did not rise high enough for the rate of the Zirc-water reaction heat to be of any significance.

The consideration of the various energy sources in the mass and energy release analysis provides assurance that all available sources of energy have been included in this analysis. Thus the review guidelines presented in Standard Review Plan Section 6.2.1.3 have been satisfied.

5.4.1.4 Mass and Energy Releases for Available NPSH Analysis (Hot Leg Double Ended Rupture, Post-Blowdown)

In support of the evaluation of recirculation spray pump and low head safety injection pump available NPSH, a LOCA long term mass and energy release analysis was completed. Mass and energy releases for use in the DEHLG evaluation, Maximum Safety injection - two train case are provided in Table 5.4-6. The DEHLG data is presented for two break paths. Break path 1 represents the mass and energy exiting from the reactor vessel side of the break. Break path 2 is the mass and energy exiting from the SG side of the break.

The large break LOCA mass and energy releases were generated using the evaluation models described in References 2 and 6. The blowdown phase mass and energy releases were calculated using the Reference 2 evaluation model, as described in Section 5.4.1.3.5.1 and provided in Table 5.4-6. The large break LOCA mass and energy releases for the reflood phase was generated using the 1975 mass and energy release evaluation model (Reference 6). Table 5.4-6 provides the hot leg mass and energy instantaneous releases, plus reflood mass and energy data for the reflood phase. The Reference 6 mass and energy release evaluation model was utilized because of its capability to calculate reflood phase transient mass and energy release data. The focus of the Reference 2 evaluation model is for the pressure and temperature response of containment. As noted in Section 5.4.1.3.3, generic studies confirm that for the hot leg break, there is no reflood peak, therefore the reflood code applicability of the Reference 2 model was not pursued. The Reference 6 evaluation model still remains a valid analytical tool that has been reviewed and approved by the NRC, although it does not exhibit the benefits of the improved model, i.e., steam water mixing model during reflood. Please note the reflood phase modeling of the Reference 6 evaluation model has been enhanced to incorporate the 1979 decay model as described in Section 5.4.1.3.5.4 for this Surry core uprating program. The DEHLG mass and energy releases in Table 5.4-6 are based on the initial conditions consistent with the design basis analysis of Section 5.4.1.3.

The analysis performed to calculate long term mass and energy releases following a postulated DEHLG is similar to the analysis described in Section 5.4.1.3. The transient is divided into four phases: blowdown, refill, reflood and post-reflood. The characteristics of the phases are also similar except for the hot leg break, where the amount of energy released from the SG is minimal because the majority of the fluid which exits the core bypasses the SG venting directly to containment.

The analysis as noted above utilized both the Reference 2 and 6 mass and energy release evaluation models. The computer models used were comprised of mass and energy release versions of the following codes: SATAN VI model (Reference 2) for blowdown, WREFLOOD model (Reference 6) for reflood phase, and GOTHIC (Reference 8) for the post-reflood phase. These codes were used to calculate the long term LOCA mass and energy releases for the hot leg break. The blowdown releases are calculated with the same version of the SATAN code described in Section 5.4.1.3.2.

The WREFLOOD code addresses the portion of the LOCA transient where the core reflooding phase occurs after the primary coolant system has depressurized (blowdown) due to the loss of water through the break and when water supplied by the Emergency Core Cooling System refills the reactor vessel and provides cooling to the core. The WREFLOOD version of the Reference 6 model does not include the enhanced steam/water mixing model of Reference 2.

5.4.2 LOCA Containment Pressure and Temperature Response

The containment pressure and temperature response is analyzed for the primary system breaks which are discussed in Section 5.4.1. Various single failures of the engineered safety features are analyzed to identify the limiting single failures.

There is one pressure peak following a Reactor Coolant System (RCS) hot leg or cold leg rupture. This pressure peak occurs near the end of the initial blowdown of the RCS after a double ended guillotine (DEG) of either a hot or cold leg. This will be referred to as the blowdown peak pressure. Its magnitude is a function of the following parameters:

1. The containment free volume.
2. The mass of air inside the containment structure (a function of initial pressure and temperature).
3. The amount of energy flow out of the break during the initial blowdown of the RCS.
4. The rate of heat removal from the containment atmosphere by the passive heat sinks within the containment structure.

A DEHLG produces the largest blowdown peak pressure. This event releases the most energy to the containment atmosphere during the initial blowdown since the hot leg pipe size is larger than that of a RCS pump discharge and there is no resistance to flow due to a RCS pump as is the case with a DEPSG. The magnitude of the blowdown peak pressure is independent of the active engineered safety feature (ESF) because ESF does not become effective until after the peak pressure occurs. However, the accumulators do have a small effect on the blowdown peak pressure.

Following the core reflooding period, the containment depressurization systems and containment passive heat sinks remove energy from the containment atmosphere at a rate sufficient to reduce the pressure to below atmospheric pressure in less than 60 minutes. The depressurization time is a function of the following parameters:

1. The containment free volume.
2. The mass of air inside the containment structure.
3. The rate of heat transfer between the containment atmosphere and the passive heat sinks within the containment structure.

4. The rate of heat removal from the containment atmosphere by the containment heat removal systems (this is significantly dependent on the ultimate heat sink temperature).
5. The rate of mass and energy release to the containment from the break following the end of core reflooding.
6. The mass of nitrogen added to the containment from the SI accumulators.

After the containment is depressurized, the depressurization systems continue to remove energy from the containment at a rate sufficient to maintain the containment at subatmospheric pressure. The heated passive heat sinks add energy back to the containment atmosphere following depressurization. The containment experiences a pressure peak less than 1.0 psig after the termination of containment spray associated with emptying the RWST.

5.4.2.1 **Containment Response Analytical Model**

The GOTHIC computer program which is used to model the containment system, the passive heat sinks, and the containment heat removal systems, was developed for the Electric Power Research Institute (EPRI) by Numerical Applications, Inc. A topical report (DOM-NAF-3) described in detail the assumptions used and the mathematical formulations employed. The use of GOTHIC for containment analysis has been approved by the NRC as documented in DOM-NAF-3-0.0-P-A (Reference 8).

GOTHIC solves the conservation equations for mass, momentum, and energy for multi-component, multi-phase flow in lumped parameter and/or multi-dimensional geometries. The phase balance equations are coupled by mechanistic models for interface mass, energy and momentum transfer that cover the entire flow regime from bubbly flow to film/drop flow, as well as single phase flows. The interface models allow for the possibility of thermal non-equilibrium between phases and unequal phase velocities, including countercurrent flow. GOTHIC includes full treatment of the momentum transport terms in multidimensional models, with optional models for turbulent shear and turbulent mass and energy diffusion. Other phenomena include models for commonly available safety equipment, heat transfer to structures, hydrogen burn and isotope transport.

5.4.2.1.1 Passive Heat Sinks

Thermal conductors are the primary heat sink for the blowdown energy. The conductors can be made up of any number of layers of different materials. One-dimensional conduction solutions are used to be consistent with the lumped modeling approach.

The thermal conductor is divided into regions, one for each material layer, with an appropriate thickness and material property for each region. GOTHIC accepts inputs for material density, thermal conductivity and specific heat. These values are obtained from published literature for the materials present in each conductor. Conductors with high heat flux at the surface and low thermal conductivity must have closely spaced nodes near the surface to adequately track the steep temperature profile. The node spacing is set so the node Biot number for each node is less than 0.1. The Biot number is the ratio of external to internal conductance.

It is not practical or necessary to model each individual piece of equipment or structure in the containment with a separate conductor. Smaller conductors of similar material composition can be combined into a single effective conductor. In this combination, the total mass and the total exposed surface area of the conductors is preserved. The thickness controls the response time for the conductors and is of secondary importance. The conductors are grouped by thickness and material type. The effective thickness for a group of wall conductors is calculated by the equation below. The heat sink material types, surface areas, and thickness are derived based on plant-specific inventories. Concrete, carbon steel, and stainless steel are the most common materials.

$$t_{eff} = \frac{\sum_{i \in group} t_i A_i}{\sum_{i \in group} A_i}$$

If there is a small air gap or a contact resistance between the containment liner and the concrete, it is modeled as a separate material layer at the nominal gap thickness with applicable material properties. This overestimates the contact resistance because convection and radiation effects will be ignored. A maximum gap conductance of 40 Btu/hr-ft^2-F is used. The gap width is determined by dividing the gap thermal conductivity by the gap conductance.

All containment passive heat sinks are included in the lumped containment volume. The primary system metal and SG secondary shells are included in the simplified RCS model that is used for the calculation of long-term mass and energy release; however, these conductors are not used for condensation or convection heat transfer with the containment atmosphere.

5.4.2.1.2 Conductor Surface Heat Transfer

The Direct heat transfer option with the DLM (Diffusion Layer Model) condensation option is used for all containment passive heat sinks except the sump floor. With the Direct option, all condensate goes directly to the liquid pool at the bottom of the volume. The effects of the condensate film on the heat and mass transfer are incorporated in the formulation of the DLM option. Under the DLM option, the condensation rate is calculated using a heat and mass transfer analogy to account for the presence of non-condensing gases.

For a conductor representing the containment floor or sump walls that will eventually be covered with water from the break and condensate, the Split heat transfer option is used to switch the heat transfer from the vapor phase to the liquid phase as the liquid level in the containment builds. A quicker transition to liquid heat transfer is more conservative for containment analysis. The Split option is used with $\alpha_{1_{max}}$, the maximum liquid fraction, set to

$$\alpha_{1_{max}} = \frac{d}{H}$$

where d is the transition water depth and H is the volume height. A reasonable value for d of 0.1 inch switches the heat transfer from the vapor phase to the liquid phase as the liquid level in the containment reaches 0.1 inch. Other values may be appropriate depending on the geometry of the floor and sump.

For conductors with both sides exposed to the containment, the Direct option is applied to both sides. Alternatively, if the conductor is symmetric about the centerplane, a half-thickness conductor can be used with the total surface area of the two sides and an insulated back side heat transfer option. The conductor face that is not exposed to the atmosphere is assumed insulated. The Specified Heat Flux option is used with the nominal heat flux set to zero.

Containment walls above grade and the containment dome have a specified external temperature boundary condition with a heat transfer coefficient of 2.0 Btu/hr-ft^2-F to model convective heat transfer to the outside atmosphere. The GOTHIC heat transfer solution scheme allows for accurate initialization of the temperature distribution in the containment wall and dome prior to the transient initiation.

A conservative containment liner response is obtained by adding a small conductor that has the same construction and properties as the liner conductor. A conductor surface area of 1 ft^2 is used to minimize impact on the lumped containment pressure and temperature response. The inside heat transfer option is the same as used for the actual liner conductor (Direct with DLM) with a multiplier of 1.2 for conservatism.

5.4.2.1.3 Spray Modeling

GOTHIC includes models that calculate the sensible heat transfer between the drops and the vapor and the evaporation or condensation at the drop surface. The efficiency—the actual temperature rise over the difference between the vapor temperature and the drop inlet temperature—cannot be directly specified in GOTHIC. The efficiency is primarily a function of the drop diameter. The GOTHIC models account for the effect of the diameter through the Reynolds number dependent fall velocity and heat transfer coefficients. A heat and mass transfer analogy is used to calculate the effective mass transfer coefficient, which is used to calculate the evaporation or condensation. Containment spray is modeled as described in DOM-NAF-3-0.0-P-A.

5.4.2.1.4 Containment Heat Removal

Heat exchangers that remove energy from the containment sump are modeled with the available heat exchanger options in GOTHIC. Use of a GOTHIC heat exchanger option dynamically couples the heat exchanger performance to the predicted primary and secondary fluid conditions. This can provide a small benefit compared to other codes (e.g., LOCTIC) that use bounding UA values to cover the fluid conditions predicted over the entire transient.

The GOTHIC heat exchanger type that closely matches the actual heat exchanger is selected. The inside and outside heat transfer areas are calculated from the heat exchanger geometry details. For tube and shell arrangements, the shell side flow area is set to the open area across the tubes at the mid-plane of the heat exchanger and the shell side hydraulic diameter is set to the tube outer diameter. The GOTHIC option for built-in heat transfer coefficients is used to determine heat transfer coefficients that depend on the primary and secondary side Reynolds and Prandtl numbers. The heat exchanger models in GOTHIC are for basic heat exchanger designs and may not account for the details of a particular heat exchanger (e.g., baffling in a tube-and-shell heat exchanger). A forcing function can be used on the primary and secondary side heat transfer coefficients to tune the heat exchanger performance to manufacturer or measured specifications. Alternatively, the heat transfer area can be adjusted to match the specified performance. Fouling factors and tube plugging are applied when conservative.

5.4.2.1.5 LOCA Mass and Energy Release to Containment

During a LOCA event, most of the vessel water will be displaced by the steam generated by flashing. The vessel is then refilled by the accumulators and the high and low pressure injection systems. GOTHIC is not suitable for modeling the refill period because it involves quenching of the fuel rods where film boiling conditions may exist. Current versions of GOTHIC do not have models for quenching and film boiling. Therefore, for the blowdown, refill and reflood stages, the mass and energy release rates are obtained from Westinghouse LOCA analysis. The Westinghouse release data includes the water from the ECCS accumulators, but the nitrogen release to containment is modeled separately in GOTHIC.

The LOCA mass and energy release rates are input to GOTHIC for the blowdown and reflood periods of the design basis LOCAs. The calculation of these release rates is described in Section 5.4.1. The mass and energy release rates used in the containment peak pressure, containment depressurization, and NPSH analyses for the RS and LSHI pumps are provided in this section. The mass and energy release rates for the DEHLG through the end of reflood are tabulated in Table 5.4-6 for maximum two-train safety injection flow. The mass and energy release rates for the reactor coolant DEPSG through the end of reflood are provided in Table 5.4-7 for maximum single-train safety injection flow.

At the end of reflood, the core has been recovered with water and the ECCS continues to supply water to the vessel. Residual stored energy and decay heat comes from the fuel rods. Stored energy in the vessel and primary system metal will also be gradually released to the injection water and released to the containment via steaming through the core or spillage into the containment sump. In addition, there may be some buoyancy-driven circulation through the intact steam generator loops that will remove stored energy from the steam generator metal and the water on the secondary side. Depending on the location of the break, the two-phase mixture in the vessel may pass through the steam generator on the broken loop and acquire heat from the stored energy in the secondary system. For these conditions, GOTHIC is capable of calculating the mass and energy release from the break into containment.

The GOTHIC long-term mass and energy release accounts for the transfer of the decay heat and the stored energy in the primary and secondary systems to the containment after the end of reflood. The energy for each source term is acquired at the end of reflood from the Westinghouse mass and energy release analysis. The rate of energy release is determined by a simplified GOTHIC RCS model that is coupled to the containment volume. Thus, the flow from the vessel to the containment is dependent on the GOTHIC-calculated containment pressure.

Lumped volumes are used for the vessel, downcomer, cold legs, steam generator secondary side, up-flow steam generator tubes and down-flow steam generator tubes. Separate sets of loop and secondary system volumes are used for the intact and broken loops with the connections between the broken loop and containment as necessary for the modeled break location. The Westinghouse calculated mass and energy inventory at the end of reflood establishes the liquid volume fractions and the fluid temperatures in the primary and secondary systems.

The primary and secondary system geometries, including primary system resistances, are consistent with the models used for non-LOCA accident analyses. In order to predict the natural circulation through the intact loops and the correct water level in the vessel and downcomer, the volumes are modeled with the correct elevations and heights. The vessel height may be adjusted so that the water and steam inventory at the end of reflood matches the vendor's boundary conditions, but this correction does not affect the hydraulic analysis.

Safety injection fluid is added to the downcomer volume (for the intact cold legs) and the broken loop cold leg. In both locations, the SI fluid mixes with the resident fluid and any vapor from the intact SGs. The SI flow is taken from the RWST until a low-low level is reached, at which time the SI fluid is taken from the containment sump.

A thermal conductor is used to model the transfer of energy stored in the shell side of the steam generator to the SG secondary fluid. The initial temperature is set to match the available stored energy specified at the end of reflood by the fuel vendor analysis. The up flow and down flow tubes on the steam generators are modeled separately with thermal conductors. This allows for the possibility of boiling in the up flow tubes and superheating of the steam in the down flow tubes. The heat transfer from the secondary side to the primary side is modeled using conductors with the inside connected to the primary system tube volumes. The Film heat transfer option is used on both sides of the tube. This option automatically accounts for heat transfer to the liquid or vapor phase as appropriate and includes boiling heat transfer modes.

5.4.2.1.6 NPSH Available

NPSHa (net positive suction head available) is the difference between the fluid stagnation pressure and the saturation pressure at the pump intake. To calculate NPSHa for a given pump, the GOTHIC containment model includes a separate small volume for the pump suction. The volume elevation and height are set so that the mid-elevation of the volume is at the elevation of the pump first-stage impeller centerline. The volume pressure (with some adjustments for sump depth) can then be used in the NPSHa calculation. The temperature in the suction volume provides the saturation pressure. The junction representing piping between the sump and the suction volume reflects the friction and form pressure drop between the sump and the pump suction. The pump suction volume also allows accurate modeling of the mixing of cold water that is injected into the suction of the RS pumps.

The single volume GOTHIC model does not account for geometry details of the sump or the liquid that is held up in other parts of the containment. GOTHIC does calculate the total amount of liquid in the containment. A correlation is used to define the sump depth or liquid level as a function of the water volume in the containment. The correlation accounts for the sump geometry variation with water depth and accounts for the holdup of water in other parts of the containment.

Worst case conditions for NPSHa depend on the time that the pumps take suction from the sump. Therefore, the parameter settings that minimize NPSHa may vary depending on the timing for the operation of the pumps. In general, settings that reduce containment pressure and increase the sump water temperature reduce the NPSHa.

The water in the sump comes from three sources: direct deposit of mass from the break, condensate from the conductors, and spray drops. The drops from the blowdown will be very small and at the saturation temperature at the containment steam partial pressure when they enter the sump. After the blowdown, the spillage water from the vessel is directly put in the sump with no heat transfer to the atmosphere or walls and equipment in the containment. This is a conservative approach for NPSH analysis. The condensate is generated at the saturation temperature at the steam partial pressure and added directly to the sump. The heat transfer between the conductors and the condensate on the way to the sump is conservatively neglected. Heat and mass transfer at the sump surface is allowed. GOTHIC's model for heat and mass transfer at a pool is in good agreement with experimental data. For NPSH analysis, the liquid temperature is greater than the vapor temperature for most of the event, so a minimum pool area is specified to minimize evaporation. With this overall approach, the predicted sump temperature is conservatively high for the duration of the simulation.

The following adjustments are made to ensure a conservative calculation of NPSHa:

1. The heat and mass transfer to the containment heat sinks are expected to be under-predicted using the Direct heat transfer model. This is non-conservative for NPSH analysis. A multiplier of 1.2 applied to the heat transfer coefficient was shown to provide adequate conservatism in the calculation.

2. All of the spray water is injected as droplets into the containment atmosphere (nozzle spray flow fraction of 1). Analyses are performed using the largest Sauter droplet size. A confirmatory analysis is performed by reducing the Sauter diameter by 2, which sufficiently covers code and spray performance uncertainty (i.e., variation in nozzle design and orientation, nozzle flow rate and different header elevations) without creating drops too small that may cause excess droplet holdup in the atmosphere. NPSH analyses are relatively insensitive over this range of droplet size, and the two cases together confirm that the effect of sprays on reducing containment pressure is maximized. The minimum NPSHa is reported from the case that provides the smaller NPSHa.

3. A conservative water holdup volume is subtracted from the containment liquid volume to reduce the sump water height.

4. The upper limit on containment free volume is used.

5. The minimum containment air pressure is used.

6. Conservative assumptions for spray and other system parameters are used in accordance with plant-specific sensitivity studies.

A modification of the NPSH methodology used for developing component design inputs was submitted to the NRC in Reference 10. This alternate methodology can be used for NPSH and LOCA analyses that develop design inputs for component design, such as determination of margin for sump strainer design. The NRC approved the alternate methodology in Reference 11, thus confirming that it can be used for the intended application stated in Reference 10.

5.4.2.1.7 LOCA - Containment Pressure and Temperature Results

The containment LOCA analysis is performed for the two limiting pipe break locations (DEPSG and DEHLG) discussed in Section 5.4.1. The DEPSG is most limiting for long-term containment temperature and pressure response. Table 5.4-7 provides the DEPSG mass and energy instantaneous releases as well as the releases for the reflood phase. The DEPSG data is presented for two break paths. Break path 1 represents the mass and energy exiting from the SG side of the break. Break path 2 is the mass and energy exiting from the pump side of the break.

Containment analysis parameters are listed in Table 5.4-17. The RS pumps start with individual delay times on 60% RWST level coincident with a CLS High High containment pressure signal.

The results of the containment pressure analysis are tabulated in Table 5.4-11. The initial containment conditions which yield the highest peak calculated containment pressure are the maximum pressure, temperature, and relative humidity, and are given in Table 5.4-10. The containment pressure and temperature transients for the hot leg double-ended guillotine are given on Figures 5.4-1 and 5.4-2, respectively.

The maximum peak containment pressure occurs after a DEHLG. As shown in Table 5.4-11, the calculated containment pressure is below the containment design pressure of 45 psig. The DEHLG is the design basis accident (DBA) for the containment structure (containment integrity DBA).

A single failure analysis is not necessary for the peak containment pressure evaluation since the peak pressure for each break case analyzed occurs early in the transient before any of the engineered safety feature (ESF) systems start.

The results of the containment depressurization analysis are tabulated in Table 5.4-12. Only a DEPSG is considered for the containment depressurization analysis since, as described earlier, this break produces the highest energy flow rates during the post-blowdown period. The containment pressure is less than 1.0 psig within one hour and less than 0 psig within 4 hours as shown in Table 5.4-12. The SI flow is based on a minimum estimate. This minimizes the credit for steam condensation due to steam/water mixing.

The initial conditions which result in the maximum depressurization time are as follows:

1. Initial containment pressure of 12.52 psia.
2. Initial containment temperature of 125°F.
3. Initial containment relative humidity of 100%.
4. Service water (ultimate heat sink) temperature of 100°F.
5. Refueling water storage tank temperature of 45°F.

The initial conditions which result in the maximum time to approach the four hour subatmospheric requirement are as follows:

1. Initial containment pressure of 10.97 psia
2. Initial containment temperature of 75°F
3. Initial containment humidity of 100%
4. Service water (ultimate heat sink) temperature of 100°F
5. Refueling water storage tank temperature of 45°F

These limiting values are consistent with the Technical Specifications. Instrumentation uncertainties for these parameters have been included in the safety analysis.

The highest depressurization peak pressure may result from service water temperatures less than the TS maximum.

A chronology of events for this DEPSG with minimum ESF for both sets of initial conditions described in this section is given in Table 5.4-13.

Representative results for containment pressure, vapor temperature, sump water temperature and RS heat exchanger duty are shown in Figures 5.4-3, 5.4-4 (illustrates containment vapor and liquid temperature) and 5.4-5, respectively. These results are based on the initial conditions which result in the maximum time to approach the four hour subatmospheric requirement as described above.

For the depressurization analysis, only the diesel generator failure is considered since all other single failures result in increased containment heat removal capability as compared to this single failure.

The results of the LOCA analysis are reported in Tables 5.4-11 and 5.4-12.

5.4.3 MSLB Containment Pressure and Temperature Response

Surry did not previously have an explicit MSLB containment response analysis. The containment response was bounded by the Beaver Valley Unit 1 MSLB analysis. Reference 9 made the comparison and described the conservatism in the Beaver Valley Unit 1 MSLB containment pressurization analysis versus Surry. MSLB analysis has been performed for Surry using GOTHIC. The GOTHIC model is as described in Section 5.4 for LOCA analysis with the exception of the mass and energy release data. GOTHIC analysis inputs are provided in Table 5.4-17.

5.4.3.1 **MSLB Mass and Energy Release to Containment**

For MSLB, the mass and energy release data is obtained from Westinghouse using NRC-approved methods. Surry does not have explicit mass and energy release data from Westinghouse. The North Anna MSLB mass and energy release data from Westinghouse was confirmed to be conservative for Surry and was applied for this analysis. The break junction uses 100-micron droplets for entrained liquid release. A range of break sizes from small split breaks to the largest double-ended break size is analyzed over the range of 0% to 114.3% of rated thermal power of 2587 MWt. Analysis of this range ensures that the most conservative results are predicted for containment pressure and temperature.

5.4.3.2 **MSLB Pressure and Temperature Analysis**

5.4.3.2.1 MSLB Peak Pressure Analysis

The maximum containment peak pressure occurs for the 1.4 ft^2 break at 0% power because it has the highest SG liquid mass and results in the largest mass release to the containment before the faulted SG dries out. Table 5.4-14 shows the results in peak pressure are less than the design limit of 59.7 psia. Table 5.4-15 shows the time sequence of events for the case with the proposed

TS air partial pressure limit of 11.3 psia. The atmosphere remains superheated for a very short time, returning to saturation within 10 seconds from the time of the break. The containment temperature and pressure peaks occur about 20 seconds before SG dryout, when condensation and the CS system overcome the steam release rate. Containment pressure drops rapidly once operator action terminates AFW to the faulted SG at 30 minutes, which stops the steam release to the containment.

SPS has cavitating venturis in the AFW lines leading to each SG that limit the flow rate to about 350 gpm. For the MSLB analyses, the mass release is 400 gpm after the faulted SG reaches dryout. This assumption provides a conservative, but reasonable long-term containment pressure and temperature response for SPS but does not affect the containment peak pressure and temperature, which occur earlier in the event.

The maximum initial air partial pressure is independent of SW temperature, because the RS system is not assumed to operate. Therefore, the maximum allowable TS air partial pressure is a constant line until the containment depressurization analyses limit the curve. In summary, a maximum operating containment air partial pressure of 11.3 psia ensures that the MSLB peak containment pressure will be less than the design limit of 59.7 psia.

5.4.3.2.2 MSLB Peak Temperature Analysis

The maximum peak temperature occurs for the 0.6 ft^2 break at 114.3% of 2587 MWt core power. This break has a saturated steam release at an enthalpy of about 1200 Btu/lbm for the entire accident. Minimum air partial pressure, maximum containment air temperature, and 0% humidity are conservative. Table 5.4-16 compares the analysis results. The increase in air pressure causes an increase in containment peak pressure but reduces the containment peak temperature. Figures 5.4-8 and 5.4-9 show the containment pressure and vapor temperature. The containment temperature peaks at 31 seconds when the break flow is reduced suddenly by the isolation of the non-faulted SGs from the steam line header. The vapor temperature decrease starting at 101 seconds is driven by the delivery of containment spray to the atmosphere. Containment pressure drops rapidly once operator action terminates AFW to the faulted SG at 30 minutes, which stops the steam release to the containment.

The analyses included an additional 1 ft^2 thermal conductor to determine a conservative containment liner temperature response in accordance with Section 3.3.3 of DOM-NAF-3A. The conductor used a 1.2 multiplier on the Direct/DLM heat transfer coefficient. The peak liner temperature for the proposed configuration was 251.1°F at 490 seconds, so the sustained superheat does not adversely affect the containment liner.

Table 5.4-1
LOCA MASS & ENERGY RELEASE ANALYSIS SYSTEM PARAMETERS
INITIAL CONDITIONS

Parameters	Value
Core Thermal Power (100.38% of 2587 MWt)	2597 MWt
Reactor Coolant System Flowrate, per Loop	88,500 gpm
Vessel Outlet Temperature	605.6°F[a]
Core Inlet Temperature	540.4°F[a]
Vessel Average Temperature	573.0°F[a]
Initial Steam Generator Steam Pressure	785 psia
Steam Generator Design	Model 51F
Steam Generator Tube Plugging	0%
Total SG Dry Weight	691,000 lbm
SG Weight in Contact with Secondary Water	474,000 lbm
Initial SG Secondary-Side fluid	113,740 lbm
Assumed Maximum Containment Backpressure	59.7 psia
Accumulator	
Water Volume	1000 ft^3
N2 Cover Gas Pressure	600 psia
Temperature	105°F
Safety Injection Delay (includes time to reach pressure setpoint)	27.0 sec

a. These are nominal values; analysis value includes +4.0°F allowance for instrument error and deadband

16	Carbon Steel Group 2	66,345	0.439 [a]
17	Carbon Steel Group 3	7454	0.906 [a]
18	Carbon Steel Group 4 [c]	2414	1.70 [a]
19	Carbon Steel Group 5	7000	2.90 [a]
29	Accumulators [c]	1276	1.0

a. Includes 0.006-inch paint layer.
b. The containment walls and dome include a liner-concrete gap conductance. The wall above grade and the dome use a constant HTC of 2.0 Btu/hr-ft^2-F and a specified temperature of 95°F on the outside.
c. The MSLB model accounts for the water in the accumulators as TC #29, different than the LOCA model (empty shell grouped with other carbon steel). TC #18 surface area of 2414 ft^2 is reduced by the accumulator surface area of 2073 ft^2 to 341 ft^2.

Table 5.4-10
CONTAINMENT LOCA ANALYSIS INITIAL CONDITIONS[a]

Air Partial Pressure	10.1 to 11.3 psia
Temperature	75 to 125°F
Relative Humidity	0 to 100 percent
RWST Temperature	45°F (maximum)
Service Water Temperature	25 to 100°F

a. Instrumentation uncertainties for these parameters have been included in the safety analysis.

Table 5.4-11
CONTAINMENT LOCA ANALYSIS PEAK PRESSURE RESULTS

Break Location	Hot Leg
Break Type	DEG
Peak Pressure	43.95 psig
Time of Peak Pressure	19.48 sec
Peak Vapor Temperature	273.3°F

Table 5.4-12
CONTAINMENT DEPRESSURIZATION RESULTS DEPSG

	Depressurization Time	Depressurization Peak Pressure
Single Failure	ESF Train	ESF Train
Initial Containment Conditions[a]		
Total Pressure	12.52 psia	10.97 psia
Temperature	125.0°F	75.0°F
Relative Humidity	100%	100%
Service Water Temperature	100.0°F	100.0°F
Depressurization Time (< 15.7 psia)	3110 sec	3038 sec
Depressurization Peak Pressure	0.34 psig	0.70 psig[b]
Depressurization Peak Pressure Time	5206 sec	5162 sec
Remains Subatmospheric Time	7732 sec	10,800 sec

a. Instrumentation uncertainties for these parameters have been included in the safety analysis.
b. Highest analysis value obtained for depressurization peak pressure.

Table 5.4-13
ACCIDENT CHRONOLOGY DEPSG, MINIMUM ESF

Time (sec)[a]		
Depressurization	Depressurization Peak	Event
2.1	2.3	CLS High High containment pressure
99.1	99.3	Containment spray delivers to containment
1861	1757	IRS spray delivered to containment
2012	1889	ORS spray delivered to containment
3110	3038	Containment pressure reaches 15.7 psia
3775	3734	Switchover to SI recirculation mode
4343	4304	Containment spray pumps stopped
5206	5162	Depressurization peak pressure occurs
7732	10,800	Containment pressure < 14.7 psia permanently

a. Times are analysis values obtained for initial conditions given in Table 5.4-12. These time values are approximate.

Table 5.4-14
MSLB CONTAINMENT PEAK PRESSURE ANALYSIS

Initial Conditions	
TS Containment Air Partial Pressure, psia	11.3
Initial Containment Pressure, psia [a]	13.52
Initial Air Temperature, F	125.5
Relative Humidity, %	100
Results	
Peak containment pressure, psia	59.48
Time of peak containment pressure, sec	215.7
Peak containment temperature, F	274.4
Time of peak containment temperature, sec	213.7

a. GOTHIC total pressure is TS air pressure + 0.25 psi uncertainty + 1.97 psia vapor pressure.

Table 5.4-15
ACCIDENT CHRONOLOGY MSLB PEAK PRESSURE ANALYSIS

Event	Time (sec)
Accident start	0.0
CLS High High containment pressure	4.2
Start SI	27.9
CS delivered to containment	101.2
Containment peak pressure	215.7
Faulted SG dryout	235.0
AFW terminated	1800
Transient Termination	7200

Table 5.4-16
MSLB CONTAINMENT PEAK TEMPERATURE ANALYSIS

Initial Conditions	
TS Containment Air Partial Pressure, psia	10.1
Initial Containment Pressure, psia [a]	9.85
Initial Air Temperature, F	125.5
Relative Humidity, %	0
Results	
Peak containment temperature, F	318.9
Time of peak containment temperature, sec	31.1
Peak containment pressure, psia	47.4
Time of peak containment pressure, sec	412.1

a. GOTHIC containment pressure = TS air pressure - 0.25 psi uncertainty (no vapor pressure).

Table 5.4-17
KEY PARAMETERS IN THE CONTAINMENT ANALYSIS

Parameter	Value
Maximum Core Power (100.38% × 2587 rated thermal power), MWt	2597
Containment Air Partial Pressure Uncertainty, psi	± 0.25
Containment Temperature, °F (includes 0.5°F uncertainty)	74.5–125.5
Containment Relative Humidity, %	0–100
SW Temperature, °F	24–101
RWST Temperature, °F (includes 1.6°F uncertainty) [a]	32–46.6
Accumulator Pressure, psia (includes uncertainty)	578-706
Accumulator Temperature, °F	75-105
Accumulator Water Volume, ft^3	975–1025
Accumulator Nitrogen Volume, ft^3 (includes uncertainty)	416-484
Minimum Service Water Flow Rate with 10% RSHX tube plugging, gpm	7789 at Accident Start [b]
Maximum Service Water Flow Rate with 0% RSHX tube plugging, gpm	10,000 [b]
ORS Pump Flow Rate, gpm	2900–3300
IRS Pump Flow Rate, gpm	3100–3650
LHSI Injection Mode Flow Rate (Single-Train), gpm	2844–3264
Maximum LHSI Recirculation Mode Flow Rate (Single-Train), gpm	3330
HHSI Injection Mode Flow Rate (Single-Train), gpm	435–528
Minimum CS Bleed Flow Rate to ORS Pump Suction, gpm	See Note c
Minimum IRS Recirculation Flow Rate to Pump Suction, gpm	300
CS Flow Rate, gpm	See Note d
IRS Piping Fill Volumes, ft^3	358–421.3
ORS Piping Fill Volumes, ft^3	456.5–558.1

a. Minimum RWST temperature of 32°F is assumed for evaluation of the inadvertent CS actuation event. Normal operating range for RWST temperature is 40–45°F.
b. SW minimum flow rate decreases as the intake canal level decreases during the accident. The initial value is specified for a canal level of 23 ft. For maximum flow, a constant 10,000 gpm is assumed throughout the accident (ORS pump NPSHa analyses are not very sensitive to this input).
c. For the RS pump NPSH analyses, the CS bleed flow is input as a function of differential pressure between the containment and the RWST (C-L in psid). The flow rate varies from 294 gpm (26.8 psid) to 325.6 gpm (-8.6 psid and maintained constant for more negative differential pressures).
d. The CS flow rate varies as a function of differential pressure between the containment and RWST (C-L in psig). The minimum single-pump flow rate varies from 2006 gpm (26.9 psid) to 2708 gpm (-4.0 psid and maintained constant for more negative differential pressures). The maximum single-pump flow rate varies from 2409 gpm (26.9 psid) to 3024 gpm (-10.0 psid and maintained constant for more negative differential pressures).

Table 5.4-17 (CONTINUED)
KEY PARAMETERS IN THE CONTAINMENT ANALYSIS

Parameter	Value
CS Spray Delivery Delay from CLS signal, sec	59–97
LHSI Pump Suction Friction Loss at maximum 1-pump flow, ft	6.8
ORS Pump Suction Friction Loss at maximum flow, ft	6.8
IRS Pump Suction Friction Loss at maximum flow, ft	2.0
CLS High High Containment Pressure, psia	27
RWST WR Level for RS Pump Start (60% ± 2.5% uncertainty)	57.5%–62.5%
ORS Pump Start Time Delay, seconds (±12 second timer uncertainty and 0 or 10 seconds for ramp to full flow depending on which is conservative)	108–142
RWST WR Level Setpoint for RMT (13.5% ± 2.5% uncertainty)	11.0–16.0%
Time to complete RMT function, minutes	2–3
Minimum RWST volume at accident initiation, gallons	384,000 (95% NR)
Minimum containment free volume, ft^3	1,730,000
Maximum containment free volume for NPSHa Analysis, ft^3	1,819,000

5.5 CONTAINMENT TESTS AND INSPECTIONS

The following information is HISTORICAL and is not intended or expected to be updated for the life of the plant.

5.5.1 Initial Containment Testing

A testing and surveillance program was in effect during construction and continues in effect during operation (See 5.5.3) to confirm that the containment can perform its intended function. The initial program consisted of construction testing, and an initial leakage rate test. Materials and fabrication inspections and tests are described in Section 15.4.

Construction testing included provisions for testing the leaktightness of all penetrations and liner welds during construction and for an air pressure test when the containment was completed to ensure the structural integrity of the containment. Electrical penetrations were assembled and tested as a unit for leaktightness following installation in the containment (Section 15.5).

Leaktightness testing of all liner welds during construction was performed by welding a structural steel gas test channel over each weld seam. For the bottom and the straight shell, the test channels were placed on the inside of the liner. For the dome, the test channels were on the outside (concrete side) of the liner.

These channels formed a space into which pure Freon at 50 psig was injected. The weld seams were then tested for leakage using a halogen leak detector. The test channels did not form a single continuous channel but were segmented for convenience in testing. Test gas was introduced through threaded connections after evacuating the channels to ensure a homogeneous test gas throughout the channel section. If a leak rate of greater than 1.8×10^{-5} cm^3/sec was found, the defective test channel seam or liner weld seam was ground out and the weld remade and retested. After testing, the gas was purged from the channels with air and the threaded connections plugged.

The air pressure test to ensure the structural integrity of the containment was performed after the liner was completed, the last concrete pour cured, and all penetration sleeves installed. The containment pressure was raised to 52 psig (115.5% of the 45 psig design pressure) and held for 1 hour, thus ensuring the structural integrity of the containment.

The initial leakage rate tests were performed at 39.2 psig and 25 psig, after the completion of construction and the installation of all systems penetrating the containment boundary. On Unit 1, an additional leakage rate test was performed at 9 psia. These testes were performed using the reference volume method as described under the leakage-monitoring system (Section 5.3.2).

5.5.2 Continuing Containment Leakage Testing

A testing program is in place to measure primary containment leakage periodically throughout the plant's operating life. The testing program includes performance of Type A tests to measure the overall integrated leakage rate, Type B tests to detect and measure local leakage across pressure-containing or leakage-limiting boundaries other than valves, and Type C tests to measure containment isolation valve leakage rates.

The leakage tests are performed in accordance with the requirements of 10 CFR 50 Appendix J, *Primary Reactor Containment Leakage Testing for Water Cooled Power Reactors.*

5.5.3 Containment Integrated Leakage Rate Test (Type A)

A Type A test program has been developed and is scheduled and conducted in accordance with 10 CFR 50 Appendix J, Option B and NEI 94-01, Revision 3-A, *Industry Guidelines for Implementing Performance-Based Option of 10 CFR 50, Appendix J, Option B*. Each Type A test establishes the measured containment leakage rate, L_{am}, which verifies that the maximum allowable leakage rate, L_a, used in the accident analysis is not exceeded.

Type A tests are conducted at periodic intervals based on historical performance of the overall containment system in accordance with 10 CFR 50, Appendix J, Option B, and NEI 94-01, Revision 3-A. The leakage rate must not exceed the allowable leakage rate (L_a) with margin as specified in the Technical Specifications.

A general inspection of the accessible interior and exterior surfaces of the containment is performed, prior to each Type A test and at periodic intervals between tests based on performance, to detect structural deterioration. Defects are resolved prior to conducting the test.

Test instrumentation includes an absolute manometer, temperature detectors, and dewpoint sensors.

The containment isolation valves are closed by their normal mode of operation. Where possible, lines subjected to containment atmosphere following a LOCA are drained and vented during the Type A test. Systems that are normally filled with water and operating under post-accident conditions are not drained and vented nor are their Type C test results included in the Type A test leakage rate. For those systems that should be vented and drained but are not, the Type C test result is added to the Type A leakage rate.

After completion of the procedural prerequisites, the containment is pressurized to slightly greater than containment design pressure (45 psig) and allowed to stabilize for a minimum of 4 hours. The Type A test period normally commences when the rate of change of the containment air temperature for the latest hour does not deviate by more than 0.5°F/hr from the average rate of change over the last 2 hours. A test computer is normally used for data acquisition and/or leakage rate calculations. The data acquisition package reads the inputs (pressure, temperature, and dewpoint temperature), converts these readings into engineering units, and stores/prints these values to be used for leakage rate calculations. The leakage rate is calculated using the absolute method of mass point analysis. The absolute method of mass point analysis consists of periodically calculating air masses within the containment structure over a period of time from pressure, temperatures, and dew point observations during the test. The air masses are computed using the ideal gas law. The leakage rate is then determined by plotting the air mass as a function of time, using a least-squares fit to determine the slope. The leak rate is expressed as a percentage of containment air mass lost in 24 hours. A 95% confidence level is calculated using a T distribution. The sum of the leakage rate at a 95% confidence level must be less than 0.75 L_a.

A verification test is performed following each Type A test. This test provides a method of assuring that systematic error or bias is given adequate consideration. The verification test consists of a superimposed leakage rate equal to 75% to 125% of L_a, which is measured independently from Type A test instrumentation. This air change and that which is measured by the containment leakage Type A instrumentation must agree within ±25% L_a.

5.5.4 Containment Penetration Leakage Rate Test (Type B)

Type B tests measure local leakage across containment pressure boundaries that are either atypically large and/or whose design incorporates resilient seals, gaskets, or sealant compounds, and piping penetrations fitted with expansion bellows.

Type B tests, except airlocks, are performed at periodic intervals based on the historical performance at each penetration in accordance with 10 CFR 50, Appendix J, Option B, and NEI 94-01, Revision 3-A, *Industry Guidelines for Implementing Performance-Based Option of 10 CFR 50, Appendix J, Option B*. Air locks are tested at the frequency described in Section 5.5.6. Type B tests are performed by either one of two methods.

The first method is to pressurize between the double o-ring seals of the cover used as the containment pressure barrier (i.e. air lock doors, electrical penetration flanges, fuel transfer blank flange). The makeup air method is used to determine the penetration leakage by applying a test pressure equal to or greater than containment design pressure (45 psig) between the o-ring seals.

The second method also uses the makeup air method when performing the full blown air lock test. The space between the inner and outer air lock door is pressurized to a test pressure equal to or greater than containment design pressure (45 psig).

The acceptance criterion for the combined leakage rate of the penetrations and valves subject to Types B and C tests shall be equal to or less than 60% of the maximum allowable leakage rate of the containment.

5.5.5 Containment Isolation Valve Leakage Rate Test (Type C)

There are two methods used in Type C tests. With either method, each valve to be tested is closed by normal operation without any preliminary exercise or adjustment.

In Method 1, the section of piping with the containment isolation valves is isolated from the remainder of the fluid system by using valves or blank flanges as necessary, and the piping is drained. The inside and outside containment isolation valves are tested individually with air at a pressure equal to or greater than containment design pressure. Test air is applied at a test connection on the inboard side (toward the inside of the containment structure) of the valve to be tested, and the leakage air is vented through a test vent on the outboard side of the valve. A flowmeter, connected in line with the pressure source, is used to measure leakage through the containment isolation valve as a function of time. In this procedure, the test airflow is directed across the valve seat from the inside-to-the-outside containment structure direction.

In Method 2, the section of piping with the containment isolation valves is isolated from the remainder of the fluid system, using valves or blank flanges as necessary, and the piping is drained. The inside and outside containment isolation valves are tested simultaneously with air at a pressure equal to or greater than containment design pressure. Test air is applied at a test connection between the two valves, and leakage air is vented through a test vent on the outboard side of the penetration. A flowmeter connected in line with pressure source is used to measure leakage through the containment isolation valves as a function of time. The containment isolation valves are typically diaphragm or symmetric butterfly type valves. The outside containment isolation valves are tested in the outward direction. The inside containment isolation valves are tested in the reverse direction. This test is equally effective for diaphragm and symmetric butterfly valves. Penetrations 90, 91, and 103 are tested using this method.

The acceptance criterion for the combined leakage rate of the penetrations and valves subject to Type B and C tests shall be equal to or less than 60% of the maximum allowable leakage rate of the containment.

Tables 5.2-1 and 5.2-2, for Units 1 and 2 respectively, identify those valves that are required to be tested in accordance with 10 CFR 50 Appendix J, Option B to ensure containment integrity during LOCA conditions. The basis for valves which are: (1) not Type C tested; (2) Type C tested but the leakage penalty is not included in the overall Type B and C total leakage; or (3) Type C tested but the leakage penalty is not included in the overall Type A leakage is provided below:

Main Steam and Feedwater Penetrations	Reason for Type C Testing Exemption
39, 40, 41, 73, 74, 75, 76, 77, 78, 87, 88, 102	These penetrations are directly connected to the steam generator secondary side and, therefore, are considered a closed system (an extension of the primary containment). In addition, the S/G remains at a pressure greater than Pa for at least the first hour and is not considered a credible leakage path from containment. Reference: T.S. Amendment 72/73 dated September 29, 1981

Component Cooling Penetrations	Reason for Type B & C Leakage Exclusion
1, 2, 4, 5, 9, 10, 11, 12, 13, 14, 16, 17, 18, 25, 26, 27, 110	These penetrations are a closed system. Containment penetration check valves and trip valves are leakage tested, but the leakage is not included in the 10 CFR 50 Appendix J Type B and C total leakage. During the associated check valve leakage test, the containment penetration manual isolation valve is leak tested in the reverse direction. The valve is tested with system pressure on the upstream side and the downstream side vented. Reference: T. S. Amendment 72/73 dated September 29, 1981

Safety Injection Penetrations	Type C Tested but Leakage Penalty not Included in Overall Type A Leakage
7, 15, 21, 23, 46, 60, 61, 62, 66, 67, 68, 69, 113	These penetrations are water filled and/or normally operating under accident conditions at a pressure greater than P_a. Therefore, these penetrations are not considered credible leakage paths from containment. Reference: NRC SER dated November 21, 1988.

RCP Seal Water Penetrations	Not Type C Tested
35, 36, 37	Needle valves are throttled open and administratively controlled. These lines remain open after a safety injection signal and contribute to the total injection flow while cooling the RCP seals. The three incoming lines have a check valve inside containment and a local manual valve (throttle valve) outside containment, combined with both a closed system and a continuous water seal at a pressure sufficient to preclude containment atmospheric leakage.

Service Water to RSHX Penetration	Reason for Type B & C Leakage Exclusion
79, 80, 81, 82, 83, 84, 85, 86	These systems are closed systems. Each train is leak tested but the leakage is not included in the 10 CFR 50 Appendix J Type B and C total leakage. The valves in these lines remain open during a design basis accident. Reference: T. S. Amendment 72/73 dated September 29, 1981.

5.5.6 Scheduling and Recordkeeping of Periodic Tests

Primary containment integrated leakage rate tests are conducted at periodic intervals based on historical performance of the overall containment system. Type A tests are only conducted while the plant is in the shutdown condition.

If any periodic Type A test fails to meet the acceptance criteria, the schedule for subsequent Type A test is determined in accordance with 10 CFR 50, Appendix J, Option B, and NEI 94-01, Revision 3-A, *Implementation Guidelines for Implementing Performance-Based Option of 10 CFR 50, Appendix J.*

Containment resilient seal penetration tests (Type B tests) were performed prior to initial criticality and are performed periodically thereafter during shutdown for refuelings, in accordance with 10 CFR 50 Appendix J, Option B, and NEI 94-01, Revision 3-A.

The personnel air lock full volume test was performed prior to initial fuel load and is performed periodically thereafter, in accordance with 10 CFR 50 Appendix J, Option B and NEI 94-01. If the air lock is open during periods when containment integrity is not required, the lock is tested only at the end of those periods. If the air lock is opened when containment integrity is required, the air lock is tested within 7 days after such opening. If the air lock door is opened more frequently then once every 7 days, the air lock seals are tested at least once every 30 days during the period of frequent opening. The personnel air lock and personnel escape hatch have testable seals and testing of the seals fulfills the 10 CFR 50 Appendix J after each use requirement. Seal tests are not substituted for the air lock full volume test.

Containment isolation valve testing (Type C tests) was performed prior to initial criticality and is performed periodically thereafter during each reactor shutdown for refueling, in accordance with 10 CFR 50 Appendix J, Option B.

The results of periodic Type A, B, and C tests are documented to show that performance criteria have been met. The comparison to previous results of the performance of the overall containment and of individual components are documented to provide a basis for the established test intervals for the containment and individual components.

5.5.7 Special Testing Requirements

Type A, B, and C tests, as applicable, are conducted following containment structure modifications in accordance with 10 CFR 50 Appendix J, Option B, and NEI 94-01, Revision 3-A, *Implementation Guidelines for Implementing Performance-Based Option of 10 CFR 50, Appendix J.*

CHAPTER 6 ENGINEERED SAFEGUARDS

6.1 GENERAL DESCRIPTION

Note: As required by the Subsequent Renewed Operating Licenses for Surry Units 1 and 2, issued May 4, 2021, various systems, structures, and components discussed within this chapter are subject to aging management. The programs and activities necessary to manage the aging of these systems, structures, and components are discussed in Chapter 18.

The engineered safeguards, together with the containment (Chapter 5), protect the public and the station in the event of the design-basis accident, as defined in Sections 14.5.1.2 and 14.5.5. The engineered safeguards are designed to minimize the accident by performing the following three functions:

1. Supply borated water to the reactor coolant system to cool the core, decrease reactivity, limit fuel rod cladding temperatures, limit the metal-water reaction, and ensure that the core remains intact.
2. Limit the driving potential, including differential pressure and time duration, for leakage out of the containment structure.
3. Reduce the concentration of airborne fission products available for leakage.

The first function is satisfied by the timely, continuous, and adequate supply of borated water to the reactor coolant system and the reactor core. The second function is satisfied by the provision of heat sinks for the condensation of steam released inside the containment, the inherent depressurization of the containment below atmospheric pressure following the design-basis accident, and means for maintaining the containment at subatmospheric conditions for an extended period of time. The third function is satisfied by providing chemical additives (NaTB) to the sump water which is recirculated by the ECCS and recirculation spray systems to enhance the spray removal of radioactive iodine from the containment atmosphere.

The engineered safeguards systems provided for satisfying these functions are as follows:

1. A safety injection system (Section 6.2) that injects borated water into the cold legs of all three reactor coolant loops.
2. Two separate low-head safety injection subsystems, either of which provides long-term removal of decay heat from the reactor core.
3. Two separate subsystems of the spray system (containment spray and recirculation spray) that operate together to reduce the containment temperature, return the containment pressure to subatmospheric, and remove heat from the containment. The recirculation spray subsystem maintains the containment subatmospheric and transfers heat from the containment to the service water system (Section 9.9).

A composite schematic diagram of the engineered safeguards systems is shown in Figures 6.1-1 and 6.1-2 for Units 1 and 2, respectively.

The safety injection system provides for the charging of borated water to the reactor coolant system from the accumulators following a LOCA. The three accumulators are self-contained and are designed to supply water as soon as the reactor coolant system pressure drops below 600 psig. Additional makeup to the reactor coolant system is provided by the charging pumps, operating in the safety injection mode, and the low-head safety injection pumps. Both the charging and low-head safety injection pumps are located outside the containment, are driven by an electric motor, are capable of being rapidly energized or operated, and are powered from the emergency power buses. The pumps also ensure an adequate supply of borated water for an extended period of time by recirculating water from the containment sump to the reactor core through two separate flow paths.

The containment spray subsystem supplies chilled borated water to the containment immediately following the receipt of the safeguards initiation signal. This subsystem includes two full-capacity, electric-motor-driven containment spray pumps that are located outside the containment and are supplied with power from the emergency buses. The containment spray pumps supply chilled water from the refueling water storage tank to the containment. Either pump is capable of furnishing sufficient spray water to prevent overpressurizing the containment structure.

The recirculation spray subsystem recirculates water from the containment sumps through service-water-cooled recirculation spray heat exchangers to the recirculation spray headers. Two of the four 50% design capacity, motor-driven recirculation spray pumps are located outside the containment. All four of the recirculation spray coolers are located inside the containment and transfer containment heat to the service water system (Section 9.9). Sodium Tetraborate Decahydrate (NaTB) is stored in baskets inside containment to increase the alkalinity of the sump water produced during an event which exceeds the CLS high-high containment pressure actuation setpoint. The NaTB solution is recirculated by the recirculation spray subsystem to ensure effective removal of radioactive iodine.

The containment spray and recirculation spray subsystems are capable of reducing the containment pressure to subatmospheric in less than 60 minutes, thus terminating all outleakage to the environment. This original design criterion was modified in conjunction with the analyses for implementation of the alternative source term. The criteria were subsequently updated to support an increase in the containment depressurization profile for the alternative source term analyses. The updated criteria require that, following the LOCA, the containment pressure be less than 2.0 psig within 1 hour and less than 0.0 psig within 6 hours. The radiological consequences analysis demonstrates acceptable results provided the containment pressure does not exceed 2.0 psig for the interval from 1 to 6 hours following the Design Basis Accident. Beyond 6 hours, containment pressure is assumed to be less than 0.0 psig, terminating leakage from containment.

The containment vacuum system removes any subsequent air inleakage after the containment pressure has been reduced to subatmospheric. Because of the inherent low-leakage design of the containment, the use of the vacuum pumps will probably not be required for several months after a major LOCA or the design-basis accident. Either of the two vacuum pumps is capable of removing sufficient air to maintain the containment subatmospheric indefinitely following any LOCA or design-basis accident, as discussed in Chapter 14.

The electrical components of all engineered safeguards may be operated on ac power provided from two independent emergency buses. Should all outside power sources fail, highly reliable onsite power is ensured by emergency generators, as described in Section 8.5. If one emergency generator should fail, the electrically driven engineered safeguards equipment may be transferred by manual control to the other emergency generator. Engineered safeguards can be manually operated from the control room. For the purpose of definition, the minimum engineered safeguards equipment started under emergency power conditions is as follows:

1. One charging pump (100% capacity).
2. One low-head safety injection pump (100% capacity).
3. Two recirculation spray pumps (100% total capacity).
4. One containment spray pump (100% capacity).

An evaluation of these systems under various conditions is presented in Chapter 14.

Periodic testing of the engineered safeguards components is performed as discussed under the individual systems later in this chapter. Components of the engineered safeguards system have been located in accessible areas, and visual inspection is performed periodically to ensure that the system is operable.

Safety-related equipment located in the containment that will be operable during and subsequent to a LOCA or steam-line break accident is as follows:

1. The inside recirculation spray pumps.
2. The inside recirculation spray pump motors.
3. The associated electrical cables for the recirculation spray pump motors.

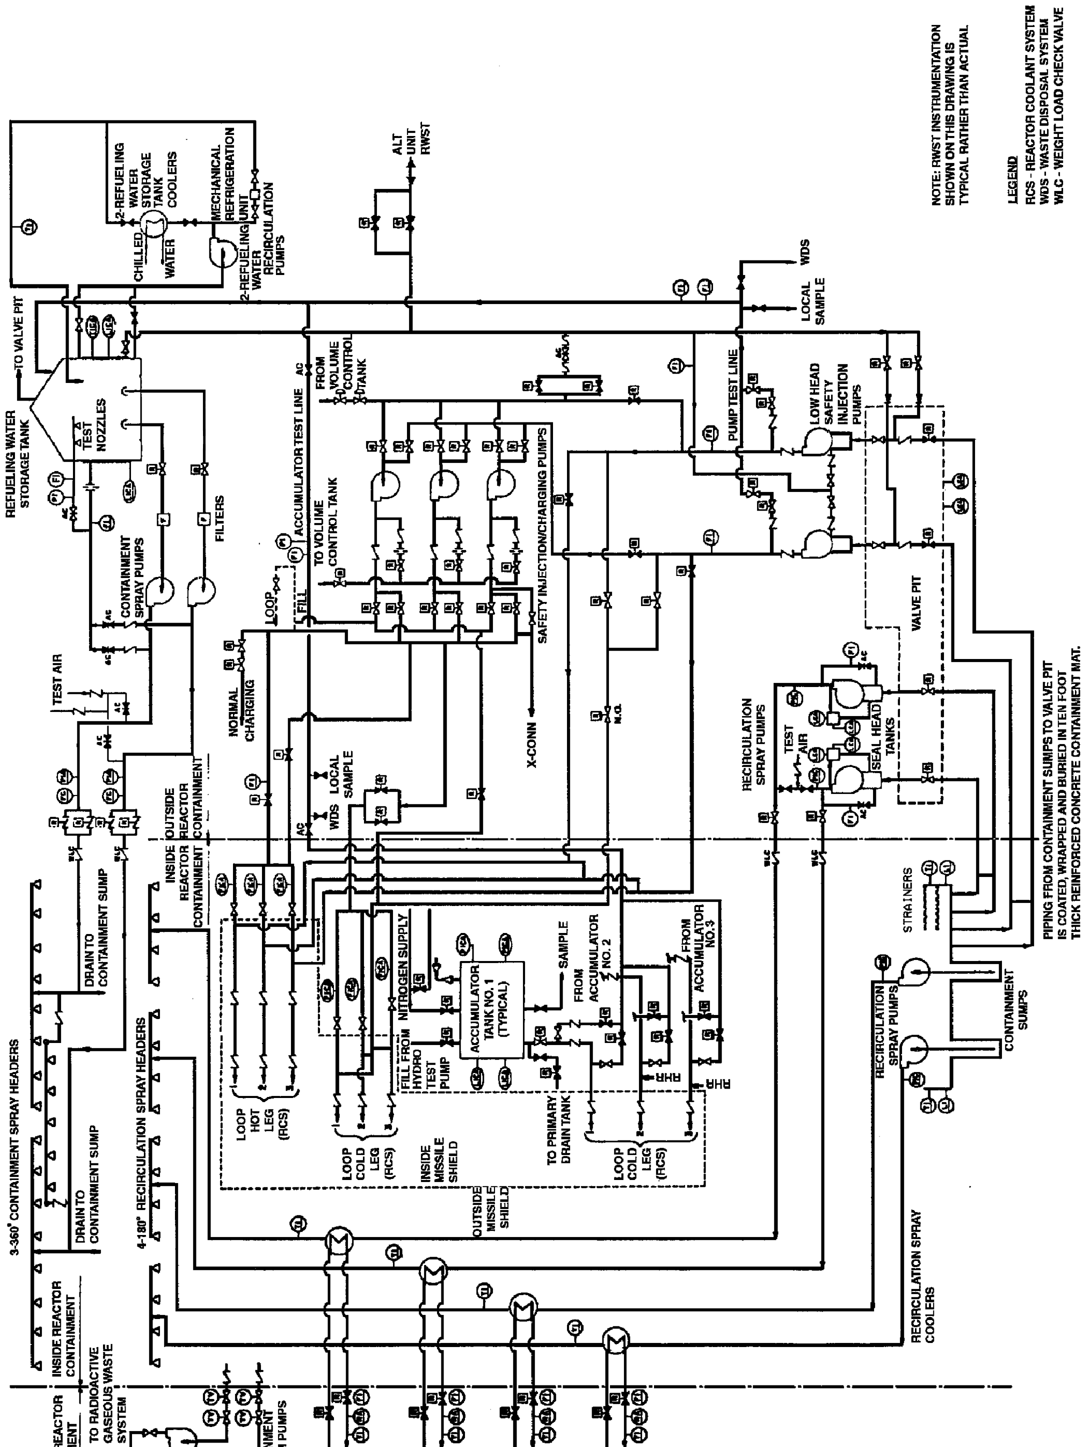

Figure 6.1-2
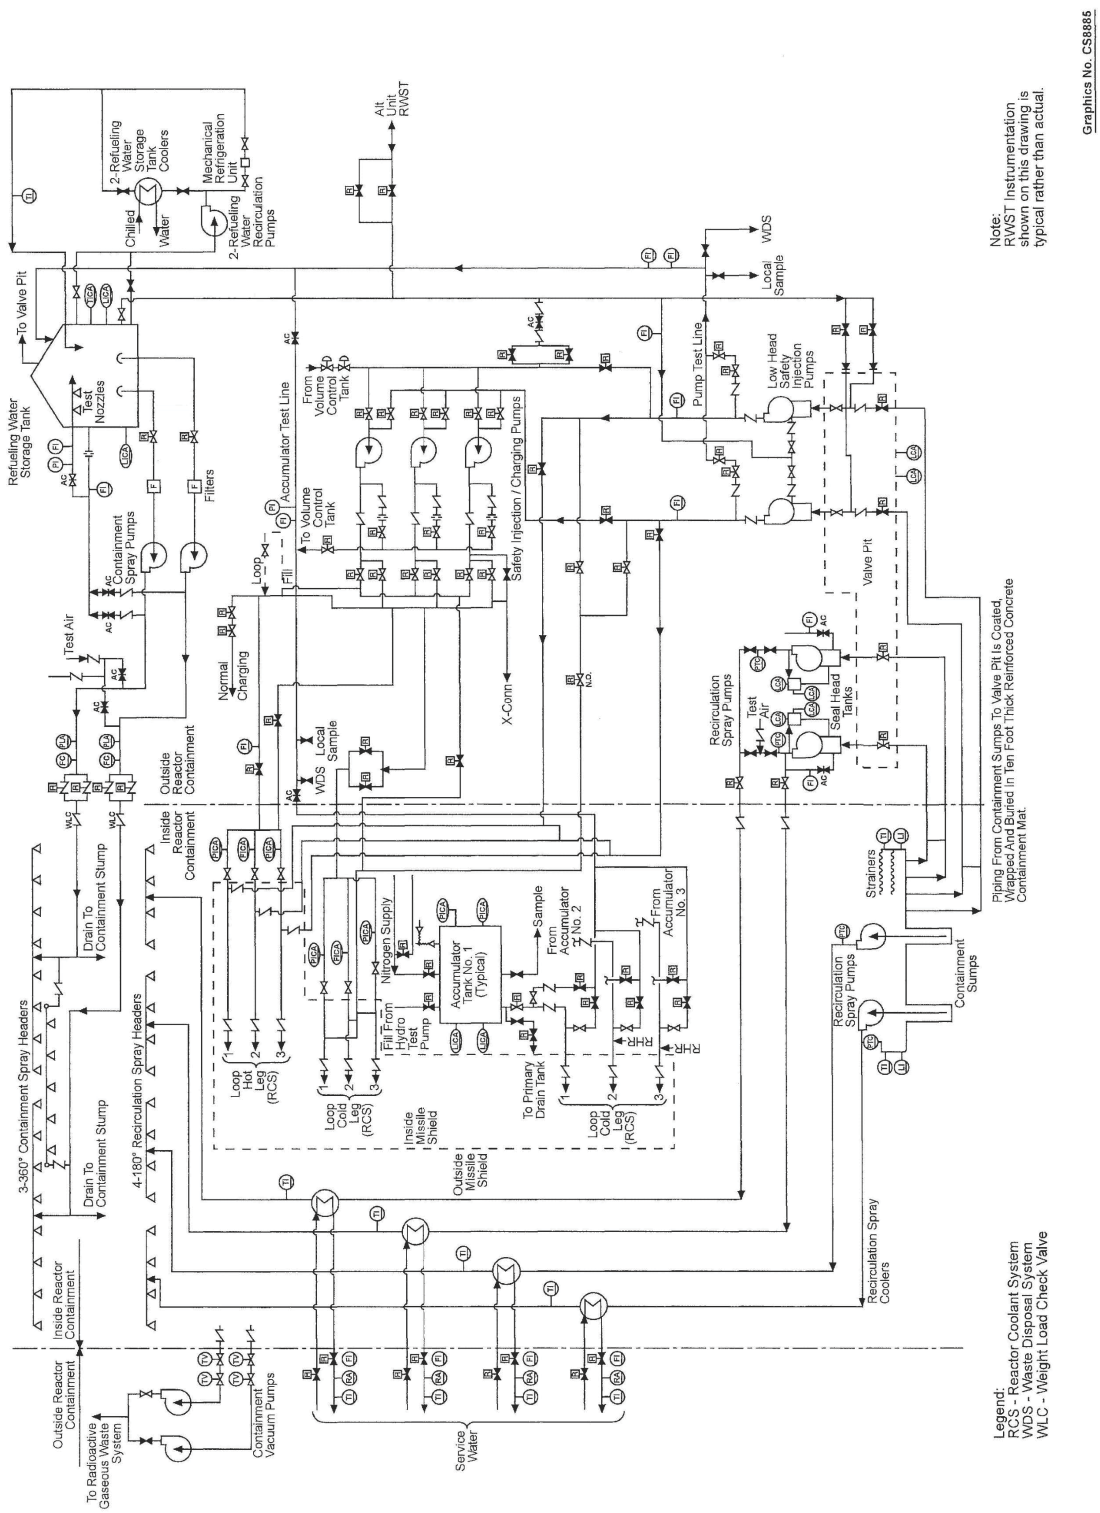
UNIT 2 ENGINEERED SAFEGUARDS SYSTEMS



Intentionally Blank

6.2 SAFETY INJECTION SYSTEM

6.2.1 Design Bases

6.2.1.1 Performance Objectives

The design bases for the safety injection system are:

1. To protect the unit and the public by maintaining clad integrity and thus minimizing the release of fission products from the fuel during the unlikely event of a LOCA.
2. To protect the core for a range of possible mishaps (evaluated as more likely than a LOCA), thereby minimizing financial loss and loss of power generation capability.

The specific technical objectives of the safety injection system are:

1. For the assumed LOCA (double-ended rupture of a reactor coolant pipe), or the LOCA associated with a control rod assembly ejection, or the rupture of a steam generator tube.
   a. To automatically deliver borated cooling water to the reactor core in large enough volume and soon enough after the accident so that:
      1) The cladding temperature is less than its melting temperature, and is less than the temperature at which gross core geometry distortion or clad fragmentation may be expected.
      2) The total core metal-water reaction is limited to less than 1%.
   b. To shut the reactor down and maintain it at 1% shutdown with all but one control rod assembly inserted (after long-term core operation at rated core power of 2587 MWt).

      These criteria ensure that the core remains in place and substantially intact to such an extent that effective cooling of the core is not impaired.
2. For the steam-line break or uncontrolled cooldown:
   a. To maintain the core in place and essentially intact so as not to impair effective cooling of the core, with the most reactive control rod assembly withdrawn, no offsite power, and a single failure in the engineered safeguards systems.
   b. To limit clad damage to an insignificant amount for the worst steam-line break, with no stuck control rod assembly, with offsite power available, and with all engineered safeguards.
   c. To prevent DNB after shutdown and during cooldown due to any single active failure, for example, the opening of a steam-line relief valve.

The safety injection system meets the intent of General Design Criteria 37 through 48, as discussed in Section 1.4, because:

1. The safety injection system objectives are met even though a loss of normal station power has occurred coincident with the accident.
2. Any single active failure during injection does not prevent the accomplishment of safety injection system objectives. One active or passive failure in the systems required for long-term safety injection system operation does not prevent the accomplishment of safety injection system objectives, nor cause the total offsite dose to exceed the limits of 10 CFR 50.67 or RG 1.183 guidelines, as appropriate, assuming credit is taken for detection and operator action.
3. Critical parts of the safety injection system and of the reactor coolant system are periodically inspected.
4. Active components of the safety injection system are tested periodically to ensure that each component is operable.
5. An integrated safety injection system test of active components is performed periodically during shutdown without introducing flow into the reactor coolant system.
6. Maintenance outages of active components are permitted only for limited periods of time.
7. It is assumed that the highest worth control rod assembly remains stuck out of the core on reactor trip.
8. Components exposed to the accident environment are designed to operate in that environment for the length of time required.

6.2.1.2 **Codes and Classifications**

Table 6.2-1 lists the codes and standards to which the safety injection system components are designed.

6.2.2 System Design and Operation

6.2.2.1 **System Description**

Adequate emergency core cooling following a LOCA is provided by the safety injection system shown in Figure 6.2-1 and Reference Drawings 1 & 2. The system components operate in the following possible modes:

1. Injection of borated water by the passive accumulators.
2. Injection of borated water initially from the refueling water storage tank with the safety injection charging pumps, and injection by the low-head safety injection pumps drawing borated water from the refueling water storage tank.
3. Recirculation of spilled coolant and injection water back to the reactor from the containment sump using the low-head safety injection pumps and by the safety injection charging pumps, if required by the situation.

The initiation signal for core cooling by the safety injection charging pumps and the low-head safety injection pumps is the safety injection signal that is actuated by any of the following:

1. Low-low pressurizer pressure.
2. High containment pressure (three-out-of-four).
3. Steam-line differential pressure (two-out-of-three between each steam line and main steam header).
4. High steam flow in any two of three steam lines (one-out-of-two per line) coincident with low steam-line pressure (two-out-of-three in steam generator header), or low T_{avg}.
5. Manual actuation.

6.2.2.1.1 Injection Phase

The principal components of the safety injection system that provide emergency core cooling immediately following a loss of coolant are the three accumulators (one for each loop), three safety injection charging pumps (which perform the charging functions during normal operation), and the two low-head safety injection pumps. The safety injection charging pumps are located in the auxiliary building. The low-head safety injection pumps are located in the safeguards area alongside the containment building with the pump impeller actually located within an extension of the containment boundary.

The accumulators, which are passive components, discharge into the cold legs of the reactor coolant piping when reactor coolant system pressure decreases below accumulator pressure, thus ensuring rapid core cooling for large breaks. They are located inside the containment, and are protected against possible missiles.

The safety injection signal opens the safety injection system isolation valves and starts the safety injection pumps. The accumulator isolation valves also receive the safety injection signal.

Following a safety injection signal, the maximum velocity of water is 125 fps in the accumulator discharge lines and approximately 40 fps in the high-head safety injection system lines (assuming two pumps deliver through 3-inch common cold leg injection lines).

When the reactor coolant system pressure falls below the accumulator pressure, the check valve opens and borated water is forced into the coolant system. The resultant hydraulic forces are controlled by snubbers located at various points on the piping system. Snubbers on the accumulator discharges lines do not eliminate the potential for water hammer; however, water hammer is not expected, since the relative low pressure of the low-head safety injection pumps would not rapidly close the check valves.

The snubbers are of the hydraulic type, which permits cyclic thermal movement. During slow cyclic excursions, the snubber exerts no restraint on the piping system. Rapid movement of the piston (caused by the hydraulic force) will cause a pressure differential between the ends of the snubber valve piston. This differential is sufficient to close the bypass ports in the valve, making the piston immovable and providing the resistive force. Snubbers are designed for tension or compression.

The valves of the high-head safety injection system open or close in approximately 10 seconds (in contrast to accumulator check valves, which open almost instantaneously), and therefore the hydraulic force should present no problem. The relatively slow closure time of these valves should present no water-hammer problems.

The safety injection charging pumps deliver borated water to the cold legs of the reactor coolant loops via separate discharge headers. These pumps provide for the makeup of coolant and add negative reactivity following a small break that does not immediately depressurize the reactor coolant system to the accumulator discharge pressure. For large breaks, they start delivery after the accumulators start their discharge.

The suction of the safety injection charging pumps is diverted from the normal suction at the volume control tank to the refueling water storage tank by the safety injection signal. (See Section 6.2.2.1.4.) The pumps feed two injection headers. The normal injection header contains redundant parallel isolation valves which open on receipt of a safety injection signal.

For large breaks, the reactor coolant system is depressurized and emptied of coolant rapidly (about 10 seconds for the largest break) and a high flow rate is required to quickly recover the exposed fuel rods and limit possible core damage. To achieve this objective, three accumulators are provided. Two low head safety injection pumps each delivering to a separate header are available to provide for an active component failure. Delivery from one low-head pump is required to supplement the accumulator discharge.

For large-area ruptures, the flow from the low-head portion of the system completes and maintains the core reflooding started by the accumulators. The accumulator injection starts core reflooding, as well as the termination of the clad temperature rise. The pumping systems ensure that the core is reflooded and that the reactor vessel is flooded at least to the nozzle. The core decay heat is removed by boiloff of the injected water, and ultimately the core is subcooled. The low-head pumps will recirculate the sump water, either directly to the reactor coolant loops for large breaks, or to the suction of the high-head pumps for small breaks, to ensure continued long-term cooling of the core.

Hot-leg connections for the low-head systems were selected to provide the optimum performance for the above functions and achieve a diversity of injection locations and flexibility to meet all long-term cooling requirements.

The cold-leg break is the most limiting, since the flow from one of the three accumulators is lost through the break, the steam-binding problem is more severe, and the clad temperatures at the end of blowdown are higher than for a comparable hot-leg break. The combination of these factors requires a larger flow for the cold-leg break. Evaluation of the high-head safety injection system show that the two unbroken cold-leg lines will deliver the required flow from one high-head pump, with allowance for part of the flow to spill through the break in the cold leg.

The low-head pumps provide the means to recirculate the sump water cooled by the spray heat exchangers and continue cooling the core through several alternate flow paths. The flow provided is in excess of that required to replace boiloff with allowance for spilling injection flow where applicable. If the loss of coolant occurred on the cold leg of one of the loops, the injected water would pass through the core to the break and ultimately subcool the core in the forced-circulation mode.

Motor-operated valves of the safety injection system that are normally energized during power operation and are under manual control, that is, valves that normally are in their ready position and do not receive a safety injection signal, have their positions indicated by position indicating lights on the control board. At any time during operation, if one of these valves is not in the ready position for injection, it is shown visually on the board. Motor operated valves of the safety injection system that are normally de-energized during power operation are verified to be in the ready position prior to removing power from the motor operator.

A detailed listing of the instrumentation readouts on the control board that the operator can monitor during initial injection is given in Table 6.2-2.

6.2.2.1.2 Changeover From Injection to Recirculation

The transfer of the safety injection suction lineup from the refueling water storage tank to the containment sump takes place automatically. The automatic transfer is initiated by a 2/4 matrix involving a refueling water storage tank level coincident with the two position key switches (one key switch for each train) being in the recirculation mode transfer position.

During the RMT sequence the following valves receive signals to reposition:

(Note: Preface each MOV number with a 1 or 2 depending upon the unit, i.e., 1-SI-MOV-1885A for Unit 1 and 2-SI-MOV-2885A for Unit 2.)

MOV-115B, D	HHSI pump suction isolation valves from the RWST
MOV-860A, B	LHSI pump suction isolation valves from the containment sump
MOV-862A, B	LHSI pump suction isolation valves from the RWST
MOV-863A, B	HHSI pump suction isolation valves from the LHSI pump discharge
MOV-885A, B, C, D	LHSI pump minimum flow recirculation isolation valves to the RWST

The valve alignment sequence begins with MOV-863A, B starting to open and MOV-885A, B, C, D starting to close when the RWST level setpoint for RMT switchover is reached. The maximum allowable operating time for these valves is one minute.

One minute after the RMT signal is generated, MOV-860A, B start to open and MOV-115B, D start to close. Once MOV-860A, B are fully opened, MOV-862A, B start to close. The maximum allowable time for this alignment is two minutes. Check valves are provided in the lines connecting the containment sump and the RWST to the LHSI pump suction to prevent cross connecting the sump with the RWST during the transfer sequence.

As described above, the entire sequence of automatic transfer (RMT) occurs within a minimum of two minutes and a maximum of three minutes. These maximum and minimum time intervals are used as inputs to the accident analyses.

The transfer system incorporates several functions to allow manual initiation of the switchover, automatic switchover as described above, bypass of system functions during refueling operations, and switchover by the existing method of individual valve alignment.

The level signals from the refueling water storage tank to the switchover circuitry is transmitted by four level transmitters located on the tank. For automatic switchover to occur, the 2/4 matrix signal coincident with the key switch in the RMT position is required. Level indication from each of these four channels is provided in the control room.

The non-safety-related refueling water storage tank level switches that were originally used to detect a refueling water storage tank low level and a refueling water storage tank high-high level have been replaced by a refueling water storage tank narrow-range level monitoring system. The refueling water storage tank narrow-range level monitoring system monitors the span between a point just below the dome bend line and the bottom of the overflow line. This span encompasses the range in which the refueling water storage tank wide-range level indicators are inaccurate due to the combined error of the indicating loops.

The refueling water storage tank narrow-range level monitoring system consists of an admittance type level probe, located in the manway at the top of the refueling water storage tank. The level probe is connected to a transmitter mounted on the platform of the refueling water storage tank. The transmitter is housed in a NEMA 4 enclosure along with a power supply, remote indicator, and adjustable setpoint relays. The transmitter supplies a 4 to 20 mA output signal which drives a channel on the refueling water storage tank wide-range level recorder in the control room. The refueling water storage tank wide-range level trend recorder chart paper has been replaced with appropriately scaled display, 0 to 100% for the refueling water storage tank wide-range level, and 90 to 100% for the refueling water storage tank narrow-range level. The adjustable setpoint relays are used to initiate the refueling water storage tank low level alarm, channel trip annunciators, and the refueling water storage tank high-high level alarm in the control room, and initiate local refueling water storage tank high-high level alarms at the entrance and at the bottom of the safeguard valve pit.

The purpose of the local valve pit alarms is to warn anyone in the valve pit or about to enter the valve pit, that a high-high level exists in the refueling water storage tank which could escalate into an overflow condition and that they should leave the area immediately.

The instrumentation for the recirculation phase is the same as that listed in Table 6.2-2 for initial injection.

6.2.2.1.3 Recirculation Phase

The coolant and refueling water spilled from the break and the water from the containment depressurization system (Section 6.3.1) collects in the containment sump, and part is returned to the reactor coolant system by the low-head safety injection pumps. The balance flows to the recirculation spray subsystem.

Because the injection phase of the accident is terminated before the refueling water storage tank is completely emptied, all pipes are kept filled with water before recirculation is initiated. Water level indication and alarms on the refueling water storage tank give the operator ample warning to terminate the injection phase while the operating pumps still have adequate net positive suction head (NPSH). These indications and alarms also inform the operator that sufficient water has been injected into the containment to allow the initiation of recirculation with the low-head safety injection pumps.

Two additional level indicators are provided for the containment sump that also indicate when injection can be terminated and recirculation initiated.

When steam dump cooldown is used for a small break in the reactor coolant system (4 inches and smaller), the steam is dumped to the condenser when outside power is available, or directly to the atmosphere when outside power is not available. As discussed in Section 14.5, the expected clad temperatures for break sizes 4-inch and smaller are limited to a value below which clad degradation is expected. When steam dump is initiated, the only activity that can be leaked into the steam is dumped to the condenser if outside power is available, in which case the air ejector radiation monitor provides additional information that activity carryover to the secondary side had not occurred as a result of the accident.

The redundant features of the recirculation loop include one low-head safety injection pump in each of two separate trains, with crossover capability at the discharge of each pump. Each pump takes suction through separate lines from the containment sump strainer. These suction lines are cross-connected prior to exiting the containment.

The design of the containment sump and piping configuration from the containment sump to the low-head safety injection pumps is illustrated in Figure 6.1-1.

After 1 day, the spray water collected is cold enough to reduce the temperature of the combined mass sufficiently for recirculation without flashing. All heat removal is through the recirculation spray subsystem. There are no heat exchangers in the safety injection system.

Those portions of the safety injection system located outside of the containment that are designed to circulate, under postaccident conditions, radioactively contaminated water collected in the containment, meet the following requirements:

1. Shielding to maintain radiation levels within the guidelines set forth in 10 CFR 100.
2. Collection of discharges from pressure-relieving devices into the drains aerated system for forwarding to the liquid waste disposal system.
3. Means to detect and control radioactivity leakage into the environs, within limits consistent with guidelines set forth in 10 CFR 100 and 10 CFR 50.67.

This criterion is met by minimizing leakage from the system. Recirculation loop leakage is discussed in Section 6.2.3.

6.2.2.1.4 Steam-Line Break Protection

A large break of a main steam system pipe causes an uncontrolled removal of heat that rapidly cools the reactor coolant, causing the insertion of positive reactivity into the core. Compensation is provided by the injection of borated water from the RWST. The isolation valves in the lines injecting into the reactor coolant system hot legs remain closed, ensuring that the safety injection flow is directed into the cold legs of the reactor coolant system.

In order to ensure a supply of RWST water to each unit's charging pumps in the unlikely event that a HELB (e.g., MSLB) outside of containment renders the affected unit's RWST or RWST supply line inoperable, a piping cross-connect is installed between the suction side of the charging pumps for Unit 1 and Unit 2 (Reference 4). Two parallel sets of normally closed trip valves, SI-TV-102A and SI-TV-102B and SI-TV-202A and SI-TV-202B, provide isolation between each unit's charging pump suction header during normal operation. A single steam line break (SLB) signal from either unit will automatically open a valve on each side of the cross-connect. This provides a suction path from the unaffected unit's RWST to the affected unit's charging pumps. If a unit is in refueling and the other unit is operating, a minimum allowable RWST level of 20.5% for the unit being refueled is required to shut down the operating unit. Check valves are installed to prevent a loss of inventory from the unaffected unit's RWST through the affected unit's broken charging pump suction line for breaks upstream of the check valves.

The containment response following a main steamline break was evaluated during the analyses performed for elimination of the boron injection tank. In 1983, Virginia Power requested a license amendment which allowed a reduction in the minimum required boric acid concentration of the boron injection tank (Reference 5). Reference 6 documented an evaluation of the MSLB containment response which was requested by NRC. The NRC, in the SER for the associated Technical Specifications changes (Reference 7), made these observations concerning the containment temperature effects of MSLB for Surry:

> The licensee has performed sensitivity studies to address the impact of reducing the BIT boron concentration on early MSLB energy release, and has concluded that the current equipment qualification temperature envelopes for the Surry plants are adequate. Since LOCA conditions dominate the containment functional design considerations, the licensee used the LOCA temperature profiles for post-accident equipment qualification in lieu of MSLB temperature profiles. Based on a review of the information submitted by the licensee, and because of the similarity of the licensee's request to other staff actions, we conclude that the licensee's proposal to eliminate the minimum boron concentration requirement in the BIT will not adversely affect the containment functional performance.

From this statement, it is concluded that containment temperature profiles associated with the large break LOCA analysis represent the limit approved by the NRC in Reference 7.

Downstream of the normally closed valves 1-SI-MOV-1890A and 2-SI-MOV-2890A and near the containment penetration area exists a beyond design basis (BDB) mechanical connection for the purpose of connecting a portable pump to inject borated/makeup water into the Reactor Coolant System (RCS) during a beyond design basis external event (BDBEE).

See Section 5.4 for MSLB evaluation.

6.2.2.2 **Components**

All associated components, piping, structures, and power supplies of the safety injection system are designed to conform with Seismic Class I criteria. Safety injection system components inside the containment are capable of withstanding or are protected from the differential pressure that may occur during the rapid containment pressure increase.

All motors, instruments, transmitters, and their associated cables located inside the containment are designed to function under postaccident temperature, pressure, and humidity conditions.

Internal wetted parts of safety injection system components are austenitic stainless steel, or other equivalent corrosion resistant materials, and hence are compatible with the spray solution over the full range of exposure in the postaccident regime.

The quality standards of all safety injection system components are given in summary form in Table 6.2-3.

6.2.2.2.1 Accumulators

The accumulators are pressure vessels filled with borated water and pressurized with nitrogen gas. During normal operation, each accumulator is isolated from the reactor coolant system by two check valves in series, only one of which is required for isolation. If the reactor coolant system pressure falls below the accumulator pressure, the check valves open and borated water is forced into the reactor coolant system. Mechanical operation of the swing-disk check valves by means of differential pressure is the only action required to open the injection path from the accumulators to the core via the cold leg.

The level of borated water in each accumulator tank is adjusted remotely as required during normal station operation. Refueling makeup water is added using the positive displacement hydrotest pump.

Water level may be reduced by draining to the RWST, primary drains tank or primary drain transfer tank. Samples of the solution in the accumulators are taken for periodic checks of boron concentration.

The accumulators are passive engineered safeguards because the nitrogen gas pressure forces injection; no external source of power or signal transmission is needed to obtain fast-acting, high-flow capability when the need arises. One accumulator is connected to each of the cold legs of the reactor coolant system.

The design capacity of the accumulators is based on the assumption that flow from one of the accumulators spills onto the containment floor through the ruptured loop. The flow from the two remaining accumulators provides sufficient water to fill the volume outside of the core barrel below the nozzles, the bottom plenum, and one-half of the core (see Figure 3.5-2).

The accumulators are carbon steel, clad with stainless steel, and designed to ASME Code, Section III, Class C. Redundant level and pressure indicators are provided with readouts on the control board. Each channel is equipped with high-level and low-level alarms. The margin between the minimum operating pressure and the design pressure provides a range of acceptable operating conditions within which the accumulator system meets its design core cooling objectives. The band is sufficiently wide to permit the operator to minimize the frequency of leakage compensating adjustments in the amount of contained gas or liquid.

The accumulator design parameters are listed in Table 6.2-4.

6.2.2.2.2 Pumps

Three safety injection/charging pumps, which are used as high-head safety injection system pumps, supply borated water to the reactor coolant system. The pumps are of the horizontal centrifugal type, driven by electric motors.

Two low-head safety injection pumps also supply water to the reactor coolant system. Table 6.2-5 lists the design parameters for the safety injection charging and low-head safety-injection pumps.

All pressure-containing parts of the pumps are chemically and physically analyzed, and the results are checked to ensure conformance with the applicable ASTM specifications. In addition, all pressure-containing parts of the pumps are liquid penetrant inspected in accordance with Appendix VIII of Section VIII of the ASME Code. The acceptance standard for the liquid penetrant test is USAS B31.1, Code for Pressure Piping, Case N-10. Parts of the pump in contact with borated water are stainless steel or equivalent corrosion-resistant material.

The pressure-containing parts of the pumps are castings conforming to ASTM A351 Grade CF8 or CF8M. Stainless steel forgings are procured per ASTM A182 Grade F304 or F316, or ASTM A336, Class F8 or F8M. Stainless steel plate is constructed to ASTM A240, Type 304 or 316. Bolting material conforms to ASTM A193. Materials such as weld-deposited Stellite or Colmonoy are used at points of close-running clearances in the pumps to prevent galling and to ensure continued performance capability in high-velocity areas subject to erosion.

Pump design is reviewed with special attention to the reliability and maintenance aspects of the working components. Specific areas include the evaluation of the shaft seal and bearing design to determine that adequate allowances have been made for shaft deflection and clearances between stationary parts.

Where the welding of pressure-containing parts is necessary, a welding procedure including joint detail was submitted for review and approval. The procedure includes evidence of qualification necessary for compliance with Section IX of the ASME Code, *Welding Qualifications*. This requirement also applies to any repair welding performed on pressure-containing parts.

The following information is HISTORICAL and is not intended or expected to be updated for the life of the plant.

The pressure-containing parts of the pump were assembled and hydrostatically tested to 1.5 times the design pressure for 30 minutes.

Each pump was given a complete shop performance test in accordance with Hydraulic Institute standards. The pumps were run at design flow and head, shut-off head, and three additional points to verify performance characteristics. Where net positive suction head is critical, this value was established at design flow by means of adjusting suction pressure.

6.2.2.2.3 Valves (General)

All parts of valves used in the safety injection system in contact with borated water are austenitic stainless steel or equivalent corrosion-resistant material. The motor operators on the injection line isolation valves are capable of rapid operation. Valves required to change position for the initiation of safety injection or isolation of the system have remote position indication in the control room.

Exceptional tightness is specified for the valves and, where possible, packless diaphragm valves are used (e.g., for instrument valves). Valves, except those that perform a control function, are provided with backseats that are capable of limiting leakage. Those valves that are normally open are backseated, with the exception of quarter-turn valves. The use of quarter-turn valves is limited to low pressure regions of the system, which helps minimize stem leakage, and the valves are not installed in a recirculation flowpath. Normally closed globe valves are installed with pressure under the seat to prevent the leakage of recirculated water through the valve stem packing. An exception to this preference includes the charging pump recirculation MOVs which are installed with pressure over the seat which assists closing thrust margin. The reversed configuration exposes the valve packing to the inlet pressure when the valve is closed.

The check valves that isolate the safety injection system from the reactor coolant system are installed adjacent to the reactor coolant piping to reduce the probability of a safety injection line rupture causing a LOCA.

The gas relief valves on the accumulators protect them from pressures in excess of the design value.

6.2.2.2.4 Motor-Operated Valves

The pressure-containing parts (body, bonnet, and disks) of the valves employed in the safety injection system are designed according to criteria established by the USAS B16.5 or MSS SP-66 specifications. The materials of construction for these parts are procured as per ASTM (S)A182, F316, or A351, Grade CF8M or CF8.

Radiographic inspection is conducted in accordance with the procedure outlined in ASTM E-94. Radiographic acceptance standards are outlined in ASTM E-71, E-186, or E-280, whichever is applicable, and meet the requirements of severity level 2, except that D, E, F, and G defects are not permissible. The body, bonnet, and disk are liquid penetrant inspected in accordance with ASME Code, Section III, paragraph N-627.

When a gasket is employed, the body-to-bonnet joint is designed as per ASME Code, Section VIII, or USAS B16.5, with a fully trapped, controlled compression, spiral-wound gasket with provisions for seal welding, or of the pressure seal design with provisions for seal welding. The body-to-bonnet bolting and nut materials are procured per ASTM A193 and A194, respectively.

The bolt material for 2-SI-MOV-2869A and 2-CH-MOV-2287C is ASTM A564, Type 630, H1100.

The following information is HISTORICAL and is not intended or expected to be updated for the life of the plant.

The entire assembled unit was hydrotested as outlined by Manufacturers Standardization Society in the Valve and Fitting Industry, Specification 61 (MSS SP-61), with the exception that the test was maintained for a minimum period of 30 minutes. Failure of the test was cause for rejection.

The seating design is of the Darling parallel disk design, the Crane split wedge design, the Westinghouse flex wedge design, the Velan globe style design, the Xomox quarter-turn plug design, or the equivalent. Except for the Xomox valves, these designs have the feature of releasing the mechanical holding force during the first increment of travel. Thus, these motor operators have to work only against the frictional component of the hydraulic imbalance on the disk and against the packing box friction in the absence of a pressure locked condition. The disks are guided to prevent chattering and provide ease of disk movement. The seating surfaces are hard-faced (Stellite No. 6. or equivalent) to prevent galling and reduce wear.

The stem material is ASTM A276, Type 316, condition B. or precipitation hardened 17-4 PH stainless, procured and heat-treated to Westinghouse specifications.

These materials are selected because of their corrosion resistance, high-tensile properties, and their resistance to surface scoring by the packing. The valve stuffing box is designed with a lantern ring leakoff connection with a minimum of a full set of packing below the lantern ring and a maximum of one-half of a set of packing above the lantern ring; a full set of packing is defined as a depth of packing equal to 1.5 times the stem diameter. The experience with this stuffing box design and the selection of packing and stem materials has been very favorable in both conventional and nuclear power stations.

The motor operator is extremely rugged. The unit incorporates a hammerblow feature that allows the motor to impact the disks away from the fore- or backseat upon opening or closing. The hammer-blow feature not only impacts the disk but allows the motor to rapidly attain its operational speed.

The following information is HISTORICAL and is not intended or expected to be updated for the life of the plant.

The valves were assembled, hydrostatically tested, seat-leakage tested (fore and back), operationally tested, cleaned, and packaged as per specifications. In some cases, extension stems were used on motor-operated valves. These valves were operationally tested initially without the extension stems. The valves were operationally tested later with the extension stems, after installation in the unit. Manufacturing procedures employed by the valve supplier, such as hard facing, welding, repair welding, and testing, were submitted to Westinghouse for approval.

For those valves that must function on the safety injection signal, the following requirements originally applied: for valves up to and including 8-inch, the valve operator completes its cycle from one position to another in 10 seconds maximum. For valves over 8 inches, the valve cycling operation occurs at a rate of 49 in/min. For all other valves in the system, the following requirements originally applied: for valves up to and including 8-inch, the valve cycling operation occurs at a rate of 12 in/min and, for valves greater than 8-inch, the valve operator completes its cycle from one position to another in 120 seconds maximum.

Current allowable valve stroke times may exceed original purchase specifications. The current allowable valve stroke times are based on safety system response requirements and/or accident analysis and are considered when developing acceptance criteria to ensure that the valve performance does not degrade below the performance required by the safety system response requirements and/or accident analysis. The acceptance criteria are developed and the tests performed in accordance with the ASME Inservice Testing Program as required by 10 CFR 50.55a(f)4.

Several motor operated valves in the SI System have been modified to prevent valve pressure locking. The valves have been modified to relieve pressure that can be trapped between the gate valve disks. The following MOVs have been modified by drilling a hole in the upstream disk: 1-SI-MOV-1842, 2-SI-MOV-2842, 1-SI-MOV-1867C,D, 2-SI-MOV-2867C,D, 1-SI-MOV-1869A,B, 2-SI-MOV-2869B, 2-SI-MOV-2860A. The following MOVs have been modified by drilling a hole in the downstream disk: 1-RH-MOV-1720A,B, 1-SI-MOV-1860A,B, 2-SI-MOV-2860B. The following MOVs have been modified by installing a downstream equalization line: 1-SI-MOV-1890A,B, 2-SI-MOV-2890A,B (Reference 8).

Valves that must function against system pressure are designed so that they function with a pressure drop equal to full system pressure across the valve disk.

The following information is HISTORICAL and is not intended or expected to be updated for the life of the plant.

Tests to demonstrate the adequacy of valve motor operators to be functional after exposure to high temperatures, pressure, and radiation were conducted in two groups.

The first group was the exposure of valve motor operators to high temperatures and pressures. Tests were conducted in simulated containment pressures and temperatures characteristic of those predicted for an accident. The results were released in Proprietary WCAP 7410-L, submitted in January 1971.

Test conditions were as follows:

1. The valve operator was located inside a pressure vessel that was at approximately 300°F and 90 psig.
2. The valve operator was cycled approximately three times under simulated valve operating loads.
3. Pressures and temperatures were reduced in step changes to 285°F at 60 psig, 219°F at 20 psig, and 152°F at atmospheric pressure or less.
4. The valve operator was cycled approximately three times at each of the levels of change. Full recordings of pertinent data were taken throughout the test.
5. The valve unit was examined after completion of the test and operating data were compared to data before exposure.

The second test group was the radiation test on a motor from the valve operator. Test conditions were as follows:

The following information is HISTORICAL and is not intended or expected to be updated for the life of the plant.

1. Two production line motors were used for this test. One was exposed to a total of 1.5×10^8 rad of gamma radiation in approximately one month. The other motor was used for the final comparative analysis.
2. Both motors were tested for coil resistance by the Wheatstone bridge method, and for insulation resistance by meggering both before and after motor vibration and reversing operations.

The compatibility of construction materials with a postaccident solution of boric acid and sodium tetraborate decahydrate is discussed in WCAP-16596 (Reference 12).

The recirculation spray sump in containment is maintained wet to provide a water seal to reduce the potential for pressure locking the LHSI pumps containment suction MOV's (Reference 9).

6.2.2.2.5 Manual Valves

The stainless steel manual globe, gate, and check valves are designed and built in accordance with the requirements outlined in the motor-operated valve description above (Section 6.2.2.2.4).

The carbon steel valves are built to conform with USAS B16.5. The materials of construction of the body, bonnet, and disk conform to the requirements of ASTM A105, Grade II; A181, Grade II; or A216, Grade WCB or WCC. The carbon steel valves pass only non-radioactive gases and were subjected to hydrostatic test as outlined in MSS-SP-61, except that the test pressure was maintained for at least 30 minutes.

6.2.2.2.6 Vent Valves

High point vents have been installed at critical points in the suction lines of the charging (HHSI) pumps, and the discharge lines of the LHSI pumps where gasses could collect.

6.2.2.2.7 Accumulator Check Valves

The pressure-containing parts of these valve assemblies are designed in accordance with MSS SP-66. Parts in contact with the operating fluid are of austenitic stainless steel or of equivalent corrosion-resistant materials procured to applicable ASTM or Westinghouse specifications.

The following information is HISTORICAL and is not intended or expected to be updated for the life of the plant.

The cast pressure-containing parts were radiographed in accordance with the procedure outlined in ASTM E-94. Radiographic acceptance standards were as outlined in ASTM E-71, E-186, or E-280, whichever was applicable, and met the requirements of severity level 2, except that D, E, F, and G defects were not permissible. The cast pressure-containing parts, machined surfaces, finished hard facings, and gasket-bearing surfaces were liquid penetrant inspected per ASME Code, Section VIII, and the acceptance standard was as outlined in USAS B31.1, Code Case N-10. The final valves were hydrotested in accordance with MSS SP-61, except that the test pressure was maintained for at least 30 minutes. The seat leakage test was conducted in accordance with the manner prescribed in MSS SP-61, except that the acceptable leakage was 3 cm^3/hr/in. of nominal pipe diameter.

The valve is designed with a low pressure drop configuration, with all operating parts contained within the body, which eliminates those problems associated with packing glands exposed to boric acid. The clapper arm shaft is manufactured from 17-4 PH stainless steel heat-treated to Westinghouse specifications. The clapper arm shaft bushings were manufactured from Stellite No. 6 or other corrosion and wear resistant material. The various working parts were selected for their corrosion-resistant, tensile, and bearing properties.

The disk and seat rings were, manufactured from a forging. The mating surfaces are hard-faced with Stellite No. 6 or other corrosion and wear resistant material to improve the valve seating life. The disk is permitted to rotate, providing a new seating surface after each valve opening.

The valves are intended to be operated in the closed position, with a normal differential pressure across the disk of approximately 1600 psi. The valves remain in this position except for testing and accumulator discharge. Since the valve is not normally required to operate in the open position, and hence be subjected to flow induced wear or impact loads caused by sudden flow reversal, it is expected that this equipment will satisfactorily perform its required functions indefinitely with minimal maintenance.

When the valve is required to function, a differential pressure of less than 25 psid will shear any particles that may attempt to prevent the valve from functioning. Although the working parts are exposed to the boric acid solution contained within the reactor coolant loop, boric acid freeze-up is not expected because the boric acid concentration is relative low.

The following information is HISTORICAL and is not intended or expected to be updated for the life of the plant.

The experience derived from the check valves employed in the similar safety injection system of the Carolinas-Virginia Tube Reactor (CVTR) indicates that the system is reliable and workable.

The following information is HISTORICAL and is not intended or expected to be updated for the life of the plant.

The CVTR emergency injection system was normally maintained at containment ambient conditions and was separated from the main coolant piping by a single 6-inch check valve. A leak detection pot was provided at a proper elevation to accumulate any leakage coming back through the check valve. A level alarm provided a signal on excessive leakage. The pressure differential was 1500 psi and the system was stagnant. The valve was located 2 to 3 feet from the main coolant piping, which resulted in some heatup and cooldown cycling. The Carolinas-Virginia Tube Reactor went critical late in 1963 and operated until 1967. During that time, the level sensor in the detection sump never alarmed due to check valve leakage.

6.2.2.2.8 Accumulator Isolation Valves

The isolation valve at each accumulator is normally closed only when the reactor is intentionally depressurized. The only other times the isolation valve is closed is for testing or maintenance purposes, for which a time limitation is specified in the Technical Specifications. The valves, however, receive a signal to open when safety injection is initiated. The valve is designed to operate with full system differential pressure. The isolation valve is normally blocked opened by de-energizing the valve motor operators when the reactor coolant pressure exceeds 1000 psig. An alarm in the control room sounds if the valve is inadvertently closed. It is not expected that the isolation valve will have to be closed because of excessive leakage through the check valves.

When the reactor coolant system is being pressurized during the normal unit heatup operation, the check valves are tested for leakage as soon as there is about 100 psi differential across the valve. This test confirms the seating of the disk and whether or not there has been an increase in the leakage since the last test. When this test is completed, the discharge line isolation valves are opened and the reactor coolant system pressure increase continued. There should be no increase in leakage from this point on, since increasing reactor coolant pressure increases the seating force and decreases the probability of leakage.

6.2.2.2.9 Relief Valves

The accumulator relief valves are sized to pass nitrogen at a rate in excess of the accumulator gas fill-line delivery rate. The relief valves also pass water in excess of the expected leak rate, but this is not necessary, because the time required to fill the gas space gives the operator ample opportunity to correct the situation. For a maximum allowable inleakage rate, there are about 6.0 hours before water reaches the relief valves. Prior to this, level and pressure alarms would have been actuated.

6.2.2.2.10 Valve Leakage Limitations

The following valve information is presented as the design information from the original equipment specifications. These valves are currently tested in accordance with ASME Inservice

Testing Program for monitoring valve performance as required by 10 CFR 50.55a(f) and replaced in accordance with current approved equipment specifications.

Exceptional tightness is specified for all valves, and packless diaphragm valves are used where possible (such as for instrument valves).

Normally open valves have backseats that limit stem leakage.

Normally closed globe valves are installed with pressure under the seat to prevent stem leakage from the more radioactive fluid side of the seat.

The manufacturer seat leakage testing for the valves was conducted in accordance with the manner prescribed in MSS-SP-61 except the test pressure was maintained for a minimum of 5 minutes. The seat leakage rate for globe, gate, and self actuated check valves was required to be less than 3 cc/hour/inch of nominal valve size. The seat leakage rate for diaphragm valves was required to have zero seat leakage.

Leakage from components of the recirculation loop, including valves, is discussed in Section 6.2.3.10.

6.2.2.2.11 Pump and Valve Motors

Electrical insulation systems for motors outside containment are supplied and tested in accordance with USASI, IEEE, and NEMA standards. Temperature rise design selection is such that normal long life is achieved even under accident loading conditions.

Motors for the valves inside the containment are designed to withstand containment environment conditions following the LOCA so that the valves can perform the required function during the recovery period.

Containment motors that must operate during and/or after the postulated accident are designed for continuous service in the postaccident containment environment. Periodic operations of the motors and tests of the insulation ensure that the motors remain in a reliable operating condition. The only motors of the safety injection system that must operate inside the containment are valve motors.

Although these motors, which are provided only to drive engineered safety features equipment, are normally run only for test, the design loading and temperature rise limits are based on the accident conditions.

Normal design margins are specified for these motors to make sure the expected lifetime includes allowance for the occurrence of accident conditions.

6.2.2.2.12 Piping

Safety injection system piping in contact with borated water is austenitic stainless steel. Piping joints are welded, except for the flanged connections at the relief valves, flow elements, and safety injection pumps.

The piping beyond the accumulator stop valves is designed for reactor coolant system conditions (2485 psig, 650°F). All other piping connected to the accumulator tanks is designed for at least 700 psig and 400°F.

The safety injection charging pump suction piping from the refueling water storage tank is designed for low-pressure losses to meet NPSH requirements of the pumps.

The safety injection high-pressure branch lines are designed for high-pressure losses to limit the flow rate out of the branch line, which may have ruptured at the connection to the reactor coolant loop. The system design incorporates the ability to isolate the safety injection charging pumps on separate headers so that full flow from at least one pump is ensured should a branch line break.

The piping is designed to meet the minimum requirements set forth in the USAS B31.1-1955 Code for Pressure Piping, USAS B36.10 and B36.19, ASTM Standards, supplementary standards, and additional quality control measures.

Minimum wall thicknesses are determined by the formula found in Section 1 of the USAS B31.1-1955 Code for Pressure Piping. This minimum thickness is increased to account for the manufacturer's permissible tolerance of –12.5% on the nominal wall and an 8% allowance for bending. Purchased pipes and fittings have a specified nominal wall thickness that is no less than the sum of that required for pressure containment, pipe bending, mechanical strength, and manufacturing tolerance.

Special attention is directed to the piping configuration at the pumps, with the objective of minimizing pipe-imposed loads at the suction and discharge nozzles.

Piping is supported to accommodate expansion due to temperature changes and hydraulic forces during an accident.

The materials for pipes and fittings are procured in conformance with requirements of the ASTM and USASI specifications. Materials are verified for conformance to specification and documented by certification of compliance to ASTM material requirements. Specifications impose additional quality control on the suppliers of pipes and fittings, as listed below:

1. Provided copies of analyses performed on both the purchased pipes and fittings.
2. Pipe branch lines between the reactor coolant pipes and the isolation stop valves conform to ASTM A376 and meet the supplementary requirement S6 for ultrasonic testing.
3. Fittings conform to the requirements of ASTM A403.

Shop fabrication of piping subassemblies is performed in accordance with specifications that define and govern material procurement, detailed design, shop fabrication, cleaning, inspection, identification, packaging, and shipment.

Welds for pipes sized 2.5 inches and larger are butt welded. Reducing tees are used where the branch size exceeds one-half of the header size. Branch connections of sizes that are equal to or less than one-half of the header size are of a design that conforms to the USASI rules for reinforcement set forth in the USAS B31.1 Code for Pressure Piping. Bosses for branch connections are attached to the header by means of full-penetration welds.

Welding was performed by welders and welding procedures qualified in accordance with ASME Code, Section IX, *Welding Qualifications*. The shop fabricator was required to submit all welding procedures and evidence of qualifications for review and approval before release for fabrication. Welding materials used by the shop fabricator required prior approval.

High-pressure piping butt welds containing radioactive fluid, at greater than 600°F temperature and 600 psig pressure, were radiographed. The remaining piping butt welds were randomly radiographed. The technique and acceptance standards were those outlined in paragraphs N-624.2 and N-625.3 of ASME Code, Section III. In addition, butt welds were liquid penetrant examined in accordance with the procedure of ASME Code, Section III, paragraph N-627.2, and the acceptance standard as defined in paragraph N-627.3. Finished branch welds were liquid penetrant examined on the outside, and the root passes were for sizes 6-inches and larger, and for schedule 80S and heavier for all sizes.

A postbending solution anneal heat treatment was performed on hot-formed stainless steel pipe bends. Completed bends were then completely cleaned of oxidation from affected surfaces. The shop fabricator was required to submit the bending, heat treatment, and cleanup procedures for review and approval before release for fabrication.

General cleaning of completed piping subassemblies (inside and outside surfaces) was governed by basic ground rules set forth in the specifications. For example, these specifications prohibited the use of hydrochloric acid and limited the chloride content of service water and demineralized water.

The packaging of the piping subassemblies for shipment was done so as to preclude damage during transit and storage. Openings were closed and sealed with tight-fitting covers to prevent the entry of moisture and foreign material. Flange facings and weld end preparations were protected from damage by means of wooden cover plates and were securely fastened in position. The packing arrangement proposed by the shop fabricator was subject to approval.

6.2.2.2.13 LHSI Strainer Assembly

The LHSI strainer assembly is designed to provide filtered borated water to both LHSI pumps during the recirculation mode. The strainer assembly consists of a number of modules which channel water to the pump suction. Modules are connected to each other by flexible metal seals. Seal closure frames with Metex seals are installed over existing flexible metal seals. The seal closure frame assemblies form the seal between adjacent strainer modules. Each module contains a number of fins which filter the water flowing into the modules. Each fin contains a number of holes 0.0625-inch (nominal) in diameter. Perforations on the strainer fins prevent particles larger than 0.06875-inch (0.0625-inch plus 10 percent) from entering the LHSI System. The total perforation area is large enough to allow sufficient flow to the suctions of the LHSI pumps to meet NPSH requirements. In addition, particles larger than 0.06875 inches were evaluated in response to gaps identified in the strainer assembly. As part of the evaluation, it was assumed that 1% of the total generated particles between 0.06875 inches (0.0625 inches plus 10 percent) and 0.1375 inches (0.125 inches plus 10 percent) would pass through the strainer. It was determined that these particles would not impact the performance of downstream components.

The LHSI strainer assembly consists of two trains which traverse along the containment wall on both sides of the sump. Each suction opening is connected to the modules via the strainer header. The strainer header is connected to each suction opening by a flanged transition adapter. The OD of the strainer header is machine cut and slip-fitted in to the new adapter ensuring that the gaps between the piping and the adapter do not exceed 0.0625 inches.

The strainer assembly is designed and fabricated to the requirements of ASME Section III, Subsection NF, Class 3. All material used in the construction of the strainer assembly is austenitic stainless steel.

The strainer assembly is capable of withstanding the full debris loading in conjunction with all design basis conditions without collapse or structural damage.

A 12-inch line provides a cross connection between the two 12-inch lines on the suction of the low-head safety injection pumps. Each of the two 12-inch LHSI suction pipes has its own suction opening connected to the strainer header. The strainer header is slip fit in to the suction opening located in the containment sump via a flanged transition adapter piece.

The design of the LHSI strainer assembly is similar to the design of the RS strainer assembly. Refer to Section 6.3.1.3 for further information.

6.2.2.3 **Electrical Supply**

Details of the normal and emergency power source for the safety injection system are presented in Chapter 8.

6.2.2.4 **Protection Against Dynamic and Environmental Effects**

The high-head safety injection lines penetrate the containment adjacent to the auxiliary building.

For most of the routing, these lines are outside each reactor coolant loop cubicle and hence are protected from missiles originating within these areas. Each line penetrates the cubicle wall near the injection point to the reactor coolant pipe. In this manner, maximum separation, and hence protection, is provided in the coolant loop area.

Coolant loop supports are designed to restrict the motion in one loop due to rupture in another to about 0.1 inch, whereas the attached safety injection piping can sustain a three-inch displacement without exceeding the working stress range. The analysis assumes that the injection flow to the ruptured loop is spilled on the containment floor.

Hangers, stops, and anchors are designed in accordance with USAS B31.1 *Code for Pressure Piping,* and ACI 318 *Building Code Requirements for Reinforced Concrete,* which provide minimum requirements on materials, design, and fabrication with ample safety margins for both dead and dynamic loads over the life of the equipment. Specifically, these standards require the following:

1. All materials used are in accordance with ASTM specifications, which establish quality levels for the manufacturing process, minimum strength properties, and for test requirements that ensure compliance with the specifications.
2. Qualification of welding processes and welders for each class of material welded and for types and positions of welds.
3. Maximum allowable stress values are established that provide an ample safety margin on both yield strength and ultimate strength.

In the event of the hypothetical double-ended severance of a reactor coolant pipe, the functional integrity of the safety injection system connections to the remaining reactor coolant loops is not impaired. This integrity is established and maintained by the application of the following design criteria:

1. The reactor vessel, steam generators, and safety injection pumps are supported and restrained to limit their movement under pipe break conditions (including a double-ended reactor coolant pipe rupture) to a maximum amount, which ensures the integrity of the main steam and feedwater piping. The safety injection piping to the intact loops is designed to accommodate the limited movement of the loop components without failure.
2. The safety injection piping serving each loop is anchored at the missile barrier in each loop to restrict incident damage to that portion of piping downstream of this point. The anchorage is designed to withstand without failure the thrust force on the safety injection branch line severed from the reactor coolant pipe discharging safety injection flow to the containment, and to withstand a bending moment equivalent to that which produces failure of the safety injection piping under the action of free-end discharge or motion of the broken reactor coolant pipe to which the safety injection piping is connected. This anchorage prevents possible failure upstream from the support point where the branch line ties in to the safety injection piping header.

The safety injection system operating equipment located outside the containment is not required to operate in the steam-air environment produced by the accident.

Motors, instruments, transmitters, and their associated cables and penetrations located inside the containment are designed to function under postaccident temperature, pressure, and humidity conditions for the length of time required.

6.2.3 Design Evaluation

6.2.3.1 Range of Core Protection

The measure of effectiveness of the safety injection system is the ability of the pumps and accumulators to keep the core flooded or to reflood the core rapidly where the core has been uncovered for postulated large-area ruptures. The result of this performance is to sufficiently limit any increase in clad temperature below a value where emergency core cooling objectives are met, as discussed in Section 6.2.1. The range of core protection as a function of break diameter provided by the various components of the safety injection system is presented in Figure 6.2-2.

Figure 6.2-2 was developed from the results of the LOCA studies presented in Section 14.5. Simulations of a sufficient number of break sizes were performed to demonstrate that the safety injection components meet the emergency core cooling requirements. The injection from the following combination of components was analyzed as discussed below:

Bar A - One safety injection charging pump.

Bar B - One safety injection charging pump and three accumulators.

Bar C - One low-head safety injection pump and two accumulators.

Bar D - One safety injection charging pump and three accumulators (small break LOCA). One safety injection charging pump, one low-head safety injection pump, and two accumulators (large break LOCA).

Note: For all of the cases, one low-head safety injection pump is required for long-term recirculation.

No credit is taken for the accumulator that is attached to the ruptured leg in the case of a cold-leg large break LOCA.

With minimum onsite emergency power available, the emergency core cooling equipment available automatically is represented by Bar D (one-out-of-three safety injection charging pumps, and three-out-of-three accumulators for a small cold-leg break; one-out-of-three safety injection charging pumps, one-out-of-two low-head safety injection pumps, and two-out-of-three accumulators for a large cold-leg break, and three-out-of-three accumulators for a hot-leg break). With these systems, the calculated maximum fuel cladding temperature is within the limits specified in 10 CFR 50.46, which meet the emergency core cooling design objectives for all break sizes up to and including the double-ended severance of the reactor coolant pipe (Section 14.5).

The three combinations (Bars A, B, and C) represent degraded cases with operation of less than the installed emergency core cooling equipment. These cases are shown only to present the capability of individual portions of the system and to demonstrate the overall margins of the system. The operation of one safety injection charging pump together with two accumulators is probably capable of providing protection over a considerably greater range than shown. However, the analysis has only considered breaks up to the 8-inch diameter.

Bar D, which is the combination of the safety equipment in Bars B and C, and which also represents the minimum engineered safeguards available automatically, provides protection as shown over the complete range of break sizes up to and including the complete circumferential fracture of a reactor coolant pipe.

For the small range of break sizes up to 2 inches, as shown in Bar A, the action of one safety injection charging pump acting alone is sufficient to maintain enough core water inventory to ensure continued core cooling.

6.2.3.2 **Borated Water Injection Chemistry**

During the injection of emergency cooling water into the reactor coolant system following a LOCA, the concentration of boron will vary depending on the depressurization history of the reactor. If depressurization were slow, the high-head pumps would inject boric acid at a concentration greater than 2300 ppm, which would be diluted by the coolant remaining in the system. Rapid depressurization would bring about early injection of water containing boric acid at a concentration greater than 2250 ppm from the accumulators. When recirculation begins, the average concentration of boric acid is (and will remain) at a concentration that will maintain the core subcritical.

The concentrations of other materials, including chlorides, are quite low in this solution, corrosion products being generally insoluble in a basic solution. Assuming 50% of the maximum core inventory is released to containment after a LOCA, the principal fission product in the sump (assuming a gross core failure) would be iodine at a range between approximately 1.6 to 1.9 ppm for 500 days of operation and approximately 3.0 to 3.6 ppm for 1000 days of operation. The temperature of the sump water is reduced below 150°F, under normal operating conditions with a minimum of two recirculation coolers in operation, after a relatively short period of time (i.e., a few hours). Below 150°F, chloride stress corrosion does not constitute a problem.

6.2.3.3 **Chemical Additives**

Containment transient analyses show that the containment spray, having a pH between 4.25 and 4.75, will be used for approximately 1½ hours if minimum safeguards operate and approximately 50 minutes if normal safeguards operate. During this period, the containment will be cooling from 280°F to approximately 140°F. At the end of the initial containment cooling period, lasting no longer than approximately one hour, the recirculation spray system will continue in service for an indefinite period; however, the pH of the recirculating spray fluid should be between 7.0 and 9.0 during the long-term postaccident period and further addition of chemical additives is not contemplated.

Sodium Tetraborate Decahydrate stored inside containment is a white crystalline chemical in granular form. The NaTB is stored inside baskets which contain the chemical until it is dissolved by the containment sump water. To eliminate particulate matter from any potential source, the containment spray subsystem includes a strainer on the suction side of the containment spray pumps. This strainer will have openings smaller than the smallest spray nozzles, and therefore will remove any particulate matter from the containment spray flow that might prevent the system from functioning. Additionally, using NaTB as a buffer does not result in any different precipitates than those that form with the original NaOH buffer and the amount of precipitates is reduced, resulting in lower strainer head losses. Therefore, the functioning of the system will not be impaired because of precipitation.

The major construction materials that will be exposed to the containment spray, and the corrosion or deterioration rates for each under maximum exposure conditions, are listed in Table 6.2-7.

The materials adversely affected by the containment spray are aluminum and zinc.

The time-temperature exposure conditions under which these materials will be exposed to the containment spray are from approximately 50 minutes to 1½ hours, with the temperature decreasing from 280° to 140°F.

The materials will also be exposed to the recirculation sprays, which have a pH between 7.0 and 9.0 for the postaccident recirculation period with the temperature at approximately 140°F.

The consequence of corrosion and/or deterioration on materials with regard to postaccident operation of the engineered safeguards is negligible because components of the engineered safeguards are constructed of stainless steel.

The corrosion rate of stainless steel is low enough in the spray to be of no practical concern (Reference 1).

Insulated, safety-related cables feed power to the engineered safeguards equipment. The safety-related insulation is impervious to the chemical spray solution. Therefore, the supply of power to the engineered safeguards components will not be impaired.

No additional hazards will be generated by the deterioration or corrosion of the materials in the containment because materials of construction, other than aluminum and zinc, are either impervious to the chemical additive spray or painted with chemical-resistant coatings. The coatings have been successfully tested under design-basis accident conditions of irradiation and high-temperature chemical spray to ensure that they will remain intact.

6.2.3.4 **System Response**

To provide protection for large-area ruptures in the reactor coolant system, the safety injection system must respond by rapidly reflooding the core following the depressurization and core voiding that is characteristic of large area ruptures. The accumulators act to perform the rapid reflooding function with no dependence on the normal or emergency power sources and also with no dependence on the receipt of an actuation signal.

The operation of this system with two of the three available accumulators delivering their contents to the reactor vessel (one accumulator spilling through the break) prevents fuel clad melting and limits the metal-water reaction to an insignificant amount (less than 1%).

The function of the safety injection pumps is to complete the refill of the vessel and supply water for long-term core cooling. Moreover, there is sufficient excess water delivered by the accumulators to tolerate a delay in starting the pumps.

Initial response of the injection systems is automatic, with appropriate allowances for delays in the actuation of circuitry and active components. The active portions of the injection systems are automatically actuated by the safety injection signal (Chapter 7). In addition, manual actuation of the entire injection system and individual components can be accomplished from the control room. In the analysis of system performance, delays in reaching the programmed trip points and in the actuation of components were conservatively established on the basis that only emergency onsite power was available.

The starting sequence of the safety injection charging pumps, the low-head safety injection pumps, and the related emergency power equipment is designed so that the delivery of the full rated flow is reached within 25 seconds after the process parameters reach the setpoints for the injection signal (Section 7.2).

For the small-break analysis, an additional delay time is allowed to account for the receipt of a safety injection signal, from low pressurizer pressure.

6.2.3.5 **Single-Failure Analysis**

A single-active-failure analysis is presented in Table 6.2-8. All credible active system failures are considered. The analysis of the LOCA presented in Section 14.5 is consistent with the single-failure analysis.

The analysis is based on the worst single failure (generally a pump failure) in the safety injection system. The analysis shows that the failure of any single active component does not prevent fulfilling the design function; also, operator action is not required to correct the malfunction.

In addition to the single-active-failure capability, an alternate flow path is available to maintain core cooling if any part of the recirculation flow path becomes unavailable. The procedure followed to establish the alternate flow path also isolates the spilling line.

Failure analyses of the emergency power supply under LOCA conditions are described in Section 8.5.

6.2.3.6 **Reliance on Interconnected Systems**

Though the safety injection system relies on support systems, such as service water, component cooling water and electrical interfaces, the flow of the water via the safety injection pumps during the injection phase is not dependent on any portion of other interconnected systems with the exception of the suction line from the refueling water storage tank. During the recirculation phase of the accident for small breaks, suction to the safety injection charging pump is provided by the low-head safety injection pumps.

To maintain the containment subatmospheric, spray recirculation and cooling must be continued following a LOCA. Initially, spray recirculation is continuous, but as the core residual heat level decreases, the recirculation is reduced and, eventually, the system may be operated intermittently.

Since heat removal from the containment must be accomplished initially through the containment spray and recirculation spray subsystem, and since this represents a more than adequate heat removal mechanism for the containment, the use of heat exchangers in the low-head safety injection system for cooling is not required. The low-head safety injection system operates to provide long-term core cooling with no heat exchangers in the system by using water from the containment sump.

6.2.3.7 **Shared Function Evaluation**

Table 6.2-9 is an evaluation of the main components, which have been previously discussed, and a brief description of how each component functions during normal operation and during an accident.

6.2.3.8 **Passive Systems**

The accumulators are a passive safety feature, in that they perform their design function in the total absence of an actuation signal or power source. The only moving parts in the accumulator injection train are in the two check valves. A discussion of the design of the accumulator check valves and isolation valves is provided in Sections 6.2.2.2.7 and 6.2.2.2.8, respectively.

The accumulators are able to accept leakage from the reactor coolant system without any effect on their availability. Table 6.2-10 indicates what inleakage rates, over a given time period, require a level adjustment at the end of the time period. In addition, these rates are compared to the maximum allowed leak rates for manufacturing acceptance tests (36 cm^3/hr, i.e., 3 cm^3/hr per inch of pipe diameter).

The accumulators are located inside the reactor containment and protected from the reactor coolant system piping and components by missile barriers. A release of the gas charge in the accumulators would cause an increase in the containment peak pressure of approximately 0.2 psi. This release of gas has been included in the containment pressure analysis for the LOCA (Section 14.5).

During normal operation, the flow rate through the reactor coolant piping is approximately 2.6 times the maximum flow rate from an accumulator during injection. Therefore, fluid impingement on reactor vessel components as a result of accumulator discharge is not restrictive during the actuation of the accumulators.

6.2.3.9 **Emergency Flow to the Core**

Special attention is given to factors that could adversely affect the accumulator and safety injection flow to the core. These factors are:

1. Steam binding in the core, including flow blockage due to loop sealing.
2. Loss of accumulator water during blowdown.
3. Short circuiting of the accumulator discharge from the core to another part of the reactor coolant system.

6.2.3.10 **External Recirculation Loop Leakage**

Table 6.2-6 summarizes the original design maximum potential leakage from leakage sources in the recirculation loop through the low-head safety injection pumps, and through the safety injection charging pumps. The actual allowable leakage for each individual component can exceed the original criteria established in Table 6.2-6.

Leakage detection exterior to the containment is achieved through the use of sump-level detection. The auxiliary building sump pumps start automatically in the event that liquid accumulates in the sump and an alarm in the control room indicates that water has accumulated in the sump. A level switch is installed in the safeguards valve pit cubicle which alarms in the main control room with pumps used as necessary to transfer fluid to the liquid waste system. Valving is provided to permit the operator to isolate individually the low-head safety injection pumps.

The injection line piping is arranged so that a water seal is provided upstream of the valves located outside the containment, and this piping can be isolated from the containment. Thus, outleakage of air from the containment to the refueling water storage tank and hence to the atmosphere is prevented.

6.2.3.11 **Pump NPSH Requirements**

To ensure adequate NPSH for the LHSI and RS systems, a combination of flow restriction, recirculation flow feedback, and spray header nozzle plugging designs are included in the present system designs.

6.2.3.11.1 Low-Head Safety Injection Pumps

The net positive suction head of the low-head safety injection pumps is evaluated for both the injection and recirculation phases of the design-basis accident. Recirculation operation gives the limiting NPSH requirement, and the net positive suction head available is determined from the containment pressure and sump water level, pump water vapor pressure and the pressure drop through the strainer assembly to the pumps.

Each of the three low-head safety injection pump discharge lines to the cold leg loops contains a cavitating venturi that limits flow to prevent pump runout and ensures that the required net positive suction head will be met for all phases of operation following a LOCA.

During the injection phase, the low-head safety injection pump flow rate will vary with reactor coolant system pressure, containment pressure, and refueling water storage tank level. During the recirculation mode, the low-head safety injection pump flow will vary with reactor coolant system pressure, the vapor pressure (and hence temperature) of the sump water, and injection path (cold leg or hot leg). Evaluation of the low-head safety injection systems show that a single low-head safety injection pump will deliver the necessary low-head core cooling flow for any postulated set of accident conditions during the injection phase or the recirculation mode phase.

The refueling water storage tank level setpoint to initiate the automatic switchover of the low-head safety injection pumps from taking a suction on the refueling water storage tank to taking a suction from the containment sump strainer is consistent with the containment spray pump and low-head safety injection pump flow rates. Section 6.3.1 presents the setpoints used in the analysis.

The refueling water storage tank temperature will be maintained below 45°F. It is conservative to use the upper extreme for the NPSH analysis, since refueling water storage tank water is used as the subcoolant to the outside recirculation spray pumps. The upper extreme is also conservative for the depressurization analysis because it is less effective as a heat sink.

The analysis of available NPSH for the LHSI pumps during recirculation is performed with the GOTHIC computer program as described in Section 5.4. The analysis is similar to that performed in Section 5.4, except that the energy flow to the containment sump is maximized instead of the energy flow to the containment atmosphere as is done for containment pressurization and depressurization analyses. The analysis maximizes the sump water vapor pressure and minimizes the containment pressure. Thus, a conservatively low available NPSH is calculated.

The parameters which are used in the transient available NPSH calculation for the LHSI pumps are specified in the Table 6.2-11. The results of the analyses are summarized in Table 6.2-12.

The transient available NPSH is shown on Figure 6.2-3. The containment sump water level is also shown on the figure. The NPSH analyses account for the 12" Incore Sump Room drain in the determination of containment water level. The available NPSH transient begins when the LHSI pump suctions are switched to the sump (i.e., start of recirculation mode). The minimum available NPSH for these pumps is calculated for minimum ESF available following a DEPSG. Under these conditions, the water temperature is maximized by the break location assumption and the sump water cooling is minimized since only one train of containment spray and recirculation spray cooling are available. The containment pressure and sump water vapor pressure for the analysis is shown in Figure 6.2-4. The sump water temperature is shown on Figure 6.2-5. The recirculation spray heat exchanger duty is shown in Figure 6.2-6.

6.2.3.11.2 Safety Injection Charging Pumps

The net positive suction head for the safety injection charging pumps is evaluated for both the injection and recirculation phases of the design-basis accident.

The end of injection phase operation gives the limiting NPSH requirement, and the net positive suction head available is determined from the elevation head and vapor pressure of the water in the refueling water storage tank, and the pressure drop in the suction piping from the tank to the pumps.

6.2.3.11.3 Recirculation Spray Pumps

A discussion of the recirculation spray pump requirements is found in Section 6.3.1.4.

To provide cold water injection to the outside recirculation spray pumps, a 2.5-inch line with an orifice is rerouted from each 10-inch containment spray line inside containment and is hard piped to the respective outside recirculation spray strainer header. A restriction orifice in this bleed line results in a flow of approximately 310 gpm (actual flow varies with containment conditions) of chilled water from the refueling water storage tank to the outside pump suction. This piping is inside containment and designed to withstand seismic effects and water hammer. The containment spray pump that provides the water to the pump suction for a given outside recirculation spray pump is powered from the same emergency bus as that outside pump.

Each inside recirculation spray subsystem includes a minimum analyzed flow back to the pump suction of 300 gpm of recirculation spray water from the outlet of its inside spray cooler. The piping runs inside the containment and is designed for seismic effects and water hammer. A restriction orifice in the 2.5-inch line provides the desired minimum 300 gpm flow back to the pump suction. Material and installation are consistent with the design for the recirculation spray subsystem.

The inside recirculation spray pumps were originally designed to pump a 3500 gpm flowrate, however, analysis has shown that 3100 gpm is adequate for containment response to meet the requirements during a design basis accident. With a minimum of 3100 gpm inside recirculation pump flowrate the spray nozzle flow will be a minimum of 2800 gpm for each of the inside pump spray headers.

To limit the flowrate of the outside recirculation spray pumps to approximately 2900 gpm, additional flow restriction has been created by plugging nozzles and adding restriction orifices.

The results of the NPSH analysis for the inside and outside recirculation spray pumps are shown on Table 6.2-13.

6.2.3.12 **Combustible Gas Control in Containment Following a DBA**

6.2.3.12.1 Design Evaluation

The hydrogen recombiner system is designed to maintain the hydrogen concentration in the containment structure below 4 volume percent following a DBA.

Per References 11 and 12, the hydrogen recombiner system is no longer credited in the design basis or safety analysis. However, the system continues to be used in the Emergency Operating Procedures (EOPs) and is maintained and periodically tested.

The internal design of the containment structures allows air to circulate freely. All cubicles and most compartments within the containment are provided with openings near the top as well as openings in the floor to allow air circulation. Convective mixing in conjunction with containment spray assures a uniform mixture of hydrogen in the containment.

Containment system experiment tests (References 2 & 3) have verified that adequate mixing of the containment atmosphere is achieved by the CSS.

6.2.3.13 **Combustible Gas Control in Containment During Non-Accident Conditions**

The portable non-safety Passive Autocatalytic Recombiner (PAR) will be used for the purpose of controlling transient levels of hydrogen in the containment’s atmosphere during normal operation. When in use, the passive recombiner is attached with wire rope to existing grating located over a reactor coolant pump cubicle. The recombiner may be stored in either Unit’s containment until needed.

The PAR was designed for Advanced Light Water Reactor (ALWR) application and is completely passive in operation, requiring no power or other support systems to serve its function. The PAR device consists of a stainless steel enclosure providing both the structure for the device and support for the catalyst material. The enclosure is open on the bottom and top and extends above the catalyst elevation to provide a chimney effect. The PAR is self starting even at room temperature with hydrogen and oxygen at concentrations far below flammability levels. The catalyst material is contained within cartridges mounted vertically within the enclosure with open gas flow channels between them. The pellets are non-soluble and will not contribute to sump pH problems. The aluminum oxide ceramic pellets are doped with palladium particles and feature a coating which has water proofing properties. The aluminum oxide ceramic pellets will themselves not generate any hydrogen from corrosion. Some pellets may crack under the high temperatures expected during severe accidents, but are not expected to migrate out of their cartridge. The PAR is self feeding, with recombination rate increasing with increasing concentrations.

During operation, the air inside the recombiner is heated by the recombination process, causing it to rise by natural convection. As is rises, replacement air is drawn into the recombiner through the bottom of the PAR and heated by the exothermic reaction, forming water vapor, and exhausted through the chimney where the heated gases mix with the containment atmosphere. A 140-176°F temperature rise across the PAR is expected for every 1% H_2 in the air. At a hydrogen concentration of 0.8%, the device will generate approximately 2500 Btu/hr. This additional heat load will pose a negligible impact on the existing containment ventilation arrangement.

6.2.4 Tests And Inspections

The Safety Injection System is subject to the applicable inservice inspection and inservice testing requirements of the ASME Code, as required by 10 CFR 50 (Code of Federal Regulations, Title 10, Part 50). Other testing and inspections are conducted to ensure availability of equipment.

6.2.4.1 **Tests**

The following information is HISTORICAL and is not intended or expected to be updated for the life of the plant.

6.2.4.1.1 Preoperational Component Testing

Preoperational performance tests of safety injection system components were performed in the manufacturer’s shops. The pressure-containing parts of the pumps were hydrostatically tested in accordance with paragraph UG-99 of Section VIII of the ASME Code. Each pump was given a complete shop performance test in accordance with Hydraulic Institute standards. The pumps were run at design flow and head, shutoff head, and at additional points to verify performance characteristics. Net positive suction head was established at design flow by means of adjusting suction pressure for a representative pump. This test was witnessed by qualified Westinghouse and Vepco personnel.

The remote-operated valves in the safety injection system are motor or air operated. Shop tests for each valve included a hydrostatic pressure test, leakage tests, a check of opening and closing time, and verification of torque switch and limit switch settings. The ability of the operator to move the valve with the design differential pressure across the gate was demonstrated by opening the valve with an appropriate hydrostatic pressure on one side of the valve.

The recirculation piping and accumulators were initially hydrostatically tested at 150% of design pressure. The service water and component cooling water pumps were tested before initial operation.

The following information is HISTORICAL and is not intended or expected to be updated for the life of the plant.

6.2.4.1.2 Preoperational System Testing

After hot functional testing and before initial fuel loading, the safety injection system was operationally tested. These tests included individual pump full-flow tests, accumulator operation, and complete system operational flow tests, with the reactor head removed. The purpose of this test was to demonstrate the proper functioning of the instrumentation and actuation circuits and to evaluate the dynamics of placing the system in operation. Water was supplied from the refueling water storage tank for this series of tests. The actuation of the pressurizer low level and pressure signals initiates the automatic start-up of the safety injection system.

The operability of the accumulators was checked by closing the stop valve, raising the pressure in the accumulator, and then opening the stop valve and observing the accumulator level change to provide an indication of system delivery. An additional check on system delivery can be made by observing the pressurizer level rise.

6.2.4.1.3 Refueling Tests

Portions of the safety injection system that can not be tested during normal plant operation are verified to operate properly through a series of tests during refueling. The refueling tests, in combination with the tests performed during normal plant operation, are used to demonstrate proper automatic operation of the safety injection signal. The tests are considered satisfactory if control board indication and visual observations indicate that all components have operated and sequenced properly. The automatic actuation circuitry, valves, and pump circuit breakers are also checked during these tests.

Back leakage through the accumulator discharge line check valves is monitored by opening the remote test valves in test lines between the remote stop valves and check valves. Flow through the test lines is measured to ascertain that these valves seat whenever the reactor system pressure is raised.

6.2.4.1.4 Normal Operation

Each active component of the safety injection system may be individually actuated on the normal power source at any time during the operation of the unit to demonstrate operability.

The chemical and volume control system charging pumps serve as the high-head safety injection pumps. As such, the operability of any pump can be demonstrated while the unit is at power. Demonstration tests can be performed at other times by employing the minimum flow recirculation line that returns to the discharge line of the volume control tank.

The test of the low-head safety injection pumps employs the minimum flow recirculation test line that returns to the refueling water storage tank. Remote-operated valves and actuation circuits are also periodically tested.

The accumulator pressure and level is continuously monitored during station operation.

The accumulators and the injection piping up to the final isolation valve are maintained full of borated water while the station is in operation. The boron concentration in the line may be diluted due to check valve back-leakage from the RCS. The accumulators are refilled with borated water as required by using the positive-displacement hydrotest pump. The boron concentration in the accumulators is sampled periodically.

The length of pipe between the valve pit and the pump suction for the safety injection system is ≈3 feet. This run of pipe is embedded in concrete. The length of pipe between the valve pit and the pump suction for the outside recirculation spray system is ≈10 ft. 6 in. The pipe employed is 12-inch, Schedule 40S, fabricated of ASTM A358, Type 304 material, in accordance with Code for Pressure Piping USAS B31.1.0, 1955 edition, plus Code Cases N-1 and N-7.

Under normal plant operating conditions, the recirculation spray piping in the valve pit is maintained dry and the low-head safety injection piping in the valve pit is subjected to RWST head pressure. Heavy wall piping has been used, and welds have been radiographed during construction.

The methods of leak detection for the piping are as follows:

Large leaks in the suction piping, which is located in the valve pit, will be detected by the following devices: (1) liquid level measuring instrumentation, (2) exhaust ventilation radiation monitor, (3) outside recirculation spray pump discharge pressure instrumentation, (4) low head safety injection flow rate instrumentation, (5) outside recirculation spray pump motor amperage instrumentation, and (6) low head safety injection pump motor amperage instrumentation. Upon detection of a potential leak from any of these sources, control room personnel will identify the affected flow path by observation of the system parameters.

With the leak path identified, the operator in the control room has the capability to remote manually isolate the leaking subsystem, leaving one recirculation loop and one safety injection loop operable, if required.

The volume of water required in the valve pit to actuate the high water level alarm in the control room is 400 gallons. A small leak rate, which may be defined as 10 percent of the total flow in the piping, will cause the alarm to sound in less than 90 seconds since the total flow in the piping is 3000 to 3500 gpm.

In the case of small leaks, specific detection of a leak is not possible; however, when the operation of these systems is initiated, the same signal diverts the ventilation air from the structure enclosing the piping outside the containment through charcoal filters. Thus, no escape of unfiltered gases or liquid to the outside environment can occur.

6.2.4.1.5 Gas Accumulation in ECCS Piping

The HHSI suction line vent valves have been installed to allow venting during operations or during non-operating vent and fill procedures to minimize the possibility of gas intrusion into the HHSI pumps. Similarly, the LHSI discharge line vent valves are used to reduce the potential for pressure surges, which may challenge the LHSI discharge line thermal relief valves upon LHSI pump starts. The LHSI discharge piping to the HHSI suction (piggy-back line) vent valves are used to minimize both the possibility of gas intrusion into the HHSI pumps and the potential for pressure surges in the LHSI discharge lines (Reference 10).

Following equipment maintenance or refueling outages where an ECCS subsystem is opened, some entrained non-condensable gases remain. Each ECCS subsystem is filled and vented in a manner deemed appropriate for removal of gases. Each ECCS subsystem is demonstrated operable prior to return to service by verifying that the ECCS piping is sufficiently full of water through Ultrasonic Testing (UT), venting or other means (Reference 20).

Accessible portions of ECCS subsystems that are susceptible to gas sources are demonstrated operable periodically by verifying that the ECCS piping outside of containment is sufficiently full of water through Ultrasonic Testing (UT), venting or other means. Maintaining the piping in the ECCS sufficiently full of water as determined by engineering analysis ensures that the system will perform properly when required to inject into the RCS. Specifically, this will prevent gas-water hammer, degraded system performance, and cavitation and gas binding of the ECCS pumps due to gas accumulation in the piping. It will also reduce the potential for pumping of non-condensable gases (e.g., air, nitrogen, or hydrogen) into the reactor vessel following an SI signal or during shutdown cooling. The ECCS discharge is inaccessible during reactor operations due to subatmospheric conditions, safety concerns and radiological concerns. The ECCS discharge piping inside containment is filled and vented upon system return to service (Reference 20).

6.2.4.2 **Inspections**

Quality standards of safety injection system components are presented in Table 6.2-3.

All components of the safety injection system are inspected periodically to demonstrate system readiness.

The pressure-containing components are inspected for leaks from pump seals, valve packing, flanged joints, and safety valves during system testing.

Piping	USAS B31.1

Table 6.2-2
SAFETY INJECTION CONTROL BOARD INDICATION

I. VALVES

System	Actuation Position on Injection	Valve No.	Description
SIS	Open	MOV-867 C, D	HHSI to RCS cold leg isolation
SIS	Normally closed	MOV-842	HHSI to RCS cold leg isolation - alternate header
SIS [c]	Normally open	MOV-865 A, B, C	SI accumulator isolation valves
SIS [a]	Shut	MOV-890 A, B	Low-head SI to RCS hot leg isolation
SIS [a]	Open	MOV-890 C	Low-head SI to RCS cold leg isolation
SIS [c]	Normally open	MOV-862 A, B	RWST to low-head SI pump isolation
SIS	Normally closed	MOV-860 A, B	Containment sump to low-head SI pump isolation valve
SIS	Normally closed	MOV-863 A, B	Low-head to high-head SI pump isolation
SIS [c]	Normally open	MOV-885 A, B, C, D	Low-head pump miniflow isolation
SIS [a, c]	Shut	MOV-869 A, B	High-head SI to RCS hot-leg isolation
SIS/CVCS	Closed	MOV-289 A, B	Normal charging isolation
SIS	Open [b]/Closed	TV-102 A, B, TV-202 A, B	RWST cross tie isolation

a. During normal operation, these valves are placed in the position shown and power is removed from the motor operator.
b. Associated trip valves open only on a steam line break (SLB) signal, otherwise trip valves remain closed.
c. These valves actuate an alarm in the control room when not in the normal position.

Notes: Individual position lights are included to indicate the full-open or full-closed position of each valve. These lights function for MOVs only when the valve motor operator power circuit is energized.

SIS = safety injection system
CVCS = chemical and volume control system
RWST = refueling water storage tank
VCT = volume control tank

Table 6.2-4
ACCUMULATOR DESIGN PARAMETERS

Number	3	
Type	Stainless steel lined/carbon steel	
Design pressure	700	psig
Design temperature	300°F	
Operating temperature	80-105°F	
Normal operating pressure	600-665	psig
Total volume	1450	ft^3
Minimum water volume at operating conditions	975	ft^3
Minimum boron concentration (as boric acid)	2250	ppm
Relief valve setpoint [a]	700 psig	

a. The relief valves have soft seats and are designed and tested to ensure zero leakage at the normal operating pressure.

Table 6.2-5
PUMP PARAMETERS[a]

Safety Injection Charging Pumps	
Number of pumps (per unit)	3
Design pressure, discharge	2735 psig
Design pressure, suction	150 psig
Design temperature	250 °F
Design flow rate	150 gpm
Maximum continuous runout flow rate	550 gpm[b]
Design head	5800 ft
Type	Horizontal centrifugal
Low-Head Safety Injection Pumps	
Number of pumps (per unit)	2
Type	Vertical centrifugal
Design pressure, discharge	150 psig
Design temperature	230°F
Design flow	3000 gpm
Design head	225 ft
Maximum flow rate	4000 gpm

a. Design information only. Various HHSI and LHSI system flow requirements are given in the appropriate system analyses.
b. Maximum continuous runout limit for 1-CH-P-1B is 575 gpm.

Table 6.2-6
TOTAL POTENTIAL EXTERNAL RECIRCULATION LOOP LEAKAGE TO ATMOSPHERE FROM THE SAFETY INJECTION SYSTEM

Items	Type of Leakage Control and Unit Leakage Rate Used in the Analysis [a]
Low-head safety injection pumps	Mechanical seal with leakoff - four drops per minute
Safety injection charging pumps	Mechanical seal with leakoff - four drops per minute
Flanges	Gasket - adjusted to zero leakage following any test - 40 drops per minute, per flange used in analysis
Pump	
Valves, bonnet to body (larger than 2 inches)	
Valves - stem leakoffs	Double packing with leakoff - 4 cm^3/hr/in stem diameter
Valves - stem leakoffs capped	Leakoff - 4 cm^3/hr/in stem diameter
Miscellaneous valves	Flanged body packed stem - four drops per minute
	Total Potential Leakage 3836 cc/hr

a. Unit leakage rates are original design criteria. The actual allowable leakage for each leakage control component may exceed the original leakage rate indicated as long as the total external recirculation loop leakage does not exceed 12,000 cc/hr as required by Section 14.5.5.3.

Table 6.2-7
CONSTRUCTION MATERIAL EXPOSURE TO CONTAINMENT SPRAY

Material	Corrosion Rate[a]
Carbon steel [b]	0.0
Stainless steel	0.0
Concrete [b]	0.0
Mineral wool	0.0
Calcium silicate and Unibestos	0.0
Aluminum	12.0 $mg/dm^2/hr$ [c]
Zinc (paint and galvanizing on steel)	0.04 $mg/dm^2/hr$ [c]
Copper	0.0
90-10 copper nickel	0.0
Polyethylene and neoprene	0.0

The maximum total duration of use for the containment spray system is approximately 60 minutes.

---

a. Less than 1 mil/yr considered to be zero corrosion rate.

b. Painted with Corlar Epoxy Chemical Resistant Enamel, which is a polyamide catalyzed epoxy resin paint.

c. Corrosion rate at 140°F, maximum exposure temperature after 1 hour. Aluminum has corrosion rate of less than 800 $mg/dm^2/hr$ at peak temperature.

Table 6.2-8
SINGLE-ACTIVE-FAILURE ANALYSIS OF SAFETY INJECTION SYSTEM

Component	Malfunction	Comments
A. Accumulator (injection phase)	Delivers to broken loop	Totally passive system with one accumulator per loop. Evaluation based on two accumulators delivering to the core and one spilling from ruptured loop.
B. Pump (injection phase)		
1. Safety injection charging	Fails to start	Three provided. Evaluation based on operation of one.
2. Low-head safety injection	Fails to start	Two provided. Evaluation based on operation of one.
C. Automatically operated valves (open on safety injection signal) (injection phase)		
1. Isolation valves at discharge of high-head safety injection pumps (cold-leg injection)	Fails to open	One of two parallel valves is required to open.
2. Low-head safety injection pump discharge isolation valves (cold-leg injection)	Fails to open	One line from each pump leading to common discharge header. Isolation valve in this line locked open.
3. Accumulator stop valves	Fails to open	One valve per accumulator, normally open, or opened if initially closed. Analysis assumes all three accumulator stop valves are open.
4. Refueling water storage tank to charging pump return valves	Fails to open	Two in parallel; one out of two is assumed to open.
D. Valves automatically closed on safety injection signal		
1. Charging line injection	Fails to close	Two valves in series are provided wherever closure is required.
2. Volume control tank discharge	Falls to close	Two valves in series are provided wherever closure is required.
E. Valves operated for recirculation		
1. Containment sump	Fails to open	Two lines in parallel; one valve either line is required to open.
2. High-head safety injection pump suction valve from low-head safety injection pump discharge	Fails to open	One recirculation line from each low-head pump. One motor-operated valve in each line, one of which must open.

Table 6.2-8 (CONTINUED)
SINGLE-ACTIVE-FAILURE ANALYSIS OF SAFETY INJECTION SYSTEM

Component	Malfunction	Comments
3. Isolation valve at suction header of low-head safety injection pump from refueling water storage tank	Fails to close	Motor valve and check valve in series. Motor valve required to close backed up by check valve.
4. Isolation valves suction to high-head safety injection pumps	Fails to close	Two motor valves in parallel, backed up by check valve and administratively controlled, normally open manual gate valve.
5. Isolated valves on the low-head safety injection system minimum flow or a test line returning to the refueling water storage tank	Fails to close	Two motor-operated valves in each minimum flow line in series with a check valve in each line.
6. Discharge valve on high-head safety injection pump	Fails to close	All are normally open. Failure of one to close does not prevent a separate recirculation path from the high-head safety injection pump discharge.
7. Suction valve on high-head safety injection pump	Fails to close	All are normally open. Failure of one to close does not prevent a separate recirculation path from the containment sump to the suction of the high-head safety injection pumps.

Table 6.2-9
SHARED FUNCTIONS EVALUATION

Component	Normal Operating Function	Normal Operating Arrangement	Accident Function	Accident Arrangement
Refueling water storage tank	Storage tank for refueling	Lined up to suction of high-head safety injection charging, low-head safety injection, and containment spray pumps	Source of borated water for core and containment cooling	Line up to suction of high-head safety injection charging, low-head safety injection, and containment spray pumps
Accumulators (3)	None	Lined up to discharge to cold legs of reactor coolant piping	Fast supply of borated water to core	Lined up to discharge to cold legs of reactor coolant piping
Safety injection charging pumps (3)	Charging	Take suction from volume control tank and discharge to normal charging connections	Supply borated water to core	Lined up to take suction from refueling water storage tank and discharge to hot and cold legs of reactor coolant piping
Low-head safety injection pumps (2)	None	Lined up to take suction from refueling water storage tank and discharge to reactor coolant piping	Supply borated water to core	Line up to take suction from refueling water storage tank and discharge to reactor coolant piping

Table 6.2-10
ACCUMULATOR INLEAKAGE [a]

Observed Leak Rate (cc/hr)	Time Period Between Level Adjustments (hours)
543	1703
272	3399
30.3	30,513

a. A maximum of approximately 30 ft^3, added to the initial amount, can be accepted in each accumulator before an alarm is sounded. The Technical Specifications establish the minimum and maximum water volume in each SI accumulator.

6.3.1 Spray System

6.3.1.1 Design Bases

The spray system consists of the containment spray subsystem and the recirculation spray subsystem, which are designed to provide the necessary cooling and depressurization of the containment after any LOCA. Spray system component data are given in Table 6.3-1.

Safety related components, piping, valves, and supports in the spray system are Seismic Category I.

The subsystems, operating together, cool and depressurize the containment to subatmospheric pressure following the design-basis accident.

The recirculation subsystem is, in addition, capable of maintaining the subatmospheric pressure in the containment for an extended period following the design-basis accident.

The removal of radioactive iodine from the containment atmosphere after a design-basis accident is accomplished through the dissolution of sodium tetraborate decahydrate into the containment sump water which is used by the recirculation spray subsystem (Section 14.5.4).

The spray system is designed to depressurize the containment to subatmospheric pressure with any one of the two containment spray pumps operating and only two of the four recirculation spray pumps operating.

6.3.1.2 Spray System Components

The spray system is designed, fabricated, inspected, and installed to meet the requirements of the General Design Criteria, as discussed in Section 1.4. The spray subsystems and their components are considered to be essential to accident prevention and/or the mitigation of accident consequences that could affect the public health and safety.

6.3.1.2.1 Pumps and Valves

The spray pumps and valves are fabricated, welded, and inspected according to the requirements of the applicable portions of the ASME Code, Sections III, VIII and IX. Materials of construction are stainless steel or equivalent corrosion-resistant materials.

Valve packing and pump seals are selected to minimize or eliminate leakage where necessary. Motor-operated valve operators are selected because their proven superior reliability in past applications ensures reliable valve operation under incident conditions.

The Teflon sleeve and packing of the outside recirculation spray system suction valves have been changed to XOMOX 7. This change reflects the review performed in accordance with NUREG-0578, Section 2.1.6.b. In this review it was found that the valves would be located in a high-radiation area as a result of a LOCA. The Teflon material is satisfactory to only 1×10^4 rads, whereas the XOMOX 7 material is satisfactory to 8×10^6 rads. The expected 60-year normal plus postaccident integrated radiation dose in this area is conservatively estimated not to exceed 8×10^6 rads.

The containment spray system piping and equipment are fabricated of ASTM A358, Type 304 stainless steel, or equivalent, which has a corrosion rate of less than 0.0001 in/yr at the 4.25 to 4.75 pH.

The recirculation spray system piping and equipment are also fabricated of Type 304 or Type 316L stainless steel, or equivalent, except for the Recirculation Spray Heat Exchanger (RSHX) tubing which is titanium, and the spray nozzles which are brass. System operating conditions are 200° to 130°F temperature and 7.0 to 9.0 pH (during the long-term postaccident period.

Per NUREG-0800 (Reference 11), stress corrosion cracking of austenitic stainless steel is inhibited in borated solutions in the hypothetical environment after the design-basis accident, when the pH is 7.0 or greater.

The systems operate at a relatively low pressure of approximately 100 psi gauge and are not highly stressed during operation, so that the inducement toward cracking is reduced.

The potential for caustic stress corrosion cracking in the containment spray system and recirculation spray system is virtually nonexistent because of the following:

1. The short duration of containment spray system operation
2. The recirculation spray solution pH is above 7.0 during the long-term postaccident period

6.3.1.2.2 Motors

Electrical insulation for motors located outside containment is in accordance with ANSI, IEEE, and NEMA standards, and is tested as required by these standards. Temperature rise design is such that normal long life is achieved even under accident loading conditions.

Winding insulation has been developed that operates at temperatures well in excess of those calculated to occur under design-basis accident conditions. This type of insulation is used in motors located inside containment.

The containment motors have been selected to ensure operation during LOCA conditions. Motor electrical insulation is in accordance with ANSI, IEEE, and NEMA standards. The motors are tested as required by these standards. Bearings are antifriction type. Bearing loading and high-temperature tests have been performed, and the expected bearing life equals, or exceeds, that specified by the Anti Friction Bearing Manufacturers Association (AFBMA).

6.3.1.2.3 Piping

Piping fabrication, installation, and testing are in accordance with the Specification for Power Plant Piping, ANSI B31.1, with supplemental requirements and inspections as necessary for use in nuclear applications. Pipe routing and supports are such that missiles generated from postulated events or the effects of LOCAs do not impair the operation of spray systems.

6.3.1.2.4 Heat Exchangers and Vessels

Heat exchangers and vessels are designed to ASME Code, Section VIII, Division 1, and have been radiographed in accordance with ASME Code Section VIII to ensure their structural integrity. Heat exchangers and vessels are of welded construction to preclude leakage.

6.3.1.2.5 Strainer Assembly

One strainer assembly is provided for both the IRS and ORS System pumps. The RS strainer assembly consists of two trains which traverse along the containment wall on both sides of the sump. The strainer assembly consists of a number of modules which channel water to the pump suction. Each suction opening is connected to the modules which form the strainer header. Modules are connected to each other by flexible metal seals. Seal closure frames with Metex seals are installed over existing flexible metal seals. The seal closure frame assemblies form the seal between adjacent strainer modules. Each module contains a number of fins which filter the water flowing into the modules. Each fin contains a number of holes 0.0625-inch (nominal) in diameter. Perforations on the strainer fins prevent particles larger than 0.06875-inch (0.0625-inch plus 10 percent) from entering the RS System. The total perforation area is large enough to allow sufficient flow to the suction of RS pumps to meet NPSH requirements.

Since the installation of the strainer assembly, inspections have identified gaps in the assembly larger than the allowable 0.0625-inch gap size. Particles larger than 0.06875 inches were evaluated in response to gaps identified in the strainer assembly. As part of the evaluation, it was assumed that 1% of the total generated particles between 0.06875 inches (0.0625 inches plus 10 percent) and 0.1375 inches (0.125 inches plus 10 percent) would pass through the strainer. It was determined that these particles would not impact the performance of downstream components.

For the ORS pumps, the strainer header is connected to each suction opening by a flanged transition adapter. The OD of the strainer header is machine cut and slip-fitted in to the new adapter ensuring that the gaps between the piping and the adapter do not exceed 0.0625 inches.

For the IRS pumps, the strainer header is connected to the pump well by installing a new casing.

The strainer assembly is designed and fabricated to the requirements of ASME Section III, Subsection NF, Class 3. All material used in the construction of the strainer assembly is austenitic stainless steel.

The strainer assembly is capable of withstanding the full debris loading in conjunction with all design basis conditions without collapse or structural damage.

The suction lines between the containment sump and the ORS pumps are cross connected. This design feature was originally provided to ensure a supply of water to each pump in the event that the suction of either pump become clogged. The current common header strainers that protect the pump suction lines are designed to withstand the full debris load that could be generated by a LOCA.

The design data of the spray system components are given in Table 6.3-1.

6.3.1.3 **Description**

6.3.1.3.1 Containment Spray System

The containment spray system consists of two completely separate trains of spray rings located in the containment dome and one common spray ring located outside the crane wall. Each train is rated at 100% capacity. The recirculation spray system is composed of two trains, each consisting of an inside recirculation spray subsystem and an outside recirculation spray subsystem. Each subsystem is approximately 50% capacity, and consists of one recirculation spray pump, one recirculation spray heat exchanger (RSHX), and one 180° coverage spray header with nozzles.

An additional ring header common to both containment spray trains is installed at Elevation 95 ft. 6 in. outside the crane wall. Check valves are installed in each branch connection from the riser to the common header to limit fill time, should one containment spray pump train fail to start.

The containment spray subsystem is shown in Figure 6.3-1, and the recirculation spray subsystem is shown in Figure 6.3-2. Elevations of all piping and components of these subsystems are shown in Figure 6.3-4.

Each of the containment spray headers draws water independently from the refueling water storage tank. The refueling water storage tank is a vertical cylinder with a flat bottom and a dome top, and is secured to a reinforced-concrete foundation. The refueling water storage tank is fabricated of ASTM A240, Type 304L stainless steel, in accordance with API STD-650. The requirements for welding, welding procedures, welder qualification, weld point efficiency, and weld inspection are in accordance with Section IX of the ASME Code and the Specification for Field Fabricated Storage Tanks (Reference 4).

The refueling water storage tank is designed as a Class I component, as described in Section 2.5, to withstand design seismic loading in accordance with the design stress criteria of ASME Code Section III, Figure N-414, *Nuclear Vessels*. The connecting piping is designed to withstand seismic loading to ensure the functioning of the system. The refueling water storage tank is provided with a manhole for inspection access.

Prior to unit operation, the water in the refueling water storage tank is cooled to a temperature of slightly below 45°F by either circulating the water through a heat exchanger that uses chilled water from the chilled water subsystem of the component cooling system (Section 9.4) or by using mechanical refrigeration units. Mechanical refrigeration units then maintain the tank water below 45°F. The tank is insulated. The refueling water storage tank also has a nozzle connection that supplies water to the safety injection system (Section 6.2).

The refueling water storage tank (RWST) is a passive component and is required only during a short period following an accident. It is provided with four channels of level indication, which provide signals to level indicators. The level indication range for the RWST is approximately 14,000 gallons at 0% level to approximately 399,000 gallons at 100% level. The RWST is maintained at greater than 387,100 gallons of borated water at or below a temperature of 45°F during normal plant power operations. Level transmitters provide input to a low level alarm and an empty alarm when RWST level drops below these respective setpoints. When two of four channels have sensed a low RWST level condition, an interlock signal is generated to allow for the start of the IRS and ORS pumps on a CLS Hi-Hi Actuation. Additionally, when two of four channels have sensed a low-low RWST level condition, a signal is generated to realign safety injection to the recirculation mode automatically. It takes approximately three minutes to realign the valves from injection to recirculation mode. The key values for the RWST assumed in the safety analysis are presented in Table 5.4-17. The safety analysis values are conservative with respect to plant operation.

The containment spray pumps are capable of supplying approximately 3200 gpm of borated water to two separate circular containment spray ring headers located approximately 96 feet above the operating floor in the dome of the containment structure and the common crane wall header at Elevation 95 ft. 6 in. Each pump is driven by an electric motor drive. The containment spray pumps are located adjacent to the containment structure and the refueling water storage tank. Each containment spray supply line to the containment contains a weight-loaded check valve. Should any water enter the manifolds during periodic testing, lines located after the check valves inside the containment drain the containment spray manifolds. The flow through the lines has been evaluated and the results of the containment accident analyses remain acceptable. A stainless steel filter is provided in the suction of each containment spray pump.

6.3.1.3.2 Recirculation Spray System

Each of the four recirculation spray subsystems shown in Figure 6.3-2 consists of a recirculation spray pump, a recirculation spray cooler, and a 180-degree spray ring header. The spray ring is located approximately 47 feet above the operating floor of the containment structure.

The four recirculation spray pumps take suction from a common containment sump strainer assembly. Each recirculation spray pump has a rated capacity of 3500 gpm. Two of the recirculation spray pumps and motors are located inside the containment structure (IRS pumps), and two pumps and motors are located outside the containment (ORS pumps). The containment sump strainer protects the IRS and ORS pump suction inlets when they are in recirculation mode. The four pumps are of the vertical deep-well type, and are of essentially the same design; however, the outside recirculation spray pumps have shaft extensions to permit locating the pump suctions at the level of the common containment sump, with the motors at an elevation slightly below ground grade. The pump motors inside the containment are selected to ensure operation under design-basis accident conditions.

The two recirculation spray pumps located outside the containment are fitted with a tandem mechanical seal arrangement. The space between the seal faces is filled with demineralized water that is maintained at a pressure slightly greater than the recirculation spray pump discharge pressure, thus preventing leakage of recirculation spray water that might be radioactive.

The recirculation spray water flows through recirculation spray coolers, where it is cooled by service water flowing under gravity, as discussed in Section 9.9. Since the recirculation spray water pressure in the coolers is greater than the service water, only outleakage can occur, and dilution of the borated water by service water in the containment is not possible. This ensures that the necessary cold shutdown margin by boron is maintained.

The service water from each cooler is monitored by means of radiation monitors to enable the defective subsystem to be shut down if outleakage occurs. Section 11.3.3 describes the process radiation monitoring devices and techniques used.

To ensure that adequate NPSH is available to the outside recirculation spray pumps, cold water is added to the spray pump suctions via bleed lines from the 10-inch containment spray risers inside the containment. Restriction orifices in these bleed lines result in a flow of approximately 310 gpm (actual flow varies with containment conditions) of chilled water from the refueling water storage tank to the outside recirculation spray pump suctions under normal operating conditions. This piping is inside containment and designed to withstand seismic effects and water hammer. Each containment spray pump can provide chilled water to either outside recirculation spray pump suction, by virtue of the recirculation spray suction cross-connect line.

Each inside recirculation spray pump suction receives a minimum analyzed flow of 300 gpm from the outlet of the respective inside spray heat exchanger. The piping runs are designed for seismic effects and water hammer. A restriction orifice is provided to obtain the minimum 300-gpm flow back to each pump suction. Material and installation are consistent with the design for the recirculation spray subsystem.

A flow rate of 3100 gpm for each of the inside recirculation spray pumps, and 2900 gpm for each of the outside recirculation spray pumps are used for containment analysis. With these pump flow rates, the minimum spray flow of 2800 gpm for each of the inside pump spray headers (i.e., minimum 3100-gpm pump flow less 300-gpm recirculation flow) and 2900 gpm for each of the outside pump spray headers is achieved. Minor variations in the inside recirculation spray and outside recirculation spray flowrates are acceptable, provided that 5700 gpm from the spray nozzles for each train is maintained to meet the requirements for the design basis accident.

Figure 6.3-5 is an isometric view that illustrates a typical arrangement of the outside recirculation spray pumps and the low-head safety injection pumps.

6.3.1.3.3 Containment Sump Strainer

The containment sump strainer protects the IRS, ORS, and LHSI pump suction inlets when they are in recirculation mode. The strainer assembly consists of modules with fins that are designed to prevent debris, large enough to clog spray nozzles, from reaching the recirculation spray subsystems. Water from the containment floor is filtered as it passes through perforated fins and into the modules. The filtered water flows through the modules to the pump suction inlets. Two separate strainer assemblies are provided, one for the four RS pumps and one for the two LHSI pumps. All components of the strainer assembly are designed to the Seismic Class I requirements.

The entire containment sump strainer assembly is raised off of the floor. The bottom of the RS strainer is six inches off the floor. The SI strainer is located on top of the RS strainer, so it sits approximately 19 inches off the floor. Since the strainer is raised off of the floor, heavy pieces of debris are prevented from reaching the fins and blocking them.

The fins filter the water as it flows into the strainer assembly and to the pumps. The fins have holes that are smaller than the size of the smallest nozzle orifice in the recirculation spray header. The finned perforated area performs the same function as the original inner sump screens. The fins are hollow tubes, which are perforated with holes having a nominal diameter of 1/16 inch. The total area of perforations through the fins is approximately 2550 ft^2 for the RS strainer and 900 ft^2 for the LHSI strainer. The perforated area of the finned strainer assembly is significantly higher than that of the removed sump screens, so the probability of the strainer becoming completely blocked is not considered to be credible. Large debris (non-buoyant) generated in other areas of containment would not be transported to the strainer because the flow velocity of the sump fluid is very low and could not lift the large dense pieces of debris. In addition, the containment floor is sloped away from the new containment strainer toward the center of containment.

The strainer is located in an area outside the crane wall. There are no high energy pipe lines overhead, so jet impingement or pipe whip from a high energy line break (HELB) is not a concern. In addition, missiles resulting from a HELB accident, for which sump recirculation is required, would not occur close enough to the strainer to damage it.

The strainer is designed to withstand the full debris load during all design basis conditions without collapse or structural damage. The strainer assembly is designed to withstand the effects of the Operating Basis Earthquake (OBE) and Design Basis Earthquake (DBE) events applicable to the containment floor elevation (-)27’-7”.

6.3.1.3.4 Containment Spray and Recirculation Spray Headers

The arrangement and sizes of the spray nozzles in the containment spray and recirculation spray subsystems have been accounted for in the determination of the spray effectiveness for these subsystems. With the inclusion of another containment spray subsystem header, new high volume nozzles were installed. The location and number of nozzles used was designed to ensure optimum spray droplet size and trajectory with the present spray pumps and system flow characteristics and to prevent excessive spray overlap that is ineffective. The overall nozzle arrangement was designed so that some of the nozzles cover a vertical annulus measuring 15 feet horizontally on either side of the spray headers. The remainder of the nozzles cover the containment volume outside the annulus.

CS spray headers. The CS spray headers contain 234 spray nozzles. The spray nozzles are sized to properly atomize the spray water to maximize the total surface area while minimizing the potential for becoming clogged by foreign matter. The spray pattern created from the spray rings forces an air flow in the containment that goes down along the outside and up the middle. The air flow assists in cooling the complete volume of the containment.

There are two independent 360-degree spray headers and one common 360-degree spray header which is located between the containment wall and the polar crane wall.

RS spray rings. There is one 180-degree spray ring for each RS subsystem. Each spray ring is a semicircular eight-inch pipe that contains 195 equally spaced sites, with 1 or 2 nozzles at each site for a total of 293 spray nozzles per header, to atomize the RS water. The inside and outside RS subsystem spray rings are arranged to form two complete 360-degree circular rings. The ESF train A and B subsystems are arranged so that the two RS subsystems in a single train provide 180-degree spray. The RS spray rings have spray nozzles that are oriented to obtain a wide distribution of varying size spray droplets. This provides adequate containment spray coverage.

In addition to the new spray headers, the Type 1HH30100 nozzles in the inside and outside recirculation spray headers have been plugged. The plugging of the nozzles increases the recirculation spray thermal effectiveness to at least 95%.

The three Model 1713A nozzles in each refueling water storage tank have been replaced with the Model 1708A nozzles. This has been done to maintain conservatism by ensuring that the most restrictive portion of the system is tested during the verification test of the containment spray system. The Spraco Model 1708A nozzles have the smallest orifice diameter and are, therefore, the most likely to become clogged if any solids were entrained within the spray fluid. See Section 6.3.1.5.2 for the method of testing.

The “A” containment spray pump suction line contains a normally isolated BDB piping connection. This piping connection allows for a portable pump to either utilize the RWST as a suction source or refill the RWST, based on the configuration of the pump, during a beyond design basis external event (BDBEE).

The entire spray system is constructed of corrosion-resistant materials, primarily stainless steel. However, other materials are used where suitable, such as brass for the spray nozzles. The system design pressure is 150 psig.

6.3.1.4 **Evaluation**

6.3.1.4.1 Low Head Safety Injection and Recirculation Spray Containment Sump Strainers

NRC Bulletin 93-02 (Reference 1) required licensees to evaluate their facilities for the potential of fibrous material installed or stored in containment to detrimentally affect the functional capability of the Emergency Core Cooling System (ECCS) due to the clogging of suction strainers. The potential effects of fibrous debris on the Surry ECCS was evaluated and provided to the NRC in response to the Bulletin (Reference 2).

NRC Generic Letter GL 2004-02 (Reference 5) required licensees to perform an evaluation of the Emergency Core Cooling and Recirculation Spray (RS) Systems function in light of the potential impact of debris blockage on the existing containment sump screens. The potential debris blockage could result in a debris-induced loss of NPSH margin during sump recirculation. The potential impact of the debris generation and transport was evaluated and provided to the NRC in response to the Generic Letter (Reference 8).

The response resulted in the completion of several evaluations and tests to determine the impacts of the new requirements in GL 2004-02 to the original containment sump screens. This resulted in the replacement of the original containment screen assembly with a passive sump strainer design.

Evaluations and tests were performed in accordance with the NEI 04-07 (Reference 6) and its associated SER (Reference 7) to ensure that the postaccident debris blockage will not impede the operation of the RS and LHSI systems in the recirculation mode.

The following evaluations and tests were performed.

- Evaluation of debris generation caused by a LOCA
- Evaluation of debris transport to the strainer
- Evaluation of downstream effects of blockage and wear on components
- Evaluation of downstream wear effects on system performance
- Evaluation of downstream effects of blockage and chemical precipitation on fuels
- Evaluation of chemical effects to quantify chemical species
- Strainer hydraulic test to determine head loss due to debris and chemical effects
- Strainer fiber bypass test

The following types of materials were determined to become debris and chemical effects contributors in the event of a LOCA or high energy line break:

- Piping and Equipment Insulation
- Insulation Jacketing
- Missile Barrier Penetration Seals
- Qualified Coatings
- Unqualified/Damaged Coatings
- Latent Debris
- Fire Stop Materials
- Foreign Material
- Aluminum Materials
- Coated and Uncoated Concrete

The amount of debris generated during a LOCA was determined such that it would maximize the head loss across the containment sump strainer during recirculation mode. A number of breaks in each high pressure system that relies on recirculation were considered to bound variations in debris generation by size, quantity, and type of debris. The breaks were selected on the piping located in the steam generator cubicles and in the pressurizer room. These areas contain the large diameter high-energy piping and largest quantity of insulation and potential debris that could be exposed to a break. All LOCA and high energy line break generated debris are conservatively evaluated as falling to the containment elevation (-)27’-7”.

Debris created by a LOCA inside the lower reactor cavity would be expected to reach the containment sump strainer through a 12-inch diameter drain hole core drilled through the primary shield wall plug in the lower portion of the reactor cavity (Incore Sump Room). The debris generated would have to pass through the narrow gap between the reactor vessel and the neutron shield tank before reaching the drain opening and convey to the containment sump strainer.

A Computational Fluid Dynamic (CFD) model of the Surry containment was developed to determine the containment spray flow velocities and water currents within containment. Based on these flow rates, debris types were determined not to transport, to transport in fractions, or transport in total. A quantity of generated debris that would be transported to the containment sump strainer was determined.

As a part of the chemical effects evaluation, the plant specific parameters were compared to the Integrated Chemical Effects Test (ICET) parameters to establish whether the ICET tests bounded the plant parameters as required by the NRC SER on NEI 04-07 evaluation guidance.

The chemical species that are expected to be released into the containment sump during the 30 days following a LOCA were quantified. These quantities were the basis for determining the quantities of the specific test chemicals used in the strainer testing.

The strainer manufacturer has performed various hydraulic tests that simulated the actual debris loading and chemical conditions specific to the Surry Power Station based on the debris generation, debris transport, and chemical effects evaluations. Fibrous, particulate, and chemical debris were added to a test rig to simulate the plant-specific chemical environment present in the water of the containment sump. Each test was operated for more than 30 days after the formation of the debris bed and initial chemical addition at specified temperatures and flow rates to assess chemical precipitate formation and head loss change. These tests sized the strainer and verified that adequate NPSH is available to support the operation of the LHSI and RS pumps during recirculation mode.

The downstream effects evaluation was performed in accordance with WCAP-16406-P (Reference 9) to determine RS System and ECCS components that are susceptible to blockage and wear due to debris bypass post-LOCA. The evaluation determined that downstream RS System and ECCS components have sufficient flow clearances in the flow paths that would allow debris to pass through openings without causing blockage.

The downstream effects evaluation determined the effects of erosive and abrasive wears on RS System and ECCS components, overall system hydraulic performance, and the system piping vibration. A wear model was developed in accordance with methodology provided in WCAP-16406-P to assess the amount of wear in RS System and ECCS components based on the initial debris concentration in the pumped fluid, the debris concentration depletion, the hardness of the wear surfaces, and the mission time. The results for wear on the manually throttled valves, orifices, containment spray nozzles, and RS heat exchanger were determined acceptable in accordance with criteria set forth in WCAP-16406-P. The dynamic performance of RS System and ECCS pumps is evaluated for wear effects on pump components. The evaluation concluded that the RS System and ECCS pumps meet the acceptance criteria for vibrations specified in WCAP-16406-P and therefore, will operate satisfactorily without excessive vibrations for a period of 30 days post-LOCA. The degraded hydraulic performance curves for RS System and ECCS pumps were developed resulting from erosive and abrasive wears of pump internal components. Changes in system resistance due to wear of system components such as orifices and manually throttled valves and degraded pump hydraulic performance were used as input to system models to evaluate whether minimum system flow requirements would be met. Modeling was then used to establish whether the degraded system resistance would cause the pumps to operate in an unacceptable run out condition. The results of the evaluation indicated that RS System and ECCS pumps are acceptable with respect to run out flow and will meet the minimum flow requirement to depressurize the containment and cool the reactor core for a period of 30 days post-LOCA.

System vibration analysis was performed to evaluate the effects of wear of RS System and ECCS piping and components downstream of the containment sump strainer. The RS System and ECCS pumps were also evaluated for hydraulically induced vibrations using maximum flows derived in the hydraulic analysis portion of the evaluation and for pump rotor dynamic analysis affected by the erosive and abrasive wears of pump internal components due to debris in the pumped fluid. The effects of wear on net positive suction head (NPSH) requirements and availability were considered to ensure cavitation would not induce unacceptable pump vibration. The evaluation indicated that the expected erosive and abrasive wear of the RS System and ECCS piping would be negligible after 30 days post-LOCA and therefore, the structural characteristics of the systems considered are not impacted. The RS System and ECCS pumps are acceptable for hydraulically induced vibration and meet the acceptance criteria for rotor dynamic vibration documented in WCAP-16406-P (Reference 9). Pump cavitation will not occur since the available NPSH exceeds the required NPSH for all RS System and ECCS pumps. Therefore, based on the acceptability of downstream wear effects and pump vibration and cavitation analyses, the evaluation concluded that the RS System and ECCS piping and components are not susceptible to excessive vibrations due to post-LOCA downstream wear.

The downstream effects evaluation was performed for fuels in accordance with WCAP-16793-NP (Reference 10) to determine the impact of fibrous, particulate, and chemical precipitant debris on the fuel and long-term cooling. The evaluation demonstrated that all of the WCAP evaluations and conclusions are directly applicable to Surry Units 1 and 2. This provided reasonable assurance that for both units, long-term core cooling will be established and maintained post-LOCA considering the presence of debris in the Reactor Coolant System and core.

Based on the above evaluations and tests, the area of perforations in the strainer was determined to be sufficient such that under full debris loading conditions there would be adequate NPSH available to the RS and LHSI pumps during accident conditions.

The change in buffer from sodium hydroxide to sodium tetraborate decahydrate has been evaluated and determined to not adversely affect the conclusions of the above evaluations and tests.

6.3.1.4.2 Recirculation Spray Nozzles

The spray system consists of two separate but parallel containment spray rings located in the containment dome and one common containment spray ring located outside the crane wall, plus four separate but parallel recirculation spray headers, each of approximately 50% capacity. The use of a separate spray header connected to the discharge of each pump results in a fixed flow rate, and allows for optimized selection of spray nozzle sizes. This arrangement gives the optimum combination of small spray particles for maximum heat transfer and larger particles for better coverage toward the center and sides of the containment. In addition, this arrangement also ensures that a failure of a component in any one subsystem does not affect the operational capability of the other subsystems.

The methods of preventing the plugging of spray nozzles in the two systems vary. For each containment spray train, the materials of construction, as well as the pump suction filter, prevent nozzle plugging. A method of nozzle testing is provided in the refueling water storage tank to ensure that no particulates that could plug the containment spray nozzles collect in the tank. Despite this precaution and regardless of strainer perforation size, some types of particles could conceivably pass lengthwise through the strainer and cause clogging of a spray nozzle. However, since the strainer perforations are smaller than the smallest spray nozzle opening, such an occurrence is considered to be highly improbable.

The containment sump strainer assembly is designed such that a single assembly provides filtered borated water to all four RS System pumps, as discussed in Section 6.3.1.3. The design feature of the strainer prevents complete failure of all suction points of the RS System. The strainers are raised off of the floor, which prevents large debris (non-buoyant) from reaching the fins and blocking them. It provides significantly large area of fin perforations that reduces the approach velocity and possibility of the strainer becoming completely blocked.

Since the redundant capacity of the recirculation spray subsystems increases from 100% after a loss-of-coolant incident to 400% to 1000% 1 day after an incident, plugging that could only occur on a long-term basis would have no significant effect on the capability of the subsystems.

6.3.1.4.3 Recirculation Spray Heat Exchangers

Initially, the heat exchangers of the recirculation spray trains are clean and dry, with maximum heat transfer capability. For long-term operation, on the order of weeks or months, there may be some fouling of the tubes on the service water side, with resultant loss in heat transfer capability. This loss of heat transfer capability is more than offset by the decrease in heat load resulting from decreasing decay heat production. One day after a LOCA, the decrease in the residual heat production rate is such that each train has sufficient heat removal capacity to hold the containment at subatmospheric pressure. With a maximum service water temperature of 100°F, the recirculation spray subsystem design is conservative. There is a minimum 100% reserve capacity in recirculation spray at the onset of an accident. Within one day after the LOCA, the reserve capacity exceeds 400%.

The recirculation spray heat exchangers are designed to Section VIII, Division I of the ASME Code, and have welded construction at all points where there could be a potential for leakage of radioactive recirculation spray water into the service water. The operating pressure of the recirculation spray water is greater than that of the service water, with a differential of approximately 100 psi; therefore, any leakage flow from the recirculation spray subsystem is into the service water system. The service water is monitored by radiation monitors to detect leakage from the defective subsystem (Section 11.3.3). If leakage above an allowable level is detected, the defective subsystem is shut down by manual operation of remote motor-operated valves that isolate the recirculation spray cooler. As a result of the above pressure difference, inleakage of non-borated water into the containment, causing dilution of the borated water in the containment, is not possible.

6.3.1.4.4 Recirculation Spray Pumps

Recirculation through the outside recirculation spray pumps presents a possibility of leakage through valve packings and from leaks in the suction and discharge piping of the pump. Valve designs are selected to reduce this potential leakage to a negligible amount. Leaks in the suction and discharge piping are controlled as follows:

1. Large leaks in the discharge piping of the recirculation spray pumps are detected by variations in the recirculation spray pump discharge pressure readings in the control room. A large decrease in pump discharge pressure indicates a pipe break and the operator in the control room could then remote-manually isolate that pump.

2. Large leaks in the suction piping in the valve pit will be detected by the following devices, which indicate in the control room: (1) high liquid level annunciation instrumentation located in the valve pit, (2) exhaust ventilation radiation monitoring, (3) outside recirculation spray pump discharge pressure and/or (4) outside recirculation spray pump motor amperage. Upon detection of a potential leak from any of these sources, control room personnel will identify the affected flow path by observation of the system parameters. Upon identification of the leaking spray line, the control room operator can remote manually isolate the leaking spray line, leaving one recirculation spray loop operable. In the case of small leaks, specific detection of a leak is not possible; however, the ventilation air from the structure (Figure 6.3-5) enclosing the piping outside the containment is discharged to the atmosphere through ventilation vent no. 2, and is automatically diverted through charcoal filters on a high-high containment pressure signal.

A periodic inspection is made of all potential points of leakage. Table 6.3-2 summarizes the potential leakage from the recirculation spray subsystem. The potential for leakage of pumped fluid from the recirculation spray pumps is minimized, due to the manner in which the pump shaft is sealed. Two mechanical seals are arranged in tandem, with a seal fluid between them. The seal fluid is supplied from a reservoir arranged in such a manner that the pressure of the seal fluid is slightly (about 1 psi) above the pumped fluid pressure at the inboard side of the inboard seal at all times. With this arrangement, assuming the inboard seal fails, seal fluid leaks through the failed seal while the other seal remains available to prevent the escape of pumped fluid to the atmosphere. A level alarm on the reservoir provides an indication of a seal failure.

A failure-mode analysis for the components of the spray system is included in Table 6.3-3.

Recirculation Spray Pump NPSH

The transient analysis of the available NPSH for the recirculation spray pumps is performed with the GOTHIC computer program. The analysis assumptions are similar to those discussed in Section 6.2.3.11 for the calculation of LHSI pump available NPSH during the recirculation phase. The minimum available NPSH generally occurs following a DEHLG. The minimum NPSH available to the outside recirculation spray pump occurs during maximum safeguards conditions, that is with two containment spray pumps supplying cold water to both outside recirculation spray pumps, concurrent with the coldest service water temperature. This combination of parameters results in the most rapid containment depressurization rates early in time and, therefore, relatively low containment pressure when the pumps start. The minimum NPSH available to the inside recirculation spray pumps occurs following a DEPSG with maximum safeguards and no single failure.

The required NPSH for each recirculation spray pump is listed in Table 6.2-13. The minimum available NPSH following the DBA is also listed in the table.

The available NPSH transients for the outside and inside recirculation spray pumps are shown on Figure 6.3-6 and Figure 6.3-10, respectively. The height of water on the floor is also shown on both figures. The NPSH analyses account for the 12" Incore Sump Room drain in the determination of containment water level. The available NPSH versus time is shown on Figure 6.3-6. The transient containment pressure and pump suction vapor pressure is shown on Figure 6.3-7. The containment sump temperature and vapor temperature are shown on Figure 6.3-8. The recirculation spray heat exchanger duty is shown on Figure 6.3-9. This information is also provided for the analysis of the inside recirculation spray pump available NPSH in Figures 6.3-10 through 6.3-13, respectively for the DEPSG break with full safeguards.

6.3.1.5 **Tests and Inspections**

6.3.1.5.1 Containment Spray Subsystem

Two types of tests are performed on the containment spray subsystem. First, during and after installation, it was tested to ensure that design criteria were met. Second, provisions have been made for testing the subsystem throughout the life of the unit to ensure that it is operational.

The following information is HISTORICAL and is not intended or expected to be updated for the life of the plant.

During the construction period, the containment spray headers were fitted with blind flanges that allowed the connection of temporary drain lines for initial testing of the subsystem. After the subsystem was completely installed, temporary connections were made to the blind flanges on the spray headers and pipe plugs were placed in the spray nozzle sockets. The containment spray pumps were started and operated over their entire range of flow, circulating water through the spray header supply lines to the spray headers and out the temporary drain connections. This provided a full-system capability test to ensure that the system met the flow requirements. It also provided for a flush of the system to remove any particulate matter that could plug the spray nozzles at a future time. At the completion of this test, the temporary drain connections were removed, the blind flanges replaced, the pipe plugs removed, the nozzle pipe nipple inspected, and the spray nozzles installed. Verification of the containment spray system response to a CLS HI-HI signal was performed during the CLS HI-HI logic testing that was also completed prior to initial reactor operation. The subsystem was then ready for operation.

With a system flush to remove particulate matter before the installation of spray nozzles, and with corrosion-resistant nozzles and piping, it is not considered credible that a significant number of nozzles would plug during the life of the unit to reduce the effectiveness of the subsystem; therefore, no means are provided for intermittent testing of the containment spray header nozzles with water. Provision was made to perform an initial air flow test on the containment spray subsystem nozzles. A compressed air source was connected to the spray header piping, and the air flow through each nozzle was individually measured by using a funnel and tubing arrangement to channel the air flow from each nozzle through a flow meter.

The containment spray subsystem nozzles will be subjected to an inspection or smoke or air test following maintenance or an activity which could cause blockage to provide indication that plugging of the nozzles has not occurred.

Means have been provided for intermittent testing of the containment spray pumps. This testing is performed periodically by opening the normally closed valves on the spray pump recirculation line, thus returning water to the refueling water storage tank. The operation of the subsystem allows the pumps to operate and recirculate a quantity of water back to the refueling water storage tank. The discharge into the refueling water storage tank is divided into two fractions, one for the major portion of the recirculation flow and the other to pass a small quantity of water through test nozzles, which are identical with those used on the containment spray headers. The purpose of the recirculation through test nozzles is to ensure that there is no particulate material in the refueling water storage tank and the containment spray subsystem that could plug or cause deterioration of the spray nozzles. The flow rate through the test nozzles is monitored and compared to the previously established flow rate obtained with the new nozzles. The presence of any particulate material that could cause plugging will be apparent through a reduction in flow rate through the nozzles. The weight-loaded check valves inside the containment are tested periodically by pressurizing the pump discharge lines with air and checking for a flow from the drain line.

Electrical insulation resistance tests are performed during the lifetime of the CS motors to verify the integrity of the insulation. Periodic tests are also performed to ensure the motors remain in a reliable operating condition.

The Containment Spray System is subject to the applicable inservice inspection and inservice testing requirements of the ASME Code, as required by 10 CFR 50 (Code of Federal Regulations, Title 10, Part 50).

6.3.1.5.2 Recirculation Spray Subsystem

The initial test for the recirculation spray subsystem included a system flush, a pump shutoff head verification, and an air flow test of the spray header. This assured that the system was cleared of debris, the pump capacities met design, and that the spray headers and nozzles were unobstructed.

The inside and outside recirculation spray pumps were designed to be operated dry for a short period of time (one minute) to verify operability. The physical arrangement of the outside recirculation spray pumps (vertical deep well with 52-foot casing height along with the permanently installed recirculation line) allows for periodic flow testing. The outside pumps are flow tested by closing the pump suction and discharge isolation valves, filling the pump casing with water and recirculating through recirculation piping from the pump discharge back to the pump casing. The inside recirculation spray pumps do not have extended pump casings or suction and discharge isolation valves. The inside recirculation spray pumps take suction from the containment sump which is maintained wet during normal operation to provide a water seal to reduce the potential for pressure locking the LHSI pumps containment suction motor operated valves (Reference 3). In order to provide for periodic flow testing of the inside recirculation spray pumps, the system is provided with recirculation piping and removable sump panels which are installed around the pump suction area during testing. The inside recirculation spray pumps are flow tested after installing and filling the temporary sump and connecting the recirculation piping using flanged spool pieces (Reference Drawing 6.3-2). Periodic flow testing of the inside and outside recirculation spray pumps is required to satisfy the inservice testing requirements of ASME Code. Due to the complexity and time required to perform flow testing of the inside recirculation spray pumps, this test is only performed during refueling outages.

The recirculation spray subsystem nozzles will be subject to an inspection or smoke or air test following maintenance or an activity which could cause blockage to provide indication that plugging of the nozzles has not occurred. The testing of system controls is discussed in Section 7.5.

Electrical insulation resistance tests are performed during the lifetime of the RS motors to verify the integrity of the insulation. Periodic tests are also performed to ensure the motors remain in a reliable operating condition.

The Recirculation Spray System is subject to the applicable inservice inspection and inservice testing requirements of the ASME Code, as required by 10 CFR 50 (Code of Federal Regulations, Title 10, Part 50).

Piping

Piping is designed to the Code for Pressure Piping, ANSI B31.1.

Valves

Recirculation Spray system valves are designed in accordance with ANSI B16.5, Steel Piping Flanges and Flanged Fittings, or ANSI B16.34, Steel Butt-Welded End Valves.

Table 6.3-2
TOTAL POTENTIAL EXTERNAL RECIRCULATION LOOP LEAKAGE TO ATMOSPHERE FROM THE RECIRCULATION SPRAY SYSTEM[a]

Item	Number of Units	Type of Leakage Control and Unit Leakage Rate Used in the Analysis	Uncollected Leakage (cc/hr)[b]	Leakage to Vent and Drain System (cc/hr)[b]
Recirculation spray pumps	2	No leakage of spray water due to tandem seal arrangement	0	0
Flanges		Assumed at 10 drops per minute per flange		
Pump	4		480	
Valves - bonnet to body (larger than Q in.)	4		460	
Valves - stem leakoffs	4	Backseated, double packing with leakoff - 1 cc/hr/in. stem diameter	0	16
Miscellaneous small valves	2	Flanged body, packed stem - one drop per minute	24	0
Total potential leakage			964	16

a. Based on two subsystems in operation under design-basis accident conditions.
b. The actual allowable leakage for each leakage control component may exceed the indicated leakage rate as long as the total external recirculation loop leakage does not exceed 3,000 cc/hr as required by Section 14.5.5.3.

Table 6.3-3
CONSEQUENCES OF COMPONENT MALFUNCTIONS

Components	Malfunction	Comments and Consequences
Containment spray pumps	Pump casing ruptures	The casing is designed for pumping the RWST contents which are maintained at approximately 45°F. Standard test pressure is 250 psig and maximum hydrostatic test pressure is 375 psig. These conditions exceed those which could occur during any operating conditions. The casings are made from cast stainless (ASTM A351-CF8). This metal has corrosion-erosion resistance and produces sound castings. The pumps conform to Class I design. Pumps are missile protected and may be inspected at any time. Rupture by missiles is not considered credible. Rupture of the pump casing is therefore not considered credible.
Containment spray pumps	Pump fails to start	The containment spray system has two parallel 100% capacity pumps. Sufficient capacity is provided by one pump in case of failure of the other pump.
Containment spray pump discharge valve	Valve fails to open	Redundant parallel valves are provided. Redundant valve carries the flow.
Containment spray pump discharge valve	Rupture of valve body	Valve body is designed for 150 lb. The castings are made from stainless steel; this material has corrosion-erosion resistance and produces sound castings. The valves are designed to be missile protected. Rupture of valve body is not considered credible.
Containment spray pumps	Weight-loaded check valve in pump discharge line sticks closed	Valve is checked periodically during refueling. In addition, parallel 100% capacity containment spray sub system is operable.
Containment spray piping	Pipe rupture	Piping is designed for 100°F temperature and 275 psig pressure. These conditions exceed those that could occur during operation. The piping is fabricated of Type 304 stainless steel; this metal has corrosion-erosion resistance. Piping is designed for Class I and is missile protected. Pipe rupture is not considered credible.
Recirculation spray pump	Pump fails to start	Four 50% rated capacity recirculation spray pumps are provided altogether.

Table 6.3-3 (CONTINUED)
CONSEQUENCES OF COMPONENT MALFUNCTIONS

Components	Malfunction	Comments and Consequences
Recirculation spray cooler	Tube or shell rupture	Four 50% rated capacity recirculation spray coolers are provided altogether. The recirculation spray coolers are designed to the ASME Code, Section VIII, Division 1. Rupture is considered unlikely. However, in the event of a rupture, motor-operated valves are provided to isolate the cooler and prevent further leakage. Another recirculation spray subsystem is used.
Outside recirculation spray pump	Rupture of pump casing	The casing is fabricated of ASTM SA452, Type 304 stainless steel; this metal is corrosion resistant. The casings are missile protected and set in concrete. Rupture of the pump casing is not considered credible.
Recirculation spray piping	Rupture of piping	Piping is fabricated of Type 304 and 316L stainless steel and designed to Class I. Piping is also missile protected. Rupture of piping is not considered credible. However, in case of pipe rupture for pipe lines to and from outside; recirculation spray pumps, isolation valves are provided.
Motor-operated valves	Loss of power to one valve due to failure of electric bus	Redundant valves are provided, electric power to valves is supplied from separate buses.
Automatic electric and control instrumentation trains to actuate consequence limiting safeguards equipment	Failure of one train	Redundant train will actuate redundant equipment.
Spray nozzles	Spray nozzles plugged	Filters are provided in the suction of the containment spray pumps. A strainer assembly with 0.0625-inch openings is provided in the suction of the recirculation spray pumps. The filters and strainer openings are small enough to prevent any material that could plug the spray nozzles from passing through.

Table 6.3-3 (CONTINUED)
CONSEQUENCES OF COMPONENT MALFUNCTIONS

Components	Malfunction	Comments and Consequences
Containment sump strainer modules and fins	Fin or strainer module failure	The fins and strainer modules are designed such that they can withstand full debris loading and have sufficiently large perforated fin area available to compensate for debris blockage. The strainers are capable of withstanding the force of full debris loading in conjunction with other conditions including seismic events.

CHAPTER 7 INSTRUMENTATION AND CONTROL

7.1 INTRODUCTION

Note: As required by the Subsequent Renewed Operating Licenses for Surry Units 1 and 2, issued May 4, 2021, various systems, structures, and components discussed within this chapter are subject to aging management. The programs and activities necessary to manage the aging of these systems, structures, and components are discussed in Chapter 18.

7.1.1 General Design Criteria

Instrumentation and controls are provided to monitor and maintain all operationally important reactor operating parameters such as neutron flux, system pressures, flow rates, temperatures, levels, and control rod positions within prescribed operating ranges.

Process variables which are required on a continuous basis for the start-up, power operation, and shutdown of the unit are indicated in, recorded in, and changed as necessary from the control room, which is a controlled access area. With controlled access, the operating staff is cognizant and in control of all test, maintenance, and calibration work and, knowing the extent to which specific and related operating tasks are in process, the staff can fully assess all abnormal plant conditions.

Criteria for instrumentation wires, cables, trays, and conduits are given in Chapter 8.

Several criteria related to all instrumentation and control systems but more specific to other plant features or systems are discussed in other chapters as listed below:

Criterion	Discussion
Suppression of power oscillations	Chapter 3
Reactor core design	Chapter 3
Quality standards	Chapter 1
Performance standards	Chapter 1
Fire protection	Chapter 9
Missile protection	Chapter 5
Emergency power	Chapter 8

7.1.2 Regulatory Guide 1.97 Program

Regulatory Guide 1.97, *Instrumentation for Light-Water-Cooled Nuclear Power Plants to Assess Plant and Environs Conditions During and Following an Accident*, contains tables of instrumentation required by the operators to monitor the plant and environs during and following an accident. This instrumentation consists of indicators that are associated with a variety of plant safe-shutdown and balance of plant systems. The intent of Regulatory Guide 1.97 is to provide the operators with the minimum essential information during and following an accident so that they will be able to mitigate and minimize the consequences of the accident. The regulatory guide has specifically determined four of the five types of instrumentation required to ensure proper indication is available to the operators. These four types (Type B, C, D, and E) are outlined in Table 3 of the regulatory guide along with their specifically assigned category, design, and qualification requirements. The fifth type of instrumentation, Type A variables, are plant specific. A Type A variable provides the operator with essential information necessary to take manual actions to mitigate an accident for which no automatic actions are provided. These instruments are characterized by their definition as stated in the regulatory guide. These definitions are:

1. Type A Variables: those variables to be monitored that provide the primary information required to permit the control room operator to take specific manually controlled actions for which no automatic control is provided and that are required for safety systems to accomplish their safety functions for design basis accident events. Primary information is essential for the direct accomplishment of the specified safety functions; it does not include those variables that are associated with contingency actions that may also be identified in written procedures.

2. Type B Variables: those variables that provide information to indicate whether plant safety functions are being accomplished. Plant safety functions are (1) reactivity control, (2) core cooling, (3) maintaining reactor coolant system integrity, and (4) maintaining containment integrity (including radioactive effluent control). Variables are listed with designated ranges and category for design and qualification requirements. Key variables are indicated by design and qualification Category 1.

3. Type C Variables: those variables that provide information to indicate the potential for being breached or the actual breach of the barriers to fission product releases. The barriers are (1) fuel cladding, (2) primary coolant pressure boundary, and (3) containment.

4. Type D Variables: those variables that provide information to indicate the operation of individual safety systems and other systems important to safety. These variables are to help the operator make appropriate decisions in using the individual systems important to safety in mitigating the consequences of an accident.

5. Type E Variables: those variables to be monitored as required for use in determining the magnitude of the release of radioactive materials and continually assessing such releases.

To further define the variables, Regulatory Guide 1.97 has assigned each variable a design and qualification category. This categorization consists of either a category 1, 2, or 3 designation, with a category 1 having the most stringent requirements, and category 3 having the least stringent. The variables are examined against twelve design and qualification criteria. However, category 2 or 3 variables may be exempt from some or all of the individual criterion's requirements. The criteria and how they are to be applied against each of the three categories are listed in Table 1, *Design and Qualification Criteria for Instrumentation*, of Regulatory Guide 1.97. The twelve category requirements consist of the following:

1. Equipment Qualification
2. Redundancy
3. Power Source
4. Channel Availability
5. Quality Assurance
6. Display and Recording
7. Range
8. Equipment Identification
9. Interfaces
10. Servicing, Testing, and Calibration
11. Human Factors
12. Direct Measurement

In response to NUREG 0737, and Regulatory Guide 1.97, Revision 3, Virginia Power has developed a programmatic approach in defining the Regulatory Guide 1.97 required equipment. The Virginia Power Regulatory Guide 1.97 program reviews examined each of the required instrumentation loops against the category design and qualification requirements. The reviews determined whether equipment upgrades to meet the regulatory guide requirements were required. The required equipment upgrades have been performed to meet the *Design and Qualification Criteria for Instrumentation* of the regulatory guide. Virginia Power has also taken exceptions to the category requirements for certain plant instruments. These exceptions to the regulatory guide have been outlined in correspondence between the NRC and Virginia Power. Virginia Power has developed a plant specific Technical Report, PE-0014, that provides a tabular identification of Regulatory Guide 1.97 instrumentation loops and circuits.

7.2 REACTOR PROTECTION SYSTEM

The reactor protection system and the engineered safeguards comprise the protective systems at the Surry Power Station. The equipment, from sensors to actuating devices, is considered a part of a given protective system.

The design objectives and functional implementation of the reactor protection system (tripping) and the engineered safeguards for the Surry units are the same as for H. B. Robinson Unit 2. The Surry reactor coolant systems have loop stop valves, where the H. B. Robinson unit does not. The presence of loop stop valves necessitates additional protection grade interlocks for the stop valve opening circuits.

As the functional requirements were translated into control equipment during the detailed design of the plant, some minor changes in equipment were made, to:

1. Reduce the amount of equipment required to accomplish a specific control function and, therefore, reduce equipment complexity and maintenance time during plant operation.
2. Modify instrument and control ranges to be consistent with the plant parameters corresponding to the increased power rating for Surry compared to that of the H. B. Robinson design.

Specific functions, however, will be accomplished with the same degree of reliability and redundance as they were in H. B. Robinson design. It should also be noted that the steam dump capacity of the Surry plant is approximately half of that provided for the H. B. Robinson plant, since the Surry plant is designed for a 50% load rejection without trip whereas the H. B. Robinson plant is designed for a 95% load rejection without trip.

All protection grade instrumentation and control systems were designed and procured by Westinghouse Electric Corporation, with the following exceptions: The containment pressure instrumentation and logic, containment spray systems, and diesel generators were in the Stone and Webster scope of supply. Westinghouse process control modules may be replaced with modules manufactured by NUS Scientech.

There are no basic differences between Surry and H. B. Robinson with respect to protection grade instrumentation and control systems because both plants are designed in accordance with the criteria established in IEEE-279 and objectives of the General Design Criteria.

Design criteria for the Surry protective systems were chosen to permit maximum effective use of process measurements both for control and protection functions, thus enhancing the capability to provide an adequate system to deal with the majority of common-mode failures as well as to provide redundancy for critical control functions. This design approach provides protective systems that monitor numerous system variables by different means, i.e., protective system diversity. Such diversity has been evaluated for a wide variety of postulated accidents (Reference 1).

Reactor protection system and engineered safety features equipment are identified as safety-related equipment by several means. The electrical cables to vital instruments and control and electrical components are color coded to identify them as vital circuits. Vital circuits are divided into three main categories:

1. The 4160V and 480V ac and 125V dc circuits fed to or from the emergency buses 1H and 2H are color-coded “orange.”
2. The 4160V and 480V ac and 125V dc circuits fed to or from the emergency buses 1J and 2J are color-coded “purple.”
3. The circuits for the four protection instrument channels are identified by red, white, blue, and yellow color coding.

In addition, colored nameplates are affixed to vital instruments and equipment used in operation. These components include air circuit breakers, panels, switchgear, voltmeters, ammeters, control switches, and other associated equipment.

The remainder of Section 7.2 is primarily concerned with the reactor protection system, although some information may also apply to the engineered safeguards. Detailed discussion of the engineered safeguards can be found in Section 7.5.

7.2.1 Design Bases

The reactor protection system and the engineered safeguards are designed in accordance with IEEE-279 *Standard, Nuclear Power Plant Protection Systems,* August 1968. Detailed descriptions of the implementation of these principles are presented in the remainder of Section 7.2 and in Sections 7.4 and 7.5.

7.2.1.1 **Control Room**

Each unit is equipped with a control room which contains those controls and instruments necessary for operation of the reactor and turbine generator under normal and accident conditions.

The control room is continuously occupied by qualified operating personnel under all operating and design-basis accident (DBA) conditions.

Sufficient shielding, distance, and containment integrity are provided to ensure that under postulated accident conditions during occupancy of the control room, control room personnel shall not be subjected to doses that, in the aggregate, would exceed the limits in 10 CFR 50, Appendix A, GDC 19. The control room ventilation consists of a system having a large percentage of recirculated air. The fresh air intake can be closed to stop the intake of airborne activity if monitors indicate that such action is appropriate.

7.2.1.2 **Core Protection Sequence**

If the reactor protection system receives signals which indicate an approach to unsafe operating conditions, the system actuates alarms, prevents control rod withdrawal, initiates load runback, and/or opens the reactor trip breakers.

The basic reactor operating philosophy is to define an allowable region of power, pressure, and coolant temperature conditions. This allowable range is defined by primary tripping functions, which include the overpower delta T trip, the overtemperature delta T trip, and the nuclear overpower trip. The operating region below these trip settings is designed so that no combination of power, temperature, and pressure could result in a departure from nucleate boiling ratio (DNBR) less than the design DNBR limit (Section 3.2.3) for any credible operational transient with all reactor coolant pumps in operation. Tripping functions in addition to the primary tripping functions stated above are provided to back up the primary tripping functions for specific abnormal conditions. A complete list of tripping functions is given in Table 7.2-1.

The dropped control rod is indicated by the rod position flat panel displays and by a rapid flux decrease on any of the power range nuclear channels.

Rod stops from nuclear overpower, overpower delta T, and overtemperature delta T deviation are provided to prevent abnormal power conditions, which could result from excessive control rod withdrawal initiated by operator violation of administrative procedures. The automatic rod withdrawal function of the reactor control system is disabled such that no control system malfunctions will result in excessive control rod withdrawal.

7.2.1.3 **Reliability, Redundancy, and Independence**

Protection and operation reliability is achieved in part by providing redundant instrumentation channels for each protective function. These redundant channels are electrically isolated and physically separated. The channel design incorporates separate sensors, separate power supplies, separate rack-mounted and panel-mounted equipment, and separate relays for the actuation of the protective function. For protective functions where two-out-of-three or two-out-of-four redundant-coincident actuation is provided, a single channel failure will not impair the protective function nor will it cause an unnecessary unit shutdown.

Reactor protection system channels are designed with sufficient redundancy for individual channel calibration and testing to be performed during power operation without degrading reactor protection. Bypass removal of one trip channel is accomplished by placing that channel in a partial-trip mode. For example, a two-out-of-three channel becomes a one-out-of-two channel. Testing will not cause a trip unless a trip condition exists concurrently in another channel.

The reactor protection system is designed so that the most probable modes of failure in each channel result in a reactor trip signal. The protection system design combines redundant sensors and channel independence with coincident trip philosophy so that a safe and reliable system is provided in which a single failure will not defeat the channel function, cause a spurious trip, or violate reactor protection criteria.

In the Westinghouse control and protection system, the control system is separate and distinct from the protection system. Although the protection system is independent of the control system, the control system is dependent upon signals derived from the protection system through isolation amplifiers. The design approach is to use fully and thereby most efficiently, for both control and protection purposes, measurements of unit variables. Little additional safety is achieved by using independent but identical measurements for control and protection.

This approach permits all equipment to be identified for protection or control and to be grouped accordingly, electrically isolated, and physically separated. In this way there is control redundancy, providing a significant increase in overall unit safety and also a protection system continuously monitoring a large number of system variables by different means. That is, there is protection system diversity.

In the reactor protection system, two reactor trip breakers are provided to interrupt power to the control rod assembly drive mechanisms. The breaker main contacts are connected in series with the power supply so that opening either breaker interrupts power to all control rod assembly drive mechanisms and permits the control rod assemblies to free fall into the core.

A bypass breaker is also provided for each reactor trip breaker. It should be noted that administrative controls alone are not relied upon to prevent simultaneous closure of both reactor trip bypass breakers. When either reactor trip bypass breaker is placed in the operate position, an alarm and annunciator is actuated in the control room. Also, closing one reactor trip bypass breaker when both breakers are in the operate position will generate a trip signal for the other reactor trip bypass breaker.

The components of the protection system are designed and arranged so that, even with an adverse environment accompanying an emergency situation, the components will function as required without interference.

Separation of redundant analog protection channels originates at the process sensors and continues through the wiring route and containment penetrations to the analog protection racks. Physical separation is used to the maximum practical extent to achieve separation of redundant transmitters. Separation of wiring is achieved using separate wireways, cable trays, conduit runs, and containment penetrations for each redundant channel. Redundant analog equipment is separated by locating components in different protection racks. Each redundant channel is energized from a separate instrument bus.

Further detail on redundancy is provided by the descriptions of the respective systems covered by Section 7.2.2. Required continuous power supply for the protection systems is discussed in Chapter 8.

7.2.1.4 **Reactivity Control**

One of the two reactivity control systems employs control rod assemblies to regulate the position of the neutron absorbers within the reactor core (Chapter 3). The other reactivity control system employs the chemical and volume control system (Chapter 9) to regulate the concentration of boric acid solution neutron absorber in the reactor coolant system.

Reactor shutdown by control rod assemblies is completely independent of the normal control functions, since the trip breakers interrupt the power to the control rod mechanisms regardless of existing control signals. Effects of continuous withdrawal of a control rod assembly and of de-boration are described in Chapter 14.

7.2.1.5 **Manual Actuation**

Means are provided for manual initiation of protective system action. Failure in the automatic system does not prevent the manual actuation of protective functions. Manual actuation is designed to require the operation of a minimum amount of equipment.

7.2.1.6 **Channel Bypass**

The system is designed to permit any one channel to be maintained, tested, or calibrated during power operation without system trip. During such operation the active parts of the system continue to meet the single-failure criterion, since the channel under test is either tripped or makes use of superimposed test signals that do not negate the process signal.

"One-out-of-two" systems are permitted to violate the single-failure criterion during channel bypass provided that acceptable reliability of operation can be otherwise demonstrated and the bypass time interval is short.

7.2.1.7 **Calibration and Testing**

The bi-stable portions of the protective system (e.g., relays, bi-stables, etc.) provide trip signals only after signals from analog portions of the system reach preset values. Capability is provided for calibrating and testing the performance of the bi-stable portion of protective channels and various combinations of the logic networks during reactor operation.

The analog portion of a protective channel (e.g., sensor and amplifier) provides an analog signal of the reactor or unit parameter. The following methods for checking the analog portion of a protective channel during reactor operation are provided:

1. Varying the monitored parameter.
2. Introducing and varying a substitute transmitter signal.
3. Cross-checking between identical channels or between channels that bear a known relationship to each other and that have readouts available.

The design provides for administrative control in order to manually bypass channels for test and calibration purposes.

The design provides for administrative control of access to all trip settings, module calibration adjustments, test points, and signal injection points.

The signal-conditioning equipment of each protection channel in service at power is capable of being calibrated and tested independently by simulated analog input signals to verify its operation without tripping the reactor. The testing scheme includes checking through the trip logic to the trip breakers. Thus, the operability of each trip channel can be determined conveniently and without ambiguity. Functional operation of the power sources for the protection system is discussed in Chapter 8.

7.2.1.8 **Functional Requirements**

The reactor protection system in conjunction with inherent plant characteristics is designed to prevent anticipated abnormal conditions from exceeding limits established in Chapters 3 and 4.

7.2.1.8.1 Completion of Protective Action (Interlock)

Where operating requirements necessitate automatic or manual bypass of a protective function, the design is such that the bypass is removed automatically whenever permissive conditions are not met. Devices used to achieve automatic removal of the bypass of a protective function are part of the protective system and are designed in accordance with the criteria of this section.

The protective systems are so designed that, once initiated, a protective action goes to completion. Return to normal operation requires action by the operator.

7.2.1.8.2 Multiple Trip Settings

For monitoring neutron flux, multiple trip settings are used. When a more restrictive trip setting becomes necessary to provide adequate protection for a particular mode of operation or set of operating conditions, the protective system as designed provides positive assurance that the more restrictive trip setting is used. The devices used to prevent improper use of less restrictive trip settings are considered a part of the protective system and are designed in accordance with the criteria presented in this section.

7.2.1.8.3 Protective Actions

The reactor protection system automatically trips the reactor when the conditions listed in Table 7.2-1 exist.

Interlocking functions of the reactor protection system prevent control rod withdrawal when a specified parameter reaches a specified value that is less than the value at which a reactor trip is initiated. The automatic rod withdrawal function of the reactor control system is disable. The interlocking functions continue to block manual rod withdrawal.

For anticipated abnormal conditions, protective systems in conjunction with inherent characteristics and engineered safeguards are designed to ensure that limits for energy release to the containment and offsite radiation exposure (as in 10 CFR 50.67 or Regulatory Guide 1.183) are not exceeded.

Each reactor trip channel is designed on the “de-energize to operate” principle; an open channel or a loss of power causes that channel to go into its trip mode.

Reactor trip is implemented by simultaneously interrupting power to the magnetic latch mechanisms on each control rod drive, so that the control rod assemblies insert by free-fall. The entire protection system is thus inherently safe in the event of a loss of power.

7.2.1.8.4 Indication, Alarms, and Annunciators

All transmitted signals (flow, pressure, temperature, etc.) that can lead to a reactor trip are either indicated or recorded for every channel.

All neutron flux power range currents (top detector, bottom detector, and algebraic difference and average of bottom and top detector currents) are indicated and/or recorded.

The protective system provides the operator with complete information pertinent to system status and safety.

Indication is provided in the control room if some part of the system has been administratively bypassed or taken out of service.

Trips are indicated and identified down to the channel level.

Alarms and annunciators are also used to alert the operator of deviations from normal operating conditions so that he may take corrective action to avoid a reactor trip. Further, actuation of any rod stop or trip of any reactor trip channel will actuate an alarm.

7.2.1.8.5 Operating Environment

The protective channels are designed to perform their function when subjected to adverse environmental conditions. See Section 7.5 for the criteria for those portions of the protective systems that must operate in a post-accident environment.

7.2.1.8.6 Seismic Design

Reactor protection system equipment is designed to ensure that it does not lose its capability to perform its function during an operating-basis earthquake or a design-basis earthquake, i.e., the equipment will shut the plant down and maintain it in a safe shutdown condition.

For the design-basis earthquake, there may be permanent deformation of the equipment provided that the capability to perform its function is maintained.

Typical protection system equipment is subjected to type tests under simulated seismic accelerations to demonstrate its ability to perform its functions. Type testing is done by using conservatively large accelerations and applicable frequencies. Analyses done for structures are not done for the reactor protection system equipment; however, the peak accelerations and frequencies are checked against those derived by structural analyses of operating-basis earthquake and design-basis earthquake loadings.

A Westinghouse topical report, WCAP-7397-L, provides the original seismic evaluation of safety-related equipment. The type tests covered by this report are applicable to the Surry Station with the exception of the process control equipment, which is covered in a supplement to WCAP-7397-L. Non-Westinghouse replacement modules have been seismically tested and are seismically qualified.

The control board is designed to withstand earthquake conditions, and an analysis was performed to verify the adequacy of the seismic design. Tests were not performed.

7.2.2 System Description

The reactor protection system provides the means for controlling the reactor in response to various measured primary and secondary variables associated with power, temperature, pressure, level, flow, and the availability of electric power. If the combination of monitored variables indicates an approach to unsafe conditions, the reactor protection system will initiate the appropriate protective action, e.g., load runback, prevention of rod withdrawal, or reactor trip (opening the reactor trip breakers).

Figure 7.2-1 illustrates typical core limits and shows the maximum trip points which are used for the protection system. The solid lines indicate a typical locus of DNBR equal to the design DNBR limit (Section 3.2.3) at four pressures, and the dashed lines indicate maximum permissible trip points for the overtemperature delta T reactor trip. Actual setpoints (the safety limits are given in the Technical Specifications) are lower to allow for measurement and instrumentation errors. The overpower delta T reactor trip limits the maximum core power independent of the DNBR.

Adequate margins exist between the nominal steady-state operating point and required trip points to preclude a spurious trip during design transients.

A block diagram of the reactor protection system showing various reactor trip functions and interlocks is shown in Figure 7.2-2. A logic diagram for the low-reactor-coolant-flow trips is shown in Figure 7.2-3.

7.2.2.1 **System Safety Features**

7.2.2.1.1 Separation of Redundant Protection Channels

The reactor protection system is designed to achieve separation between redundant protection channels. The channel design is applied to the analog and the logic portions of the protection system and is illustrated by Figure 7.2-4. Although the illustration is for four-channel redundancy, the design is applicable to two-channel and three-channel redundancy.

Separation of redundant analog channels originates at the process sensors and continues along the wiring route and through containment penetrations to the analog protection racks. Isolation of wiring is achieved by using separate wireways, cable trays, conduit runs, and containment penetrations for each redundant channel. Analog equipment is separated by locating redundant components in different protection racks. Each redundant channel is energized from a separate ac power feed. Logic equipment separation is achieved by providing separate racks, each associated with individual trip breakers.

Cables have been installed in accordance with VEPCO specification, *Criteria for Installation and Identification of Electrical Cables.*

Cables pertaining to reactor protection and engineered safety features are installed so that redundant circuits are separated and this separation is readily identified. Separation of redundant circuits is obtained by one of the following:

1. Rigid metal conduit (following separate routes).
2. Horizontal separation of horizontal cable trays without barriers.
3. Vertical separation of horizontal cable trays by means of barriers or tray covers (redundant channels are not combined in one tray or conduit).

A color-coded system is provided to identify individual safety channels, and additional colors are used to identify redundant safety trains. The color-coding scheme is an aid to both the installer of cable and the inspector.

1. Power cables and control cables are separated. Where possible, power cables are not installed in the same tray with control cables. Where it is necessary to install power cables in the same tray with control cables, a distance of at least 1/4 diameter of the power cable is maintained between the power and control cables. For safety circuits, where power and control cables are in the same tray, the power cable is contained in interlocked armor. Power cable is defined as any cable carrying 60A or supplying a 30-hp or larger motor. All power cables in trays are installed only one layer deep.
2. Control and instrument cables are usually run in separate trays; however, there are some areas where control and non-sensitive instrumentation cables are run in the same tray.
3. Cables from redundant protection channels or trains are never intermixed within a tray.

4. Non-vital cables such as annunciator, computer, or instrument cables may be routed with the protection system cables; however, they are separated wherever practical.

The cables to the penetrations in the cable tunnel and vaults are routed in two separate cable runs. There is a total of 90 penetrations, 5 rows high by 18 rows long.

The penetrations are arranged so that power, control, and instrumentation cables are separated from each other within a train and the two trains are never intermixed. The minimum distance between redundant services is never less than 2 feet at the penetrations.

Cable de-rating factors are in accordance with standards of the Insulated Power Cable Engineers' Association. Power cables 60A and over are rated and sized for 90°C operation. The sizing of power cables includes service factor where applicable, de-rating factors for maintained cable spacing of 1/4 diameter, and fire stops, if used. Where power cable spacing is less than 1/4 diameter (maintained), the power cables are treated as random filled and de-rated with base ampacities using applicable industry standards.

Control cables may be installed in cable trays in a random manner up to 80% of tray capacity, computed using the cross-sectional area of the cable. Control cables must meet one of the following conditions:

1. No appreciable conductor I^2R heating loss (interlocks, indicating lamps, controls, etc.).
2. Intermittent duty (valve operators).
3. Cable for continuous operation must use a derating factor of 50%-maximum continuous operation 60A or 30 hp - maximum wire size No. 4 AWG copper.

Instrument cables are installed in trays in a random manner up to 80% of tray capacity, computed by using the cross-sectional area of the cable, without derating. The protection of cables is either by protective relays or circuit breakers that are individually selected for each circuit.

Smoke detectors and carbon dioxide protection are provided in non-occupied areas of cable runs, such as cable tray rooms and cable tunnels. The cable purchased will not propagate fire, and sleeves are sealed after installation of cables. Additional horizontal and vertical fire stops are provided where required. No temperature monitoring of cables is provided. Each cable and wireway is permanently identified with markers.

The criteria for location and routing of instrument lines and transmitters were similar to the criteria established for electrical cables run between the transmitters and penetrations. For example, redundant transmitters and sensing lines are separated, and redundant devices are separated by a minimum of 2 feet, or additional protection is provided.

In reference to Reference Drawings 1 and 2, all cables from the Unit 1 reactor containment pass through a common vault area. Two protection channels and one train are routed on one side of the vault separated by metal tray covers, and the redundant channels and train are routed in a similar manner on the other side. This area is free from combustible materials, potential missile-generating devices, and is protected by fire detection equipment and a carbon dioxide deluge system. Unit 2 is completely isolated from Unit 1.

The reactor trip bi-stables are mounted in the analog protection racks and are the final operational component in an analog protection channel.

Each bi-stable drives logic relays “C” and “D” as shown on Figure 7.2-4. The contacts from the “C” relays are interconnected to form the required actuation logic for trip breaker 1. The transition from channel identity to logic identity is made at the logic relay coil/relay contact interface. As such, there is both electrical and physical separation between the analog and the logic portions of the protection system. The above logic network is duplicated from trip breaker 2 by using the contacts from the “D” relays. Therefore, the two redundant reactor trip logic channels will be physically separated and electrically isolated from one another. The reactor protection system consists of identifiable channels that are physically, electrically, and functionally separated and isolated from one another.

7.2.2.1.2 Loss of Power

A loss of power in the reactor protection system causes the affected channel to trip. All bi-stables operate in a normally energized state and go to a de-energized state to initiate action.

7.2.2.1.3 Reactor Trip Signal Testing

Provisions are made, for process variables, to manually place the output of the bi-stable in a tripped condition for “at power” testing of all portions of each trip circuit including the reactor trip breakers. Administrative procedures require that the final element in a trip channel (required during power operation) be placed in the trip mode before that channel is taken out of service for repair or testing so that the single-failure criterion is met by the remaining channels. In the source and intermediate ranges where the trip logic is one out of two for each range, bypasses are provided for this testing procedure.

Nuclear instrument power range channels are tested by superimposing a test signal on the sensor signal so that the reactor trip protection is not bypassed. Based upon coincident logic (two-out-of-four) this will not trip the reactor.

Provision is made for the insertion of test signals in each analog loop. Verification of the test signal is made by portable instruments at test points specifically provided for this purpose. This enables testing and calibration of meters and bi-stables. Transmitters and sensors are checked against each other and against precision readout equipment when required during normal power operation.

7.2.2.1.4 Process Analog Protection Channel Testing

The basic arrangement of elements comprising a representative analog protection channel is shown in Figure 7.2-5. These elements include a sensor or transmitter, power supply, bi-stable, bi-stable trip switch and proving lamp, test-operate switch, test annunciator, test signal injection jack, and test points. A portion of the logic system is also included to illustrate the overlap between the typical analog channel and the corresponding logic circuits. The analog system symbols are given in Table 7.2-2.

Each protection rack includes a test panel containing those switches, test jacks, and related equipment needed to test the channels contained in the rack. An interlocked, hinged cover encloses the test panel. Opening the cover or placing the test-operate switch in the TEST position automatically initiates an alarm. The test panel cover is designed in such a way that it cannot be closed (and the alarm cleared) unless the test signal plugs (described below) are removed. Closing the test panel cover mechanically returns the test switches to the OPERATE position.

Test procedures require the bi-stable output relays of the channel under test to be placed in the tripped mode before proceeding with the analog channel tests. Thus, for the channel under test, the relay elements in the two-out-of-three or the two-out-of-four coincident matrices are in the tripped mode during the entire test of that channel. This ensures that the remaining channels of the two-out-of-three or the two-out-of-four protective functions meet the single-failure criterion during the entire channel test. Placing the bi-stable trip switch in the tripped mode de-energizes (trips) the bi-stable output relays and connects a proving lamp to the bi-stable output circuit. This permits the electrical operation of the solid-state bi-stable to be observed and the bi-stable setpoint relative to the channel analog signal to be verified. Upon completion of the test of the analog channel, the bi-stable trip switches must be manually reset to their operate mode. Closing the cover of the test panel does not transfer the bi-stable trip switches from their tripped to their operate position.

Analog channel tests are accomplished by simulating a process measurement signal, varying the simulated signal over its signal span, and checking the correlation of bi-stable setpoints, channel readouts, and other loop elements with precision portable readout equipment. Test jacks are provided in the test panel for injection of the simulated process signal into each process analog protection channel. Test points are provided in the channel to facilitate an independent means for precision measurement and correlation of the test signal. With the exception of temperature loops that are monitored by special provisions, this procedure does not require any tools nor does it involve in any way the removal or disconnection of wires in the channel under test. In general, the analog channel circuits are arranged so the channel power supply is loaded and provides sensing circuit power during channel test. Load capability of the channel power supply is thereby verified by the channel test.

7.2.2.1.5 Nuclear Instrumentation Channel Testing

Nuclear instrumentation system channels are tested by superimposing the test signal on the actual detector signal being received by the channel. The output of the bi-stable is not placed in a tripped condition before testing. A valid trip signal would then be added to the existing test signal and thereby cause channel trip at a somewhat lower percent of actual reactor power. Protection bi-stable operation is tested by increasing the test signal (level signal) to the bi-stable trip level and verifying operation at control board alarms and/or at the nuclear instrumentation racks.

A nuclear instrumentation channel that can cause a reactor trip through one-out-of-two protection logic (source or intermediate range) is provided with a bypass function that prevents the initiation of a reactor trip from that particular channel during the short period that it is undergoing test. The power range channels do not require bypass of the reactor trip function for test, since the protection logic is two out of four. The power range dropped-rod alarm is activated from a one-out-of-four logic. The channel test condition is alarmed on the nuclear instrumentation drawer and at the main control board. Administrative control is required to ensure that only one protection channel is placed in the bypass condition at any one time. The power range reactor trips are not affected by the test function described above. Therefore these power range trips are active if required. No provision has been made in the channel test circuit for reducing the channel signal level below that signal being received from the nuclear instrumentation detector.

7.2.2.1.6 Logic Channel Testing

The general design features of the logic system are described below. The trip logic channels for typical two-out-of-three and two-out-of-four trip functions are shown in Figure 7.2-6. The analog portions of these channels are shown in Figure 7.2-7. Each bi-stable drives two relays, one for each train. Contacts from the “A” and “C” relays are arranged in a two-out-of-three and two-out-of-four trip matrix for trip breaker 1.

The above configuration is duplicated for trip breaker 2 by using contacts from the “B” and “D” relays. A series configuration is used for the trip breakers, since they are actuated (opened) by undervoltage coils. This approach is consistent with a de-energize-to-trip preferred failure mode. The planned logic system testing includes exercising the reactor trip breakers to demonstrate system integrity. Bypass breakers are provided for this purpose. During normal operation, these bypass breakers are open. Administrative control will be used to minimize the amount of time these breakers are closed and to prevent simultaneous closure of both bypass breakers. Indication of a closed condition of either bypass breaker is provided locally and on the test panel, and on the control room bench board.

As is shown in Figure 7.2-6, the trip signal from the logic network is simultaneously applied to the main trip breaker associated with the specific logic chain as well as the bypass breaker associated with the alternate trip breaker. Should a valid trip signal occur while bypass breaker AB-1 is bypassing trip breaker TB-1, trip breaker TB-2 will be opened through its associated logic train. The trip signal applied to TB-2 is simultaneously applied to AB-1, thereby opening the bypass around TB-l. Trip breaker TB-l would have either been opened manually as part of the test, or it would be opened through its associated logic train, which would be operational (or tripped) during a test.

An auxiliary relay is located in parallel with the undervoltage coils of the trip breakers. This relay is connected to a test panel mounted white test lamp. The test lamp is used to indicate transmission of a trip signal through the logic network during testing. Lights are also provided to indicate the status of the logic relays.

The following procedure illustrates the method used for testing TB-l and its associated logic network:

1. From the Train B test panel, close bypass breaker AB-1 with the breaker pushbutton, then trip AB-1 from the test panel and visually verify operation. Should AB-1 fail to open, then immediately trip AB-1 with the local trip pushbutton.
2. Close AB-1 from the Train B test panel and make test connections for timing of TB-1.
3. At the trip breaker cubicle, push and hold the “Auto Shunt Trip Block” pushbutton for the TB-1 Breaker.
4. Push the “Auto Shunt Trip Test” pushbutton for TB-1 and verify TB-1 does not trip.
5. Release the “Auto Shunt Trip Test” pushbutton only and sequentially de-energize the trip relays (A1, A2, A3) for the logic combination (1-2, 1-3, 2-3). Verify that the logic network de-energizes the undervoltage coil on TB-l for each logic combination. Verify TB-1 opens by observing breaker position lamps at the test panel and record TB-1 elapsed time.
6. Release the “Auto Shunt Trip Block” pushbutton.
7. For the remaining logic combinations, sequentially de-energize the trip relays (A1, A2, A3) and verify that the logic network de-energizes the undervoltage coil on TB-l (by observing the UV status lamp) for each logic combination.
8. Close TB-1 from the control room benchboard.
9. Depress the “Auto Shunt Trip Test” pushbutton for the “A” reactor trip breaker momentarily and verify TB-1 trips.
10. Remove all test connections and close TB-1 from the benchboard.
11. Open bypass AB-1 from the Train B test panel.

In order to minimize the possibility of operational errors (such as tripping the reactor inadvertently or only partially checking all logic combinations), each logic network includes a logic channel test panel. This panel includes those switches, lights, and pushbuttons needed to perform the logic system tests. This arrangement is illustrated in Figure 7.2-8. The test switches used to de-energize the trip bi-stable relays operate through interposing relays as shown in Figures 7.2-5 and 7.2-7. This approach avoids violating the separation philosophy used in the analog channel design. Thus, although test switches for redundant channels are conveniently grouped on a single panel to facilitate testing, physical and electrical separation of redundant protection channels are maintained by the inclusion of the interposing relay, which is actuated by the logic test switches.

Modifications to the reactor trip switchgear were implemented to satisfy action items in NRC Generic Letter 83-28 (Reference 4), to improve reactor trip system reliability.

The reactor trip switchgear was modified to provide a redundant/backup means to automatically trip the breakers. An automatic shunt trip relay was installed which de-energizes on a reactor trip signal and energizes the shunt trip attachment to trip the breaker. The automatic shunt trip relay, test pushbuttons, and test jack connectors are located on a panel installed into the reactor trip breakers instrument compartment.

Test jack connectors and pushbuttons are provided to test the automatic shunt trip devices and to verify breaker operations and response time.

7.2.2.1.7 Primary Power Source

The source of electrical power for the measuring elements and the actuation of circuits in the engineered safeguards instrumentation and the reactor protection system are described in Chapter 8.

7.2.2.2 **Protective Actions**

Rapid reactivity shutdown is provided by the insertion of control rod assemblies by free-fall. Duplicate series-connected circuit breakers supply all power to the control rod assembly drive mechanisms. The control rod assembly must be energized to remain withdrawn from the core. Automatic reactor trip occurs upon the loss of power to the control rod assemblies. The trip breakers are opened by the undervoltage coils on both breakers. The undervoltage coils, which are normally energized, become de-energized by any one of the several trip signals.

The design of the devices providing signals to the circuit breaker undervoltage trip coils is such as to cause these coils to trip the breaker on reactor trip signal or power loss.

Certain reactor trip channels are automatically bypassed at low power where they are not required for safety. Nuclear source range and intermediate range trips are specifically provided for protection at low power or subcritical operation. At higher power operations they are bypassed by manual action.

During power operation, a sufficient amount of rapid shutdown capability in the form of control rod assemblies is administratively maintained by means of the control rod insertion limit monitors. Administrative control requires that all shutdown group rods be in the fully withdrawn position during power operation except during low power physics testing.

Reactor trips, means of actuation, and the coincident circuit requirements are listed in Table 7.2-1. The interlocks, referred to in Table 7.2-1, are listed in Table 7.2-3.

7.2.2.2.1 Manual Reactor Trip

The manual actuating devices are independent of the automatic trip circuitry and are not subject to failures which make the automatic circuitry inoperable. Actuating either of two manual trip devices located in the control room initiates a reactor trip and a turbine trip.

7.2.2.2.2 Power Range High-Neutron-Flux Reactor Trip

This circuit trips the reactor when two of the four power range channels read above the trip setpoint. There are two independent trip settings, a high and a low setting. The high trip setting provides protection during normal power operation. The low setting, which provides protection during start-up, can be manually bypassed when two out of the four power range channels read above approximately 10% power (P-10). A reading of three out of the four channels below 10% automatically reinstates the trip function. The high setting is always active.

7.2.2.2.3 Intermediate Range High-Neutron-Flux Reactor Trip

This circuit trips the reactor when one out of the two intermediate range channels reads above the trip setpoint. This trip, which provides protection during reactor start-up, can be manually bypassed if two out of four power range channels are above approximately 10%. Three out of four channels reading below this value automatically reinstate the trip function. The intermediate channels (including detectors) are separate from the power range channels.

7.2.2.2.4 Source Range High-Neutron-Flux Reactor Trip

This circuit trips the reactor when one of the two source range channels reads above the trip setpoint. This trip, which provides protection during reactor start-up, can be manually bypassed when one of two intermediate range channels reads above the P-6 setpoint value, and it is automatically reinstated when both intermediate range channels decrease below this value (P-6). This trip is also bypassed by two out of four high-power-range signals (P-10). The trip function can also be reinstated below the P-10 setpoint value by an administrative action requiring coincident manual actuation. The trip point is set between the source range power level corresponding to the P-6 setpoint value and the maximum source range power level.

7.2.2.2.5 Overtemperature Delta T Reactor Trip

The purpose of this trip is to protect the core against departure from nucleate boiling. The allowable delta T for this tripping function is continuously calculated for each loop from the following equation:

$$\Delta T \leq \Delta T_0 \left[K_1 - K_2 \left(\frac{1 + \tau_1 s}{1 + \tau_2 s} \right) (T - T') + K_3 (P - P') - f(\Delta I) \right]$$

where: ΔT_0= indicated ΔT at rated thermal power, °F
T= average reactor coolant temperature, °F
T'= reference average reactor coolant temperature, °F
P= pressurizer pressure, psig
P'= reference pressurizer pressure, psig
K_1= OTΔT equation coefficient, unitless
K_2, K_3= OTΔT equation coefficients accounting for DNB effect of variations in system temperature and pressure, $°F^{-1}$, $psig^{-1}$
ΔI= P_{top}-P_{bot}, where P_{top} and P_{bot} are the percentage of power in the top and bottom halves of the core, respectively
$f(\Delta I)$= function to account for DNB effect of axial power skewing
τ_1, τ_2= lead-lag time constants, sec
s= Laplace transform variable, sec^{-1}

The allowable delta T is calculated for each reactor coolant loop. A trip occurs when the delta T in two out of the three (2/3) loops exceed the allowable delta T as calculated by the above equation. Initiation of automatic turbine load runback by means of an overtemperature delta T signal is discussed in Section 7.2.2.5.

7.2.2.2.6 Overpower Delta T Reactor Trip

The purpose of this trip is to protect against excessive power level (fuel rod rating protection). The allowable delta T for this tripping function is continuously calculated for each loop from the following equation:

$$\Delta T \le \Delta T_0\left[K_4 - K_5\left(\frac{\tau_3 s}{1+\tau_3 s}\right)T - K_6(T - T') - f(\Delta I)\right]$$

where: ΔT_0= indicated ΔT at rated thermal power, °F
T= average reactor coolant temperature, °F
T'= reference average reactor coolant temperature, °F
K_4= OPΔT equation coefficient, unitless
K_5, K_6= OPΔT equation coefficients accounting for effect of variations in system temperature $°F^{-1}$
ΔI= P_{top}-P_{bot}, where P_{top} and P_{bot} are the percentage of power in the top and bottom halves of the core, respectively
$f(\Delta I)$= function to account for effect of axial power skewing
τ_3= lead-lag time constant, sec
s= Laplace transform variable, sec^{-1}

The allowable delta T is calculated for each reactor coolant loop. A trip occurs when the delta T in two of the three (2/3) loops exceeds the allowable delta T as calculated by the above equation. Initiation of automatic turbine load runback by means of an overpower delta T signal is discussed in Section 7.2.2.5.

7.2.2.2.7 Pressurizer Low-Pressure Reactor Trip

The purpose of this trip is to protect against excessive core steam voids and to limit the necessary range of protection afforded by the overtemperature delta T trip. This trips the reactor on coincidence of two out of the three low pressurizer pressure signals. This trip is blocked when three of the four power range channels and two of the two turbine first-stage pressure channels read below approximately 10% power (P-7). Each channel is lead-lag compensated.

7.2.2.2.8 Pressurizer High-Pressure Reactor Trip

The purpose of this trip is to limit the range of required protection from the overtemperature delta T trip and to protect against reactor coolant system overpressure. The reactor is tripped on coincidence of two out of the three high pressurizer pressure signals.

7.2.2.2.9 Pressurizer High Water Level Reactor Trip

This trip is provided as a backup to the pressurizer high-pressure reactor trip. The coincidence of two out of the three pressurizer high water level signals trips the reactor. This trip is blocked when three of the four power range channels or two of two turbine first-stage pressure channels read below approximately 10% power.

7.2.2.2.10 Low Reactor Coolant Flow Reactor Trips

These trips protect the core from departure from nucleate boiling following a loss-of-coolant flow. The means of sensing loss-of-coolant flow are described below:

1. A low-flow signal generated by two out of three low-flow signals per primary coolant loop will cause a reactor trip. Above the P-7 setpoint (approximately 10% power), low flow in any two loops results in a reactor trip. Above the P-8 setpoint (approximately 35% power), low flow in any loop results in a reactor trip.
2. Opening of the reactor coolant pump breakers results in a reactor trip by acting directly on the reactor trip circuits. Above the P-7 setpoint the reactor trips on two open-breaker signals. Above the P-8 setpoint the reactor trips on one open-breaker signal. One open-breaker signal is generated for each reactor coolant pump.
3. Above the P-7 setpoint an undervoltage or underfrequency signal from any two reactor coolant pump buses results in a reactor trip. There is one underfrequency and two undervoltage sensors per bus. An underfrequency signal (2/3) directly trips all of the reactor coolant pumps, and if the power level is above the P-7 setpoint, a reactor trip will also result. These trips do not meet IEEE-279 from sensor to actuation device and are therefore backup trips.

The logic for these tripping functions is shown schematically in Figure 7.2-3.

7.2.2.2.11 Safety Injection System Actuation Reactor Trip

A reactor trip occurs when the safety injection system is actuated. The means of actuating the safety injection system trips are:

1. Low-low pressurizer pressure.
2. High steam-line differential pressure.
3. High steam flow in coincidence with low steam-line pressure or low T_{avg}.
4. High containment pressure.
5. Manual.

These trips are listed in Table 7.2-1. Since the safety injection system actuations not only trip the reactor but initiate various components of the engineered safeguards, the logic diagrams and chain of events may be found in Figure 7.5-1.

7.2.2.2.12 Turbine Trip Reactor Trip

A turbine trip is sensed by two out of three signals from autostop oil pressure or four out of four stop valve closure signals. A turbine trip causes a direct reactor trip above approximately 10% power and results in a controlled short-term release of steam to the condenser, which removes sensible heat from the reactor coolant system and thereby avoids steam generator safety valve actuation.

In addition, this trip is independently actuated by the Anticipated Transient Without Scram (ATWS) Mitigation System Actuation Circuitry (AMSAC) should the RPS fail to actuate a trip. Above a preset turbine power (C-20 permissive), two out of three low steam generator water level signals in two out of three steam generators will initiate a trip provided a time delay incorporated into the AMSAC is satisfied.

The following conditions automatically trip the turbine generator:

1. Turbine overspeed.
2. Generator transformer and line faults or both output breakers open above 15% turbine power.
3. Low condenser vacuum.
4. Thrust-bearing oil high pressure.
5. Low lube oil pressure.
6. Low auto-stop oil pressure.
7. Low intake canal level.

8. Both feedwater pumps tripped.
9. Electro-hydraulic control power failure.
10. Anti-motoring.
11. Safety Injection.
12. High-high steam generator level.
13. High-high sixth point feedwater heater level (time delay).
14. Stop valves shut.
15. Reactor trip.
16. Manual trip.
17. AMSAC actuation.

7.2.2.2.13 Low Feedwater Flow Reactor Trip

This trip protects the reactor from a sudden loss of its heat sink. The trip is actuated by a steam/feedwater flow (low feedwater flow) mismatch (one out of two) in coincidence with low water level (one out of two) in any steam generator.

7.2.2.2.14 Low-Low Steam Generator Water Level Reactor Trip

The purpose of this trip is to protect the steam generator in the case of a sustained steam/feedwater flow mismatch of insufficient magnitude to cause a flow mismatch reactor trip. The trip is actuated on two out of the three low-low water level signals in any steam generator. This trip is blocked for a steam generator in a loop with the loop stop valves closed.

In addition, a further drop in steam generator water level will cause an independently actuated trip by AMSAC under the same conditions specified in Section 7.2.2.2.12 above.

7.2.2.3 **Rod Stops**

Rod stops are added to prevent a reactor trip or prevent an abnormal condition from increasing in magnitude, which would cause a reactor trip. The automatic rod withdrawal function of the reactor control system is disabled. Rod stops continue to prevent unintentional manual rod withdrawal.

Rod stops are given in Table 7.2-4. Some of these have been previously noted under permissive circuits but are listed again, for completeness.

Rod stops actuated by overpower delta T or overtemperature delta T initiate turbine runback via load reference.

7.2.2.4 **Rod Drop Detection**

Two independent systems are provided to sense a rod drop: a rod bottom position detection system, and a system that senses sudden reduction in ex-core neutron flux. Both detection systems initiate alarms in the main control room.

The rod drop detection circuit from neutron flux consists basically of a derivative network. Since a dropped control rod assembly rapidly depresses the local neutron flux, the decrease in flux is detected by one or more of the power range detectors. The sudden decrease in detector current appears as a signal out of the derivative network. A signal output greater than a preset value (approximately 5%) trips an associated bi-stable. Any one of the four power range channels will actuate the rod drop alarm. The dropped-rod circuit is described in Section 7.4.3.

The backup indication for the dropped control rod assembly is the rod bottom signal derived for each rod from its individual position indication system. With the position indication system, initiation of protection is not dependent on location, reactivity worth, or power distribution changes.

Figure 7.4-2 indicates schematically the nuclear instrumentation system, including the dropped control rod assembly alarm.

7.2.2.5 **Automatic Turbine Load Runback**

Load runback is also initiated by an approach to an overpower or overtemperature condition. This will prevent high power operation, which might lead to a minimum DNBR less than the design DNBR limit (Section 3.2.3).

A turbine load reference reduction is initiated by an overtemperature or overpower delta T signal in two out of three loops.

The turbine runback signal is accompanied by rod withdrawal stops.

7.2.2.6 **Control Group Rod Insertion Monitor**

The control group rod insertion limit, Z_{LL}, is calculated as a linear function of power. The equation is:

$$Z_{LL} = A(\Delta T)_{auct} + C$$

where A is a preset, manually adjustable gain and C is a preset, manually adjustable bias. The $(\Delta T)_{auct}$ is the auctioneered value of the temperature differences. Each loop has its measured value for delta T; the auctioneered value is the median value.

An insertion limit monitor with two alarm setpoints is provided for the control banks. See Figure 7.2-9 for illustration of the monitor circuit. A description of control and shutdown rod groups is provided in Section 7.3. The “low” alarm alerts the operator of an approach to a reduced shutdown reactivity situation requiring boron addition by following procedures with the chemical and volume control system. If the actuation of the "low-low" alarm occurs, the operator should take immediate action to add boron to the system.

7.2.2.7 **Reactor Coolant Flow Measurement**

Elbow taps are used on each of the three loops in the reactor coolant system as an instrument device that indicates the status of the reactor coolant flow. The basic function of this device is to provide information as to whether or not a reduction in flow rate has occurred. The correlation between flow reduction and elbow tap readout has been well established by the following equation: $\Delta P/\Delta P_o = (\omega/\omega_o)1.8$, where ΔP_o is the referenced pressure differential with the corresponding referenced flow rate ω_o and ΔP is the pressure differential with the corresponding referenced flow rate ω. The full-flow reference point was established during initial unit start-up. The low-flow trip point was then established by extrapolating along the correlation curve. The technique has been well established in providing core protection against low coolant flow in Westinghouse pressurized water reactor plants. The expected absolute accuracy of the channel is within ±10%, and field results have shown the repeatability of the trip point to be within ±1%. The analysis of the loss-of-flow transient presented in Section 14.2.9 assumes instrumentation error of ±3%.

7.2.2.8 **Reactor Coolant Pump Trip**

Generic Letter 85-12 (Reference 2) required the implementation of an approved manual reactor coolant pump (RCP) trip criterion. The need for RCP trip is a result of excessive peak clad temperatures during small-break LOCA events with forced reactor coolant flow. The trip criteria must distinguish between LOCA and non-LOCA events where forced reactor coolant flow is beneficial to transient mitigation. RCP trip criterion is based on subcooling margin concurrent with at least one HPSI pump in operation and capable of delivering flow to the Reactor Coolant System (RCS).

7.2.3 System Evaluation

7.2.3.1 **Departure From Nucleate Boiling**

The following is a description of how the reactor protection system prevents departure from nucleate boiling.

The variables affecting the DNBR are:

1. Thermal power.
2. Coolant flow.
3. Coolant temperature.
4. Coolant pressure.

5. Core power distribution.

Figure 7.2-1 illustrates the typical core limits for which the DNBR for the hottest fuel rod is equal to the design DNBR limit (Section 3.2.3) and shows the locus of the overpower and overtemperature delta T reactor trips as a function of T_{avg} and pressure. This illustration is derived from the inlet-temperature versus power relationships.

Figure 7.2-10 illustrates “T_{avg} - delta T” protection. Periodic measurements using the incore instrumentation system are used to verify that the actual core power distribution is within design limits.

Reactor trips for a fixed high pressurizer pressure and for a fixed low pressurizer pressure are provided to limit the pressure range over which core protection depends on the overpower and overtemperature delta T trips.

Reactor trips on nuclear overpower and low reactor coolant flow are provided for direct, immediate protection against rapid changes in these parameters. However, for all cases in which the calculated DNBR approaches the design DNBR limit (Section 3.2.3), a reactor trip on overpower and/or overtemperature delta T would also be actuated.

The delta T trip functions are based on the differences between measured hot-leg and cold-leg temperatures. These differences are proportional to core power.

The delta T trip functions are provided with a nuclear differential flux feedback to reflect a measure of axial power distribution. This will assist in preventing an adverse axial distribution that could lead to exceeding the allowable core conditions.

In the event of a difference between the upper and lower ion chamber signals that exceeds the desired range, automatic feedback signals are provided to reduce the overpower/overtemperature trip setpoints, to block rod withdrawal, and to reduce the load to maintain appropriate operating margins to these trip setpoints.

7.2.3.2 **Control/Protection Interaction**

7.2.3.2.1 Nuclear Flux

Four power range nuclear flux channels are provided for overpower protection. On three-loop plants only one signal is used for automatic control. If any channel fails in such a way as to produce a low output, that channel is incapable of proper overpower protection. In principle, the same failure may cause rod withdrawal and hence overpower; however, the automatic rod withdrawal capability of the reactor control system has been disabled. The two-out-of-four overpower trip logic will ensure an overpower trip if needed even with an independent failure in another channel.

In addition, the control system will respond only to rapid changes in indicated nuclear flux; slow changes or drifts are compensated by the temperature control signals. Finally, an overpower signal from any nuclear channel will block rod withdrawal. The setpoint for this rod stop is below the reactor trip setpoint. Automatic rod withdrawal function of the reactor control system is disabled.

7.2.3.2.2 Coolant Temperature

The delta-T and T_{avg} signals developed in the reactor protection system for overtemperature delta-T and overpower delta-T reactor trips are also used in the reactor control system for rod position, steam dump, feedwater and pressurizer level control. Circuit isolators are installed to prevent a failure in the reactor control system from propagating back into the protection channels. In the control system, the delta-T and T_{avg} signals from each of the three protection channels are sent to Median Signal Selector (MSS) auctioneering circuits. The MSS is designed to prevent a failed protection system delta-T or T_{avg} signal from precipitating an inaccurate control system response. Under normal operating conditions with no failures in any RCS narrow range temperature instrument channel, the MSS will reject both the highest and lowest of the three signals received and pass to the control system only the signal whose value falls between the high/low extremes (i.e., median signal). If two of the three input signals have identical values, the MSS will select one of the two identical signals for control until a deviation between the two is detected, at which point the median signal will be passed to the control system as discussed above. If one of the three inputs should fail completely, the MSS will reject the failed signal and select the highest of the remaining two valid inputs for reactor control. The use of the Median Signal Selector circuits in the reactor control system satisfies the Control and Protection System interaction requirements of IEEE 279-1971, and prevents a spurious low temperature signal from causing rod withdrawal. Automatic rod withdrawal function of the reactor control system is disabled. Disabling automatic rod withdrawal also prevents unintended rod withdrawal on other spurious signals.

7.2.3.2.3 Pressurizer Pressure

Three pressurizer pressure protection channel signals are used for high-pressure and low-pressure protection and as inputs to the overtemperature delta T trip protection function (Figure 7.2-11). Two separate channels are used to control pressurizer spray and heaters and power-operated relief valves.

A spurious high-pressure signal from one channel can cause low pressure by actuation of pressurizer spray and/or a relief valve. Additional redundancy is provided in the protection system to ensure underpressure protection, i.e., two-out-of-three low-low-pressure reactor trip logic and two-out-of-three logic for safety injection.

The pressurizer heaters are incapable of overpressurizing the reactor coolant system. The maximum steam production rate of the pressurizer heaters is a fraction of the steam relief capacity of the pressurizer. Therefore, overpressure protection is not required for a pressure control failure; however, two-out-of-three high-pressure trip logic is used.

In addition, either of the two power-operated relief valves can easily maintain pressure below the high-pressure trip point. Each relief valve is controlled by an independent pressure channel, one of which is independent of the pressure channel used for heater control. Separation between heater control and one relief valve further precludes the likelihood of overpressurization of the system by a spurious low-pressure signal. Finally, the rate of pressure rise achievable with heaters is slow, and ample time and pressure alarms are available for operator action.

7.2.3.2.4 Pressurizer Level

High pressurizer level in two of the three pressurizer level channels will initiate a reactor trip. Isolated output signals from these channels are used for pressurizer level control. A level control failure could fill or empty the pressurizer at a slow rate (on the order of half an hour or more) (Figure 7.2-12).

A reactor trip on pressurizer high level is provided to prevent filling the pressurizer in the event of a rapid thermal expansion of the reactor coolant. A rapid change from high rates of steam relief to water relief could be damaging to the safety valves, relief piping, and pressure relief tank. However, a level control failure cannot actuate the safety valves because the high-pressure reactor trip is set below the safety valve set pressure. With the slow rate of charging available, overshoot in pressure before the trip is effective is much less than the difference between reactor trip and safety valve set pressures. Therefore, a control failure does not require protection system action. In addition, ample time and alarms are available for operator action.

7.2.3.2.5 Steam Generator Water Level/Feedwater Flow

Before describing control and protection interaction for these channels, it is beneficial to review the protection system basis for this instrumentation (Figure 7.2-13).

The basic function of the reactor protection circuits associated with low steam generator water level and low feedwater flow is to preserve the steam generator heat sink for removal of long-term residual heat. Should a complete loss of feedwater occur with no protective action, the steam generators would boil dry and cause an overtemperature/overpressure excursion in the reactor coolant. Reactor trips on temperature, pressure, and pressurizer water level will trip the unit before there is any damage to the core or reactor coolant system. Redundant auxiliary feedwater pumps are provided to prevent residual heat after trip from causing thermal expansion and discharge of the reactor coolant through the pressurizer relief valves. Reactor trips act before the steam generators are dry to reduce the required capacity and starting time requirements of these pumps and to minimize the thermal transient on the reactor coolant system and steam generators. Independent trip circuits are provided for each steam generator for the following reasons:

1. Should severe mechanical damage occur to the feedwater line to one steam generator, it is difficult to ensure the functional integrity of level and flow instrumentation for that unit. For instance, a major pipe break between the feedwater flow element and the steam generator

would cause high flow through the flow element. The rapid depressurization of the steam generator would drastically affect the relation between downcomer water level and steam generator water inventory.

2. It is desirable to minimize thermal transients on a steam generator for credible loss of feedwater accidents. It should be noted that controller malfunctions caused by a protection system failure affect only one steam generator. Also, they do not impair the capability of the main feedwater system under either manual control or automatic control. Hence, these failures are far from being the worst case with respect to decay heat removal with the steam generators.

A spurious high signal from the feedwater flow channel being used for control would cause a reduction in feedwater flow and prevent that channel from tripping. A reactor trip on low-low water level, independent of indicated feedwater flow, will ensure a reactor trip if needed.

In the event of an Anticipated Transient Without Scram (ATWS) event, the ATWS Mitigation System Circuitry (AMSAC) will trip the turbine, trip the reactor, isolate blowdown lines, and start the auxiliary feedwater pumps.

In addition, the three-element feedwater controller incorporates reset on level, such that with expected controller settings a rapid increase in the flow signal would cause only a small decrease in level before the controller reopened the feedwater valve. A slow increase in the feedwater signal would have no effect at all.

A spurious low steam flow signal would have the same effects as a high feedwater signal, discussed above.

A spurious high water level signal from the protection channel used for control will tend to close the feedwater valve. This level channel is independent of the level and flow channels used for reactor trip on low-flow coincident with low level.

The actual plant response to the controlling steam generator level channel depends on the initial power level, as discussed in the subparagraphs below. In the evaluation which follows, it is postulated that in addition to the spurious high signal from the steam generator level channel controlling feedwater flow, there is a failure in an additional level channel, consistent with the design requirements of IEEE-279 for evaluation of control and protection channel interactions. Since the steam generator low-low level protection function requires two out of three channels, this function would be rendered inoperable on the steam generator experiencing the loss of feedwater.

1. 0% to approximately 20% power

   Below approximately 20% power, feedwater is normally manually controlled via the main feedwater regulating valve bypass valves. Therefore it is highly unlikely that the failure of the single level channel will result in reduced feedwater flow to a steam generator. In addition, the low power level condition results in a significant allowed operator action time to respond to reduced feedwater flow conditions before the ANS Condition II criteria applicable to the loss of normal feedwater accident are violated. Manual control of the feedwater flow also serves to increase the level of operator awareness to the status of the feedwater system and steam generator inventory. If the operator does not take action, either a high pressurizer water level trip or a low-low steam generator level signal in one of the other steam generators will trip the reactor prior to exceeding any of the applicable acceptance criteria.

2. Approximately 20% power to approximately 54% power

   The low feedwater flow trip may not be available at power levels below approximately 54% power for a 1/N loss of feedwater event because measure steam flow may not be high enough to trip the high steam flow bistables. If the heatup is severe enough, the pressurizer water level could exceed the pressurizer high water level trip setpoint.

   If a reactor trip were generated, it would: (1) alert the operator of an abnormal condition and (2) cause the voids in the shell-side inventories of the unaffected steam generators to collapse and drop the water levels below the low-low level trip setpoint, thereby actuating the auxiliary feedwater system.

   In addition, secondary heat sink requirements at power levels below 54% power can be satisfied by the unaffected steam generators due to the reduced decay heat loads. These unaffected steam generators will continue to remove heat from the RCS until a low-low level signal is generated. If the RCS heats up rapidly, or if the letdown capacity is sufficient to prevent the high pressurizer water level trip, the overtemperature delta-T trip will preclude any potential violations of the core thermal limits. Thus, due to diversity in the design of the reactor protection system, an automatic reactor trip signal will be generated by one of the signals identified above if required.

3. Approximately 54% to 100% power

   If power level is greater than approximately 54%, the IEEE-279 scenario is protected by the steam/feed flow mismatch coincident with 1/3 low steam generator level reactor trip function. The low feedwater flow function is not a direct substitute for steam generator low-low level in that it does not provide for automatic initiation of auxiliary feedwater. However, the inventory in the unaffected steam generators will provide the necessary secondary heat sink for decay removal until the water level drops sufficiently to generate a low-low signal in the unfaulted generators and initiate AFW. Again, the high pressurizer water level signal will trip the reactor before the pressurizer can go water solid and overtemperature delta-T will provide backup protection in the event that the core thermal limits are approached.

7.2.3.2.6 Steam-Line Pressure

Three pressure channels per steam line are used for steam-line break protection. These are combined with other signals as shown in Table 7.2-1. Two-out-of-three high steam flow in coincidence with two-out-of-three low T_{avg} or in coincidence with two-out-of-three low steam-line pressure and two-out-of-three differential pressure between any steam line and steam-line header will actuate safety injection.

7.2.3.2.7 Anticipated Transient Without Scram (ATWS) Mitigation System Actuation Circuitry (AMSAC)

Pursuant to the requirements of 10 CFR 50.62, an AMSAC system has been installed to respond to an accident sequence should the reactor protection system (RPS) fail to shut down the reactor. The design basis for the system is summarized in Reference 4. The AMSAC provides a turbine trip, reactor trip, and auxiliary feedwater initiation, sends a signal to automatically close the steam generator blowdown valves, and trips the power supply breakers to the control rod motor generators.

The AMSAC design utilizes two turbine impulse chamber pressure sensors (one from two separate channels), as well as nine steam generator narrow range level sensors (three per steam generator) set at a range below the existing low-low level trip settings. The coincidence of two out of three steam generator level sensors taken twice and two out of two turbine impulse chamber pressure sensors detecting a pressure (load) greater than 37% automatically initiates the AMSAC. Time delays, which are set inverse to power, have been incorporated into the AMSAC circuitry to allow the RPS to function initially, if functioning properly. However, if the RPS does not initiate a reactor trip, the AMSAC will trip the reactor. These time delays are set based on consideration of the time that the steam generators take to boil down to the low-low level setpoint upon loss of main feedwater.

The AMSAC has been designed and installed to meet the following criteria:

1. Diversity - The AMSAC logic circuits have been designed and installed to be diverse from the RPS to the extent practicable.
2. Logic Power Supplies - The AMSAC logic circuit power supplies are normally powered from non-safety-related power sources independent of the RPS and capable of operating on a loss of offsite power. They can be powered from EDG #1 (Unit 1) and EDG #2 (Unit 2) by manual action.
3. Maintenance Bypasses - Bypass switches have been installed in the control room to block operation of the AMSAC's output relays when performing maintenance on the AMSAC.
4. Operating Bypasses - The C-20 permissive is utilized as the AMSAC operating bypass to enable the control room operator to bring the plant up in power during start-up to avoid spurious AMSAC actuations at power levels below 37% nominal turbine load.

The AMSAC generic design specified in Reference 6 called for AMSAC to be enabled when first stage turbine impulse pressure exceeded 40% (nominal) turbine load. This generic setpoint applies to all Westinghouse PWRs and is based on representative ATWS analyses which show that below 40% power an ATWS event without AMSAC produced only limited Reactor Coolant System (RCS) voiding. The Virginia Power AMSAC design specifies a nominal permissive (C-20) setpoint based on the generic setpoint of 40% turbine load minus an allowance for channel inaccuracies in the turbine impulse pressure channels themselves.

In some of the Reference 6 discussions, turbine load and reactor power are used interchangeably. In reality, turbine load, as represented by impulse pressure, and reactor power are not linearly related and the two values tend to deviate as power and load are reduced. The setpoint development did not specifically address this nonlinearity between turbine impulse pressure and reactor power.

As discussed in Reference 6 and supporting documents, the power level at which AMSAC is required to maintain the peak RCS pressure below the 3200 psig faulted stress limit for an ATWS has been shown generically to be 70% Rated Thermal Power (RTP). At power levels below 40% reactor power, an ATWS with no AMSAC would limit RCS voiding in the first 10 minutes to values less than obtained for the full power case with AMSAC.

For power levels between 40% and 70%, voiding is not predicted to occur until well after the peak RCS pressure is reached. Additional studies of the loss of feedwater ATWS have shown that for a C-20 setpoint corresponding to 50% RTP, the voiding that would occur without AMSAC was still less than that expected for the full power case with AMSAC (Reference 7).

Therefore the current Surry AMSAC design meets its design basis, provided AMSAC is armed at ≤40% turbine load (nominal) or ≤50% Rated Thermal Power.

Above 37% turbine load, the C-20 permissive will automatically arm the AMSAC logic. Upon the loss of a turbine impulse pressure signal or when turbine load decreases below 37%, the C-20 permissive will be blocked as noted in Table 7.2-1. The time delay is sufficient to avoid spurious trips while ensuring that the AMSAC will perform its function in the event of a turbine trip (loss of load trip).

5. Manual Initiation - Installation of the AMSAC does not preclude manual initiation of the AMSAC functions by utilizing existing manual controls for turbine trip, reactor trip, and auxiliary feedwater actuation, if necessary.
6. Electrical Independence from the RPS - Isolators have been installed at the interfaces in the AMSAC between safety-related and non-safety-related circuitry.
7. Physical Separation from Existing RPS - The AMSAC receives signals from the existing steam generator level and turbine impulse pressure instrumentation systems. However, the AMSAC cable routing is independent of RPS cable and the AMSAC equipment cabinets are located such that interaction with the RPS cabinets is precluded. Train separation requirements have also been maintained.

8. Environmental Qualification - AMSAC mitigation equipment is not required to be environmentally qualified, however, the equipment is located in mild environments in the station and will not be impacted by anticipated operational occurrences.
9. Testability at Power - End-to-end testing of the AMSAC system is performed every refueling outage. When the plant is at power, the system can be tested with the AMSAC outputs bypassed. The bypass is accomplished through permanently installed bypass switches. Status outputs to the main control board provide indication to the control room operator that the AMSAC system's outputs have been bypassed.
10. Seismic Qualification - The AMSAC panel and its components are Seismic Class I and have been seismically qualified to the requirements of IEEE-344-1975.

7.2.3.3 **Normal Operating Environment**

The normal operating environment for the main control room, and the qualification of protective equipment therein, is discussed in Section 7.7.

The average operating environment for equipment within the containment is normally maintained below 125°F. The reactor protection system instrumentation within the containment is designed for continuous operation. The temperature of the ex-core neutron detectors is maintained at or below 135°F. The detectors are designed for continuous operation at 135°F and will withstand operation at 175°F for short durations.

REACTOR TRIPS

Reactor Trip	Coincidence Circuitry and Interlocks	Comments
10. Safety injection signal (actuation)	Low-low pressurizer (2/3); or 3/4 high containment pressure; or 2/3 high differential pressure between any steam line and steam-line header; or high main steam flow in 2/3 steam lines (1/2 per line) in coincidence with either 2/3 low T_{avg} or 2/3 low stem-line pressure; or manual 1/2 (see 7.2, System Description - Protective Action for Interlocks)	Trips main feedwater pumps, which closes the associated discharge valves. Closes all feedwater control valves. Low pressurizer pressure coincident with low pressurizer level. SIS may be blocked below 2000 psig. High steam flow in coincidence with low T_{avg} or low steam-line pressure may be manually blocked below approximately 543°F.
11. Turbine-generator trip	2/3 low auto stop oil pressure interlocked with P-7 or closure of all turbine stop valves as sensed by 2 switches per stop valve (interlocked with P-7)	
12. Steam/feedwater flow mismatch, coincident with low steam generator level	1/2 steam/feedwater flow mismatch in coincidence with 1/2 low steam generator water level, any loop.	
13. Low-low steam generator water level	2/3, any loop.	
14. Intermediate range neutron flux	1/2, manual block permitted by P-10.	Below P-10 automatic reset.
15. Source range neutron flux	1/2, manual block permitted by P-6, interlocked with P-10.	Automatic block above P-10 and automatic reset below P-6.
16. Steam generator water level (AMSAC)	2/3 per steam generator in 2/3 loops after a time delay, interlocked with C-20.	Blocked below C-20 after a time delay.

7.3 REACTOR CONTROL SYSTEM

7.3.1 Design Bases

The reactor automatic control system is designed to reduce transients for the designed load perturbations, so that reactor trips will not occur for these load changes. Automatic rod withdrawal has been defeated; therefore, the automatic system can only respond to load reductions. Compensation for load increase must be performed manually.

The functional design of the reactor control and protection systems for the Surry Station is the same as that for H. B. Robinson Unit 2. In translating the functional requirements into control and protection equipment during the detailed design of the plant, there were some minor changes in equipment in order to:

1. Reduce the amount of equipment required to accomplish a specific control or protection function, and therefore reduce equipment maintenance time during plant operation.
2. Modify instrument and control ranges to be consistent with the plant parameters corresponding to the increased power rating of the Surry Station over that of the reference design (H. B. Robinson Unit 2).

Specific functions, however, are accomplished with the same degree of reliability and redundancy as the reference design.

Overall reactivity control is achieved by the combination of chemical shim and control rod assemblies. Long-term regulation of core reactivity is accomplished by adjusting the concentration of boric acid in the reactor coolant. Short-term reactivity control for power changes is accomplished by moving control rod assemblies.

The function of the reactor control system is to provide automatic control of the control rod assemblies during power operation of the reactor. The system uses input signals including neutron flux, isolated delta T and T_{avg} signals from the reactor protection system, and turbine load. The chemical and volume control system (Section 9.1) supplements the reactor control system by boration and dilution.

There is no provision for a direct continuous visual display of primary coolant boron concentration. When the reactor is critical, the best indication of reactivity status in the core is the position of the control group in relation to power and average coolant temperature.

There is a direct relationship between control rod position and power, and it is this relationship that establishes the calculated lower insertion limit displayed on the rod insertion limit recorder. There are two alarm setpoints to alert the operator to take corrective action in the event a control group approaches or reaches its lower limit.

Any unexpected change in the position of the control group under automatic control, or a change in coolant temperature under manual control, provides a direct and immediate indication of a change in the reactivity status of the reactor. In addition, periodic samples are taken for determination of the coolant boron concentration. The variation in concentration during core life provides a further check on the reactivity status of the reactor, including core depletion.

The reactor control system is designed to enable the reactor to follow load changes automatically when the output is above approximately 15% of nominal power. With automatic rod withdrawal disabled, control rod positioning may be performed manually for withdrawal and automatically for insertion when plant output is above this value, and insertion or withdrawal can be performed manually at any time.

The operator is able to select any single bank of rods for manual operation. This is accomplished with a multi-position switch so that he may not select more than one bank. He may also select automatic or manual reactor control; in either case, however, the control banks can be moved only in their normal sequence, with some overlap as one bank reaches its full withdrawal position and the next bank begins to withdraw. Relay interlocks, designed to meet the single-failure criterion, are provided to preclude simultaneous withdrawal of more than one bank of rods except in overlap regions.

The original design of the system enables the nuclear unit to accept a step load increase of 10% and a ramp increase of 5% per minute within the load range of 15% to 100% without reactor trip, subject to possible xenon limitations. Similar step and ramp load reductions are possible within the range of 100% to 15% of nominal power. With automatic rod withdrawal disabled, rods are manually withdrawn during load increase transients to maintain coolant average temperature near the programed value.

The control system is capable of restoring coolant average temperature to within the programmed temperature deadband following a scheduled or transient change in load. The coolant average temperature can be maintained by automatic or manual rod insertion during load decrease transients and manually during load increase transients.

The pressurizer water level is programmed to be a function of the average coolant temperature. This is to minimize the requirements on the chemical and volume control and waste disposal systems resulting from coolant density changes during loading and unloading from full power to zero power.

Following a reactor and turbine trip, sensible heat stored in the reactor coolant is removed, without actuating the steam generator safety valves, by means of controlled steam dump to the condenser and by injection of feedwater into the steam generators. Reactor coolant system temperature is reduced to the no-load condition. This no-load coolant temperature is maintained by steam dump to the condensers, which removes residual heat.

7.3.2 System Description

The reactor control system is designed to provide stable system control over the full range of automatic operation throughout core life without requiring operator adjustment of setpoints other than normal calibration.

A simplified block diagram of the reactor control system is shown in Figure 7.3-1. The reactor control system controls the reactor coolant average temperature by regulation of control bank rod position. The system is capable of restoring reactor coolant average temperature to the programmed value following a decrease in load. With automatic control rod withdrawal disabled, manual control rod withdrawal may be needed to restore the coolant average temperature to the programmed value following an increase in load. The programmed coolant average temperature increases linearly from zero power to the full-power condition.

The reactor control system will also compensate, to a certain extent, for reactivity changes caused by fuel depletion and/or xenon transients. Long-term compensation for these two effects is periodically made by adjustments of the boron concentration to return the control rod bank to its normal operating range.

The reactor coolant loop average temperatures are determined from hot-leg and cold-leg measurements in each reactor coolant loop. These signals are derived in the reactor protection system and sent to the reactor control system via circuit isolators. The error between the programmed average temperature and the median value of the average measured temperatures from each of the reactor coolant loops constitutes the primary control signal, as shown on Figure 7.3-2. An additional control input signal is derived from the reactor power versus turbine load mismatch signal. This additional control input signal improves system performance by enhancing response and reducing transient peaks. From these input signals, the rod direction command signals are derived. The rod speed command signal varies over the corresponding range of 3.75 to 45 inches per minute, depending on the magnitude and the rate of change of the input signals. The rod direction command signal is determined by the positive or negative value of the temperature difference signal. The rod speed and rod direction command signals are fed to the rod control system.

7.3.2.1 **Control Rod Assembly Arrangements**

There are 48 control rod assemblies (Section 3.3). The rods are divided among control and shutdown banks. There is a total of 16 control rod assemblies in the two shutdown banks. There are four control banks containing eight control rod assemblies each. The only control rod assemblies that can be manipulated under automatic control are the control rod assemblies in the control banks. Each control bank is divided into two groups to obtain smaller incremental reactivity changes per step. All control rod assemblies in a group are electrically paralleled to move simultaneously. There is individual position indication for each assembly.

7.3.2.2 **Rod Control**

7.3.2.2.1 Control Group Rod Control

The automatic rod control system maintains the average reactor coolant temperature by adjusting the positions of the control rod assemblies.

The rod control system is capable of restoring programmed average temperature following a change in load. The coolant average temperature can be maintained by automatic or manual rod insertion during load decrease transients and manually during load increase transients. The reactor coolant average temperature increases linearly from zero power to full power.

The control system will also initially compensate for reactivity changes caused by fuel depletion and/or xenon transients. Final compensation for these two effects is made by adjusting the boron concentration. The control system then readjusts the control group in response to changes in coolant average temperature resulting from changes in boron concentration.

The control rod assemblies are divided into two shutdown and four control banks, and each bank is divided into two groups, to follow load changes over the full range of power operation. Each group in a bank is driven by the same variable-speed rod drive control unit, which moves the groups sequentially one step at a time. The sequence of motion is reversible; that is, a withdrawal sequence is the reverse of the insertion sequence. The variable-speed sequential rod control affords the ability to insert a small amount of reactivity at low speed to accomplish fine control of reactor coolant average temperature about a small temperature deadband.

Manual control is provided to move a control bank in or out at a preselected fixed speed.

When the reactor power reaches approximately 15%, the operator may select the AUTOMATIC position, where the IN-HOLD-OUT lever is out of service and rod motion is controlled by the reactor control and protection systems. An interlock (P-2, Table 7.2-3) limits automatic control to reactor power levels above 15%. In the AUTOMATIC position, the rods are again inserted in a predetermined programmed sequence by the automatic programming equipment. However, rod withdrawal can only be performed manually. Manual rod withdrawal occurs in a predetermined sequence as discussed below.

Programming is set so that, as the first control bank out reaches a preset position near the top of the core, the second bank begins to move out simultaneously with the first bank. This staggered withdrawal sequence continues until the unit reaches the desired power level. The programmed insertion sequence is the opposite of the withdrawal sequence, i.e., the last control bank out is the first control bank in.

With the simplicity of the rod program, the minimal amount of operator selection, and two separate direct position indications available to the operator, there is very little possibility that rearrangement of the control rod sequencing could occur.

7.3.2.2.2 Shutdown Banks Control

The shutdown banks of control rods, together with the control banks, are capable of shutting the reactor down. The shutdown banks are used in conjunction with the control banks to provide shutdown margin of at least 1.77% following reactor trip, with the most reactive control rod in the fully withdrawn position for all normal operating conditions. The shutdown groups are manually controlled during normal operation and are moved at a constant speed. Any reactor trip signal causes them to fall into the core. They are fully withdrawn during power operation and are withdrawn first during start-up. Criticality is always approached by withdrawing the control groups after withdrawal of the shutdown groups.

7.3.2.2.3 Interlocks

Measurements of turbine first-stage pressure provide indication when outside of the automatic control range below 15% of nominal power (P-2, Table 7.2-3). The manual controls are further interlocked with measurements of nuclear flux and delta T to prevent approach to an overpower condition (P-1).

7.3.2.3 **Rod Drive Performance**

7.3.2.3.1 Control Rod Assemblies

The control banks are driven by a sequencing, variable-speed rod drive programmer. In a control bank of assemblies, control groups (each containing a small number of assemblies) are moved sequentially in a cycle so that all groups are maintained within one step of each other. The sequence of motion is reversible; that is, the withdrawal sequence is the reverse of the insertion sequence. The sequencing speed is proportional to the control signal from the reactor control system. This provides control group speed control proportional to the demand signal from the control system. A rod drive mechanism control center is provided to receive sequenced signals from the programmer and to actuate switches in series with the coils of the rod drive mechanisms. Two reactor trip breakers are placed in series with the supply for the coils. To permit on-line testing, a bypass breaker is provided across each of the two trip breakers.

The power for the entire complement of control and shutdown rod drive mechanisms is provided by a system composed of two ac motor-generator sets. The sets consist of squirrel cage induction motors driving synchronous alternators.

The total capacity of the system, including the overload capability of each motor-generator set, is such that a single set out of service does not cause limitations in rod motion during normal plant operation. In order to minimize reactor trip as a result of a unit malfunction, the power system is normally operated with both units in service.

Figure 7.3-3 shows the power supply to the rod control equipment and control rod drive mechanisms. The power supply connections from the reactor trip breakers to the rod control equipment are in protective enclosures and are sized to handle 1000A. The minimum current required to hold the control rods is approximately 150A. A failure in this power supply bus downstream of the trip breakers that results in an open circuit or short circuit would be detected by the dropping of the rods. There are no other power sources in the reactor trip breaker switchgear or the rod control equipment with sufficient capacity to hold a control rod assembly in position in the event that it became crossed with the trip breaker output bus and the trip breakers were tripped.

Flywheels on the motor-generator sets and high-speed regulators on each unit enable the rods to ride through a complete loss of ac power for one second during electrical transients.

7.3.2.3.2 Rod Position Indication

Two separate systems are provided to sense and display control rod position, as described below:

1. Analog system - An analog signal is generated by measuring the position of each control rod assembly. This is accomplished by means of a linear position transmitter.

   An electrical coil stack is placed above the stepping mechanisms of the control rod magnetic jacks external to the pressure housing.

   When the associated control rod is at the bottom of the core, the magnetic coupling between a primary and secondary is small, and there is a small voltage induced in the secondary. As the control rod is raised by the magnetic jacks, the relatively high permeability of the lift rod causes an increase in magnetic coupling. Thus, an analog signal proportional to rod position is obtained.

   Direct, continuous readout of every control rod assembly position is presented to the operator by redundant rod position flat panel displays.

   The individual analog rod position signals are fed to the plant computer system for monitoring and readout. A deviation monitor alarm is actuated if any rod differs in its measured position from its group step demand position by a preset value. The alarm will reflash in the event of subsequent rod deviations which exceed the preset value. When reactor power is below 50%, the preset deviation values are increased. However, the increased limits may not be utilized for more than one hour in the previous 24 hours prior to increasing power above 50%. When reactor power is less than 50%, the amount of time in the past 24 hours that the increased deviation limits have been utilized will be tracked by the computer. The deviation monitor alarm also indicates bank sequence errors and when any shutdown bank has inappropriately left its fully withdrawn position.

   A rod bottom condition for each rod is indicated on the redundant rod position flat panel displays.

2. Digital system - The digital system counts pulses generated in the rod drive control system programmer. One counter is associated with each group of control rod assemblies. Readout of the digital system is in the form of electromechanical add-subtract counters reading the number of steps of demanded rod position with one display for each group. These readouts are mounted on the control panel.

The digital and analog systems are separate systems; each serves as backup for the other. Operating procedures require the reactor operator to compare the digital and analog readings upon recognition of any apparent malfunction. Therefore, a single failure in rod position indication does not in itself lead the operator to take erroneous action in the operation of the reactor.

7.3.2.4 **Primary System Pressure Control**

Reactor coolant system pressure is controlled by the use of the pressurizer. Inside the pressurizer water and steam are maintained at saturation temperature and pressure by electrical heaters and water spray. The electrical immersion heaters are located near the bottom of the pressurizer. The pressurizer has five heater groups comprised of one proportional heater group and four (backup) heater groups.

The pressurizer pressure control is normally operated with the proportional heater group in automatic. Each group of the backup heaters can be operated in standby or manually energized. When all backup heater groups are in standby, the proportional heater group is used to control small pressure variations due to heat losses, including losses due to a small continuous spray. The spray nozzle is located in the top of the pressurizer. A small continuous spray flow is maintained to reduce thermal stresses and maintain uniform water chemistry. Any backup heater groups that are in standby will automatically energize when the pressurizer pressure controller signal drops below a given value, or when pressurizer level rises above a given value.

Operation with one or more backup heater groups manually energized will result in an increase in pressure controller signal. Additional spray is automatically initiated when the pressure controller signal is above a given setpoint. The spray rate increases proportionally with increasing pressure, until it reaches a maximum value. Steam condensed by the spray reduces the pressurizer pressure. Adequate spray flow exists to maintain pressure when all of the backup heaters are energized. A continuous spray is maintained automatically, in equilibrium with the heat output of the energized backup heaters. Operation in this configuration allows stable pressure control. It reduces thermal stresses and thermal shock, by avoiding thermal stratification in the surge line. It also allows a rapid equalization of boron concentration between the pressurizer and the RCS.

Two power-operated relief valves limit system pressure for large load reduction transients. Spring-loaded safety valves limit system pressure following a complete loss of load without direct reactor trip or turbine bypass.

7.3.2.5 **Pressurizer Level Control**

The water inventory in the reactor coolant system is maintained by the chemical and volume control system. During normal unit operation, the pressurizer level is controlled by the charging-flow controller, which controls the charging-flow control valve to produce the flow demanded by the pressurizer-level controller. The pressurizer water level is programmed as a function of coolant average temperature. The pressurizer water level decreases as the load is reduced from full load. This is the result of coolant contraction following programmed coolant temperature reduction from full power to low power. The programmed level is designed to match as nearly as possible the level changes resulting from the coolant temperature changes. To permit manual control of pressurizer level during start-up and shutdown operations, the charging-flow control valve can be manually regulated from the control room.

7.3.2.6 **Secondary System Control**

A review of the effects of the power uprate to a core power of 2587 MWt was conducted and the control systems and instrumentation were found to be adequate. The secondary system includes the steam generators and the condensate and feedwater systems.

The main steam, condensate, and feedwater systems are shown on Reference Drawings 1, 2, and 3.

All equipment is designed with highly reliable components. Maximum use is made of solid-state components in the electronic instruments; spring-loaded diaphragm control valves are employed to fail safe on loss of air or power.

All instrumentation and controls, where possible, are installed outside of the containment structure and in locations accessible for inspection and maintenance. Automatic control instruments in selected systems are provided with backup manual control through transfer switches. Alarms are provided to warn of abnormal conditions.

7.3.2.6.1 Turbine Steam Dump

The purpose of the steam dump valve system is to reduce reactor coolant system transients following a substantial turbine load reduction by dumping main steam directly to the condenser, thereby maintaining an artificial load on the steam generators. The control rod system can then reduce the reactor power to a new equilibrium value without causing overtemperature and/or overpressure conditions.

Following a reactor and turbine trip, sensible heat stored in the reactor coolant is removed without actuating the steam generator safety valves by means of a controlled steam dump to the condenser and by injection of feedwater to the steam generators. Reactor coolant system temperature is reduced to the no-load condition. This no-load coolant temperature is maintained by steam dump to the condensers, which removes residual heat.

The steam dump control system is designed to relieve steam from the steam generators to the condenser, to reduce the sensible heat in the primary system in the event of complete load rejection down to auxiliary load, and to maintain the steam generator pressure during hot standby conditions.

The turbine steam dump capacity was designed to be 40% of full-load steam flow at full-load steam pressure, all of which flows to the main condenser via the steam dump lines. For the measurement uncertainty recapture (MUR) power uprate, the steam dump capacity was reviewed for a bounding NSSS power of 2609 MWt. It was determined that the steam dump capacity could be as low as 28.7% of the steam flow rate corresponding to 2609 MWt NSSS power. Since this result was less than the 40% design criterion, the NSSS control system margin-to-trip analyses was reviewed. It was determined that there was acceptable margin to all relevant reactor trip setpoints for a 50% load rejection from 2609 MWt NSSS power.

When a load rejection occurs, if the change in the required program temperature of the reactor coolant system differs from the actual average temperature by more than a predetermined amount, a signal will actuate that portion of the steam dump system needed to reach the new program temperature.

The required number of steam dump valves choke or modulate full open, depending upon the magnitude of the temperature error signal upon receiving a loss-of-load signal. The dump valves can be modulated after they are full open by the reactor coolant average temperature signal.

The turbine steam dump flow reduces proportionally as the control rods act to reduce the average reactor coolant temperature. The artificial load is therefore removed as the reactor coolant average temperature is restored to its programmed equilibrium value.

7.3.2.6.2 Steam Generator Water Level Control

Each steam generator is equipped with a three-element feedwater controller (Figure 7.2-13) that maintains a programmed water level as a function of load on the secondary side of the steam generator. The three-element feedwater controller regulates the feedwater valve by continuously comparing the feedwater flow signal, the water level signal, and the steam flow signal, which is compensated by steam pressure signal. The steam generators are operated in parallel, both on the feedwater and on the steam side.

Continued delivery of feedwater to the steam generators is required as a sink for the heat stored and generated in the reactor coolant following a reactor trip and turbine trip. An override signal closes the feedwater valves when the average coolant temperature is below a given temperature or when the respective steam generator level rises to a given value.

Following a turbine trip, the main feedwater valves are closed on low T_{avg}. This provides an optimum heat sink. Subsequently, the operator remotely controls the feedwater regulating bypass valves to maintain the steam generator water level. Manual override of the feedwater control system is available at all times.

7.3.2.6.3 Turbine Control

The turbine control system is designed to regulate the steam flow to the turbine as a function of load or speed.

7.3.3 Design Evaluation

7.3.3.1 **Unit Stability**

The rod control system is designed to limit the amplitude and the frequency of continuous oscillation of reactor coolant average temperature about the control system setpoint within acceptable values. Continuous oscillation can be induced by the introduction of a feedback control loop with an effective loop gain that is either too large or too small with respect to the process transient response, i.e., instability induced by the control system itself. Because stability is more difficult to maintain at low power under automatic control, no provision is made to provide automatic control below 15% of full power.

The control system is designed to operate as a stable system over the full range of automatic control throughout core life.

7.3.3.2 **Step Load Changes Without Steam Dump**

A typical power control requirement is to restore equilibrium conditions, without a trip, following a ±10% step change in load demand, over the 15% to 100% power range for automatic control. With the automatic control rod withdrawal function disabled, manual control rod withdrawal will be required to restore equilibrium conditions following a 10% step increase in load. The design must necessarily be based on conservative conditions, and a greater transient capability is expected for actual operating conditions. A load demand greater than full power plus a small tolerance band is prohibited by the turbine control load limit devices.

The function of the control system is to minimize the reactor average coolant temperature deviation during the transient within a given value, and to restore average temperature to the programmed setpoint within a given time. The coolant average temperature can be maintained by automatic or manual rod insertion during load decrease transients and manually during load increase transients. Excessive pressurizer pressure variations are prevented by using spray and heaters in the pressurizer.

The margin between the overtemperature delta T setpoint and the measured delta T is of primary concern for step load changes. This margin is influenced by nuclear flux, pressurizer pressure, average reactor coolant temperature, and temperature rise across the core.

7.3.3.3 **Loading and Unloading**

Ramp loading and unloading of 5% per minute can be accepted over the 15% to 100% power range under manual control for loading and automatic or manual control for unloading without tripping the unit. The function of the control system is to maintain the reactor coolant average temperature as a function of turbine-generator load. The minimum control rod speed provides a sufficient reactivity insertion rate to compensate for the reactivity changes resulting from the moderator and fuel temperature changes.

The coolant average temperature increases during loading and causes a continuous insurge to the pressurizer as a result of coolant expansion. The sprays limit the resulting pressure increase. Conversely, as the coolant average temperature is decreasing during unloading, there is a continuous outsurge from the pressurizer resulting from coolant contraction. The heaters limit the resulting system pressure decrease. The pressurizer level is programmed so that the water level is above the setpoint at which the heaters cut out during the loading and unloading transients. The primary concern during loading is to limit the overshoot in average coolant temperature and to provide sufficient margin in the overtemperature delta T setpoint.

The automatic load controls are designed to safely adjust the unit generation to match load requirements within the limits of the unit capability and warranted power.

7.3.3.4 **Loss of Load With Steam Dump**

The reactor control system is designed to accept 50% load rejection without trip. No reactor trip or turbine trip should be actuated for load losses in this range. The automatic turbine steam dump system is able to accommodate this abnormal load rejection and to reduce the effects of this transient imposed upon the reactor coolant system. The reactor power is reduced at a rate consistent with the capability of the rod control system. Reduction of the reactor power is automatic down to 15% of full power. The steam dump flow reduction occurs as fast as the control rod assemblies are capable of inserting negative reactivity.

The pressurizer relief valves might be actuated for the most adverse conditions, e.g., the most negative Doppler coefficient, and the minimum incremental rod worth. The relief capacity of the power-operated relief valves is sized large enough to limit the system pressure to prevent actuation of high-pressure reactor trip for the above conditions.

7.3.3.5 **Turbine-Generator Trip With Reactor Trip**

Whenever the turbine-generator unit trips at an operating level above 10% power, the reactor also trips. The unit is operated with a programmed average temperature as a function of load, with the full load average temperature significantly greater than the saturation temperature corresponding to the steam generator pressure at the safety valve setpoint. The thermal capacity of the reactor coolant system is greater than that of the secondary system, and because the full-load average temperature is greater than the no-load steam temperature, a heat sink is required to remove heat stored in the reactor coolant to prevent actuation of steam generator safety valves for a trip from full power. This heat sink is provided by the combination of controlled release of steam to the condenser and by makeup of cold feedwater to the steam generators.

The steam dump system is controlled from the reactor average coolant temperature signal, whose setpoint values are reset upon trip to the no-load value. Actuation of the steam dump must be rapid, to prevent actuation of the steam generator safety valves. With the steam dump valves open, the average coolant temperature starts to reduce quickly to the no-load setpoint. A direct feedback of temperature acts to proportionally close the valves to minimize the total amount of steam that is dumped.

Following the turbine trip, the steam voids in the steam generator will collapse, and the fully opened feedwater valves will provide sufficient feedwater flow to restore water level in the downcomer. The feedwater flow is cut off when the average coolant temperature decreases below a given temperature value or when the steam generator water level reaches a given high level.

Additional feedwater makeup is then controlled manually to restore and maintain steam generator level while ensuring that the reactor coolant temperature is at the desired value. Residual heat removal is maintained by the steam generator pressure controller (manually selected), which controls the amount of steam flow to the condensers. This controller operates the same steam dump valves to the condensers that are used during the initial transient following turbine and reactor trip.

The pressurizer pressure and level fall rapidly during the transient because of coolant contraction. The pressurizer water level is programmed to match as near as possible the level changes as a result of coolant temperature changes and so that the water level is above the setpoint at which the heaters are turned off on low pressurizer level. If heaters become uncovered following the trip, the chemical and volume control system will provide full charging flow to restore water level in the pressurizer. Heaters are then turned on to restore pressurizer pressure to normal.

The steam dump and feedwater control systems are designed to prevent the average coolant temperature from falling below the programmed no-load temperature following the trip to ensure adequate reactivity shutdown margin.

7.3 REFERENCE DRAWINGS

The list of Station Drawings below is provided for information only. The referenced drawings are not part of the UFSAR. This is not intended to be a complete listing of all Station Drawings referenced from this section of the UFSAR. The contents of Station Drawings are controlled by station procedure.

7.4 NUCLEAR INSTRUMENTATION SYSTEM

7.4.1 Design Bases

7.4.1.1 Fission Process Monitors and Controls

The Nuclear Instrumentation System is used primarily for reactor protection. It permits monitoring of neutron flux and generates appropriate trip and alarm functions for various phases of reactor operating and shutdown conditions. It also provides a secondary control function, and indicates reactor status during start-up and power operation. Ex-core neutron flux detectors were added to meet R.G. 1.97 and Appendix R requirements. These are discussed in Section 7.10. The nuclear instrumentation system uses information from the three separate types of instrumentation channels to provide three discrete protection levels. Each range of instrumentation (source, intermediate, and power) provides the necessary overpower reactor trip protection required during operation in that range. The overlap of instrument ranges provides reliable continuous protection from source to the intermediate and low power ranges. As the reactor power increases, the overpower protection level is increased (administratively) after satisfactory higher-range instrumentation operation is obtained. Automatic reset to more restrictive trip protection is provided when reducing power.

Several types of neutron detectors, with appropriate solid-state electronic circuitry, are used to monitor the leakage neutron flux from a completely shut down condition to 120% of full power. The power range channels are capable of recording overpower excursions up to 200% of full power.

The neutron flux covers a wide range between these extremes. Therefore, monitoring with several ranges of instrumentation is necessary. The lowest range (source range) covers six decades of leakage neutron flux.

The lowest observed count rate depends on the strength of the neutron sources in the core and the core multiplication associated with the shutdown reactivity. This is generally greater than one count per second. The next range (intermediate range) covers approximately eight decades. Detectors and instrumentation are chosen to provide overlap between the higher portion of the source range and the lower portion of the intermediate range. The highest range of instrumentation (power range) covers slightly more than two decades of the total instrumentation range. This is a linear range that overlaps with the higher portion of the intermediate range (the intermediate range monitors go off-scale at any point greater than 70% of rated power based on the core loading pattern). The overlap for all detector ranges is shown in Figure 7.4-1 in terms of leakage neutron flux. Start-up-rate indication for the source and intermediate range channels is provided at the control console and on the nuclear instrumentation panel.

The system described above provides control room indication and recording of reactor neutron flux during core loading, shutdown, start-up, and power operation, as well as during subsequent refueling. Reactor trip and rod-stop control and alarm signals are provided by this system for safe plant operation. Control and permissive signals are transmitted to the reactor control and protection system for automatic plant control. Equipment failures and test status information are annunciated in the control room.

7.4.2 System Description

The nuclear instrumentation system (Figure 7.4-2) consists of eight independent channels: two of these are the source range, two are the intermediate range, and four are the power range channels. In addition, there are three auxiliary channels: the visual-audio count rate channel, the comparator channel, and the start-up-rate channel. The various detectors associated with the eight primary channels are shown in relative position with respect to the core configuration on Figure 7.4-3.

7.4.2.1 **Protection Philosophy**

Nuclear unit protection assurance, is obtained from the three ranges of ex-core nuclear instrumentation. Separation of redundant protective channels is maintained from the neutron sensor with its associated cables to the signal conditioning equipment in the control room with its associated output wiring, indicating or recording devices, and protective devices. Where redundant protective channels are combined to provide non-protective functions, the required signals are derived through isolation amplifiers. These devices are designed so that open or short-circuit conditions, as well as the application of 120V ac or 140V dc to the isolated side of the circuit will have no effect on the input or protective side of the circuit. As such, failures on the non-protective side of the system will not affect the individual protection channels. Redundant channels are powered from independent power sources, each channel being provided with the necessary power supplies for its detectors, signal conditioning equipment, trip bi-stables, and associated trip relays. The nuclear instrumentation channels are mounted in four separate racks to provide the necessary physical separation between redundant channels.

The overpower protection provided by the ex-core nuclear instrumentation consists of three discrete levels. Continuation of start-up operation or power increase requires a permissive signal from the higher-range instrumentation channels before the lower-range level trips can be manually blocked by the operator.

A one-out-of-two intermediate-range permissive signal (P-6, Table 7.2-3) is required prior to source range level trip blocking and detector high-voltage cutoff. Source range level trips are automatically reactivated and high voltage restored when both intermediate range channels are below the permissive (P-6) level. There are provisions for administratively reactivating the source range level trip and detector high voltage if required. Source range level trip block and high-voltage cutoff are automatically maintained by the same power range permissive (P-10), which permits blocking of the intermediate range and power range (low range) flux level trips.

The intermediate range level trip and power range (low range) level trip can only be blocked after satisfactory operation and permissive information are obtained from two out of four power range channels. Individual blocking switches are provided so that the power range (low range) trip and intermediate range trip can be independently blocked. These trips are automatically reactivated when any three of the four power range channels are below the permissive (P-10) level, thus ensuring automatic activation of more restrictive trip protection.

Blocking of any reactor trip function is indicated by the control board permissive status lights. Channels that provide reactor unit protection through one-out-of-two or one-out-of-four logic matrices are equipped with positive detent-type trip-bypass switches to enable channel testing. The trip-bypass condition for individual channels is indicated at the control board and at the nuclear instrumentation racks. The reactor unit protection afforded by the highest-setpoint, power range trip is never blocked or bypassed.

7.4.2.2 **Source Range Instrumentation**

Two independent source range channels are provided. Each receives pulse-type signals from a proportional counter. The preamplified detector signal is received by the source range instrumentation conditioning equipment located in the control room racks. The detector signal, which is a random count rate proportional to leakage neutron flux, is conditioned for conversion to an analog signal proportional to the logarithm of the neutron flux count rate.

The isolated analog signals from each channel are sent to various recording and indicating devices to provide the operator with necessary start-up information. Bi-stable units also located in the racks are used to generate alarms and reactor trip signals. Trip signals from the bi-stables are transmitted to relays in the protection relay racks, where the necessary logic involved in generating reactor trip signals is performed.

An isolated count-rate signal derived from either channel is connected to a scaler-timer. This same signal also feeds the audio count-rate channel, which provides an audible count-rate signal, proportional to the neutron flux. Speakers are provided both in the containment and in the control room. Start-up-rate indication is also provided for each source range channel. These signals are generated from the isolation amplifier output, since there is no protection function involved.

7.4.2.3 **Intermediate Range Instrumentation**

Two independent, compensated ionization chambers provide extended flux coverage from the upper end of the source range to any point greater than 70% of rated power based on core loading patterns. The equipment for each channel, including the high-voltage and compensating voltage power supplies, are located in separate drawers. To maintain separation between these redundant channels, the drawers are mounted in separate racks. The signal conditioning equipment furnishes an analog output voltage proportional to the logarithm of the neutron flux spectrum. Each channel covers approximately eight decades of leakage flux. Isolation amplifiers (for start-up-rate circuits, remote recording, remote indication, etc.) and bi-stable amplifiers (for permissives, rod-stop, and reactor trip) use this analog voltage to indicate plant status and provide the necessary plant protection functions. All relays associated with plant control or protection are located in the logic or auxiliary relay racks.

7.4.2.4 **Power Range Instrumentation**

Four dual-section, uncompensated ionization chambers are used for power range flux detection. Each chamber provides two current signal outputs (one from each section) to signal conditioning equipment in the control room racks. Each chamber has an independent high-voltage power supply. The individual current signals obtained from each section of the detector are proportional to upper-core and lower-core neutron flux, respectively. These provide core flux status information at the instrument racks and, through isolation amplifiers, provide the same information at the control console. A separate output furnishes bias signals used in the overpower and overtemperature delta T reactor trip functions. The individual current signals are combined to provide an average signal proportional to average core flux in the associated core quadrant. This average signal is conditioned to provide an analog voltage signal for use in permissive, control, and protection bi-stable amplifiers.

Isolation amplifiers, which provide remote control signals and core power status information to the operator and plant computer system (PCS), also utilize the average power analog signal. The four power range channels are operated from separate ac sources and are housed in separate racks so that a single failure will not cause loss of protection functions. Redundant relays for the protection functions are located in the logic portion of the protection system.

Isolated analog outputs from each power range channel are compared in a separate auxiliary channel drawer. This comparator provides the operator with annunciation of deviations in average power between the four power range channels. Switches are provided to defeat this comparison for a failed channel so that subsequent deviations or failures among the three remaining channels are annunciated.

7.4.2.5 **Equipment Design**

The ex-core nuclear instrumentation system consists of various plug-in-type modules that perform the functions indicated on Figure 7.4-2 for the source, intermediate, and power ranges. Components designed to military specifications are used, where possible, in conjunction with a conservative design stressing reliability, derating of components and circuits, and the use of field-proven circuits. On-line testing and calibration features are provided for each channel. The test signals are superimposed on the normal sensor signal during plant operation. This permits valid trip conditions to override the test signal, unless the sensing element is disconnected from the circuit for maintenance activities.

7.4.3 Components

7.4.3.1 Detectors

The nuclear instrumentation system employs six detector radial locations containing a total of eight detectors (two proportional counters, two compensated ionization chambers, and four dual-section, uncompensated ionization chamber assemblies) installed around the reactor in the primary shield. Windows in the primary shield minimize leakage flux attenuation and distortion.

Boron fluoride proportional counters having a nominal thermal neutron sensitivity of 10 counts/neutron/cm^2/sec (cps/nv) provide pulse signals to the source range channels. These detectors are installed on opposite “flat” portions of the core at an elevation approximating the quarter-core height.

Compensated ionization chambers serve as neutron sensors for the intermediate range channels, and are located in the same instrument wells and detector assemblies as the source range detectors. These detectors have a nominal thermal neutron sensitivity of 4×10^{-14}A/n/cm^2/sec. Gamma sensitivity is less than 3×10^{-11}/Roentgen/hr when operated uncompensated, and is reduced to approximately 3×10^{-13}A/R/hr in compensated operation. The detectors are positioned at an elevation corresponding to the center of the quarter-core height.

The detector assemblies containing one each of the above-mentioned detectors use watertight, corrosion-resistant, steel enclosures. High-density polyethylene, used as a moderator-insulator within the detector assemblies, will be confined at temperatures associated with a LOCA. The detectors are connected to the junction box at the bottom of the detector well by special high-temperature, radiation-resistant cables.

The remaining four detector assemblies contain the power range ionization chambers. Each provides two current signals corresponding to the neutron flux in the upper and lower sections of a core quadrant. These detectors have a total neutron sensitive length of 10 feet and a nominal thermal neutron sensitivity for each section of 1.7×10^{-13}A/n/cm^2/sec. Gamma sensitivity of each section is approximately 10^{-10}A/R/hr.

The detector assemblies for power range operation are installed vertically and located equidistant from the reactor vessel at all points, and, to minimize neutron flux pattern distortions, within one foot of the reactor vessel. Cabling from individual detector wells to the containment penetrations and to the instrument racks in the control room is routed in individual conduits, with physical separation between the penetrations and conduits associated with redundant protective channels.

7.4.3.2 Source Range Components

The source range output information is tabulated in Table 7.4-1. The detector for each source range channel is a Boron-10 lined proportional counter. The signal received from the counter has a range of 1 to 10^6 pulses per second randomly generated, and is received through a fixed gain pulse preamplifier located outside the containment. The preamplifier optimizes the signal-to-noise ratio and also furnishes high-voltage coupling to the detector.

The preamp has internal provisions for generating self-test frequencies of 10 counts per second (cps) and 10.24 kcps. These test oscillator circuits are energized by a switch located on the associated source range drawer. The source range channel power supplies furnish low voltage for preamp operation as well as low voltage for the drawer-mounted modules. The preamp is solid-state in design, with discrete components, and includes an impedance matching network between the preamp output and the 75-ohm triaxial or superscreen cable.

The preamp output is received at the postamplifier located on the source range drawer. This module provides amplification and discrimination, both of which are adjustable. Discrimination is provided between neutron flux pulses and combined noise and gamma-generated pulses. The discriminator supplies two outputs: one output (isolated) to a scaler-timer unit on the visual-audio channel drawer (see source range auxiliary equipment), and the other to a pulse shaper (transistorized flip-flop circuit) that supplies a constant amplitude pulse to the log integrator module within the source range drawer.

Logarithmic integration of the pulse signal is performed in another modular unit to obtain an analog dc signal. The log signal is then amplified for local indication on the front panel of the source range drawer, and is also delivered through a parallel run to the source range level bi-stables and isolation amplifier. The analog output signal is proportional to the count rate being received from the sensor, and is displayed by the front panel meter on a scale calibrated logarithmically from 10^0 to 10^6 cps. The solid-state isolation amplifier provides five analog outputs, all of which are adjustable through attenuator controls. Three outputs are used as follows: as remote indication (0−1 ma); as remote recording (0−37.5 mV dc); and as an input to the PCS (0−5V dc). A 0−10V dc output is used by the start-up-rate amplifier to produce a start-up-rate indication at the main control board. The remaining output (0−5V dc) is a spare.

All bi-stables employ a basic plug-in module with the external wiring determining the mode of operation (latching or non-latching) and direction of output change with rising power. Bi-stables have two adjustments: “Trip Level” and “Differential.” The first adjustment determines the trip point of the bi-stable, while the second determines the “dead zone” difference between the trip and release points of the bi-stable. The bi-stable module card includes a relay driver circuit made up of a silicon-controlled rectifier and full-wave bridge configuration. The bi-stable output controls are the silicon-controlled rectifier gate, which, in turn, controls conduction of the full-wave bridge supplying the power to drive up to four 115V ac Westinghouse BF relays. Relays are located remote from the nuclear instrumentation system racks.

Of the three bi-stables monitoring the source range level amplifier signal, one is a spare, one is used to monitor shutdown flux level only, and the third monitors source range operation during shutdown and start-up operation and provides a reactor trip on high flux level. The reactivity of the core during shutdown is monitored by a bi-stable to ensure protection of plant personnel working in the containment. Bi-stable tripping will initiate local visual and audible annunciation and remote audible annunciation of any abnormal increase in core activity. Visual annunciation occurs at the nuclear instrumentation system rack and on the main control board. Audible annunciation is handled by the annunciator located in the control room, and the evacuation horn located in the containment.

These annunciators ensure that plant personnel are alerted to any potentially hazardous condition. This bi-stable action is manually blocked by deliberate operator action during plant start-up. Blocking is continuously annunciated at the control board during source range operation and is automatically blocked by permissive P-6. The bi-stable trip point is approximately one-half decade above the flux level recorded during full shutdown.

The source range level bi-stable monitors the core reactivity during the full span of source range operation, until such time as the intermediate range channels assume control of that portion of the reactor protection that is being supplied by nuclear instrumentation. At that time, when the intermediate range permissive P-6 is available, the source range reactor trip bi-stable may be manually blocked, and high voltage removed from the B10 detector by the operator's actuation of two momentary-contact switches located on the main control board.

A fourth bi-stable-relay driver unit is used as a high-voltage failure monitor. Loss of this voltage actuates the bi-stable, the relay driver, and then the associated relay. The relay provides control board annunciation through a one-out-of-two matrix formed with a similar relay controlled by the other source range channel. Failure of either source range high voltage actuates this common annunciator on the main control board. During normal operation, the source range high voltage will be cut off (as described above) when manual block of the source range trips is initiated. In this instance, loss of high-voltage annunciation will be intentionally defeated to prevent the alarming of a condition that is not abnormal.

A test-calibrate module is also included in each source range drawer for self-check of that particular channel. A multiposition switch on the source range front panel controls this module and also the operation of the built-in oscillator circuits in the preamp. The module is capable of injecting test signals of either 60, 10^3, 10^5 or 10^6 cps at the input to the post amplifier, or a variable dc voltage corresponding to 1 to 10^6 cps at the input to the log amplifier. An interlock between the trip bypass switch and the test-calibrate switch will prevent inadvertent actuation of the reactor trip circuits, (i.e., the channel cannot be put in the test mode unless the trip is defeated). Trip bypass will be annunciated on the source range drawer and on the main control board, per IEEE 279 Standard, Section 4.13. Operation of the test-calibrate module will be annunciated on the control board as "Nuclear Instrumentation System Channel Test." This common annunciator for all nuclear instrumentation system channels is alarmed when any channel is placed in the test position, and alerts the operator that a test is being performed at the nuclear instrumentation system racks.

7.4.3.3 **Source Range Auxiliary Equipment**

7.4.3.3.1 Visual-Audio Count Rate

The visual-audio count rate receives a signal from each of the source range channels. This isolated signal originates at the discriminator output in each source range channel. A switch on the audio count-rate drawer selects either source range channel for monitoring. The selected signal is fed to a scaler-timer unit that permits count accumulation in the preset time or preset count mode. A visual display to five decimal places is presented through counting strips located on the front of the audio count-rate drawer.

A “Scale Factor” switch permits division of the scaler output signal by 10, 100, or 1000. This signal, derived from the printer output of the scaler, is conditioned and sent to two of the audio amplifiers, which power two speakers: one speaker located in the control room, and the other in the containment. These speakers give personnel an audible indication of the count rate. Since the audio amplifier signal is taken from the coded scaler output, adjustment of the scale factor switch will alter only the audible count rate. This enables the operator to maintain the audible count rate at a distinguishable level.

7.4.3.3.2 Remote Count-Rate Meter

The remote meter indication is an analog signal proportional to the count rate being received, and is obtained from the 0 to 1 mA isolation amplifier output.

The meter is mounted on the main control board and calibrated logarithmically from 10^0 to 10^6 cps. This meter gives the same indication at the control board as is displayed by the local meter on the corresponding source range drawer.

7.4.3.3.3 Remote Recorder

This recorder is capable of continuously recording the nuclear instrumentation system channels. Each channel is directly connected to the multipen recorder. In the case of the source ranges, a 0 to 37.5 mV dc signal, proportional to the count rate range of 10^0 to 10^6 cps, is supplied for recording during source range operation.

7.4.3.3.4 Start-up-Rate Circuitry

The start-up-rate drawer receives four input signals (0−10V dc), one from each of the source and intermediate range channels. Four rate amplifier modules condition these signals and output four rate signals to the respective control room start-up-rate meters. A test module is provided that can inject a test signal into any one of the rate circuits, and can be monitored on a test meter mounted on the front panel of this drawer. Two power supplies are provided to ensure rate indication from at least one source and intermediate range channel pair.

7.4.3.4 **Intermediate Range Components**

Intermediate range output information is tabulated in Table 7.4-2. Each intermediate range channel receives a direct current signal from a compensated ion chamber, and supplies positive high voltage and compensating (negative) high voltage to its respective detector. The compensating high voltage is used to cancel the effects of gamma radiation on the signal current being delivered to the intermediate range channel. Both high-voltage supplies will be adjustable through controls located inside the channel drawer. The detector signal is received by the intermediate range logarithmic amplifier. The modular unit, comprising several operational amplifiers and associated discrete solid-state components, produces an analog voltage output signal that is proportional to the logarithm of the input current. This signal is used for local indication and is monitored by the isolation amplifier and the various bi-stable relay-driver modules within the intermediate range drawer. A 10^{-11}A signal is continuously inserted, and serves as a reference during gamma compensation. Local indication is provided by a meter mounted on the front panel of the drawer, which has a logarithmic scale calibration of 10^{-11} to 10^{-3}A.

The isolation amplifier is the same solid-state module that is used in the source range; it supplies the same five outputs for the same usage. Six bi-stable relay-driver units are used in the intermediate range drawer to provide the following functions:

1. One monitors the positive high voltage.
2. One monitors the compensating high-voltage.
3. One provides the permissive P-6.
4. One provides rod-stop (blocks manual rod withdrawal).
5. One provides reactor trip.
6. One serves as a spare.

The intermediate range permissive P-6 bi-stable drives two Westinghouse BF relays (for redundancy), and the relays from each channel are combined in one-out-of-two matrices to provide the permissive function and control board annunciation of permissive availability. Permissive P-6 permits simultaneous manual blocking of the source range trips, and removal of the source range detector high voltage. Once source range blocking has been performed, the operator may, through administrative action, defeat permissive P-6 and reactivate the source range high-voltage and trip functions if required. This defeat is accomplished by the coincident operation of two control-board-mounted, momentary-contact switches. This provision, however, is only operational below permissive P-10, which is supplied by the power range channels. Above P-10, the defeat circuit is automatically bypassed and permissive P-6 is maintained which, in effect, maintains source range cutoff. The level bi-stable relay-driver unit that provides the intermediate range rod-stop function also drives two Westinghouse BF relays. Again, one-out-of-two matrices formed by the relays from the two intermediate range channels supply the rod-stop function and control board annunciation. Blocking of the outputs of these matrices is administratively performed when nuclear power is above permissive P-10, and can only be accomplished by deliberate operator action on two control-board-mounted switches.

The intermediate range reactor trip function is provided by a similar circuit arrangement, the only difference being the trip point of the bi-stable units. The same control board switches that control blocking of the rod-stop matrices also provide blocking action for the reactor trip matrices. These blocks are manually inserted when the power range instrumentation indicates proper operation through activation of the P-10 permissive function. On decreasing power, however, the more restrictive intermediate range trip functions are automatically reinserted in the protective system. While these trips are blocked, there will be continuous illumination on the main control board of "Intermediate Range Trip and Rod Stop Blocked." The high-voltage failure monitors provide both local and remote annunciation upon failure of the respective high-voltage supplies. A common "Intermediate Range Loss of Detector Voltage" and separate "Intermediate Range Loss of Compensate Voltage" are provided as control board annunciators for the intermediate ranges.

Administrative testing of each intermediate range channel is provided by a built-in test-calibrate module that injects a test signal at the input to the log amplifier. The signal is controlled by a multiposition switch on the front of each intermediate range drawer. A fixed 10^{-11}A signal is available, along with a variable 10^{-10} through 10^{-3}A signal, selectable in decade increments.

As in source range testing, the test switch on the intermediate range must be operated in coincidence with a trip bypass on the drawer. An interlock between these switches prevents injection of a test signal, until the trip bypass is in operation. Removal of the trip bypass also removes the test signal.

7.4.3.5 **Intermediate Range Auxiliary Equipment**

7.4.3.5.1 Remote Meter

The remote meter indication is in the form of an analog signal (0–1 mA) proportional to the ion chamber current. The isolation amplifier in each channel supplies this output to a separate meter. Meter calibration is 10^{-11} to 10^{-3}A.

7.4.3.5.2 Remote Recorder

This is the same recorder described above for the source range. A 0 to 50 mV dc signal from the isolation amplifier is supplied to the recorder and is proportional to the ion chamber current range of 10^{-11} to 10^{-3}A. All the intermediate range signals are connected to the recorder.

7.4.3.6 **Power Range Components**

The power range output information is tabulated in Table 7.4-3. The power range detector is a long, uncompensated ion chamber assembly consisting of two separate neutron-sensitive sections. Each section supplies a current signal to the associated power range. There is one high-voltage power supply per channel that supplies voltage to both sections of the associated detector. The two signals are received at the channel input and handled through separate shunt, filter board assemblies. There is a meter range/rate switch for each digital ammeter located on the front panel of the power range drawer. Each meter range/rate switch has four positions, namely 400µA/slow, 4000µA/slow, 400µA/fast, and 4000µA/fast. The switch selects shunt resistors for the meter but never interrupts the ion chamber signal to the power range channel. The circuit is so designed that a failure of the meter or switch will not interrupt the signal to the average power circuitry.

The individual currents are displayed on the two front ion chamber current meters and are then sent to separate isolation amplifiers. There are two isolation amplifiers monitoring each of the two individual current signals. The unit feeding the delta T protection function is being used for its impedance-matching characteristics rather than isolation. All of the isolation amplifiers are capable of providing the same five output ranges as the isolation amplifiers previously described in relation to the source and intermediate ranges. Two of the isolation amplifiers (used as impedance matching networks), one monitoring each of the currents, supply signals to the delta T reset. The other two isolation amplifiers provide output for the remote recorder, remote meter, and PCS. The individual current signals are then sent to a summing amplifier module that outputs a linear 0 to 10V dc signal proportional to their average. The output of this unit will feed a linear amplifier with two controls: one a “Zero” adjust located on the module itself, the other a “Gain” adjust with a calibrated dial located on the drawer’s front panel. The output signal from this unit corresponds to 0% to 120% of full power and is displayed on a percent full-power meter on the front panel of the power range drawer. This same signal is delivered directly to three isolation amplifiers, a dropped-rod sensing assembly, and six bi-stable relay-driver modules. These isolation amplifiers are identical to those previously described, and the outputs are the same in number and range but are used in different functions. (Specific outputs from the amplifiers are discussed in the auxiliary equipment section that follows.)

The dropped-rod sensor assembly is an operational amplifier unit that incorporates an adjustable lag network at one input and a non-delayed signal on the other. The unit compares the actual power signal with the delayed power signal received through the lag network, and amplifies the difference. This amplified differential signal is delivered to a bi-stable relay-driver unit that trips when the level of this signal exceeds a preset amount. Tripping of this unit indicates a power level change over the lag period, which would be indicative of a dropped rod. This bi-stable unit is a latching type, ensuring that the necessary action will be initiated and carried to completion. Specifically, the unit controls dual Westinghouse BF relays which, in one-out-of-four logic matrices, provide a control board annunciation signal, and a PCS input signal. A reset switch on the associated power range drawer must be operated manually to reset the bi-stable.

The bi-stable units that sense the power level signal, as derived by the linear amplifier, are non-latching and perform the following functions: (1) overpower rod-stop (blocks manual rod withdrawal); (2) permissive functions; (3) low-range reactor trip; and (4) high-range reactor trip.

The overpower rod-stop and permissive bi-stables are units that trip on high power level and control Westinghouse BF relays in the remote relay racks. The rod-stop relay matrices (one-out-of-four) provide a rod-stop function to the rod control system and a main control board annunciation. Two-out-of-four logic, developed by relays controlled through the respective power range bi-stables, provide the signals required for the permissive functions. One set of relays provides permissive P-10, as previously discussed regarding its use in the source range and intermediate range. One set of relays provides permissive P-8, as previously discussed in Section 7.2.2 regarding low reactor coolant flow trips. One other group of relays is provided as a spare.

Permissives P-8 and P-10 are supplied solely by nuclear instrumentation. For this reason, the nuclear instrumentation design provides for main control board annunciation of P-8 and P-10 availability. Permissive P-10 is used in all three ranges of nuclear instrumentation, while P-8 is provided by nuclear instrumentation for use in the reactor protection system.

The low-range trip bi-stable actuates two Westinghouse BF relays in the logic system. The two relays provide redundance within the logic portion of the protection system. Each relay is used in a separate matrix with the relays from the other power range channels to continue the redundancy. The logic circuitry formed by the contacts on these relays provide for one-out-of-four and two-out-of-four logic outputs. The low-range trip relays provide the following functions: (1) PCS input (single channel); (2) low-range trip annunciation (two-out-of-four coincidence); (3) reactor trip signal to reactor protection system (two-out-of-four coincidence); and (4) annunciation of “Single Channel Low-Range Trip” (one-out-of-four).

Provisions for manually blocking the low-range trip become available when two-out-of-four power ranges exceed the permissive P-10 level. Operator action on two control-board-mounted momentary-contact switches then initiates the blocking action. A control board permissive status light, “Power Range Low-Range Trip Blocked,” will be illuminated continuously when the trip function is blocked. On decreasing power, three of four power ranges below the P-10 power level will automatically reactivate the low-range trip.

The high-range reactor trip logic circuitry is developed identical to the low-range reactor trip circuitry, but no provision for blocking is included. The high-range trip remains active at all times to prevent any continuation of an overpower condition.

An additional bi-stable unit monitors the high-voltage power supply in the power range. Operation of this unit is identical to that for the source and intermediate ranges. The bistable provides relay actuation in the remote relay racks on failure of power range high voltage. While there is a separate relay for each power range, they control a common “Power Range Loss of Detector Voltage” annunciator on the main control board. Separate local indication of high-voltage failure is provided on the power range drawers.

The test-calibrate module provided on each power range is capable of injecting test signals at several points in the channel. In all cases, the test signals are superimposed on the normal signal. A bypass of the dropped-rod circuit is not required during channel test since this circuit produces only an alarm through one-out-of-four logic matrix for a sudden power change. Test signals can be injected independently or simultaneously at the input of either ammeter-shunt assembly to appear as the individual ion chamber currents. Operation of the test-calibrate switch on any power range will cause the "Channel Test" annunciator to be alarmed on the main control board.

7.4.3.7 **Power Range Auxiliary Equipment**

7.4.3.7.1 Comparator

The comparator receives an isolated signal from each of the four power range detectors. These signals are conditioned in separate operational amplifier circuits and then compared with one another to determine if a preset amount of deviation of power levels has occurred between any two power ranges. Should such a deviation occur, the comparator output will operate a remote relay to actuate the control board annunciator, "Power Range Channel Deviation." This alarm will alert the operator to either a power unbalance being monitored by the power ranges, or to a channel failure. Through other indicators, the operator can then determine the deviating channel(s) and take corrective action. Should correction of the situation not be immediately possible (e.g., a channel failure, rather than reactor condition), provisions are available to eliminate the failed channel from the comparison function. The comparator can then continue to monitor the active channels.

7.4.3.7.2 Remote Recorder

Each power range channel supplies a 0 to 50 mV dc signal proportional to 0-120% full power to the nuclear power recorder. The signals from Power Ranges Number 1, Number 2, Number 3, and Number 4 are connected directly to the recorder. All four signals are continually indicated on control board meters.

7.4.3.7.3 Remote Meter

The remote meters receive the 0 to 1 mA isolated output that is available from each power range. This indication corresponds to that shown on the power range drawer. The signal is displayed on a meter scale calibrated from 0 to 120% of full power.

7.4.3.7.4 Overpower Recorders

A pair of recorders is used to monitor the individual average power indications from the four power ranges. Each recorder provides continuous monitoring of two power range channels, and has a full-scale deflection time of 0.25 second. The recorders are capable of displaying overpower excursions up to 200% of full power. A power range isolated output of 0-50 mV dc will correspond to the range of 0 to 200% full power for these recorders.

7.4.3.7.5 Ion Chamber Current Recorders

A recorder is provided to record the upper and lower ion chamber currents for each power range detector. Two isolated outputs (0−5V dc), one from each of the ion chamber isolation amplifiers, are provided for each recorder. Comparison of the two traces is an indication of the flux difference between the upper and lower sections of a given detector.

7.4.3.7.6 Delta Flux Remote Meter

Four control-board-mounted meters display the flux difference between the upper and lower ion chambers directly for each of the power range detectors.

7.4.3.8 **Miscellaneous Control and Indication Panel**

Switches are provided on this panel to permit a failed power range channel's overpower-rod-stop function to be bypassed, and its overpower-rod-stop signal to the rod control system to be supplied by signals derived from active channels. This allows normal power operation to continue while the failed channel is repaired.

Two panel mounted indicating lights, one for the upper section of the core and one for the lower section of the core are provided and are illuminated for a deviating condition or for a failed power range detector. Each power range detector provides an upper and a lower flux signal corresponding to the neutron flux in the upper section and in the lower section of a core quadrant. These upper and lower flux signals are compared and alarm the following conditions:

1. A high deviation of any upper section from the average of all the upper sections.
2. A high deviation of any lower section from the average of all the lower sections.

High deviation alarms will occur, one for the upper section and one for the lower section, when any individual section is greater than a preset amount above the average. These alarms warn the operator that a quadrant power tilt exists when the power level is above 50% power. The alarm circuits are automatically defeated when all sections are below 50% of rated power.

Additionally, two panel mounted indicating lights, one for each deviation comparison, are illuminated when all sections are below 50% of rated power.

In the event of a failed power range channel, bypass switches located on the panel are provided to defeat a failed power range channel input to an upper or lower section deviation comparison. This feature permits the continued monitoring of the core with a power range channel out of service.

7.4.3.9 **Output Information**

Tables 7.4-1, 7.4-2, and 7.4-3 provide the nuclear instrumentation system control and indication output information for the source, intermediate, and power ranges, respectively.

7.4.4 System Evaluation

7.4.4.1 Philosophy and Setpoints

During plant shutdown and operation, three discrete, independent levels of nuclear protection are provided from the three ranges of ex-core nuclear instrumentation. The basic protection philosophy is that the level protection is present in all three ranges to provide a reliable, rapid, and restrictive protection system that is not dependent upon operation of higher-range instrumentation.

Reliability is obtained by providing redundant channels that are physically and electrically separated. Fast trip response is an inherent advantage of using level trip protection in lieu of start-up-rate protection (with a long time constant) during plant start-up. More restrictive operation is an inherent feature, since an increase in power cannot be performed until satisfactory operation is obtained from higher-range instrumentation, which permits administrative bypass of the lower-range instrumentation. On decreasing power level, protection is automatically made more restrictive. Start-up accidents while in the source range are rapidly terminated without significant increases in nuclear flux, and with essentially no power generation or reactor coolant temperature increase.

The indications and administrative actions required by this protection system are readily available to the operator and should result in a safe, uncomplicated increase of power.

7.4.4.2 Reactor Trip Protection

During reactor start-up, the operator is made aware of satisfactory operation of one or more intermediate range channels by annunciation (audible and visual) at the control board. The source and intermediate range flux level information is also readily available on recorders and indicators at the control console. At this time, if both intermediate range channels are functioning properly, the operator would depress the two manual block switches associated with the source range logic circuitry, thus causing cutoff of source range detector voltages and blocking the trip logic outputs. The manual block should not be initiated, however, until at least one decade of satisfactory intermediate range operation is obtained. The permissive P-6 annunciation is continuously displayed by the control board status lights.

Continuation of the start-up procedure in the intermediate range would result in a normal power increase and the receipt of a permissive signal from the power range channels when two out of four channels exceed 10% of full power. The operator is alerted to this condition by a control board permissive status light. Indicators (one per channel) and a recorder also indicate unit status in terms of percent full power. If the operator does not block the intermediate range trip and continues the power increase, a rod stop will automatically occur from either of the intermediate range channels. The operator should depress the momentary “Manual Block” push-buttons associated with the intermediate range rod stop and reactor trip logic. This would transfer protection to the low-range trips for the four power range channels. The permissive P-10 status light would be continuously displayed, as was P-6. The two low-range manual block switches must be depressed to initiate blocking prior to continuation of the power increase. The permissive functions associated with administrative trip blocking and automatic reactivation are provided with the same separation and redundancy as the trip functions.

When power operation is decreasing to lower levels, more restrictive trip protection is automatically afforded when three out of four power range channels are below permissive P-10, and when two out of two intermediate range channels are below the permissive P-6.

7.4.4.3 **Rod-Drop**

An additional alarm function provided by the power range instrumentation is backup to the rod-drop detection of the rod bottom bi-stables on the rod position system. The nuclear instrumentation rod-drop detection is provided by comparison of the average nuclear power signal with the same signal, as conditioned by an adjustable lag network. This method provides a response to dynamic signal changes associated with a dropped-rod condition, but does not respond to the slower signal changes associated with normal plant operation. Main control room alarm actuation from at least one of the four power range channels will occur for any dropped-rod condition.

Each rod-drop sensing circuit has associated with it a bi-stable amplifier driving two relays in separate logic relay racks. The logic relay matrices are connected in a one-out-of-four “OR” configuration to initiate a control room alarm. The dropped rod detection circuit also illuminates the dropped rod window on the individual NIS rack that detected the dropped rod.

7.4.4.4 **Control and Alarm Functions**

Various control and alarm functions are obtained from the three ranges of ex-core nuclear instrumentation during shutdown, start-up, and power operation. These functions are used to alert the operator to conditions that require administrative action, and alert personnel to unsafe reactor conditions. They also provide signals to the rod control system for automatic blocking of rod withdrawal during plant operation to avoid unnecessary reactor trips.

7.4.4.4.1 Source Range

No control functions are obtained from the source range channels. Alarm functions are provided, however, to alert the operator of any inadvertent changes in shutdown reactivity. Visual annunciation of this condition is at the control board, with audible annunciation in the containment and control room. This alarm can either be blocked before start-up or can serve as the start-up alarm in conjunction with administrative procedures.

7.4.4.4.2 Intermediate Range

Both alarm and control functions are supplied by the intermediate range channels. Blocking of rod withdrawal is initiated by either intermediate range channel on high flux level. This condition is alarmed at the control board to alert the operator that rod stop has been initiated. In addition, the intermediate range actuates the P-6 permissive status light when either channel exceeds the P-6 permissive level. This alerts the operator to the fact that he must take administrative action to manually block the source range trips to prevent an inadvertent trip during normal power increase.

7.4.4.4.3 Power Range

The power range channels provide alarm and control functions similar to those in the intermediate range. An overpower rod-stop function from any of the four power range channels inhibits rod withdrawal and is alarmed at the control board. The power range channels also actuate the P-10 permissive status light when two of the four channels exceed the permissive P-10 level. As in the case of P-6 in the intermediate range, this alerts the operating personnel that administrative action (namely, blocking of intermediate and low-range trips) is required before any further power increase may take place.

A permissive status light is provided for P-8, “Nuclear Power Below P-8.” The extinguishing of the P-8 permissive status light alerts the operator that the one-out-of-three low-flow trips and one-out-of-three pump-breaker-open trips are now active. These trips are blocked while the status light is illuminated. Additional functions are provided in the power range of operation. A dropped control rod will be sensed by one or more of the power range channels, and this condition will initiate an alarm on the main control room annunciator and illuminate a dropped rod window on the individual NIS rack that detected the dropped rod.

Another function is a power range channel deviation alarm. This alarm is furnished by the comparator channel through a comparison of the average power level signals being supplied by the power range channels. Actuation of this alarm alerts the operator to a power imbalance between the channels so that corrective action can be taken. Additionally, two signals, supplied through isolation amplifiers, are provided by each power range channel: one signal is used for the upper section deviation alarm and one signal is used for the lower section deviation alarm. Actuation of these alarms alerts the operator to a power imbalance between the detector upper or between the detector lower sections so that corrective action can be taken. These ion chamber signals are discussed in Section 7.4.3.8.

In the case of a failed channel, defeat switches are provided to defeat a channel’s input to the channel deviation comparison as well as the detector section deviation comparisons.

7.4.4.5 **Power Supply**

The nuclear instrumentation system draws its primary power from the vital instrument buses, whose reliability is discussed in Chapter 8. Redundant nuclear instrumentation system channels are powered from separate buses. The loss of a single vital instrument bus would result in the initiation of all reactor trips associated with the channels deriving power from that source. During power operation, the loss of a single bus would not result in a reactor trip, since the power range reactor trip function operates from two-out-of-four logic. If the bus failure occurred during source or intermediate range operation (one-out-of-two logic), a reactor trip condition would result.

7.4.4.6 **Safety Factors**

The relation of the power range channels to the reactor protection system has been described in Section 7.2. To maintain the desired accuracy in trip action, the total error from drift in the power range channels will be held to ±1.0% at full power. Routine tests and calibration will ensure that this degree of deviation is not exceeded. Bi-stable trip setpoints of the power range channels will also be held to an accuracy of ±1.0% of full power.

7.5 ENGINEERED SAFEGUARDS

7.5.1 Design Bases

The engineered safeguards instrumentation measures temperatures, pressures, flows, and levels in the reactor coolant system, main steam system, reactor containment, and auxiliary systems. They actuate the engineered safeguards systems, and monitor their operation. Transmitted signals (flow, pressure, temperature, etc.) that can cause actuation of the engineered safeguards are either indicated or recorded in the control room.

The instrumentation and control systems provided to initiate the engineered safeguards systems are defined as safety-grade equipment and meet the safety standards applicable at the time of purchase and installation. Accident mitigation equipment subjected to a changing environment was evaluated in response to the NRC I&E Bulletin 79-01B (Reference 1) as described in Section 7.5.3.5.1.

Design criteria for redundancy and separation are similar to those used for the reactor protection system (Section 7.2). A list of emergency safeguards actuation functions is given in Table 7.5-1.

The engineered safeguards systems are actuated by the redundant logic and coincidence networks similar to those used for reactor protection. Each network actuates a device that operates the associated engineered safeguards equipment, motor starters, and valve operators. The channels are designed to combine redundant sensors, independent channel circuitry, and coincident trip logic. Where possible, different but related parameter measurements are utilized. This ensures a safe and reliable system in which a single failure will not defeat the intended function. The action-initiating sensors, bi-stables, and logic are shown in the figures included in the detailed engineered safeguards actuation instrumentation description given in Section 7.5.2. The engineered safeguards instrumentation system actuates (depending on the severity of the condition) the safety injection system, containment isolation, containment spray system, and the diesel-generators, and trips the containment vacuum system.

Availability of control power to the engineered safeguards trip channels is continuously indicated. The loss of instrument power to the sensors, instruments, or logic devices in the engineered safeguards instrumentation places that channel in the trip mode, except for containment spray initiating channels and the recirculation mode transfer (RMT) circuitry, which have been designed on an energize to operate basis. These systems were designed in this way to preclude their spurious operation on a loss of power.

The redundant batteries supplying power to the vital bus system are classified as passive components and are therefore subject to passive type failures. The definition of a passive failure is a failure which will not occur until after accident mitigation has entered the recirculation phase (post-RMT). Thus, should a LOOP/LOCA occur, the loss of a battery or dc bus will not credibly occur until after the unit enters the recirculation phase. This ensures the CLS Hi-Hi and RMT energize to actuate circuitry has power available during all credible design basis events.

The engineered safeguards systems are divided into protective safeguards and consequence limiting safeguards. The protective safeguards consist of the safety injection system. The consequence limiting safeguards include the spray system, containment isolation system, and the containment vacuum system. These systems are described in detail in Chapter 6. The control system logic diagrams for these safeguards are shown in Figures 7.5-1 and 7.5-2.

7.5.1.1 **Safety Injection**

Active safety injection components are actuated upon low-low pressurizer pressure, high containment pressure signals, high differential steam pressure between any steam lines and the main steam header, or high steam-line flow signals coincident with either low temperature average or low steam-line pressure signals. These actuating channel circuits are described in Section 7.2.

The signal that actuates safety injection low-low pressurizer pressure can be manually blocked when the pressurizer pressure reaches 2000 psig. This is only done during a controlled plant cooldown when the reactor is shut down. The signal that actuates safety injection on high containment pressure cannot be blocked and thus is available even when the low pressurizer pressure actuation signal is blocked. The purpose of the manual block of the signal on low pressurizer pressure is to prevent inadvertent safety injection actuation when the plant is being cooled down and depressurized.

A safety injection signal will isolate the feedwater lines by closing all control valves (main and bypass valves), trip the main feedwater pumps which in turn close the pump discharge valves, and thereby actuate the auxiliary feedwater system (Section 10.3.5), and will actuate the necessary valves required to allow the safety injection system to operate properly. Section 6.2 describes the safety injection system.

The passive accumulators of the safety injection system do not require signal or power sources to perform their functions. The actuation of the active portion of the engineered safeguards is from signals described in Table 7.2-1.

7.5.1.2 **Consequence Limiting Safeguards**

The consequence limiting safeguards system is operated by three signals: two initiation signals and one reset signal. The two initiation signals are the high containment pressure signal and the high-high containment pressure signal. The reset signal is the containment low-pressure signal. The high containment pressure signal is actuated when the containment pressure increases to a value in the range of 3.0 psig. The high-high containment pressure signal is actuated when the containment pressure increases to a value in the range of 8.3 psig. The containment low-pressure signal is actuated when the containment pressure is reduced to approximately atmospheric pressure after either a high containment pressure or high-high containment pressure signal.

The high containment pressure signal allows for a reactor shutdown without initiation of the spray system. This signal generates a safety injection signal. The high containment pressure signal also closes trip valves located in normally operating systems penetrating the containment that are not required to control the reactor coolant system pressure and containment pressure rise (Table 7.5-2).

The high-high containment pressure signal, indicating a LOCA, initiates the spray system and completes the containment isolation by actuating the remaining isolation trip valves.

The containment low-pressure signal indicates a return of the containment pressure to approximately atmospheric, and allows manual reset of the control circuits of the consequence limiting safeguards system.

Four pressure channels are connected to operate on a three-out-of-four basis, and are designed to operate on pressure increase. Each pressure channel sends a signal to two sets of redundant matrices, one set for the high containment pressure point and the other set for the high-high containment pressure point. Each of the two matrices in the high containment pressure matrix set sends a backup signal to initiate a safety injection, which in turn de-energizes the containment vacuum pumps and trips containment isolation valves. Each of the two redundant matrices in the high-high containment pressure matrix set operates one containment spray subsystem, one recirculation spray subsystem, trips containment isolation valves, and sends a backup signal to the electrical circuit that is normally actuated by one of the two redundant high containment pressure matrices. When three out of four signals of the correct value are received simultaneously from the pressure channels by a matrix, an initiation signal (either a high containment pressure signal or a high-high containment pressure signal) is emitted accordingly. When two out of four signals are received simultaneously from the pressure channels by a matrix indicating a return to low containment pressure, the initiation signal emitted by that matrix is canceled and the electrical circuit controlling the components operated by the matrix can be manually reset. The pressure channels are connected to the open taps of the leakage monitoring system outside the containment at a point before the pressure monitoring instrument (Section 5.3.2), and the containment isolation trip valves.

The safeguards design provides physically separated redundant components, and a capability to test devices used to derive a final output signal, in accordance with IEEE-279 requirements.

7.5.1.3 **Spray Subsystems**

Each redundant high-high containment pressure matrix emits a signal that actuates an electrical control circuit that operates one of the two redundant containment spray trains, and two of the four redundant recirculation spray trains. Each signal opens the appropriate motor-operated valves and starts a containment spray pump by supplying power to the electric motor for the pump.

In the case of the recirculation spray system, each CLS Hi Hi actuation circuit in conjunction with a RWST low level signal immediately starts an inside recirculation spray pump and initiates a two minute delayed start of the outside recirculation spray pump. The delay for starting the outside recirculation spray pump is sufficient to avoid overloading the EDG with high starting loads from two RS pumps.

The containment spray pumps may be stopped manually, after the control circuit controlling the pump has been manually reset. The control circuit can only be reset after a containment low-pressure signal is activated. Containment spray flow status is provided to the plant NUREG-0696 MUX system for remote display in the control room and other locations.

The recirculation spray system can also be stopped manually. The inside recirculation spray pumps can be stopped after the respective control circuits have been manually reset following a containment low-pressure signal. The outside recirculation spray pumps can be stopped at any time. This ability is necessary to control possible leakage in the suction and discharge piping (Section 6.3).

7.5.1.4 **Containment Vacuum System**

7.5.1.4.1 Normal Operation

The control system for the vacuum pumps compares an input signal of the containment air partial pressure with the actual containment air partial pressure, and provides for starting of the mechanical vacuum pumps if the actual containment air partial pressure is 0.1 psia greater than the desired input value. The containment air partial pressure may be varied between 9 and 10.3 psia depending upon the capability of the engineered safeguards to depressurize the containment within 60 minutes after a design-basis accident. Two redundant control channels are provided to operate the containment vacuum pumps. Each vacuum pump is operated through a three-position HAND-OFF-AUTO switch to permit either manual or automatic vacuum pump start. Either redundant control channel can actuate either containment vacuum pump. If the switch is in the OFF position, and the containment air partial pressure is greater than 0.1 psia above the setpoint, an alarm will alert the operator in the control room to manually start a vacuum pump, using the HAND position of the switch. If the switch is in the AUTO position, the alarm is received and a vacuum pump starts automatically. The actual partial pressure of air in the containment is not measured, but is obtained by subtracting the partial water vapor pressure signal from the containment total pressure signal.

The total containment pressure signal is measured in each channel by a pressure transmitter that transmits a signal functionally related to the actual containment total pressure. The partial water vapor pressure in the containment is derived by locating resistance temperature detectors, one for each channel, at the cooling coil outlet in each of three transition duct sections in the containment air recirculation system. The temperature measured in each transition duct is virtually saturated, and the sensed temperature is essentially the dewpoint temperature. The three temperature signals in each channel are transmitted to an auctioneer unit associated with the same channel, which selects the lowest temperature (lowest water vapor partial pressure condition). The temperature signal from the auctioneer in each channel is transmitted to an instrument that relates the temperature reading to a corresponding water vapor pressure, and transmits a signal functionally related to the water vapor partial pressure. The water vapor partial pressure signal and the total air pressure signal in each channel are sent to an instrument that subtracts the vapor partial pressure from the total air pressure, and transmits a signal functionally related to the partial air pressure. The value of partial air pressure desired in the containment is set on an instrument common to both channels and containing an adjustable setpoint mechanism, which transmits a signal functionally related to the desired partial pressure of air. The desired partial air pressure signal from the common instrument and the actual partial air pressure of each channel are compared. To eliminate the possibility of two different setpoints, a common instrument is used to set the desired partial air pressure in both channels.

When the actual containment air partial pressure increases 0.1 psia above the desired value, either channel of the control system energizes an electrical circuit that either sounds an alarm to signal the operator in the control room to manually start and operate a mechanical vacuum pump, or sounds the alarm and initiates starting and operating one mechanical vacuum pump directly, depending on the setting of the three-position switch in the control system. If the containment air partial pressure continues to increase, an alarm indicating that containment pressure is still rising is actuated. This alarm sounds when the partial containment air pressure has increased 0.20 psia above the desired containment air partial pressure. When the alarm is sounded in the control room, the operator initiates an orderly reactor shutdown in accordance with Technical Specifications.

When the actual containment air partial pressure falls 0.1 psia below the desired containment air partial pressure, the mechanical vacuum pump stops. If the pump does not stop, an alarm sounds.

The high-capacity steam jet air ejector is used to evacuate the containment before plant start-ups, and at other times is secured by administrative control.

7.5.1.4.2 Off-Normal Operation

The containment vacuum pumps are manually or automatically started in the event of a small rupture in the reactor coolant system piping. When the containment air partial pressure is 0.1 psia greater than the desired value, a containment vacuum pump automatically starts, or an alarm signals the operator to manually start a containment vacuum pump, depending on the setting of the three-position switch in the control system.

A small rupture in the reactor coolant piping will cause an increase in the vapor partial pressure in the containment, due to the mass of vapor added to the containment atmosphere by the flashed reactor coolant. Total pressure of the containment atmosphere will be further increased due to the heating of air in the containment resulting from energy released from the flashing reactor coolant in addition to the increase caused by the vapor partial pressure. The result is that total pressure will increase more rapidly than vapor pressure, which would be interpreted as an increase in the containment air partial pressure by the instrumentation provided to perform this calculation. Several measurements, as described in Section 7.5.1.4.1 are made to determine the air partial pressure. They are recorded in the control room.

An increase in temperature measured in each transition duct, and the vapor partial pressure derived from these temperature readings when the vacuum pump is started, could indicate a small rupture in the coolant system or main steam system within the containment. The operator would then take steps to determine the location of the leak, isolate it, and shut down the vacuum pump as required.

The option to operate the containment vacuum pumps automatically is provided in keeping with the overall plant concept of automatic control, since automatic operation of these pumps would not result in an excessive or uncontrolled release of radioactivity.

Alarms are provided to signal that pump operation is required and to signal that the containment pressure has continued to rise with a vacuum pump in operation. The only difference between the manual and automatic mode of operation is that, in the automatic mode, the vacuum pump automatically starts at the same time an alarm is sounded to signal that pump operation is required, whereas, in the manual mode, the pump must be started by the operator when the alarm sounds. In addition, in the automatic mode, the vacuum pump is shut down automatically if the containment air partial pressure continues to rise.

The alarm that signals that the containment pressure is still rising while the vacuum pump is operating is provided for both the manual and the automatic modes of operation. In the manual mode, the operator immediately takes over pump operation manually, determines the cause of the continual pressure rise in the containment, shuts off the vacuum pump if necessary, and also, if necessary, begins to initiate an orderly reactor shut down. In the automatic mode, the vacuum pump is automatically shut down when this alarm is initiated. Since this alarm and trip are set at 0.10 psia above the pressure that signals that pump operation is required (0.20 psia above the desired setpoint), the amount of radioactivity that will be released, even with a small rupture in the reactor coolant piping and with automatic pump operation, will be minor, since this incremental pressure increase will occur in a short period of time.

In addition to the alarms and trips described above, the containment vacuum pumps are disconnected from the automatic control circuits on actuation of a safety injection signal, i.e., the vacuum pumps receive a signal to shut down and the vacuum system isolation valve solenoids are de-energized.

The following information is HISTORICAL and is not intended or expected to be updated for the life of the plant.

The following discussion was the response to a request from the NRC during initial licensing to analyze the expected radioactive release from the containment in the event of a DBA and a small rupture in the reactor coolant system piping. Although the X/Q value used in the discussion is non-conservative compared to current standards, this analysis is considered bounded by the current large break LOCA dose analysis.

A small rupture in the reactor coolant system piping, assumed to be equivalent to a 2.6-inch-inside-diameter pipe, will cause the containment pressure to reach the high-pressure value in approximately four minutes. If the containment vacuum pumps are operating during the four-minute period before the pumps are de-energized and the isolation valves tripped, i.e., if the operator did not consider pump shutdown necessary when the alarm sounded to indicate continual containment pressure rise, then the expected radioactive release from the containment will be 0.288 Ci of Xe-133 equivalent and 0.00058 Ci of I-131 equivalent. This activity release is based on 1% failed fuel and equilibrium corrosion products in the reactor coolant. An unfiltered, uncontrolled release of this activity from the containment, χ/Q of 8×10^{-4} sec/m^3, and the assumption of a “puff” ground release, will result in a whole-body dose at the exclusion boundary of 0.01 mrem and a thyroid dose of about 0.25 mrem, both well below the limits suggested in 10 CFR 100. This incident is therefore not considered to be a hazard to the public.

The vacuum pump discharge passes through charcoal and particulate filters and the radiation monitors of the waste gas system before entering the environment. The particulate and charcoal filters further reduce the activity released. In addition, activity released to the environment in excess of the limits of 10 CFR 20 will be terminated by radiation monitors, which isolate the discharge of the containment vacuum pumps on high activity levels.

In the event of a design-basis accident as the containment pressure rises, the vacuum pumps will be automatically de-energized when the pressure increases to 0.20 psia above the setpoint. The vacuum pumps receive additional trip signals directly from a safety injection signal and indirectly from high containment pressure to ensure that the pumps are shut down. Therefore, the radioactive releases from the containment through the vacuum pump flow path will be negligible.

7.5.1.5 **Containment Isolation**

The containment isolation system is described in Section 5.2. The containment isolation system is designed to actuate and stroke the isolation valves completely closed to seal off the containment from the outside atmosphere when the pressure inside the containment reaches a predetermined setpoint.

The isolation trip valves are actuated by the safety injection system, the high containment pressure signal, or the high-high containment pressure signal, according to the functions of the line in which the trip valve is located (see Table 5.2-1). When the pressure setpoints are reached, each matrix operates electrical circuits to actuate electrically operated isolation valves directly, or to de-energize solenoid valves that release air from the diaphragm of pneumatically operated valves. Where two containment isolation trip valves are located on the same line, each trip valve is operated by a different redundant matrix. In lines containing only one trip valve, the trip valve is operated by both redundant matrices. However, lines containing one automatic trip valve have another isolation barrier, such as a check valve or a membrane barrier. All instruments, controls, and electrical equipment are supplied in accordance with ANSI, IEEE, and NEMA standards.

7.5.2 System Description

7.5.2.1 **Engineered Safeguards Actuation Instrumentation**

The engineered safeguards system actuation circuitry and hardware layout are designed to maintain channel isolation up to and including the bi-stable-operated logic relay similar to that of the reactor protection circuitry, as discussed in Section 7.2. The general arrangement of this layout is shown in Figure 7.5-3, with supplemental detailing in Figures 7.5-4 and 7.5-5. Although a four-channel system is illustrated in Figure 7.5-3, circuitry and hardware layout discussion is sufficiently general to apply to an n-channel system. Channel separation is maintained by providing separate racks for each analog protection channel, and separate relay rack compartments for each logic train. Channel identity is lost in the relay wiring required for matrix logic makeup. It should be noted that although channel individualization is lost, twin matrix logic trains are developed, thus ensuring a redundant actuation system.

The engineered safeguards system bi-stables drive the logic relay coils “C” and “D” as shown in Figures 7.5-3 and 7.5-5. These logic relay coils are de-energized by their bi-stables when an abnormal condition exists; the only exceptions to this “de-energized to operate” principle are the initiation of containment spray on CLS Hi Hi and the initiation of RWST recirculation mode transfer (RMT). Contacts of the relay are arranged so as to develop the logic matrix or combinations of signals required to initiate action. For example, in Figure 7.5-3 these relay contacts are shown directly below the relay coil. Since these coils would normally be energized, their contacts would remain open, and thus an open circuit between the voltage source and master actuating relay would exist. Dropping any of the two logic relay coils that would cause their corresponding contacts to close would complete the circuit and energize the master actuating relays. Although the illustration here is for a two-out-of-four (2/4) matrix make, the design and sequence of operation for (x_1/x_2) logic matrices makeup is the same. The master actuating relay (M) is a latch-type relay with two coils, an operate (M/0) and reset (M/R) coil, and electric reset. Once the logic matrix is made up, as described above, the circuit that energizes the master actuating relay is complete. Figure 7.5-3 illustrates the master actuating relay, and an enlarged view may be found in Figure 7.5-4. With a potential across the relay, the operate coil is energized, thus closing the M contacts, which energizes the slave relays (SRs and TD) as shown in Figure 7.5-3; the master relay is latched into this position until the reset coil is energized. Manual reset of the master actuating relay may be accomplished, after a time delay following its operation to ensure completion of the actuation sequence, by operating the reset switch (see Figures 7.5-3 and 7.5-4). With the reset coil energized, all of the M contacts are returned to their de-energized positions, as shown in Figure 7.5-3. It should be noted that once reset action is taken, the master relay operation is blocked by the reset relay R until the safeguards initiating signal clears, at which time it is automatically unblocked and restored to service. Resetting the master relay does not interfere with the operational status of the engineered safeguards equipment.

Annunciation is provided for the consequence-limiting-safeguards-initiated signal, the consequence-limiting-safeguards-reset-permissive signal, the safety-injection-initiated signal, and the safety-injection-blocked signal.

7.5.2.2 **Instrumentation Used During a Loss-of-Coolant Accident**

Instruments provided and designed to function following the major LOCA are those that govern the operation of engineered safeguards. Pressurizer pressure and level, and steam generator flow, and level sensors are located inside the containment because an equivalent signal cannot be obtained from a sensor location more isolated from the reactor. Steam generator pressure sensors are located outside the containment. It should be emphasized, however, that for the large LOCAs the initial suppression of the transient is independent of any detection or actuation signal because the water level will be restored to the core by the passive accumulator system.

Pumps used for safety injection and initial containment spray are located outside the containment. The operation of the equipment can be verified by instrumentation that reads in the control room. This instrumentation will not be affected by the accident. The containment sump level and refueling water storage tank instrumentation will provide information for evaluating the conditions necessary to initiate the recirculation mode of operation.

The containment level instrumentation has been changed to meet the requirements of TMI-2, NUREG-0578, Section 2.1.9. The system now utilizes redundant wide range level transmitters and redundant narrow range transmitters installed inside the reactor containment. The transmitters are qualified to IEEE-323-1974 and IEEE-344-1975 standards.

The wide-range level loops have the capability of measuring a level in the containment equivalent to approximately 580,000 gallon capacity and the narrow-range level loops have the capability of measuring to the top of the containment sump.

One of the redundant loops for wide-range level and one of the loops for narrow-range level is recorded on the postaccident monitoring recorder in the control room. The second redundant loop for both wide and narrow-range level can be real-time plotted through the PCS Emergency Response and Safety Parameter (ERG/SPDS) displays in the MCR, Technical Support Center and other locations.

Instrumentation has been added to monitor containment spray flow and backup pressurizer heater status during and following an accident. Containment spray flow instrumentation will provide a direct means for the Control Room operator to determine if containment spray flow is being provided. Likewise, pressurizer heater status will provide a direct means for the Control Room operator to determine satisfactory operation of the pressurizer heaters. Both containment spray flow and pressurizer heater status provide input to the plant NUREG-0696 MUX system for remote display in the Control Room and other locations.

Wide-range pressure transmitters have been added outside containment to measure containment pressure as described in Section 7.5.3.5.

Depending upon the magnitude of the loss-of-coolant incident, information relative to the pressure of the reactor coolant system will be useful to the operator to determine when it would be permissible to stop one of two LHSI pumps in the event of a small break. Regulatory Guide 1.97 reactor coolant system instrumentation as well as the discharge pressure of the charging pumps, as read on instrumentation outside the containment, will serve this purpose.

Consideration has been given to all the instrumentation and information that is necessary for recovery following a loss-of-coolant incident. Instrumentation external to the reactor containment, such as radioactivity monitoring equipment, will not be affected by this postulated incident, and will be available to the operator.

Safety-related postaccident monitoring panels for Units 1 and 2 have been installed in the control room, in response to NUREG-0578, Sections 2.1.5a, 2.1.6b, and 2.1.9. The panels are designed to IEEE 344-1975 and the original plant separation criteria. The components have been designed to meet, as a minimum, IEEE 323-1971. The panel contains switches and indicators for equipment such as containment isolation valves, RCS vent valves, and postaccident hydrogen indicators.

7.5.2.3 **Calibration and Testing**

The engineered safeguards actuation channels are designed with sufficient redundancy to provide the capability for channel calibration and test during power operation. Bypass removal of one actuation channel is accomplished by placing that channel in a tripped mode; i.e., a two-out-of-three matrix logic becomes a one-out-of-two matrix logic. Testing does not trip the system unless a trip condition occurs in a concurrent channel.

7.5.2.3.1 Analog Channel Testing

Engineered safeguards analog channel testing is identical to process analog protection channel testing as described in Section 7.2.2.1.4.

7.5.2.3.2 Logic Testing

Figures 7.5-3, 7.5-4, and 7.5-5 illustrate the basic logic test scheme. Test switches are located in the associated relay racks rather than in a single test panel. The following procedures indicate the method of testing the logic matrices:

1. Test of either train A or train B is made at one time; this is under administrative control.

2. A selection of the function to be tested is made. Figure 7.5-4, for example, illustrates some of these functional matrices.

3. The relay logic test switch is first turned to the test position, which opens the circuit to the master actuating relay (logic test switches as shown in Figure 7.5-4 or location 1 as shown in Figures 7.5-3 or 7.5-5) and energizes the “on test” labeled lamp (see position 3 of switch C_1 or D_1 in Figure 7.5-5).

   The master actuating relay is removed from this part of the test in order to avoid unintentional starting of the engineered safeguards equipment. Intentional start is available through the other train that has operational status and the other functional matrices not under test.

4. When the logic test switch is depressed in the test position, the circuit that normally energizes the logic relay coil is de-energized, thus closing the logic relay contacts operated by that coil (i.e., opening of C_1 at location 2 shown in Figure 7.5-3 or 7.5-5 will close the two logic relay contacts directly below C_1 in Figure 7.5-3). By repeating the above sequence for C_2, C_3, C_4, one can simulate all actuating logic combinations required to make up the logic required to develop the matrix. Thus, in Figure 7.5-3, a complete test of a two-out-of-four matrix is made with the following combinations: C_1 and C_2, C_1 and C_3, C_1 and C_4, C_2 and C_3, C_2 and C_4, and C_3 and C_4.

5. Proper development of a logic matrix would be indicated by the lighting of the matrix test lamps, as shown in Figure 7.5-4, and identified in Figure 7.5-5 as L_2.

6. With the testing of the logic matrix complete (i.e., steps 1 to 5), the matrix is returned to operational status by returning all test switches for that particular functional matrix to the “operate” position. The control board annunciator warns the operator of any test switch left in the test position, and thus the return to operational status through the action of the individual performing the test is verified by the operator at the control board. Testing procedures for the logic matrix of train B are identical to those described above for train A.

7. Verification of master actuating coil integrity is made by connecting an ohmmeter across the coil terminals.

8. Verification of slave coil integrity can be checked by connecting an ohmmeter across the coil terminals.

7.5.3 System Evaluation

Redundant instrumentation has been provided for all inputs to the protective systems and vital control circuits. Where wide process variable ranges and precise control are required, both wide-range and narrow-range instrumentation is provided. Instrumentation components are selected from standard commercially available products with proven operating reliability. The instrument power to electrical and electronic instrumentation required for safe and reliable operation is supplied from the four instrument buses.

The engineered safeguards systems are arranged so that there are multiple, separate, and independent pumping paths for delivering and circulating borated water to the reactor coolant system and to the spray system. This philosophy of multiplicity, separation, and independence has been extended to include the power sources as well as the signal sources, cabling, relays, etc., required for system actuation.

7.5.3.1 **Safety Injection**

Credible accident conditions requiring emergency core cooling would involve low pressurizer pressure and level. The present design for emergency core cooling is accomplished by the safety injection system actuation from primary system variables. Actuation is initiated by low-low-pressurizer pressure.

Pressurizer pressure is sensed by fast response pressure transmitters. An overall one-second channel response time is used, which is more than adequate to cover the response characteristics of the tripping channels.

Instrument delays are small in comparison with the computed lag in pressurizer pressure, which lags behind the reactor coolant pressure during blowdown. The successful operation of the engineered safeguards involves only actuation control function, with the single exception of the steam generator water level control function associated with unit cooldown using the auxiliary feedwater pump.

A safety injection block switch is provided to permit the primary system to be depressurized and its water level lowered for maintenance or refueling operations without actuation of the safety injection system. This manual block switch is interlocked with pressurizer pressure in such a way that the blocking action is automatically removed as operating pressure is approached. If two out of three pressure signals are above this preset pressure, blocking action cannot be initiated. The block condition is annunciated in the control room.

7.5.3.2 **Consequence Limiting Safeguards**

The design of the control system for the consequence limiting safeguards includes manual test switches for individual testing of all equipment in the system and for testing the system itself.

The containment vacuum control system, which starts and operates the mechanical vacuum pumps and the alarms, has adjustable setpoint mechanisms that allow the operator to change the setpoint value as required due to atmospheric conditions or experience gained in operating the plant.

7.5.3.3 **Containment Isolation System**

The system design offers a reliable and safe method for achieving the design-basis objectives.

Reliability in this system is ensured by the ability to calibrate and test each pressure-sensing device and monitor each manual reset relay during plant operation without removal from the system.

A fail-safe design is provided. On loss of air or control power, the pneumatically and solenoid-operated isolation valves close.

The three features that ensure the proper operation of this system are the location of pressure-sensing devices outside containment, continuous monitoring of valve positions, and indication of the availability of control power on the main control board.

The electrical circuits have manual reset relays, and each solenoid valve has a manual reset pushbutton designed to prevent accidental reopening of any isolation valve. The reset buttons on the control board must be set before the manual pushbutton on each solenoid valve can open any trip valve. As each pushbutton is reset, air is admitted through the solenoid valve to open the isolation valve. When all solenoid valves have been reset and isolation valves opened, tripping of the circuits can occur only if a trip signal initiates the action or the operator manually trips the relays in the control room.

See Section 5.2.2 for a discussion of the condenser air ejector discharge and vent system.

7.5.3.4 **Motor and Valve Control**

For starting pump and fan motors, the control relays are energized to energize the closing coil on the circuit-breaker of the motor-starter. When motor-starters are used, the starter operating coil is supplied by power from the same source as the subject motor. When circuit-breakers are used for motor control, the circuit-breakers close, and trip coils are supplied by power from a 125V dc battery bus, as outlined in Chapter 8.

For valve motor control, the control relay causes the coil on the main contactor for the closing circuit to be energized. The closing circuit is de-energized by the torque or limit switch on the valve operator, thereby ensuring that the valves have closed to a leak-tight position.

Air-actuated containment isolation valves are spring-loaded to close upon loss of air pressure.

An as-built tabulation of all valves and dampers actuated by engineered safeguards signals is provided in Table 7.5-2. The table includes component designation, service, safety function, signal source, and a statement of whether the safety function can be overridden or bypassed.

7.5.3.5 **Environmental Capability**

The engineered safeguards instrumentation equipment inside containment is designed to operate under the postaccident environment of a steam-air mixture and radiation.

Electrical equipment for the engineered safeguards is located inside the containment and in the auxiliary building. The equipment located inside the containment that must function in the postaccident environment is listed below. The expected length of time that the equipment will be required to function following an accident is also given.

1. Emergency core cooling system containment isolation actuation sensors (first five minutes after accident).
2. Emergency core cooling system motor-operated valves and flow instrumentation (first five minutes after accident).
3. Accumulator level instrumentation (first five minutes after accident).
4. Containment sump level instrumentation three hours after accident, which is considered to be the maximum period after a LOCA for emptying the refueling water storage tank into the sump, thereby ensuring that the sump is sufficiently filled for the recirculation phase.
5. Air-operated and motor-operated containment isolation valves (operation completed in first five minutes after accident).
6. Containment pressure instrumentation (continuous service).
7. Power and instrumentation cables for the above-listed equipment.

The design considerations and specifications to be used in the selection of motors that must function in the postaccident environment are discussed in Chapter 6. Similar application criteria apply to the specifications of control and instrumentation equipment and other electrical equipment.

Failure of the above equipment after the specific time will not increase the severity or consequences of the accident. The reactor protection control and instrumentation equipment and electrical equipment for engineered safeguards located in the Auxiliary Building will operate in a normal ambient environment following a LOCA. Auxiliary Building equipment in the containment sump-water recirculation loop is listed below:

1. Safety injection/charging lines and charging pumps.
2. Flow, temperature, and pressure instrumentation for the safety injection/charging system.
3. Power and instrument cables for the above.

Areas of high radiation would exist inside the containment and in those portions of the auxiliary building near safety injection/charging system equipment following a major LOCA. The maximum intregrated six-month LOCA dose in the containment would be approximately 3.7×10^7 rads. The maximum intregrated six-month LOCA dose plus sixty year normal operation dose in the charging cubical (lower elevation) of the Auxiliary Building would be approximately 1.2×10^7 rads. The ability of electrical equipment in the emergency core cooling system to withstand radiation exposure would be limited by radiation effects on electrical insulation materials and motor bearing lubrication.

The electrical equipment for the emergency core cooling system located in the containment use only radiation-resistant insulating materials. These insulating materials have a threshold for radiation damage that might affect their function of 10^8 rad or higher. They therefore provide considerable margin above the maximum postaccident radiation dose that would result from the exposure times specified above.

The lower ambient temperatures and radiation levels in the auxiliary building permit the use of normal elastomer or plastic insulation materials. These materials have a threshold for radiation damage of 10^6 rad or higher. Where required, because of location in possible high-radiation areas, motor bearings are lubricated with radiation-rated lubricants.

The pressure sensors that monitor containment conditions subsequent to a LOCA are capable of indicating pressures from 0 psia to 65 psia. The temperature sensors that monitor containment conditions subsequent to a LOCA are capable of indicating temperatures from 40°F to 400°F. The pressure and temperature sensors that monitor containment conditions subsequent to a LOCA are capable of indicating conditions more severe than those associated with the design basis of the containment. The pressure and temperature conditions for the design basis of the containment are 45 psig and 280°F.

The requirements of TMI-2 Short Term Lessons Learned, NUREG-0578 and subsequent clarifications contained in the NRC letter dated October 30, 1979, required that there be a continuous indication of containment pressure provided in the control room with an indication capability to three times the containment design pressure. As a result, redundant Class 1E pressure transmitters were added to the existing containment pressure measuring tubing with the capability of measuring a pressure range of 0 to 180 psia. The pressure transmitters are qualified to IEEE 323-1971 and IEEE 344-1975.

Each transmitter has an indicator associated with it. These indicators are mounted on the main control board and provide continuous indication of the containment pressure over the range of 0 to 180 psia. One of the redundant loops for the containment pressure measurement is recorded in the control room on the postaccident monitoring recorder. The second redundant loop can be real-time plotted through the PCS ERG/SPDS displays in the MCR, Technical Support Center, and other locations.

7.5.3.5.1 Environmental Qualification of Safety-Related Electrical Equipment

In response to IE Bulletin 79-01B, a program was established to review the environmental qualification of safety-related electrical equipment located inside the containment. Later, a supplement to IE Bulletin 79-01B was issued and further defined the scope of the review to include not only equipment inside the containment, but also equipment in areas of the plant where changing environmental conditions (temperature, pressure, humidity, radiation) occur during and as a result of the accident conditions being reviewed.

The IE Bulletin 79-01B review was submitted in two separate parts. The 45-day review (Reference 1), reflected equipment qualifications to FSAR commitments. The review included a list of safety-related systems that are required to achieve or support (1) emergency reactor shutdown, (2) containment isolation, (3) reactor core cooling, (4) containment heat removal, (5) core residual heat removal, and (6) prevention of significant release of radioactive material to the environment. This list is included on Table 7.5-3. Equipment identified as requiring a review were analyzed for conditions of temperature, pressure and humidity inside and outside the containment, and for submergence, aging, chemical spray, and radiation.

Revision 4 to the 90-day review (Reference 2), was also submitted. It included a list of electrical equipment required to mitigate an accident and/or safely shut down the plant and that are subjected to a changing environment due to the accidents. The report reflects the updated Status of Qualification of the electrical equipment. Results of the NRC's safety evaluation for the environmental qualification of safety-related equipment at the Surry Power Station are contained in Reference 3.

Table 7.5-1
ENGINEERED SAFEGUARDS ACTUATION FUNCTIONS

Actuation Signal	Coincidence Circuitry and Interlocks	Comments
I. Containment Isolation Actuation Function		
1. Hi CLS	Coincidence of 3/4 containment high pressure or 1/2 manual	Closes containment isolation valves for the following lines: instrumentation air suction supply line, radiation monitoring gas and particulate sample supply line, air ejector vent to containment line.
2. HiHi CLS	Coincidence of 3/4 containment high-high pressure or 2/2 manual	Closes containment isolation valves for the following systems: CC, IA, MS.
3. Safety injection actuation	Coincidence of 2/3 Low Low pressurizer pressure or 1/2 manual	Closes containment isolation valves for the following systems: CH, RC, BD, CC, CV, DA, DG, LM, SS, VG, SI (N2 supply), MS (drains).
II. Main Steam Lines Isolation Actuation Function		
1. Main steam line isolation	High steam line flow in 2 out of 3 lines (1/2 per line) coincident with either low T_{avg} in 2 out of 3 loops or low steam pressure in 2 out of 3 lines	Closes main steam line isolation valves.
2. Hi Hi CLS	3/4 high-high containment pressure signal or 2/2 manual	Closes main steam line isolation valves.
3. Manual per steam loop	1/1 per steam line	Closes main steam line isolation valves.
III. Auxiliary Feedwater Actuation Function		
1. Turbine driven pump start	Coincidence of 2/3 low-low level in any two steam-generators, or loss of power to station service busses; or manual 1/1, or AMSAC initiated	Starts turbine driven pump.
2. Motor-driven pumps start	2/3 low-low level in any steam-generator, or trip of both main feedwater pumps, or safety injection signal, or manual 1/1, or total loss of reserve station service power, or AMSAC initiated	Start motor driven pump.

Table 7.5-1 (CONTINUED)
ENGINEERED SAFEGUARDS ACTUATION FUNCTIONS

Actuation Signal	Coincidence Circuitry and Interlocks	Comments
IV. Main Feedwater Isolation Function		
1. Safety injection actuation	SI actuation	Close main feedwater control valves (fast closure).
2. Hi Hi steam generator level	2/3 high high level in steam generator	Close main feedwater control valves (fast closure).

a. These circuits have features that could prevent immediate operation of the component when the engineered safeguards signal is actuated. Such features are a necessary part of the circuit (such as a limit switch), or they require conscious effort by an operator to prevent operation (such as manipulation of a pushbutton or a selector switch). A valve limit switch could act to delay safeguards-initiated operation if the valve was in mid-travel and had to complete the travel sequence before operating in response to the safeguards signal. A pushbutton or selector switch held in the actuated position gives the operators an option, in some cases, of delaying component response to an emergency safeguards signals.

b. A key-operated switch is under administrative control to prevent inadvertent component operation and to satisfy the requirements of IEEE Standard 279-1971.

c. A mode switch is under administrative control to prevent inadvertent alignment of this damper during refueling (Section 9.13.4.1).

a. These circuits have features that could prevent immediate operation of the component when the engineered safeguards signal is actuated. Such features are a necessary part of the circuit (such as a limit switch), or they require conscious effort by an operator to prevent operation (such as manipulation of a pushbutton or a selector switch). A valve limit switch could act to delay safeguards-initiated operation if the valve was in mid-travel and had to complete the travel sequence before operating in response to the safeguards signal. A pushbutton or selector switch held in the actuated position gives the operators an option, in some cases, of delaying component response to an emergency safeguards signals.

b. A key-operated switch is under administrative control to prevent inadvertent component operation and to satisfy the requirements of IEEE Standard 279-1971.

c. A mode switch is under administrative control to prevent inadvertent alignment of this damper during refueling (Section 9.13.4.1).

7.6 INCORE INSTRUMENTATION

7.6.1 Design Basis

The incore instrumentation is designed to yield information on the neutron flux distribution at selected core locations. Using the information thus obtained, it is possible to confirm the reactor core design parameters. The system provides means for acquiring data only, and performs no operational unit control.

7.6.2 System Description

7.6.2.1 General

The incore instrumentation system consists of retractable flux thimbles, which run the length of selected fuel assemblies, and moveable fission detectors which are inserted into the retractable flux thimbles. The detectors are used to collect flux distribution data. The retractable flux thimbles are shown in Figures 7.6-1 and 7.6-2.

Fifty core locations on each unit are capable of housing retractable flux thimbles. Each flux thimble houses 3 core exit thermocouples (1 in service with 2 installed spares) used to measure core exit temperature in post accident conditions as required by Reg Guide 1.97. The core exit thermocouples are not a functional part of the incore system, however, the incore system provides a means of placing the core exit thermocouple in the core. The core exit thermocouples provide input to the Inadequate Core Cooling System and are discussed in more detail in Section 7.9.

The thimbles are retractable and are inserted into the reactor at the seal table. Caps may be installed in the event a thimble location must be removed from service. Technical Specifications provide the requirements for the number and location of operable flux thimble locations.

The data collected by the incore system in conjunction with previously calculated analytical information is used to determine the fission power distribution. This method is more accurate than using calculational methods alone. The data collected by the incore system may also be used to calculate coolant enthalpy distribution ($F_{\Delta h}$), total peaking factor (F_Q), and the fuel burnup distribution. Once analyzed, the measured data is compared to power distribution and thermal/hydraulic limits which is the primary way to determine the maximum allowable power output. The radial and axial power distribution may also be evaluated by comparing the power distribution between quadrants.

7.6.2.2 Thermocouples

Three chromel-alumel, grounded, twinax, thermocouples are permanently installed at the tip of each of the 50 flux thimbles. The thermocouples and extension leads are installed in the annulus of the non-concentric flux thimble inner calibration tube and the outer sheath as shown in Figures 7.6-1 and 7.6-2. The thermocouple extension leads are mineral insulated with stainless steel sheaths. For each guide tube, one thermocouple circuit is active and monitored by the Emergency Response Facilities Data Acquisition System, which provides parallel data to the

Inadequate Core Cooling Monitor System and the PCS. The other two thermocouples associated with each flux thimble are installed spares.

7.6.2.3 **Movable Neutron Detectors**

7.6.2.3.1 Mechanical Configuration

The neutron flux detectors, remotely positioned in the core, provide remote readout for flux mapping. The basic system for the insertion of these detectors is as shown in Figure 7.6-3. Retractable flux thimbles, which contain thermocouples and the calibration tube, are pushed into the reactor core through thimble guide tubes (conduits). These thimble guide tubes extend from the bottom of the reactor vessel down through the concrete shield area, then up to a thimble seal table.

The retractable thimbles are closed at the leading (reactor) ends, are dry inside, and the calibration tube serves as the pressure barrier between the reactor water pressure and the atmosphere. Mechanical seals between the retractable thimbles and the thimble guide tubes are provided at the seal table, as shown on Figures 7.6-1 and 7.6-2.

Surry Power Station is in the process of replacing the Westinghouse designed flux thimbles and seal table seals shown on Figure 7.6-1 with the design that is shown on Figure 7.6-2. The replacement project is planned for implementation over several refueling outages. The configuration of the flux thimbles does not change and will consist of an inner calibration tube that is used to insert and withdraw the in-core neutron detectors, three type K, grounded thermocouples and an outer tube. The inner tube is also part of the Reactor Coolant System pressure boundary. The principal difference between the Westinghouse and replacement designs is in the high and low pressure seals and the seal housing at the top of the flux thimble guide tube. Detailed descriptions of each design are included in Surry Power Station vendor technical manuals and applicable vendor drawings.

During reactor operations, the retractable thimbles are stationary. They are extracted downward from the core during refueling to avoid interference within the core. A space above the seal table is provided for the retraction operation.

The drive system for the insertion of the miniature detectors consists of a combination of drive assemblies, five-path rotary transfer devices, and ten-path rotary transfer devices, as shown in Figure 7.6-3. The drive system pushes hollow helical-wrap drive cables into the core. Miniature detectors are attached to the leading ends of the cables, and small-diameter sheathed coaxial cables are threaded through the hollow centers back to the ends of the drive cables. Each drive assembly consists of a gear motor that pushes a helical-wrap drive cable and detector through a selective thimble path by means of a special drive box, and includes a storage device that accommodates the total drive cable length. Further information on mechanical design and support is provided in Chapter 3.

7.6.2.3.2 Control and Readout Description

The control and readout system provides means to rapidly traverse the miniature neutron detectors to and from the reactor core at 72 ft/min, and to traverse the reactor core at 12 ft/min while plotting the thermal neutron flux versus detector position. The control system consists of two sections, one physically mounted with the drive units, and the other contained in the control room. Limit switches in each tubing run provide signals to the path display to indicate the active detector path during the flux mapping operation. Each gear box drives an encoder for position indication. One five-path group path selector is provided for each drive unit to route the detector into one of the flux thimble groups or to storage. A ten-path rotary transfer assembly is used to route a detector into any one of up to ten selectable thimbles. Manually operated isolation valves on each thimble allow free passage of the detector and drive cable when open. When closed, these valves prevent steam leakage from the core in case of a thimble rupture. Provision is made to separately route each detector into a common flux thimble to permit cross calibration of the detectors.

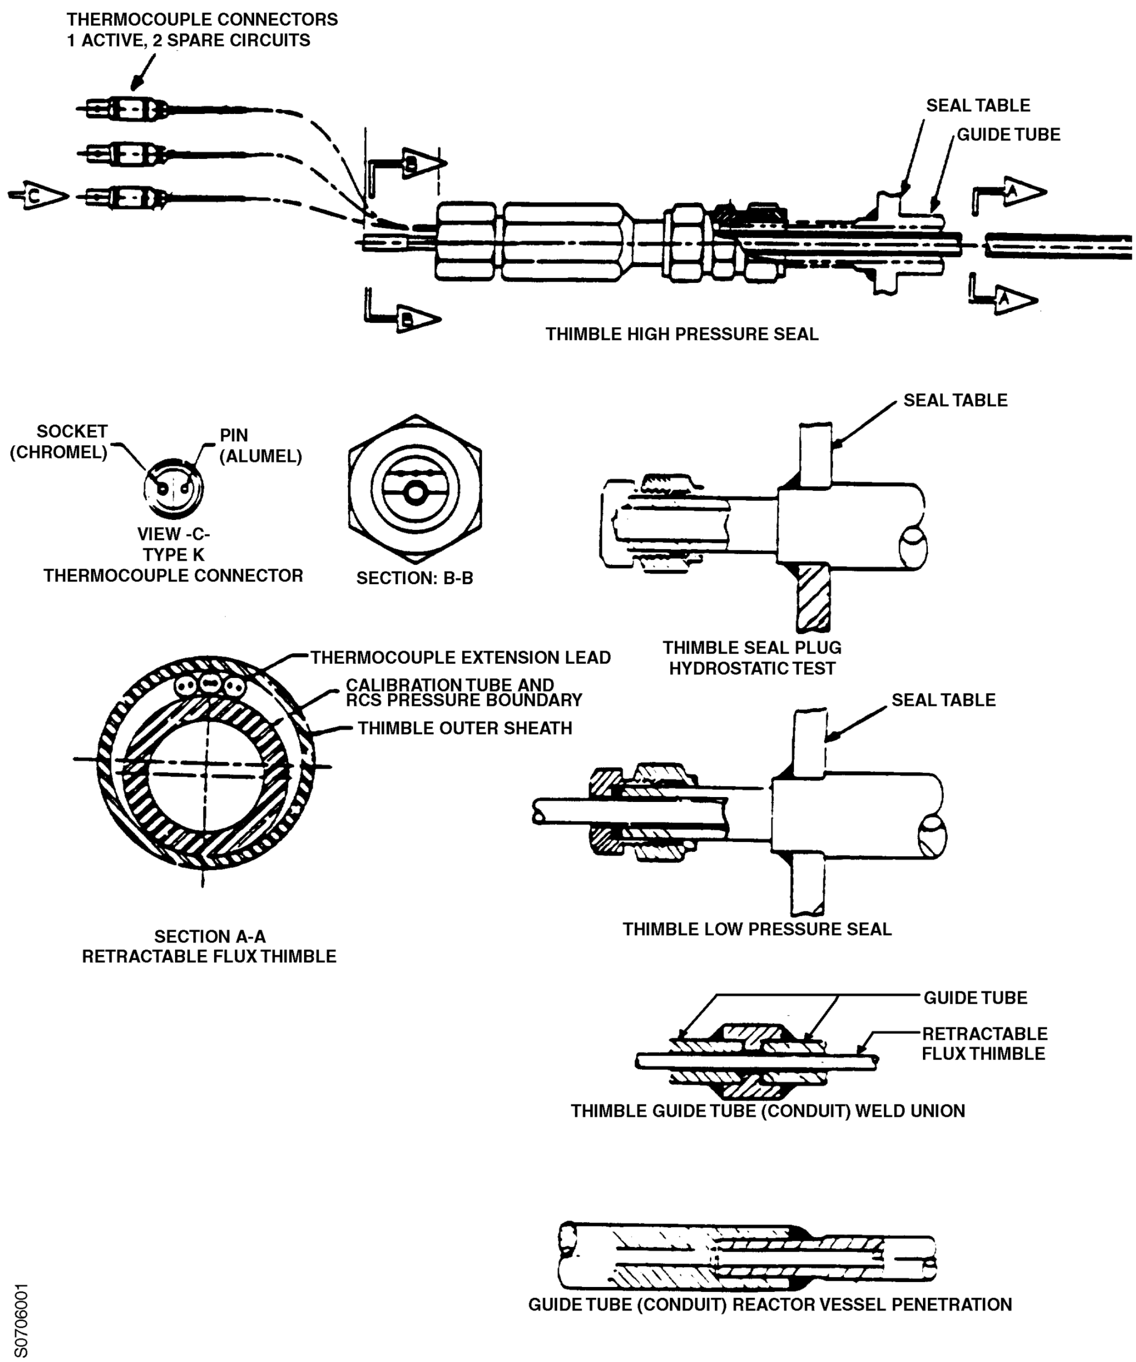
The control room contains the necessary equipment for control, position indication, and flux recording. Panels are provided to indicate the position of the detectors, and for plotting the flux level versus the detector position. Additional panels are provided for such features as drive motor controls, core path selector switches, plotting, and gain controls. A flux-mapping operation consists of selecting (by panel switches) flux thimbles in given fuel assemblies at various core locations. The detectors are driven to the top of the core and stopped automatically. An x-y plot (position vs. flux level) is initiated with the slow withdrawal of the detectors through the core from the top to a point below the bottom. In a similar manner, other core locations are selected and plotted.

Each detector provides axial flux distribution data along the center of a fuel assembly. Various radial positions of detectors are then compared to obtain a flux map for a region of the core.

7.6.3 System Evaluation

The thimbles are distributed nearly uniformly over the core, with about the same number of thimbles in each quadrant. The measured nuclear peaking factor (F_Q) is increased by 8% to account for uncertainties, prior to being compared to its limit. An appropriate allowance for the measurement uncertainty for the nuclear hot-channel factor ($F\Delta h$) has been incorporated into the statistical DNBR limit. If either factor exceeds its limit, core power is reduced until the violation is eliminated.

Figure 7.6-1
INCORE INSTRUMENTATION - DETAILS WESTINGHOUSE DESIGN



Upon Completion of Design Change 00-003, this figure will no longer be applicable. The configuration of the flux thimble tubes will be as shown on Figure 7.6-2.

INCORE INSTRUMENTATION - DETAILS REPLACEMENT DESIGN

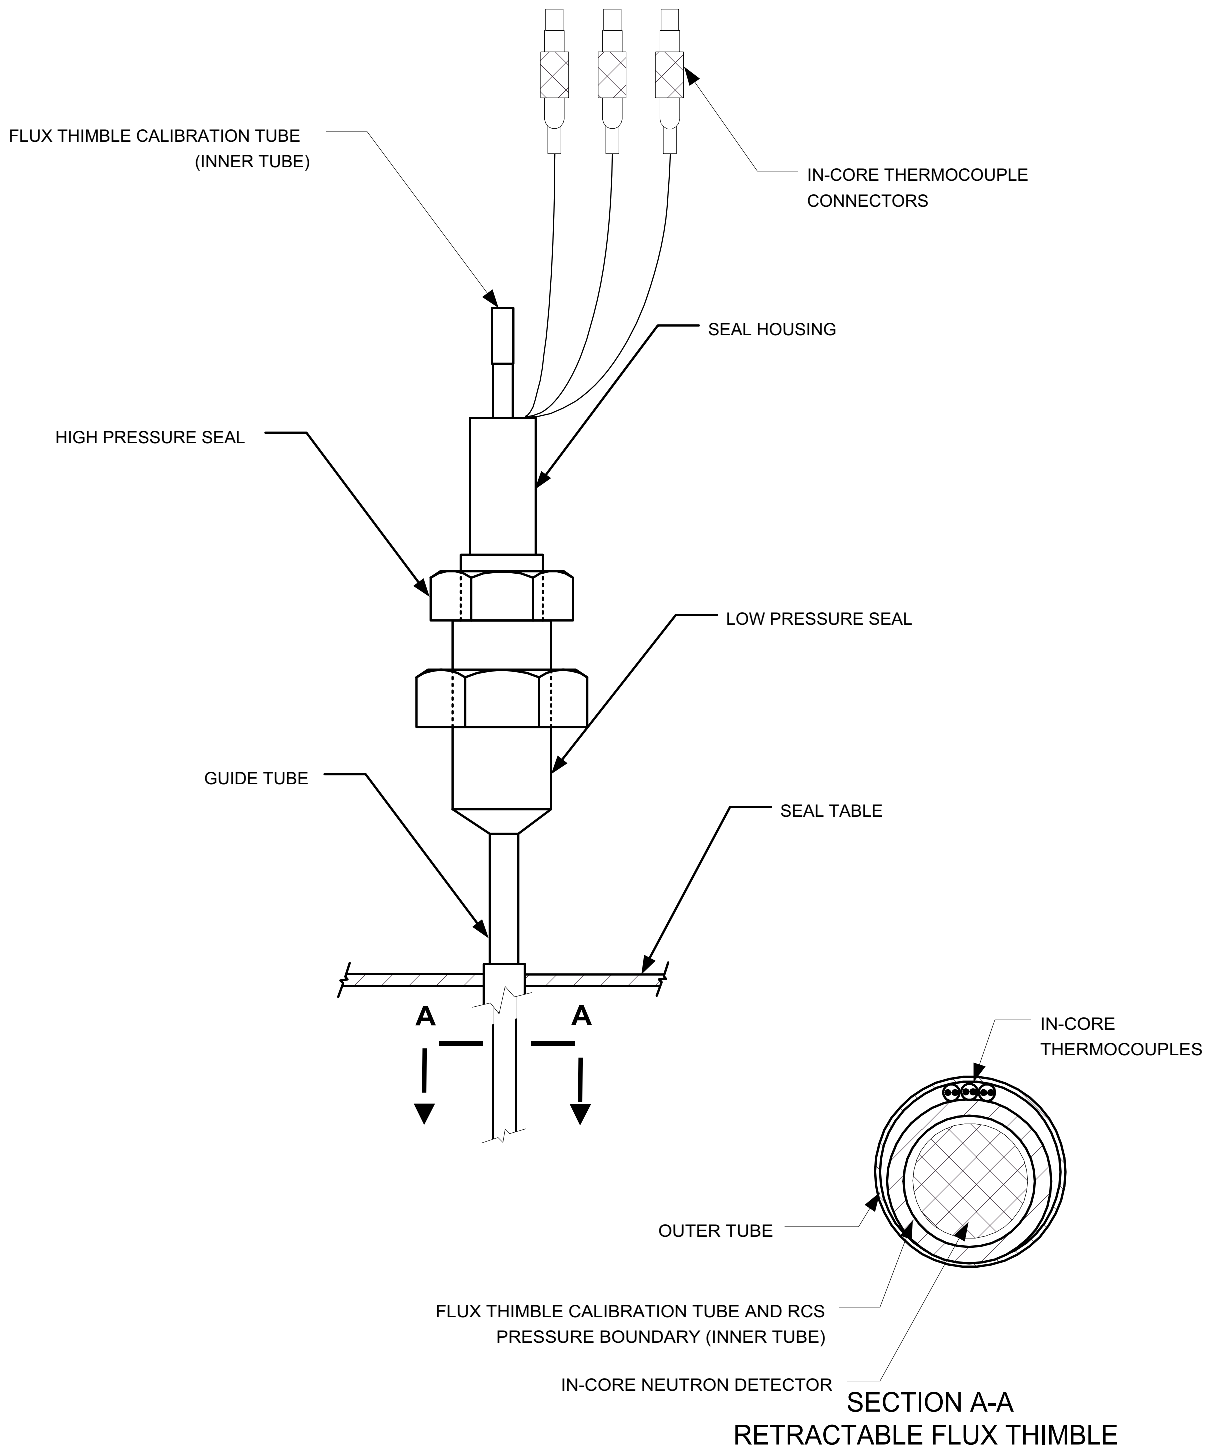

Figure 7.6-3
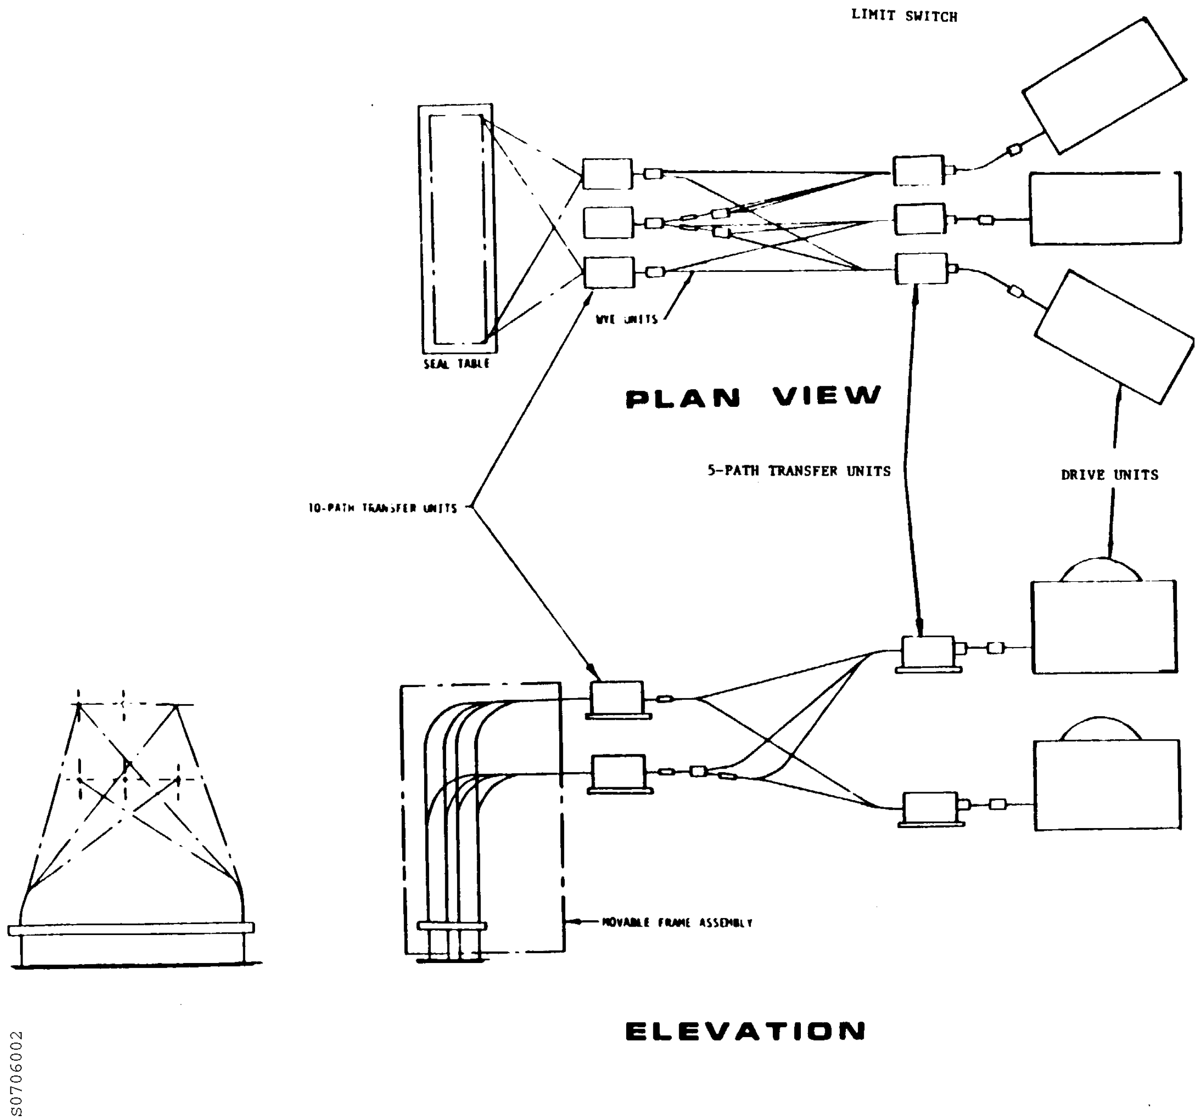
INCORE MECHANISMS



7.7 OPERATING CONTROL STATIONS

The control room, located in the service building, contains controls and instrumentation necessary to start up, operate, or shut down both units. It is one of the most important parts of the station, with pertinent interrelated information presented for the safe and reliable operation of the plant, including periods of transient and accident conditions. In the event that this area becomes inaccessible, the reactors can be brought to and maintained in a hot-shutdown condition at auxiliary control stations located in the Emergency Switchgear Rooms below the control room. There is a separate auxiliary control station for each unit. In addition, controls for certain auxiliary systems not directly involved with power generation, such as water treating and waste disposal, are located at remote control stations. The control room is shown in Figure 7.7-1 and Reference Drawing 1.

7.7.1 Design Bases

The station is equipped with a control room that contains controls and instrumentation necessary for operation of the reactors and turbine-generators under normal and accident conditions.

The control room, which is continuously occupied by qualified operating personnel under all operating and design-basis accident (DBA) conditions, is designed to permit single operator supervision of the units during normal steady-state conditions and to use additional operators to assist the control room operator during abnormal conditions.

The control room has three independent communication systems. One system consists of telephones leased from the local telephone company. These telephones and several outside trunk lines service the station for outside calls. This system may or may not be available under emergency conditions. A second system, a communication and voice paging system, is provided to interconnect the entire station. This system is energized from the emergency power buses. The third system is sound-powered, with telephone jacks and interconnecting wires at each major control point for test purposes. Sound-powered telephones are installed at various stations in the reactor containment. This system is accessible so that roving operators or service personnel may have easy communication with the control room or one another. This system does not rely on any power source, so it will be available at all times.

In addition to the above communications systems, onsite and offsite communications equipment has been installed to provide for notification of the NRC, as well as corporate, state, and local authorities on a 24-hour basis. A tri-band trunked radio system with redundant systems exists for radiological monitoring teams and security and recovery operations. Communications with the Corporate Emergency Response Center (CERC) are also provided on redundant systems.

Also, additional offsite communication equipment is installed and staged on-site using mobile satellite phones for a beyond design basis (BDB) event.

Sufficient shielding, distance, and containment integrity are provided to ensure that control room personnel shall not be subjected to doses that in the aggregate would exceed the limits in 10 CFR 50, Appendix A, GDC 19 during occupancy of, ingress to, and egress from the control room. All equipment in this area has been designed to minimize the possibility of a condition that could lead to possible inaccessibility or evacuation. For events analyzed to implement the alternate source term, which is described in Regulatory Guide 1.183, the control room dose limits are specified in 10 CFR 50.67.

The auxiliary control stations, also highly protected, are designed with a minimum of simple control actions required to bring and maintain the reactor in a hot-shutdown condition. It is not desirable to include marginal controls that would require more operator coordination, bypassing or deactivating of protective circuits, and unorthodox operating procedures.

Temperature in the control room and adjoining equipment room is maintained for personnel comfort at 75±10°F. The electronic equipment is tested and calibrated at the factory for the design temperature range from 40°F to 110°F. Qualification testing has demonstrated that the protective instrumentation remains operable up to 120°F, as there is a possible calibration shift above this range. The Plant Computer System equipment in the control room is designed to operate up to 95°F. This 120°F limit establishes the maximum temperature above which plant shutdown is required. Thus, there is a wide margin between design limits and the normal operating environment for control room equipment.

7.7.2 System Description

The primary objectives in the control room layout are to provide the necessary controls to start, operate, and shut down each unit, with sufficient information display and alarm indication to ensure safe and reliable operation under normal and accident conditions. Special emphasis is given to maintaining control integrity during accident conditions.

The equipment in the control room is arranged to reflect the fact that certain systems normally require more operator attention than others. The main control board is the central item in the control room. The control board for Unit 1 is completely independent of the control board for Unit 2. Each control board has a bench section, and a vertical section located behind the bench section. Most of the essential instruments and controls for power operation, and protective equipment that is immediately needed in cases of emergency, are mounted on the bench console sections in functional groupings. Recorders and indicators are mounted on the vertical back panels in agreement, wherever appropriate, with the functional groupings of the bench sections. The engineered safeguards section of the control board is designed to minimize the time required for the operator to evaluate the system performance under accident conditions.

Auxiliary vertical panels are provided in the control room, where their use simplifies control of certain auxiliary systems, or systems that only require occasional operator attention, such as turbine supervision, radiation monitoring, and liquid and gaseous waste disposal.

Illuminated window and audible alarm units are incorporated into the control room to warn the operator if abnormal conditions are approached by any system. Independent annunciator systems for each unit have their own identifying alarm horn tones. Indications and alarms are also provided so that the control room operator is made aware of any deviation from normal conditions at remote control stations. Many of these conditions are also alarmed by the unit performance-and-alarm monitoring system. Audible containment alarms are initiated automatically by the radiation monitoring system. Audible alarms are sounded in appropriate areas through the station if high-radiation conditions are present.

Instrumentation and control equipment is designed with reliable components. The temperature in the control room and emergency switchgear and relay rooms may vary from 65°F to 85°F. Safety systems, such as process instrumentation, nuclear instrumentation, and relay racks will continue to function within design accuracy in ambient temperatures up to 120°F. In addition, a reliable source of electric power, described in Section 8.4.3, is provided to ensure continual operation of vital unit and station instrumentation. Emergency lighting is also provided. The control room is further discussed in Section 11.3.6.

Two 100% redundant air handling units, fed from different power sources, are provided for the main control room and emergency switchgear and relay room of each unit. Each air handling unit is supplied chilled water by one of two chillers connected to the same power source as the respective air handling unit. Since the main control rooms are common, if only one of the four control room cooling units remains operable, the control room temperature will level off under 90°F. As the latent heat is negligible, humidity is not a factor. A double failure (both operating air-handling units failing concurrently) is required to jeopardize the temperature control. In this very unlikely event, the control room would reach 120°F in about 45 minutes, which would still provide sufficient time to start the redundant air handling units or shut down the reactor. Onsite testing was performed to prove the installed performance of the air-conditioning systems.

Qualification testing has been performed on various safety systems, such as process instrumentation, nuclear instrumentation, and relay racks. This testing involved demonstrating operation of safety functions at elevated ambient temperatures to 120°F for control room equipment and in full postaccident environment for required equipment in containment. Detailed results of some of these tests are proprietary to the suppliers, but are on file at the suppliers and available for audit by qualified parties.

The control room is designed to be available at all times. Accessibility to this area is from three points, thus ensuring entry for emergency personnel. Safe occupancy of the control room during an abnormal condition is provided for in the design of the service building. Adequate shielding and air conditioning are used to maintain tolerable radiation and air temperature levels in the control room. Ventilation consists of totally contained redundant recirculating air-conditioning systems designed to continue operation under all normal and emergency conditions. Fresh air intake and exhaust for normal use are from other independent systems, which can be valved off to stop the intake of airborne activity if monitors indicate that such action is appropriate. Makeup air, under emergency conditions, is available from emergency ventilating units supplying air through high-efficiency charcoal filters. With all normal outside air makeup shut off, the quality of the air will be maintained with the carbon-filtered emergency ventilation.

To limit the possibility and potential magnitude of a fire in the control room, the following are incorporated into its design:

1. Noncombustible materials are used in construction.
2. Control and instrumentation cable and switchboard wiring are used that meet the flame test described in Insulated Power Cable Engineers Association, Publication S-61-402, and National Electrical Manufacturers Association, Publication WC5-1968.
3. The main control boards are wired with flame-retarding switch-board-type conductors. The two main control boards are physically separated.
4. Control room furnishings are of metal construction with the exception of chairs, Corian desktops for the Senior Reactor Operator console and Plant Computer consoles, anti-fatigue flooring, and carpeting.
5. All control information is transmitted to the control room by electrical signals or low-pressure air signals. Transmitted signals from the containment structure and any other high-radiation areas are electrical.
6. Combustible supplies, such as records, logs, procedures, manuals, etc., are minimized.
7. Fire detection alarms are provided in the control room. These alarms are actuated from remote detectors sensitive to smoke and located in the vicinity of instrumentation cabinets, air-conditioning system ducts, and in other areas susceptible to fire.
8. All areas of the control room are readily accessible for extinguishing.
9. Portable fire extinguishers and breathing apparatuses are provided.
10. The control room is occupied at all times by an operator who has been trained in fire extinguishing techniques.
11. The control room is separated from the emergency switchgear and relay rooms by a 3-hour fire-resistant barrier. The emergency switchgear and relay rooms of each unit are separated from each other by a 3-hour fire wall.

Further description of the fire protection provisions is given in Section 9.10.

Therefore, any fires in the control room are expected to be of such small magnitude that they could be extinguished by a hand fire extinguisher. The resulting smoke and vapors are removed by the ventilation system. In addition, the control room is protected from outside fire, smoke, or airborne radioactivity by pressure-tight penetrations, weather-stripped doors, absence of windows, by the positive air pressure maintained in the area during normal operation, and by the ability to isolate the control room envelope during emergency conditions. Fire-rated doors are installed as access doors leading into the control room complex.

The probability of the control room becoming inaccessible as a result of fire or other causes is considered extremely small. However, if the operator must leave the control room, operating procedures require that he trip the reactors and turbine-generators before leaving so as to bring the station automatically to the no-load condition, thus ensuring control at the auxiliary control stations. Each reactor unit can be brought to and maintained in a hot-shutdown condition from its auxiliary control station, which is provided with the following alternate control provisions:

1. Removal of core residual heat.
2. Boration of the reactor coolant system.
3. Maintenance of pressurizer level and pressure.

These functions require the operation of auxiliary feedwater pumps, charging pumps, and boric acid transfer pumps. Appropriate process instrumentation, such as pressurizer pressure and level, and steam generator pressure and level, are provided in the auxiliary control stations. This equipment is sufficient to safely maintain the unit or units for an extended period of time in a hot-standby condition.

The principal point of control in the auxiliary control station is an instrument panel. The following equipment is controlled at this panel:

1. Turbine driven auxiliary feed pump start-stop control switch.
2. ‘A’ auxiliary feed pump motor start-stop control switch.
3. ‘B’ auxiliary feed pump motor start-stop control switch.
4. Motor-operated valves - auxiliary feed pump discharge open-close control switches (6).
5. Steam generator wide range water level indicators.
6. No. 1A charging pump motor start-stop control switch.
7. No. 1B charging pump motor start-stop control switch.
8. No. 1C charging pump motor start-stop control switch.
9. No. 1A boric acid pump motor start-stop control switch.
10. No. 1B boric acid pump motor start-stop control switch.
11. Charging flow control valve control switch.
12. Boric acid filter discharge to charging pump suction motor-operated valve control switch.
13. Pressurizer pressure indicator.
14. Pressurizer level indicator.

15. Pressurizer heater backup groups control switch.
16. Main steam header pressure indicators.
17. Main steam pressure indicators
18. Charging flow indicator

The capability of operating the residual heat removal pumps and component cooling water pumps from the emergency switchgear room, as discussed in Sections 9.3.2.1, 9.4.3.1, and 9.10.4.1, has been incorporated by the addition of a transfer switch and a control switch on each pump's breaker compartment at the switchgear. This capability, which has been incorporated in both units, has been installed to be used in the event a fire disables or causes evacuation of the control room. These plant features have been added in accordance with the requirements of 10 CFR 50 Appendix R.

Additional remote monitoring panels have been installed in the cable tray area of Unit 1. The panels provide indication of two reactor coolant loops hot- and cold-leg temperatures, RCS and steam generator pressures, pressurizer level, and steam generator wide range water levels, and source and wide-range excore neutron flux. The panels are shared by both units.[1] Signals to the panels are transmitted from instruments dedicated to the panel via cables independently routed from cables transmitting the same data to instrumentation in the control room and on the auxiliary shutdown panel.

Seismically-qualified transmitters are installed in the containments of each unit, parallel to existing RCS and steam generator pressure transmitters, and the pressurizer level, and steam generator wide-range level transmitters. Sensing lines for these transmitters are connected to the existing transmitter sensing lines, outside the crane wall, and are seismically qualified. The spare elements of existing dual head hot-leg RTDs are used and connected to temperature transmitters mounted in the remote monitoring panel. One element of the dual element cold-leg RTD's is used to provide the cold-leg temperature to the remote monitoring panel. Cables inside and outside the containment servicing the transmitters for the remote monitoring panel and spare RTD elements are routed independently from the cables for associated parallel transmitters and RTD element, furnishing identical information to control room and auxiliary shutdown panel instrumentation. In order to meet the requirements of 10 CFR 50 Appendix R additional transmitters and cables providing indication at the remote monitoring panels for RCS pressure, pressurizer level, and steam generator wide-range water levels have also been installed. Instrumentation sensing lines are routed independently with fire barriers as required to maintain specific separation from at least one parallel channel of indication available in the control room or auxiliary shutdown panel. This separation meets the requirements of Appendix R.

---

1. Panel RMP is powered from either unit's Appendix R Distribution Panel by a selector switch. Panel ASC-RMP, Unit 1 section is powered from Unit 2. Panel ASC-RMP, Unit 2 section is powered from Unit 1.

One remote monitoring panel (ASC RMP-1) contains one indicator for each of the following RCS parameters with a selector switch which aligns the indicator to either the Unit 1 or Unit 2 instrument transmitter outputs.

Steam Generators A, B, and C Wide-Range Levels

Pressurizer Level

RCS Wide-Range Pressure

RCS Loop 1 Hot-Leg Temperature (Units 1 & 2)

RCS Loop 2 Hot-Leg Temperature (Unit 1)

RCS Loop 3 Hot-Leg Temperature (Unit 2)

The 120V ac power from the Appendix R Panels is isolated by a selector switch, which aligns to either Unit's power, and protective relays. Loss of either unit's power at the panel is alarmed by an annunciator on the auxiliary ventilation panel (VNTX) which is shared by both units in the main control room.

The second remote monitoring panel (PNL-REM) contains six indicators for each unit. Indicators are provided for:

Steam Generator A Pressure

Steam Generator B Pressure (Unit 1 only)

Steam Generator C Pressure (Unit 2 only)

RCS Loop 1 Cold Leg Temperature

RCS Loop 2 Cold Leg Temperature (Unit 1 only)

RCS Loop 3 Cold Leg Temperature (Unit 2 only)

Source Range Neutron Flux

Wide Range Neutron Flux

Power for Unit 1 instrumentation on each remote monitoring panel is supplied by the Unit 2 Appendix R power system. Similarly, the Unit 2 instrumentation is supplied by the Unit 1 Appendix R power system. This assures that power will be available to the instrumentation of the affected unit following a fire in that unit's emergency switchgear room, cable tunnel or cable vault. Power to both Remote Monitoring Panels can also be supplied by a portable generator should power be lost to both Unit 1 and 2.

Alternative shutdown instrumentation for either unit's reactor is provided by the remote monitoring panels, which can be used in conjunction with the operation of the unaffected unit's charging pumps and the manual operation of applicable valves in the affected unit. The panels are to be utilized in the event that a fire disables the instrumentation on the affected unit's main board and auxiliary shutdown panel.

Should an Extended Loss of AC Power (ELAP) occur to both Units, backup power to both Remote Monitoring Panels is available for 12 hours via uninterruptable power supply (UPS). This ensures continuous monitoring capability is available until a portable generator can be deployed.

7.7.3 System Evaluation

7.7.3.1 Control Room

The control room is designed to provide the operator with the controls, indication, and alarms necessary to control the station during normal or abnormal conditions.

Necessary information is available to the operator in the control room following a LOCA. Monitored information is available for postaccident analysis.

7.7.3.2 Detailed Control Room Design Review

NUREG-0737, "Clarification of TMI Action Plan Requirements" (Reference 1), published in October 1980, provided a comprehensive and integrated plan to improve safety at power reactors. NUREG-0737 item I.D.1, "Control Room Design Reviews," required the development of a Detailed Control Room Design Review (DCRDR) to identify and correct control room design deficiencies. The NRC subsequently issued Supplement 1 to NUREG-0737 (Reference 2) to clarify and replace the previous DCRDR requirements in NUREG-0737.

In accordance with NUREG-0737 Supplement 1, Vepco submitted a DCRDR Program Plan (Reference 3). This was confirmed by the Commission's Order dated June 12, 1984 (Reference 4). Surry performed a human factors engineering (HFE) review of the SPS Units 1 & 2 control room. A Vepco letter from July 1984 (Reference 5) subsequently changed the DCRDR Program Plan by providing replacement pages reflecting the authorization of the use of the Westinghouse Owners Group Emergency Response Guidelines as the basis for the Task Analysis and the Verification and Validation activities. The result of the HFE review was submitted in a DCRDR Final Summary Report (Reference 6). This HFE review used the accepted human factors principles in NUREG-0700 (Reference 7) and NUREG-0801 (Reference 8) as guidance. The NRC reviewed the Vepco DCRDR Program Plan and Final Summary Report and concluded that Vepco's DCRDR program satisfied the requirements of item I.D.1 of Supplement 1 to NUREG-0737 (Reference 9). Following the initial NRC approval, a reassessment of the remaining DCRDR corrective actions were submitted (Reference 10, Reference 11, Reference 12) and approved in accordance with the NRC's safety evaluation reports (Reference 13, Reference 14).

The following HFE activities were performed as part of the initial SPS Units 1 & 2 DCRDR. These activities were required by the Commission's Order (Reference 4) which confirmed the commitment to implement a CRDR Program Plan per NUREG-0737 Supplement 1. The performance of these activities was reviewed and approved by the NRC, as documented in the NRC Safety Evaluation (Reference 9), per the guidelines set forth in Chapter 18.1 of NUREG-0800 (Reference 15) and other accepted human factors principles. These activities confirmed that the control room is capable of being used to safely operate the plant during emergency conditions.

7.8 COMPUTER SYSTEM

7.8.1 Design Bases

The main purposes of the computer are to provide supplementary information to the operator, to effectively assist him in the operation of the nuclear steam supply system and turbine-generator cycle of each unit, to inform him of off-normal conditions, and to provide data communication, display and control functions for non-safety related equipment at the Low Level Intake Structure. The design of the control boards provides the operator with sufficient information for proper and safe operation of the unit if the computer system is unavailable.

7.8.2 System Description

The Plant Computer System (PCS) is designed to obtain data by scanning analog and digital field sensors and retrieve data from the Emergency Response Facility (ERF) data acquisition system, feedwater heater level control system and other peripheral plant systems. Operator (OWS) and Engineering (EWS) workstations act as primary data collection devices and then transmit that data to a secondary system historian, which will store easily retrievable data. Engineering workstations also provide the means to program the system. The PCS provides data and trending on visual displays, which can be printed. The system has the capability to log trip and post-trip data, and alarm when various off-normal conditions exist. Monitoring programs are also included for surveillance of reactor control and protection system operations and for nuclear process calculations and performance checks of systems and components. In addition to operator support functions, the PCS also serves as the Emergency Response Facility System, fulfilling the requirements of NUREG-0737 and NUREG-0696.

7.8.2.1 **Analog Scanning**

The computer continuously scans all preselected analog inputs at rates consistent with system requirements. Provisions are included for scanning some points faster than others. Those inputs that can change rapidly, or those associated with safety of the unit and associated with trip functions, are scanned at a rate suitable for detecting abnormal changes.

A limit-checking program is provided for determining that the analog values are within allowable instrument ranges. Out-of-range inputs are recorded and documented.

7.8.2.2 **Alarming**

Multiple high and/or low alarm setpoints can be assigned to each analog input. During each scan cycle, the analog values are compared to the associated setpoints to determine if they are outside the preset limits. A value in alarm is printed out or displayed on the OWS alarm screen and accompanied by an audible signal.

When the off-normal point returns to normal, the system again prints out or indicates a suitable message to this effect.

For example, a Delta-Flux Alarm Program monitors delta-flux in the reactor core and alerts the operator when a delta-flux alarm condition exists. There are two alarm states. They are: (1) above a preset power level when delta-flux has exceeded its allowable limit, and (2) below this power level if the allowable limit has been exceeded for a preset cumulative amount of time in the past 24 hours. Either alarm condition will set a computer contact closure output to actuate an annunciator alarm on the main control board. The annunciator will not clear until both of the computer alarms have returned to normal. Additionally, the alarm screen on the PCS OWS will indicate the associated system alarm point has changed state and requires operator attention. Most PCS alarms do not go to the annunciator system. They are displayed on the PCS alarm screens only.

7.8.2.3 **Alarm Review**

The operator may request a printout of all off-normal alarm inputs. This alarm review program documentation is very useful to a new shift, or for the operator to quickly determine the status of all station measurements.

7.8.2.4 **Analog Trend**

The analog trend function is used for recording suspected fluctuations or ramps in any measurements, or for obtaining data for future analysis of transients during start-up or load changing.

7.8.2.5 **Digital Trend**

The PCS provides visual displays of trends on the OWS. Any point in the system can be monitored on the workstation.

7.8.2.6 **Digital Display**

Visual displays are included on the operator workstations. Any analog input or addressable value can be displayed on this display.

7.8.2.7 **Sequence of Events**

These inputs usually are directly or closely associated with tripping the unit. A review of these events, in proper sequence, helps to analyze the causes and effects of unit trips and assists in trouble-shooting and returning the unit to service.

7.8.2.8 **Normal and Summary Logging**

Normal and summary logging for analog inputs, and calculated unit calorimetric variables, are provided.

7.8.3 System Evaluation

The PCS associated with each unit functions independently from the normal reactor control and protection system and engineered safeguards. The PCS provides control, communication, and display functions for non-safety related systems that do not provide reactor control functions.

Intentionally Blank

7.9 INADEQUATE CORE COOLING (ICC) SYSTEM

In response to NUREG-0578 (Reference 1), instrumentation to detect inadequate core cooling has been installed at Surry Units 1 and 2.

7.9.1 Design Bases

The Inadequate Core Cooling (ICC) system meets all the requirements of Regulatory Guide 1.97 (Reference 2). The ICC system, per unit, consists of the following three redundant subsystems that share common redundant calculator devices and continuous control room displays; Core Exit Thermocouple System, Core Cooling Monitor System, and Reactor Vessel Level Instrumentation System.

The system provides means for acquiring data only, and performs no operational unit control. Redundant displays in the control room graphically depict selected parameters, parameter trends, and system diagnostic information. An alarm is actuated in the control room on ICC system failure.

The safety-grade signal inputs, calculator devices and displays are qualified to IEEE-323 (Reference 3) or IEEE-344 (Reference 4).

7.9.2 System Description

7.9.2.1 **Core Exit Thermocouple (CET) System - Subsystem of ICC System**

The Core Exit Thermocouple System uses inputs from all the incore thermocouples to calculate and display temperature of the reactor coolant as it exits the core.

The CET system consists of Type K, grounded, stainless steel sheathed thermocouples. Refer to UFSAR Section 7.6.1, 7.6.2.1, and 7.6.2.2 for description of the quantity and design of the thermocouples.

One safety-related thermocouple from each flux thimble (25 for Train A and 25 for Train B) is wired to the redundant ICC calculators in the control room via the electrical penetrations and Station Multiplexer System.

The Cold junction compensation is performed internally at the remote multiplexer (MUX).

The thermocouples measure the core exit temperature in a range of 0 - 2300°F.

7.9.2.2 **Reactor Vessel Level Instrumentation Systems (RVLIS) - Subsystem of ICC System.**

The Reactor Vessel Level Instrumentation System (RVLIS) uses various parameters to calculate and to display the water level height in the reactor vessel during all plant conditions.

RVLIS uses differential pressure (d/p) measuring devices to measure vessel level or relative void content of the circulating primary coolant system fluid. The system is redundant and includes automatic compensation for potential temperature variations of the impulse lines. Essential information is displayed in the main control room in a form directly usable by the operator.

The functions performed by the RVLIS are as follows:

- Assist in detecting the presence of a gas bubble or void in the reactor vessel
- Assist in detecting the approach to ICC
- Indicate the formation of a void in the RCS during forced flow conditions

Refer to Figure 7.9-1 for the RVLIS schematic

The RVLIS utilizes two redundant sets of three differential pressure (d/p) cell transmitters. These cells measure the pressure drop from the bottom of the reactor vessel to the top of the vessel, and from the hot legs to the top of the vessel.

This d/p measuring system utilizes cells of differing ranges to cover different flow behaviors with and without reactor coolant pump operation as follows:

- Reactor Vessel - Upper Range. The d/p cell, LT1, shown in Figure 7.9-1 provides a measurement of reactor vessel level above the hot leg pipe when the reactor coolant pump (RCP) in the loop with the hot leg connection is not operating.
- Reactor Vessel - Dynamic Head Range. The d/p cell, LT3, shown in Figure 7.9-1 provides a measurement of the pressure drop across the reactor core and internals assemblies for any combination of RCP operation (1, 2, or 3 pumps running). Comparison of the measured pressure drop with the normal, single-phase pressure drop provides an approximate indication of the relative void content or density of the circulating fluid. This instrument monitors coolant conditions on a continuing basis during forced flow conditions.
- Reactor Vessel - Full Range. The d/p cell, LT2, shown in Figure 7.9-1 provides a measurement of reactor vessel level from the bottom of the vessel to the top of the vessel during natural circulation conditions.

To provide the required accuracy for level measurement, temperature measurements (T1 through T7) of the impulse lines are provided as shown on Figure 7.9-1. These measurements, together with the reactor coolant temperature measurements (hot leg RTDs) and wide range RCS pressure, are employed to compensate the d/p transmitters outputs for differences in system density and reference leg density, particularly during the change in the environment inside the containment structure following an accident.

The d/p cells are located outside of the containment to eliminate the large reduction (approximately 15%) of measurement accuracy associated with the change in the containments environment (temperature, pressure, radiation) during an accident. The cells are also located outside of containment so that system operation including calibration, cell replacement, reference leg checks, and filling are made easier.

7.9.2.3 **Core Cooling Monitor System - Subsystem of ICC System**

The Core Cooling or Subcooled Margin Monitor System uses various parameters to calculate saturation temperature and subcooled margins for the primary loops during all plant conditions. These input parameters provide the plant operators with complete information on core cooling.

Software algorithms determine the equivalent saturation temperature (T_{sat}) based on RCS wide range pressure. This (T_{sat}) value is used to determine the subcooled margin from the average of the five highest core exit thermocouples. An alarm is actuated in the control room on approach to saturation temperature.

7.10 EX-CORE NEUTRON FLUX MONITOR SYSTEM

7.10.1 Design Bases

The Ex-Core Neutron Flux Monitor System is designed to meet the requirements found in Appendix R of 10 CFR 50 and Regulatory Guide 1.97. These requirements are in addition to those used in the original design basis of the station.

The instrumentation required by R.G. 1.97 is redundant Category I, Seismic Class 1, and Class 1E. R.G. 1.97 requires wide range indication over a range of 10^{-6} to 100% of full reactor power. The system that has been installed provides Source Range Indication over a range of 0.1 to 10^5 cps and Wide Range Indication over a range of 10^{-8} to 200% of full power.

The portions of the system that are required to meet R.G. 1.97 requirements have been designed to meet IEEE-323-1974 and IEEE-344-1975.

7.10.2 System Description and Evaluation

The Ex-Core Neutron Flux Monitor System consists of two redundant Channels. These Channels are made up of detector assemblies, amplifiers and processor units and indicators.

The Ex-Core Neutron Flux Monitor is designed to provide to the operator the reactor neutron flux level from source level (shutdown) to 200% of full reactor power.

Fission chambers were chosen to monitor post-accident neutron flux because of their proven high reliability to a harsh environment and because of their relative insensitivity to a high gamma flux.

The signal from the detector is composed of a series of charge pulses. The pulses result from alpha decay of the uranium coating in the detector, from gamma photon interaction with material in the electrodes of the detector, and from the fissioning of uranium atoms when a neutron is absorbed. The pulse signal from alpha decay and from gamma radiation is an unwanted signal and can be eliminated by amplitude discrimination because the neutron pulse signal is much larger.

The number of pulses per unit time from the detector is proportional to the magnitude of the neutron flux at the detector. The magnitude of the neutron flux in the reactor core is proportional to the fission power being generated in the reactor. Since the magnitude of the neutron flux at the detector is proportional to the magnitude of the neutron flux in the reactor core, the pulse rate from the detector is proportional to reactor power.

The neutron flux monitor measures the number of pulses per unit time from the detector over the range from source level to the level where the error from countrate loss, due to coincident pulses, becomes unacceptable. From about two decades below the upper end of the countrate range to full reactor power, the neutron flux monitor measures the mean square value of the time variant signal from the detector. This mean square value is proportional to the average rate of neutron pulses and is not dependent on the pulses being individually identifiable, yet provides good discrimination against alpha and gamma signal.

The direct current signal from the detector provides a linear measurement of the reactor power. The direct current signal contains the alpha and gamma signal; however, on a linear scale from 0 to 200% of reactor power, it is less than 0.1% of full scale and, therefore, is not a problem. The direct current measurement inherently contains less statistical variation than the countrate or means square measurements and therefore, the measurement can be provided with a faster response time.

Source and Wide Range outputs from the Processor units are transmitted to the following locations (outputs are also available for the Technical Support Center):

Channel #1 (Red)	NIS Panel 1 Remote Monitoring Panel
Channel #2 (White)	NIS Panel 2

Indication at the NIS Panel and Remote Monitoring Panel consists of a set of two vertical edgewise meters. Displays for each area include both source range (0.1 to 10^5 cps) and wide range (10^{-8} to 200% of Reactor Power) neutron flux levels. They are intended to be available during all plant conditions.

The purpose of reactor power level indication is to confirm that the Reactor Shutdown function has been accomplished following an accident (in the case of the NIS Panel and TSC indicators), or fire (in the case of the Remote Monitoring Panel indicators).

In the event of a fire which requires the evacuation of the Control Room or causes the inoperability of control room reactor parameter indication, the Red Channel will be utilized to monitor reactor neutron flux level at the Remote Monitoring Panel.

The Ex-Core Neutron Flux Monitor System is also equipped with circuitry which provides continuous self-diagnostics of the integrity of the detector, cables, and power supplies. Failure of any of these components will generate a “non-operable” alarm in the Control Room.

The Ex-Core Neutron Flux Monitor System is normally supplied power from the 120V Vital AC Distribution System, Channels 1 and 2. In the event of a fire which causes the loss of control room indication and the normal electric distribution system, Channel 1 can be transferred to a back-up power source that is supplied from the other unit. In the event of a complete loss of ac power, a portable generator can be used to feed the Channel 1 Ex-Core system.

The system is designed so that all components which require calibration are located externally to the containment.

Should an Extended Loss of AC Power (ELAP) occur to both Units, backup power to the Channel 1 Ex-Core system is available for 12 hours via UPS. This ensures continuous monitoring capability is available until a portable generator can be deployed.

7.11 LEVEL INSTRUMENTATION TO PREVENT LOSS OF SHUTDOWN COOLING

In order to address concerns associated with loss of residual heat removal (RHR) capability while the Reactor Coolant System (RCS) is partially filled (i.e., mid-loop operation), a level standpipe has been permanently installed in the containment annulus to monitor reactor coolant level during plant shutdown and refueling.

An alternate means of determining the RCS level during mid-loop operation, which is independent of the level standpipe, is the ultrasonic measurement of the water level in the "B" hot leg piping.

7.11.1 System Description

7.11.1.1 Level Standpipe

The level standpipe is connected to the RCS at the top of the pressurizer and at a drain line from the Loop C cold leg. Local visual indication is provided at the standpipe in the containment annulus. Remote indication is also provided on the control room main board. An annunciator, which alarms on low reactor level, is also provided in the control room. The low level setpoint is set at a level prior to reaching RHR pump suction nozzle vortex initiation.

The standpipe and associated instrumentation is used only during shutdown and refueling conditions. During other plant conditions, the standpipe is isolated from the RCS by double isolation valves at each RCS connection.

7.11.1.2 Ultrasonic Level Indication System

An ultrasonic level indication system is installed as a secondary means of monitoring RCS drain down level independent of the level standpipe system. An ultrasonic transducer is mounted on the exterior of the "B" loop hot leg piping to provide RCS level indication. Remote indication is provided via a recorder located on the control room vertical board. A low level alarm is also provided by the ultrasonic level measurement which is connected to the standpipe low level alarm window. Either of the level measurement systems can activate the alarm on low RCS level.

The ultrasonic level indication system is only used in mid-loop operation during shutdown and refueling and is de-energized during normal plant operation.

CHAPTER 8 ELECTRICAL SYSTEMS

Note: As required by the Subsequent Renewed Operating Licenses for Surry Units 1 and 2, issued May 4, 2021, various systems, structures, and components discussed within this chapter are subject to aging management. The programs and activities necessary to manage the aging of these systems, structures, and components are discussed in Chapter 18.

8.1 GENERAL DESCRIPTION AND SUMMARY

The electrical systems include the equipment and the systems necessary to generate power and deliver it to the high-voltage switchyard. They also include facilities for providing power and controlling the operation of electrically driven auxiliary equipment and instrumentation. The main electrical connections are shown in Figure 8.3-1. A review of the effects of the power uprate to a core power of 2589.3 MWt was conducted and the electrical systems were found to be adequate.

This chapter describes the electrical system for Unit 1. The Unit 2 electrical system is identical but completely independent of Unit 1, with the exception of an emergency diesel generator common to both and used as a backup should the individual unit emergency diesel generators fail. The reserve station service transformer banks are common to both Units 1 and 2, and are sized to start up a single unit or to shut down both units.

The output of the main generator is fed into and operated as an integral part of the overall company electrical distribution system.

The normal station service power system is designed to provide continuous power to the station auxiliaries during periods of generation and to transfer automatically to the reserve station service power system to ensure continued power to equipment when the main generator is off the line.

The plant non-safety-related auxiliary systems are supplied by off site power during start-up, shutdown, or hot standby conditions. Safety-related auxiliary systems are normally supplied by offsite power during all modes of plant operation.

In general, all auxiliaries of major equipment will be connected to the same power distribution branch as the major pieces of equipment, the only exceptions being those appurtenances that will be required to operate when the major piece of equipment shuts down. An example is a pump discharge motor-operated valve that must be closed when the pump stops.

Critical instrumentation is fed from a reliable and stable vital bus system to ensure continuous monitoring and control of critical instrument channels.

There are no ac or dc circuits on safety-related systems that, upon voltage failure, automatically switch to an alternate bus energized from a redundant power source. There are provisions which ensure that, on loss of the normal power source to a particular bus, an alternate power source automatically is placed in service to supply the bus. These capabilities are discussed individually in the applicable sections.

Station batteries are provided for circuit breaker control power, emergency lighting, and operating power for vital equipment until normal power is restored or onsite emergency generation is available.

8.2 DESIGN BASES

The electrical systems are designed to supply electrical power to all essential unit equipment during normal operation and under accident conditions.

The main generator, described in Section 10.3.3, establishes the facility operating limits and requires the plant to be operated between a 0.905 lagging and a 0.96 (0.97 for Unit 2) leading power factor. As system reactive load changes, generator excitation can be adjusted to ensure operation within the required power factor limits. The system grid also has banks of shunt reactors that can be connected in order to adjust the power factor.

Electrical system components vital to unit safety, including the diesel generators, are designed and protected as necessary so that their integrity is not impaired by potential earthquakes, high winds, floods, or disturbances on the external electrical system. Cables, motors, and other electrical equipment required for operation of the engineered safeguards are suitably protected against the effects of either a nuclear system accident or a severe external environmental phenomenon, in order to ensure a high degree of reliability. The enclosures for motors and electrical switchgear are selected to suit the local conditions and are designed in accordance with specifications issued by the National Electrical Manufacturers Association (NEMA).

Essential electrical equipment components are specified to withstand, without loss of function, the maximum conditions expected during normal operating and post-accident environments, and during operation of the safeguard equipment during the accident. It is expected that the maximum accident conditions within the containment will be 280°F at 45 psig for 30 minutes. The environmental qualification of safety-related electrical equipment is discussed further in Chapter 7. Should suitable equipment not be available, the detailed plant design incorporates features to modify the environment to be compatible with the equipment.

In the containment, essential electrical components and conductors are protected from the forces generated during an incident by group separation. By physically separating each group and providing conductor barriers where necessary, the failure of one group does not jeopardize any other group. In the case of multiple instrument channels in one location, such as the channels associated with the single pressurizer, physical separation is carried out as far as possible and the circuitry arranged so that multiple instrument failures are always in the safe direction. Electrical cable connections are run from the instrument transmitter to the area outside the crane support wall using the shortest path while providing separation between redundant channels. The crane wall acts as a further barrier against any forces generated during an accident.

In general, the 4160V and 480V switchgear are of metal-clad deadfront construction with closing and tripping control power taken from the station batteries. Each starter or breaker cubicle is isolated from the adjacent cubicle with metal barriers, and each bus section is physically separated from all others. The main feeds to the 4160V switchgear from the unit station service transformers are shielded single conductors with volcanized chlorinated polyethylene based compound jacket installed in ladder type trays, with 1.00 - 2.00-diameter spacings between conductors. The cable portion of the main feeds to the 4160V switchgear from the reserve transformers A and B are hypalon jacketed with maintained spacing of 0.9 diameter to 1.0 diameter. RSST C main feed to the 4160V switchgear is TS-CPE (thermoset Chlorinated Polyethene) jacketed with maintained spacing between 1.25 diameter to 1.4 diameter. The RSST feeders consist of overhead bus and cable in cable tray. One reserve transformer feeder has separate routing to the 4160V switchgear, physically isolated from all other transformer secondary leads.

All switchgear associated with engineered safeguards equipment is separated from the main switchgear area and is readily accessible in the main control area. For all leads supplying engineered safety equipment, the cable is 3/c with interlocked armor overall, run in ladder trays or properly mounted and supported when run external to ladder trays, or 3-1/c triplexed, run in conduit, with the exceptions of the 480V equipment supplied from motor control centers and the emergency generator leads. The only 480V exceptions are for 30-hp motors and smaller. The emergency generator leads entering the emergency switchgear room from the duct bank have been derated for cable in conduit in accordance with Insulated Power Cable Engineers Association (IPCEA) standards. In Mechanical Equipment Room No. 5, power cables are installed in ladder type trays. In the emergency switchgear room, some of the cables have been run in ladder type trays which have solid covers placed directly on the top of the trays and may have a solid transite or asbestos blanket placed on the bottom of the trays prior to installation of cables. This installation has the same protection integrity as cable in conduit and facilitates installation and inspection of these critical cables.

Power and control cables are distributed from the switchgear and control area by means of rigid metal conduits or ladder type cable trays. Control cables are of single or multiconductor construction with insulation rated at 600 or 1000V and with overall flame-retardant jackets. Low-voltage instrument connections are made using flame-retardant insulated cables, rated at 300 or 600V. These cables are provided with a total coverage electrostatic shield and an overall flame-retardant jacket.

The normal current rating of all insulated conductors is limited to that continuous value which does not cause excessive insulation deterioration from heating. Selection of power conductor sizes are based on *Power Cable Ampacities*, published by the IPCEA. Feeder cables which are greater than 2000 MCM will have their continuous ampacity rating determined and derated utilizing References 1-6 as applicable. Cables using this method are derated for losses due to skin effect, proximity effect, eddy current, thermal losses due to jacket, insulation, dielectric losses and ambient air as well as derated for apparent tray depth for cables with top covers.

Fire-resisting fillers, tapes, binders, and jackets were specified for all cable construction. Cable tray installations have approved fire stops in both horizontal and vertical runs and are provided with a solid raised cover or a corrugated solid aluminum cover if minimum separation distance requirements between trays are not maintained. Covers may be omitted on top trays run under solid floors. All conduit installations consist of plastic conduit encased in concrete or exposed rigid metal conduit.

Electrical equipment and cables are specified such that the application is within the normal rating or temperature rise stated by the manufacturer. During normal operating conditions, electrical equipment or cables that are found operating in excess of the manufacturer's stated normal rating or temperature rise are analyzed for continued use.

All connections at the 22-kV voltage level are made with isolated phase construction designed for self-cooling.

The station batteries are sized to operate circuit breaker controls, instrumentation, emergency lighting, and vital nuclear channels for two hours without benefit of any station power. The battery chargers are connected to the emergency bus and provide charging current to the battery and load when the emergency bus is energized.

Lighting distribution and intensities have been selected in accordance with the recommendations of the Illumination Engineering Society (IES).

8.3 SYSTEM INTERCONNECTIONS

Unit 1 and Unit 2 are connected with the Vepco system at a transmission substation near the station. The connection is essentially a double one, since it is made through both the 230-kV and 500-kV transmission systems.

Electrical energy generated by Unit 1 at 22 kV is raised to 230 kV by the main transformer and delivered to the 230-kV switchyard. Electrical energy generated by Unit 2 at 22 kV is raised to 500 kV by the main transformer and delivered to the 500-kV switchyard by way of a motor operated air breaker (MOAB) and isolation breakers. The MOAB is located between the Unit 2 main transformer and the generator isolation breakers and permits the isolation breakers to be closed while Unit 2 is off the line. Reclosing the isolation breakers while Unit 2 is off-line is important for ensuring proper voltage levels are maintained offsite and hence grid stability. The MOAB is manually operated from the switchyard and is not designed to be operated under load. Control interlocks prevent the MOAB from being operated unless the isolation breakers are open. Figure 8.3-1 and Reference Drawing 1 are single-line diagrams of the transmission substation for the Surry Power Station.

The main generator feeds electrical power at 22 kV through an isolated-phase bus to the main step-up single-phase transformers and the unit station service transformers located adjacent to the turbine building. The primary side of each 22/4.16-kV station service transformer is connected to the unit isolated-phase bus at a point between the generator terminals and the low-voltage connection of the main step-up transformers. There are three station service transformers per unit. They supply three independent 4160V auxiliary buses and are designed to limit the short-circuit fault duty on any one bus to within the interrupting capability of the 250-MVA air circuit breakers.

During start-up and emergencies, reserve station service power for the auxiliaries of either unit is normally supplied from the Switchyard Transformers No. 1 (which is a 500/36.5-kV transformer that is connected to the 500-kV bus), No. 2, (which is a 230/36.5-kV transformer that is connected to the 230-kV bus #4), or No. 4 (which is a 230/36.5-kV transformer that is connected to the 230-kV bus #3). The 500-kV and 230-kV systems are independent and provide alternative sources of reserve power that can be expanded for future units and lines as required. Each Switchyard Transformer is capable to provide power to an Emergency Bus on each Unit.

The primary sides of the reserve station service transformers are connected to the 36.5-kV windings of either of Transformers Nos. 1, 2 or 4 in the high-voltage switchyard. During start-up, shutdown, or hot standby conditions, station service power is taken from the reserve station service transformers. The screenwell area is supplied through either of two 34.4-kV to 4.16-kV transformers, each of which is supplied from 34.5-kV Buses 5, 6, or 7 in the switchyard. Underground lines are installed to feed each screenwell transformer.

The 230-kV and 500-kV switchyards are of the “breaker and a half” design.

The normal operating ranges are from 220 to 245 kV for the 230-kV switchyard and 505 to 535 kV for the 500-kV switchyard. The emergency buses are serviced by transformers with automatic tap changers that ensure nearly constant load voltages during long-term grid voltage transients. The normal operating range on the emergency buses is 4200 to 4400V.

Two gas turbines are installed at the Surry site east of the 230-kV substation. One unit is rated at 16 MW and the other at 25 MW. These units are a part of the Vepco system and are primarily used for load peaking. One gas turbine has a black start capability with a start-up time of approximately 10 minutes. These two units are controlled and operated locally at the switchyard. The two generators are connected in parallel to the low-voltage side of a 13.2/230-kV transformer. Each generator has a breaker that is used for synchronizing and tripping. The high-voltage side of the transformer is connected to the No. 4 230-kV bus. Four additional combustion turbines rated at 82 MW each are located southeast of the switchyard. These units are controlled and operated independently of Surry Power Station, but their generators are connected to the transmission system via the 230-kV switchyard as shown in Figure 8.3-1 and Reference Drawing 1.

Transmission system connections for Unit 1 consist of the following lines, which are integral parts of the Vepco transmission system:

1. One 230-kV line to the Yadkin substation near Portsmouth, Virginia.
2. One 230-kV line to the Wards Creek substation in Disputanta, Virginia.
3. One 230-kV line to the Chuckatuck substation in Suffolk, Virginia.
4. One 230-kV line to the Churchland substation in Portsmouth, Virginia.
5. One 230-kV line to the Winchester substation in Hampton, Virginia.
6. Two 230-kV lines to the Gravel Neck Combustion Turbines, which are located near Surry Power Station.
7. One 230-kV line to the Colonial Trail substation in Surry, Virginia.

Additional transmission system connections for Unit 2 consist of:

1. One 500-kV line to the Septa substation near Surry, Virginia.
2. One 500-kV line to the Chickahominy substation in Providence Forge, Virginia.
3. One 500-kV line to the Suffolk substation near Portsmouth, Virginia.
4. One 500-kV line to the Skiffe’s Creek substation near Williamsburg, Virginia

Surry Power Station lies along two main transmission line rights-of-way. Each right-of-way includes transmission lines that principally route toward east and west locations in the Vepco system.

The transmission system can handle the full output of both units at Surry upon the loss of any two transmission circuits connected to the Surry substation. Figure 8.3-2 is a location map showing the Surry Power Station, associated transmission lines, and their system connections.

8.3 REFERENCE DRAWINGS

8.4 STATION SERVICE SYSTEMS

8.4.1 4160V System

Alternating current station service power is distributed from the 4160V switchgear. This switchgear is energized from the main generator and unit station service transformers during normal operation, or from the reserve station service transformer source during start-up, hot standby, or shutdown operation (Section 8.2). The 4160V system is duplicated for Unit 2.

The 4160V switchgear is arranged in three independent bus sections. Each bus section has a capacity of about 3000A. Each feeder or motor circuit is protected by overcurrent relays that trip the associated breaker for a sustained overload of a sufficient magnitude or a fault.

During unit start-up, the total ac demand of the unit is supplied from the reserve station service source. After the unit has attained operating conditions and the turbine generator is synchronized and connected to the system, the station service load is transferred to the unit station service transformers. This transfer is performed without a power interruption by momentarily feeding the 4160V switchgear from both the reserve and unit station service transformers. The feeds from the reserve station service transformers are then disconnected and the turbine generator will supply its own auxiliaries.

To include the possibility of two-unit simultaneous loading of the reserve station service (RSS) system, within its design capability, a load shedding system was installed to remove the overloads on the RSS system. This system provides for automatic load shedding of selected non-safety-related loads from both units which limits RSST loading to under 4000A per transformer. The scheme ensures that the voltages available on the emergency buses will be within acceptable limits. A manual override switch is provided in the control room to allow manual restarting of the shed loads under a controlled condition. With the addition of bus cooling, the transfer bus feeder breakers and adjacent bus cubicles (15D1, 15D2, 15E1, 15E2, 15F1, 15F2) are rated for 4000A continuously.

To improve the worst case voltage profiles due to large blocks of load receiving simultaneous starting signals under safety injection (SI) conditions and ensure the successful starting of safety-related loads, modifications to the secondary automatic load tap changers (ALTCs) on the reserve station service transformers (RSSTs), and automatic starting of selected large non-Class 1E loads were made. The modifications included:

1. Upon receipt of an SI signal or two unit load shed signal, the adjustable time delay of the RSST ALTC mechanisms will be bypassed. Under normal conditions the ALTCs are designed for a delay of approximately 30 seconds before the tap changing mechanisms react to a voltage change. The result in bypassing this feature is to enable the ALTC to react as quickly as possible to adjust the secondary RSST voltage to the preset level.

2. The automatic starting of selected large non-Class 1E loads is blocked. These loads that are prevented from auto starting are the condensate, bearing cooling, and component cooling pump motors. The auto-start block will remain in effect for 60 seconds following an SI signal and 315 seconds following a Consequence Limiting Safeguards (CLS) signal. This feature will prevent any voltage degradation of the emergency buses as a result of starting of non-Class 1E loads. These motors may be manually started, however, independent of the auto-start block.

Loss of normal supply to any bus section automatically trips the normal source breaker and closes the alternate source breaker.

Motors larger than approximately 300 hp are operated at 4160V and are arranged for across-the-line starting. One circuit from each bus section feeds two 4160/480V station service transformers. The 480V system is described in Section 8.4.2.

Two independent sections of emergency 4160V bus and switchgear are provided. Each section is sized to carry 100% of the emergency load. These emergency sections are energized from the reserve station service transformer during normal operation, start-up, and shutdown. In the event of total loss of offsite power, the emergency 4160V buses are isolated from the normal supply and energized from the diesel generators, as described in Section 8.5.

A manually operated air circuit breaker location is provided so that a 4160V emergency bus section may be connected to the redundant emergency bus section. This feature is used for maintenance or abnormal conditions only, and is under administrative control. The breaker will be tagged in the disconnect position for an operating unit.

8.4.2 480V System

The 480V ac station service system distributes and controls power for all 480V, 240V, and 120V ac station service demands. The source of power for the 480V ac system buses is from the counterpart 4160V ac system buses. The 480V ac system is divided into three double-ended bus sections, and each section is fed from a counterpart 4160V ac bus through individual 4160/480V ac station service transformers. This system is shown in Figure 8.3-1.

The switchgear is metal-clad, with 125V dc operated air circuit breakers, and arranged with six independent bus sections. The 4160/480V transformers are air-cooled.

Normal operation is with the bus sections independent of each other. Motors up to approximately 300 hp are connected to the 480V switchgear. Reduced unit output is possible with two 480V bus sections out of service.

Motor control centers are located throughout the station and are used for 480V power distribution and control of motors rated at 100 hp or less. In most cases, motor control centers are fed from 480V switchgear buses through breakers, while in some instances, motor control centers dedicated to a specific system are fed from other motor control centers via breakers due to physical space constraints and power supply requirements.

Engineered safeguards equipment items operating at 480V are fed from independent 480V buses and switchgear that are energized from either the reserve station service power or the diesel generators. When 480V emergency power sources are connected in a manner which would provide the capability of manually transferring loads from one source to a second source, isolation breakers are used upstream of the transfer switch to ensure that a single failure will not affect both power sources.

8.4.3 120V Alternating Current Vital Bus System

There are four separate 120V ac vital buses, each supplied by an independent 15 kVA inverter power supply. The inverter is housed within an electrical cabinet, which also contains a rectifier/charger, a static transfer switch, a manual bypass switch, and a voltage regulating line conditioner (RLC). This configuration is shown in Reference Drawing 1. The inverters are supplied in pairs by a common station battery. Each inverter pair and one battery form a safety train of uninterruptible power. There are two station batteries and inverter pairs per nuclear unit at Surry, which provide two independent redundant uninterruptible power supply (UPS) electrical trains. Normally, the inverter load is absorbed by the UPS rectifier/charger.

Upon rectifier/charger failure, the battery will pick up the inverter load. The UPS outputs are regulated automatically to a nominal 120V ac and 60 Hz. Upon inverter failure, the static switch will transfer the vital bus load to the RLC alternate source (120V ac, nominal) within 1/4 cycle.

The vital buses constitute a very reliable electrical system and provide a stable source of power to vital instruments and equipment. The redundant batteries are classified as passive components and are therefore subject to passive type failures. The definition of a passive failure is a failure which will not occur until after accident mitigation has entered the recirculation phase (post-RMT). Thus should a LOOP/LOCA occur, then the loss of a battery or dc bus will not credibly occur until after the unit enters the recirculation phase. For circuits that have been designed as energize to operate, analyses have been performed to ensure they meet the requirements for active component failure.

Each remote monitoring panel shares certain instrumentation from both units with the instrumentation from one unit being powered by the emergency power system of the other unit when vital buses are not available due to a disabling fire in the control room. This assures that indications of the selected parameters will be available for both units even if the fire disables the emergency power system of the affected unit. See Section 7.7.2 for additional discussion of this capability which was incorporated to satisfy the requirements of 10 CFR 50 Appendix R. In the event of a complete loss of ac power, a portable generator can be used to feed the Remote Monitoring Panels.

Should an Extended Loss of AC Power (ELAP) occur to both Units, backup power to both Remote Monitoring Panels is available for 12 hours via UPS. This ensures continuous monitoring capability is available until a portable generator can be deployed.

A modification to the vital bus voltage indication was accomplished to prevent a false indication of the loss of vital bus voltage. This could occur if the breaker used for the indication were inadvertently left open when the bus was energized. The modification provides for direct tapping of the vital bus via a 6A in-line fuse in lieu of the breaker.

The 120V, 60-Hz output of each UPS inverter is grounded and connected to two distribution cabinets. The distribution cabinets have 15A and 20A branch circuit breakers to feed reactor protection and other vital instrument channels. Reactor protective schemes have redundant channels and the power sources are provided from redundant vital bus cabinets.

Because of the fail-safe circuitry of the reactor protective instrumentation, a power source failure to an instrument channel results in a reactor trip signal from the affected channel. Multiple power supplies are provided to prevent a common power supply failure from initiating a false reactor trip.

The UPS are assembled from high-quality components, conservatively designed for long life and continuous operation. By avoiding the use of electromechanical devices, routine maintenance downtime is greatly reduced. There are no vacuum tubes or moving parts in the completely static vital bus supply system. Magnetic amplifiers, transistors, and silicon rectifiers are used to provide trouble-free operation.

8.4.4 125V Direct Current System

The Class 1E 125V dc batteries supply power for operation of switchgear, annunciators, vital bus inverters, and emergency lighting, as shown in Reference Drawing 2. The 1A battery provides 1 of 2 concurrent feeds to the Unit 1 main control room Hathaway annunciator. (The other concurrent feed is 120V ac from emergency diesel generator backed control room lighting panelboard 01-EP-LP-1C1.) The 2A battery provides 1 of 2 concurrent feeds to the Unit 2 main control room Hathaway annunciator. (The other concurrent feed is 120V ac from emergency diesel generator backed control room lighting panelboard 02-EP-LP-2C1.) The principal equipment items in this system are two nominal 125V dc lead-acid batteries, two UPS rectifier/charger, and two battery distribution switchboards.

The turbine generator emergency auxiliary oil pumps are connected to an independent black 60-cell battery powered from two static battery chargers supplied from normal motor control centers. Additionally, the normal power feed to the AMSAC inverter is from the same bus. The backup power feed to the AMSAC inverter is provided from a normal motor control center or an emergency motor control center via a transfer switch. This system is shown in Figure 8.4-1.

The batteries are of the central power station type and are designed for continuous duty. Each battery consists of a number of cells connected in series comprising a nominal 125V dc.

Each cell is of the sealed type, assembled in a shock-absorbing, clear plastic container, with covers bonded in place to form a leakproof seal. The batteries are mounted on protected, corrosion-resistant, earthquake-resistant racks for security and to facilitate maintenance. The two Class 1E battery areas are separated from each other and from the switchgear room.

Normally, the two battery bus sections are operated independently, with the bus tie breakers open. The UPS rectifier/chargers supply power for operation of equipment connected to that bus section and maintain a floating charge on the associated battery. The manually operated bus tie breakers provide for parallel operation of the bus sections with either battery out of service for maintenance.

The four UPS static battery rectifier/chargers (two per 125V-dc bus) are identical, each having an output of 350A at 130V dc with an input of 480V ac, three-phase. Each UPS rectifier/charger is equipped with a dc voltmeter, ammeter, ac failure relay, and low dc voltage alarm relay. Low ac or low dc voltage is alarmed in the control room. Battery bus ground indicators are located in the control room. Battery voltage is indicated to the operator on the main control board and continuously recorded on recorders located in the Emergency Switchgear Room. The UPSs are energized from emergency motor control centers.

The battery distribution switchboards are NEMA Class II metal-clad structures, each with a 125V dc, two-wire ungrounded main bus, and two-pole manually operated air circuit breakers.

During normal operation, the 125V dc load is fed from the battery chargers with the batteries floating on the systems. Upon loss of station ac power, the entire direct current load is drawn from the batteries. The batteries are sized for two hours of operation, after which it is assumed that station power or emergency generation power will be available to energize the battery chargers. The basis for sizing the station batteries for two hours without benefit of any station power is a carryover from the criteria used on non-nuclear power stations where emergency generators were not available to provide power to the battery chargers or turbine auxiliaries for safe coastdown. The batteries will be required for approximately 10 seconds between loss of station power and the availability of emergency ac power to supply the Class 1E battery chargers.

For each unit, a separate non-Class 1E battery, battery charger, and distribution switchboard are available for use in the screenwell structure.

8.4.5 Lighting System

Normal lighting for turbine areas, reactor containments, auxiliary building, fuel building, and service buildings is provided from local lighting cabinets located in the area of service. These cabinets except those for the control room, are fed from a double-ended lighting switchboard that is energized from two independent 250-kVA, single-phase, 4160-240/120V dry type, self-ventilated transformers. Normally the two buses of the double-ended switchboard are separate. They are capable of being tied together if one transformer fails.

The two control room lighting cabinets are each fed from local 37.5-kVA, single-phase 480-240/120V, dry type, self-ventilated transformers. The Unit 1 control room lighting transformer is supplied from the 480V 1H1-1 (Unit 1) bus and the Unit 2 control room lighting transformer is supplied from the 480V 2H1-1 (Unit 2) bus. The 1H1-1 and 2H1-1 emergency motor control centers are backed by different emergency diesel generators. Control room lighting cabinet (panelboard) 01-EP-LP-1C1 also provides 1 of 2 concurrent feeds to the Unit 1 main control room Hathaway annunciator. (The other concurrent feed is 125V dc from the Class 1E, 1A battery.) Control room lighting cabinet (panelboard) 02-EP-LP-2C1 also provides 1 of 2 concurrent feeds to the Unit 2 main control room Hathaway annunciator. (The other concurrent feed is 125V dc from the Class 1E, 2A battery.)

Normal lighting for the office building and remote areas is supplied through local 480-120/240V, single-phase, dry type transformers. Emergency lighting for remote areas is provided by local self-contained, battery-powered emergency lighting units.

Emergency lighting for turbine areas, auxiliary building, service buildings and various other locations is normally de-energized. These lights are automatically switched to the dc system upon sensing loss of voltage on the lighting switchboard. Emergency lighting for the reactor containment is energized at all times from an independent dc circuit. The turbine room operating floor also has an independent feed from the battery and automatically comes on if lighting intensity falls below certain levels. Emergency lighting feeds are provided from both units to the control room and turbine room mezzanine to provide the best possible protection.

Additional individually battery-powered emergency lanterns have been installed to facilitate access to and egress from the control room, emergency switchgear and relay rooms, service building cable vaults, cable tunnels, turbine building areas, mechanical equipment room no. 5, containment penetration cable vaults, diesel-generator rooms, first aid room and electric shop. These fixtures are automatically energized upon loss of normal ac bus power. They are powered from self-contained 6V or 12V batteries and static battery chargers, and use directionally adjustable lamps. The light fixtures are designed for eight hours.

Emergency lighting for the Technical Support Center (TSC) automatically transfers to the uninterruptible power supply (UPS) upon detection of the loss of the normal power source. Emergency lighting provides illumination for at least 15 minutes upon transfer to the TSCs UPS which will allow for an orderly shutdown of the Emergency Response Facility Data Acquisition System and exiting the area. The duration of emergency lighting for the TSC can be extended by manual transfer of the backup feed for the TSC UPS to the AAC diesel generator.

A post-fire emergency lighting system has been installed to facilitate operation and/or monitoring of safe shutdown equipment after a postulated fire in any area and access/egress routes thereto. This lighting system incorporates the use of the emergency diesel backed control room lighting system, diesel backed security lighting, self-contained 6V or 12V batteries and static charger units and emergency power units (consisting of self contained batteries, static charger and inverter) all located in the area served. Additionally, portable battery-powered lanterns are available for use in containment. This post-fire emergency lighting system will provide sufficient illumination for a minimum of eight hours to enable an operator to reach the safe shutdown equipment and perform required functions. Added equipment is seismically mounted in areas with safety related equipment and added cables are environmentally qualified in accordance with IEEE 323-1974.

8.4.6 Alternate AC (AAC) System

In response to 10 CFR 50.63, the Alternate AC (AAC) system was installed to provide ac power to one emergency bus on each unit during a Station Blackout (SBO) event. The AAC system is non-safety related and is designed in accordance with Regulatory Guide 1.155 and NUMARC 87-00, Appendix B.2.

The electrical design consists of a single 4160V ac diesel driven generator with a continuous rating of 3300 kW and a 2000-hour rating of 3640 kW. The generator is connected to the station via 4 kV buses 0M and 0L as shown in Reference Drawing 1. Bus 0L is located in the Unit 2 normal switchgear room and provides connection from bus 0M to transfer buses D and E which in turn allows connection to emergency buses 1J and 2H respectively. The diesel generator can provide power to the emergency buses within 10 minutes of determining that an SBO event has occurred and is sized to carry the loads necessary to bring both units to a safe shutdown condition and maintain them in a safe shutdown condition for the postulated 4 hour SBO event duration.

Following the loss of power on either the D or E transfer bus in conjunction with the loss of power on the F transfer bus, the diesel generator receives an automatic start signal. Momentary trip signals to breakers associated with the 0M and 0L buses ensure that the AAC system is initially isolated. Once the generator has reached proper speed and voltage, breakers automatically close to power buses 0M and 0L. Manual action is then required to energize transfer buses D or E. The normal power supply to the TSC UPS and the TSC MCC is from the Unit 2 “C” station service transformer or from RSST “C” via Transfer bus “F.” Following a loss of normal power supply, the TSC UPS and the TSC MCC can be powered from the AAC System via either transfer bus D or E following manual breaker re-alignment.

The AAC diesel generator is independent from the emergency diesel generators. The AAC diesel generator and its auxiliaries are housed in a separate building located south of the Radwaste Facility. The air start system contains sufficient capacity for 5 starts and the fuel oil system for the AAC diesel contains sufficient fuel to operate the diesel generator at 3640 kW for the postulated 4-hour SBO duration. To maintain the system in a standby state, a keep warm system consisting of a jacket water heater with a circulating pump and a lube oil heater with a circulating pump is provided. An ungrounded 125V dc system is provided for the 4 kV and 480V ac switchgear controls, diesel generator controls, and generator protection.

Annunciation is provided in the main control room to alert operators to alarm conditions. An “AAC System Trouble” alarm indicates that a malfunction or system protective action has occurred. An “AAC Diesel Generator Trip” alarm indicates that the diesel generator has tripped due to an engine or generator protective action. An “RSST A Parallel with RSST B” alarm indicates that the two RSSTs have been paralleled through Bus 0L. A “Bus 0L Trouble” alarm indicates that a protective relay actuation or a blown fuse alarm has occurred on this bus. In addition, a local annunciator in the AAC building provides additional details on alarm conditions.

Intentionally Blank

8.5 EMERGENCY POWER SYSTEM

The electrical power distribution system for the Surry Power Station provides duplicate systems for emergency components. Each system is continuously energized from the external system grid or from onsite diesel generators. The system is designed such that should a loss of offsite power (LOOP) occur, the onsite diesel generators will power the emergency power system. A loss of offsite power is defined as a loss of offsite power to both units (see Section 9.9).

Each unit has two 4160V emergency buses to supply safety-related auxiliary loads. These buses are normally supplied from the reserve station service transformers, as described in Section 8.3. The reserve station service transformers have automatic tap changers, which ensure nearly constant load voltages during long-term grid voltage transients. Tap changing is activated by any excursion in the reserve station service transformer output voltage, outside of the load tap changer setpoint range, that lasts for greater than 30 seconds. Upon activation, the load tap changer can step, approximately once every 2 seconds for up to 16 steps from neutral, in either the increase or decrease direction to restore transformer output voltage. The change increments average 0.625% of the neutral tap voltage per step. Emergency bus loads are designed to operate within ±10% of rated voltage, and the automatic tap changer configuration maintains emergency bus voltage within this range.

The circuits that supply power to the emergency buses through switchyard Transformers Nos. 1, 2, and 4 are known as “primary sources.” Each primary source is capable to provide power to an Emergency Bus on each Unit.

In addition to the “primary sources,” each unit has an additional offsite power source, which is called the “dependable alternate source.” This source can be made available in eight hours by removing a unit from service, disconnecting its main generator from the isolated phase bus, and feeding offsite power through the main step-up transformer and normal station service transformers to the emergency buses.

In the event of a complete loss of ac power and no emergency diesels, only dc power from the batteries is available. The only equipment operable would be the steam-driven auxiliary feedwater pump for maintaining makeup to the steam generator, and core heat removal, and the instrumentation supplied by the four vital buses whose power is supplied by the dc/ac inverters. There would be a dc lube-oil pump oil supply to the main turbine and the seal-oil pump oil supply to the main turbine and seal of the system for the main generator. Only natural circulation of reactor coolant would be possible, and makeup to the primary would require restoration of power to the ac emergency buses. The procedures used for station blackout and restoration of transmission systems are considered adequate to cope with the postulated event.

As a backup power source for the emergency buses, an onsite, independent, automatically starting emergency power system is provided. It supplies power to vital auxiliaries if a normal power source is not available and consists of three diesel generators for the two units. The Unit 1 diesel generator and the Unit 2 diesel generator are dedicated to emergency buses 1H and 2H, respectively. A third diesel generator is provided as a “swing diesel” and is shared by Units 1 and 2. Each diesel generator has 100% capacity and is connected to independent 4160V emergency buses. The third diesel is configured to preferentially load to the Unit 2 4160V bus (J Bus) with a loss of offsite power without a SI. If a unit experiences an SI signal that unit’s J Bus will be energized by the third diesel. The Unit 1 and Unit 2 diesel generators also supply power for certain common or shared plant systems/components, such as the Auxiliary Feedwater System pumps and cross connect valves, the Main Control Room and Emergency Switchgear Room (MCR/ESGR) Air Conditioning System chillers and air handling units, MCR/ESGR Emergency Ventilation System fans, Auxiliary Building Ventilation System fans, and the Containment Hydrogen Analyzers.

Each emergency bus provides power to the following operating engineered safeguards equipment:

1. One containment spray pump.
2. One charging pump (high-head safety injection pump). Two charging pumps on ‘H’ Bus (only when normal offsite power is available).
3. One low-head safety injection pump.
4. One recirculation spray pump inside containment.
5. One recirculation spray pump outside containment.
6. One motor control center for valves, instruments, control air compressor, fuel-oil pumps, etc.
7. Control area air-conditioning equipment—two air recirculating units, one water chilling unit, one service water pump, and one chilled water circulating pump.
8. One charging pump service water pump for charging pump intermediate seal coolers and lube-oil coolers.
9. One motor-driven auxiliary feedwater pump.

Safeguards equipment items are duplicated and connected to separate emergency buses. In the event of an equipment failure on one emergency bus coincident with a diesel-generator failure on the other bus, it is possible to connect both electrical buses to one generator so that the equipment normally powered from one diesel generator could be powered from another diesel generator if required. The emergency connection would be made under strict administrative control by manual operation of the bus tie breaker. If the loss of normal power is not accompanied by a loss-of-coolant accident, the safeguards equipment is not required. Under this condition, other plant auxiliary equipment, such as a component cooling pump, residual heat removal pump, etc., may be operated manually up to the capacity of the emergency generators. Instrumentation is provided to indicate diesel-generator loading.

If any safeguard equipment fails to operate automatically, manual operation is possible from the control room or at the switchgear. The switchgear for each diesel generator is physically and electrically isolated from the switchgear for the other diesel generators.

Three of five water chilling units (chillers) and the associated auxiliaries in the main control room and emergency switchgear and relay room air conditioning system are capable of being powered from either one of two emergency buses. In addition to providing operational and maintenance flexibility, this manual transfer capability ensures 100% air-conditioning capacity with any credible single failure.

It should be noted that one charging pump motor can be connected to either emergency bus. If an operator selects emergency bus H to energize the swing motor, he locks out the alternate circuit breaker connection to emergency bus J by means of a control switch on the main control board. In addition, a breaker mechanism interlock is provided to block closing of the alternate feeder breaker, when the selected breaker is closed.

Each diesel generator is reliable in operation. This reliability is achieved by use of duplicate or independent components or subsystems as follows:

1. Fuel system - Duplicate fuel systems with independent fuel and transfer pumps, strainers, and filters are provided.
2. Air supply starting system - Duplicate air starting systems with independent compressor, valves, and accumulators are provided.
3. Control storage battery - Each unit has its own independent control storage battery.
4. Control equipment - Each unit has individual control panels, metering, regulation, and excitation equipment.

Each diesel generator is provided with two starting subsystems. Each subsystem is sized for two engine starts without outside power. During automatic starts, both subsystems are activated to start the diesel generator. Each engine also has an independent day tank (combined base tank and auxiliary wall tank) with capacity for at least one hour of full-load operation. The auxiliary wall tanks are filled by transferring fuel from either one of two buried, tornado-missile-protected fuel-oil storage tanks, each having a 20,000-gallon capacity. Two 100%-capacity fuel-oil transfer pumps are provided for each diesel generator and are powered from the emergency buses to ensure that an operating diesel generator has a continuous supply of fuel. The buried fuel-oil storage tanks contain a 7-day supply of fuel (35,000-gallon minimum) for the full-load operation of one diesel generator. In addition, there is a 210,000-gallon above-ground fuel-oil storage tank onsite that is used for transferring fuel to the buried tanks. Provisions are in place to permit inspection and related repair of a buried fuel-oil storage tank during plant operation. While one buried tank is out of service, the verification of onsite and offsite fuel-oil sources is required to ensure an adequate supply of fuel-oil remains available.

The diesel engine starting circuitry accepts the following signals:

1. Undervoltage/degraded voltage or open phase condition on emergency bus.
2. Safety injection signal.
3. High-High consequences limiting safeguards.
4. Manual.

Conditions that render the diesel generator incapable of responding to an automatic emergency start signal are:

1. Diesel-generator output differential current fault.
2. Diesel-generator output overcurrent fault.
3. No diesel-generator field.
4. Overspeed.

(The above four conditions must be reset prior to any start.)

5. Manual stop from local or remote locations.
6. Control room switch in “exercise” instead of “auto.”
7. Engine control cabinet (at the diesel) switch in “local start.”
8. Necessary circuit breakers in “off” position.
9. Low starting air pressure.
10. Less than required fuel inventory.
11. Low battery voltage.

Alarms and annunciators actuate in the control room and the local diesel-generator control panel when a fault condition associated with the diesel generator exists. An emergency diesel auto-start-disabled alarm is obtained in the control room whenever the local diesel control panel selector switch is in the “local start” position or when the “auto-exercise” switch on the remote control room panel is in the “exercise” position. If any of the other disabling conditions exist, an emergency generator trouble alarm will be received in the control room.

If required, the emergency buses can be powered from the onsite diesel generators. During accident conditions, each diesel generator set is sized to start and accept load in equal to or less than 10 seconds of the start signal. The starting load capacity is 12,500 kVA. The diesel generators have a cumulative 2000-hour rating of 2750 kW. The allowable EDG loading will not exceed these values. Engineering controls and incorporates load additions into worst-case voltage profiles and load calculations to ensure EDG ratings are not exceeded. The starting, accelerating, and loading times of the diesel generators using simulated loads were witnessed and checked before the units were accepted from the engine manufacturer. The continued ability to accept load is tested as described in Section 8.6.

The emergency buses are protected from either a degraded voltage, a loss-of-voltage, or an open phase condition. The voltage of each bus is monitored on each phase with separate single-phase loss-of-voltage relays, two parallel three-phase degraded voltage relays, and three three-phase open phase relays. Each separate set of relays will provide the input to a coincident two-out-of-three logic scheme. The setpoints (setting limits) for these three protection schemes are provided in the Technical Specifications. The system operation is described below:

- Under degraded voltage conditions (nominally, below 92.7% of rated voltage), the two-out-of-three logic scheme will initiate an alarm in the control room at 10 seconds, start the diesel generators at 50 seconds, and initiate the transfer of the Class 1E emergency buses from the offsite source to the diesel generators at 60 seconds. If a safety-injection or consequence-limiting safeguards signal is concurrent with the degraded voltage, the 10-, 50-, and 60-second time delays are effectively bypassed. The diesel generator is started upon receipt of the safety injection or consequence-limiting safeguards signal and, following the degraded voltage signal 7-second delay, the transfer from offsite to onsite power is initiated. Upon transfer initiation with a safety injection or consequence-limiting safeguards condition, the offsite source feeder breakers to the Class 1E buses, the stub bus tie breaker, the residual heat removal pumps, the component cooling pumps, and one of the two “H” Bus charging pumps are automatically tripped.

- On a loss-of-voltage condition (nominally, below 75% of rated voltage), the separate relays will trip and, after a time delay, initiate an automatic transfer of the Class 1E emergency buses from the offsite source to the diesel generator. The time delay for this first level (loss-of-voltage) protection is nominally 2 seconds. Both this time delay and the nominal 7-second time delay for second level (degraded voltage) conditions, discussed above, meet NRC staff positions on undervoltage protection allowable time delays, in that they will allow for system voltage transients while ensuring that the diesel generator energizes the emergency bus within 10 seconds of the loss-of-voltage signal (assumed in the accident analysis), and they will not cause the failure of any equipment attached to, and associated with, the Class 1E power system.

- For an open phase condition (nominally, above 6% negative sequence voltage), the two-out-of-three logic scheme will energize an Undervoltage Protection auxiliary relay for the associated bus which starts the EDG and transfers following the same process as the Undervoltage/Degraded voltage protection scheme. The open phase condition negative sequence voltage relays include an inverse time characteristic which introduces a trip time delay based on the magnitude of negative sequence voltage sensed. A time dial setting of 10 is used for the open phase of less than 5 seconds for any open phase condition sensed at an emergency bus.

For degraded voltage, loss-of-voltage, and open phase conditions, once the diesel generator reaches the necessary voltage and speed (95 ±2% of nominal bus voltage and 870 ±20 rpm, respectively) and the 2.2-second residual voltage time delay is satisfied, the diesel generator output breaker will close. The time delay relay is actuated when the normal feeder breaker opens. This time delay, based upon analysis, is sufficient to permit residual bus voltages to dissipate to allowable levels and prevents equipment damage that could be caused by an out-of-phase transfer. Upon closing of the output breaker, the loss-of-voltage and under-voltage protection schemes are automatically bypassed so that automatic bus unloading will not occur. However, should the diesel-generator breaker(s) open, both protection schemes are automatically reinstated. The open phase protection scheme is blocked when the normal supply breaker is open.

Safety-injection and consequence-limiting safeguards conditions impact loading on the diesel generator. For a safety injection condition, the charging pump and low-head safety injection pump receive immediate starting signals. At 50 seconds after the safety injection, the steam generator auxiliary feedwater pumps are started. At approximately 90 seconds after the safety injection, the filter exhaust fans are started for a consequence-limiting safeguards condition, the charging pump, low head safety injection pump plus the containment spray pumps receive immediate start signals. In addition to the delayed starting of the steam generator auxiliary feedwater pumps, the filtered exhaust fans start at 90 seconds, the inside recirculation spray pumps start at 120 seconds and the outside recirculation spray pumps start at 300 seconds. On a loss of offsite power or open phase event, the emergency diesel generator load sequencing scheme is initiated to ensure that previously running loads are re-energized without exceeding diesel generator operational ratings. This scheme will trip certain loads, if they have been running, and resequence them onto the emergency bus - provided that all other breaker closure permissives are satisfied.

For running loads, the load sequencing scheme is independent of safety injection or consequence-limiting safeguards logic for the affected loads and, therefore, could be concurrent. The affected loads and their resequence times after EDG breaker closure upon LOOP are listed below.

1. Outside recirculation spray pumps are resequenced after 10 seconds.
2. Inside recirculation spray pumps are resequenced after 20 seconds.
3. Filter Exhaust Fans (1-VS-F-58A & B) are resequenced after 30 seconds.
4. Pressurizer Heaters are resequenced after 180 seconds.
5. Auxiliary feedwater pumps are resequenced after 10 seconds with only an SI signal present and after 140 seconds with hi-hi CLS signal present.

The design basis accident analysis discussed in Chapters 5 and 14 considers a loss of coolant accident (LOCA) to occur coincident with a loss of offsite power (LOOP). It is not necessary to evaluate potential impacts on the performance of other systems resulting from a

LOOP subsequent to a LOCA because that scenario is not part of the Surry licensing basis. NRC Information Notice 85-91, *Load Sequencers for Emergency Diesel Generators*, identified a potential problem with the diesel loading sequence if a LOOP should occur subsequent to a LOCA. Virginia Power evaluated this situation with respect to emergency diesel generator loading even though the Surry licensing basis considers the LOOP to occur coincident with the LOCA. The evaluation identified that, after implementation of appropriate modifications to emergency diesel sequencing logics, a LOOP subsequent to a LOCA would not result in overloading of the emergency diesel generators.

Voltage and frequency for the emergency diesel generators are automatically set. However, voltage and frequency can also be adjusted by the operator if outside of the procedural limits. Frequency is controlled to 59.67-60.33 Hz and voltage is controlled to 4000-4400 volts. These procedural limits have been used in hydraulic calculations for maximum horsepower and minimum and maximum flows that are used in the safety analyses.

The single failure of a dc system (e.g., station battery) can adversely affect the shedding of loads and opening of supply breakers in one emergency power system train. However, because of the redundant trains and the diverse dc supplies to the supply breakers, the system design would not be impacted to such an extent that adequate diesel generator operation could be prevented.

The degraded voltage setpoints were chosen to preclude inadvertent load shedding during transient undervoltage conditions that could potentially occur when large loads are started.

The emergency bus is protected (nominally, between 75% and 92.7% of rated voltage) from a degraded voltage condition after a 60-second time delay. However, safety-grade motors were purchased or analyzed to start at 70% of rated voltage (72% for LHSI pump motors 1-SI-P-1A and 2-SI-P-1A and 2-SI-P-1B); thus, the motors will all start and accelerate through the range of degraded voltage.

General Electric SAM timers have been added in the trip circuit of transfer breakers 15D1, 15El, and 15Fl. The timers provide a time-delay trip of 300 milliseconds if the normal feeder breakers to the emergency breakers do not trip. If they do trip, the timers are dropped out of the delay circuit allowing 15D1, 15E1 or 15FI to remain closed. This prevents a loss of power to transfer bus D, E or F due to an under-voltage condition that might exist on emergency bus 1J, 2H or either 1H or 2J, respectively.

Another level of undervoltage protection exists on the 4 kV transfer buses D, E and F. This protection system has a voltage setpoint greater than or equal to 46.7% of nominal voltage. Actuation of the relays will automatically start the auxiliary feedwater pump and align appropriate motor-operated valves under consequence-limiting safeguards.

An additional open phase detection system exists on Switchyard Transformer No. 1. This detection system monitors open phase events on the primary side of that transformer which may not be detected by the negative sequence voltage relays at the 4kV emergency buses. Actuation of this detection system will annunciate a trouble alarm in the main control room. Operators will diagnose and investigate the event.

Control circuits for safety-related loads are designed so that a degraded voltage will not adversely affect operation. All safety-related loads are operated either by circuit breakers or by motor controllers. The circuit breakers are supplied with 125V dc control power, which comes from the station battery bus. The 125V dc control power is supplied via fuses in the individual breakers. The original fuses were replaced by smaller fuses to allow for electrical coordination with the breaker in the 125V dc distribution panel feeding the entire bus. This change was necessary to conform to the requirements of Appendix R to 10 CFR 50 and assures availability of power sources to safe shutdown equipment. (See Section 9.10.3.4 for additional information.) Therefore, operation of these breakers is independent of emergency bus voltage. The motor controllers are supplied with ac control power from an internal transformer, which steps down line voltage to 120V ac. Therefore, motor controller operation is dependent on line voltage. Safety-related motor controllers will operate satisfactorily with line voltage at values greater than the undervoltage setpoint for diesel-generator loading.

Each piece of vital equipment is connected to the auxiliary electrical power system with an exclusive circuit. Each circuit has an air circuit breaker overcurrent fault protection, and a control switch with red, amber, and green indicating lights mounted in the control room. The red lights show that the power circuit is available. The green light is lit when the power circuit is de-energized and monitors the availability of control power. Simultaneous lighting of the amber and green lights indicates an automatic trip of a feeder or source circuit. Major items have meters to indicate circuit current. Isolation of a failed circuit is automatic and is identified by the indicating lights in the control room. Automatic tripping functions also energize an audible signal to alert the control room operator. Individual protective relays have signal targets to indicate that automatic operation has taken place.

Original plant design included two 4160/480V load center transformers per unit, 1H and 1J and 2H and 2J. With the addition of the 1H1, 1J1, 2H1 and 2J1 transformers, studies were performed in 1979 for Unit 1 (Reference 1) and in 1980 got Unit 2 (Reference 2) to confirm the load capability of the 480V emergency power system and to verify the adequacy of voltage profiles on Class 1E buses during various modes of plant operation. (The 480V emergency power system is shown on Figure 8.3-1.)

In accordance with the NRC Generic Letter (Reference 3), dated August 8, 1979, entitled *Adequacy of Station Electrical Distribution System Voltages*, Vepco performed analyses to determine the adequacy of the Surry Power Station electrical distribution system. The review consisted of:

1. Analytically determining the capacity and capability of the offsite power system and onsite distribution system to automatically start as well as operate all required loads within their required voltage ratings in the event of: (1) an anticipated transient, or (2) an accident (such as a LOCA) without manual shedding of any electric loads.
2. Determining if there are any events or conditions which could result in the simultaneous or consequential loss of both required circuits from the offsite network to the onsite electrical distribution system and thus violate the requirement of General Design Criterion 17.

The criteria used in the technical evaluation of the analysis included General Design Criterion 5 (Sharing of Structures, Systems, and Components), General Design Criterion 13 (Instrumentation and Control), and General Design Criterion 17 (Electric Power System) of Appendix A to 10 CFR 50, IEEE Standard 308-1974, ANSI C84.1-1977 and the NRC staff positions and guidelines provided in the August 8, 1979, letter.

In Reference 4 it was concluded that the Surry Units 1 and 2 offsite power system and the onsite distribution system are capable of providing acceptable voltages for worst-case station electric load and grid voltages. Analysis results are included in Reference 5. Continued assurance that acceptable voltages are available is maintained using calculation(s) which are periodically updated.

The voltage level and current loading of all station distribution buses are displayed in the control room. The status of the switchyard breakers and the source of reserve station power are readily available to the operator. Indicating lights show the source of power to each bus. Alternate sources may be manually selected by the operator, but prearranged automatic transfer takes place on failure of the normal source. The following instruments are provided in the control room to monitor emergency bus voltage performance:

1. Battery voltage indication.
2. Battery ground indication.
3. Emergency bus voltage.
4. Emergency bus frequency.
5. Emergency bus undervoltage alarm.
6. Low battery voltage alarm.
7. Emergency bus overvoltage alarm.
8. Hi battery voltage alarm.
9. Emergency bus open phase condition alarm.

Routine control of normal and standby electrical power is from the control room. However, essential loads can also be controlled from the emergency switchgear located below the control room. The emergency switchgear is designed so that local operation is possible with or without control power.

Control switches on the main control board are clearly identified by system. Emergency switchgear and control centers are identified as control devices for essential components.

The diesel-generator panel contains instruments and controls to serve the emergency bus. Provisions for synchronizing the diesel generator manually with the reserve station service power systems are also provided. The generators are manually synchronized with the system and loaded for periodic load tests.

The diesel generators and associated equipment are located in a Class I and tornado-protected structure. Each generator and its associated equipment will withstand, without loss of function, either the design-basis earthquake or the atmospheric pressure drop associated with the design tornado.

Emergency switchgear is located in the shielded control area below the control room. Status of the emergency power bus can be determined at the emergency switchgear. Emergency distribution air circuit breakers can be manually operated at the switchgear (Section 7.7).

Switchgear associated with the electrical feeds to the emergency buses are enclosed in metal housings and protected from the weather.

Essential electrical components and circuits are located and distributed within protected zones. All cables, conductors, motors, pumps, control stations, etc., are identified by a mark number or by function. The markings consist of painted stencils or marked tags applied or attached to each component.

Lines, valves and equipment subject to freezing or crystallization of boron are electrically heat traced and insulated. The heat source is automatically energized when the temperature drops below preset limits. Therefore, icing or crystallization could not interfere with the or injection of coolant during accident conditions.

8.6 TESTS AND INSPECTIONS

All electrical equipment was specified for manufacture in strict accordance with the latest requirements of the National Electrical Manufacturers Association (NEMA), the Institute of Electrical and Electronic Engineers (IEEE), or the American National Standards Institute, Inc. (ANSI) standards, where applicable.

Electrical equipment was protected during shipment and was properly stored at the job site during construction.

The installation of all equipment was under the supervision of a qualified electrical construction engineer. Special attention was given to mechanical alignment and electrical ground connections. The dielectric of all insulation was measured and corrected if necessary before the equipment was energized.

The control power for operating major motor starters is supplied from the station batteries. These batteries are kept at a constant voltage, and they are monitored continuously for voltage variations or undesired ground connections.

Each major motor or other piece of electrical equipment is protected by overcurrent relays that will disconnect the device if fault current is present. The protective relays are set and calibrated by Vepco trained personnel.

The availability and proper action of standby equipment are checked periodically while the unit is in operation.

Testing of the automatic operation of the voltage transfer system at the 4160V level can be performed. Successful operation of the 4160V transfer scheme does not prevent a unit shutdown but is designed to provide station service power automatically when a main generator is out of service.

Each standby power system was installed and checked out several months before criticality. The initial installation was tested to verify the starting speed and loading ability before being accepted. After acceptance, the emergency power systems were operated on a routine test schedule. These routine operations for several months before criticality recognized the initial failure rate and were sufficient to achieve a proven and mature standby power system.

The diesel generators are essential parts of the engineered safeguards system. Starting, loading, and full-load operability of the diesel generators are tested in accordance with Technical Specifications. One method of conducting this test is to connect all operating safeguards equipment to an emergency bus that is not to be tested. The alternative emergency bus is then given a full operational test by opening its normal source breaker. The loss of voltage on the bus being tested automatically starts the emergency generator, closes the generator breaker, and re-energizes that emergency bus system. By placing the starters in either the operating or test position, individual components or systems may be checked completely or the test may be limited to the operation of the motor starters. During the testing of one emergency generator system, the alternative system is still available if required.

The Technical Specifications also include a refueling test requirement for simulating the loss of offsite power in conjunction with a safety injection actuating signal. To preclude a potential reactor coolant system pressurization transient, the breakers for the high-head and low-head safety injection pumps are placed in the test mode so that the pumps will not start. (The operability of these pumps is the subject of a separate monthly test.) This refueling test verifies diesel-generator starting and loading, as well as the starting of required loads.

During power operation, the station batteries and diesel-generator batteries are periodically checked in accordance with Technical Specifications to provide an indication of battery cells becoming unserviceable before they fail. An equalizing or overvoltage charge is applied to the batteries and is applied long enough to bring all cells up to an equal voltage. If these tests reveal a weak cell or a weakening trend in any cell, replacements are made as necessary. A disconnected battery or broken cell connector would be revealed during these equalizing charges. Periodically, the battery charger is disconnected and the ability of the battery to maintain voltage and assume the dc load is verified. This test will uncover any high-resistance connections or cell internal malfunctions.

During construction, checks and inspections were made to ensure that complete separation was maintained between vital equipment to ascertain redundant systems. The separation of the dc power supply system was verified before operation by performing functional checks on the two battery trains. Verification was provided by removing one battery train from service and operating the equipment on the other train. Checks were made to ascertain that the proper equipment was actuated. This procedure was followed for checking both dc battery trains.

CHAPTER 9 AUXILIARY AND EMERGENCY SYSTEMS

Note: As required by the Subsequent Renewed Operating Licenses for Surry Units 1 and 2, issued May 4, 2021, various systems, structures, and components discussed within this chapter are subject to aging management. The programs and activities necessary to manage the aging of these systems, structures, and components are discussed in Chapter 18.

9.1 CHEMICAL AND VOLUME CONTROL SYSTEM

The chemical and volume control system is used to:

1. Adjust the concentration of the chemical neutron absorber for chemical reactivity control.
2. Maintain the proper water inventory in the reactor coolant system.
3. Provide the required seal-water flow for the reactor coolant pump shaft seals.
4. Provide high-pressure flow to the safety injection system.
5. Provide for reactor coolant cleanup and degasification.
6. Maintain the proper concentration of corrosion-inhibiting chemicals in the reactor coolant.
7. Provide a means for filling the reactor coolant system.
8. Provide a means for draining the reactor coolant system to the primary drain system by means of the excess letdown flow path.

The chemical and volume control system has provision for injecting the following chemicals into the reactor coolant system, as required:

1. Hydrogen
2. Lithium hydroxide
3. Hydrogen peroxide
4. Hydrazine
5. Zinc Acetate

9.1.1 Design Bases

During normal unit operation, the chemical and volume control system is designed to automatically provide boric acid solution at a preset concentration, which matches the reactor coolant system boron concentration, to compensate for minor leakage of reactor coolant.

The chemical and volume control system design also permits the addition of a preselected quantity of reactor primary-grade makeup water or concentrated boric acid solution at a preselected flow rate to the reactor coolant system.

The chemical and volume control system has the capacity to achieve cold shutdown of both units, each with one control rod assembly completely withdrawn following a refueling shutdown. One boric acid storage tank has sufficient capacity (if maintained above the low-level alarm point) to provide a cold shutdown for one unit with one control rod assembly completely withdrawn.

9.1.1.1 Redundancy of Reactivity Control

In addition to the reactivity control achieved by the control rod assemblies, as detailed in Section 7.3, reactivity control is provided by the chemical and volume control system, which regulates the concentration of boric acid solution in the reactor coolant system. Under postulated system malfunctions, the system is designed to prevent uncontrolled or inadvertent reactivity changes that might stress the system beyond design limits.

9.1.1.2 Reactivity Shutdown Capability

Normal reactivity shutdown capability is provided by control rod assemblies, with boric acid injection used to compensate for the xenon transient and for unit cooldown. Any time that the unit is at power, the quantity of boric acid retained in the boric acid storage tanks and ready for injection always exceeds that quantity required for a cold shutdown.

The boric acid solution is transferred from the boric acid storage tanks by boric acid transfer pumps to the suction of the charging pumps, which inject boric acid into the reactor coolant. Any charging pump and any boric acid transfer pump is capable of being operated from diesel-generator power on loss of primary power. Boric acid is injected by one charging and one boric acid transfer pump at the approximate reactivity insertion rate of -0.14% delta k/k per minute, which shuts the reactor down in 25 minutes with no rods inserted. In 25 additional minutes, enough boric acid can be injected to compensate for xenon decay, although xenon decay below the equilibrium operating level does not begin until approximately 20 hours after shutdown from full power. Additional boric acid is added if it is desired to bring the reactor to cold shutdown conditions.

On the basis of the above, the injection of boric acid provides backup shutdown reactivity capability, independent of control rod assemblies, which normally serve this function in the short-term situation. Shutdown for long-term and reduced-temperature conditions is accomplished with boric acid injection using redundant components.

The reactivity control systems provided are capable of making and holding the core subcritical for any cold shutdown, hot shutdown, or hot operating condition, including those resulting from power changes. The maximum excess reactivity expected for reload cores occurs at the beginning of life, no xenon conditions. A total of 48 control rod assemblies is provided. The assemblies are divided into two categories comprising four control banks and two shutdown banks.

The control banks, used in combination with soluble boron, provide control of the reactivity changes at power throughout the life of the core. The control banks are used to compensate for short-term reactivity changes at power that might be produced due to variations in reactor power requirements or in coolant temperature. The soluble boron control is used to compensate for the slower changes in reactivity throughout core life, such as those due to fuel depletion and fission product buildup and decay.

The reactor core, together with the reactor control system and the reactor protection system, is designed so that the minimum departure from nucleate boiling ratio (DNBR) will not be less than the design DNBR limit (Section 3.2.3) and there will be no fuel melting during normal operation, including anticipated transients.

Shutdown control rod assemblies are provided to supplement the control rod assembly control groups to make the reactor at least 1.77% delta k/k subcritical following trip from any credible operating condition to the hot shutdown condition. This assumes the highest-worth control rod assembly remains in the fully withdrawn position.

Sufficient shutdown capability is also provided to ensure no DNB occurs for the most severe anticipated cooldown transient associated with a single active failure, i.e., accidental opening of a steam bypass valve or relief valve. This is achieved with a combination of control rod assemblies and automatic boron addition via the safety injection system with the highest-worth rod being fully withdrawn. Manually controlled boric acid addition is used to maintain the shutdown margin for the long-term conditions of xenon decay and reactor coolant system cooldown.

9.1.1.3 **Codes and Classifications**

The codes and classifications of chemical and volume control system components are stated in Table 9.1-1.

Both the regenerative and excess letdown heat exchangers are classified Class C according to the ASME Code, Section III. At the time of procurement, these heat exchangers met all of the requirements for Class C vessels. Westinghouse supplemented these minimum requirements with the following additional requirements:

1. Welded tube to tube sheet joints.
2. Gas leak test of tube to tubesheet welds in addition to full differential pressure hydrostatic tests.
3. Special tube to tubesheet weld procedure qualifications.
4. Ultrasonic or eddy current test of tubing.
5. Dye penetrant examination of tube to tubesheet welds and root pass as well as final pass to all other pressure containing welds.
6. Fatigue analysis as required by paragraph 415.1 of Section III to demonstrate that the unit can withstand the transients that it is expected to experience during its design life.

In addition, Westinghouse equipment specifications for the regenerative and excess letdown heat exchangers met the basic requirements of Appendix IX of the ASME Code, except that Westinghouse did not require nondestructive test personnel to be qualified to American Society for Nondestructive Testing procedures. Where the suppliers' personnel were not so qualified, Westinghouse assured that suppliers' personnel were adequately qualified by periodic observation of their performance, and Westinghouse also performed the customary final inspections. As noted above, Westinghouse quality assurance levels and quality control procedures were in excess of standard code requirements for Class C vessels.

The replacement tube bundle for the Unit 1 Excess Letdown Heat Exchanger (1-CH-E-4) was fabricated to ASME Section VIII, Div. 1, 1992 and A92 requirements. Code reconciliation concluded that the original requirements were met or exceeded, including the additional requirements previously specified. The fabrication and testing were witnessed by Virginia Power personnel and by an Authorized Nuclear Inspector, as applicable.

9.1.2 System Design and Operation

The chemical and volume control system is shown in Figure 9.1-1 and Reference Drawings 1 through 3. The system is provided with overpressure devices, such as safety valves, to protect components whose design pressure and temperature are less than the reactor coolant system design limits. System discharge from overpressure protective devices and other system leakages are directed to closed system.

System design enables post-operational hydrostatic testing to applicable code test pressures, with the relief valves gagged. After hydrostatic testing, the relief valves are set at the system design pressure.

The components in the chemical and volume control system that the two units share are the three boric acid storage tanks and the boric acid batch tank. These tanks are listed in Table 9.1-2.

9.1.2.1 **System Description**

During normal unit operation, reactor coolant flows through the letdown line from the reactor coolant pump discharge side of reactor coolant loop number 1 cold leg, and returns through the charging line to the reactor coolant pump discharge side of the cold leg of loop number 2. The charging line has a check valve located downstream of the charging line isolation valve. An excess letdown path from the reactor coolant system is provided in the event that the normal letdown path is nonfunctional. Reactor coolant can be discharged from each reactor coolant loop, or all loops concurrently, through the common loop drain header to the tube side of the excess letdown heat exchanger. Each of the connections to the reactor coolant system loops has an isolation valve located close to the loop piping.

Reactor coolant entering the chemical and volume control system flows through the shell side of the regenerative heat exchanger, where its temperature is reduced. The coolant then flows through the letdown orifices to reduce the coolant pressure. The letdown flow leaves the reactor containment and enters the auxiliary building, where it undergoes a second temperature reduction in the tube side of the nonregenerative heat exchanger, followed by a second pressure reduction by a low-pressure letdown valve. After passing through one of the mixed-bed demineralizers, where anionic and cationic impurities are removed, coolant flows through the reactor coolant filter and enters the volume control tank through a spray nozzle. Reactor coolant letdown flow is diverted to the boron recovery system (Section 9.2) on a high-level signal from the volume control tank.

The cation-bed demineralizer, located downstream of the mixed-bed demineralizer, is used intermittently to control cesium activity in the coolant and also to remove excess lithium, which is formed from B^{10}(n, a) Li^{7} reaction.

Hydrogen is automatically supplied, as determined by pressure control, to the vapor space in the volume control tank, which is predominantly hydrogen and water vapor. The hydrogen within this tank is, in turn, the supply source to the reactor coolant. Fission gases are periodically removed from the system by venting the volume control tank to the vent and drain system (Section 9.7) or by diverting the letdown stream to the primary drain tank and then to the gas stripper in the boron recovery system before a cold or refueling shutdown. The coolant flows from the volume control tank to the charging pumps, which raise the coolant pressure above that in the reactor coolant system. The coolant then enters the containment, passes through and is heated in the tube side of the regenerative heat exchanger, and then returns to the reactor coolant system.

A portion of the high-pressure charging flow is injected into the reactor coolant pumps between the pump impeller and the shaft seal so that the seals are not exposed to high-temperature reactor coolant.

From the injection flow of 8 gpm, 2.5 gpm passes through the pump radial bearing, shaft seal and then on to the chemical and volume control system, and 5.5 gpm passes through the thermal barrier heat exchanger and into the reactor coolant system, where it constitutes a portion of reactor coolant system water makeup. Shaft seal leakage flow is filtered, cooled in the seal-water heat exchanger, and returned to the suction of the charging pumps. Coolant injected through the reactor coolant pump labyrinth seals returns to the volume control tank by the normal letdown flow path through the regenerative heat exchanger. Indication of seal injection flow is provided locally and in the control room.

When the normal letdown flow route is not in service, labyrinth seal injection flow is returned to the suction of the charging pumps through the excess letdown and seal-water heat exchangers.

Boric acid is dissolved in heated water in the batching tank to a concentration of at least 7.0% (but not > 8.5%) by weight. The lower portion of the batching tank is jacketed to utilize low-pressure steam to permit heating of the batching tank solution. One of four boric acid transfer pumps is used to transfer this concentrated solution to the boric acid storage tanks. Small quantities of boric acid solution from the boric acid storage tanks are metered from the discharge of an operating boric acid transfer pump for blending with the water supplied to makeup for normal leakage losses, or for increasing the reactor coolant boron concentration during normal load follow operation. Electric immersion heaters maintain the solution in the boric acid storage tanks at an elevated temperature to prevent precipitation. The design temperature to ensure that the boric acid remains in solution at its highest concentrations is ≥112°F.

During unit start-up, normal operation, load reductions, and shutdowns, liquid effluents containing boric acid flow from the reactor coolant system through the letdown line and are collected in the boron recovery system (Section 9.2). Cover gases displaced during the filling of volume control tanks are vented to the gaseous waste disposal system (Section 11.2.5).

During the unit cooldown phase and when the unit is in cold shutdown, the residual heat removal loop is operated to control Reactor Coolant System (RCS) temperature. Because of the lower pressure in the reactor coolant system, insufficient pressure exists to maintain flow through the letdown orifices. A purification flow path is provided to remove fission and corrosion products, and other solid and liquid impurities. During the time that the RHR system is secured and the reactor coolant system is above 350°F the purification flow isolation valve, 1-RH-HCV-1142, is normally closed and is opened as required to fill the system from letdown.

A portion of the flow leaving the residual heat exchangers passes through the nonregenerative heat exchanger, mixed-bed demineralizers, reactor coolant filter, and volume control tank. The fluid then is pumped by the charging pump through the tube side of the regenerative heat exchanger into the reactor coolant system and, through the auxiliary spray line, into the pressurizer.

The letdown orifice isolation valves and the pressurizer auxiliary spray valves are equipped with quick-disconnect instrument air fittings to allow connection to a portable air source for local operation. The operation of the letdown orifice isolation valves provides an alternate letdown path during plant cooldown following a postulated fire in accordance with the requirements of Appendix R to 10 CFR 50. The analysis for Appendix R requires that the auxiliary spray valve be closed and disabled to ensure pressurizer pressure control. The auxiliary spray valve quick disconnect is not credited in the Appendix R analysis.

A beyond design basis (BDB) piping connection exists off of a 2” connection on the charging pump discharge header. This connection allows for the discharge hose of a portable pump to connect to this header. The hose is connected to the BDB piping via one of two different temporary adapter fittings. The adapter fitting that must be used is dependent on the current reactor operating condition. The purpose of this connection is to allow the portable pump to inject borated/makeup water into the RCS during a beyond design basis external event (BDBEE).

Two RCS injection standpipes are located in the Auxiliary Building. These standpipes can be used as hose extensions to facilitate the rapid deployment of the hoses for the BDB connection on this system. (Note: these standpipes are not physically connected to the Chemical and Volume Control (CH) System.)

Table 9.1-2 lists principle component data for the chemical and volume control system, Table 9.1-3 lists system performance requirements, and Table 9.1-4 gives data for reactor coolant fission product concentrations.

9.1.2.2 Reactor Coolant Activity Concentration, Monitoring, and Control

The parameters used in the calculation of the reactor coolant fission product inventory for the original plant design, including pertinent information concerning the coolant cleanup flow rate and the demineralizer effectiveness, are presented in Table 9.1-5. The results of the calculations are presented in Table 9.1-4. In these calculations, the defective fuel rods are assumed to be uniformly distributed throughout the core and the fission product escape rate coefficients are therefore based upon an average fuel temperature. Volume control tank noble gas concentrations with 1% failed fuel are shown in Table 9.1-6.

The fission product activity in the reactor coolant in the letdown stream of the regenerative heat exchanger during operation with small cladding defects in 1% of the fuel rods is computed using the following differential equations:

For parent nuclides in the coolant,

$$\frac{dN_{wi}}{dt} = DV_i N_{C_i} - \left(\lambda_i + R_{\eta_i} + \frac{B'}{B_O - tB'}\right) N_{wi}$$

For daughter nuclides in the coolant,

$$\frac{dN_{wj}}{dt} = DV_j N_{C_j} - \left(\lambda_i + R_{\eta_i} + \frac{B'}{B_O - tB'}\right) N_{wj} + \lambda_i N_{wi}$$

Where:

N = population of nuclide units

D = fraction of fuel rods having defective cladding

R = purification flow, coolant system volumes per sec

B_o = initial boron concentration, ppm

B' = boron concentration reduction rate by feed and bleed, ppm/sec

t = time, sec or fraction

η = removal efficiency of purification cycle for nuclide

λ = radioactive decay constant

v = escape rate coefficient for diffusion into coolant

Subscript C refers to “core”
Subscript w refers to “coolant”
Subscript i refers to “parent nuclide”
Subscript j refers to “daughter nuclide”

During unit operation, continuous monitoring of the reactor coolant is accomplished by means of high-range and low-range gross activity monitors. These monitors, which are described in Section 11.3.3, are capable of determining any sudden increase in activity level due to failed fuel within the range of 10^{-4} μCi/cc to 10^{3} μCi/cc.

The Technical Specification limit on reactor coolant activity provides adequate protection to the general public. The limits on reactor coolant system leakage and on effluent releases govern the potential release of coolant activity to the environment during normal reactor operation, and have been established on the basis of the limiting values of reactor coolant activity. The reference accident considered for the bases is the steam generator tube rupture (Section 14.3.1).

Rupture of a steam generator tube would allow a portion of the reactor coolant activity to enter the steam and feedwater systems outside the containment. In this event, the radioactive noncondensable gases would be detected by the radiation monitor located in the air ejector effluent line. When the radioactivity level reaches the alarm setpoint of the monitor, trip valves in the effluent line automatically actuate to divert the flow to the containment and to close the vent to atmosphere. Once safety injection is initiated, the air ejector exhaust is automatically isolated from containment. The ejector would then vent to the turbine building via vents in the ejector loop seals. The effluent can also be manually routed through the ventilation vent no. 2 at a location equipped with a high range radiation monitor. The radiological consequences of a steam generator tube rupture have been evaluated and determined to be acceptable as discussed in Section 14.3.1.

9.1.2.3 **Tritium Production**

9.1.2.3.1 Overall Tritium Sources

Within a pressurized light-water reactor, tritium is formed from several sources. The greatest potential source is the fissioning of uranium fuel, which yields tritium as a ternary fission product at a rate of approximately 8×10^{-5} atoms per fission, or 1.05×10^{-2} Ci/MWt/day. Boron-bearing burnable poison and secondary source rods are also a source of tritium. The amount of tritium appearing in the reactor coolant from these three sources is a function of the fuel, burnable poison, and secondary source cladding material permeability to tritium.

A direct source of tritium in the reactor coolant is the reaction of neutrons with dissolved boron used for reactivity control. The boron concentration is approximately 2000 ppm at the beginning of the fuel cycle, and is reduced to zero at the end of the fuel cycle. Neutron reactions with lithium are also a direct source of tritium. Lithium is present for pH control, and as a product of boron reactions with neutrons. The amount of lithium present, however, is carefully controlled to approximately 0.7-3.7 ppm by demineralization and/or chemical additions. A minute amount of tritium is also produced by neutron reactions with naturally occurring deuterium in light water.

9.1.2.3.2 Specific Tritium Sources

9.1.2.3.2.1 *Ternary Fissions - Clad Diffusion.* A program was undertaken by Westinghouse to determine the source of tritium in the reactor coolant in operating plants with both stainless steel and Zircaloy cladding. This program clearly indicated that, for the then-current generation of Westinghouse reactors with Zircaloy-clad fuel, 1% or less of the tritium produced in the fuel would diffuse through the cladding into the coolant.

The Ginna plant (nominal 1455 MWt) has Zircaloy cladding. At one point, after approximately 8 months of operation, the tritium concentrations were less than 0.3 μCi/cc in the reactor coolant. The monthly discharges from the plant averaged approximately 5 Ci/month. Experiences at the Beznau (Switzerland) and Jose Cabrera (Spain) plants were comparable. A program to follow the buildup of tritium at the Ginna plant indicated a potential source from the core which was 1% or less of the ternary fissions generated in the fuel.

Westinghouse has in the past assumed that 30% of the tritium from ternary fissions would diffuse through the Zircaloy-clad fuel. Such fuel was used as a basis for systems and operational design. Present experience indicates that this was conservative.

Like Zircaloy, ZIRLO and Optimized ZIRLO are made of approximately 98% zirconium. The properties of ZIRLO and Optimized ZIRLO cladding relative to tritium release are not expected to differ significantly from Zircaloy (References 2 and 4).

9.1.2.3.2.2 *Boron Reactions.* The neutron reactions with boron that result in the production of tritium are:

B^{10} (n, 2 α) T

B^{10} (n, α) Li^7 (n, n α) T

B^{11} (n, T) Be^9

B^{10} (n, d) Be^{9*} (n, α) Li^6 (n, α) T

Of the above reactions, only the first two contribute significantly to tritium production in a pressurized-water reactor. The B^{11} (n, T) Be^9 reaction has a threshold of 14 MeV and a cross section of 5 mb. Since the number of neutrons produced at this energy is less than 10^9 n/cm^2/sec, the tritium produced from this reaction is negligible. The B^{10} (n, d) reaction may be neglected, since Be^{9*} produced in this reaction has been found to be unstable.

9.1.2.3.2.3 *Lithium Reactions.* The neutron reactions with lithium resulting in the production of tritium are:

Li^7 (n, n α) T

Li^6 (n, α) T

In Westinghouse reactors, lithium is used for pH adjustment of the reactor coolant. The reactor coolant lithium concentration is maintained between 0.7 and 3.7 ppm lithium by the addition of Li^7OH and by the use of cation resin. This demineralizer will remove any excess of lithium such as could be produced in the B^{10} (n, α) Li^7 reaction.

The Li^6 (n, α) T reaction is controlled by limiting the Li^6 impurity in the Li^7OH used in the reactor coolant and by lithiating the demineralizers with 99.9 atom% Li^{7}.

9.1.2.3.2.4 *Control Rod Sources.* In a fixed burnable poison rod the two primary sources of tritium generation are the B^{10} (n, 2 α) T and the B^{10} (n, α) Li^7 (n, n α) T reactions. Unlike the coolant where the Li^7 level is controlled at 0.7-3.7 ppm, there is a buildup of Li^7 in the burnable poison rod. Tritium production in a burnable poison rod is approximately 72 Ci/lb B^{10} during its first cycle of exposure.

The control rod materials used are Ag-In-Cd, which are not tritium sources.

9.1.2.3.2.5 *Secondary Source Rods.* In a Secondary Source rod, the primary source of tritium generation is the irradiation of Beryllium. The neutron reactions that result in the production of tritium are:

Be^9 (n, α) He^6 (β) Li^6 (n, α) T

Be^9 (n, γ) Be^{10} (n) Li^8 + T

Be^9 (n) Li^7 + T

Li^7 (n, n α) T

Of the above reactions, the first reaction is the primary source of tritium production from the sources. The permeability of the secondary source pellets and cladding (stainless steel) to tritium is high. Secondary sources were not analyzed as potential sources of tritium in the reactor for the original plant design and are not included in Table 9.1-7. As stated in Section 9.1.2.3.2.1, conservative assumptions regarding the release of tritium from the fuel (30%) were made in the original analyses. The original analyses, with this assumption, account for potential tritium release from the source rods.

9.1.2.3.2.6 *Deuterium Reactions.* Since the amount of naturally occurring deuterium in water is less than 0.0015, the tritium produced from this reaction is negligible (less than 1 Ci per year).

9.1.2.3.2.7 *Total Tritium Sources.* Tritium sources in the reactor coolant systems of the Surry units are listed in Table 9.1-7. They are presented on the basis of the original plant design of 12 months of operation at 2546 MWt and a 0.8 load factor.

Two columns are presented in the tables; a previous design value and the presently expected tritium release value to the reactor coolant. The design values are based on a release of 30% of the tritium produced being diffused through the fuel cladding.

A tritium limit is established to meet the allowable concentration in the circulating water discharge. For one unit, the production rate of tritium due to ternary fission is calculated to be 7850 Ci/yr., and 30%, as a design basis, is assumed to be released to the coolant by recoil through the cladding. (See Table 9.1-7.) To this is added tritium from other sources, for a total of approximately 2745 Ci/yr. of total tritium activity added to the reactor coolant during the initial fuel cycle, and 2750 Ci/yr. during an equilibrium fuel cycle. Using the projected turnover rate of four reactor coolant system volumes per year or more, the tritium activity in the primary coolant should never increase beyond about 2.5 μCi/cc.

9.1.2.4 **Reactor Makeup Control**

Reactor makeup control consists of an instrument and control group arranged to provide a manually preselected makeup composition to the charging pump suction header or the volume control tank. The makeup control functions are designed to maintain desired operating fluid inventory in the volume control tank and to adjust reactor coolant boron concentration for chemical shim reactivity control.

Makeup for normal primary system leakage is regulated by reactor makeup control, which is set by the operator to blend water from the primary-water tanks with concentrated boric acid to match the reactor coolant boron concentration. Makeup is added automatically if the volume control tank level falls below a preset value.

Reactor makeup control is designed to operate from the control room by manually preselecting makeup composition to the charging pump suction header or the volume control tank. This maintains the desired operating fluid inventory in the volume control tank and adjusts the reactor coolant boron concentration for proper reactivity control. The operator can stop the makeup operation at any time in any operating mode by remotely closing the makeup stop valves, or by placing the makeup mode control switch to stop.

One primary-water supply pump and one boric acid transfer pump normally are operated. If either pump trips, an alarm alerts the operator to a deviation of flow rate from the control setpoint. The standby primary water makeup pump will start automatically due to low header pressure, or it may be started manually. The standby boric acid transfer pump is started manually.

Makeup water to the reactor coolant system is provided through the chemical and volume control system from the following sources:

1. The primary-water tanks, which provide water for primary coolant dilution when the reactor coolant boron concentration is to be reduced.
2. The boric acid storage tanks, which supply a concentrated boric acid solution when reactor coolant boron concentration is to be increased. Water chemistry for the boric acid storage tanks is shown in Table 9.1-8.
3. The refueling water storage tank, which supplies borated water for emergency makeup.

4. The chemical mixing tank, which is used to inject small quantities of solution when additions of a pH control chemical are necessary.

Seal-water inleakage to the reactor coolant system requires a continuous letdown of reactor coolant to maintain the desired inventory. In addition, bleed and feed of reactor coolant is required for removal of impurities and adjustment of boric acid in the reactor coolant.

9.1.2.4.1 Automatic Makeup Mode

The automatic makeup mode of operation of the reactor coolant water makeup control scheme provides boric acid solution at a preset concentration to match the boron concentration in the reactor coolant system. The automatic makeup compensates for minor leakage of reactor coolant without causing significant change in the boron concentration of the coolant.

Under normal unit operating conditions, makeup control is set for automatic operation. A preset low-level signal from the volume control tank level controller causes the automatic makeup control action to increase the speed on the normally running boric acid transfer pump, open the makeup stop valve to the charging pump suction, modulate closed the concentrated boric acid control valve, and modulate open the reactor primary-water makeup control valve. One primary-water supply pump is always in operation. The flow controllers then blend the makeup stream according to the preset concentration. Makeup addition to the charging pump suction header causes the water level in the volume control tank to rise. At a preset high-level point, the makeup is stopped, the reactor primary-water makeup control valve closes, the boric acid transfer pump returns to low speed, the concentrated boric acid control valve opens, and the makeup stop valve to the charging pump suction closes.

9.1.2.4.2 Dilution Mode

The dilution mode of operation permits addition of a preselected quantity of reactor primary-grade water makeup at a preselected flow rate to the reactor coolant system. The operator selects the dilution mode, sets the reactor primary-water makeup flow controller setpoint to the desired flow rate, sets the reactor primary-water makeup batch integrator to the appropriate quantity if desired, and initiates system start. This opens the primary-grade water makeup control valve, which delivers primary-grade water to the volume control tank. Excessive rise of the volume control tank water level is prevented by automatic actuation of a three-way diversion valve, which routes the reactor coolant letdown flow to the boron recovery system. When the appropriate quantity of reactor primary-water makeup is added, the batch integrater causes the reactor primary-water makeup control valve to close, or the operator stops the makeup by placing the makeup mode control switch to stop.

9.1.2.4.3 Boration Mode

The boration mode of operation permits the addition of a preselected quantity of concentrated boric acid solution at a preselected flow rate to the reactor coolant system. The operator selects the boration mode, sets the concentrated boric acid flow controller setpoint to the desired flow rate, sets the concentrated boric acid batch integrater to the appropriate quantity if desired, and initiates system start. This opens the makeup stop valve to the charging pumps suction and the boric acid control valve. It also increases the speed on the normally operating boric acid transfer pump, which delivers a boric acid solution of at least 7.0% (but not 8.5%) by weight to the charging pump suction header.

When the appropriate quantity of concentrated boric acid solution is added, the batch integrator causes the boric acid transfer pump to return to low speed and closes the makeup stop valve to the suction of the charging pumps. The operation may be terminated manually at any time by actuating the makeup stop valve, or placing the makeup mode control switch to stop.

The operator usually initiates the boration mode of operation. There is no automatic actuation of the system except in the case of a volume control tank low-low-level signal. In this event, the charging pump suction is aligned to the refueling water storage tank, which contains boron nominally at 2400 ppm.

The maximum rate of boration of the primary system with the 60-gpm discharge of a boric acid transfer pump directed to the charging pump suction is 14.1 ppm/minute assuming 7.0 weight percent boric acid in the tanks. This provides compensation for a cooldown rate of approximately 4.9°F/min at the end of core life when the moderator temperature coefficient is most negative.

The maximum rate of boration corresponding to charging and letdown at the maximum design letdown flow rate of 120 gpm and assuming suction from the refueling water storage tank at the nominal (mid-point of range) concentration of 2400 ppm, is 5.5 ppm/min. At the end of cycle, this boration rate is adequate to compensate for a cooldown rate of 1.9°F/min.

9.1.2.4.4 Alarm Functions

Reactor makeup control is provided with alarm functions to call the operator’s attention to the following conditions:

1. Deviation of reactor primary-water makeup flow rate from the control setpoint.
2. Deviation of concentrated boric acid flow rate from the control setpoint.
3. High-level and low-level in the volume control tank. The high-level alarm indicates that the level in the tank is approaching a high level resulting in 100% diversion of the letdown stream to the boron recovery system. The low-level alarm indicates that the level in the volume control tank is approaching a low-low or emergency level in a case where the primary makeup control selector is not set for the automatic makeup mode and the volume control tank level drops below the makeup initiation point.
4. Low-low level in the volume control tank.

9.1.2.5 **Charging Flow Control**

Three single-speed horizontal centrifugal charging pumps are used to supply charging flow to the reactor coolant system and to perform the safety injection function, as discussed in Sections 6.1 and 6.2. The charging mode and the safety injection mode represent separate operating ranges on the pump head curves.

A flow transmitter on the charging line upstream of the regenerative heat exchanger transmits a signal to an indicator-controller in the control room. The controller regulates a throttling valve in the charging line to maintain a preset charging flow. A reactor coolant system pressurizer water level error signal resets the charging flow setpoint to provide corrective action. If the pressurizer level increases, the error signal changes the charging flow setpoint to a lower value which causes the control valve to move towards the closed position. The controller is provided with adjustable maximum and minimum flow limits. Maximum flow is limited to prevent entry into the safety injection mode and start-up of the standby charging pump during normal unit transient conditions. Minimum flow is limited to prevent flashing downstream from the letdown orifices.

Flow verification is provided by charging flow indication or, when the system is aligned to the fill header, by fill header flow indication. Separate power sources supply each indication. This increases the system reliability so that if a loss of a vital bus occurs, the operator could verify a flow of water entering the cooling system by re-aligning flow through the unaffected flow path.

A pressure switch in the charging pump discharge header actuates an alarm and starts a standby charging pump if the discharge header pressure falls to a preset low level.

The safety injection signal overrides any other associated control signal.

9.1.2.6 **Components**

A summary of principal component data is given in Table 9.1-2.

9.1.2.6.1 Regenerative Heat Exchanger

The regenerative heat exchanger is designed to recover the heat from the letdown stream by reheating the charging stream during normal operation. This exchanger also limits the temperature rise that occurs at the letdown orifices during transient periods when letdown flow exceeds charging flow.

The letdown stream flows through the shell of the regenerative heat exchanger, and the charging stream flows through the tubes. The exchanger is fabricated of austenitic stainless steel, and is of all-welded construction. The regenerative heat exchanger is capable of withstanding the thermal and pressure stresses resulting from the expected transients in working fluid temperature and pressure.

9.1.2.6.2 Letdown Orifices

Parallel letdown orifices are used to control the flow of the letdown stream during normal operation and reduce the coolant pressure to a value compatible with the nonregenerative heat exchanger design. Two orifices are used to attain maximum purification flow at normal reactor coolant system operating pressure, and the third orifice serves as a spare.

The orifices are placed in service by remote manual operation of their respective isolation valves. The standby orifice is used in parallel with the normally operating orifices in order to increase letdown flow when the reactor coolant system pressure is below normal. This arrangement provides standby capacity for control of letdown flow. Each orifice is constructed of austenitic pipe containing a corrosion-resistant and erosion-resistant insert bored to the diameter required.

9.1.2.6.3 Nonregenerative Heat Exchanger

The nonregenerative heat exchanger cools the letdown stream to the operating temperature of the mixed-bed demineralizers. Reactor coolant flows through the tube side of the exchanger while component cooling water flows through the shell. The letdown stream outlet temperature is automatically controlled by a temperature control valve in the component cooling water outlet stream. The unit is a multiple-pass-tube heat exchanger. All surfaces in contact with the reactor coolant are austenitic stainless steel, and the shell is carbon steel.

9.1.2.6.4 Mixed-Bed Demineralizers

Two flushable mixed-bed demineralizers maintain reactor coolant purity by the use of a Li^7 cation resin and a hydroxyl-form anion resin. These resins remove fission and corrosion products and, in addition, the borated reactor coolant converts the anion resin to the borate form. The resin bed is designed to reduce the concentration of ionic isotopes in the purification stream (except for cesium, tritium, and molybdenum) by a minimum factor of 10.

Each demineralizer is sized to accommodate the maximum letdown flow. One demineralizer serves as a standby unit for use when the operating demineralizer becomes exhausted during operation.

The demineralizer vessels are fabricated of austenitic stainless steel and are provided with suitable connections to facilitate resin replacement. The vessels are equipped with a resin retention screen. Each demineralizer has sufficient capacity to operate for one core cycle with 1% defective fuel rods.

9.1.2.6.5 Deborating Demineralizers

When required, two anion demineralizers remove boric acid from the reactor coolant system fluid. The demineralizers are intended for use near the end of a core cycle when boron concentrations are low, but can be used at any time if required. Hydroxyl-based ion-exchange resin is used to reduce reactor coolant system boron concentration by releasing a hydroxyl ion when a borate ion is adsorbed.

When the resin is saturated, it is flushed to the spent-resin storage tank and new resin is added.

Each demineralizer is sized to remove that quantity of boric acid from the reactor coolant system necessary to maintain full-power operation near the end of core life without the use of the boron recovery system.

If desired, one of the two anion demineralizer vessels can be loaded with cation resin and used as a cation demineralizer to support control of Cesium and Lithium.

9.1.2.6.6 Cation-Bed Demineralizer

A demineralizer using a flushable cation resin bed in the hydrogen form is located downstream from the mixed-bed demineralizers and is used when required to control the concentration of Li^7 that builds up in the coolant from the B^{10} (n, α) Li^7 reaction. The demineralizer also has sufficient capacity to maintain the cesium-137 concentration in the coolant below 1.0 μCi/cc with 1% defective fuel. The demineralizer is used to control cesium as necessary during operation. The demineralizer vessel is fabricated of austenitic stainless steel and is provided with suitable connections to facilitate resin replacement when required. The vessel is equipped with a resin retention screen.

9.1.2.6.7 Reactor Coolant Filter

The filter collects resin fines and particulates using a filter element with a particle retention of 25 μm or less if such fines should carry over into the letdown stream. The vessel is fabricated of austenitic stainless steel, and is provided with connections for draining and venting. Design flow capacity of the filter is equal to the maximum purification flow rate.

Disposable synthetic filter elements are used. The reactor coolant filter is considered for replacement when there is a high-pressure differential across the filter or when a portable radiation monitor exceeds a dose rate limit.

9.1.2.6.8 Volume Control Tank

The volume control tank is the collecting point in the system for letdown flow, makeup, and chemical additions. It has surge capacity to compensate for changes in reactor coolant volume resulting from power level increases and the deadband in the reactor control temperature instrumentation.

A hydrogen gas overpressure is maintained in the volume control tank to control the hydrogen concentration in the reactor coolant between 5 and 50 cm^3/kg of water at standard temperature and pressure. A spray nozzle is located inside the tank on the inlet line from the reactor coolant filter. This spray nozzle provides liquid-to-gas contact between the incoming liquid and the hydrogen atmosphere in the tank.

A remotely operated vent valve discharging to the vent and drain system permits removal of gaseous fission products, when desired, which are stripped from the reactor coolant at this location. The volume control tank also acts as a head tank for the charging pump suction header. The tank is constructed of austenitic stainless steel.

9.1.2.6.9 Charging Pumps

Three charging pumps inject coolant into the reactor coolant system. These pumps also perform the safety injection function as discussed in Sections 6.1 and 6.2. The pumps are of the single-speed horizontal centrifugal type, and all parts in contact with the reactor coolant are constructed of austenitic stainless steel or other material of adequate corrosion resistance. These pumps have a mechanical seal and auxiliary gland bushing. This arrangement minimizes the possibility of reactor coolant leakage to the outside atmosphere. Pump leakage is collected in a catch container with overflow routed to the auxiliary building sump for disposal. The pump design prevents lubricating oil from contaminating the charging flow.

Each pump is designed to provide the full charging flow and the reactor coolant pump seal-water supply during normal seal leakage. Each pump is designed to provide rated flow against a pressure equal to the sum of the reactor coolant system safety valve pressure and the piping, valve, and equipment pressure losses at the design charging flows. The capacity of each charging pump permits operation at normal charging line flow with one reactor coolant pump shaft seal operating normally while the other two reactor coolant pumps are operating with significant seal flow. The capacity of each pump includes margin for recirculation flow. The recirculation flow is sufficient to protect the pumps when pump discharge valves are closed during testing or when pump discharge flow is low at minimum charging conditions.

9.1.2.6.10 Chemical Mixing Tank

The primary use of the chemical mixing tank is for the preparation of solutions for pH control and oxygen scavenging; it has a capacity more than sufficient to prepare a solution of pH control chemical for the reactor coolant system. It is fabricated of austenitic stainless steel. The capacity of the chemical mixing tank is determined by the quantity of 35% hydrazine solution necessary to increase the concentration in the reactor coolant by 10 ppm. The chemical mixing tank may also be used to add hydrogen peroxide to the reactor coolant. This occurs during refueling outages and is used to solubilize crud for controlled removal.

9.1.2.6.11 Excess Letdown Heat Exchanger

The excess letdown heat exchanger cools reactor coolant letdown if the normal letdown path is blocked. It is designed to cool a letdown flow equal to the nominal injection rate through three reactor coolant pump labyrinth seals. The unit is designed to reduce the letdown stream temperature from the cold-leg temperature to 195°F. The letdown stream flows through the tube side, and component cooling water circulates through the shell side. All surfaces in contact with the reactor coolant are austenitic stainless steel, and the shell is carbon steel. All tube joints are welded. The unit is designed to withstand 12,000 step changes in the tube fluid temperature from 80°F to the cold-leg temperature.

9.1.2.6.12 Seal-Water Heat Exchanger

The seal-water heat exchanger removes heat from three sources: reactor coolant pump seal-water, reactor coolant discharged from the excess letdown heat exchanger, and charging pump recirculation flow. Reactor coolant flows through the tubes, and component cooling water is circulated through the shell side. The tubes are welded to the tubesheet because undesirable leakage could occur in either direction. All surfaces in contact with reactor coolant are austenitic stainless steel, and the shell is carbon steel.

The exchanger is designed to cool the excess letdown flow and the sealwater flow to the temperature normally maintained in the volume control tank if all the reactor coolant pump seals are leaking at the maximum design leakage rate.

9.1.2.6.13 Seal-Water Filter

The filter collects particulates using a filter element with a particle retention of 25 μm or less from the reactor coolant pump seal-water return from the excess letdown heat exchanger flow. The filter is designed to pass the sum of the excess letdown flow and the maximum design leakage from the reactor coolant pump seals. The vessel is constructed of austenitic stainless steel and is provided with connections for draining and venting. Disposable synthetic filter elements are used.

9.1.2.6.14 Boric Acid Filter

The boric acid filter collects particulates using a filter element with a particle retention of 25 μm or less from the boric acid solution being pumped to the charging pump suction line or boric acid blender. The filter is designed to pass the design flow of two boric acid pumps operating simultaneously. The vessel is constructed of austenitic stainless steel, and the filter elements are disposable synthetic cartridges. Provisions are available for venting and draining the filter.

9.1.2.6.15 Boric Acid Storage Tanks

Boric acid solution mixed in the batching tank is stored in three electrically heated boric acid storage tanks shared by both units. One tank is normally aligned for each unit and supplies boric acid for reactor coolant makeup. Makeup to the boric acid storage tanks is typically done by a batching process applied to the third tank which is not assigned to either unit. As needed, the aligned tanks may be filled from the third “unaligned” tank in order to maintain an adequate boric acid supply to each unit. The three tanks combined have sufficient boric acid capacity to provide cold shutdown for the two units, each with one control rod assembly completely withdrawn, following a refueling shutdown on both units. Each tank, if maintained above the low-level alarm point, can supply sufficient boration to provide cold shutdown for one unit with a control rod assembly completely withdrawn.

During reactor operation, it is necessary to recirculate the boric acid solution in the boric acid storage tanks and the associated piping in order to prevent localized precipitation of boric acid. Sampling frequency and water chemistry requirements to preclude precipitation are found in Table 9.1-8.

The concentration of boric acid solution in storage is at least 7.0% (but not > 8.5%) by weight. Periodic manual sampling and corrective action, if necessary, ensure that these limits are maintained. As a consequence, measured amounts of boric acid solution can be delivered to the reactor coolant to control the boron concentration. Each boric acid storage tank has an overflow with a water loop seal that is connected to the high level liquid waste tanks. The boric acid storage tanks are constructed of austenitic stainless steel.

9.1.2.6.16 Batching Tank

The batching tank is sized to hold one week's makeup supply of boric acid solution for transfer to the boric acid storage tanks. The basis for makeup is reactor coolant leakage of 0.5 gpm at beginning of core life. A local sampling point is provided for verifying the solution concentration prior to transferring it to the boric acid storage tank or for draining the tank. A tank manway is provided with a removable screen to prevent entry of foreign particles. In addition, the tank is provided with an agitator to improve mixing during batching operations. The tank is constructed of austenitic stainless steel and is not used to handle radioactive substances. The tank is provided with a steam jacket for heating the boric acid solution to ≥128°F.

9.1.2.6.17 Boric Acid Storage Tank Heaters

Two 100%-capacity electric immersion heaters in each boric acid storage tank are designed to maintain the temperature of the boric acid solution at ≥128°F with an ambient air temperature of 40°F, thus ensuring a temperature in excess of the solubility limit (108°F for a 14,858-ppm boron solution). The heaters are sheathed in incoloy.

9.1.2.6.18 Boric Acid Transfer Pumps

Four centrifugal two-speed pumps are used to circulate or transfer the boric acid solution. The pumps circulate the boric acid solution and inject boric acid into the charging pump suction header or furnish boric acid to the boric acid blender. Although one pump normally is used for boric acid batching and transfer for each unit and one for boric acid injection for each unit, either pump may function as standby for the other. The design head of one pump is sufficient, considering line and valve losses, to deliver rated flow to the charging pump suction header when volume control tank pressure is at the maximum operating value. All parts in contact with the solutions are austenitic stainless steel or other suitable corrosion-resistant material.

The boric acid transfer pumps are operated either automatically or manually from the control room. A main control room annuciator alarms when the system is in the nonautomatic control mode. Reactor makeup control operates one of the pumps automatically when the boric acid solution is required for makeup or boration.

9.1.2.6.19 Boric Acid Blender

The boric acid blender promotes thorough mixing of the concentrated boric acid solution and primary-grade water for the reactor coolant makeup circuit.

The blender consists of a conventional pipe fitted with a perforated tube insert. All material is austenitic stainless steel. The blender decreases the pipe length required to homogenize the mixture.

9.1.2.6.20 Electrical Heat Tracing

Electrical heat tracing is installed under the insulation on all pumps, piping, valves, line-mounted instrumentation, and components normally containing a concentrated boric acid solution. The heat tracing is designed to prevent boric acid precipitation due to cooling, by compensating for heat loss.

Exceptions are:

1. Lines that may transport concentrated boric acid but are subsequently flushed with reactor coolant or other liquid of low boric acid concentration during normal operation.
2. The boric acid storage tanks, which are provided with immersion heaters.
3. The batching tank, which is provided with a steam jacket.

Heat tracing tapes are resistant to mechanical, chemical, and heat damage, and are covered by protective and heat-retaining insulation. Duplicate tracing on sections of the chemical and volume control system normally containing boric acid solution provides backup if the operating tracing malfunctions. Monitoring electrical equipment allows functional testing of the heat tracing. The existence of a condition requiring redundant tracing to be operated will be indicated by an alarm in the control room. Circuit test results are documented in appropriate test procedures.

9.1.2.6.21 Valves

Valves that perform a modulating function are equipped with two sets of packing and an intermediate leakoff connection that discharges directly, or via a floor drain, to the vent and drain system. All other valves have stem leakage control. Globe valves are installed with flow over the seat when such an arrangement reduces the possibility of leakage. An exception to this preference includes the charging pump recirculation MOVs which are installed in a configuration that will expose the valve packing to the inlet pressure when the valve is closed. Basic material of construction is stainless steel for all valves except the batching tank steam jacket valves, which are carbon steel.

Isolation valves are provided at all connections to the reactor coolant system. Connections to the reactor coolant system that pass through the containment are equipped with isolation devices, as described in Section 5.2.

Relief valves are provided for lines and components that might be pressurized above design pressure by improper operation or component malfunction. Pressure relief for the tube side of the regenerative heat exchanger is provided by a spring-loaded check valve around the charging line isolation valve. The valve relieves to the reactor coolant system.

All relief valves used in systems handling radioactive fluids are of the closed bonnet design and are constructed of stainless steel.

9.1.2.6.22 Piping

All chemical and volume control system piping handling radioactive liquid is austenitic stainless steel. All piping joints and connections are welded, except where flanged connections are required to facilitate equipment removal for maintenance and hydrostatic testing. Piping, valves, equipment, and linemounted instrumentation, which normally contain concentrated boric acid solution, are heated by electrical tracing to ensure solubility of the boric acid.

Portions of the stainless steel piping systems may contain stagnant oxygenated borated water during plant operations. Stagnant borated water in these portions may exist for periods of time longer than one week. Piping integrity is verified by periodic inservice inspection.

9.1.2.6.23 Zinc Injection System

Zinc is injected into the RCS for dose reduction and/or mitigation of Primary Water Stress Corrosion Cracking. The zinc injection system includes an injection skid which provides a small, continuous flow into the CVCS system. The skid is comprised of a common zinc solution tank and two separate pumping trains to ensure uninterrupted flow to the CVCS. Each train consists of a 5 ml/min max. positive displacement pump, pressure gauge and appropriate valves. Either pump can draw from the tank. The system injects into the Letdown Radiation Monitor line before it empties into the Volume Control Tank.

9.1.3 System Design Evaluation

9.1.3.1 **Availability and Reliability**

A high degree of functional reliability is ensured in the chemical and volume control system by providing standby components where performance is vital to safety and by ensuring safe response to the most probable mode of failure. Special provisions include duplicate heat tracing with alarm protection of lines, valves, and components normally containing concentrated boric acid.

The chemical and volume control system has three high-pressure charging pumps, each capable of supplying the required reactor coolant pump seal and makeup flow. The two units' charging systems are cross-connected to allow the use of the opposite unit's charging pumps to bring the disabled unit to cold shutdown during certain emergency conditions. Operation of the safety related manual cross-connect isolation valves is procedurally controlled. Reactor coolant pump seal injection is isolated on the fire affected unit prior to aligning the cross-connect during certain fire scenarios.

The electrical equipment of the chemical and volume control system for each unit is arranged so that redundant items are powered from two separate independent emergency electrical distribution systems consisting of 4160V and 480V buses (Figure 8.3-1). One charging pump and one boric acid transfer pump are powered from each train of the emergency electrical distribution system. A third charging pump is available which can be powered from either 4160V emergency bus. In case of loss of normal ac power, the emergency buses are automatically powered from the standby emergency diesel generators.

9.1.3.2 **Control of Tritium**

An analysis of the production of tritium in the reactor coolant is presented in Table 9.1-7. Even if all the tritium produced in the reactor coolant is discharged from the plant, the concentration of tritium in the discharge canal would be 4.8×10^{-6} Ci/cm^3 or less than 0.2% of that allowed by 10 CFR 20. This analysis was based in part on 30% of the fission-produced tritium diffusing through the clad. The expected diffusion with zirconium clad is less than 1%.

During normal operation, tritium will be present in the following systems:

1. Reactor coolant system.
2. Chemical and volume control system.
3. Sampling system.
4. Vent and drain system.
5. Liquid waste system.
6. Refueling water storage system.

The distribution of tritium among these systems will be dependent on the operating parameters of the plant.

Essentially all of the tritium is in chemical combination with oxygen as a form of water. Therefore, any leakage of coolant to the containment atmosphere carries tritium in the same proportion as it exists in the coolant. Thus, the level of tritium in the containment atmosphere, when it is sealed from outside air ventilation, is mainly a function of tritium level in the reactor coolant. In addition, it depends on the cooling water temperature at the ventilation cooling coils, and the presence of leakage other than reactor coolant as a source of moisture in the containment air.

All effluents discharged from the liquid waste system will be sampled and analyzed before release. Tritium releases to the environment resulting from primary system leakage will be accounted for by analysis of the containment atmosphere prior to containment purging and by periodic analysis of the steam generator blowdown.

There are two major considerations with regard to the presence of tritium in the reactor coolant, neither of which is limiting in the operation of the Surry units:

1. Possible station personnel hazard during access to the containment, since leakage of reactor coolant during operation causes an accumulation of tritium in the containment atmosphere.

2. Release of tritium to the environment.

9.1.3.3 Leakage Provisions

All chemical and volume control system valves and piping for radioactive services are designed to permit essentially zero leakage. The components designated for radioactive service are provided with welded connections to prevent leakage. However, flanged connections are provided on each charging pump suction and discharge, on each boric acid pump suction and discharge, on the relief valve inlets and outlets, on three-way valves, and on the flow meters to permit removal for maintenance.

The centrifugal charging pumps are provided with leakoffs which direct leakage to the auxiliary building sump. All valves that are larger than 2-inch and that are designated for radioactive service at an operating fluid temperature above 212°F are provided with a stuffing box and lantern leakoff connections. All control valves are provided with stuffing box and leakoff connections or are totally enclosed, and leakage is essentially zero for these valves.

Diaphragm valves are provided where the operating pressure is 200 psig or below and operating temperature is 200°F or below. Leakage is essentially zero for these valves.

9.1.3.4 Incident Control

The letdown line and the reactor coolant pump seal-water return lines penetrate the reactor containment. The letdown line contains air-operated valves inside the reactor containment and one air-operated valve outside the reactor containment, which is automatically closed by the containment isolation signal.

The reactor coolant pump seal-water return lines contain one motor-operated isolation valve outside the reactor containment, which is automatically closed by the containment isolation signal.

The seal-water injection lines to the reactor coolant pumps and the charging line are inflow lines penetrating the reactor containment. Each line contains two check valves in series inside the reactor containment to provide isolation of the reactor containment should a break occur in these lines outside the reactor containment.

9.1.3.5 **Malfunction Analysis**

9.1.3.5.1 Malfunction During a Loss-of-Coolant Accident

To evaluate system safety, failures or malfunctions are assumed concurrent with a loss-of-coolant accident (LOCA), and the consequences are analyzed. Proper consideration is given to station safety in the design of the system. Results of this analysis are presented in Table 9.1-9.

If a rupture takes place between a reactor coolant loop and the first isolation valve or check valve, a loss of reactor coolant occurs. The first isolation or check valve is always located as close as possible to the reactor coolant loop pipe. The analysis of a LOCA is discussed in Chapter 14.

If a rupture occurs in the chemical and volume control system outside the containment, or at any point beyond the first check valve or remotely operated isolation valve, actuation of the valve limits the release of coolant and ensures continued functioning of the normal means of heat dissipation from the core. For the general case of a rupture outside the containment, the largest source of radioactive fluid subject to release is the volume control tank. The consequences of such a release are discussed in Chapter 14.

9.1.3.5.2 Boration/Dilution Performance

When the reactor is subcritical during Refueling Shutdown, Cold Shutdown, Intermediate Shutdown, and Hot Shutdown, any change in core reactivity is continuously monitored by boron tri-fluoride proportional counters (i.e., SRNI) and indicated in the Main Control Room by visual and audible count rate indicators. In addition, RCS letdown divert valve position, VCT level, PG tank levels and PG header flow rate all provide indication in the Main Control Room of a potential mismatch between charging and letdown and unexpected usage of PG water. A high dilution flow rate event during shutdown operation is precluded by the Technical Specification requirement to close the main primary grade makeup flow path during all shutdown modes.

The boron dilution in shutdown operating conditions is discussed in Section 14.2.5.3. Dilution malfunctions during Power Operation or Reactor Critical are analyzed and the consequences discussed in Section 14.2.5.4.

At least two separate and independent flow paths are available for normal reactor coolant boration, i.e., the charging line or the reactor coolant pump seal labyrinths. The malfunction or failure of either flow path does not result in the inability to borate the reactor coolant system. An alternate flow path is always available for emergency boration of the reactor coolant. As backup to the boration system, the operator can also align the refueling water storage tank outlet to the suction of the charging pumps, if required.

A single malfunction in one of the boron makeup subsystems does not preclude the ability to maintain proper boron concentration in both units simultaneously.

Subsequent to complete loss of seal injection water to the reactor coolant pump seals, low charging pressure in the system header (below a preset value) automatically starts a standby charging pump. Even if the seal-water injection flow is not reestablished, the unit can operate if component cooling water is available, since the thermal barrier cooler cools the reactor coolant flow that passes through the thermal barrier cooler and seal leakoff from the pump volute. How long the unit can operate is determined by monitoring the reactor coolant pump bearing and seal temperatures, to ensure they remain within operating limits (Reference 3).

To ensure an alternate shutdown capability independent of cables, system, or components in the area, a remote monitoring panel which will monitor vital primary parameters and a cross connect between the two units' charging pump discharge lines has been incorporated. Operation of the cross connect is strictly manual. The cross connect is located in the auxiliary building.

9.1.3.5.3 Loss of Boric Acid Tank Concurrent With Loss of Offsite Power

The Surry reactors would not normally be brought to a cold shutdown condition without offsite power, but would remain in the hot standby condition. However, if it became necessary to bring the reactor to a cold shutdown condition in the event of a loss of offsite power, natural circulation and other emergency equipment could be used to do so.

In the event of a complete loss of offsite power and turbine trip, there would be a loss of power to the station auxiliaries, i.e., the reactor coolant pumps, main feedwater pumps, etc. The emergency diesel generators would start automatically to supply plant vital loads. Vital instruments are supplied by buses obtaining power from inverters, which in turn obtain power from the emergency batteries.

The auxiliary feedwater system would start automatically. It consists of two motor-driven auxiliary feedwater pumps that obtain power from the emergency diesels, and one steam-driven auxiliary feedwater pump that utilizes steam from the secondary system and exhausts to the atmosphere. Equipment required to inject boron into the reactor coolant system (the charging pump, and boric acid transfer pump) is supplied by the diesel generator. Feedwater required for cooldown is supplied by the auxiliary feedwater system. Steam would be released to atmosphere via the steam generator atmospheric relief valves, thereby dissipating the reactor heat energy. The air compressor required to ensure the functionality of the atmospheric relief valves is supplied by the diesel generators. Natural circulation could be used to circulate the coolant through the system to effect cooldown, as has been demonstrated by tests on reactors of similar design.

One tank, if maintained above the low-level alarm, can supply sufficient boric acid to provide cold shutdown for one unit with a control rod assembly completely withdrawn (Section 9.1.2.6.15). Similarly, the quantity of boric acid would be sufficient for the condition postulated, where the reactor is to be shut down after power operation shortly after refueling.

9.1.3.6 **Galvanic Corrosion**

The only types of materials that are in contact with each other in borated water are stainless steels, Inconel, and Stellite or other corrosion and wear resistant valve materials, and zirconium alloy (e.g., Zircaloy, ZIRLO, or Optimized ZIRLO) fuel element cladding. These materials have been shown to exhibit only an insignificant degree of galvanic corrosion when coupled to each other.

For example, the galvanic corrosion of Inconel versus 304 stainless steel resulting from high-temperature tests (575°F) in lithiated, boric acid solution was found to be less than -20.9 mg/dm^2 for the test period of 9 days. Further galvanic corrosion would be trivial, since the cell currents at the conclusion of the tests were approaching polarization. Zircaloy versus stainless steel Type 304 was shown to polarize at 180°F with lithiated, boric acid solution in less than 8 days, with a total galvanic attack of -3.0 mg/dm^2. Stellite versus stainless steel Type 304 was polarized in 7 days at 575°F in lithiated boric acid solution, with a total galvanic corrosion of -0.97 mg/dm^2 (Reference 1).

These tests show that the effects of galvanic corrosion are insignificant in systems containing borated water.

9.1.4 Minimum Operating Conditions

The minimum operating conditions for the chemical and volume control system are contained in the Technical Specifications.

9.1.5 Tests and Inspections

Periodic testing, calibration, and inspection are conducted on the various instrument channels to ensure proper instrument response and operation of alarm functions. The minimum frequencies for testing, calibrating, and inspection are contained in the Technical Specifications.

Most components are in use regularly during power operation; therefore, assurance of the availability and performance of the system and equipment is provided.
