Chapter 7

INSTRUMENTATION AND CONTROL SYSTEMS

7.1 INTRODUCTION

Chapter 7 presents design and performance information for instrumentation and control (I&C) of safety-related and major plant control systems used throughout the plant. The design and performance considerations of these systems, safety function, and their mechanical aspects are described in other chapters.

7.1.1 IDENTIFICATION OF SAFETY-RELATED SYSTEMS

The systems are classified according to Regulatory Guide 1.70, Revision 2. Table 7.1-1 lists safety-related and safe shutdown systems and identifies the designer and/or the supplier. Other control systems are listed in Table 7.7-1. Table 7.1-2 identifies I&C systems that are identical to those of a nuclear power plant of similar design that received NRC design or operation approval through the issuance of either a construction permit or an operating license.

The following is a brief description of reactor protection (trip) system (RPS), engineered safety feature systems, safe shutdown systems, safety-related display instrumentation and other systems required for safety.

7.1.1.1 Reactor Protection System

The I&C initiate reactor shutdown via automatic control rods insertion (scram) if selected variables exceed preestablished limits. This action prevents fuel damage, limits nuclear system pressure, and restricts the release of radioactive material.

7.1.1.2 Primary Containment and Reactor Vessel Isolation Control System

The I&C initiate automatic closure of various reactor pressure boundary and primary containment isolation valves if monitored system variables exceed preestablished limits. This action limits the loss of coolant from the reactor coolant pressure boundary (RCPB) and the release of radioactive materials from either the RCPB or the primary containment.

7.1.1.3 Emergency Core Cooling System

The I&C provide automatic initiation and control of specific core cooling systems, namely, high-pressure core spray (HPCS) system, automatic depressurization system (ADS), low-pressure core spray (LPCS) system, and the low-pressure coolant injection (LPCI) system. This provides adequate core cooling following a loss-of-coolant accident (LOCA) to prevent fuel cladding failure from excessive temperatures.

7.1.1.4 Neutron Monitoring System

The I&C use in-core neutron detectors to monitor core neutron flux. The neutron monitoring system (NMS) provides signals to the RPS trip logic to scram the reactor. Average neutron flux or average simulated thermal power is measured by the average power range monitors (APRM) and is used as the overpower indicator during power operation. Intermediate range monitors (IRM) are used as power indicators during startup and shutdown. The NMS also provides power level indication during all modes of operation.

Also included within NMS is the Oscillation Power Range Monitor (OPRM), which is used to detect thermal hydraulic oscillations.

7.1.1.5 Process Radiation Monitoring System

Radiation monitors are provided on process lines to monitor/detect and provide trip signals to limit the release of radiation:

a. Main steam line radiation monitors,
b. Reactor building exhaust radiation monitors, and
c. Standby service water radiation monitors.

7.1.1.6 Main Control Room and Critical Switchgear Rooms Heating, Ventilating, and Air Conditioning System

In the event of an F, A, or Z signal, the normal control room fresh air intake valves close. The signal energizes the control room emergency filtration units which divert air through the filters to pressurize the main control room. The main control room kitchen exhaust fan and its isolation damper are also shut off by the F, A, Z signals.

7.1.1.7 Standby Service Water System

The I&C automatically initiate cooling water flow to vital equipment during abnormal plant conditions.

7.1.1.8 Containment Atmosphere Control System

The I&C monitor the concentration of hydrogen and oxygen gas present in the primary containment during and after a postulated LOCA.

7.1.1.9 Reactor Core Isolation Cooling System

The I&C provide makeup water to the reactor vessel in the event the reactor becomes isolated accompanied by a loss of flow from the reactor feedwater system during normal plant operation or plant transients.

7.1.1.10 Standby Liquid Control System

The I&C in conjunction with manual initiation provide a redundant reactivity control system that can shut the reactor down from rated power to the cold condition in the event that all withdrawn control rods cannot be inserted manually by the reactor manual control system to achieve reactor shutdown.

7.1.1.11 Leak Detection System

The I&C provide various temperature, pressure, level, and flow sensors to detect, annunciate, and isolate (in certain cases) water and steam leakage paths in selected reactor systems.

7.1.1.12 Residual Heat Removal System - Shutdown Cooling Modes

The I&C in conjunction with manual initiation of either the normal or alternate shutdown provide cooling to remove decay and sensible heat from the reactor vessel so that the reactor can be refueled and serviced.

7.1.1.13 Fuel Pool Cooling and Cleanup System

The I&C monitor fuel pool water temperature.

7.1.1.14 Suppression Pool Temperature Monitoring System

The I&C are provided to determine when special operating procedures are required to avoid elevated suppression pool temperatures.

7.1.1.15 Standby Gas Treatment System

The I&C control standby gas treatment (SGT) system operation during abnormal conditions to limit radioactive material releases.

7.1.1.16 (DELETED)

7.1.1.17 Safety-Related Display Instrumentation

The I&C provide information to the reactor operators to support manual safety actions or to allow assessment of safety system status.

7.1.1.18 Containment Instrument Air System

The I&C provide uninterruptable instrument air or nitrogen to essential ADS valve accumulators inside primary containment.

7.1.1.19 Residual Heat Removal System - Containment Spray Cooling Mode

The I&C provide for the manual initiation of the residual heat removal (RHR) system subsystem that condenses steam in the drywell and suppression chamber following a LOCA. The drywell sprays (with or without the RHR heat exchangers) may be used to remove airborne radioactivity from the containment atmosphere in response to a LOCA.

7.1.1.20 Remote Shutdown System

The I&C provide the capability for safe shutdown of the reactor in the event the main control room becomes uninhabitable.

7.1.1.21 Recirculation Pump Trip

The I&C are provided to supplement plant shutdown at the end of a fuel cycle when control rod worths are reduced by core nuclear characteristics.

7.1.1.22 Residual Heat Removal System - Suppression Pool Cooling Mode

The I&C in conjunction with the suppression pool temperature monitor provides information to the reactor operators to support manual initiation of this subsystem of the RHR system that cools the suppression pool water to avoid elevated pool temperatures.

7.1.1.23 Anticipated Transient Without Scram Recirculation Pump Trip

The I&C trip the reactor recirculation pump motors in the event of an anticipated transient without scram (ATWS).

7.1.1.24 Anticipated Transient Without Scram - Alternate Rod Insertion

The I&C provide an alternative method of inserting the control rods in the event of an ATWS.

7.1.2 IDENTIFICATION OF SAFETY CRITERIA

The I&C equipment design is based on the need to have the system perform its intended function while meeting the requirements of applicable general design criteria (GDC), regulatory guides, industry standards, and other documents. See Sections 7.2 through 7.6 for a discussion of the design bases for each safety-related system.

7.1.2.1 Regulatory Requirements

The plant safety-related systems have been examined with respect to specific regulatory requirements that are applicable to the instrument and controls of these systems. The specific regulatory requirements pertaining to each system's I&C is specified in Table 7.1-3. For a discussion of the degree of conformance see the individual systems analysis portions in Sections 7.1 through 7.6.

7.1.2.2 Regulatory Conformance - 10 CFR 50 Appendix A

Section 3.1 provides a discussion of those GDC that apply equally to all safety-related, safe shutdown, and augmented quality systems described in this chapter and include GDC 1, 2, 3, 4, 10, 13, 54, 55, and 56. Those GDC which do not apply equally to all safety-related, safe shutdown, and augmented quality systems are discussed for each system in the analysis portion of Sections 7.2 through 7.6.

7.1.2.3 Conformance to Institute of Electrical and Electronics Engineers Standards

The following is a discussion of those IEEE Standards which apply equally to all safety-related systems described in this chapter. Those IEEE Standards which do not apply equally to all safety-related systems are discussed for each system in the analysis portion of Sections 7.2 through 7.6:

IEEE 308-1974 - Class IE Power Systems for Nuclear Power Generating Stations

IEEE 308-1974 is described in Section 8.3.

IEEE 317-1972 - Electric Penetration Assemblies in Containment Structures*

All containment electrical penetration assemblies used for circuits routed into primary containment are designed to withstand, without loss of containment integrity, the maximum postulated overcurrent vs. time conditions, assuming a single failure of the circuit primary

*For the replacement of the electrical penetration modules, use the version of IEEE 317 that is in effect at the time of purchase and documented in the design specifications.

overcurrent protection apparatus. See also Sections 1.8 (Regulatory Guide 1.63), 3.8.6, and 8.1.5.2.

IEEE 323-1971 - Qualifying Class 1E Equipment for Nuclear Power Generating Stations

Written procedures and responsibilities are developed for the design and qualification of all Class 1 electric equipment. This includes preparation of specifications, qualification procedures, and documentation. Qualification testing or analysis is accomplished prior to release of the engineering design for production. Standards manuals are maintained containing specifications, practices, and procedures for implementing qualification requirements, and an auditable file of qualification documents is available for review. See Sections 1.8.2, 1.8.3, 3.10 and 3.11 for a description of conformance to IEEE 323. NUREG 0588-Category II invokes IEEE-323-1971 with additional regulatory positions.

IEEE 336-1971 - Installation, Inspection, and Testing Requirements for Instrumentation and Electric Equipment During the Construction of Nuclear Power Generating Stations

Where applicable, purchase and contract specifications define installation, inspection, and testing requirements for plant I&Cs. See the Energy Northwest Operational Quality Assurance Program Description (OQAPD).

IEEE 338-1975 - Periodic Testing of Nuclear Power Generating Stations

IEEE 338 is presented on a system basis in the analysis portions of Sections 7.2 through 7.6 as part of the discussion of Regulatory Guide 1.22 compliance.

IEEE 344-1971 and 1975 - Seismic Qualification of Class 1E Equipment

Safety-related I&C equipment is classified as Seismic Category I, designed to withstand the effects of the safe shutdown earthquake (SSE) and remain functional during normal and accident conditions. Qualification and documentation procedures used for Seismic Category I equipment and systems are identified in Section 3.10 and Table 3.2-1. Section 3.10.1.2 identifies compliance to these standards and applicable exceptions.

IEEE 379-1972 - Application of Single Failure Criterion to Nuclear Power Generating Stations

The extent to which the single failure criteria of IEEE 379 is satisfied is specifically covered for each system in the analysis of IEEE 279, paragraph 4.2, in Sections 7.2 through 7.6.

IEEE 384-1974 - Independence of Class 1E Equipment and Circuits

The safety-related systems described in Sections 7.2 through 7.6 meet the independence and separation criteria for redundant systems in accordance with IEEE 279, paragraph 4.6.

The electrical power supply, instrumentation, and control wiring for redundant safety-related circuits are physically separated to preserve redundancy and ensure that no single credible event will prevent completion of the protective function. Credible events include but are not limited to the effects of short circuits, pipe rupture, pipe whip, high-pressure jets, missiles, fire, earthquake, and falling objects, and are considered in the basic plant design.

The independence of wiring, tubing, piping, and control devices for safety-related controls and instrumentation is achieved by physical space or barriers between separation groups of the same protective function.

The criteria and bases for the independence of safety-related I&Cs, electrical equipment, cable, cable routing, marking, and cable derating, are discussed in Section 8.3.1.4. Fire detection and protection in the areas where cabling is installed is described in Appendix F.

IEEE 387-1972 - Diesel-Generator Units Applied as Standby Power Supplies for Nuclear Power Generating Stations

Design and qualification testing of the standby power system used to furnish electrical power to safety loads conforms to IEEE 387 to ensure that system requirements for redundancy, single failure criteria, adequate capacity, capability, and reliability are adequately met. The standby power source as an integrated system component satisfies the requirements of IEEE 308 as discussed in Section 8.3. Section 8.3.1.2.2 identifies compliance to these standards and applicable exceptions.

7.1.2.4 Conformance to Regulatory Guides

The following is a discussion of Regulatory Guides which apply to safety-related systems described in this chapter. Unique applications of Regulatory Guides are discussed for each system in the applicable analysis portion of Sections 7.2 through 7.6 and Section 1.8.

Regulatory Guide 1.11 (March 1971)

All instrument lines that penetrate the primary containment vessel, which are part of safety-related systems, meet the requirements of Regulatory Position C.1. This is accomplished by redundancy, independence, by allowing for safety system testability, by line orificing or sizing, by including automatic or remote manual (from the control room) line shutoff capability if line integrity is lost, and by a conservative design at the individual penetrations.

All other instrument lines that penetrate the primary containment vessel meet the requirements of Regulatory Position C.2.a by the same factors discussed above.

See Section 6.2.4.3.2.4 for further discussion.

Regulatory Guide 1.22

Lifting of leads and/or removal of fuses is required to perform a number of surveillance tests. Surveillance tests for which lifting of leads and/or removal of fuses is required fall into the following categories: (1) tests for thermocouples, (2) tests requiring introduction of test equipment into the instrument channel, (3) tests that otherwise would be unreasonably complex, (4) tests which must be performed before entering the mode in which normally testable, and (5) tests on systems or components for which the configuration permits no reasonable alternative.

Plant procedures for these surveillance tests include instructions explicitly requiring the reconnecting of the lifted leads and/or replacement of fuses. Restoration is documented and verified in accordance with guidance provided in Information Notice 84-37.

Regulatory Guide 1.29 (September 1978)

All safety-related I&C equipment is classified as Seismic Category I, designed to withstand the effects of the SSE and remain functional during normal and accident conditions. Qualification and documentation procedures used for Seismic Category I equipment and systems are identified in Section 3.10 and Table 3.2-1.

Regulatory Guide 1.30 (August 11, 1972)

The quality assurance requirements of IEEE 336-1971 (see Section 7.1.2.3 discussion above) were applicable during the plant design and construction phases and implemented as an operational quality assurance program during plant operation in response to Regulatory Guide 1.30. The specific requirements of Regulatory Guide 1.30 are met as discussed in the OQAPD.

Regulatory Guide 1.40 (March 16, 1973)

The containment recirculation and head area return fans have been qualified for use in containment in accordance with IEEE 334-1974. Qualification testing was successfully performed on a prototype fan for motor heat aging, fan resonant search, vibration endurance, and LOCA simulation. Recirculation and head area return fans will be used as the hydrogen mixing system in the event of a LOCA. See also Section 9.4.11.3.

Regulatory Guide 1.47 (1973)

Each safety-related system described in Sections 7.2, 7.3, 7.4, and 7.6 is provided with an automatically or operator initiated system level bypass and inoperability annunciator. Each system level annunciator is located on the panel containing the controls for the specific system.

In addition to system level annunciation, component level indicators are provided near the system lever annunciator to indicate the cause of the system bypass or inoperability.

A switch is provided for manual actuation of each system level annunciator to allow display of those bypass or inoperable conditions which are expected to occur at a frequency less than once per year and are not automatically indicated.

Typically, the following bypasses or inoperabilities cause actuation of system level (and component level) annunciation for the affected system:

a. Pump motor breaker not in operating position,

b. Loss of pump motor control power,

c. Loss of motor-operated valve control power/motive power,

d. Logic power failure,

e. Logic in test,

f. Position of remote-manual valves which do not receive automatic alignment signals, and

g. Bypass or test switches actuated.

The manually induced inoperable or bypass condition of an auxiliary supporting system, typically, also results in the loss of function (immediate or delayed) of another safety-related or important-to-safety system. To ensure that the operators recognize that more than one system may be out-of-service, typically, an inoperable or bypassed auxiliary support system will not only cause actuation of the auxiliary support system, system-level annunciator, but also will cause the actuation of the system-level annunciator of the supported system. The exception to this typical design is the diesel generator system, the battery system, and the standby service water system. For these three systems, an inoperable or bypass condition will not result in the actuation of the supported systems, system-level annunciators. However, component-level indicating lamps will be actuated at each of the supported system locations to alert operators of the auxiliary system out-of-service condition. These three systems are not designed to cascade to all the supported systems since each has its own out-of-service annunciation. This design reduces potential operator confusion and also distraction that may occur during a transient or accident event.

Regulatory Guide 1.63 (October 1973)

All containment electrical penetration assemblies used for circuits routed into primary containment are designed to withstand, without loss of containment integrity, the maximum postulated overcurrent vs. time conditions, assuming a single failure of the circuit primary overcurrent protection apparatus. See also Sections 7.1.2.3 (IEEE 336), 1.8, 3.8.6, and 8.1.5.2.

Regulatory Guide 1.68 (November 1973)

Plant preoperational and initial startup test program requirements are discussed in Section 14.2.7.

Regulatory Guide 1.73 (January 1974)

Auxiliary equipment associated with valve operators are tested in accordance with the requirements of Regulatory Guide 1.73. Design service conditions are implemented in the tests. Conservative values of the environmental variables during and after a design-basis accident are used in the tests to ensure that the testing is carried out under more severe environmental conditions than those expected.

Regulatory Guide 1.75 (January 1974)

Regulatory Guide 1.75 is not applicable to the Columbia Generating Station (CGS) design. However, a complete description of the CGS physical and electrical separation criteria is discussed in Section 8.3.1.4.

Regulatory Guide 1.80 (June 1974)

Plant preoperational testing of instrument air systems is discussed in Sections 14.2.7 and 14.2.12.

Regulatory Guide 1.89 Revision 1 (June 1984)

Regulatory Guide 1.89 Revision 1 is applicable to the CGS design as clarified in Sections 1.8.2 and 1.8.3. Qualification of Class 1E equipment is discussed in Section 3.11.

7.1.2.5 Instrument Errors

The design of each safety-related system considers instrument drift, setability, and repeatability in the selection of I&C in the determination of setpoints. Adequate margin between safety limits and instrument setpoints is provided to allow for instrument error. The allowable values are listed in the Technical Specifications. The Licensee Controlled Specifications (LCS) also

contain information related to instrument setpoint determinations. The amount of instrument error is determined by test and experience. The setpoint is selected based on these known errors. The surveillance frequency is increased on instrumentation that demonstrates a tendency to drift or decreased based on stable performance characteristics.

7.2 REACTOR PROTECTION (TRIP) SYSTEM

7.2.1 DESCRIPTION

The reactor protection system (RPS) is designed to cause rapid insertion of control rods (scram) to shut down the reactor when specific variables exceed predetermined limits.

7.2.1.1 Reactor Protection System Description

Schematic arrangements of RPS mechanical equipment and information displayed to the operator are shown in Figure 7.2-1. The RPS component control logic is shown in Figure 7.2-2. The RPS instrumentation is listed in Table 7.2-1. The RPS channel and logic arrangement are shown in Figure 7.2-3. The RPS actuators and logic arrangement are shown in Figure 7.2-4. Trip system logic is shown in Figure 7.2-5. Sensor input arrangements are shown in Figures 7.2-6, 7.2-7, 7.2-8, 7.2-9, and 7.2-10.

The RPS instrumentation is divided into sensor trip channels, trip logic, and trip actuator logic.

During normal operation, all sensor contacts and trip contacts essential to safety are closed; channels, logic, and actuators are energized.

There are at least four sensor trip channels for each variable. The sensor trip channels are designated as A1, A2, B1, and B2. Each sensor trip channel is associated with the trip logic of the same designation.

Trip actuator logics A1 and A2 (trip system A) outputs are combined in a one-out-of-two logic arrangement to control the "A" pilot scram valve solenoid in each of the four rod groups (a rod group consists of approximately 25% of the total of control rods). Trip actuator logic B1 and B2 (trip system B) outputs control the "B" pilot scram valve solenoids in each of the four rod groups.

When a sensor trip channel contact opens, the trip logic deenergizes the trip actuator logic which deenergizes the pilot scram valves associated with that trip actuator logic. However, the other pilot scram valves for each rod must also be deenergized before the scram valves provide a reactor scram.

There are two pilot scram valves and two scram valves for each control rod. Each pilot scram valve is solenoid operated, with the solenoids normally energized. The pilot scram valves control the air supply to the scram valves for each control rod. With either pilot scram valve energized, air pressure holds the scram valves closed. The scram valves control the supply and discharge paths for control rod drive (CRD) water.

When both actuator logic A1 or A2 and B1 or B2 are tripped, air is vented from the scram valves and allows CRD water to act on the CRD piston. Thus, all control rods are scrammed. The water displaced by the movement of each rod piston is exhausted into a scram discharge volume (SDV).

To restore the RPS to normal operation following any single actuator logic trip or a scram, the trip actuators must be reset manually. After a 10-sec delay reset is possible only if the conditions that caused the scram have been cleared. The trip actuators are reset by operating switches in the main control room. Two reset push button switches (A1/B1 and A2/B2) are provided.

There are two 125-V dc solenoid-operated backup scram valves that provide a second means of controlling the air supply to the scram valves for all control rods. When the solenoid for either backup scram valve is energized, the associated backup scram valve vents the air supply for the scram valves. This action initiates insertion of any withdrawn control rods regardless of the action of the scram pilot valves. The backup scram valves solenoids are energized (initiate scram) when trip logic A1 or A2 and B1 or B2 are both tripped.

The RPS receives power from two high inertia ac motor generator (MG) sets. A flywheel provides high inertia sufficient to maintain voltage and frequency within 5% of rated values for at least 1 sec following a momentary loss of power to the drive motor (see Section 8.3.1.1.6).

Alternate power is available to each RPS bus and is manually switched to the bus as necessary for maintenance of the RPS MG sets. The alternate power switch is interlocked to prevent simultaneous feeding of both buses from the same source. The switch also prevents paralleling of an MG set with the alternate supply.

The RPS is designed to use a fail-safe logic and actuation scheme. Therefore, the power supplied by the RPS MG sets to hold RPS components energized is expendable and considered non-safety-related. However, to ensure that overvoltage, undervoltage, or underfrequency do not damage safety-related components within the RPS, two series redundant Class 1E bus monitoring and tripping devices are provided between the RPS bus and each of the non-Class 1E power sources. These devices trip whenever the voltage and frequency exceed predetermined limits (see Figure 8.3-2 and Section 8.3.1.1.6).

An electrical protection assembly (EPA) consisting of Class 1E protective circuitry is installed between the RPS and each of the power sources, which consists of two MG sets and alternate voltage supplies. The EPA provides redundant protection to the RPS and other systems which receive power from the RPS buses by acting to disconnect the RPS from the power source circuits. See Figure 7.2-11.

Sensor trip channel inputs to the RPS causing reactor scram are discussed in the following paragraphs.

7.2.1.1.1 Neutron Monitoring System Trip

To protect the fuel against high heat generation rates, neutron flux is monitored and initiates a reactor scram when predetermined limits are exceeded.

Neutron monitoring system instrumentation is described in Section 7.6. Figure 7.2-6 clarifies the relationship between neutron monitoring system (NMS) channels, NMS logic, and the RPS logic. The NMS sensor channels are considered to be part of the NMS and not the RPS; however, the NMS logic channels are considered to be part of the RPS. Each NMS logic channel receives signals from one intermediate range monitor (IRM) channel and one average power range monitor (APRM) channel.

The NMS logic is arranged so that failure of any one logic channel cannot prevent the initiation of a high neutron flux or simulated thermal power scram. As shown in Figure 7.6-3, there are eight NMS logic channels associated with the RPS. Each RPS logic channel receives inputs from two NMS logic channels.

The source range monitors (SRMs) are not credited to perform any safety function in the plant design basis transients. For that reason, the trip signal inputs from the SRMs are normally removed from the RPS circuitry by the installation of "shorting links". With the "shorting links" installed, the SRM indication and rod block remain fully operable but the SRM trip is bypassed.

The "shorting links" are required to be removed to support performance of shutdown margin testing in Mode 5 under Limiting Condition for Operation (LCO) 3.10.8, "Shutdown Margin (SDM) Test — Refueling." The removal of the "shorting links" during this testing provides a noncoincident NMS trip when any SRM exceeds the high-high flux trip setpoint, any IRM exceeds the high flux trip setpoint. The removal of the "shorting links" is required to be verified within 8 hours prior to placing the Mode switch into the startup/hot standby position and at least once per 12 hours during the time the Mode switch is in the startup/hot standby position when in Mode 5.

7.2.1.1.1.1 Intermediate Range Monitors. The IRMs monitor neutron flux between the upper portion of the SRM range to the lower portion of the APRM range. The IRM detectors are positioned in the core remotely from the control room.

The IRM is divided into two groups of four IRM channels arranged in the core as shown in Figure 7.6-8. Two IRM channels are associated with each of the trip logic channels of the RPS. The arrangement of IRM channels allows one IRM channel in each group to be bypassed without compromising the IRM trip function.

The NMS scram logic trip contacts for IRM can be bypassed by selector switches located on the reactor control benchboard in the main control room. The IRM channels A, C, E, and G bypasses are controlled by one selector switch. Channels B, D, F, and H are controlled by a second selector switch. Each selector switch will bypass only one IRM channel at any time. Bypassing an IRM channel will not inhibit the NMS from providing a protective action when required.

Each IRM channel includes four trip circuits. One trip circuit is used as an instrument trouble trip. It operates on four conditions: (1) when the high voltage drops below a preset level, (2) when one of the modules is not plugged in, (3) loss of negative 15-V dc, or (4) the IRM not in the OPERATE position. Each of the other trip circuits is specified to trip when preset downscale or upscale levels are reached.

The reactor mode switch determines whether IRM trips are effective in initiating a reactor scram. With the reactor mode switch in REFUEL or STARTUP, an IRM upscale or inoperative trip signal actuates an NMS trip of the RPS. At least one IRM channel in each RPS trip system must trip to cause a scram.

7.2.1.1.1.2 Average Power Range Monitors. There are four APRM channels. Each APRM channel consists of an APRM instrument, 2/4 logic module, quad low voltage power supply, local power range instrument, and a calibration/monitoring panel. The APRM channels receive and average input signals from the local power range monitor (LPRM) channels and provide a continuous indication of average reactor power from a few percent to greater than rated reactor power.

The APRMs supply neutron flux high, simulated thermal power, and INOP trip signals to the 2-Out-of-4-Voters. The outputs from all four APRM channels instruments go to each 2-Out-of-4-Voter (logic) module. Each of the 2/4 logic modules interface to one of the four RPS input channels (A1, A2, B1, and B2). The trip outputs from all four APRMs are sent to each 2/4 logic module, such that each input sent to the RPS is a voted result of all four APRMs. A trip output to the RPS is provided when at least two of the same type of trip inputs is in a tripped state for at least two non-bypassed ARPMs.

APRM channel instrumentation trip inputs to the 2/4 logic modules can be bypassed by a single fiber optic selector switch on the reactor control benchboard in the main control room. Each 2/4 logic module is designed to receive a fiber optic bypass of its "home" APRM instrument. The state of that bypass signal is retransmitted to the other 2/4 logic modules in an isolated manner. Each 2/4 logic module will bypass the appropriate channel trip inputs when a bypass signal is active (modulated light is detected) for the APRM channel. Each 2/4 logic module will provide trip outputs to RPS as a voted result of the three unbypassed APRMs when one channel is bypassed, resulting in a 2/3 logic configuration. Bypassing an APRM will not inhibit NMS from performing its safety function. If a bypass indication from more than one APRM channel is received, none of the APRM inputs to the 2/4 logic modules will be bypassed and a trouble alarm will be generated by the "home" APRM.

Each APRM channel receives an independent flow signal input from each of the two recirculation loops and determines the total recirculation driving flow by summing these loop flow inputs. A total of eight loop flow signals are sensed from four pairs of elbow taps. Each pair has an elbow tap in each recirculation loop.

Total recirculation flow rate is calculated by each APRM chassis by adding the flow values for each loop to obtain total flow. The total flow value is used to produce flow biased APRM scram and APRM rod block setpoint values increase proportionally with total recirculation flow rate. The total recirculation flow is also used in the OPRM enable logic.

The LPRM signals are averaged to achieve an APRM flux value. The APRM flux value is then adjusted by a manually entered or digitally transferred gain factor to allow calibration of the APRM. The APRM power is processed through a first order filter with a six second time constant to calculate simulated thermal power. Each APRM channel also calculates a flow signal that is used to determine the APRM's flow –biased rod block and scram setpoints. The APRM simulated thermal power upscale rod block and scram trip setpoints are varied as a function of reactor recirculation flow. The slope of the upscale rod block and scram trip response curves is set to track the required trip setpoint with recirculation flow changes. These calculations are all performed by the digital processor and results in a digital representation of APRM and simulated thermal power, and of the flow-biased rod block and scram setpoints.

At least one APRM voter in each trip system of the RPS must trip to cause a scram. A simplified circuit arrangement is shown in Figure 7.6-11.

Each APRM also includes an Oscillation Power Range Monitor (OPRM) Upscale function. The OPRM Upscale Function receives input signals from the LPRMs within the reactor core, which are combined into the "cells" for evaluation by the OPRM algorithms. Upon detection of thermal hydraulic oscillations, the OPRM initiates an automatic RPS trip signal (see Section 7.6.1.4.4).

In addition to the IRM upscale trip, a fast response APRM trip function with a setpoint of 15% power is active when the reactor mode switch is in the "startup" position.

Diversity of trip initiation for excursions in reactor power is provided by the NMS trip signals and reactor vessel high pressure trip signals. An increase in reactor power will initiate protective action from the NMS as discussed above. This increase in power will cause reactor pressure to increase due to a higher rate of steam generation with no change in turbine control valve position resulting in a trip from reactor vessel high pressure. These variables are independent of one another and provide diverse protective action for this condition.

7.2.1.1.2 Reactor Vessel Pressure

A reactor vessel pressure increase during reactor operation compresses the steam voids and results in increased reactivity; this causes increased core heat generation that could lead to fuel failure and system overpressurization. A scram counteracts a pressure increase by quickly reducing core fission heat generation. The reactor vessel high pressure scram works in conjunction with the pressure relief system to prevent reactor vessel pressure from exceeding the maximum allowable pressure. The reactor vessel high pressure scram setting also protects the core from exceeding thermal hydraulic limits that result from pressure increases during events that occur when the reactor is operating below rated power and flow.

Reactor pressure is monitored by four redundant pressure switches, each of which provides a reactor high pressure signal input to one of the four RPS sensor trip channels.

7.2.1.1.3 Reactor Vessel Water Level

Decreasing water level while the reactor is operating at power decreases the reactor coolant. Should water level decrease too far, fuel damage could result as steam voids form around fuel rods. A reactor scram reduces the fission heat generation within the core.

Reactor vessel water level is monitored by four redundant differential pressure switches each of which provides a reactor vessel low water level (trip level 3) signal input to one of the four RPS sensor trip channels.

Diversity of trip initiation for breaks in the reactor coolant pressure boundary (RCPB) is provided by reactor vessel low water level trip signals and high drywell pressure trip signals.

7.2.1.1.4 Turbine Throttle Valve Position

With the reactor above 29.5% power, generator load rejection or a turbine trip will initiate closure of the turbine throttle valve which can result in a significant addition of positive reactivity to the core as the reactor vessel pressure rise causes steam voids to collapse. The turbine throttle valve closure scram initiates a scram earlier than either the NMS or reactor vessel high pressure to provide required margin below core thermal-hydraulic limits for this category of abnormal operational transients. The scram counteracts the addition of positive reactivity caused by increasing pressure by inserting negative reactivity with control rods. Although the reactor vessel high pressure scram, in conjunction with the pressure relief system, is adequate to preclude overpressurizing the nuclear system, the turbine throttle valve closure scram provides additional margin to the reactor vessel pressure limit.

Turbine throttle valve closure inputs to the RPS originate from eight redundant valve stem position switches mounted on the four turbine throttle valves. Each of the switches opens before the valve is more than 10% closed to provide the earliest positive indication of closure. Each switch provides an input signal to one of the four RPS sensor trip channels. The logic is arranged so that closure of three or more valves is required to initiate a scram. The switches are arranged so that no single failure can prevent a turbine throttle valve closure scram.

Diversity of trip initiation for increases in reactor vessel pressure due to termination of steam flow by turbine throttle valve or governor valve closure is provided by reactor vessel high pressure and high neutron flux trip signals.

Turbine throttle valve closure trip bypass is effected by four pressure switches sensing turbine first stage pressure. The turbine throttle valve closure scram is automatically bypassed if the turbine first stage pressure is less than that corresponding to 29.5% of rated reactor power. The bypass is automatically removed above 29.5% of reactor power.

7.2.1.1.5 Turbine Governor Valve Position

Generator load rejection or a turbine trip with the reactor above 29.5% power automatically initiates fast closure of the turbine governor valves which results in a significant addition of positive reactivity to the core as nuclear system pressure rises. The turbine governor valve fast closure scram initiates a scram earlier than either the NMS or nuclear system high pressure to provide required margin below core thermal-hydraulic limits for this category of abnormal operational transients. The scram counteracts the addition of positive reactivity resulting from increasing pressure by inserting negative reactivity with control rods. Although the nuclear system high pressure scram, in conjunction with the pressure relief system, is adequate to preclude overpressurizing the nuclear system, the turbine governor valve fast closure scram provides additional margin to the nuclear system pressure limit. The turbine governor valve fast closure scram setting is selected to provide timely indication of governor valve fast closure.

Turbine governor valve fast closure inputs to the RPS originate from oil line pressure switches on each of four fast acting governor valve hydraulic mechanisms. Each pressure switch provides an input signal to one of the four RPS sensor trip channels. If hydraulic oil line pressure is lost, a turbine governor valve fast closure scram is initiated.

Automatic turbine governor valve fast closure scram bypass is provided as described above for the turbine throttle valve.

7.2.1.1.6 Main Steam Line Isolation Valves Position

The main steam line isolation valve (MSIV) closure can result in a significant addition of positive reactivity to the core as nuclear system pressure rises.

Two redundant position switches mounted on each of the eight MSIVs provide an MSIV closure signal to the RPS. Each of the switches is arranged to open before the valve is more than 10% closed to provide the earliest positive indication of closure. Either of the two channels sensing isolation valve position can signal valve closure.

Each RPS sensor trip channel logic receives signals from the valves associated with two steam lines. The arrangement of signals within each logic requires closing of at least one valve in each of the two steam lines associated with that logic to cause a trip of that logic. Closure of at least one valve in three or more steam lines is required to initiate a scram.

At plant shutdown and during initial plant startup, a bypass is required for the MSIV closure scram trip to properly reset the RPS. This bypass is in effect when reactor pressure is less than scram setpoint pressure and the mode switch is in the shutdown, refuel, or startup position. The bypass allows plant operation when the MSIVs are closed during low power operation. The operating bypass is removed when the mode switch is placed in RUN.

Diversity of trip initiation due to main steam isolation is provided by reactor vessel high pressure and reactor power trip signals.

7.2.1.1.7 Scram Discharge Volume Water Level

Water displaced by the CRD pistons during a scram goes to the SDV. If the SDV fills with water so that insufficient capacity remains for the water displaced during a scram, control rod movement would be hindered during a scram. To prevent this situation, the reactor is scrammed when the water level in the discharge volume is high enough to verify that the volume is filling up, yet low enough to ensure that the remaining capacity in the discharge volume can accommodate a scram.

Two transmitter/level switches (non-indicating) and two transmitter/level indicating switches directly connected to each of two instrument volumes monitor the volumes for abnormal level. They provide redundant and diverse input to the RPS scram function. One transmitter on each instrument volume also provides input for the control room annunciation and control rod withdrawal block function. The four level switches and the four level indicating switches are interconnected (one of each per trip channel) with the RPS system and initiate a reactor scram on high water level while sufficient volume for full scram still exists within the SDV. To provide diversity for the RPS function the two transmitters per channel use a different sensing operating principle and have a different transmitter manufacturer. The level switches and the level indicating switches in each channel are also from different manufacturers. This arrangement provides diversity, as well as redundancy, to ensure that no single event can prevent a scram caused by SDV high water level.

A scram is automatically initiated when sufficient capacity still remains in the discharge volume to accommodate a scram.

The SDV high water level trip bypass is controlled by the manual operation of two key-locked switches, a bypass switch, and the mode switch. The mode switch must be in the shutdown or refuel position to allow manual bypass of this trip. This bypass allows the operator to reset the RPS scram relays so that the SDV may be drained. Resetting the trip actuators opens the SDV vent and drain valves. An annunciator in the main control room indicates the bypass condition.

7.2.1.1.8 Drywell Pressure

High pressure inside the drywell may indicate a break in the RCPB. Scram is initiated to minimize the possibility of fuel damage. Drywell pressure is monitored by four redundant pressure switches. Each switch provides an input to one of the four RPS sensor trip channels.

7.2.1.1.9 Manual Scram

A scram can be initiated manually. There are four scram switches, one for each of the four RPS trip logic channels. The manual scram switches are arranged in two groups of two switches. One group contains the A1 and B1 switches and the other group contains the A2 and B2 switches. To initiate a manual scram, at least two switches in a group must be depressed. By operating the manual scram switch for one logic channel at a time and then resetting that logic, each actuator logic can be tested for manual scram capability.

7.2.1.1.10 Reactor Mode Switch Manual Scram

Even though the action is not a safety function, reactor scram can be initiated by placing the mode switch in the shutdown position. The mode switch consists of four independent banks of contacts. A shutdown position contact from each of the four banks is a scram input to the associated RPS trip logic channel. The relationship of the reactor mode switch position and its scram function is shown in Figure 7.2-2.

The scram signal, initiated by placing the mode switch in the shutdown position is automatically bypassed after 10 sec by a timer which allows the CRD hydraulic system valve lineup to be restored to normal before the control room operator can reset the RPS logic.

7.2.1.2 Design Basis

The RPS is designed to provide timely protection against the onset and consequences of conditions that threaten the integrity of the fuel barrier and the RCPB. Chapter 15 identifies and evaluates events that jeopardize the fuel barrier and RCPB. The methods of assessing barrier damage and radioactive material releases, along with the methods by which abnormal events are identified, are presented in that chapter. Variables are monitored to provide protective actions to the RPS indicating the need for reactor scram.

7.2.1.2.1 Variables Monitored to Provide Protective Actions

a. NMS trip,
b. Reactor vessel system high pressure,
c. Reactor vessel low water level,
d. Turbine throttle valve closure,
e. Turbine governor valve fast closure,
f. Main steam line isolation,
g. SDC high level, and
h. Drywell high pressure.

The plant conditions that require protective action involving the RPS are described in Chapter 15.

7.2.1.2.2 Location and Minimum Number of Sensors

Neutron flux is the only essential variable of significant spatial dependence that provides inputs to the RPS. The basis for the number and locations of sensors is discussed in the following. The other requirements are fulfilled through the combination of logic arrangement.

Two transient analyses are used to determine the minimum number and physical location of required LPRMs for each APRM.

The first analysis is performed with operating conditions of 100% reactor power and 100% recirculation flow using a continuous rod withdrawal of the maximum worth control rod. In the analysis, LPRM detectors are mathematically removed from the APRM channels. This process is continued until the minimum numbers and locations of detectors needed to provide protective action are determined for this condition.

The second analysis is performed with operating conditions of 100% reactor power and 100% recirculation flow using a reduction of recirculation flow at a fixed design rate. Again, LPRM detectors are mathematically removed from the APRM channels. This process is continued until the minimum numbers and locations of detectors needed to provide protective action are determined for this condition.

The number of LPRM detector signals available as inputs to an APRM channel shall satisfy the following criteria:

a. The number of operable LPRM detector inputs shall be at least 20. The PRNM provides an alarm and rod block. CGS enforces operability administratively.
b. The number of operable LPRM detector inputs per core axial level (A, B, C, or D) shall be at least 3. The PRNM provides an alarm and rod block. CGS enforces operability administratively.
c. The number of LPRM detector inputs that have become inoperable (and bypassed) since the most recent APRM calibration shall be less than 10. This requirement is enforced by administrative means and the Operation and Maintenance (O&M) Manual.

7.2.1.2.3 Prudent Operational Limits

Limits for each safety-related variable trip setting are selected with sufficient margin so that a spurious scram is avoided. It is then verified by analysis that the release of radioactive materials following postulated gross failures of the fuel or the RCPB is kept within acceptable bounds. Design basis operational limits, as listed in the Technical Specifications, are based on operating experience and constrained by the safety design basis and the safety analysis. The selection of tentative scram trip settings has been developed through analytical modeling, experience, historical use of initial setpoints, and adoption of new variables and setpoints as experience was gained. The initial setpoint selection method provided for settings which were sufficiently above the normal operating levels (to preclude the possibilities of spurious scrams or difficulties in operation), but low enough to protect the fuel and pressure barrier. As additional information becomes available or systems are changed, additional scram variables are provided using the above method for initial setpoint selection. The selected scram settings are analyzed to verify that they are conservative and that the fuel, fuel barriers, and nuclear system process barriers are adequately protected. In all cases, the specific scram trip point selected is a conservative value that prevents damage to the fuel or RCPB, taking into consideration previous operating experience and the analytical models.

7.2.1.2.4 Margin

The margin between operational limits and the limiting conditions of operation (scram) for the RPS are those parameters listed in the Technical Specifications. Annunciators are provided to alert the reactor operator of the onset of unsafe conditions.

7.2.1.2.5 Levels

Levels requiring protective action are specified in the Technical Specifications. These levels are design basis limits and are provided in the Technical Specifications as allowable values.

7.2.1.2.6 Malfunctions, Accidents, and Other Unusual Events Which Could Cause Damage to Safety Systems

Unusual events are defined as malfunctions, accidents, and others which could cause damage to safety systems. Chapters 3, 6, 9, 15, and Appendix F describe the following credible accidents and events: floods, storms, tornadoes, earthquakes, fires, loss-of-coolant accident (LOCA), pipe break outside containment, feedwater line break, and missiles. Each of these events is discussed below for the RPS.

All components essential to the operation of the RPS are designed, fabricated, and mounted to Class 1E standards. However, even though the sensors initiating reactor scram which monitor turbine throttle valve position and turbine governor valve fast closure are designed and purchased Quality Class 1, Seismic Category I, they are physically mounted on equipment which is not Seismic Category I/Quality Class 1, and are located in the turbine generator building which is not Seismic Category I but has been shown to maintain its structural integrity following an safe shutdown earthquake (SSE) (see Section 3.8).

For this reason other diverse variables (reactor pressure and neutron flux trips), which are Seismic Category I and Quality Class 1, may be relied on for reactor scram if components in the turbine generator building fail.

7.2.1.2.6.1 Floods. The buildings containing RPS components have been designed to meet the probable maximum flood (PMF) at the site location. See Section 2.4. For a discussion of internal flooding protection see Sections 3.4 and 3.6.

7.2.1.2.6.2 Storms and Tornadoes. The buildings containing RPS components, except the turbine generator building, have been designed to withstand all credible meteorological events and tornadoes as described in Section 3.3.

7.2.1.2.6.3 Earthquakes. The structures containing RPS components, except the turbine building, have been seismically qualified as described in Sections 3.7 and 3.8 and will remain functional during and following a SSE. However, as stated previously, other diverse variables (reactor pressure and neutron flux trips) may be relied on for reactor scram if components in the turbine generator building fail. The design features that prevent the following postulated

failures of turbine throttle and governor valve closure signals to the RPS during a seismic event from affecting other channels of the RPS from performing as required are the following:

a. Shorts to ground: Each trip function input circuit to the RPS is individually fused to prevent degradation of other channels if a short to ground occurs on one channel. This protection also applies to the turbine throttle and governor valve closure trip inputs to the RPS. Therefore, a short to ground would be interrupted by the protective fuses eliminating any interaction or degradation of other channels, as well as resulting in a channel trip due to "fail-safe" logic;

b. Opens: The normal operating state of the RPS trip inputs is a closed contact condition. Therefore, an open in an RPS input channel circuit would result in failure in the safe direction causing a trip of that channel with no degradation or interaction with other channels; and

c. Hot shorts: Reactor protection system cabling that is routed from trip instrumentation through the turbine generator building is enclosed in conduit. Each trip channel has a separate and dedicated conduit. Therefore, hot shorts would be confined to one channel of trip instrumentation and would not degrade or interact with other protective channels.

7.2.1.2.6.4 Fires. To protect the RPS in the event of a postulated localized raceway or panel fire, the RPS trip logics have been divided into four separate sections within two separate RPS panels. The sections within a panel are isolated by electrical separation barriers. If a fire were to occur within one of the sections or in the area of one of the panels, the RPS functions would not be prevented by the fire. The use of separation and barriers ensures that, even though some portion of the system may be affected, the RPS will continue to provide the required protective action. See Appendix F for a discussion of Appendix R fire effects on the RPS.

Within the control room Power Generation Control Complex (PGCC) (underfloor cable routing ducts) heat detectors and products of combustion detectors are provided to initiate a Halon fire suppression system.

Throughout main plant areas, redundant RPS cables are routed in separate raceway divisions sufficiently separated such that a fire cannot affect more than one RPS division.

7.2.1.2.6.5 Loss-of-Coolant Accident. The following RPS system components are located inside the drywell and would be subject to the effects of a design basis LOCA:

a. NMS cabling from the detectors to the main control room,

b. MSIV (inboard) position switches,

c. Reactor vessel pressure and reactor vessel water level instrument taps and sensing lines, which terminate outside the drywell, and

d. Drywell pressure instrument taps.

These items have been environmentally qualified to remain functional during and following a LOCA as discussed in Section 3.11.

7.2.1.2.6.6 Pipe Break Outside Primary Containment. Protection for pipe break outside primary containment is described in Section 3.6.

7.2.1.2.6.7 Missiles. Missile protection for RPS components is described in Section 3.5.

7.2.1.2.7 Minimum Performance Requirements

Minimum performance requirements for RPS instrumentation and controls are provided in the Technical Specifications.

7.2.1.3 Final System Drawings

Functional and architectural design differences between the PSAR and FSAR are listed in Table 1.3-8.

7.2.2 ANALYSIS

The RPS is designed such that loss of plant instrument air, a plant load rejection, or a turbine trip will not prevent the completion of the safety function.

7.2.2.1 Conformance to 10 CFR 50, Appendix A - General Design Criteria

The following is a discussion of conformance to those General Design Criteria (GDC) which apply specifically to the RPS. See Section 3.1 for a discussion of GDC that apply equally to all safety-related systems.

GDC 12 - Suppression of Reactor Power Oscillations

The system design provides protection from excessive fuel cladding temperatures and protects the RCPB from excessive pressures which threaten the integrity of the system. Abnormalities are sensed, and if protection system limits are reached, corrective action is initiated through an automatic scram.

GDC 15 - Reactor Coolant System Design

The RPS provides sufficient margin to ensure that the design conditions of the RCPB are not exceeded during any condition of normal operation, including anticipated operational

occurrences. If the monitored variables exceed their predetermined settings, the system automatically responds to maintain the variables and systems within allowable design limits.

GDC 20 - Protection System Functions

The RPS monitors the appropriate plant variables to maintain the fuel barrier and RCPB and initiates a scram automatically when the variables exceed predetermined limits.

GDC 21 - Protection System Reliability and Testability

The RPS is designed with two groups of redundant sensor channels and four independent and separated output channels. No single failure can prevent a scram and removal from service of any component or channel will not result in loss of required minimum redundancy.

GDC 22 - Protection System Independence

The redundant portions of the RPS are separated such that no single failure or credible natural disaster can prevent a scram, except the turbine scram inputs which originate from the Seismic Category II turbine building. Reactor pressure and power are diverse to the turbine scram variables. In addition, drywell pressure and vessel water level are diverse variables.

GDC 23 - Protection System Failure Modes

The RPS is designed (including logic and actuated devices) to be fail safe. A complete loss of electrical power or air supply will result in a reactor scram. Postulated adverse environments will not prevent a scram.

GDC 24 - Separation of Protection and Control Systems

The RPS has no direct interaction with any plant control system. However, the RPS does receive inputs from the reactor mode switch and the NMS which also provide inputs to plant control systems through isolation devices.

GDC 25 - Protection System Requirements for Reactivity Control Malfunctions

The RPS provides protection against the onset and consequences of conditions that threaten the integrity of the fuel barrier and the RCPB. Any monitored variable which exceeds the scram setpoint will initiate an automatic scram and not impair the remaining variables from being monitored, and if one channel fails the remaining portions of the RPS will function.

GDC 29 - Protection Against Anticipated Operational Occurrences

The RPS is highly reliable and will provide a reactor scram in the event of anticipated operational occurrences.

7.2.2.2 Conformance to IEEE Standards

The following is a discussion of conformance to IEEE 279-1971, Criteria for Protection Systems for Nuclear Power Generating Stations, that applies specifically to the RPS system. See Section 7.1.2.3 for a discussion of IEEE standards that apply equally to all safety-related systems.

General Functional Requirement (IEEE 279-1971, paragraph 4.1)

The RPS automatically initiates the appropriate protective actions whenever the conditions described in Section 7.2.1.1 reach predetermined limits with precision and reliability assuming the full range of conditions and performance discussed in Section 7.2.1.2.

Single Failure Criterion (IEEE 279-1971, paragraph 4.2)

Each of the conditions (variables) described in Section 7.2.1.1 is monitored by redundant sensors supplying input signals to redundant trip logics. Independence of redundant RPS equipment, cables, instrument tubing, etc., is maintained and single failure criteria preserved through the application of the Columbia Generating Station separation criteria as described in Section 8.3.1.4 to ensure that no single credible event can prevent the RPS from accomplishing its safety function.

Quality of Components and Modules (IEEE 279-1971, paragraph 4.3)

For a discussion of the quality of RPS components and modules see Section 3.11.

Equipment Qualification (IEEE 279-1971, paragraph 4.4)

Vendor certification requires that the sensors associated with each of the RPS trip variables, manual switches, and trip logic components perform in accordance with the requirements listed on the purchase specification as well as in the intended application. This certification in conjunction with the existing field experience with these components in this application will serve to qualify these components.

For a complete discussion of RPS equipment protection and qualification see Sections 3.5, 3.6, 3.10, and 3.11.

Channel Integrity (IEEE 279-1971, paragraph 4.5)

For a discussion of RPS channel integrity under all extremes of conditions described in Section 7.2.1.2, see Sections 3.10, 3.11, 8.2.1, and 8.3.1.

Channel Independence (IEEE 279-1971, paragraph 4.6)

The RPS channel independence is maintained through the application of the Columbia Generating Station separation criteria as described in Section 8.3.1.4.

Control and Protection System Interaction (IEEE 279-1971, paragraph 4.7)

See Section 7.2.2.1 (GDC24).

Derivation of System Inputs (IEEE 279-1971, paragraph 4.8)

The RPS trip variables are direct measures of a reactor overpressure condition, a reactor overpower condition, or abnormal conditions within the RCPB except as follows:

Due to the normal throttling action of the turbine governor valves with changes in the plant power level, measurement of governor valve position is not an appropriate variable from which to infer the desired variable, which is "rapid loss of the reactor heat sink." Consequently, a measurement of governor valve closure rate is necessary.

Protection system design practice has discouraged use of rate sensing devices for protective purposes. In this instance, it was determined that detection of hydraulic actuator operation would be a more positive means of determining fast closure of the governor valves.

Loss of pressure in the hydraulic oil lines which initiates fast closure of the governor valves is monitored. These measurements provide indication that fast closure of the governor valves is imminent.

This measurement is adequate and a proper variable for the protective function taking into consideration the reliability of the chosen sensors relative to other available sensors and the difficulty in making direct measurements of governor valve fast-closure rate.

Capability for Sensor Checks (IEEE 279-1971, paragraph 4.9)

See Section 7.2.2.3 (Regulatory Guide 1.22).

Capability for Test and Calibration (IEEE 279-1971, paragraph 4.10)

See Section 7.2.2.3 (Regulatory Guide 1.22).

Channel Bypass or Removal from Operation (IEEE 279-1971, paragraph 4.11)

The MSIV and the turbine throttle valve closure trip variables have no provision for sensor removal from service because of the use of valve position limit switches as the channel sensor.

During periodic tests of any one trip channel, a sensor may be valved out of service and returned to service under administrative control procedures. Since only one sensor is valved out of service at any given time during the test interval, protective action capability for RPS automatic initiation is maintained through the remaining redundant instrument channels.

A sufficient number of IRM channels is provided to permit any one IRM channel in a given trip system to be manually bypassed and still ensure that the remaining operable IRM channels comply with the IEEE 279 single failure design requirements.

One IRM manual bypass switch has been provided for each RPS trip system. The mechanical characteristics of this switch permit only one of the four IRM channels of that trip system to be bypassed at any time. To accommodate a single failure of this bypass switch, electrical interlocks have also been incorporated into the bypass logic to prevent bypassing of more than one IRM in that trip system at any time. Consequently, with any IRM bypassed in a given trip system, three IRM channels remain in operation to satisfy the protection system requirements.

A single manual APRM bypass switch is provided for all four APRM channels. This is a mechanical/optical switch that allows only one APRM channel to be bypassed at any time. This interlock is accomplished independently in each of the APRM/OPRM 2-Out-of-4-Voter Channels. With any one APRM channel bypassed, the three remaining operating channels provide the necessary protection of the reactor. Bypassing an APRM channel bypasses both the APRM and OPRM trips from that channel. None of the 2-Out-of-4-Voter channels can be bypassed.

The mode switch produces operating bypasses which need not be annunciated because they are removed by normal reactor operating sequence.

Operating Bypasses (IEEE 279-1971, paragraph 4.12)

For a discussion of RPS operating bypasses see Sections 7.2.1.1 and 7.2.1.1.4 through 7.2.1.1.7.

Indication of Bypasses (IEEE 279-1971, paragraph 4.13)

For a discussion of bypass and inoperability indication see Section 7.1.2.4 (Regulatory Guide 1.47).

Access to Means for Bypassing (IEEE 279-1971, paragraph 4.14)

Access to means of bypassing any safety action or safety function is under the administrative control of the control room supervisor/shift manager. Other approved methods of controlling access to bypasses are also used. These include key locks with administrative control of the access to keys, procedurally controlled equipment lineups, e.g., locked valve checklists, and the use of mechanical locking devices and annunciators and other indications, e.g., BISI (Regulatory Guide 1.47, Bypass and Inoperable Status Indication for Nuclear Power Plant Safety Systems, described in Section 7.1.2.4). These additional methods help to prevent inadvertent bypasses or to alert the plant operators to safety function bypasses occurring either from equipment failures or from manually induced bypasses that result as part of testing, maintenance, or equipment repair activities.

Key-locked control switches that provide a means of controlling the access to a safety function bypass are designed to allow key removal only in the "safe" or "accident" positions. Access to the associated keys is procedurally controlled. When not in use, keys are under the administrative control of the control room supervisor/shift manager and stored in a key locker. The keys are audited once per day by the control room supervisor/shift manager. When operation of a key-locked control switch is required to be immediate, such as in the case of the reactor mode switch, the key may be left in the lock during normal plant operation to ensure timely actuation.

Multiple Set Points (IEEE 279-1971, paragraph 4.15)

There are no multiple setpoints within the RPS.

Completion of Protective Action Once it is Initiated (IEEE 279-1971, paragraph 4.16)

Once the RPS trip logic is deenergized as a result of a sensor trip channel becoming tripped or the depressing of a manual scram push button, the scram contractor seal-in contact opens and completion of protective action is achieved without regard to the state of the initiating sensor trip channel.

After initial conditions (variable trip and logic deenergization) return to normal, deliberate operator action is required to return (reset) the RPS logic to normal (energized).

Manual Initiation (IEEE 279-1971, paragraph 4.17)

See Section 7.2.2.3 (Regulatory Guide 1.62).

Access to Set Point Adjustments, Calibration, and Test Points (IEEE 279-1971, paragraph 4.18)

During reactor operation, access to setpoint or calibration controls is not possible for the following RPS trip variables: SDV high water level, MSIV closure, and turbine throttle valve closure.

Access to setpoint adjustments, calibration controls, and test points for all other RPS trip variables are under the administrative control of the control room operator.

Identification of Protective Actions (IEEE 279-1971, paragraph 4.19)

When any one of the redundant RPS trip sensors exceeds its setpoint value, a control room annunciator is initiated to identify that variable and a printed record is available from the computer work stations.

Information Readout (IEEE 279-1971, paragraph 4.20)

The RPS is designed to provide the operator with accurate and timely information pertinent to its status. It does not give anomalous indications that would confuse the operator.

System Repair (IEEE 279-1971, paragraph 4.21)

During periodic testing of the RPS sensor channels (except as noted below), the operator can determine defective components and replace them during plant operation.

During reactor operation, the control room operator is able to determine failed sensors for the following RPS trip variables, but subsequent repair can only be accomplished during reactor shutdown: MSIV closure, turbine throttle valve closure, neutron monitoring (APRM) system, and neutron monitoring (IRM) system.

Replacement of IRM and LPRM detectors must be accomplished during plant shutdown. Repair of the remaining portions of the NMS may be accomplished during plant operation by appropriate bypassing of the defective instrument channel. The design of the system facilitates rapid diagnosis and repair.

Identification of Protection Systems (IEEE 279-1971, paragraph 4.22)

The RPS components are identified with an RPS designation colored marker plate. Cabling outside the cabinets is identified specifically as RPS wiring. (See also Section 8.3.1.3.) Redundant racks are identified by the identification marker plates of instruments on the racks.

7.2.2.3 Conformance to NRC Regulatory Guides

The following is a discussion of conformance to those Regulatory Guides that apply specifically to the RPS. See Section 7.1.2.4 for a discussion of Regulatory Guides which apply equally to all safety-related systems.

Regulatory Guide 1.22 (February 1972), Period Testing of Protection System Actuation Function

The RPS can be tested during reactor operation by the following separate tests:

The manual scram test verifies the ability to deenergize the scram pilot valve solenoids without scram by using the manual scram push button switches. By depressing the manual scram button for one trip logic, the trip actuators are deenergized, opening contacts in the actuator logics.

After the first trip channel is reset, the second trip channel is tripped manually and so forth for the four manual scram buttons. In addition to control room and computer printout indications, scram group indicator lights verify that the actuator contacts have opened and interrupted power to the scram solenoids.

The single rod scram test verifies the capability of each rod to scram. It is accomplished by operating two toggle switches on the hydraulic control unit for the particular CRD. Timing traces can be made for each rod scrammed.

The sensor test involves applying a test signal to each RPS sensor trip channel in turn and observing that a logic trip results. The test signals can be applied to the processing sensing instrumentation (pressure and differential pressure) through calibration taps.

During plant operation, the operator can set the turbine throttle valve or main steam line closure logic test switch in test position and actuate the other valve, which completes the respective channel trip with annunciation and computer logging. The operator can then confirm that the main steam line isolation and turbine throttle valve limit switches operate during valve motion, from full open to full closed and vice versa, by comparing the time that the RPS channel trip occurs with the time that the valve position indicator lights in the control room signal that the valve is fully open and fully closed. This test does not confirm the exact setpoint, but does provide the operator with an indication that the limit switch operates between the limiting positions of the valve. During reactor shutdown, calibration of the main steam line isolation and turbine throttle valve limit switch set point at a valve position of less than or equal to 10% closure is possible by physical observation of the valve stem.

During reactor operation, a test and calibration of the individual hydraulic oil line pressure sensors associated with turbine control valve fast closure when the plant is operating above 29.5% of rated power may be accomplished by valving one sensor out-of-service at a time and introducing a test pressure input.

The APRMs are calibrated to reactor power by using a reactor heat balance and the traversing in-core probe (TIP) system to establish the relative local flux profile. The LPRM gain settings are determined from the local flux profiles measured by the TIP system once the total reactor heat balance has been determined.

The gain adjustment factors for the LPRMs are produced as a result of the computer calculations involving the reactor heat balance and the TIP flux distributions. The APRM and LPRM gains are adjusted using the instrument's front panel display or accepting the APRM gain calculated from the Percent Core Thermal Power (%CTP) and LPRM Gain adjustment factors that are downloaded from the core monitoring system. These adjustments, when incorporated into the LPRMs, permit the nuclear calculations to be completed for the next operating interval and establish the APRM calibration relative to reactor power.

During reactor operation, one manual scram push button may be depressed to test the proper operation of the switch and trip logic relay. Once the RPS is reset, the other switches may be depressed to test their operation one at a time. For each such operation, a control room annunciation will be initiated and the process computer will print the identification of the pertinent trip.

Operation of the reactor mode switch from one position to another may be employed to confirm certain aspects of the RPS trip channels during periodic test and calibration at shutdown only. During tests of the trip channels, proper operation of the mode switch contacts can be easily verified by noting that certain sensors are connected into the RPS logic and that other sensors are bypassed in the RPS logic in an appropriate manner of the given position of the mode switch.

In the startup and run modes of plant operation, procedures may be used to confirm that SDV high water level trip channels cannot be bypassed as a result of the operating bypass switch. In the shutdown and refuel modes of plant operation, a similar procedure may be used to bypass all four SDV trip channels. Due to the discrete "on-off" nature of the bypass function, calibration is not meaningful.

Administrative control must be exercised to valve one turbine first-stage pressure sensor out-of-service for the periodic test. During this test, a variable pressure source may be introduced to operate the sensor at the setpoint value. When the condition for bypass has been

achieved on an individual sensor under test, the control room annunciator for this bypass function will be initiated. If the RPS trip channel associated with this sensor is in its tripped state, the process computer will log the return to normal state for the RPS trip logic. When the plant is operating above 29.5% of rated power, testing of the turbine throttle valve and governor valve fast closure trip channels will confirm that the bypass function is not in effect.

Operation of the reset switch following a trip of one RPS trip system will confirm that the switch is performing its intended function. Operation of the reset switch following trip of both RPS trip systems will confirm that all portions of the switch and relay logic are functioning properly since half of the control rods are returned to a normal state for one actuation of the switch.

A manual scram switch permits each individual trip logic, trip actuator, and trip actuator logic to be tested on a periodic basis. Testing of each process sensor of the protection system affords an opportunity to verify proper operation of these components. Calibration of the time response of the trip channel relays and trip actuators may be accomplished by connection of external test equipment.

Regulatory Guide 1.53 (June 1973), Application of the Single Failure Criterion to Nuclear Power Plant Protection Systems

See Section 7.2.2.2 (IEEE 279-1971, Paragraph 4.2).

Regulatory Guide 1.62 (October 1973), Manual Initiation of Protective Actions

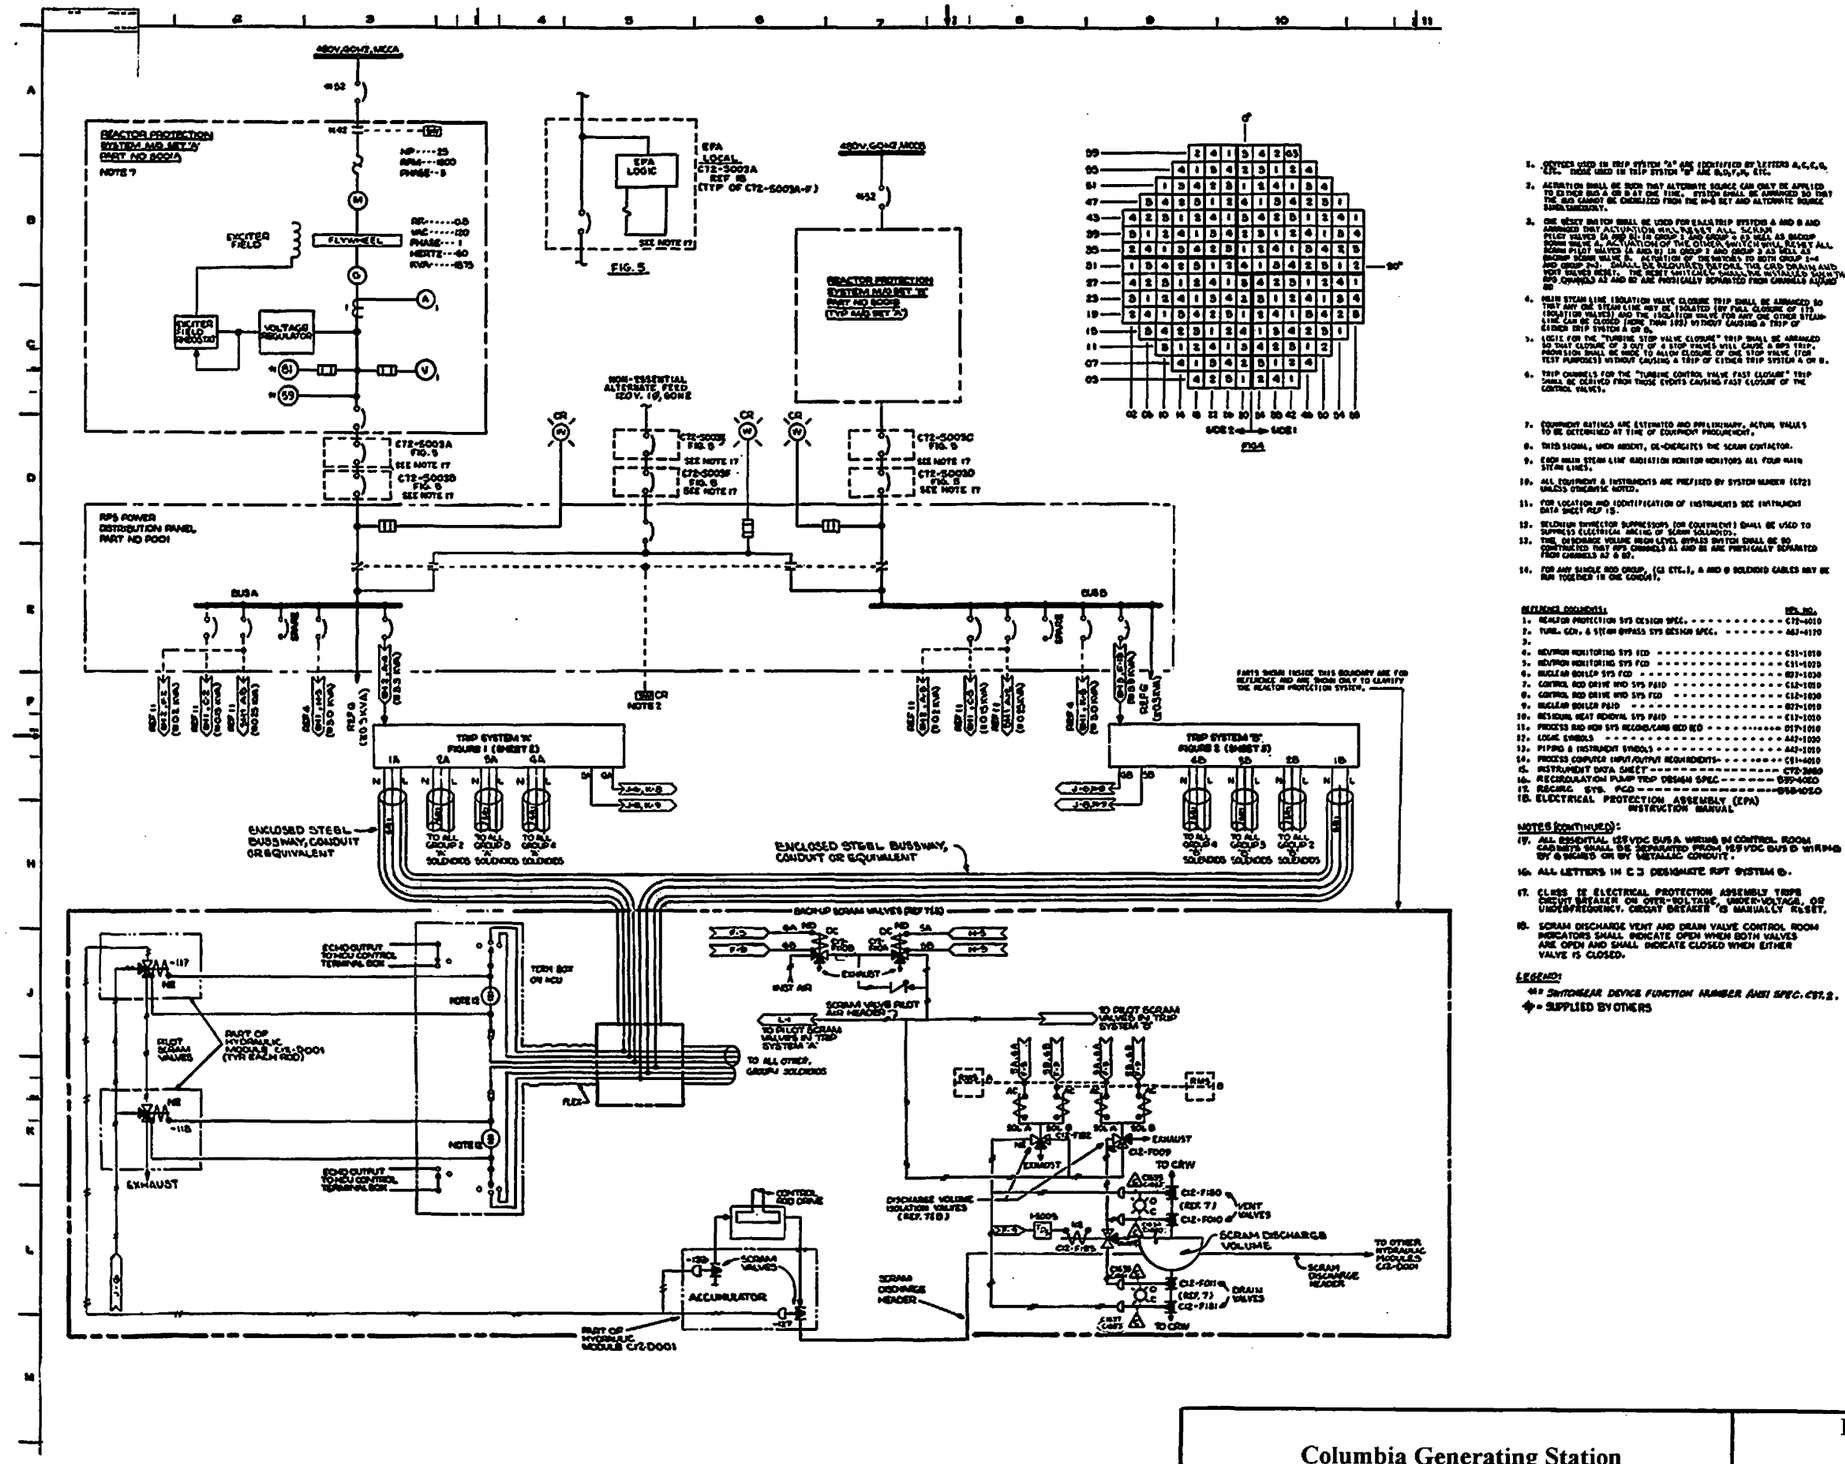
Means are provided for manual initiation of the RPS at the system level through the use of four push button switches located on the control room bench board.

Operation of two switches (one in each trip system) accomplishes the initiation of all actions performed by the automatic initiation circuitry.

Placing the reactor mode switch in the shutdown position will also cause a system level initiation.

Table 7.2-1

Reactor Protection System Instrumentation



Function	Instrument[a]
Scram	
Reactor vessel high pressure	Pressure switch (B22-N023A-D) MS-PS-23A-D

[a] Instruments in parentheses are the GE designation.

1. CONTACTS USED IN TRIP SYSTEM "A" ARE IDENTIFIED BY LETTERS A, C, E, G, ETC. THOSE USED IN TRIP SYSTEM "B" ARE B, D, F, H, ETC.
2. ACTUATION SHALL BE SUCH THAT AUTOMATIC SOURCE CAN ONLY BE APPLIED TO ELIMINATE BUS A OR BUS B AT ONE TIME. SYSTEM SHALL BE ARRANGED SO THAT THE BUS CANNOT BE ENERGIZED FROM THE M-G SET AND AUTOMATIC SOURCE SIMULTANEOUSLY.
3. ONE HONEY SWITCH SHALL BE USED FOR EACH TRIP SYSTEM'S A AND B AND ARRANGED THAT ACTUATION SHALL ENERGIZE ALL SCRAM PILOT VALVES IN ONE BAY IN GROUP 1 AND GROUP 3 AS WELL AS BACKUP SCRAM VALVE A. ACTUATION OF THE OTHER SWITCH WILL ENERGIZE ALL SCRAM PILOT VALVES IN AND BY IN GROUP 2 AND GROUP 4 AS WELL AS BACKUP SCRAM VALVE B. ACTUATION OF EITHER SWITCH OF EITHER GROUP 2 AND GROUP 3 SHALL BE REQUIRED TO ACTUATE TWO CRD DRAIN AND VENT VALVES EACH. THE HONEY SWITCHES SHALL BE INTERLOCKED SUCH THAT BOTH CHANNELS A AND B ARE PHYSICALLY SEPARATED FROM CHANNELS A AND B.
4. MAIN STEAM LINE ISOLATION VALVE CLOSURE TRIP SHALL BE ARRANGED SO THAT ANY ONE STEAM LINE MAY BE ISOLATED (BY FULL CLOSURE OF ITS ISOLATION VALVES) AND THE ISOLATION VALVE FOR ANY ONE OTHER STEAM LINE CAN BE CLOSED (NOT MORE THAN ONE) WITHOUT CAUSING A TRIP OF EITHER TRIP SYSTEM A OR B.
5. LOGIC FOR THE "TURBINE STOP VALVE CLOSURE" TRIP SHALL BE ARRANGED SO THAT CLOSURE OF 2 OUT OF 4 STOP VALVES WILL CAUSE A RPS TRIP. PROVISION SHALL BE MADE TO ALLOW CLOSURE OF ONE STOP VALVE (FOR TEST PURPOSES) WITHOUT CAUSING A TRIP OF EITHER TRIP SYSTEM A OR B.
6. TRIP CHANNELS FOR THE "TURBINE CONTROL VALVE FAST CLOSURE" TRIP SHALL BE DERIVED FROM THOSE EVENTS CAUSING FAST CLOSURE OF THE CONTROL VALVES.
7. EQUIPMENT RATINGS ARE ESTIMATED AND PRELIMINARY. ACTUAL VALUES TO BE DETERMINED AT TIME OF EQUIPMENT PROCUREMENT.
8. THIS SIGNAL, WHEN ABSENT, DE-ENERGIZES THE SCRAM CONTACTOR.
9. EACH MAIN STEAM LINE RADIATION MONITOR MONITORS ALL FOUR MAIN STEAM LINES.
10. ALL EQUIPMENT & INSTRUMENTS ARE PREFIXED BY SYSTEM NUMBER (C72) UNLESS OTHERWISE NOTED.
11. FOR LOCATION AND IDENTIFICATION OF INSTRUMENTS SEE INSTRUMENT DATA SHEET REF 19.
12. SELENIUM RECTIFIER SUPPRESSORS (OR EQUIVALENT) SHALL BE USED TO SUPPRESS ELECTRICAL ARCING OF SCRAM SOLENOIDS.
13. THE OVERRIDE VOLUME HIGH LEVEL BYPASS SWITCH SHALL BE SO CONSTRUCTED THAT ITS CHANNELS A1 AND B1 ARE PHYSICALLY SEPARATED FROM CHANNELS A2 & B2.
14. FOR ANY SINGLE ROD GROUP, (SE ETC.), A AND B SOLENOID CABLES MAY BE RUN TOGETHER IN ONE CONDUIT.

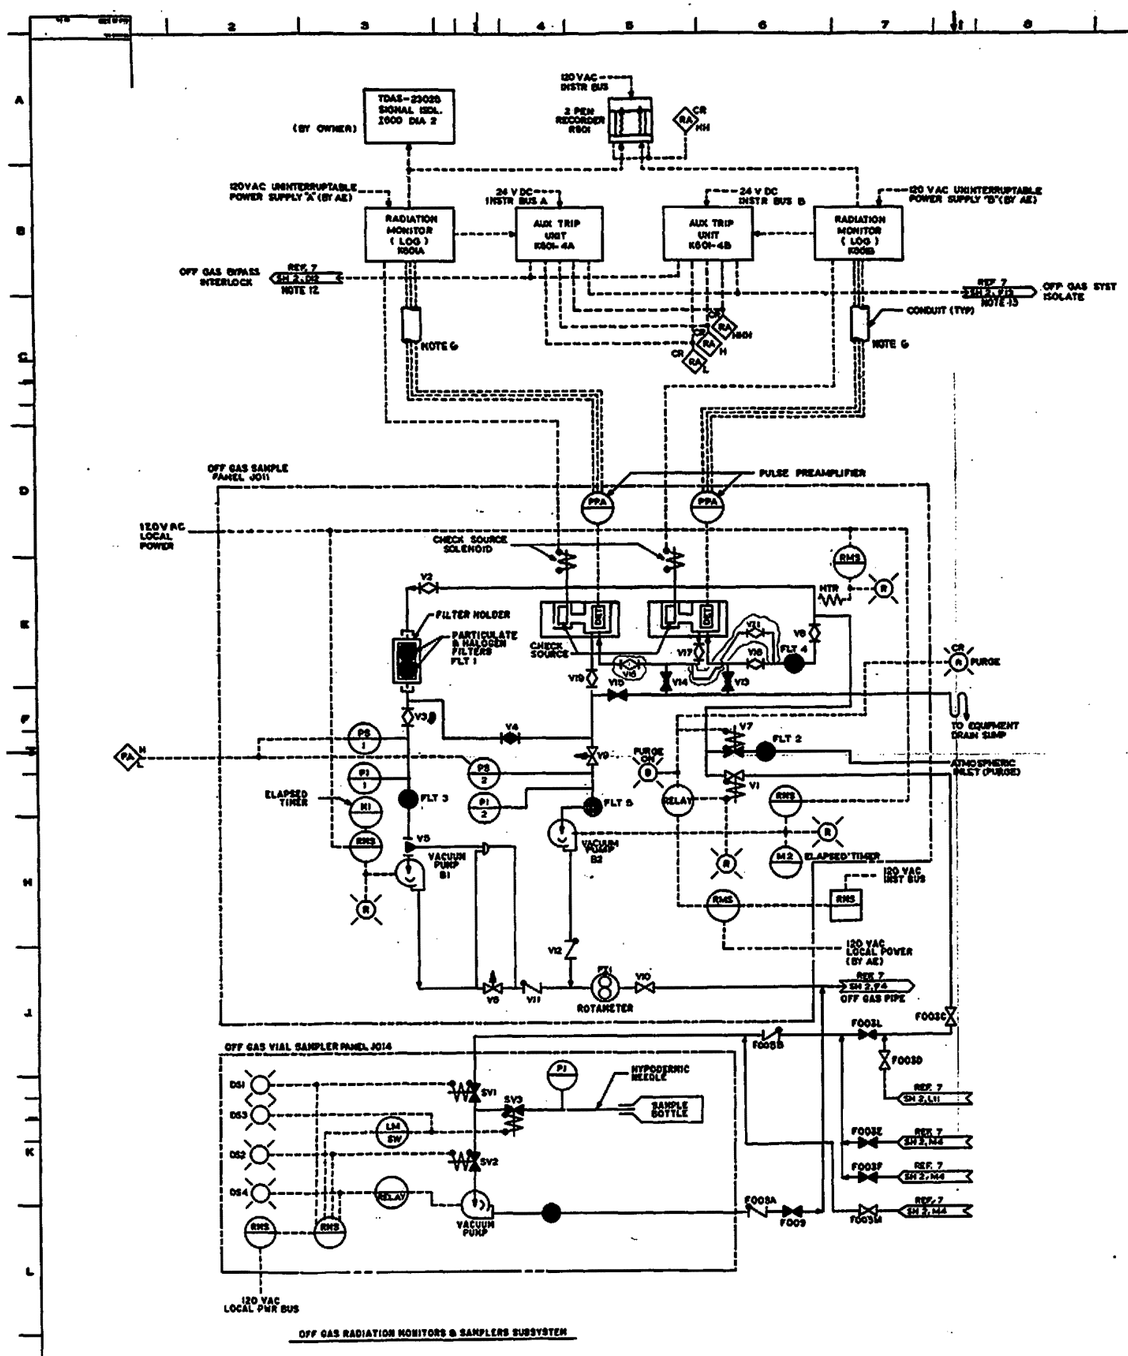
NOTES:



1. THE OFF GAS VENT PIPE GAS SAMPLE LINE SHALL BE 1" X 0.065" WALL THICKNESS SEAMLESS STAINLESS STEEL TUBING. THE TUBING MIN BEND RADIUS SHALL BE 3D". THE TUBING LENGTH SHALL BE JOINED WITH SWAGELOK TYPE 1810-6-316 UNIONS. THE TUBING SHALL SLOPE SO THAT THE CONDENSATE WILL RUN TO DRAIN TEE.
2. A REMOVABLE SECTION SHALL BE PROVIDED NEAR THE ISOKINETIC PROBE FOR THE INSERTION OF A CHARCOAL FILTER HOLDER. THE FITTINGS ETC. SHALL PROVIDE SMOOTH TRANSITIONS WITHOUT DISCONTINUITIES OR REDUCING THE CROSS SECTIONAL AREA OF THE FLOW STREAM.
3. TEE SHALL BE UNION TEE SWAGELOK TYPE 1810-6-316.
4. ALARMS ARE ACTUATED BY RELAYS IN TRIP AUX. UNITS.
5. THE MAIN STEAM LINE RADIATION MONITOR DETECTORS (K003) SHALL BE LOCATED WITHIN THE STEAM LINE TUNNEL AS CLOSE AS PRACTICAL TO THE PRIMARY CONTAINMENT. THE DETECTORS SHALL BE ARRANGED SUCH THAT EACH DETECTOR WILL VIEW ALL STEAM LINES WITH APPROXIMATELY THE SAME RESPONSE. IT IS RECOMMENDED THAT THE DETECTOR OR DETECTOR ASSEMBLY BE FASTENED TO A ROD OR A PIPE AND INSERTED INTO SEALED PIPE WELLS FROM OUTSIDE THE STEAM TUNNEL. CARE-FULLY ROUTE CABLES TO MINIMIZE HEAT EXPOSURE. NO LEAD SHIELDING IS REQUIRED.
6. ALL CABLES SHALL COMPLY WITH GE ENGR. SPEC REF 3.
7. ADDITIONAL ALARM IN RADWASTE BLDG (RAM) RADWASTE MONITOR ONLY.
8. DRAIN AT THE LOWER POINT OF OFF GAS SAMPLE LINE. SAMPLE LINE SHALL HAVE 2 MINUTE TRANSIT TIME TO ALLOW FOR DECAY.
9. TWO OUT OF TWO HIGH HIGH RADIATION (RAHH) TRIP (CHANNELS A AND B) SHALL:
   -- SHUTDOWN AND ISOLATE (OUTBOARD VALVE) REACTOR BUILDING VENTILATION SYSTEM.
   TWO OUT OF TWO HIGH-HIGH RADIATION (RAHH) TRIP (CHANNELS C AND D) SHALL:
   -- SHUTDOWN AND ISOLATE (INBOARD VALVE) REACTOR BUILDING VENTILATION SYSTEM.
10. ONE HIGH HIGH RADIATION (RAHH) OR INOPERATIVE TRIP OUT OF TWO ON TRIP SYSTEM "A" AND ONE HIGH-HIGH RADIATION (RAHH) OR INOPERATIVE TRIP OUT OF TWO ON TRIP SYSTEM "B" SHALL:
    -- CLOSE REACTOR WATER SAMPLE VALVES.
    -- TURN OFF MECHANICAL VACUUM PUMP & CLOSE MECHANICAL VACUUM PUMP LINE VALVE.
    -- ANY ONE HIGH RADIATION TRIP (RAH) SHALL ALARM.
11. FOR LOCATION AND IDENTIFICATION OF INSTRUMENTS SEE INSTRUMENT DATA SHEET (ASME REP 60).
12. ANY ONE UPSCALE TRIP (RAH) SHALL CLOSE BYPASS LINE VALVE, OPEN TREATMENT LINE VALVE AND ALARM.
13. ISOLATE OFF-GAS SYSTEM OUTLET AND DRAIN VALVES AND ALARM (REF 9).
14. *SUPPLIED AND MOUNTED BY OTHERS.*
15. HIGH-HIGH RADIATION TRIP SHALL RESULT IN AN OPEN INHIBIT CIRCUIT.
16. EITHER HIGH OR HIGH-HIGH RADIATION TRIP SHALL RESULT IN AN OPEN CIRCUIT.
17. ANY ONE HIGH-HIGH (RAHH) OR DOWNSCALE (RAL) RADIATION TRIP SHALL ALARM.

7.3 ENGINEERED SAFETY FEATURE SYSTEMS

7.3.1 DESCRIPTION

The instrumentation and controls include the operation of the following engineered safety feature (ESF) systems (see Figures 7.3-1 through 7.3-15):

a. Emergency core cooling system (ECCS),

b. Primary containment and reactor vessel isolation control systems (PCRVICS),

c. Residual heat removal (RHR) system - containment spray cooling mode (CSCM),

d. RHR system - suppression pool cooling mode (SPCM),

e. Standby service water (SW) system,

f. Main control room and critical switchgear rooms heating, ventilating, and air conditioning (HVAC) system,

g. Reactor building ventilation and pressure control system,

h. Standby gas treatment system (SGT),

i. Containment instrument air (CIA) system, and

The sources which supply power to the ESF systems originate from onsite ac and/or dc safety-related buses or, as in the case of the PCRVICS fail safe logic, from safety-related Division 1 and 2 power and the non-safety-related reactor protection system (RPS) motor generator (MG) sets. See Chapter 8 for a complete discussion of the ESF systems power sources.

7.3.1.1 System Description

7.3.1.1.1 Emergency Core Cooling Systems

The ECCS is a network of the following systems. See Sections 6.3.1 and 6.3.2.

a. High-pressure core spray (HPCS) system,
b. Automatic depressurization system (ADS),
c. Low-pressure core spray (LPCS) system, and
d. Low-pressure coolant injection (LPCI) mode of the RHR system.

The following plant variables are monitored and provide automatic initiation of the ECCS when these variables exceed predetermined limits:

a. Reactor vessel water level

A low water level in the reactor vessel could indicate that reactor coolant is being lost through a breach in the reactor coolant pressure boundary (RCPB) and that the core is in danger of becoming overheated as the reactor coolant inventory diminishes. See Figure 10.3-2 for a schematic arrangement of reactor vessel instrumentation.

b. Drywell pressure

High pressure in the drywell could indicate a breach of the RCPB inside the drywell and that the core is in danger of becoming overheated as reactor coolant inventory diminishes.

7.3.1.1.1.1 High-Pressure Core Spray System.

Function

The purpose of the HPCS is to provide high pressure reactor vessel core spray for a small line break loss-of-coolant accident (LOCA) which does not depressurize the reactor vessel. In addition HPCS is redundant to the ADS system for mitigation of the consequences of various events described in Chapter 15. The HPCS can provide core cooling or reactor vessel inventory makeup following accidents and various design basis transients described in Chapter 15. See also Section 6.3.2.2.1. The HPCS also provides for core cooling during a station blackout event.

Operation

Schematic arrangements of system mechanical equipment is shown in Figure 6.3-4. The HPCS system component control logic is shown in Figures 7.3-4 and 7.3-7. Instruments are listed in Table 7.3-1. Operator information displays are shown in Figures 7.3-7 and 7.3-4.

The HPCS is initiated automatically by either reactor vessel low water level (trip level 2) or drywell high pressure. The system is designed to operate automatically for at least 10 minutes without any actions required by the control room operator. Once initiated the HPCS logic seals-in and can be reset by the operator only when the initial conditions return to normal. See Figure 7.3-7 for a schematic representation of the HPCS system initiation logic.

Reactor vessel water level (trip level 2) is monitored by four redundant differential pressure switches. The switch contacts are arranged in a one-out-of-two twice logic arrangement to ensure that no single event can prevent the initiation of the HPCS.

Initiation diversity is provided by drywell pressure which is monitored by four redundant pressure switches. The switches are electrically connected in a one-out-of-two twice logic arrangement to ensure that no single instrument failure can prevent the initiation of the HPCS.

The HPCS components respond to an automatic initiation signal as follows (actions are simultaneous unless stated otherwise):

a. The HPCS diesel generator is signaled to start and its protective relays are bypassed. Once the diesel is started it signals its cooling water pump to start. See Section 6.3.1.1;

b. The HPCS pump motor is signaled to start;

c. The normally open pump suction valve from the condensate storage tank HPCS-V-1 (MO F001), is signaled to open;

d. The test return valve HPCS-V-23 (MO F023) is signaled to close; and

e. The HPCS injection valve HPCS-V-4 (MO F004) is signaled to open.

If the pump is running but discharge flow is low enough that pump overheating may occur, the minimum flow return line valve HPCS-V-12 (MO F012) is signaled to open. The valve is automatically closed if flow is normal.

If water level in the condensate storage tanks falls below a predetermined level, the suppression pool suction valve HPCS-V-15 (MO F015) automatically opens. When HPCS-V-15 (MO F015) is fully open the condensate storage tank suction valve HPCS-V-1 (MO F001) automatically closes. Two level switches mounted on a Seismic Category I standpipe in the reactor building are used to detect low water level in the condensate storage tanks. Either switch can cause automatic suction transfer. If the condensate supply line fails, the suction supply for HPCS-P-1 pump transfers to the suppression pool. Either of two instruments mounted on the supply line in the reactor building sense a low water level in the supply line as a broken pipe. The suppression pool suction valve also automatically opens if high water level is detected in the suppression pool. Two level switches monitor suppression pool water level and either switch can initiate opening of the suppression pool suction valve. To prevent losing suction to the pump, the suction valves are interlocked so that one suction path must be open before the other closes.

The HPCS provides makeup water to the reactor until the vessel water level reaches the high level trip (trip level 8) at which time the injection valve HPCS-V-4 (MO F004) is automatically closed. The pump will continue to run on minimum flow recirculation. The injection valve will automatically reopen if vessel level again drops to the low level (trip level 2) initiation point.

The HPCS pump motor and injection valve are provided with manual override controls. These controls permit the reactor operator to manually control the system following automatic initiation.

7.3.1.1.1.2 Automatic Depressurization System.

Function

The ADS is designed to provide automatic depressurization of the reactor vessel by activating seven safety/relief valves (SRVs). These valves vent steam to the suppression pool in the event the HPCS cannot maintain reactor water level following a LOCA. The ADS reduces reactor pressure so that flow from the low pressure ECCS, LPCI system and LPCS, can inject into the reactor vessel in time to cool the core and limit fuel cladding temperature. See also Section 6.3.2.2.2.

Operation

Schematic arrangements of system mechanical equipment is shown in Figure 10.3-2. The ADS component control logic is shown in Figure 7.3-8. Instruments are listed in Table 7.3-2. Operator information displays are shown in Figures 10.3-2 and 7.3-8.

The ADS is made up of two independent trip systems (A&B).

To prevent inadvertent actuation of the ADS, two channels of logic for each ADS trip system are used. Both channels must be activated to actuate ADS. See Figure 7.3-5 for a schematic representation of the ADS initiation logic.

One channel includes two differential pressure sensor inputs monitoring reactor vessel low water level (trip level 3 and trip level 1). The low water level trip (trip level 3) provides confirmation of a reactor vessel low water level condition. The other channel includes only a single reactor vessel low water level (trip level 1) input.

To ensure that adequate makeup water is available after the vessel has been depressurized each logic channel includes a pump discharge pressure permissive signal indicating RHR or LPCS system available for vessel water makeup. Any one of the three RHR pumps or the LPCS pump is sufficient to permit automatic depressurization.

After receipt of the initiation signals and a time delay, one or both of the two solenoid pilot air valves are energized. This allows pneumatic pressure from the accumulator to act on the air cylinder operator. Each ADS trip system timer can be reset manually to delay system initiation. If reactor vessel water level is restored by HPCS prior to the end of the time delay, ADS initiation will be prevented. Also, either or both ADS trip systems may be initially inhibited to eliminate resetting the timer.

The ADS trip system A actuates the "A" solenoid pilot valve on each ADS relief valve. Similarly, the ADS trip system B actuates the "B" solenoid pilot valve on each ADS relief valve. Actuation of either solenoid pilot valve causes the ADS valve to open and provide depressurization.

Two control switches (one for each trip system solenoid) are located in the main control room for each SRV associated with the ADS. Each switch controls one of the two solenoid pilot valves.

7.3.1.1.1.3 Low-Pressure Core Spray.

Function

The purpose of the LPCS is to provide low-pressure reactor vessel core spray following a LOCA when the vessel has been depressurized and vessel water level has not been restored by the HPCS. The LPCS is functionally diverse to the LPCI mode of the RHR system (see Section 6.3.2.2.3).

Operation

Schematic arrangements of system mechanical equipment is shown in Figure 6.3-4. The LPCS component control logic is shown in Figure 7.3-9. Instruments are listed in Table 7.3-3. Operator information displays are shown in Figure 7.3-9.

The LPCS is initiated automatically by either reactor vessel low water level and/or drywell high pressure. The system is designed to operate automatically for at least 10 minutes without any actions required by the control room operator. Once initiated the LPCS logic seals-in and can be reset by the control room operator only when the initial conditions return to normal. See Figure 7.3-9 for a schematic representation of the LPCS system initiation logic.

Reactor vessel water level (trip level 1) is monitored by two redundant differential pressure switches. To provide diversity drywell pressure is monitored by two redundant pressure switches. The vessel level switch contacts and the drywell pressure switch contacts are connected in a one-out-of-two twice logic arrangement so that no single instrument failure can prevent initiation of LPCS.

The LPCS components respond to an automatic initiation signal simultaneously (or sequentially as noted) as follows:

a. The Division 1 diesel generator is signaled to start,

b. The normally closed test return line to the suppression pool valve LPCS-V-12 (MO F012) is signaled closed,

c. If power from the normal auxiliary or backup transformer is available at the pump motor bus, the LPCS pump is signaled to start. If the startup transformer is supplying the pump motor buses, sequential starts of ECCS pumps are required to prevent excessive voltage drops on the buses. This is accomplished by delaying the start of LPCS pump by 9.5 sec.

d. Reactor pressure is monitored by a pressure switch which senses the reactor vessel pressure. When the reactor vessel pressure is low enough to protect the LPCS from over-pressure and power is available to the pump motor bus, the injection valve is signaled to open.

The LPCS pump discharge flow is monitored by a flow indicating switch. When the pump is running and discharge flow is low enough that pump overheating may occur, the minimum flow return line valve LPCS-FCV-11 (MO F011) is opened. The valve is automatically closed if flow is normal.

The LPCS pump suction from the suppression pool valve LPCS-V-1 (MO F001) is normally open, the control switch is key locked in the open position, and thus requires no automatic open signal for system initiation.

The LPCS pump and injection valve are provided with manual override controls. These controls permit the operator to manually control the system subsequent to automatic initiation.

7.3.1.1.1.4 Residual Heat Removal System - Low Pressure Coolant Injection Mode.

Function

Low-pressure coolant injection is an operating mode of the RHR system. The purpose of the LPCI system is to provide low-pressure reactor vessel coolant makeup following a LOCA when the vessel has been depressurized and vessel water level is not restored by the HPCS (see Section 6.3.2.2.4).

Operation

Schematic arrangements of system mechanical equipment is shown in Figure 5.4-15. The LPCI component control logic is shown in Figure 7.3-10. Instruments are listed in Table 7.3-4. Operator information displays are shown in Figures 7.3-10 and 5.4-15.

The LPCI system is initiated automatically by either reactor vessel low water level or drywell high pressure (one-out-of-two-twice logic). The system is designed to operate automatically for at least 10 minutes without any actions required by the control room operator. Once initiated, the LPCI logic seals-in and can be reset by the control room operator only when initial conditions return to normal. See Figure 7.3-10 for a schematic representation of the LPCI initiation logic. To provide diversity, reactor vessel water level (trip level 1) and drywell pressure are monitored by two redundant differential pressure switches.

To initiate the Division 2 LPCI (loops B and C) the vessel level switch contacts and the two drywell pressure switch contacts are connected in a one-out-of-two-twice arrangement so that no single instrument failure can prevent initiation of LPCI.

The Division 1 LPCI (loop A) receives its initiation signal from the LPCS logic.

The LPCI system components respond to an automatic initiation signal simultaneously (or sequentially as noted) as follows (the loop A components are controlled from the Division 1 logic; the loop B and C components are controlled from the Division 2 logic):

a. The Division 2 diesel generator is signaled to start from the loop B and C initiation logic;

b. If offsite power is not available and the diesel generators are supplying the pump motor buses, sequential loading of the diesel generators is required. This is accomplished by delaying the start of LPCI pumps A and B by 5 sec while allowing the LPCS and LPCI C pumps to start immediately. The same start sequence is maintained for the LPCS and LPCI pumps when the pump motor buses are supplied from the normal auxiliary or backup transformer. If the startup transformer is supplying the pump motor buses, sequential starts of ECCS pumps are required to prevent excessive voltage drops on starting. This is accomplished by delaying the start of LPCS and LPCI C pumps by 9.5 sec and delaying LPCI A and B pump starts by 19.4 sec;

c. Reactor pressure is monitored by a pressure switch for each LPCI injection valve RHR-V-42A, RHR-V-42B, and RHR-V-42C (MO FO42A, B, C). When the reactor pressure is low enough to protect the LPCI from overpressure and power is available at the associated pump motor bus, the injection valve is signaled to open;

d. The following normally closed valves are signaled closed to ensure proper system lineup:

1. The test return line to the suppression pool valves RHR-V-24A, RHR-V-24B (MO F024 A, B), RHR-V-21, and

2. The suppression pool spray valves RHR-V-27A and RHR-V-27B (MO F027 A, B).

e. The normally open heat exchanger bypass valves RHR-V-48A and RHR-V-48B (MO F048 A, B) are signaled open. The open signal is automatically removed 10 minutes after system initiation to allow operator control of the valve for throttling purposes if cooling using RHR heat exchangers is required.

The flow in each LPCI discharge line is monitored when the pump is running. Whenever the discharge flow is below the minimum flow setpoint, the respective minimum flow valve RHR-FCV-64A, RHR-FCV-64B, or RHR-FCV-64C (MO F064A, B or C) will automatically start to open in approximately 8 sec, to prevent pump overheating. The valve is automatically closed if the flow is above the minimum flow setpoint. The time delay is provided to limit reactor vessel inventory loss during the shutdown cooling mode of the RHR system (see Section 5.4.7.2.6).

The three RHR pump suction from the suppression pool valves RHR-V-4A, RHR-V-4B, RHR-V-4C (MO F004 A, B, C) and the RHR heat exchanger inlet valves RHR-V-47A, RHR-V-47B, (MO F047 A, B) which are locked open (with power removed) and outlet valves RHR-V-3A, RHR-V-3B (MO F003 A, B) have their control switches in the open position, and thus require no automatic open signal for system initiation.

The two series SW crosstie valves RHR-V-115 (MO F094) and RHR-V-116 (MO F093) have their control switches key locked in the close position, and thus require no automatic close signal for system initiation.

The two series containment spray valves RHR-V-16A, RHR-V-16B, (MO F016 A, B) and RHR-V-17 and RHR-V-17B (MO F017 A, B), the two series RHR heat exchanger vent valves RHR-V-73A, RHR-V-73B, RHR-V-74A, and RHR-V-74B (MO F073 A, B and MO F074 A, B), and the RHR shutdown cooling mode suction valves RHR-V-6A and RHR-V-6B (MO F006 A, B) are all normally closed and thus require no automatic close signal for system initiation.

The LPCI pump motors and injection valves are provided with manual override controls. These controls permit the operator to manually control the system subsequent to automatic initiation.

7.3.1.1.2 Primary Containment and Reactor Vessel Isolation Control System (PCRVICS)

Function

The PCRVICS includes the instrument channels, trip logic, and actuation circuits that automatically initiate valve closure providing isolation of the primary containment and/or reactor vessel, and initiation of systems provided to limit the release of radioactive materials.

See Section 6.2.4 and Table 6.2-16 for a complete description of primary containment and reactor vessel process lines and isolation signals applied to each.

Operation

Schematic mechanical arrangements of containment isolation valves and other components initiated by PCRVICS are shown in Figures 5.4-15, 10.3-2, 5.4-7, 5.4-11, 5.4-22, 9.3-9, 9.3-12, and 3.2-2. The PCRVICS component control logic is shown in Figures 7.3-1, 7.3-8, 7.3-10 and 7.4-1. Instruments are listed in Table 7.3-5. Operator information displays are shown on these figures.

During normal plant operation, the isolation control system sensors and trip logic that are essential to safety are energized. When abnormal conditions are sensed, instrument contacts open and deenergize the trip logic and thereby initiate isolation. Once initiated, then the PCRVICS trip logic seals-in and may be reset by the operator when the initiating conditions return to normal.

The PCRVICS trip logic provides isolation signals to the main steam line isolation valves (MSIVs) MS-V-22A, MS-V-22B, MS-V-22C, MS-V-22D (AO F022 A, B, C, D) and MS-V-28A, MS-V-28B, MS-V-28C, MS-V-28D (AO F028 A, B, C, D); to the main steam line drain valves MS-V-16 (MO F016), MS-V-67A, MS-V-67B, MS-V-67C, MS-V-67D (F067 A, B, C, D), and MS-V-19 (MO F019); to the reactor water sample valves RRC-V-19 (MO F019) and RRC-V-20 (F020); to the RHR shutdown cooling system valves RHR-V-8 (MO F008), RHR-V-9 (F009), RHR-V-23 (F023), RHR-V-40 (F040), RHR-V-49 (F049), RHR-V-53A, RHR-V-53B (F053 A, B), RHR-V-123A, RHR-123B (F099 A, B); to the reactor water cleanup (RWCU) system valves RWCU-V-1 (MO F001) and RWCU-V-4 (F004); to the drywell equipment drain valves EDR-V-19 (AO F019) and EDR-V-20 (F020); to the drywell floor drain valves FDR-V-3 (AO F003) and FDR-V-4 (F004); to the TIP system valves, TIP-V-1, TIP-V-2, TIP-V-3, TIP-V-4, TIP-V-5, and TIP-V-15; and to the RCIC system valves, RCIC-V-63 (MOF063), RCIC-V-8 (F008) and RCIC-V-76 (F076).

Each MSIV has two control solenoids. Each solenoid receives inputs from two redundant logic channels. A signal from either can deenergize the solenoid. For any one valve to close automatically, both of its solenoids must be deenergized.

The MSIV logic has a minimum of four redundant instrument channels for each measured variable. One channel of each variable is connected to one trip logic. One group of redundant logic (A, C) is used to control one solenoid of both inboard and outboard valves of all four main steam lines, and the other group of redundant logic (B, D) is used to control the other solenoid of both inboard and outboard valves. The four PCRVICS trip logic channels are arranged in a one-out-of-two twice logic combination (trip logic A or C and B or D). See Figure 7.3-2.

The main steam line drain valves, drywell equipment and floor drain valves, reactor water sample valves, the RWCU system, and RHR system isolation valves also operate in pairs. The outboard valves close if the Division 1 isolation logic (A and B) is tripped, and the inboard valves close if the Division 2 logic (C and D) is tripped. See Figure 7.3-3. The RCIC system isolation valves are initiated closed by the leak detection system signals listed in Section 7.3.1.2.1.d. See Figure 7.4-1.

The PCRVICS also provides signals to start the SGT, to remove nonessential loads from essential buses, and to isolate the reactor building ventilation system and the primary containment purge and vent system.

The following variables provide inputs to the PCRVICS logics for initiation of reactor vessel and drywell isolation, as well as the initiation or trip of other plant functions when predetermined limits are exceeded. Combinations of these variables, as necessary, provide initiation of various isolating and initiating functions as identified in Table 6.2-16 and described below.

7.3.1.1.2.1 Reactor Vessel Low Water Level. A low water level in the reactor vessel could indicate that reactor coolant is being lost through a breach in the RCPB and that the core is in danger of becoming overheated as the reactor coolant inventory diminishes.

Reactor vessel low water level initiates closure of various valves. The closure of these valves is intended to isolate a breach of the pipelines, conserve reactor coolant by closing off process lines, and limit the escape of radioactive materials from the primary containment through process lines that communicate with the primary coolant boundary or primary containment.

Three reactor vessel low water level isolation trip settings are used to complete the isolation of the primary containment and the reactor vessel. The first (and higher) reactor vessel low water level isolation trip (trip level 3) initiates closure of all RHR system isolation valves. The main steam lines are left open to allow the removal of heat from the reactor core. The second (and lower) reactor vessel low-low water level isolation trip (trip level 2) isolates the Group 2, 3, 4

and 7 primary containment isolation valves and also provides inputs to logic which trips or initiates other plant equipment.

The third (lowest) reactor vessel low-low-low water isolation trip (trip level 1) isolates the Group 1 primary containment isolation valves which include MSIVs and main steam line drain valves.

Reactor vessel low water level (Level 3) is monitored by four redundant differential pressure switches. Each provides a low water level input to one of the four PCRVICS trip logic.

Reactor vessel water low-low (Level 2) and low-low-low (Level 1) are monitored by four redundant differential pressure transmitters with dual trip units. Each trip unit provides a Level 2 or Level 1 input to the PCRVICS trip logic.

Diversity of trip initiation for pipe breaks inside of primary containment is provided by drywell high pressure sensors.

7.3.1.1.2.2 Drywell High Pressure. High pressure in the drywell could indicate a breach of the RCPB inside the drywell and that the core is in danger of becoming overheated as reactor coolant inventory diminishes.

Drywell pressure is monitored by four redundant pressure switches. Each switch provides an input to one of the four trip logic channels.

7.3.1.1.2.3 Main Steam Line - High Radiation. The main steam line radiation monitors sense the gross release of fission products from the fuel and initiates action to contain the released fission products.

Four redundant detectors monitor the gross gamma radiation from the main steam lines. Each provides an input to one of the four PCRVICS trip logic channels.

Each channel consists of a gamma-sensitive ion chamber and a log radiation monitor. Each log radiation monitor has three trip circuits. One upscale trip circuit is used to initiate closure of the reactor water sample valves, mechanical vacuum pump trip, gland seal condenser exhauster trip, and an isolation alarm. The second circuit is used for a high alarm and is set at a level below that of the upscale trip circuit. The third circuit is a downscale alarm. The inoperative condition actuates the isolation alarm and produces the same isolation described above for the upscale trip circuit.

7.3.1.1.2.4 Main Steam Line - Tunnel High Ambient Temperature or High Differential Temperature. A leak in a main steam line is indicated by a high ambient temperature or a high differential temperature for this area. The automatic closure of main steam line isolation and

drain valves prevents the excessive loss of reactor coolant and the release of a significant amount of radioactive material from the RCPB.

There are four main steam line high ambient temperature channels within the steam tunnel and four high differential temperature channels between the main steam line tunnel and the reactor building. These eight channels monitor and actuate main steam line isolation logic which is deenergized by high ambient or high differential temperature condition.

Diversity of trip initiation signals for the main steam line tunnel high ambient or high differential temperature is provided by main steam line high flow and steam line low pressure instrumentation.

7.3.1.1.2.5 Main Steam Line - High Flow. Main steam line high flow could indicate a breach in a main steam line. Automatic closure of isolation valves prevents excessive loss of reactor coolant and release of significant amounts of radioactive material from the RCPB.

Sixteen redundant differential pressure switches, four for each main steam line, monitor the main steam line flow. Four differential pressure switches for each main steam line provide inputs to each of the four trip logic channels.

When a significant increase in main steam line flow is detected, trip signals initiate closure of all main steam line isolation and drain valves.

7.3.1.1.2.6 Main Steam Line - Low Pressure. Low steam pressure at the turbine inlet while the reactor is operating could indicate a malfunction of the nuclear system pressure regulator in which the turbine governor valves or turbine bypass valves become fully open, thus causing rapid depressurization of the reactor vessel. From reduced power the rate of decrease of nuclear system saturation temperature could exceed the allowable rate of change of vessel temperature. A rapid depressurization of the reactor vessel while the reactor is near full power could result in undesirable differential pressures across the channels (around some fuel bundles) of sufficient magnitude to cause mechanical deformation of channel walls. Such depressurizations without adequate preventive actions could require thorough vessel analysis or core inspection prior to returning the reactor to power operation.

Four redundant pressure sensors, one for each main steam line, monitor main steam line pressure and each provides an input to one of the four trip logic channels.

When a significant decrease in main steam line pressure is detected, the PCRVICS initiates closure of all main steam line isolation and drain valves.

The main steam line low pressure trip is bypassed by the reactor mode switch in the shutdown, refuel, and startup modes of reactor operation. In the run mode, the low pressure trip function is active.

7.3.1.1.2.7 Reactor Building Ventilation Exhaust Radiation Monitor. There are four radiation monitors arranged in two sets of two channels each, (A, B) and (C, D), which make up the process radiation monitor (PRM) reactor building vent radiation monitor isolation system. Each channel has a trip signal output used for shutdown and isolation of the reactor building ventilation system, startup of the SGT, and trip and/or isolation of various other plant functions. The trip output is provided in response to either high radiation in the ventilation exhaust plenum (upscale trip) or instrument failure (downscale trip). The downscale trip also initiates an alarm to alert the operator to instrument trouble conditions. See Section 11.5 for additional details.

7.3.1.1.2.8 Reactor Water Cleanup System - High Differential Flow. High differential flow in the RWCU system could indicate a breach of the RCPB of the cleanup system. The flow at the inlet to the system is compared with the flow at the outlets of the system.

A differential flow signal is developed from the compared inlet-outlet flow signals and applied to the two (inboard or outboard) logic trip channels. When an increase in RWCU system differential flow is detected, the PCRVICS initiates closure of the RWCU system isolation valves. This isolation function is not credited in the accident analysis.

Diversity of trip initiation signals for RWCU system isolation is provided by instrumentation for reactor water level, differential flow, high blowdown flow, and ambient or differential temperature in RWCU equipment areas.

The RWCU system high differential flow trip is bypassed by an automatic timing circuit during normal RWCU system surges. This time delay bypass prevents inadvertent system isolations during system flow transients.

7.3.1.1.2.9 Reactor Water Cleanup System - Area High Ambient Temperature or High Differential Temperature. High temperature in the equipment room areas of the RWCU system could indicate a breach of the RCPB in the cleanup system.

Redundant ambient temperature or differential temperature sensors monitor the RWCU system area temperatures. When a significant increase in RWCU system area ambient or differential temperature is detected the PCRVICS initiates closure of RWCU system isolation valves.

The output trip signal of each sensor initiates a logic trip and closure of either the inboard or outboard RWCU system isolation valve.

Diversity of trip initiation signals for high differential temperature is provided by two pair of differential temperature elements and associated differential temperature switches. Each pair of temperature elements and its differential temperature switch are associated with one of two logic channels.

7.3.1.1.2.10 Reactor Water Cleanup System - High Blowdown Flow. High flow conditions in the RWCU blowdown to the main condenser or radwaste line is indicative of a high-energy line break condition. Flow in this line is monitored by two redundant flow sensors which measure flow at the same point and apply flow signals to the trip logic channels. One flow signal is provided to the inboard trip channel and one to the outboard trip channel.

When an increase in RWCU blowdown flow is detected, the PCRVICS initiates closure of the RWCU system isolation valves.

The high blowdown flow trip logic contains a time delay feature which prevents inadvertent system isolations due to normal flow transients.

7.3.1.1.2.11 Residual Heat Removal System - Area High Ambient Temperature or High Differential Temperature. High temperature in the equipment room areas of the RHR system could indicate a breach in the RCPB in the RHR system.

Redundant ambient temperature or redundant differential temperature sensors monitor the RHR system area temperatures. Half of the ambient and differential temperature sensors are associated with one trip logic. The remaining temperature channels are associated with the other trip logic. The ambient temperature elements are located in each RHR equipment area. The differential temperature elements are located in the ventilation supply and ventilation exhaust of RHR pump rooms A and B.

When an increase in RHR system area ambient temperature or differential temperature is detected, the PCRVICS initiates closure of the RHR system isolation valves.

The output trip signal of each sensor initiates a trip logic and closure of either the inboard or outboard RHR system isolation valve.

Diversity of trip initiation signals for RHR line break is provided by ambient temperature, differential temperature, and shutdown cooling flow instrumentation. An increase in ambient temperature, differential temperature, or flow will initiate RHR system isolation.

7.3.1.1.2.12 Residual Heat Removal System - Flow Rate Monitoring. High flow in the RHR system suction line from the reactor vessel could indicate a breach in the RCPB in the RHR system.

Two redundant differential pressure switches, one for each trip logic, monitor the RHR shutdown cooling mode suction line. The output trip signal of each sensor initiates a logic trip and closure of either the inboard or outboard RHR system isolation valve. The RHR suction high flow trip is not credited within the Columbia Generating Station (CGS) accident analysis.

7.3.1.1.2.13 Main Condenser Vacuum Trip. The main turbine condenser low vacuum signal could indicate a leak in the condenser. Initiation of automatic closure of various valves will prevent excessive loss of reactor coolant and the release of significant amounts of radioactive material.

Four redundant vacuum switches monitor the main condenser vacuum. Each switch provides an input to one of four trip logic channels.

When a significant decrease in main condenser vacuum is detected, the PCRVICS initiates closure of all main steam line isolation and drain valves.

Main condenser low vacuum trip can be bypassed manually when the turbine throttle valve is less than 90% open and reactor pressure is below 1060 psig.

7.3.1.1.2.14 Reactor Core Isolation Cooling System Isolation Signals. The RCIC isolation signals for RCIC steam line high flow and RCIC pipe routing/equipment area high ambient temperature or high differential temperature are a subset of the RCIC leak detection system and are described in Section 7.6.1.3.4.

7.3.1.1.3 DELETED

7.3.1.1.4 Residual Heat Removal System - Containment Spray Cooling Mode

Function

The CSCM is an operating mode of the RHR system. It is designed to condense steam in the suppression chamber air volume and/or the drywell atmosphere following a LOCA. See Section 5.4.7. The drywell spray (with or without the RHR heat exchangers) is used to remove airborne radioactivity from the containment atmosphere in response to a LOCA. Drywell sprays are started within the first 15 minutes post-LOCA.

Operation

The RHR system control logic is shown in Figure 7.3-10. Instruments are listed in Table 7.3-7. Operator information displays are shown in Figure 7.3-10.

The CSCM is initiated by the control room operator by diverting RHR flow to either the suppression pool or the drywell by opening valves RHR-V-27A, RHR-V-27B (MO F027A, B) or RHR-V-16A, RHR-V-16B (MO F016A, B), and RHR-V-17A, RHR-V-17B (MO F017A, B).

The following conditions must exist before the operator can initiate the drywell spray cooling loop:

a. The LOCA signal which automatically initiated LPCI must still exist;

b. One of the two redundant drywell pressure switches must indicate high pressure; and

c. The operator must close the LPCI injection valve RHR-V-42A, RHR-V-42B (MO F042A, B).

7.3.1.1.5 Residual Heat Removal System - Suppression Pool Cooling Mode

Function

The SPCM is an operating mode of the RHR system. It is designed to prevent suppression pool temperature from exceeding predetermined limits following a reactor blowdown of the ADS or SRVs. The SPCM mode is also used during RCIC operation and SRV testing.

Operation

Component control logic is shown in Figure 7.3-10. Instruments are listed in Table 7.3-8. Operator information displays are shown in Figure 7.3-10.

The SPCM is initiated by the control room operator either during normal plant operation or following a LOCA when the suppression pool temperature monitoring system (see Section 7.6) indicates that pool temperature may exceed a predetermined limit.

During normal plant operation the operator initiates the SPCM as follows:

a. The RHR pump (A or B) is started. The standby SW pump is started and the RHR heat exchanger SW discharge valve RHR-V-68A, RHR-V-68B (MO 0068 A, B) is signaled to open automatically when the SW pump starts.

b. The RHR test return line valve RHR-V-24A, RHR-V-24B (MO F024 A, B) is opened.

c. The RHR heat exchanger inlet valves RHR-V-47A, RHR-V-47B (MO F047 A, B) are locked open (with power removed) and outlet valves RHR-V-3A, RHR-V-3B (MO F003 A, B) are throttled as necessary. The heat exchanger bypass valve RHR-V-48A, RHR-V-48B (MO F048 A, B) and valve RHR-V-24A, RHR-V-24B (MO F024 A, B) are throttled as necessary.

Subsequent to a LOCA the operator initiates the SPCM as follows:

a. Once reactor vessel water level has been restored, the LPCI flow must be terminated by closing the LPCI injection valve RHR-V-42A, RHR-V-42B (MO F042 A, B). Closing the injection valve causes the LOCA initiation logic to be overridden and allows operator control of the system;

b. The RHR test return line valve RHR-V-24A, RHR-V-24B (MO F024 A, B) control logic also has LOCA signal override provisions. This allows the operator to open the valve; and

c. The RHR heat exchanger inlet valves RHR-V-47A, RHR-V-47B (MO F047 A, B) are locked open (with power removed) and outlet valves RHR-V-3A, RHR-V-3B (MO F003 A, B) are throttled as necessary. The heat exchanger bypass valve RHR-V-48A, RHR-V-48B (MO F048 A, B) (a 10-minute timer keeps this valve open following a LOCA) and valve RHR-V-24A, RHR-V-24B (MO F024 A, B) are throttled as necessary.

7.3.1.1.6 Standby Service Water System

Function

The SW system provides cooling water to the diesel generators, the RHR heat exchangers, the HPCS, RCIC, LPCI, and LPCS auxiliary equipment (e.g., room cooler, pump motor bearing cooler, pump seal cooler), and the essential HVAC chillers. See Section 9.2.

Operation

Schematic arrangements of system mechanical equipment is shown in Figure 9.2-12. The SW component control logic is shown in Figure 7.3-12. Instruments are listed in Table 7.3-9. Operator information displays are shown in Figures 7.3-12 and 9.2-12.

The SW system is automatically initiated as follows:

a. The Division 1 SW pump P-1A is started automatically when either the RHR A pump, the LPCS pump, or the Division 1 diesel generator is started,

b. The Division 2 SW pump P-1B is started automatically when either the RHR B pump, RHR C pump, the Division 2 diesel generator, or the RCIC pump is started, and

c. The HPCS SW pump HPCS-P-2 (C002) is automatically started when the HPCS diesel generator is started.

Once the SW pumps are started the following occurs:

a. The RHR heat exchanger SW discharge valves RHR-V-68A and RHR-V-68B are signaled open, and

b. After the SW pumps discharge pressure exceeds a minimum value the pump discharge valves SW-V-2A, SW-V-2B, and SW-V-29 are signaled to open.

7.3.1.1.7 Main Control Room and Critical Switchgear Rooms Heating, Ventilating, and Air Conditioning System

Schematic arrangements of system mechanical equipment are shown in Figure 9.4-1. Component control logic is shown in Figure 7.3-13. Instruments are listed in Table 7.3-10. Operator information displays are shown in Figure 9.4-1 and Figure 7.3-13.

For a complete description of the main control room and critical switchgear rooms HVAC instrumentation and controls see Section 9.4.1.

7.3.1.1.8 Standby Gas Treatment System

Schematic arrangements of system mechanical equipment are shown in Figure 3.2-2. The SGT component control logic is shown in Figure 7.3-14. Instruments are listed in Table 7.3-11. Operator information displays are shown in Figure 3.2-2 and Figure 7.3-14.

For a complete description of the SGT instrumentation and controls see Section 6.5.1.

7.3.1.1.9 Reactor Building Ventilation and Pressure Control System

Function

The reactor building ventilation and pressure control system automatically maintains the reactor building or secondary containment at a negative pressure below atmospheric pressure by controlling the reactor building exhaust or SGT fan units. See Section 9.4.2.

Operation

Schematic arrangements of system mechanical equipment are shown in Figure 9.4-2. System component control logic is shown in Figure 7.3-14. Instruments are listed in Table 7.3-12. Operator information displays are shown in Figure 9.4-2 and Figure 7.3-14.

The differential pressure is monitored by eight redundant differential pressure transmitters, four in Division 1 and four in Division 2, which measure the differential pressure across the

exterior of four sides of the reactor building to inside the reactor building (572 ft el.). The signal indicating the least differential pressure from the four differential pressure transmitters in one division is selected and is used to control the position of the blades of the normal reactor building exhaust fan unit in that division. On the initiation of the SGT by containment isolation signals high drywell pressure, low reactor water level, or reactor building exhaust high radiation, the reactor building pressure control system then controls the secondary containment pressure by controlling the SGT fan units (see Section 6.5.1).

7.3.1.1.10 Containment Instrument Air System

Function

The purpose of the CIA system is to provide clean, dry, pressurized gas to the main steam relief valves and isolation valves inside primary containment. The pressurized nitrogen or air is normally provided by a non-safety-related source to a single header which delivers the operating gas to the relief and isolation valves. Under normal conditions, the non-safety-related source also provides working pressure to two headers which serve as the safety-related backup system for seven relief valves designated for the ADS function. However, a safety-related, bottled nitrogen source is available to maintain operating pressure to the seven divisionally separated ADS valves, in the event that the non-safety-related sources fail (see Figure 9.3-2).

In the event of failure of the non-safety-related portions of the system, which is indicated by low header pressure and detected by three pressure switches, the bottled nitrogen automatically maintains header pressure to the ADS valves. The non-safety-related portion of the system is isolated from the safety-related ADS portion upon receipt of the low header pressure signal. See Section 9.3.1.5.2.

The local stepping controller used for sequential nitrogen bottle opening is equipped with a local wheel index counter. A remote counter display is also located near the backup N_2 supply bottles inside of the reactor building (see Section 9.3.1.2.2). In addition, a low-header pressure alarm is provided to alert the operator to the loss of the ADS pneumatic supply.

Operation

Schematic arrangements of system mechanical equipment is shown in Figure 9.3-2. The CIA component control logic is shown in Figure 7.3-15. Instruments are listed in Table 7.3-13. Operator information displays are shown in Figures 7.3-15 and 9.3-2.

The CIA system is always in operation. The instrumentation and controls of the system perform the following functions:

a. Monitor CIA system header pressure,

b. Isolate the non-safety-related portion of system in the event of failure in this portion, and

c. Maintain CIA system header pressure in the event of item b by sequentially opening nitrogen bottles.

7.3.1.2 Design Basis

The ESF systems are designed to provide timely protection against the onset and consequences of conditions that threaten the integrity of the fuel barrier and the RCPB. Chapter 15 identifies and evaluates events that jeopardize the fuel barrier and RCPB. The methods of assessing barrier damage and radioactive material releases, along with the methods by which abnormal events are identified, are presented in Chapter 15.

7.3.1.2.1 Variables Monitored to Provide Protective Action

The following variables are monitored to provide protective actions by the ESF systems:

a. HPCS
   1. Reactor vessel low water level (trip level 2),
   2. Drywell high pressure;

b. ADS
   1. Reactor vessel low water level (trip level 3),
   2. Reactor vessel low water level (trip level 1);

c. LPCS and LPCI

   1. Reactor vessel low water level (trip level 1),
   2. Drywell high pressure;

d. PCRVICS

   1. Reactor vessel low water level (trip level 3),

   2. Reactor vessel low-low water level (trip level 2),

   3. Reactor vessel low-low-low water level (trip level 1),

   4. Main steam line high radiation,

   5. Main steam line tunnel high ambient or high differential temperature,

6. Main steam line high flow,

7. Main steam line low pressure,

8. Reactor building ventilation exhaust high radiation,

9. RWCU high differential flow or high blowdown flow,

10. RWCU pipe routing and equipment area high ambient temperature or high differential temperature,

11. RHR area high ambient temperature or high differential temperature,

12. RHR shutdown cooling suction high flow,

13. Main condenser low vacuum,

14. Drywell high pressure,

15. RCIC steam line high flow, and

16. RCIC pipe routing area high temperature, or equipment area high ambient temperature or high differential temperature;

e. DELETED;

f. CSCM - drywell high pressure,
- suppression chamber high pressure;

g. SPCM

1. Suppression pool temperature,
2. Drywell high pressure,
3. Reactor vessel low water level (trip level 1);

h. SW System - RHR, LPCS, RCIC, or diesel generator start;

i. Main control room and critical switchgear room HVAC

1. High room temperature;

j. Reactor building ventilation and pressure control - reactor building to fuel pool area differential pressure;

k. SGT

1. Reactor vessel low water level (trip level 2),
2. Drywell high pressure,
3. Reactor building ventilation high radiation;

l. CIA System - instrument air header low pressure;

The plant conditions which require protective action involving the ESF systems are described in Chapter 15.

7.3.1.2.2 Location and Minimum Number of Sensors

See the Technical Specifications for ESF systems, which identifies the minimum number of sensors to monitor safety-related variables. There are no sensors in the ESF systems which have a spatial dependence.

7.3.1.2.3 Prudent Operational Limits

Operational limits for each safety-related variable trip setting are selected with sufficient margin so that a spurious ESF system initiation is avoided. It is then verified by analysis that the release of radioactive materials, following postulated gross failures of the fuel or the nuclear system process barrier, is kept within acceptable bounds.

7.3.1.2.4 Margin

The margin between operational limits and the limiting conditions of operation of ESF systems are listed and the bases stated in the Technical Specifications.

7.3.1.2.5 Levels

Levels requiring protective action are specified in the Technical Specifications.

7.3.1.2.6 Range of Transient, Steady State, and Environmental Conditions

See Section 3.11 for environmental conditions. See Sections 8.2.1 and 8.3.1 for the maximum and minimum range of energy supply to ESF instrumentation and controls. All ESF instrumentation and controls are specified and purchased to withstand the effects of energy supply extremes.

7.3.1.2.7 Malfunctions, Accidents, and Other Unusual Events Which Could Cause Damage to Safety System

Chapters 3, 6, 9, 15, and Appendix F describe the following credible accidents and events: floods, storms, tornadoes, earthquakes, fires, LOCA, and pipe break outside containment. Each of these events is discussed below for the ESF systems.

7.3.1.2.7.1 Floods. The buildings containing ESF systems components have been designed to meet the probable maximum flood (PMF) at the site location. See Section 2.4. For a discussion of internal flooding protection see Sections 3.4.1.4.1.2, 3.4.1.5.2, and 3.6.

7.3.1.2.7.2 Storms and Tornadoes. The buildings containing ESF systems components have been designed to withstand meteorological events described in Section 3.3.

7.3.1.2.7.3 Earthquakes. The structures containing ESF systems components have been seismically qualified as described in Sections 3.7 and 3.8 and will remain functional during and following a safe shutdown earthquake (SSE). Seismic qualification of instrumentation and electrical equipment is discussed in Section 3.10.

7.3.1.2.7.4 Fires. To protect the ESF systems in the event of a postulated fire, the redundant portions of the systems are isolated by electrical separation barriers. If a fire were to occur within one of the sections or in the area of one of the panels, the ESF systems functions would not be prevented by the fire. The use of spatial separation and barriers ensures that even though some portion of the systems may be affected, the ESF systems will continue to provide the required protective action. A fire detection system using heat detectors and combustion product detectors is provided in Power Generation Control Complex (PGCC) floor sections and in panels containing ESF systems components mounted on these floor sections. A Halon fire suppression system is provided in the same areas.

7.3.1.2.7.5 LOCA. The ESF systems components functionally required during and/or following a LOCA have been environmentally qualified to remain functional as discussed in Section 3.11.

7.3.1.2.7.6 Pipe Break Outside Primary Containment. The ESF systems are designed and qualified to remain functional during and/or following these events. See Section 3.6.

7.3.1.2.7.7 Missiles. Protection for safety-related components is described in Section 3.5.

7.3.1.2.8 Minimum Performance Requirements

Minimum performance requirements for ESF instrumentation and controls are provided in the Technical Specifications.

7.3.1.3 Final System Drawings

Functional and architectural design differences between the PSAR and FSAR are listed in Table 1.3-8.

7.3.2 ANALYSIS

7.3.2.1 Engineered Safety Feature Systems - Instrumentation and Controls

Chapter 15 and Chapter 6 evaluate the individual and combined capabilities of the ESF systems.

The ESF systems are designed such that a loss of instrument air, plant load rejection, or turbine trip will not prevent the completion of the safety function.

7.3.2.1.1 Conformance to 10 CFR 50 Appendix A

The following provides information regarding conformance to those General Design Criteria (GDC) which apply specifically to the ESF systems. See Section 3.1 for a discussion of GDC which apply equally to all safety-related systems.

GDC 33

See Sections 7.3.1.1.1.1 and 3.1.2.4.4.

GDC 34

See Section 7.3.1.1.6 and 3.1.2.4.5.

GDC 35

See Sections 7.3.1.1.1, 7.3.1.1.6, and 3.1.2.4.6.

GDC 36, 37, 39, 40, 42, 43, 45, 46, and 61

See Section 7.3.2.1.3, Regulatory Guide 1.22.

GDC 38

See Sections 7.3.1.1.4, 7.3.1.1.5, and 7.3.1.1.6, and 3.1.2.4.9.

GDC 41

See Sections 7.3.1.1.8 and 3.1.2.4.12.

GDC 44

See Sections 7.3.1.1.6 and 3.1.2.4.15.

GDC 60 and 61

See Sections 7.3.1.1.8, 7.3.1.1.3, 3.1.2.6.1, and 3.1.2.6.2.

GDC 64

See Sections 7.3.1.1.2 and 7.3.1.1.8.

7.3.2.1.2 Conformance to IEEE Standards

The following provides information regarding conformance to IEEE 279-1971, Criteria for Protection Systems for Nuclear Power Generating Stations, which apply specifically to the ESF systems. See Section 7.1.2.3 for a discussion of IEEE standards which apply equally to all safety-related systems.

General Functional Requirement (IEEE 279-1971, paragraph 4.1)

The ESF systems that automatically initiate appropriate protective actions, whenever the parameters described in Section 7.3.1.2.1 reach predetermined limits, with precision and reliability assuming the full range of conditions and performance are discussed in Sections 7.3.1.2 and Chapter 15.

Single Failure Criterion (IEEE 279-1971, paragraph 4.2)

The ESF systems are not required to meet the single failure criterion on an individual system (division) basis. However, on a network basis, the single failure criteria does apply to ensure the completion of a protective function. Redundant sensors, wiring, logic, and actuated devices are physically and electrically separated such that a single failure will not prevent the protective function. See Section 8.3.1.4 for a discussion of the CGS separation criteria.

Quality Components (IEEE-279-1971, paragraph 4.3)

For a discussion of the quality of ESF system components and modules see Section 3.11.

Equipment Qualification (IEEE 279-1971, paragraph 4.4)

Vendor certification requires that the sensors associated with the ESF system variables, manual switches, and trip logic components located in mild environments perform in accordance with the requirements listed on the purchase specification as well as in the intended application. This certification, in conjunction with the existing field experience with these components in this application, will serve to qualify these components.

For a complete discussion of ESF equipment seismic and harsh environment qualification see Sections 3.10 and 3.11.

Channel Integrity (IEEE 279-1971, paragraph 4.5)

For a discussion of ESF systems channel integrity under extreme conditions described in Section 7.3.1.2, see Sections 3.10, 3.11, 8.2.1, and 8.3.1.

Channel Independence (IEEE 279-1971, paragraph 4.6)

The ESF systems channel independence is maintained through the application of the CGS separation criteria as described in Section 8.3.1.4.

Control and Protection Interaction (IEEE 279-1971, paragraph 4.7)

There are no ESF system and control system interactions.

Derivation of System Inputs (IEEE 279-1971, paragraph 4.8)

The ESF variables are direct measures of the desired variables requiring protective actions. See Sections 7.3.1.1.1 through 7.3.1.1.10.

Capability of Sensor Checks (IEEE 279-1971, paragraph 4.9)

See Section 7.3.2.1.3, Regulatory Guide 1.22.

Capability for Test and Calibration (IEEE 279-1971, paragraph 4.10)

See Section 7.3.2.1.3, Regulatory Guide 1.22.

Channel Bypass or Removal from Operation (IEEE 279-1971, paragraph 4.11)

During periodic tests of any one ESF system channel, a sensor may be valved out of service and returned to service under the administrative control procedures. Since only one sensor is valved out of service at any given time during the test interval, protective action capability for

ESF system automatic initiation is maintained through the remaining redundant instrument channels.

Operating Bypasses (IEEE 279-1971, paragraph 4.12)

The ESF systems contain the following operating bypasses.

The PCRVICS has two bypasses: (1) main steam line low pressure operating bypass which is imposed by means of the mode switch in the "startup" position (not in "run"). The mode switch cannot be left in this position above approximately 15% of rated power without initiating a scram. Therefore, the bypass is removed by placing the mode switch in the "run" position via the normal reactor operating sequence, and (2) the low condenser vacuum bypass which is imposed by means of four manual bypass switches in conjunction with closure of the turbine throttle valves, the reactor mode switch in any position other than "run," and reactor pressure below the low-pressure setpoint. Bypass removal is accomplished automatically by the opening of the turbine throttle valves or raising reactor pressure above the interlock pressure setpoint or manually by placing any of the four bypass switches in normal position or by placing the mode switch in the "run" position.

Indication of Bypasses (IEEE 279-1971, paragraph 4.13)

For a discussion of bypass and inoperability indication see Section 7.1.2.4, Regulatory Guide 1.47.

Access to Means for Bypassing (IEEE 279-1971, paragraph 4.14)

Access to means of bypassing any safety action or safety function is under the administrative control of the control room supervisor/shift manager. Other approved methods of controlling access to bypasses are also used. These include key locks with administrative control of the access to keys, procedurally controlled equipment lineups, e.g., locked valve checklists, and the use of mechanical locking devices and annunciators and other indications, e.g., BISI (Regulatory Guide 1.47, Bypass and Inoperable Status Indication for Nuclear Power Plant Safety Systems, described in Section 7.1.2.4). These additional methods help to prevent inadvertent bypasses or to alert the plant operators to safety function bypasses occurring either from equipment failures or from manually induced bypasses that result as part of testing, maintenance, or equipment repair activities.

Key-locked control switches that provide a means of controlling the access to a safety function bypass are designed to allow key removal only in the "safe" or "accident" positions. Access to the associated keys is procedurally controlled. When not in use, keys are under the administrative control of the control room supervisor/shift manager and stored in a key locker. The keys are audited once per day by the control room supervisor/shift manager. When operation of a key-locked control switch is required to be immediate, such as in the case of the

reactor mode switch, the key may be left in the lock during normal plant operation to ensure timely actuation.

Multiple Trip Settings (IEEE 279-1971, paragraph 4.15)

There are no multiple set points within the ESF systems.

Completion of Protective Action Once Initiated (IEEE 279-1971, paragraph 4.16)

Each of the automatically ESF system initiation control logic channels seal-in electrically and remain energized after initial conditions return to normal. Deliberate operator action is required to return (reset) an ESF system logic to normal.

Manual Initiation (IEEE 279-1971, paragraph 4.17)

See the discussion of Regulatory Guide 1.62 in Section 7.3.2.1.3.

Access to Setpoint Adjustments (IEEE 279-1971, paragraph 4.18)

All access to ESF system setpoint adjustments, calibration controls, and test points are under the administrative control of the control room operator.

Identification of Protective Actions (IEEE 279-1971, paragraph 4.19)

The ESF protective actions are directly indicated and identified by annunciators located in the main control room and a printed record is available from the process computer and transient data acquisition system.

Information Readout (IEEE 279-1971, paragraph 4.20)

The ESF systems are designed to provide the operator with accurate and timely information pertinent to their status. They do not introduce signals that could cause anomalous indications confusing to the operator.

System Repair (IEEE 279-1971, paragraph 4.21)

The ESF systems are designed to permit repair or replacement of components.

Recognition and location of a failed component will be accomplished during periodic testing or by annunciation in the main control room.

Identification (IEEE 279-1971, paragraph 4.22)

The ESF panels are identified by nameplates. The nameplate shows the division to which each panel or rack is assigned and also identifies the function in the system of each item of the control panel. The system to which each externally mounted relay belongs is identified on the relay panels.

Wiring and cabling outside of panels are labeled to indicate its divisional assignment as well as its system assignment (see Section 8.3.1.3).

7.3.2.1.3 Conformance to Regulatory Guides

The following is a discussion of conformance to those Regulatory Guides which apply specifically to the ESF systems. See Section 7.1.2.4 for a discussion of Regulatory Guides which apply equally to all safety-related systems.

Regulatory Guide 1.22 - 1972

The ESF systems instrumentation and controls are capable of being tested during normal plant operation (unless that testing is detrimental to plant availability) to verify the operability of each system component. Testing of safety-related sensors is accomplished by valving out each sensor, one at a time, and applying a test pressure source or as in the case of the main steam line radiation sensors, the sensors may be removed and test sources applied. This verifies the operability of the sensor, sensor contacts, and the sensor setpoint. Associated logic components are typically tested during plant shutdown conditions when component activation is not detrimental to plant operation. Functional operability of temperature sensors may be verified by readout comparisons, applying a heat source to the locally mounted temperature sensing elements or by continuity testing.

For the HPCS, LPCS, and LPCI, testing for functional operability of the control logic relays can be accomplished by use of plug-in test jacks and switches in conjunction with single sensor tests. Annunciation is provided in the main control room whenever a test plug is inserted in a jack to indicate to the operator that an ECCS is in a test status.

Operability of air-operated, solenoid-operated, and motor-operated valves is verified by actuating the valve control switches and monitoring the position change by position indicating lights at the control switch.

The ESF systems are provided with indications, status displays, annunciation, and computer printouts which aid the control room operator during periodic system tests to verify component operability.

Regulatory Guide 1.53 - 1973

See IEEE 279 paragraph 4.2 in Section 7.3.2.1.2.

Regulatory Guide 1.62 - 1973

The HPCS, LPCS, and the Division 2 LPCI system can be manually initiated at the system level from the main control room by actuation of armed push buttons. The LPCS push button also initiates the Division 1 LPCI system.

The ADS and the PCRVICS (except RCIC is manually isolated at the system level by its "Manual Isolation Push Button") are manually initiated at the system (division) level by actuation of two armed push buttons (one for each logic channel). The CIA system provides pneumatic pressure for opening of the ADS valves and is normally in service. A safety-related source of pressurized nitrogen will automatically come on line if the normal supply cannot maintain system pressure above a preset pressure. There is no remote manual initiation of the CIA system.

The CSCM is manually initiated at the system (division) level by actuation of the RHR pump start control switch and by opening the containment spray or suppression chamber spray valves.

If SM-7 or SM-8 is powered from TR-S, then the LPCS, LPCI A/B/C pump will not start when actuated with the manual arm and depress pushbuttons unless there is an associated valid Drywell Pressure – High or Reactor Vessel Water Level – Low Low, Level 2 signal. If needed, the desired pump system can be manually initiated.

The SPCM is manually initiated from the main control room by actuation of system pump and valve controls.

The SW system is manually initiated at the system (division) level by actuation of the pump start control switch.

The main control room and critical switchgear HVAC is manually initiated at the system (division) level by actuation of individual fan start control switches.

The SGT is manually initiated at the system (division) level by actuation of the system start control switch.

The actuation of the system level manual initiation switches simulates all the actions of automatic or manual (individual equipment initiation) system actuation.

NOTES:

1. WHEN TEST SOLENOID PILOT IS ENERGIZED, THE MAIN STEAM ISOLATION VALVE OPERATOR IS SLOWLY EXHAUSTED (60 SEC CLOSURE TIME) WHILE VALVE IS CLOSED BY ACTION OF THE VALVE SPRING WITHOUT AID OF AIR PRESSURE.
2. THE ALARMS AND VALVE INDICATING LIGHTS SHOWN ON THE FCD ARE SYSTEM REQUIREMENTS IN ADDITION TO THOSE SHOWN ON THE SYSTEM P&ID ADDITIONAL INFORMATION ON ALARMS, VALVE POSITION INDICATING LIGHTS, AND PROCESS INSTRUMENTATION NOT SHOWN ON THIS FCD MAY BE OBTAINED FROM REF. 1. AUXILIARY RELAYS & DEVICES ARE NOT SHOWN ON FCD EXCEPT WHERE REQUIRED TO CLARIFY FUNCTION.
4. MAIN STEAM LINE ISOLATION LOGIC A & C, RPS "A" SOLENOID LOGIC AND THE VALVE TEST SOLENOID SHALL BE POWERED FROM THE REACTOR PROTECTION SYSTEM M-G SET A: LOGIC B & D AND RPS "B" SOLENOID LOGIC FROM RPS M-G SET B.
5. ALL EQUIPMENT AND INSTRUMENTS ARE PREFIXED BY SYSTEM NO. B22 UNLESS OTHERWISE NOTED.
6. FOR LOCATION AND IDENTIFICATION OF INSTRUMENTS SEE INSTRUMENT DATA SHEET LISTED IN MPL (REF. 22)
7. AUTO DEPRESSURIZATION CONTROL LOGIC CIRCUIT SHALL HAVE REDUNDANT POWER SUPPLIES SO THAT A SINGLE FAILURE WILL NOT DISABLE THE AUTO DEPRESSURIZATION FUNCTION.
8. THE NUCLEAR BOILER SYS SHALL BE DESIGNED IN ACCORDANCE WITH REF. 18 AND WITH "PROPOSED CRITERIA FOR NUCLEAR POWER PLANT PROTECTION SYSTEMS IEEE 279" AS APPLICABLE TO THE CONTROL CIRCUITRY.
9. ISOLATION LOGIC SHALL BE "FAILSAFE", I.E., LOGIC SHALL BE DESIGNED TO INITIATE ISOLATION FUNCTIONS WHEN DE-ENERGIZED.
10. *REMOVED*
11. REMOVED
12. THE DEVICES IN THIS AREA, AS WELL AS OTHER DEVICES IN THIS LOGIC ARE ESSENTIAL AND MUST MEET THE REQUIREMENTS OF IEEE 279.
13. ALARM FROM ROTARY CONTACT
14. AE TO SUPPLY DEVICE TYPE, NUMBERS AND QUANTITY.
15. SEE REF. 4 FOR INITIATION OF "SELECT ROD INSERT".

NOTES:

1. PUMP MOTOR SHALL BE PROTECTED WITH OVERLOAD PROTECTION. PROTECTION RELAYS ARE TO BE APPLIED SO AS TO MAINTAIN POWER ON THE MOTOR AS LONG AS POSSIBLE WITHOUT IMMEDIATE DAMAGE TO EMERGENCY POWER SYSTEM.
2. VALVE MOTORS ARE TO BE PROVIDED WITH THERMAL OVERLOAD TRIPS AND ANNUNCIATION. THE PHASE 1 & 3 OVERLOAD DEVICES SHALL BE IN THE MOTOR CIRCUIT AND THE PHASE 2 OVERLOAD DEVICE IN THE ANNUNCIATOR CIRCUIT. IN ADDITION, VALVE MOTOR CIRCUITS ARE TO BE PROVIDED WITH SHORT CIRCUIT CURRENT PROTECTIVE TRIPS.
3. FOR ADDITIONAL ALARMS AND PROCESS INSTRUMENTATION NOT SHOWN, SEE LPCS SYSTEM P &ID.
4. UNLESS OTHERWISE NOTED, ALL RMS SHALL BE 3 POSITION SWITCHES, "CLOSE" "AUTO" "OPEN", SPRING RETURN TO "AUTO" FROM "CLOSE" OR "OPEN".
5. CONTROL AND MOTIVE POWER FOR LPCS SHALL BE FROM SAME SOURCE AS THE RHR LOOP "B" EQUIPMENT (REF. 5).
6. THE LPCS SYSTEM SHALL BE DESIGNED IN ACCORDANCE WITH IEEE 279-1971 AND REF. DOC. 8.
7. THE PRESENCE OF THIS POWER SUPPLY SIGNAL IS EXCLUSIVE OF THE TR-S POWER SUPPLY SIGNAL AND VICE VERSA.

Columbia Generating Station
Final Safety Analysis Report

Control Logic Diagram - Standby Gas Treatment System

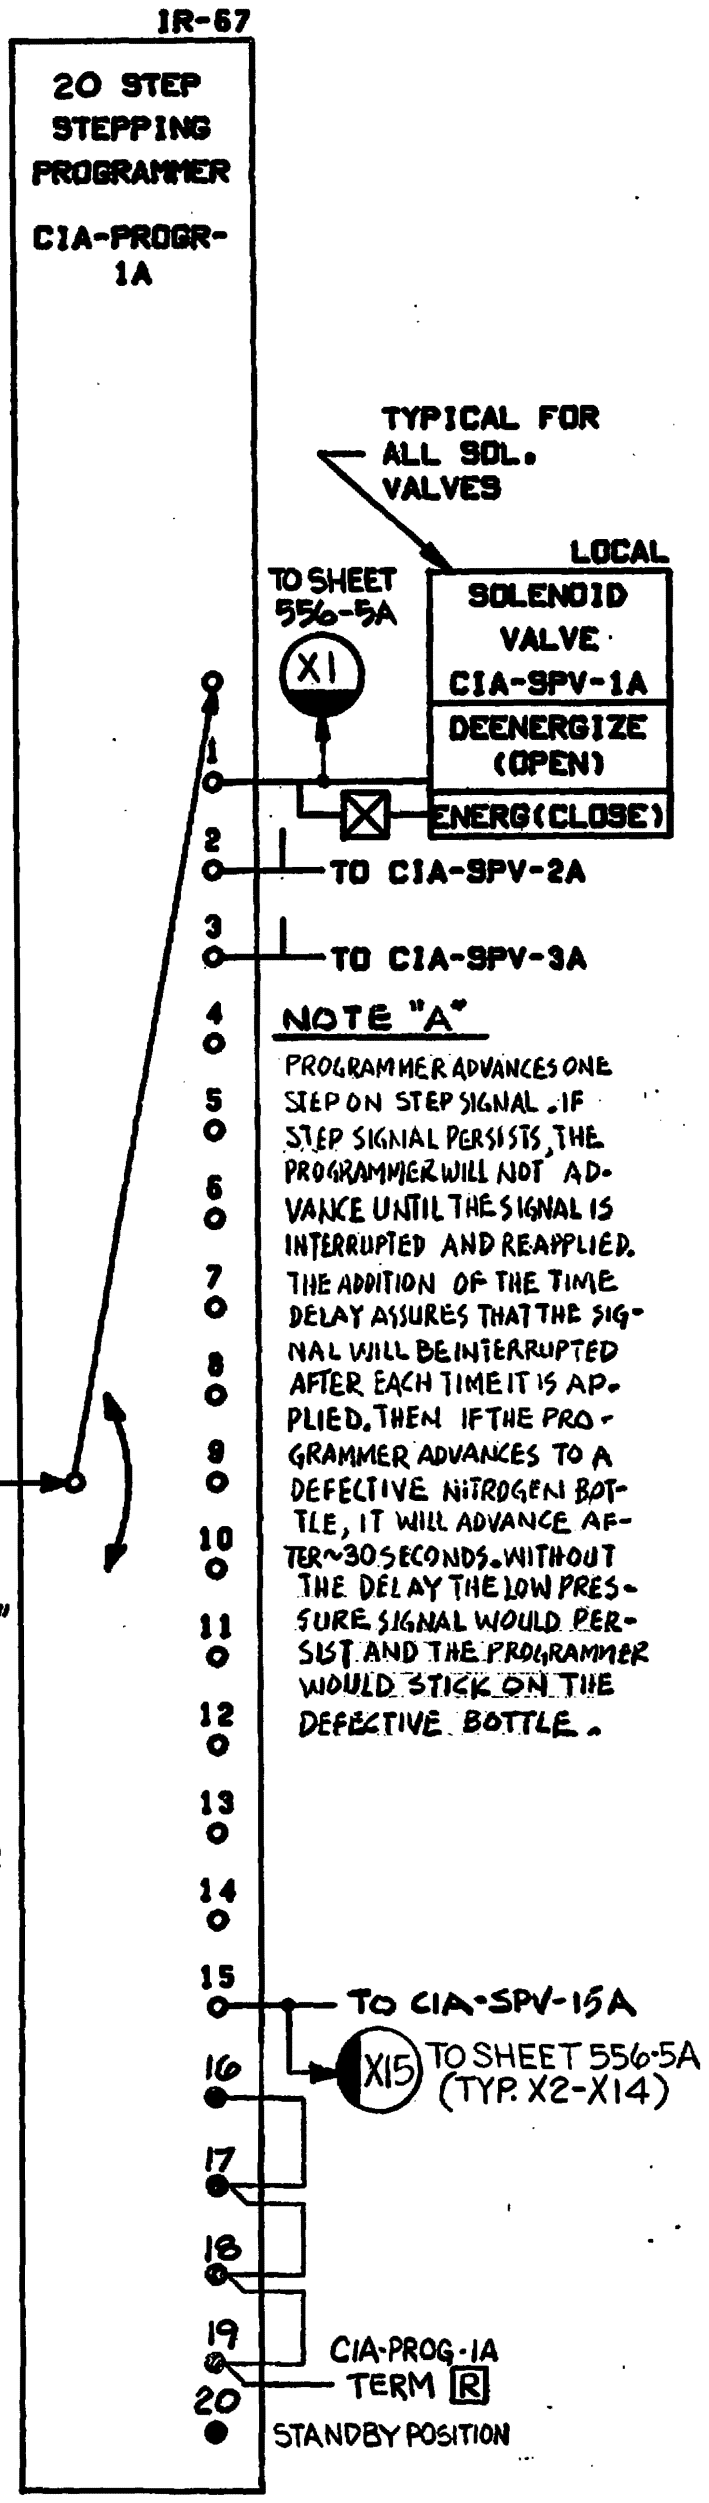
Draw. No. M620-544-12 | Rev. 5 | Figure 7.3-14.10

NOTE "D"

WHEN A NITROGEN BOTTLE EMPTIES ITS CONTENTS, THE DECREASE IN PRESSURE ACTUATES THE PROGRAMMER STEPPING MOTOR VIA PRESSURE SWITCHES THUS CAUSING THE PROGRAMMER TO SEQUENCE TO THE NEXT STEP. THE PROGRAMMER OUTPUT WILL DE-ENERGIZE (OPEN-SOLENOID VALVE) AT THIS NEW STEP AND WILL HOLD ALL PRECEDING STEP OUTPUTS DE-ENERGIZED (SOLENOID VALVES - OPEN) UNTIL THE PROGRAMMER IS RESET BACK TO STEP-0. ALL STEPS WHICH HAVE NOT BEEN SEQUENCED WILL REMAIN ENERGIZED (SOLENOID VALVES - CLOSED)

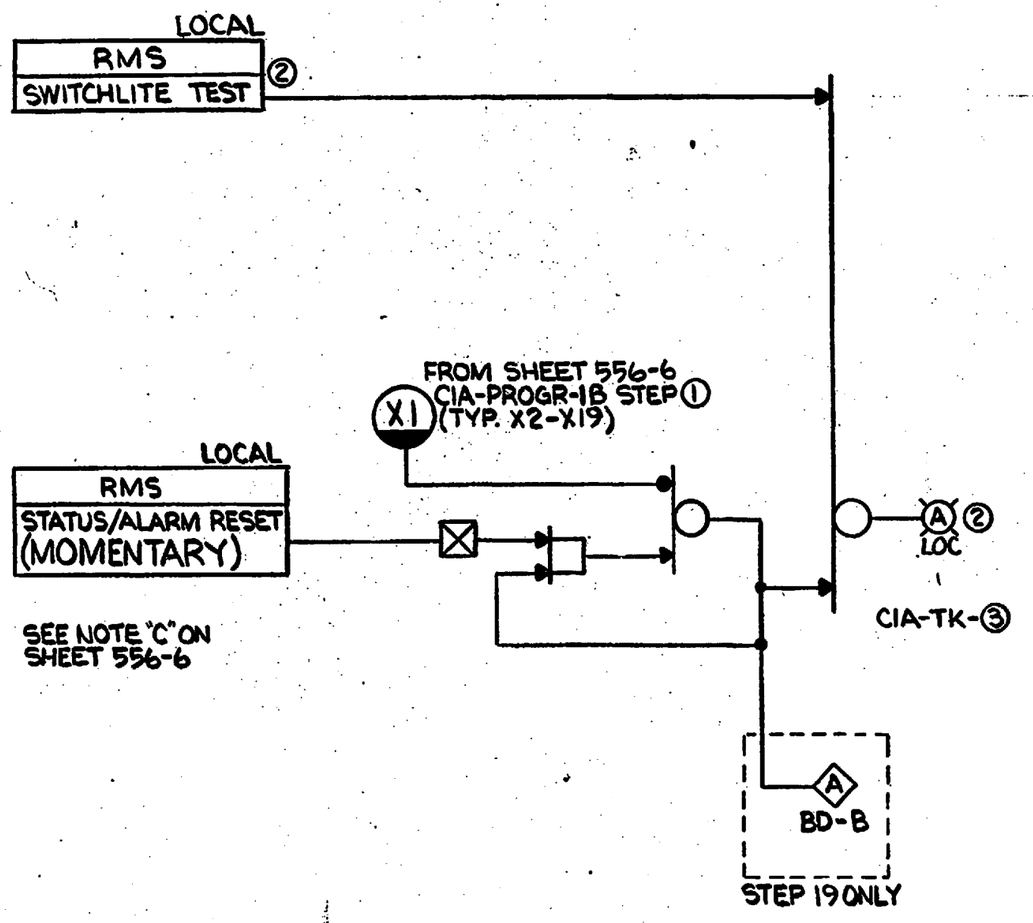


"E" TIME DELAY RELAY INFORMATION IS CONTROLLED ON E514-30 & E514-31.

"F" REFER TO INSTRUMENT MASTER DATA SHEETS FOR SETPOINT INFORMATION.

NOTE "B"

ONCE THE STEP SIGNAL IS APPLIED, THE PROGRAMMER SEALS IN AND ADVANCES TO THE NEXT STEP BEFORE THE LOSS OF ~30 SECONDS TIME DELAY SIGNAL INTERRUPTS THE STEP SIGNAL.



NOTE "A"

PROGRAMMER ADVANCES ONE STEP ON STEP SIGNAL. IF STEP SIGNAL PERSISTS, THE PROGRAMMER WILL NOT ADVANCE UNTIL THE SIGNAL IS INTERRUPTED AND REAPPLIED. THE ADDITION OF THE TIME DELAY ASSURES THAT THE SIGNAL WILL BE INTERRUPTED AFTER EACH TIME IT IS APPLIED. THEN IF THE PROGRAMMER ADVANCES TO A DEFECTIVE NITROGEN BOTTLE, IT WILL ADVANCE AFTER ~30 SECONDS. WITHOUT THE DELAY THE LOW PRESSURE SIGNAL WOULD PERSIST AND THE PROGRAMMER WOULD STICK ON THE DEFECTIVE BOTTLE.

NOTE "C"

AFTER EACH USE OF PROGRAMMER AND BOTTLES, RESET PROGRAMMER TO ZERO, AND PRESS RESET BUTTON AT REMOTE N_2 BOTTLE STATION #1A.

7.4 SYSTEMS REQUIRED FOR SAFE SHUTDOWN

7.4.1 DESCRIPTION

This section discusses the instrumentation and controls of the following systems required for safe plant shutdown:

a. Reactor core isolation cooling (RCIC) system,

b. Standby liquid control (SLC) system,

c. Residual heat removal shutdown cooling mode (RHR-SDC),

d. Remote shutdown system (RSS),

e. Anticipated transient without scram recirculation pump trip system (ATWS-RPT), and

f. Anticipated transient without scram alternate rod insertion (ATWS-ARI).

The systems discussed in this section are all capable of assisting the operator in achieving a safe plant shutdown. The remote shutdown and SLC systems are manually operated backups to the control room and reactor manual control systems, respectively, and are only required for special event conditions. Their use is not required to achieve a safe shutdown under normal, transient, or accident conditions. The normal shutdown cooling mode of residual heat removal (RHR) is available to the operator to remove residual heat when the reactor is shut down. Recirculation pump trip (ATWS-RPT) is used in conjunction with alternate rod insertion (ARI) and SLC to mitigate an ATWS event. Design of the ATWS-RPT and ARI systems is in accordance with the criteria provided in Reference 7.4-1. Loss of any of the systems will not impede safe shutdown of the plant. As such these systems are not required to be safety-related (except RCIC and alternate RHR SDC) and have not been designed to meet safety system requirements.

The sources that supply power to the safe shutdown systems originate from onsite ac and/or dc safety-related and non-safety-related buses. See Chapter 8 for a complete discussion of the safety-related and non-safety-related power sources.

7.4.1.1 Reactor Core Isolation Cooling System

7.4.1.1.1 Function

The RCIC system (see Section 5.4.6.2) is designed to maintain or supplement reactor vessel water inventory during the following conditions.

a. Normal Operation. When the reactor vessel is isolated from its primary heat sink (main condenser) and accompanied by a loss or unavailability of the reactor feedwater system; and

b. When the plant is being shut down and normal coolant flow from the feedwater system is stopped before the reactor is depressurized to a level where the reactor shutdown cooling mode of the RHR system can be placed into operation.

7.4.1.1.2 Operation

Schematic arrangements of system mechanical equipment are shown in Figure 5.4-11. The RCIC system component control logic is shown in Figure 7.4-1. Instruments are listed in Table 7.4-1. Operator information displays are shown in Figures 5.4-11 and 7.4-1.

The RCIC system can be initiated either manually or automatically. The control room operator can initiate RCIC by operating the manual initiation push button which simulates an automatic initiation or by activating each piece of equipment sequentially as required.

The RCIC system is automatically initiated by four redundant level switches, arranged in a one-out-of-two-twice logic configuration, which sense reactor vessel low water level (trip level 2).

The RCIC steam line isolation and the turbine steam exhaust motor-operated valves are normally open with their control switches key locked in the open position, and the turbine trip and throttle valve is normally open and these valves require no change of position for automatic system initiation. (Note: the key locked control switches do not prevent automatic isolation of these valves.)

The RCIC system responds to an automatic initiation signal as follows (actions are simultaneous unless stated otherwise):

a. The pump suction from the condensate storage tanks valve RCIC-V-10 (MO F010) is signaled open;

b. To ensure pump discharge flow is directed to the reactor vessel only, the test return line to the condensate storage tanks valves RCIC-V-22 (MO F022) and RCIC-V-59 (MO F059) are signaled closed;

c. The turbine steam inlet and the turbine lube oil cooler cooling water supply valves RCIC-V-45 (MO F045) and RCIC-V-46 (MO F046) are signaled to open;

d. When the turbine steam inlet valve RCIC-V-45 (MO F045) starts to open, the RCIC pump discharge to reactor vessel valve RCIC-V-13 (MO F013) and the turbine lube oil cooler supply valve RCIC-V-46 (F046) are signaled open. Valves RCIC-V-13 (MO F013) and RCIC-V-46 (F046) are prohibited from opening or if open, automatically closes when RCIC-V-45 (MO F045) or the turbine trip and throttle valve RCIC-V-1 (MO F001) is closed. A one-out-of-two-twice limit switch logic trips the main turbine on the opening of RCIC-V-13 (MO F013) and RCIC-V-45 (MO F045) to limit moisture introduction;

e. The barometric condenser vacuum tank vacuum pump is signaled to start; and

f. When valve RCIC-V-45 (MO F045) leaves the closed position the RCIC turbine is accelerated until the automatic flow controller setpoint is reached and the system discharge flow is controlled by the turbine electronic governor mechanism.

RCIC flow may be directed away from the vessel by diverting the pump discharge to the CST. This is accomplished by closing injection valve RCIC-V-13 and opening the test return valves (RCIC-V-22 and 59). The system is returned to injection mode by closing RCIC-V-59 and then opening RCIC-V-13. This mode of operation will not be used during events where an unacceptable source term is identified in primary containment. Diverting RCIC flow to the CST is not a safety-related function nor does this mode affect the ability of RCIC to initiate during plant transients. The system automatically switches to injection mode if the water level decreases to the low level initiation point (Level 2).

During system operation if the barometric condenser vacuum tank water level becomes high the condenser condensate discharge pump is automatically started and the condensate returned to the RCIC pump suction. When the system is not operating excess tank water is discharged through isolation valves RCIC-V-4 (AO F004) and RCIC-V-5 (AO F005) to the equipment drain system.

In the event the water level in the condensate storage tanks should become low the RCIC pump suction is automatically transferred from the condensate storage tank(s) to the suppression pool by opening valve RCIC-V-31 (MO F031). Two level switches mounted on a Seismic Category I standpipe in the reactor building are used to detect low water level in the condensate storage tank(s). Either switch can cause automatic suction transfer. Once valve RCIC-V-31 (F031) is fully open the condensate storage tank valve RCIC-V-10 (MO F010) is automatically closed.

The RCIC system includes design features which provide system equipment protection or accomplish primary containment isolation if certain types of abnormal events occur. The RCIC turbine is automatically shut down by closing the turbine trip and throttle valve, RCIC-V-1 (MO F001), if any of the following conditions are detected:

a. RCIC isolation signals:
   i. Low reactor pressure
   ii. High steam line flow
   iii. Instrumentation line break
   iv. High differential temperature across RCIC area cooler
   v. RCIC equipment area high temperature
   vi. High turbine exhaust diaphragm pressure
   vii. Manual isolation
b. Turbine overspeed
c. High turbine exhaust pressure
d. Low pump suction pressure
e. Low pressure in the RCIC discharge header(1)
f. Manual turbine trip actuated by the control room operator.

The steam inlet valve RCIC-V-45 (MO F045) is automatically closed and the turbine is shut down if the reactor vessel high water level (level 8) is reached. The isolation valve for RCIC turbine lube oil cooling water, RCIC-V-46 (MO F046), automatically closes if RCIC-V-45 (MO F045) closes, or if the turbine trip and throttle valve RCIC-V-1 closes. Valves RCIC-V-45 (MO F045) and RCIC-V-46 (MO F046) will reopen automatically and the turbine restarts when the water level is subsequently reduced to the low level initiation (level 2).

To protect the RCIC pump from overheating during low flow conditions the pump discharge flow and pressure are monitored. If the pump discharge pressure switch indicates the pump is running and the pump discharge flow switch indicates low flow, the minimum flow return line valve RCIC-V-19 (MO F019) is automatically opened. The minimum flow valve is automatically closed when flow is normal or when either the turbine trip and throttle valve (RCIC-V-1) or the steam inlet valve RCIC-V-45 (MO F045) is closed.

Air operated (AO) valves RCIC-V-25, RCIC-V-26, and RCIC-V-54 (AO F025, AO F026, and AO F054) and a condensate drain pot are provided in a drain pipe line arrangement just upstream of the turbine inlet valve. On receipt of an RCIC initiation signal, the drainage path is isolated by closing RCIC-V-25 and RCIC-V-26 (AO F025 and AO F026). The water level in the steam line drain condensate pot is controlled by a level switch and a valve RCIC-V-54 (AO F054) which energizes to allow condensate to flow out of the drain pot by bypassing the steam trap, in the event that the trap fails to adequately remove the condensate.

The RCIC system turbine exhaust line vacuum breaker isolation valves RCIC-V-110 (MO F080) and RCIC-V-113 (MO F086) are normally open but close automatically following system trip when both the low steam line pressure and high drywell pressure setpoint are exceeded.

NOTE: (1) This equipment protection feature has been disabled by placing the RCIC-RMS-PIS1 switch in the OVERRIDE position.

The leak detection and other protective signals of RCIC system will automatically signal the steam line warmup valve RCIC-V-76 (MO F076) closed, override the key lock control switch position and signal the steam line inboard isolation valve RCIC-V-63 (MO F063) and the outboard steam line isolation valve RCIC-V-8 (MO F008) closed if any of the following abnormal conditions exist:

a. Redundant temperature switches sense RCIC pump room area ventilation air inlet and outlet high differential temperature or high ambient temperature;

b. Redundant temperature switches sense RCIC pipe routing area high ambient temperature;

c. Redundant differential pressure switches sense RCIC steam line high flow or instrument line break (after an approximate 3 sec delay);

d. Redundant pressure switches sense RCIC turbine exhaust diaphragm high pressure. Both switches in the same division must actuate to cause isolation; and

e. A pressure switch senses RCIC low steam supply pressure.

For a complete description of the RCIC system leak detection isolation signal, see Section 7.6.1.3.1.

The RCIC system may be isolated after initiation by the control room operator by actuation of a push button which causes the outboard steam line isolation valve to close.

7.4.1.2 Standby Liquid Control System

7.4.1.2.1 Function

The SLC system (see Section 9.3.5) instrumentation is designed to initiate injection of a liquid neutron absorber into the reactor. Other instrumentation is provided to maintain this liquid chemical solution well above saturation temperature in readiness for injection.

The SLC system is a redundant method of manually shutting down the reactor to cold shutdown conditions from normal operation or from anticipated transient conditions when manual control rod insertion capability is lost. For the anticipated transient condition, boron solution can be injected into the reactor pressure vessel by running both SLC pumps simultaneously. The quantity of boron required to shut down the nuclear reaction can be injected in approximately 1 hr (see Section 9.3.5.2).

7.4.1.2.2 Operation

Schematic arrangements of system mechanical equipment is shown in Figure 9.3-14. The SLC system component control logic is shown in Figure 7.4-2. Operator information displays are shown in Figures 9.3-14 and 7.4-2.

The SLC system is initiated by the control room operator by turning the SYSTEM A or the SYSTEM B or both key locked switches to the OPERATE positions. When either or both of these switches are activated, both of the explosive-operated valves fire and both tank discharge valves (SLC-V-1A and SLC-V-1B) start to open immediately. The pumps are interlocked so that at least one of the two storage tank discharge valves (or the test tank discharge valve when testing) must be open for either or both pumps to run.

When the SLC system is initiated, the outboard isolation valve of the reactor water cleanup (RWCU) system is automatically closed. This prevents removal of the injected boron by the RWCU demineralizers.

7.4.1.3 Residual Heat Removal System/Shutdown Cooling Mode

7.4.1.3.1 Function

The normal shutdown cooling mode (see Section 5.4.7.1) of the RHR system is used when the reactor is shutdown and, if available, can be used for long-term cooling after vessel water level has been restored following accident conditions.

The RHR-SDC consists of instrumentation designed to provide decay heat removal capability for the core by accomplishing the following:

a. Reactor cooling during shutdown operation after the vessel pressure is reduced to approximately 48 psig,

b. Cooling the reactor water to a temperature at which reactor refueling and servicing can be accomplished, and

c. Diverting part of the shutdown flow to the reactor vessel head to condense the steam generated from the hot walls of the vessel while it is being flooded.

7.4.1.3.2 Operation

See Section 5.4.7.2.6 for a complete description of the RHR-SDC operation.

7.4.1.4 Remote Shutdown Systems

7.4.1.4.1 Function

The RSS are designed to achieve a cold reactor shutdown from outside the main control room following these postulated conditions:

a. The plant is at normal operating conditions and all plant personnel have been evacuated from the main control room and it is inaccessible;

b. The initial event that causes the main control room to become inaccessible is assumed to be such that the reactor operator can manually scram the reactor before leaving the main control room. Though the capability exists to manually scram from outside the control room, plant procedures realistically call for scramming before exiting the control room;

c. The main turbine pressure regulators may be controlling reactor pressure via the bypass valves. However, in the interest of demonstrating that the plant can accommodate even loss of the turbine controls, it is assumed that this turbine generator control panel function is also lost. Therefore, main steam line isolation is assumed to occur at a specified low turbine inlet pressure and reactor pressure is relieved through the relief valves to the suppression pool;

d. The reactor feedwater system which is normally available is also assumed to be inoperable. Reactor vessel water inventory is provided by the RCIC system or automatic depressurization system (ADS) and RHR as described in Section 7.4.1.4.2; and

e. Emergency dc power is assumed to be available.

The RSS are required only during times of main control room inaccessibility when normal plant operating conditions exist, i.e., no transients or accidents are occurring. Following such an event the remote shutdown function is provided by two redundant systems: the RSS and the alternate RSS.

7.4.1.4.2 Operation

Some of the existing systems used for normal reactor shutdown operation are also used in the remote shutdown capability to shut down the reactor from outside the main control room. The functions needed for remote shutdown control are provided with manual transfer switches that override controls from the main control room and transfer the controls to the remote shutdown control panels. Remote shutdown control is not possible without actuation of the transfer

devices. Necessary power supplies and control logic are also transferred. Operation of the transfer switches causes an alarm in the main control room.

During a main control room fire it has been postulated that high-to-low pressure interface valves RHR-V-8 and RHR-V-9 (series isolation valves) can simultaneously open. This would result in a loss-of-coolant accident (LOCA) outside the primary containment with no mitigation; these valves cannot close against a 1000 psi differential. For this reason, during normal plant operation, power is removed from RHR-V-9. This precludes operation via spurious control circuit energization. Access to the remote shutdown panel is administratively and procedurally controlled. All system equipment controls (for essential valves and pumps) necessary for proper system lineup and complete system control are located on the remote shutdown panels.

The remote shutdown function can be effected by one of two redundant systems. The primary (preferred) system uses the RHR system loop B (RHRB) while the secondary uses RHR loop A and is designated as the alternate RSS. The RCIC system is not required for reactor safe shutdown when using the minimum systems analyzed in GE document NEDO-24708A. Consequently, the mode of depressurization used for the alternate RSS is based on a rapid depressurization (ADS) in going from event initiation directly to cold shutdown where the low pressure system (RHR A) is used in the alternate shutdown cooling mode. This flow path uses the suppression pool as a heat sink when the service water system (SW loop A) is needed to bring the reactor to the cold low pressure condition.

When the RCIC system is available, then manual actuation of relief valves and the initiation of the RCIC system will maintain reactor water inventory and bring the reactor to a hot shutdown condition after scram. During this phase of shutdown, the suppression pool will be cooled by operating the RHR system in the suppression pool cooling mode. Reactor pressure will be controlled and core decay and sensible heat rejected to the suppression pool by relieving steam pressure through the relief valves.

Manual operation of the relief valves will cool the reactor and reduce its pressure at a controlled rate until reactor pressure becomes so low that the RCIC system is unable to sustain operation. The RHR system will then be operated in the shutdown cooling mode using the RHR system heat exchanger to cool reactor water and bring the reactor to the cold low pressure condition.

Equipment/functions that have transfer and control switches or indicators located on the remote shutdown and the alternate remote shutdown control panels are shown in the Licensee Controlled Specifications.

7.4.1.5 Anticipated Transient Without Scram - Recirculation Pump Trip

7.4.1.5.1 Function

The ATWS-RPT function is to trip the reactor recirculation pumps in the event of an abnormal operating occurrence in conjunction with failure of the reactor protection system (RPS).

7.4.1.5.2 Operation

Schematic arrangement of system mechanical equipment is shown in Figure 5.4-6.

The ATWS-RPT is automatically initiated by reactor vessel low water level (level 2) and/or reactor vessel high pressure. Instruments are listed in Table 7.4-2. The sensor logic configuration is "one-out-of-two-twice" for tripping the reactor recirculating pump feeder breakers. See Figure 7.4-3.

The ATWS-RPT system is an energize-to-operate system. The sensor logic channels and the feeder breaker trip coil circuitry receive power from the 125-V dc batteries from Divisions 1 and 2.

7.4.1.6 Anticipated Transient Without Scram - Alternate Rod Insertion

7.4.1.6.1 Function

The ATWS-ARI function is to actuate valves in the scram air header to reduce the air pressure in the header allowing the scram inlet and discharge valves to open providing an alternate scram. The design is diverse and independent from the RPS.

7.4.1.6.2 Operation

Schematic arrangement of the system mechanical equipment is shown in Figure 4.6-5. Logic arrangement is shown in Figures 7.4-4 and 7.4-5.

The ATWS-ARI is automatically initiated by reactor vessel low water level or reactor vessel high pressure. Instruments are listed in Table 7.4-3. The sensor logic configuration is "two-out-of-two" for either parameter input for energizing the scram air header exhaust solenoid valves to vent the header. The system can also be actuated manually. The ATWS-ARI is an energize-to-operate system. The sensor logic channels and solenoid valves receive power from the 125-V dc batteries from Divisions 1 and 2.

7.4.1.7 Design Basis

The safe shutdown systems are designed to provide timely protection against the onset and consequences of conditions that threaten the integrity of the fuel barrier and the reactor coolant pressure boundary (RCPB). Chapter 15 identifies and evaluates events that jeopardize the fuel barrier and RCPB. The methods of assessing barrier damage and radioactive material releases, along with the methods by which abnormal events are identified, are presented in Chapter 15. No design basis accident shall be considered for the RSS systems (including LOCA). Therefore, control of engineered safety feature (ESF) systems for protective action outside the main control room is not required.

7.4.1.7.1 Variables Monitored to Provide Protective Actions

All safe shutdown systems are initiated by operator actions, with the exception of ATWS-RPT and ATWS-ARI which are actuated by level and/or pressure sensors and RCIC which is activated by low reactor vessel water level (level 2).

The plant conditions which require protective action involving safe shutdown are described in Chapter 15.

7.4.1.7.2 Location and Minimum Number of Sensors

The Technical Specifications identify the minimum number of sensors required to monitor safety-related variables. There are no sensors in the safe shutdown systems which have a spatial dependence.

7.4.1.7.3 Prudent Operational Limits

Prudent operational limits for each safety-related variable trip setting are selected with sufficient margin so that a spurious safe shutdown system initiation is avoided. It is then verified by analysis that the release of radioactive materials, following postulated gross failures of the fuel or the nuclear system process barrier, is kept within acceptable bounds.

7.4.1.7.4 Margin

The margin between operational limits and the allowable values for safe shutdown systems are addressed for those parameters listed in the Technical Specifications.

7.4.1.7.5 Levels

Levels requiring protective action are established in the Technical Specifications.

7.4.1.7.6 Range of Transient, Steady State, and Environmental Conditions

See Section 3.11 for environmental conditions. See Sections 8.2.1 and 8.3.1 for the maximum and minimum range of energy supply to the safe shutdown systems instrumentation and controls. All safety-related instrumentation and controls are specified and purchased to withstand the effects of energy supply extremes.

The ATWS-RPT and ATWS-ARI systems are required to function only during an anticipated operational occurrence, not a design basis accident. Therefore, all the ATWS-RPT and ATWS-ARI equipment is located outside containment and is qualified for the temperature, pressure, humidity, and radiation levels experienced during the anticipated operational occurrence.

7.4.1.7.7 Malfunctions, Accidents, and Other Unusual Events Which Could Cause Damage to Safety Systems

Chapter 15 describes the following credible accidents and events: floods, storms, tornadoes, earthquakes, fires, LOCA, pipe break outside containment, and feedwater line break. Each of these events is discussed below for the safe shutdown systems.

7.4.1.7.7.1 Floods. The buildings containing safe shutdown system components have been designed to meet the probable maximum flood (PMF) at the site location. See Section 2.4. For a discussion of internal flooding protection see Sections 3.4 and 3.6.

7.4.1.7.7.2 Storms and Tornadoes. The buildings containing safe shutdown system components have been designed to withstand meteorological events described in Section 3.3.

7.4.1.7.7.3 Earthquakes. The structures containing safe shutdown system components have been seismically qualified (or shown to maintain integrity) as described in Sections 3.7 and 3.8 and will remain functional during and following a safe shutdown earthquake (SSE). Seismic qualification of instrumentation and electrical equipment is discussed in Section 3.10.

7.4.1.7.7.4 Fires. To protect the safe shutdown systems in the event of a postulated fire, the redundant portions of the safe shutdown systems are isolated by electrical separation barriers or physical distance. The use of separation and barriers ensures that even though some portion of the systems may be affected, the safe shutdown systems will continue to provide the required protective action. A fire detection system using heat detectors and product of combustion detectors is provided in power generation control complex (PGCC) floor sections and in panels containing safe shutdown system components mounted on these floor sections. A Halon fire suppression system is provided in the same areas. See Appendix F for a discussion of Appendix R fire protection.

7.4.1.7.7.5 Loss-of-Coolant Accident. The safe shutdown systems components located inside containment which are functionally required following a LOCA have been environmentally qualified to remain functional as discussed in Section 3.11.

7.4.1.7.7.6 Pipe Break Outside Primary Containment. Protection is provided for safe shutdown system components, as required from the effects of breaks outside primary containment. See Section 3.6.

7.4.1.7.7.7 Missiles. Protection for safe shutdown systems is described in Section 3.5.

7.4.1.7.8 Minimum Performance Requirements

Minimum performance requirements for safe shutdown systems instrumentation and controls are provided in the Technical Specifications.

7.4.1.8 Final System Drawings

Functional and architectural design difference between the PSAR and FSAR are listed in Table 1.3-8.

7.4.2 ANALYSIS

The safe shutdown systems are designed such that loss of instrument air, a plant load rejection, or a turbine trip will not prevent the completion of the safety function. No abnormal operation is assumed for the RSS which, by itself, performs no safety-related function.

7.4.2.1 Conformance to 10 CFR 50 Appendix A - General Design Criteria

The following is a discussion of conformance to those general design criteria (GDC) which apply specifically to the safe shutdown systems. See Section 3.1 for a discussion of GDC which apply equally to all safety-related systems.

GDC 19 - Control Room

The RSS consists of equipment located outside the control room which is sufficient to provide and ensure safe shutdown of the reactor.

GDC 34 - Residual Heat Removal

Refer to Section 3.1.2.4.5.

7.4.2.2 Conformance to IEEE Standards

The following is a discussion of conformance to IEEE 279-1971 which applies specifically to the safe shutdown systems. See Section 7.1.2.3 for a discussion of IEEE Standards which apply equally to all safety-related systems.

General Functional Requirement (IEEE 279-1971, paragraph 4.1)

Since the RSSs, by themselves, do not perform any safety-related function, they do not fall within the criteria set by IEEE 279. However, since certain RSS components interface with safety-related systems, such as RHR and RCIC, during normal operation, they are part of those systems and meet the design criteria for those systems.

Remote shutdown is provided by two redundant systems: the Division 2 RSS and the Division 1 alternate RSS. Portions of these systems are electrically separated by the physical and spatial requirements described in Section 8.3.1.4. A design basis fire in the main control room that fails all components to their worst operational state is considered an incredible event. As such only the Division 2 power distribution system for the Division 2 remote shutdown is completely isolated from the effects of a main control room fire. Control room interaction that would result in the loss of power to the alternate RSS as well, is not considered credible per Columbia Generating Station (CGS) SSER commitments (licensing condition 12). The RSSs consist of components that are qualified to Quality Class I and Seismic Category I requirements. Operation of any RSS transfer switch is annunciated in the main control room.

The RCIC is automatically initiated when reactor vessel water level is determined to be below a predetermined limit.

The SLC system is initiated by the control room operator. Display instrumentation in the control room provides the operator with information on reactor vessel water level, pressure, neutron flux level, control rod position, and scram valve status allowing assessment of the need for initiation of the SLC system.

The ATWS-RPT and ATWS-ARI are automatically initiated when reactor vessel low water level and/or reactor vessel high pressure predetermined limits are exceeded. ATWS-RPT and ATWS-ARI do not perform a safety-related function and do not fall within the criteria of IEEE 279. However, applicable paragraphs of IEEE 279 are addressed in the following paragraphs:

Single-Failure Criterion (IEEE 279-1971, paragraph 4.2)

The reactor shutdown cooling function is safety related and required to comply with single failure requirements of IEEE 279 and GDC 34. However, the preferred RHR-SDC suction path uses a single loop of the RRC system through two series, redundant division, isolation

valves RHR-V-8 and RHR-V-9 and is, therefore, not single failure proof. To meet the single failure requirements of IEEE 279 and GDC 34, a safety related, single failure proof design for this function is provided by the alternate shutdown cooling mode of RHR. See Section 5.4.7.1.1 and the notes to Figure 15.2-10, Activity C1 or C2 for a complete discussion of the alternate shutdown cooling mode of RHR. The alternate shutdown cooling mode is safety related and single failure proof in that two redundant divisions of equipment are available. Since the normal shutdown cooling mode is the preferred path, Energy Northwest will maintain all the preferred path components as safety related, Quality Class I.

The RCIC system alone is not required to meet the single-failure criterion. The RCIC initiation and isolation initiation sensors and associated logic do, however, meet the single-failure criterion for automatic system initiation or isolation. The single-failure criteria is met through physical and electrical separation of equipment as described in Section 8.3.1.4.

The SLC system serves as backup to the control rod drive (CRD) system for controlling reactivity if the CRD fails and is required for ATWS. It is not necessary for the SLC system to meet the single failure criterion.

The ATWS-RPT and ATWS-ARI are not required to meet the single failure criterion. However, with the exception of the electrical power and the final actuating equipment the system is designed to the single failure criterion.

Quality of Components and Modules (IEEE 279-1971, paragraph 4.3)

See Section 3.11 for safe shutdown system conformance. The ATWS-ARI components are selected to satisfy the quality requirements in Reference 7.4-1.

Equipment Qualification (IEEE 279-1971, paragraph 4.4)

Vendor certification requires that the safe shutdown system sensors, manual switches, and logic components perform in accordance with the requirements listed on the purchase specification as well as in the intended application. This certification, in conjunction with the existing field experience with these components in this application, will serve to qualify these components.

For a discussion of safe shutdown system equipment qualification see Sections 3.5, 3.6, 3.10, and 3.11.

Channel Integrity (IEEE 279-1971, paragraph 4.5)

For a discussion of RCIC and SLC system Channel Integrity under all extremes of conditions described in Sections 7.4.1.1 and 7.4.1.2, see Section 3.11.

Channel Independence (IEEE 279-1971, paragraph 4.6)

Channel independence is maintained through application of the CGS separation criteria as described in Section 8.3.1.4.

Control and Protection Interaction (IEEE 279-1971, paragraph 4.7)

The RCIC, SLC, ATWS-RPT, and ATWS-ARI systems have no interaction with plant control systems.

Derivation of Systems Inputs (IEEE 279-1971, paragraph 4.8)

All inputs to the RCIC system, RSS, RHR-SDC, ATWS-RPT, and ATWS-ARI that are essential to their operation are direct measures of appropriate variables.

The SLC system display instrumentation in the control room provides the operator with directly measured information on reactor vessel water level, pressure, neutron flux level, control rod position and valve status. Based on this information the operator can assess the need for the SLC system.

Capability for Sensor Checks (IEEE 279-1971, paragraph 4.9)

See Section 7.4.2.3, Regulatory Guide 1.22.

Capability for Test and Calibration (IEEE 279-1971, paragraph 4.10)

See Section 7.4.2.3, Regulatory Guide 1.22.

Channel Bypass or Removal from Operation (IEEE 279-1971, paragraph 4.11)

Calibration of a sensor which introduces a single instrument channel trip will not cause a protective action without the coincident trip of a second channel. Removal of a sensor from operation during calibration does not prevent the redundant instrument channel from functioning.

Operating Bypasses (IEEE 279-1971, paragraph 4.12)

There are no operating bypasses within the safe shutdown systems.

Indication of Bypasses (IEEE 279-1971, paragraph 4.13)

For a discussion of bypass and inoperability indication see Section 7.1, with the exception of ATWS-RPT and ATWS-ARI, which are under administrative control.

Access to Means for Bypassing (IEEE 279-1971, paragraph 4.14)

Access to means of bypassing any safety action or safety function is under the administrative control of the control room supervisor/shift manager. Other approved methods of controlling access to bypasses are also used. These include key locks with administrative control of the access to keys, procedurally controlled equipment lineups, e.g., locked valve checklists, and the use of mechanical locking devices and annunciators and other indications, e.g., BISI (Regulatory Guide 1.47, Bypass and Inoperable Status Indication for Nuclear Power Plant Safety Systems, described in Section 7.1.2.4). These additional methods help to prevent inadvertent bypasses or to alert the plant operators to safety function bypasses occurring either from equipment failures or from manually induced bypasses that result as part of testing, maintenance, or equipment repair activities.

Key-locked control switches that provide a means of controlling the access to a safety function bypass are designed to allow key removal only in the "safe" or "accident" positions. Access to the associated keys is procedurally controlled. When not in use, keys are under the administrative control of the control room supervisor/shift manager and stored in a key locker. The keys are audited once per day by the control room supervisor/shift manager. When operation of a key-locked control switch is required to be immediate, such as in the case of the reactor mode switch, the key may be left in the lock during normal plant operation to ensure timely actuation.

Multiple Set Points (IEEE 279-1971, paragraph 4.15)

There are no multiple setpoints within the safe shutdown systems.

Completion of Protective Action Once it is Initiated (IEEE 279-1971, paragraph 4.16)

The RCIC is automatically stopped on high vessel water level, system malfunction trip signals or if steam supply pressure drops below that necessary to sustain turbine operation.

The SLC system explosive valves remain open once fired. The injection valves will not close, and discharge pump motors will continue to run unless terminated by operator action. The ATWS-ARI system once initiated will actuate valves in the scram air header thus providing an alternate method to scram. This action will continue until the trip logic is cleared and the operator resets the system.

Manual Initiation (IEEE 279,1971, paragraph 4.17)

See Sections 7.4.1.1, 7.4.1.2, 7.4.1.3, 7.4.1.4, 7.4.1.5, and 7.4.1.6 for a discussion of the manual initiation of RCIC, SLC, RHR-SDC, RSS, ATWS-RPT, and ATWS-ARI systems.

Access to Set Point Adjustment (IEEE 279-1971, paragraph 4.18)

All access to setpoint adjustments for RHR-SDC, RCIC, ATWS-RPT, and ATWS-ARI are under administrative control of the control room supervisor/shift manager.

The operation of the SLC system is not dependent on or affected by any setpoint adjustment or calibration.

Identification of Protective Actions (IEEE 279-1971, paragraph 4.19)

Automatic initiation of the RCIC system is annunciated in the control room.

The ATWS-RPT breaker trip is annunciated in the control room. The ATWS-ARI system initiation is annunciated in the control room.

The explosive valve status of the SLC system, once fired, is indicated in the control room.

Information Readout (IEEE 279-1971, paragraph 4.20)

The RCIC, ATWS-RPT, and ATWS-ARI systems are designed to provide the operator with accurate and timely information pertinent to their status. They do not give anomalous indications confusing to the operator.

The SLC system discharge pressure of the pumps and storage tank level is indicated in the control room.

System Repair (IEEE 279-1971, paragraph 4.21)

The RCIC, SLC, ATWS-RPT, and ATWS-ARI systems are designed to permit repair or replacement of components during normal plant operation.

Recognition and location of a failed component will be accomplished during periodic testing or by annunciation in the control room.

Identification (IEEE 279-1971, paragraph 4.22)

Controls and instruments for RCIC, SLC, ATWS-RPT, and ATWS-ARI systems are located in the main control room and clearly identified by nameplates. Relays are located in separate panels for RCIC, SLC, ATWS-RPT, and ATWS-ARI systems use only. Relays and panels are identified by nameplates. All wiring and cabling is labeled to indicate its divisional assignment as well as its system assignment (see Section 8.3.1.3).

7.4.2.3 Regulatory Guides Conformance

Regulatory Guide conformance for remote shutdown control and instrumentation is provided in this chapter for each system whose instrumentation and controls interface with the RSS.

Conformance to Regulatory Guides for the RHR shutdown cooling mode is discussed in Section 7.3.2.

The following is a discussion of conformance to those Regulatory Guides which apply specifically to the RCIC, SLC, ATWS-RPT, and ATWS-ARI systems. See Section 7.1.2.4 for a discussion of Regulatory Guides which apply equally to all safety-related systems.

Regulatory Guide 1.22 - Periodic Testing of Protection System Actuation Functions

The RCIC system, with the exception of RCIC-V-13 (injection valve), is capable of being completely tested during normal plant operation to verify that each element of the system is capable of performing its intended safety function. RCIC-V-13 is operability tested during plant shutdown.

The explosive valves may be tested during plant shutdown. The explosive valve control circuits are continuously monitored and annunciated in the control room. The remainder of the SLC system may be tested during normal plant operation to verify that each element is capable of performing its intended function.

Testing of RCIC, SLC, ATWS-RPT, and ATWS-ARI systems sensors during normal plant operation is accomplished by valving out each sensor from its process line and applying a test pressure source. This verifies the operability of the sensor, its calibration range, and the operability of associated control room logic components.

Also, the ATWS-RPT trip logic up to the breaker trip can be tested during plant operation. The ATWS-ARI trip logic can be tested up to the solenoid valves during plant operation.

Regulatory Guide 1.53 - Application of the Single-Failure Criterion to Nuclear Power Plant Protection Systems

See Section 7.4.2.2 and IEEE 279, paragraph 4.2, for the RCIC, SLC, ATWS-RPT, and ATWS-ARI systems.

Regulatory Guide 1.62 - Manual Initiation of Protective Actions

The SLC system is actuated by two key-locked switches on the main control room console. Operating either switch starts one of the injection pumps, actuates both of the explosive valves,

opens both pump suction motor-operated valves, and closes the RWCU system outboard isolation valve.

The ATWS-RPT feeder breakers can be initiated manually from the main control room by actuation of the feeder breaker control switch.

The ATWS-ARI scram air header blowdown valves can be manually initiated from the main control room.

The RCIC system can be manually initiated for vessel water level makeup.

NOTES:

1. THE RCIC SYS IS ARRANGED FOR TEST OF PUMP AT FULL FLOW AT ANYTIME EXCEPT WHEN INITIATION SIGNAL OR AUTO ISOLATION SIGNAL IS ACTIVATED, IN EVENT THE INITIATION SIGNAL OCCURS WHILE TEST IS UNDERWAY, THE SYS AUTOMATICALLY RETURNS TO STARTUP MODE.
2. ALL POWER FOR OPERATION OF D.C. VALVE MOTORS SHALL ORIGINATE FROM A PLANT D.C. BUS. POWER FOR AC OPERATED VALVES SHALL ORIGINATE FROM AN EMERGENCY AC BUS.
3. ALL EQUIPMENT & INSTRUMENT PREFIXED BY SYS NO. (E51-) UNLESS OTHERWISE NOTED.
4. ISOLATION SIGNAL SWITCHES SHALL BE OF THE TYPE THAT CLOSE CONTACTS FOR THE SPECIFIED ISOLATION EVENT. WHERE AUXILIARY RELAYS ARE USED IN THE ISOLATION CHANNELS THEY SHALL BE POWERED FROM STATION BATTERIES. (REF.10).
5. AUXILIARY RELAYS & DEVICES NOT SHOWN ON FUNCTIONAL CONTROL DIAGRAMS EXCEPT WHERE REQUIRED TO CLARIFY FUNCTION.
6. FURNISHED WITH TURBINE.
7. THE RCIC SYS SHALL BE DESIGNED IN ACCORDANCE WITH REF.10.
8. THE RCIC SYS SHALL BE DESIGNED IN ACCORDANCE WITH "PROPOSED CRITERIA FOR NUCLEAR POWER PLANT PROTECTION SYS, IEEE-279" INSOFAR AS PRACTICAL.
9. RCIC SYS PUMP MOTORS SHALL BE PROVIDED WITH A TRIP (WHICH WILL BE ANNUNCIATED) AND AN ALARM ON OVERLOAD. DC VALVE OPERATOR MOTORS SHALL TRIP ON OVERLOAD (TRIPS SHALL BE ANNUNCIATED.). AC VALVE OPERATOR MOTORS SHALL ALARM AND TRIP ON OVERLOAD. TRIP SHALL BE SET HIGHER THAN ALARM.

7.5 SAFETY-RELATED DISPLAY INSTRUMENTATION

7.5.1 SUMMARY DESCRIPTION

7.5.1.1 General

This section describes the instrumentation that provides information to the operator to enable him to assess the status of safety-related systems and the need to perform required safety functions including a discussion of conformance to Regulatory Guide 1.97.

The safety-related display instrumentation is listed in Table 7.5-1. It tabulates equipment identified on the various figures located in Sections 7.2, 7.3, 7.4, and 7.6.

The instrumentation and ranges shown in Table 7.5-1 are selected on the basis of giving the reactor operator the necessary information to perform normal plant operations and yet the capability to track process variables pertinent to safety following design-basis accidents (DBAs).

The following information is provided to the control room operator to monitor reactor conditions and allow assessment of safety system status following a DBA.

The power sources to the instrumentation described in this section originate from the Division 1, Division 2, or Division 3 safety-related emergency ac and/or dc buses unless indicated otherwise.

7.5.1.1.1 Reactor Water Level

Two divisionally separated ranges of water level instrumentation are provided: wide range and fuel range.

Wide range water level is sensed by two divisionally separated differential pressure transmitters. The signals are displayed in the control room on two recorders. Wide range instruments cover the level from +60 in. to -150 in.

Fuel range water level overlaps the wide range to provide water level in the actual core region. Level is sensed by two divisionally separated differential pressure transmitters. The level is displayed in the control room on a recorder and an indicator. The fuel range covers from -310 in. to -110 in.

The two ranges provide continuous level indication from 60 in. above the bottom of the dryer skirt to 150 in. below the top of the active fuel. Both ranges have a common zero reference point located 527.5 in. above the inside bottom of the reactor vessel.

In addition to the wide range and fuel zone range, the following are provided.

Upset range water level is sensed by a single channel to monitor from 0 in. to 180 in. and is recorded in the control room.

Shutdown range water level is sensed by a single channel to monitor from 0 in. to +400 in. and is indicated in the control room.

The combination of all fourranges monitor from just below the bottom of the active fuel to the top of the reactor head, a total span of -310 in. to +400 in.

In response to NRC Bulletin 93-03 a continuous backfill capability was added for the reactor pressure vessel (RPV) level reference legs to ensure the level instrumentation system design is of high functional reliability for long-term operation by minimizing the transport of dissolved noncondensable gas down the reference legs. The control rod drive (CRD) system is the source of backfill water as described in Section 4.6.1.

7.5.1.1.2 Reactor Pressure

Reactor pressure is sensed by two divisionally separated pressure transmitters. These pressure transmitters are recorded in the control room.

7.5.1.2 Reactor Shutdown Indication

The following information is provided to the control room operator to monitor reactor shutdown.

a. Control rod status lamps indicating each rod fully inserted. Power is supplied from a highly reliable non-Class 1E uninterruptible power supply (UPS) system;

b. Control rod scram pilot valve position status lamps indicating open valves;

c. Neutron monitoring power range channels and recorders downscale. The power sources are from reactor protection system (RPS) motor-generator (MG) sets;

d. Source range neutron monitoring channels and recorders on scale. When fully withdrawn from the core, the range covered is approximately 10% to 10^{-3}% power. When fully inserted, the range is 10^{-3}% to -10^{-7}% power;

e. Annunciators for RPS variables and trip logic in the tripped state. Power is supplied from a Class 1E power source;

f. The computer work stations provide logging of trips and control rod position log and provides thermal hydraulic information to the operator which is used to

keep the plant operating within Technical Specifications limits. Power is supplied by a non-Class 1E UPS power source; and

g. Reactor water sample analysis to determine soluble boron concentration via the postaccident sample station.

7.5.1.3 Primary Containment and Reactor Vessel Isolation Indication

The following information is provided to the control room operator to monitor the integrity of the primary containment.

a. Power operated primary containment isolation valve (excluding check valves) position indication is displayed (valve position indicating lamps) at valve controls in the control room which are Class 1E and is also displayed by a non-Class 1E transient data acquisition system (TDAS) (see Section 7.7). The non-Class 1E RPS MG sets provide an acceptable power supply in conjunction with the independently powered TDAS display. Although the hardened containment vent primary containment isolation valves are power operated, their function is to operate in a beyond-design-basis event. Position indication is provided at the controls in the control room. These valves are spring closed with the operating pneumatics isolated and locked requiring a manual action to place in service and therefore, are not powered from a Class 1 E supply.

b. Main steam line flow indication;

c. Annunciators for the primary containment and reactor vessel isolation system variables and trip logic in the tripped state. Power is supplied by Class 1E power; and

d. Process computer logging of trips. Power is from a non-Class 1E UPS power supply.

7.5.1.4 Emergency Core Cooling System and Reactor Core Isolation Cooling Indication

The following information is provided to the control room operator to monitor emergency core cooling system (ECCS) and reactor core isolation cooling (RCIC) system status.

a. Annunciators for high-pressure core spray (HPCS), low-pressure core spray (LPCS), residual heat removal (RHR), automatic depressurization system (ADS), and RCIC sensor initiation logic trips;

b. Flow and/or pressure indications for each ECCS and RCIC are provided;

c. ECCS and RCIC valve position indication;

d. Process computer logging of trips in the ECCS and RCIC. Power is provided from the UPS, a highly reliable non-Class 1E power supply;

e. Transient data acquisition system display of RCIC and ECCS functions. Power is provided from the UPS, a highly reliable non-Class 1E power supply; and

f. Main steam safety/relief valve (SRV) position indication.

7.5.1.5 Containment Indications

The following information is provided to the control room operator to monitor primary containment status.

7.5.1.5.1 Primary Containment Pressure Monitoring

There are two divisions of drywell pressure monitoring instruments. Each division consists of three monitoring ranges. The narrow range is -5 to +3 psig; the intermediate range is 0 to 25 psig; and the high range is 0 to 180 psig. Each range is recorded and the narrow range is indicated in the control room.

7.5.1.5.2 Primary Containment Temperature

Containment temperature is monitored continuously by a recorder in the control room. Points of measurement are as follows:

Points	Description
4*	Air inlet vicinity recirculation pump motors
5*	Fan coil inlets
5	Fan coil outlets
3*	RPV head flange area
6	Sacrificial shield annulus
3	CRD area

* Some of these points are summed to provide average drywell temperature information during normal operation and postaccident conditions.

2	RPV head area
5	SRV area
3*	Fan coil inlet minus annulus air
5	Upper drywell area return ducts
5	Miscellaneous areas
2	Suppression chamber air temperature
2	Suppression pool water temperature

Drywell average temperature and suppression chamber air temperature are recorded in the control room. Indication from all points is also available.

7.5.1.5.3 Primary Containment Radiation

The atmosphere of the primary containment is monitored for low levels (leak detection) and high levels [loss-of-coolant accident (LOCA)] of radioactivity and recorded in the control room on two redundant recorders.

The leak detection monitoring system consists of two identical divisionally separated offline samplers with racks located in the reactor building sample rooms. Each sample rack has a two-channel unit containing a particulate and a noble gas scintillation detector. The detectors are of high sensitivity to detect the presence or increase of radioactivity in the atmosphere indicating small leaks in the reactor coolant pressure boundary (RCPB). The output signals from the detectors are sent to panels in the main control room, which contain count ratemeters, recorders, and controls.

An air sample is piped from the containment atmosphere to the local leak detector racks and returned to containment. The control room operator has complete control of the operation and checking of the monitor system from the main control room. The leak detection channels described above are isolated when a LOCA occurs because they would rapidly be saturated by the high levels of radioactivity.

The LOCA detection system provides a means to detect a rupture of the RCPB which has released large amounts of radioactive material into primary containment. The LOCA detection system consists of two divisionally separated redundant systems. Each system contains an

* Some of these points are summed to provide average drywell temperature information during normal operation and postaccident conditions.

ionization chamber type detector located inside the primary containment. The LOCA monitors provide signals to panels in the main control room, which contain count ratemeters and recorders.

7.5.1.5.4 Primary Containment Hydrogen and Oxygen Concentration

Atmosphere samples from a minimum of two locations inside the primary containment and one location in the suppression chamber are sequentially monitored for hydrogen and oxygen percentage levels by each of two redundant analyzer systems (see Figure 9.4-8).

Each gas analyzer system contains a hydrogen and an oxygen sensor with calibrated resistance temperature detectors (RTDs) and pressure transducers that allow a microprocessor in the H_2-O_2 analyzer system to automatically compensate the measured H_2 or O_2 concentrations for changes in temperature and pressure. The microprocessor provides for periodic calibration of the analyzers. All gases are pumped back to the primary containment at all times.

The analyzers are single range, i.e., 0 to 30% hydrogen and 0 to 30% oxygen. The output signal from each analyzer is sent to a recorder in the main control room. Two redundant (divisional) recorders are provided. Each analyzer has three adjustable alarm contacts which annunciate abnormal conditions (Hi H_2, Hi O_2, and Hi Hi O_2) in the main control room.

7.5.1.5.5 Suppression Chamber Pressure

Suppression chamber pressure is recorded in the control room from two separate pressure transmitter systems. Range of recording is from 0 to 100 psig.

7.5.1.5.6 Suppression Pool Temperature Monitoring

Postaccident suppression pool temperature data is provided by four thermocouples, one per wetwell quadrant, which feed signals to a summer via millivolt to current converters (MV/Is). The average suppression pool temperature is then recorded and displayed in the control room. Backup thermocouples are available for use in the monitoring scheme. See Section 7.6.1.7 for additional information.

7.5.1.5.7 Suppression Pool Water Level Monitoring

Both wide range and narrow range suppression pool water level are monitored by two sets of redundant Class 1E sensors. Each sensor consists of one level transmitter which provides a signal to a recorder in the control room. The range of these sensors is $\pm$25 in. from normal water level in the pool for the narrow range and 2 ft to 52 ft for the wide range.

7.5.1.6 Monitoring for Radioactive Release to the Environment

7.5.1.6.1 Building Effluent Gas Monitors

The effluent activity from the reactor building ventilation exhaust, the condenser offgas system, the condenser vacuum pump system, and the standby gas treatment system (SGTS) is monitored by using an offline monitoring and sampling system. This system is described in Section 11.5.2.2.1.5. Both the postaccident and normal operational data are recorded in the control room and trended via computer work stations. The turbine building effluent release path is monitored using an isokinetic system. A sample is withdrawn from the duct through an array of isokinetic nozzles then through particulate and charcoal filters and into a low range and high range set of gas detectors. Each of these effluent stacks or ducts have a continuous vent flow rate monitoring system as described in Section 7.5.2.2.3. As described in Sections 11.5.2.2.1.5 and 11.5.2.2.1.6, signals from these radiation detectors are sent to a ratemeter and recorder located in the control room. Similar systems are installed to monitor the radwaste building ventilation release path as described in Section 11.5.2.2.1.7, except that flow rate monitoring is available on computer work stations rather than on a separate flow recorder. Even though flow monitoring is Category 2 which requires environmental qualification, TDAS is not environmentally qualified. However, TDAS is located in the main control room (a mild environment) and is designed for this service environment. If TDAS is unavailable, radwaste building effluent flow will be determined in accordance with the ODCM.

7.5.1.6.2 Meteorological Conditions

The wind speed, wind directions, and stratified atmospheric temperature information is sensed by the meteorological tower primary and backup instrumentation and is recorded in the control room. Indicated meteorological conditions are used to calculate doses downwind due to a radiation release. Wind speed and direction is monitored by separate channels at the 33 ft and 245 ft elevations. Primary and backup channels provide the air temperature difference between 33 ft and 245 ft elevations.

7.5.1.7 Radiation Exposure (Postaccident) (See Section 12.3.4.2)

High range area radiation monitors are located inside the reactor building to monitor the exposure rates at entry points to that building following an accident. These also serve to provide indication of any radioactive releases into the reactor building from the primary containment and provide trend monitoring during accident conditions. Signals from the detectors are recorded in the control room.

7.5.1.8 Postaccident Sampling System

The postaccident sampling system provides a means for obtaining grab samples of highly radioactive liquid samples of primary coolant directly from the reactor vessel, the RHR loops, or the suppression pool and atmospheric samples of the drywell, wetwell, and reactor building. All samples may be transported for analysis in the onsite or offsite facilities.

7.5.1.9 Primary System Relief Valve Position Indication

Two methods are available to monitor SRV position in the main control room:

a. Direct indication: Uses linear variable differential transformers (LVDTs) mounted directly on the relief valves. These sensors generate a voltage signal proportional to valve lift which is processed to provide an OPEN/CLOSED indication and annunciation; and

b. Tail pipe thermocouples: Uses thermocouples attached to the SRV tailpipes which monitor the temperature rise in the piping resulting from open or leaking relief valves. These signals are recorded and annunciated.

7.5.1.10 Power Supply Status Monitoring

Voltage indication for standby power buses of 4160-V ac and 480-V ac switchgear are provided in the control room. Voltage and amperage indication is also provided for batteries, battery chargers, inverters, and dc and UPS buses.

7.5.1.11 Primary Water Source Indication

The amount of feedwater flow to the reactor is detected by flow transmitters located on the feedwater lines. The flow rate is recorded in the control room. The reserve of water available in the condensate storage tanks is monitored and transmitted to the control room for operator information.

7.5.1.12 Residual Heat Removal System

Residual heat removal system loops A and B may function in several different modes. The flow for each of these modes, except for the reactor vessel head spray, is indicated by a single flow meter for each loop. The flow rate for each mode is determined by observing both indicated flow and valve position. The head spray has its own individual flow meter. All flow information is displayed in the control room.

Residual heat removal system loop C functions only in one mode. The flow rate for this mode is also displayed in the control room.

Heat from the RHR loops A and B is removed via heat exchangers. The outlet temperature of the heat exchangers is recorded in the control room.

7.5.1.13 Standby Liquid Control System

The standby liquid control (SLC) system flow into the reactor is monitored and displayed in the control room. Additionally, the SLC system tank level is displayed in the control room as a backup indication to the flow.

7.5.1.14 (DELETED)

7.5.1.15 High Levels in Radioactive Liquid Tanks

Each tank used to hold or collect radioactive liquids is equipped with a level indicating system. The level is recorded on local panels in the radwaste building.

7.5.1.16 Emergency Ventilation Damper Position Indication

Damper position indication is provided in the control room for all dampers necessary to prevent release of radioactive gases to the environment or for the protection of operating personnel during accident conditions.

7.5.1.17 Standby Service Water System

Flow rate in each loop is detected by a flow transmitter providing signals to indicators in the control room. The spray pond temperature is indicated in the control room. The spray pond provides the source of cooling water to engineered safety feature (ESF) components.

7.5.1.18 Spent Fuel Pool Cooling System

The temperature of the spent fuel pool is monitored by instrumentation that provides indication and hi-alarms in the control room.

7.5.1.19 Main Control Room Heating, Ventilating, and Air Conditioning

Redundant temperature indications are provided in the control room to monitor control room temperature.

7.5.1.20 Standby Gas Treatment System

Each division of the SGTS is provided with loop flow indication in the control room.

7.5.1.21 Containment Instrument Air

Each division of the containment instrument air (CIA), the common header and both ADS main steam relief valve trains, provides system line pressure indication in the control room. The sequence programmers for the backup nitrogen bottles on each train provide annunciator signals to the control room when the last bottles are connected to the train manifolds.

7.5.1.22 Safety Parameter Display

7.5.1.22.1 Description

The safety parameter display system (SPDS) design is based on the emergency response information system (ERIS) concept developed by the BWR Owner's Group. The ERIS control room information requirements are defined as a minimum by the Emergency Procedures Guidelines (EPG).

The purpose of the SPDS is to assist control room personnel in making quick assessments of plant safety status. The functional criteria for the SPDS are described in NUREG-0696. These requirements are satisfied using human engineered hard-wired control room instrumentation. Additional support information that is useful for emergency response is supplied by the Graphic Display System (GDS). The displays provide information related to the following plant functions:

a. Reactivity control,
b. Reactor core cooling and heat removal,
c. Reactor coolant system integrity,
d. Radioactivity control, and
e. Containment integrity.

7.5.1.22.2 Conformance to NUREG-0696

The overall SPDS design consists of two display systems. The human engineered hard wired control room instrumentation needed to comply with Regulatory Guide 1.97 is the primary source of plant safety status. These displays are Class 1E and sufficiently concentrated to allow rapid safety assessment. (Additional information is contained in Appendix B, TMI Item I.D.1.)

The hard-wired control room displays afford continuous parameter status indication. Real time validation of critical parameters is accomplished by comparison of signals from redundant divisions. Operating procedures and operator training provide guidance resolution of unsuccessful data validation. Recorders indicate magnitude and trend of important parameters, and alarms provide audible notification of an unsafe operating condition. Redundant

divisionally separate instrumentation provided for critical parameters ensures a very high degree of reliability during both plant operation and cold shutdown.

Additional support information is supplied by the GDS. The GDS consists of high performance human factored HMI displays of critical plant functions. The GDS and Class 1E equipment are adequately isolated to meet IEEE 279-1974. Data is collected and processed by the control room real time data acquisition systems (see Section 7.7.1.15). Processed data of critical parameters is subsequently formatted and available for display in the control room automatically or on request.

The HMI display of critical parameters is a dedicated function with formatted displays capable of indicating approaches to off normal conditions for critical plant parameters. Control room displays are available on a separate HMI on an "ON DEMAND" or "AUTOMATIC" basis as required. Power to the data acquisition system, computer processor, and HMI displays is uninterruptible. All analysis and display hardware is located in the main control room, however, both the TSC and EOF have access to any event response aid function.

The HMI displays provide continuous indication of plant safety status. Where applicable, real time validation of each signal is accomplished by comparing redundant signals. Display formats were developed by the BWR Owners' Group based on critical parameters and the EPG. Displays are capable of showing the magnitude and trend of critical parameters and parameter vs. parameter displays needed to support EPG requirements. The hardware and software designs allow system expansion and flexibility in display formats. The use of highly reliable components ensures a very high degree of reliability.

7.5.2 ANALYSIS AND DESIGN BASIS

7.5.2.1 Design Basis

The safety-related display instrumentation is designed to provide the operator with all necessary information to assess the status of transients or accidents from their onset to a safe cold shutdown condition, to assess the status of safety-related systems used to mitigate the event, and to allow timely operator actions as necessary.

Chapter 15 identifies and evaluates events that jeopardize the fuel barrier and RCPB. The methods of assessing barrier damage and radioactive material releases, along with the methods by which abnormal events are identified, are discussed in Chapter 15.

Variables monitored are listed in Table 7.5-1. These variables have been selected using the methodology established in Regulatory Guide 1.97, NUREG-0737, and the EPG.

The safety-related display instrumentation is categorized into types in accordance with Regulatory Guide 1.97, Revision 2 or 3, and according to the primary function during a transient or accident condition. These types are as follows:

Type A Variables

Those variables to be monitored that provide the primary information required to permit the control room operator to take specific manually controlled actions for which no automatic control is provided and that are required for safety systems to accomplish their safety functions for DBA events. Primary information is information that is essential for the direct accomplishment of the specified safety functions; it does not include those variables that are associated with contingency actions that may also be identified in written procedures.

A variable included as Type A does not preclude it from being included as Type B, C, D, or E or vice versa.

Type B Variables

Those variables that provide information to indicate whether plant safety functions are being accomplished.

Type C Variables

Those variables that provide information to indicate the potential for being breached or the actual breach of the barriers to fission product releases.

Type D Variables

Those variables that provide information to indicate the operation of individual safety systems and other systems important to safety. These variables are to help the operator make appropriate decisions in using the individual systems important to safety in mitigating the consequences of an accident.

Type E Variables

Those variables to be monitored as required for use in determining the magnitude of the release of radioactive materials and continually assessing such releases.

The instruments are further divided into categories by their importance to the operator during and following an accident, and to the importance to safety of the specific measured variable. These categories are as follows:

Category 1

Category 1 provides the most stringent requirements for equipment qualification and pertains to monitoring key variables.

Category 2

Category 2 display instruments require less stringent equipment qualification and generally applies to instrumentation designed for indicating system operating status.

Category 3

Category 3 display instruments are used as backup displays for Category 1 and Category 2 and to aid in diagnosing the type of transient or accident and determining the extent of damage, if any.

7.5.2.2 Analysis

The safety-related display instrumentation provides adequate information to allow the reactor operator to perform the necessary manual safety functions and to assess plant and system status during normal operation, transients, and accident conditions.

Normal Operation

The information channel ranges were selected on the basis of giving the reactor operator the necessary information to perform all the normal plant startup, steady state maneuvers, and to be able to track all the process variables pertinent to safety.

Abnormal Transient Occurrences

The ranges of indicators and recorders provided are capable of covering the extreme of process variables and provide adequate information for all abnormal transient events.

Accident Conditions

Information readouts are designed to accommodate all credible accidents for operator actions, information, and event tracking requirements, and cover all other design basis events or incident requirements.

Postaccident monitoring instrumentation provides the operator with plant status information during and following an accident. The information is needed to follow the progress of an accident, assist the operator to safely shut down the reactor, assess the extent and type of

damage, if any, and to monitor critical parameters for extended periods of time if extensive damage has occurred.

7.5.2.2.1 Conformance To 10 CFR 50 Appendix A, General Design Criteria

The following is a discussion of conformance to those General Design Criteria (GDC) that apply specifically to the safety-related display instrumentation. See Section 7.1.2.2 for a discussion of GDC which apply equally to all safety-related systems.

GDC 13, Instrumentation and Control

Instrumentation is provided to monitor variables and systems over their anticipated ranges for accident conditions as appropriate to ensure adequate safety.

GDC 19, Control Room

The safety-related instrumentation meets the requirements that a control room be provided from which actions can be taken to maintain the nuclear power unit in a safe condition under accident conditions, including LOCAs, and that equipment, including the necessary instrumentation, at appropriate locations outside the control room be provided with a design capability for prompt hot shutdown of the reactor.

GDC 64, Monitoring Radioactivity Releases

The safety-related instrumentation includes the capability of monitoring the reactor containment atmosphere, spaces containing components for recirculation of LOCA fluid, effluent discharge paths, and the plant environs for radioactivity that may be released from postulated accidents.

7.5.2.2.2 Conformance To IEEE Standards

The following is a discussion of conformance to those IEEE Standards which apply specifically to the safety-related display instrumentation. See Section 7.1.2.3 for a discussion of IEEE Standards which apply equally to all safety-related systems.

7.5.2.2.2.1 IEEE Standard 279-1971, Criteria for Protection Systems for Nuclear Power Generating Stations. The safety-related display instrumentation is part of the protection systems and provides information to the reactor operator during and after accident conditions, allowing assessment of reactor status, safety system status, and allowing the operator to control safety systems when necessary.

General Functional Requirements (IEEE 279-1971, paragraph 4.1)

The safety-related display instrumentation, in addition to providing the reactor operator the necessary information to perform normal plant operations, also provides information that allows assessment of plant and safety system status during and after transients and DBAs.

Single Failure Criterion (IEEE 279-1971, paragraph 4.2)

The safety-related display instrumentation that is recommended by Regulatory Guide 1.97, Revision 2, to be redundant is designed to meet the single failure criterion.

Quality of Components and Modules (IEEE 279-1971, paragraph 4.3)

For a discussion of the quality classifications and qualification of components and modules see Sections 3.2, 3.10, and 3.11.

Equipment Qualification (IEEE 279-1971, paragraph 4.4)

For a discussion of equipment qualification see Sections 7.5.2.2.2.2 (IEEE 323-1974), 3.10, 3.11, and 1.8.3 for conformance.

Channel Integrity (IEEE 279-1971, paragraph 4.5)

The safety-related display instrumentation is designed to provide information to the reactor operator under extreme conditions. See Sections 3.10, 3.11, 8.2.1, and 8.3.1.

Channel Independence (IEEE 279-1971, paragraph 4.6)

Safety-related display instrumentation independence is maintained through the application of separation criteria as described in Section 8.3.1.4.

Control and Protection System Interaction (IEEE 279-1971, paragraph 4.7)

There is no interaction between control systems and that safety-related display instrumentation which is part of the protection system.

Derivation of System Inputs (IEEE 279-1971, paragraph 4.8)

The safety-related display instrumentation, where feasible and practical, is a direct measure of the desired variable.

Capability for Sensor Checks (IEEE 279-1971, paragraph 4.9)

The safety-related display instrumentation input sensors can be either perturbed, inputs substituted, or cross checked for proper operability. See Regulatory Guide 1.22 compliance in each of the sections in this chapter for a discussion of sensor check capability.

Capability for Test and Calibration (IEEE 279-1971, paragraph 4.10)

See the compliance discussion of Regulatory Guide 1.22 in each section of this chapter.

Channel Bypass or Removal from Operation (IEEE 279-1971, paragraph 4.11)

Removal from service of sensors which provide inputs to the safety-related display instrumentation is discussed in the respective system discussions in this chapter on compliance to IEEE 279.

Operating Bypasses (IEEE 279-1971, paragraph 4.12)

This paragraph does not apply as the safety-related display instrumentation does not incorporate operating bypasses.

Indication of Bypasses (IEEE 279-1971, paragraph 4.13)

This paragraph does not apply as the safety-related display instrumentation does not incorporate bypasses.

Access to Means for Bypassing (IEEE 279-1971, paragraph 4.14)

Access to instrument valves is administratively controlled. Access to other means of bypassing are located in the control room and are also under administrative control.

Multiple Setpoints (IEEE 279-1971, paragraph 4.15)

This paragraph does not apply as the safety-related display instrumentation does not incorporate multiple setpoints.

Completion of Protective Action Once it is Initiated (IEEE 279-1971, paragraph 4.16)

This paragraph does not apply as the safety-related display instrumentation does not provide protective action.

Manual Initiation (IEEE 279-1971, paragraph 4.17)

This paragraph does not apply as the safety-related display instrumentation does not provide manual initiation.

Access to Setpoint Adjustments, Calibration, and Test Points (IEEE 279-1971, paragraph 4.18)

Access to calibration adjustments are under administrative control.

Identification of Protective Actions (IEEE 279-1971, paragraph 4.19)

Certain safety-related display instrumentation is specifically designed to identify the need for operator-initiated protective actions while others only provide the reactor operator the necessary information to identify plant and safety system status.

Information Read-Out (IEEE 279-1971, paragraph 4.20)

The safety-related display instrumentation is designed to provide the operator with accurate, complete, and timely information to determine plant status and avoids anomalous indications which could confuse the reactor operator.

System Repair (IEEE 279-1971, paragraph 4.21)

The operator can identify and repair most failed sensors, recorders, or indications during plant operation. However, there are sensors such as neutron monitoring [local power range monitor (LPRM) and intermediate range monitor (IRM)] which cannot be replaced or repaired during plant operation and must be repaired or replaced during plant shutdown.

Identification (IEEE 279-1971, paragraph 4.22)

The safety-related display instrumentation is specifically identified on the control panels so that the operator can easily discern that they are intended for use under accident conditions.

7.5.2.2.2.2 IEEE Standard 323-1974, Standard for Qualifying Class 1E Equipment for Nuclear Power Generating Stations. Safety-related display instrumentation as recommended by Regulatory Guide 1.97, Revision 2. See Section 3.11 for equipment requirements based on NUREG-0588, 10 CFR 50.49, and IEEE-323.

7.5.2.2.3 Regulatory Guide Conformance

Regulatory Guide 1.32. Safety-related display instrumentation as recommended by Regulatory Guide 1.97, Revision 2, is powered from vital buses and, if necessary, with battery backup where momentary interruption is intolerable; or as noted in text discussion (see Section 7.5.1).

Regulatory Guide 1.75, Revision 1. Redundant or diverse channels are provided where necessary as recommended by Regulatory Guide 1.97, Revision 2. These channels are electrically independent and physically separated from each other as discussed in Section 8.3.

Regulatory Guide 1.89, Revision 1. Safety-related display instrumentation is qualified to Regulatory Guide 1.89, Revision 1 as recommended by Regulatory Guide 1.97, Revision 2 or Revision 3 as clarified in Section 1.8.3.

Regulatory Guide 1.100, Revision 1. Safety-related display instrumentation as recommended by Regulatory Guide 1.97, Revision 2 or Revision 3, meets the seismic qualifications requirements of IEEE-344-1975 as clarified in Section 3.10.1.2 and is purchased to the requirements in Regulatory Guide 1.100 which states that instrumentation should continue to read within the required accuracy following, but not necessarily during, a safe shutdown earthquake.

Regulatory Guide 1.97, Revision 2. Instruments meet the recommendations required by category and type as described in Revision 2 unless noted in the text discussions as meeting Revision 3 requirements.

An item by item general discussion of display instrumentation and the degree of conformance to Regulatory Guide 1.97 requirements is provided below and in Section 7.5.1.1. See Table 7.5-1 for instrument ranges, Regulatory Guide 1.97 category, and other specific information.

Neutron Flux (Table 7.5-1, item 3)

The facility operating license required the installation of a neutron flux monitoring system in the form of ex-core wide range monitors that were in conformance with the requirements of Regulatory Guide 1.97. The required wide range monitoring system was installed in 1989. Authorization to delete the license condition and remove the equipment was granted by the NRC in May 2000 (Amendment 162, Reference 7.5-4). The authorization was based on a demonstration that the wide range monitors were unnecessary because the originally installed neutron monitoring systems met the alternate criteria described in NEDO-31558 for post-accident neutron flux monitoring systems (References 7.5-1 and 7.5-3). Two exceptions to this are that the APRM system accuracy does not satisfy the NEDO-31558 requirements under all post accident conditions and that the NEDO-31558 requirement for an uninterruptible power source is not met. It was shown that alternate means are available to meet the intent of NEDO-31558 for both of these exceptions, and these alternate means were accepted by the NRC (References 7.5-3 and 7.5-4).

The installed neutron monitoring system (NMS) consists of the source range, intermediate range, and APRM/LPRM monitoring systems. The existing source range and intermediate

range detectors are powered from Class 1E power; the average power range instruments are powered from the reactor protection bus which is a highly reliable source backed up by a diesel generator. There are 43 strings of local power range detectors, 8 intermediate range detectors and 4 source range detectors. These are divided into two redundant divisions. The source and intermediate range detectors are inserted or retracted from the core by Quality Class 2 drive units; however, the drive units are supplied from reliable power supplies and failure of all drive units simultaneously is extremely remote even under accident conditions. The drive units are only required to drive the detector into the core. Any failure after insertion is inconsequential. If all drive units did fail and the source range monitors could not be inserted, the range of indicated power when withdrawn is sufficient to ensure that the reactor is subcritical since the source range instruments monitor a range of 10^{-3}% to 10% power even in the fully withdrawn position. Neutron flux level indication is provided by recorders in the control room.

In accordance with the NRC authorization described above, the ex-core wide range neutron monitoring (WRM) system has been deactivated. The two detectors located in the drywell between the reactor pressure vessel and the sacrificial shield wall and the two preamplifier assemblies located on the reactor building 522' elevation have been abandoned in place. The amplifiers, recorders, and other hardware located in the main control room have been removed. The associated electrical cables have been spared in place.

Coolant Level in the Reactor (Table 7.5-1, item 2)

Regulatory Guide 1.97 recommends that reactor level be monitored from below the core support plate to the centerline of the main steam lines by Category 1 instruments.

There are two divisionally separated ranges of level instrumentation to cover the full range of reactor water level as discussed in Section 7.5.1.1.1. Additionally, a single channel (Category 3) of “upset” range (high) level and a single channel of shutdown range indication is also provided.

RCS Soluble Boron Concentration

Regulatory Guide 1.97 recommends measurement of the soluble boron concentration in the circulating primary coolant.

Grab samples of the circulating primary coolant will be analyzed by either the onsite of offsite facilities for determination of soluble boron concentration. These facilities will have capability to analyze 0 to 1000 ppm of soluble boron concentration in RCS.

Boiling Water Reactor Core Thermocouples

Regulatory Guide 1.97 recommends the installation of in-core thermocouples.

Columbia Generating Station (CGS) concurs with LRG and BWR Owners' Group that core thermocouples do not provide adequate indication of approach to or existence of inadequate core cooling. Energy Northwest's response to Generic Letter 84-23 closed this issue.

Primary System Pressure (Table 7.5-1, item 1)

Regulatory Guide 1.97 recommends that primary system pressure be monitored from 15 psia to 1500 psig by Category 1 instruments.

Redundant Class 1E pressure indicators with a range of 0 to 1500 psig are provided.

Control Rod Position Indication (Table 7.5-1, item 39)

Regulatory Guide 1.97 recommends that Category 3 indication be provided to indicate when a rod is in or not in.

A rod position display of full-in and full-out position provides this information.

Drywell Pressure (Table 7.5-1, item 37)

Regulatory 1.97 recommends Category 1 redundant instruments covering a range from 10 psia to three times design pressure.

Redundant channels are recorded, each having three ranges, a narrow range for -5 to +3 psig, an intermediate range for 0 to 25 psig, and a high range for 0 to 180 psig.

Drywell Sump Level

Regulatory Guide recommends that the drywell sump level be measured by Category 1 instruments.

The drywell equipment and floor drain sumps drain by gravity to the reactor building equipment drain sump and reactor building floor drain sumps respectively. On a LOCA, the containment isolation valves from these drywell sumps flange lines close, isolating the sumps. Any major drywell flooding at this time will overflow these sumps and spill into the suppression pool via the downcomers.

When a LOCA isolation signal is not present the drywell sump drains to the reactor building sump where flow and sump level are continuously monitored in the control room.

Primary Containment Valve Position Indication (Table 7.5-1, item 40)

Regulatory Guide 1.97 recommends Category 1, closed-not closed indication on power operated primary containment isolation valves.

Valve position for each applicable containment isolation valve is provided at the valve controls in the control room.

Redundancy requirements are met by the two valve criteria required for containment isolation.

Radioactivity Concentration or Radiation Level in Circulating Primary Coolant

Regulatory Guide 1.97 recommends that Category 1 redundant detection systems be installed to measure this parameter. The recommended range is one-half Technical Specifications limit to 100 times Technical Specifications limit in R per hour.

There is presently no instrument available which will accomplish this task. Prior to isolation of main steam lines, the condenser offgas system and the main steam line radiation monitors will give immediate warning of fuel failure. The postaccident sampling system (see Section 11.6) provides monitoring and a measure of primary coolant activity after an accident. For details about offgas system and main steam line radiation monitors, see Section 11.5.

Analysis of Primary Coolant

Regulatory Guide 1.97 recommends provisions be made to analyze the primary coolant to determine the extent of core damage. This is a Category 3 system.

A postaccident sampling system (see Section 11.6) providing for grab samples of the primary coolant, suppression pool water, drywell atmosphere, wetwell atmosphere, and reactor building atmosphere is provided. Grab samples will be analyzed in onsite or offsite facilities. Grab samples of the reactor building equipment and floor drain sumps may also be taken with the same equipment.

Primary Containment Area Radiation (Table 7.5-1, item 8)

Regulatory Guide 1.97 recommends that the radiation levels in the primary containment be monitored by redundant Category 1 instruments.

Two detectors are located inside containment that have a range 10^0 R/hr to 10^7 R/hr. These monitors respond to gamma radiation of 60 KeV as required by Regulatory Guide 1.97 to detect the ^{133}Xe gases. These radiation monitors display on recorders located in the control room.

Suppression Pool Water Level (Table 7.5-1, item 14)

Regulatory Guide 1.97 recommends suppression pool level indication on redundant Category 1 instruments. The range (50 ft) is from below the ECCS suction to 5 ft above normal level.

Narrow and wide range instrumentation is provided as discussed in Section 7.5.1.5.

Drywell Hydrogen and Oxygen Concentrations (Table 7.5-1, items 10 and 11)

License Amendment No. 189 approved monitoring the containment hydrogen concentrations with Category 3 equipment and containment oxygen concentrations with Category 2 equipment as defined in Regulatory Guide 1.97. Ranges should be 0 to 30% for hydrogen and 0 to 10% for oxygen and the equipment capable of operating from 12 psia to design pressure.

H_2-O_2 analyzers are provided with ranges of 0 to 30% for both gases and are capable of operating from 12 psia to 45 psig. The H_2-O_2 levels are recorded in the control room.

Noble Gas Effluent Radioactivity Monitors (Table 7.5-1, item 15)

To monitor radioactive noble gases vented to the atmosphere, Regulatory Guide 1.97 recommends off-line sampling systems and radioactive gas monitoring systems on all building exhausts where releases may occur. These monitoring systems would be Category 2 with ranges from 10^{-6} $\mu Ci/cm^3$ to a high of between 10^3 and 10^5 $\mu Ci/cm^3$ depending on the release points.

The Reactor Building Elevated Release Duct monitoring system provides Type E and C, Category 2 and 3 data in units of $\mu Ci/cm^3$ via three overlapping detectors. Each detector provides signal to a channel (low, intermediate, high) on the associated recorder. A composite signal is also provided to a fourth channel on the recorder. This system is discussed in detail in Section 11.5.2.2.1.5.

Note: the previous Reactor Building Elevated Release Duct monitoring system is presently de-terminated, but is still connected to its associated Control Room recorder (see Table 7.5-1, item 15, note c for specific de-termed channels). As the system is de-terminated, any data displayed and recorded on the recorder associated with the previous system is not useable.

Radiation Exposure Rate (Table 7.5-1, item 20)

Regulatory Guide 1.97 (for Type E) recommended that area radiation detectors be provided to indicate major releases from the primary containment.

There are three detectors located at specified reactor building entry points and inside the building to provide the required coverage. They have a range of 10^{-1} to 10^4 R/hr, are Category 3 instruments, and are recorded in the control room.

These monitors provide coverage for these areas described by Regulatory Guide 1.97. Additionally, grab samples of the reactor building atmosphere may be obtained from the postaccident sample system. These high range area monitors provide coverage for personnel access and long-term surveillance (see Reactor Building or Secondary Containment Area Radiation below).

Main Feedwater Flow Rate (Table 7.5-1, item 23)

Regulatory Guide 1.97 recommends a Category 3 indicator to display the feedwater flow rate. Feedwater flow indication is provided in the control room.

Condensate Storage Tank Level (Table 7.5-1, item 24)

Regulatory Guide 1.97 recommends that the condensate storage tank levels be indicated on Category 3 instruments.

Instrumentation is provided for this parameter with display in the control room.

Suppression Chamber Pressure (Table 7.5-1, item 12)

Regulatory Guide 1.97 recommends that a Category 2 flow instrument be provided to indicate suppression pool spray flow. Suppression pool pressure is the key variable and pressure will indicate whether or not spray flow has been established. Knowing the actual amount of spray flow in gpm is of no value. However, valve position, RHR pump running indication, RHR system flow (all indicated in the control room), and suppression chamber pressure will indicate the presence or absence of spray flow. Suppression chamber pressure will also be a basis for whether or not drywell spray initiation will be required, given a high drywell pressure condition.

Suppression Pool Water Temperature (Table 7.5-1, item 13)

Regulatory Guide 1.97 recommends temperature indication of the suppression pool water. This indication would be Category 2 and have a range of 30°F to 230°F. See Section 7.6.1.7 for the CGS design.

Drywell Atmosphere Temperature (Table 7.5-1, item 7)

Regulatory Guide 1.97 recommends that the drywell atmosphere temperature be monitored with a range of 40°F to 440°F on Category 2 instruments. CGS has provided instrumentation monitoring a 50°F to 400°F range.

Postaccident drywell temperature data is provided by four thermocouples located in the drywell area. These thermocouples feed signals to a summer via MV/Is. The average drywell

temperature is then recorded and displayed in the control room. Backup thermocouples are available for use in the monitoring scheme.

Drywell Spray Flow (Table 7.5-1, item 25)

Regulatory Guide 1.97 recommends a drywell spray flow instrument capable of monitoring flow from 0 to 110% of flow. This instrument should be Category 2.

Drywell spray flow is provided by RHR pump flow indication. Valve position indication and drywell pressure will indicate proper flow path. Residual heat removal flow is indicated in the control room.

Primary System Safety/Relief Valve Position (Table 7.5-1, item 21)

Regulatory Guide 1.97 recommends monitoring the SRV position, closed or not closed, with Category 2 instruments.

Monitoring the SRV position is provided as discussed in Section 7.5.1.9.

This is also backed up by the suppression pool temperature and level instrumentation.

Reactor Core Isolation Cooling Flow Rate (Table 7.5-1, item 4)

Regulatory Guide 1.97 recommends RCIC be monitored from 0 to 110% of design flow with Category 2 instruments.

Reactor core isolation cooling pump discharge flow monitoring is provided. This, in conjunction with verification of RCIC system valve lineup, provides indication of system operability. Flow indication and valve position are displayed in the control room.

High-Pressure Core Spray Flow Rate (Table 7.5-1, item 5)

Regulatory Guide 1.97 recommends that HPCS flow be monitored from 0 to 110% of design flow with Category 2 instruments.

High-pressure core spray pump discharge flow monitoring is provided. This in conjunction with verification of HPCS system valve lineup provides indication of system operability. Flow indication and valve position are displayed in the control room.

Low-Pressure Core Injection Flow Rate (Table 7.5-1, item 25)

Regulatory Guide 1.97 recommends that low-pressure coolant injection (LPCI) flow be monitored from 0 to 110% of design flow with Category 2 instruments.

Residual heat removal (LPCI) pump discharge flow monitoring is provided. This in conjunction with verification of RHR system valve lineup provides indication of system operability. Flow indication and valve position are displayed in the control room.

Low-Pressure Core Spray Flow Rate (Table 7.5-1, item 6)

Regulatory Guide 1.97 recommends that LPCS flow be monitored from 0 to 110% of design flow with Category 2 instruments.

Low-pressure core spray pump discharge flow monitoring is provided. This, in conjunction with verification of LPCS system valve lineup, provides indication of system operability. Flow indication and valve position are displayed in the control room.

Standby Liquid Control System Flow (Table 7.5-1, item 27)

Regulatory Guide 1.97 recommends that the flow rate in the SLC system be monitored by Category 2 instruments.

Standby liquid control system flow monitoring is provided. Display is provided in the control room.

Standby Liquid Control System Tank Level (Table 7.5-1, item 28)

Regulatory Guide 1.97 recommends SLC system tank level indication be monitored by Category 2 instruments.

The SLC system tank level instruments are provided as Category 3. Level indication is provided in the control room.

Residual Heat Removal System Flow Rate (Table 7.5-1, item 25)

Regulatory Guide 1.97 recommends that RHR system flow be monitored from 0 to 110% of design flow with Category 2 instruments.

Residual heat removal pump discharge flow monitoring is provided. This in conjunction with RHR pump suction and discharge pressures and verification of RHR system valve lineup provides indication of system operability. Flow indication and valve position are displayed in the control room.

Residual Heat Removal Heat Exchanger Outlet Temperature (Table 7.5-1, item 26)

Regulatory Guide 1.97 recommends that the RHR heat exchanger outlet temperature be monitored by Category 2 instruments with a range of 32°F to 350°F.

Columbia Generating Station considers this instrumentation to be backup to RHR/service water (SW) flow indications. For this reason Category 3 (Class 1E powered) instrumentation is provided.

Existing instrumentation is not Class 1E but is adequate for monitoring this parameter. Indication is provided in the control room since other Class 1E indication of system performance such as RHR flow and standby service water flow to heat exchanger are provided.

Cooling Water Temperature to ESF System Components (Table 7.5-1, item 31)

Regulatory Guide 1.97 recommends Category 2 instruments with a range of 32°F to 200°F.

Present instruments measure water temperature of the spray pond. This is the source of water for the ESF systems. The range of these instruments is 0°F to 200°F.

Further temperature indication is provided on the outlet of each individual heat exchanger in the ESF systems. There is sufficient indication available to verify proper operation of the system.

Cooling Water Flow to ESF System Components (Table 7.5-1, items 29 and 30)

Regulatory Guide 1.97 recommends Category 2 flow instruments to monitor flow in the ESF cooling system.

The SW return lines to the spray ponds are monitored by flow transmitters providing signals to indication in the control room for service water loop A and B. The HPCS service water loop status is detected by a pressure transmitter providing a signal to an indicator in the control room.

High Radioactivity Liquid Tank Level (Table 7.5-1, item 36)

Regulatory Guide 1.97 recommends that all tanks containing radioactive liquids be provided with tank level indication (Category 3 instruments).

All tanks designed to handle radioactive liquids are equipped with remote reading tank level instruments. The indicators are located in the radwaste building which is accessible following a DBA.

Emergency Ventilation Damper Position (Table 7.5-1, item 38)

Regulatory Guide 1.97 recommends Category 2 indication for the open-closed position of emergency ventilation dampers.

The position status on all emergency ventilation dampers is displayed in the control room.

Status of Standby Power and Other Energy Sources Important to Safety (Table 7.5-1, items 16 and 22)

Regulatory Guide 1.97 recommends that status information be provided for all standby power and other energy sources such as pneumatic or hydraulic power.

Voltage indication for standby electrical buses of 4.16-kV is displayed in the control room. Additionally, all vital 480-V switchgear voltage readout is provided along with all battery, battery charger, and inverter voltage and amperage. The pneumatic pressure for the CIA is also displayed in the control room.

Reactor Building or Secondary Containment Area Radiation (Table 7.5-1, item 20)

Regulatory Guide 1.97, Revision 3 (for Type E) recommends that area radiation monitors be placed inside buildings or areas where access is required to service equipment important to safety and in the reactor building. This is to monitor for significant releases, for release assessment, and for long-term surveillance.

Three high range area monitors with a range of 10^{-1} R/hr to 10^{4} R/hr are located in the reactor building. They are located to monitor specific entry points to the building (to e1. 471 ft via door R202, e1. 501 ft via door R305, and e1. 606 ft via door R702). These are the same monitors discussed above in the item on radiation exposure rate. Portable equipment will be used whenever personnel enter a radiation area as required by entry procedures.

Airborne Particulate and Halogen Materials Released from Plant (Table 7.5-1, item 15)

Note: the previous Reactor Building Elevated Release Duct monitoring system is presently de-terminated, but is still connected to its associated Control Room recorder (see Table 7.5-1, item 15, note c for specific de-termed channels). As the system is de-terminated, any data displayed and recorded on the recorder associated with the previous system is not useable. Additionally, the replacement system no longer provides the on-line monitoring function described below. The requirement to measure and record the release of particulates and halogens into the atmosphere is now met by means of off-line sampling and laboratory analysis.

Regulatory Guide 1.97 recommends that particulates and halogens be sampled at the identified plant release points. Onsite analysis capabilities are required. This sampling equipment should be Category 3 equipment. Off-line monitoring systems with low range and intermediate detectors are provided. These systems are provided for the turbine building exhaust and the radwaste building exhaust.

Particulates and halogens, as well as noble gases, are monitored and recorded by the on-line gamma spectroscopy system for the reactor building elevated release duct.

Radiation Exposure Meters at Various Locations Around the Plant

Regulatory Guide 1.97 recommends that continuously monitoring samplers be located at various locations around the plant to assess releases from the plant.

Adequate release information is already available through ventilation release point monitoring and atmospheric conditions information available from the meteorologic conditions information center located onsite. Backup monitoring facilities are readily available on the Hanford Reservation from fixed and mobile units.

Airborne Radiohalogens and Particulates (Portable)

Regulatory Guide 1.97 recommends portable sampling with onsite analysis capability for airborne halogens and particulates.

Portable air samples and a radioanalytical laboratory are maintained by the plant health physics group capable of measuring concentrations from 10^{-9} $\mu Ci/cm^3$ to 10^{-3} $\mu Ci/cm^3$.

Plant and Environs Radiation (portable)

Regulatory Guide 1.97 recommends portable monitoring instrumentation capable of measuring gamma and beta dose rates from 10^{-3} R/hr to 10^{4} R/hr.

The plant health physics personnel maintain such portable instruments onsite.

Plant and Environs Radioactivity

Contrary to the Regulatory Guide 1.97 recommendation regarding the availability of a portable multichannel gamma ray spectrometer, alternative, equivalent methods are used to meet the intent of Regulatory Guide 1.97, Revision 2, Table 2, Plant and Environs Radioactivity (portable instrumentation).

Computerized dose projection capability is provided in certain emergency centers, with the capability to back fit field team sample results to verify initial dose projection calculations.

Detection of fission products in the accident effluent stream is indicated by the presence of iodine. Field team air sample results are obtained by purging noble gasses from a silver zeolite cartridge and measuring the remaining radioactivity, which is conservatively assumed to be iodine until proven otherwise by a detailed analysis. Determination of the presence of iodine in the air sample indicates a degree of failed fuel cladding and fission product barrier breakdown.

Onsite radiological analytical capability exists within the plant to perform detailed analysis. Near site capability is also available at the Emergency Operations Facility to perform detailed analysis of field team samples. Additionally, agreements exist through Washington and Oregon analytical laboratories for analysis of field team samples by their respective emergency plans. This analytical and release assessment capability meets the intent of Regulatory Guide 1.97 without the need to maintain portable multichannel gamma-ray spectrometers.

Wind Direction and Speed (Table 7.5-1, items 17 and 18)

Regulatory Guide 1.97 recommends that wind speed and direction be available on Category 3 instruments. Wind speed should be monitored from 0 to 67 mph and the direction from 0° to 360°.

Wind speed and direction is determined by instruments located on the meteorological tower and transmitted to the meteorological information center. This information is recorded in the control room.

Estimation of Atmospheric Stability (Table 7.5-1, item 19)

Regulatory Guide 1.97, based on vertical temperature differences spaced at set intervals down the meteorological tower, recommends that atmospheric stability (temperature inversion) be detected.

Vertical temperature stratification information is recorded in the control room.

Postaccident Sampling System (See Section 11.6)

Onsite and/or offsite facilities are provided to analyze primary coolant and containment air grab samples for variables and ranges listed in Regulatory Guide 1.97.

Reactor Building Pressure (Table 7.5-1, item 41)

Reactor building pressure is the controlling variable for the SGTS during accident conditions. Flow through the SGTS is automatically regulated to maintain the reactor building at minus 0.25 in. water column to prevent outleakage of potentially radioactive gases.

Emergency Core Cooling System Pump Room Flood Level (Table 7.5-1, item 42)

One level switch is provided in each of the ECCS and the RCIC pump rooms to monitor room flood conditions (due to breaks and/or leaks) in the rooms. Annunciators and safety-related indications are activated in the control room if flood levels reach 6 in. above the floor.

Fuel Pool Cooling Flow (Table 7.5-1, item 43)

Two redundant flow transmitters (one for each loop) monitor loop flows and send signals to control room indicators.

Fuel Pool Temperature (Table 7.5-1, item 44)

Two redundant temperature elements monitor fuel pool water temperature and send signals to control room indicators.

Standby Service Water Radiation (Table 7.5-1, item 45)

For a short period of time during RHR shutdown cooling mode operation the RHR system pressure may exceed that of the SW system. If any RHR heat exchanger tube leaks have developed, it is possible, during accident conditions, to bypass secondary containment radioactivity release processing. To ensure that releases are monitored and appropriate actions taken as required, each of the SW Division 1 and Division 2 loops is provided with a radioactivity monitor providing input to a continuous indication located on a control room back panel. In addition, high radioactivity levels are annunciated in the control room and also recorded on a panel recorder.

Radioactive Gaseous Effluent Release Path Vent Flow Rate (Table 7.5-1, item 9)

Regulatory Guide 1.97 (for Type E) recommends that all effluent release paths from the plant be monitored from 0 to 110% of design flow, for the purpose of release assessment. The three release paths for CGS are via the reactor, turbine, and radwaste buildings. All three are monitored and trended on the plant TDAS system. Additionally the reactor building vent flow is recorded in the control room and the turbine building vent flow is recorded locally.

[a] The instruments meet the recommendations required by the category type as described in Regulatory Guide 1.97, Revision 2, unless otherwise noted in text discussion.

[b] These instruments are Technical Specifications postaccident monitoring instrumentation.

[c]Channel is de-termed. This channel no longer provides usable data to the display/recorder.

7.6 ALL OTHER INSTRUMENTATION SYSTEMS REQUIRED FOR SAFETY

7.6.1 DESCRIPTION

The instrumentation and control systems required for safety not discussed in other sections include the following:

a. Process radiation monitoring system,
b. High-pressure/low-pressure systems interlocks,
c. Leak detection system (LDS),
d. Neutron monitoring system (NMS),
e. Recirculation pump trip (RPT) system,
f. Spent fuel pool cooling and cleanup (FPC) system, and
g. Suppression pool temperature monitoring (SPTM) system.

The sources which supply power to the safety-related systems described in this section originate from onsite ac and/or dc safety-related buses or, as in the case of the fail-safe NMS logic and portions of the LDS, from the non-safety-related reactor protection system (RPS) motor-generator (MG) sets. See Chapter 8 for a complete description of the safety-related systems power sources.

7.6.1.1 Process Radiation Monitoring System

The safety-related portions of the process radiation monitoring system are described in Section 7.3.1.1.2.

7.6.1.2 High-Pressure/Low-Pressure Systems Interlocks and Alarms

7.6.1.2.1 Function

Instrumentation and controls are provided to prevent overpressurization of low-pressure piping which interface with the reactor coolant pressure boundary (RCPB).

7.6.1.2.2 Operation

Flow diagrams for the systems involved are shown in Figures 5.4-11, 5.4-15 and 6.3-4.

Component control logic and alarms for the systems involved are shown in Figures 7.3-7, 7.3-9, 7.3-10 and 7.4-1. Instruments are listed in Table 7.6-1.

High-pressure/low-pressure interlocks are provided to sense reactor pressure and prevent the following valves from opening until reactor pressure is below system design pressure:

Interlocked Process Line	Type	Valve
Residual heat removal (RHR) shutdown cooling suction	MO	RHR-V-9 (F009) RHR-V-8 (F008)
RHR shutdown cooling return	MO	RHR-V-53A RHR-V-53B (F053)
RHR head spray	MO	RHR-V-23 (F023)
LPCI injection	MO	RHR-V-42A,B,C (F042)
LPCS injection	MO	LPCS-V-5 (F005)

The interlock for RHR-V-9, suction valve inside the primary containment is redundant and diverse from the interlock for RHR-V-8, suction valve outside the primary containment to ensure that at least one of two valves in series will always isolate when required. Diversity is provided by selecting pressure sensors from two different manufacturers.

Each sub-system process line listed below is provided with an overpressure switch. The pressure switch activates an alarm in the control room to alert the operator to an intersystem leakage situation where a leaking shutoff valve may result in the sub-system pressure exceeding design limits.

The associated pressure switches are shown on the respective system flow diagrams.

a. RHR shutdown cooling suction,
b. RHR A, B, and C pump discharge,
c. Low-pressure core spray system (LPCS) pump discharge,
d. High-pressure core spray (HPCS) pump suction, and
e. Reactor core isolation cooling (RCIC) pump suction.

7.6.1.3 Leak Detection System

The safety-related portions of the LDS are as follows:

a. Main steam line leak detection,
b. RCIC system leak detection,

c. RHR system leak detection,
d. Reactor water cleanup (RWCU) system leak detection,
e. Drywell/reactor building leak detection,
f. Auxiliary steam line leak detection,
g. ECCS pump room flooding detection.

7.6.1.3.1 Function

The LDS instrumentation and controls are designed to monitor leakage from the RCPB plus other specific leakage within the Reactor Building and initiate alarms and/or isolation when predetermined limits are exceeded. See Sections 5.2.5, 3.6.1.15.3 and 9.3.3.2.2.1.

7.6.1.3.2 Operation

LDS instrument arrangement drawings which contain operator information displays are shown in Figures 7.6-1 and 7.6-2. Instruments are listed in Table 7.6-2.

Systems or parts of systems that are in direct communication with the reactor vessel are provided with leakage detection systems.

The required leakage detection system inside the primary containment is designed with a capability to detect leakage less than established leakage rate limits. See the Technical Specifications for the specific values.

Major components within the primary containment that by nature of their design are sources of leakage (e.g., pump seals, equipment warming drains), are collected ultimately in an equipment drain sump located in the reactor building and thereby identified.

Equipment associated with systems within the primary containment (e.g., vessels, piping, fittings) share a common volume. Steam or water leaks from such equipment are collected ultimately in the floor drain sumps located in the reactor building and identified if possible.

Each of the sumps is protected against overflowing to prevent leaks of an identified source from masking those from unidentified sources.

Outside the primary containment, the piping within each system monitored for leakage is in compartments or rooms separate from other systems as feasible so that leakage may be detected by sump or room level, ambient or differential area temperature, or high process flow.

Sensors, wiring, and associated equipment of the LDS that are associated with the isolation valve logic are designed to withstand the conditions that follow a design-basis loss-of-coolant accident (LOCA) (see Section 3.11).

The operator is kept aware of the status of the LDS variables through displays or recorders that indicate the measured variables in the control room. If a trip occurs, the condition is annunciated in the control room.

7.6.1.3.3 Main Steam Line Leak Detection

The safety-related portions of the main steam line LDS are described in Section 7.3.1.1.2.

7.6.1.3.4 Reactor Core Isolation Cooling System Leak Detection

The steam lines of the RCIC system are monitored for leaks by the LDS. Leaks from the RCIC will cause a change in at least one of the following monitored parameters.

The RCIC LDS consists of the following:

a. Equipment area and pipe routing area high ambient and equipment area differential temperature,
b. High flow rate (differential pressure) through the steam line,
c. The turbine exhaust diaphragm high pressure, and
d. Low steam line inlet pressure.

If the monitored variables indicate that a leak may exist, the detection system initiates an RCIC isolation signal (after an approximate 3 sec delay for RCIC high flow).

The following sections describe each of the RCIC leak detection methods.

7.6.1.3.4.1 Reactor Core Isolation Cooling Area Temperature Monitoring. The RCIC area ambient and differential temperature monitoring circuits are similar to those described for the main steam line tunnel temperature monitoring system (see Section 7.3.1.1.2).

Two redundant temperature monitoring channels are provided. Each redundant instrument provides input to one of two logic channels (Division 1 or 2).

Using 1 out of 2 logic, any RCIC equipment area or pipe routing area high ambient or equipment area high differential temperature initiates an isolation of the RCIC system.

A bypass/test switch is provided in each logic channel for the purpose of testing the temperature monitor without initiating RCIC system isolation.

Diversity is provided by RCIC steam line flow and pressure monitoring.

7.6.1.3.4.2 Reactor Core Isolation Cooling Steam Flow Rate Monitoring. The steam line flow rate from the reactor vessel to the RCIC turbine is monitored by redundant differential pressure switches. In the presence of a leak, the flow rate monitor responds by generating the auto-isolation signal. A time delay in each logic division prevents inadvertent system isolations due to pressure spikes. See Section 7.4.1.1.2.

Diversity is provided by ambient temperature, differential temperature, and RCIC steam line pressure monitoring.

7.6.1.3.4.3 Reactor Core Isolation Cooling Turbine Exhaust Diaphragm Pressure Monitoring. The RCIC turbine exhaust diaphragm pressure is monitored by four redundant pressure switches. In the presence of a leak, the RCIC system responds by generating the isolation signal. See Section 7.4.1.1.2.

Using 2 out of 2 logic high turbine exhaust diaphragm pressure initiates isolation of the RCIC system.

Diversity is provided by ambient temperature and differential temperature.

7.6.1.3.4.4 Reactor Core Isolation Cooling Pressure Monitoring. The steam line pressure from the reactor vessel leading to the RCIC turbine is monitored by four redundant pressure switches. In the presence of a leak, the RCIC system responds by generating the auto-isolation signal. See Section 7.4.1.1.2.

Using 2 out of 2 logic low pressure in the steam line initiates isolation of the RCIC system.

Diversity is provided by ambient temperature, differential temperature, and RCIC steam line flow monitoring.

7.6.1.3.5 Residual Heat Removal System Leak Detection

Leaks from the RHR system are detected by equipment area ambient or differential temperature monitoring and by the shutdown cooling suction flow rate. If the monitored parameters indicate that a leak exists, the LDS initiates an RHR isolation signal.

The RHR LDS consists of the following:

a. Equipment area high ambient or high differential temperature,

b. Shutdown cooling suction line high flow rate.

Outputs from both circuits are used to generate the RHR auto-isolation signal (one for each division) to isolate the inboard and outboard isolation valves.

The following is a description of each RHR leak detection method.

7.6.1.3.5.1 Residual Heat Removal Area Temperature Monitoring. The RHR area temperature monitoring circuit is similar to the one described for the main steam line tunnel temperature monitoring system (see Section 7.3.1.1.2).

Two redundant temperature monitoring channels are provided. Each redundant instrument provides input to one of two logic channels (Division 1 or 2).

Using 1 out of 2 logic, high RHR area ambient or differential temperature initiates an RHR isolation signal closing the RHR inboard and outboard isolation valves.

A bypass/test switch is provided in each logic channel for the purpose of testing the temperature monitor without initiating RHR system isolation.

7.6.1.3.5.2 Residual Heat Removal Flow Rate Monitoring. Flow rate monitoring is provided on the RHR shutdown cooling suction line by redundant differential pressure switches.

Flow rates in excess of predetermined limits indicate a line leak or break.

Two redundant differential pressure switches monitor flow and each provides an input to one of the two logic channels (Division 1 or 2).

Using 1 out of 2 logic, the high flow rate initiates an isolation of the RHR inboard and outboard isolation valves.

Diversity is provided by ambient and differential temperature monitoring.

7.6.1.3.6 Reactor Water Cleanup System Leak Detection

The RWCU LDS monitors differential flow, blowdown flow, and temperature. Automatic isolation of the RWCU system isolation valves is initiated when high differential flow, high blowdown flow, or high temperature exists.

The RWCU LDS consists of the following:

a. Leakage monitoring by the flow comparison of RWCU system water inlet and outlet flow rate,

b. Ambient and differential temperature monitoring, and

c. Monitoring the RWCU blow down line to the main condenser for high flow to mitigate a high energy line break.

The following is a description of each RWCU leak detection method:

7.6.1.3.6.1 Reactor Water Cleanup Differential Flow Monitoring. The RWCU system inlet flow is compared to RWCU outlet flow to the feedwater lines or to the main condenser. A flow element, flow transmitter, and square root converter for each of these three lines provides signals to a common flow summer which trips two differential flow alarm units on a high differential flow condition. The high differential flow rate initiates a 45-sec time delay which bypasses the isolation signal during the normal operational system surges, i.e., pump startup or valving changes. If the high differential flow conditions still exists after the time delay, then isolation is initiated. Flow and differential flow indications are provided in the main control room.

Using 1 out of 2 logic in each logic channel (Division 1 or 2), the RWCU flow comparison monitoring initiates RWCU isolation signal. The signal closes the inboard and outboard isolation valves, after a time delay, when the flow rate difference exceeds a preset limit.

Diversity is provided by ambient and differential temperature.

7.6.1.3.6.2 Reactor Water Cleanup Area Temperature Monitoring. See Section 7.3.1.1.2.

7.6.1.3.6.3 Condenser Blowdown Line Flow Monitoring. The RWCU blowdown line to the main condenser is monitored to detect a high energy line break. Two redundant flow transmitters provide flow signals to two flow alarm units in the main control room. The Division 2 signal closes the inboard isolation valve and the Division 1 signal closes the outboard isolation valve when blowdown flow exceeds a preset limit after a specified time delay.

7.6.1.3.7 Drywell Floor Drain Leak Detection

The drywell floor drain sump collects unidentified leakage within the drywell. The leakage is gravity fed to the Reactor Building floor drain sump. The flow is monitored and leakage in excess of the acceptable limit is annunciated in the control room.

7.6.1.3.8 Drywell Equipment Drain Leak Detection

The drywell equipment drain sump collects identified leakage within the drywell. The leakage is gravity fed to the Reactor Building equipment drain sump. The flow is monitored and leakage in excess of the acceptable limit is annunciated in the control room.

7.6.1.3.9 Reactor Building Floor Drain and Equipment Drain Sumps Leak Detection

The floor drain sumps leak detection instrumentation is designed to detect leakage from unidentified sources. The equipment drain sump leak detection instrumentation is designed to detect leakage from identified sources.

A level switch is mounted in each sump and controls the associated sump pump. The sump pump starts when the upper sump level is exceeded and turns off when the level in the sump reaches the lower setpoint. A timer is started and stopped by the upper and lower sump level switches respectively. If the timer exceeds a predetermined setpoint, high flow is annunciated. The timer resets to read when the sump pump stops. A second timer starts timing when the sump pump stops. If the sump pump starts before the second timer reaches a predetermined setpoint, high flow rate is annunciated. The timer is reset to read when the sump pump starts.

A level switch is provided for each sump for high sump water level annunciation purposes. The alarm setpoint is set above the pump start setpoint and will actuate an alarm in the main control room in the event the sump water level exceeds the switch setpoint.

In addition, the ECCS pump room floor drain sumps are provided with a drain header shutoff valve. This valve will isolate the sump from another connected pump room in the event the sump water level exceeds the valve control level switch setpoint, thus minimizing common mode flooding of more than a single pump room (see Figure 9.3-12). See Section 3.6.1.5.2 for the RCIC/CRD pump rooms.

7.6.1.3.10 Emergency Core Cooling Systems Pump Room Flooding Detection

A Class 1E level switch is provided for each of the RHR-A, RHR-B, RHR-C, RCIC, LPCS, and HPCS pump room area. Each level switch is set 6 in. above the pump room floor and will activate an alarm in the main control room in the event the pump room water level exceeds the level switch setpoint (see Figure 7.6-2). See Section 9.3.3.2.2.1.

7.6.1.3.11 Drywell Atmosphere Radiation Monitoring System

The drywell atmosphere is continuously monitored for gaseous and particulate radioactivity by redundant sampling systems. In each system the sample is drawn into the sample system by its vacuum pump. Flow control is provided to ensure proper sample flow. The sample flow path is from the sample point inside the primary containment, through the inlet isolation valve to the particulate monitor chamber. Here the sample is passed through a fixed filter where the particulate matter is deposited while allowing the noble gases to pass through.

After removal of any particulate matter as described above, the gaseous sample passes into a volume chamber where a second scintillation detector checks for noble gas activity.

The sample gas then proceeds through the flow control device, vacuum pump, return line isolation valve, and is discharged back into the primary containment.

7.6.1.3.12 Auxiliary Steam Line Leak Detection

Auxiliary steam line leak detection consists of redundant temperature sensors, temperature monitor with alarm/isolation output function, and the isolation valves (see Section 3.6.1.15.3).

When any one of the four temperature elements detects abnormally high temperature, the logic circuit actuates the closure of auxiliary steam line isolation valves (AS-V-68A or AS-V-68B) and provides audible alarm in the main control room.

Auxiliary steam line leak detection instrumentation provides testable features for motor-operated valve (MOV) closure tests.

7.6.1.4 Neutron Monitoring System

The safety-related portions of the NMS include the intermediate range monitor (IRM), local power range monitor (LPRM), average power range monitor (APRM), and oscillation power range monitor (OPRM).

The NMS instrumentation and controls are designed to monitor reactor power (neutron flux) from startup through full power operation.

The NMS uses in-core detectors, either fixed (LPRM) or removable (IRM), to determine neutron flux levels.

The NMS will initiate a scram when predetermined limits are exceeded and provide operator information during and after accident conditions.

The NMS component control logic is shown in Figure 7.6-3.

7.6.1.4.1 Intermediate Range Monitor

7.6.1.4.1.1 Function. The IRM monitors neutron flux from the upper portion of the source range monitor (SRM) to the lower portion of the power range monitor (APRM) as shown in Figure 7.6-4.

7.6.1.4.1.2 Operation. The IRM has eight channels, each of which includes one detector that can be positioned in the core by remote control. See Figures 7.6-5 and 7.6-6. The detectors are inserted into the core for a reactor startup and are withdrawn after the reactor mode selector switch is placed in the RUN position.

Each detector assembly consists of a fission chamber attached to a low-loss, quartz-fiber-insulated transmission cable. When coupled to the signal conditioning equipment, the detector produces a reading of full scale on the six most sensitive ranges (8 KHz 16 KHZ flux level bandwidth). The detector cable is connected underneath the vessel to a triple-shielded cable that is connected to the preamplifier.

The preamplifier converts current pulses to voltage pulses, modifies the voltage signal, and provides impedance matching. The preamplifier output signal is then sent to the IRM signal conditioning electronics (see Figure 7.6-7).

Each IRM channel input signal from the preamplifier can be amplified and attenuated. The IRM preamplification is selected by a remote range switch that provides 10 ranges of increasing attenuation (the first six called low range and the last four called high range). As the neutron flux of the reactor core increases the signal from the fission chamber is attenuated to keep the input signal to the inverter in the same range. The output signal, which is proportional to neutron flux at the detector, is amplified and supplied to a locally mounted meter, a remote meter and recorder.

The IRM scram trip functions are discussed in Section 7.2.1.1. The IRM setpoints are listed in the Technical Specifications.

The IRM range switches must be up-ranged or down-ranged to follow increases and decreases in power within the range of the IRM to prevent either a scram or a rod block. The IRM detectors must be inserted into the core whenever these channels are needed and withdrawn from the core, when permitted, to prevent unnecessary burnup.

7.6.1.4.2 Local Power Range Monitor

7.6.1.4.2.1 Function. The LPRMs provide localized neutron flux detection over the full power range for input to the APRM.

7.6.1.4.2.2 Operation. The LPRM includes 43 detector strings having detectors located at different axial heights in the core; each detector string contains four fission chambers. Figure 7.6-8 shows the LPRM detector radial layout scheme.

The LPRM assembly consists of four neutron detector (ion chambers) permanently installed in a housing (see Figure 7.6-9), each with an associated solid sheath cable. The chambers are vertically spaced in the LPRM detector assemblies in a way that gives adequate axial coverage of the core, complementing the radial coverage given by the horizontal arrangement of the LPRM detector assemblies.

Each chamber consists of two concentric cylinders, that act as electrodes. The inner cylinder (the collector) is mounted on insulators and is separated from the outer cylinder by a small

gap. The gas between the electrodes is ionized by the charged particles produced as a result of neutron fissioning of the uranium-coated outer electrode. The chamber is operated at a polarizing potential of approximately 100-V dc. The negative ions produced in the gas are accelerated to the collector by the potential difference maintained between the electrodes. In a given neutron flux, all the ions produced in the ion chamber can be collected if the polarizing voltage is high enough. When this situation exists, the ion chamber is considered to be saturated. Output current is then independent of operating voltage.

Each assembly also contains a calibration tube for a traversing in-core probe. The enclosing tube around the entire assembly contains holes that allow circulation of the reactor coolant water to cool the ion chambers. Numerous tests have been performed on the chamber assemblies including tests of linearity, lifetime, gamma sensitivity, and cable effects (Reference 7.6-1). A modified LPRM assembly is used for measurement of electro-chemical corrosion potential (ECP). The modified assembly contains three ECP sensor strings, in addition to the neutron detectors. LPRM operation in the modified assembly is not affected by the ECP electrodes.

The current signals from the LPRM detectors are transmitted through coaxial cable to the LPRM amplifiers in the control room. The amplifier is a linear current amplifier whose voltage output is proportional to the current input and therefore proportional to the magnitude of the neutron flux. Low-level output signals are provided that are suitable as an input to the computer, recorders, etc. The output of each LPRM amplifier is isolated to prevent interference of the signal by inadvertent grounding or application of stray voltage at the signal terminal point.

When a central control rod is selected for movement, the output signals from the amplifiers associated with the nearest 16 LPRM detectors are displayed on reactor control panel meters. The four LPRM detector signals from each of the four LPRM assemblies are displayed on 16 separate meters. The operator can readily obtain readings of all the LPRM amplifiers by selecting the control rods in order. The trip circuits for the LPRM provide trip signals to activate lights, instrument inoperative signals, and annunciators. See Table 7.6-3. These trip circuits are powered from the 24-V dc power supply and are set to trip on loss of power. They also trip when power is not available for the LPRM amplifiers.

The trip levels can be adjusted from 2% to 100% of full-scale deflection and are accurate to ±1% of full-scale deflection in the normal operating environment.

Each LPRM channel may be individually bypassed. When the maximum number of bypassed LPRMs associated with any APRM channel has been exceeded, an inoperative trip is generated by that APRM.

Each individual detector chamber of the assembly is a moisture-proof, pressure-sealed unit. The detector assemblies are designed to operate up to 600°F and 1250 psig. The wiring, cables, and connectors located within the drywell are designed for continuous duty up to 165°F, 55% relative humidity and a 3-hr single exposure rating of 340°F at 100% relative humidity.

Power for the LPRM system is supplied by the two RPS buses. The PRNM equipment receives power from 120 Vac 50/60 Hz. Each PRNM chassis (LPRM) is powered by redundant Low Voltage Power Supply (LVPS) modules contained with a single Quad Low Voltage Power Supply (QLVPS) chassis. One LVPS module is connected to RPS power bus A and the other LVPS module connected to RPS power bus B. For maximum variation in the input voltage or line frequency, the overextended ranges of temperature and humidity, the output voltage varies no more than 2 V.

7.6.1.4.3 Average Power Range Monitor

7.6.1.4.3.1 Function. The function of the APRM is to average signals from the LPRMs and provide a continuous indication of average reactor power from a few percent to greater than rated reactor power. The APRM also provides signals to the OPRM which are used to detect thermal hydraulic oscillations.

7.6.1.4.3.2 Operation. The APRM has four redundant channels. Each channel uses input signals from a number of LPRM detectors.

The APRM compares corrected LPRM values to high and low trip points and averages the filtered readings to obtain a value for the reactor average instantaneous neutron flux value (readings from bypassed LPRMs are automatically excluded from the average). Each APRM channel can average the output signals from as many as 43 LPRMs. Assignment of LPRMs to an APRM follows the pattern shown in Figure 7.6-10. Position A is the bottom position, Positions B and C are above Position A, and Position D is the topmost LPRM detector position. The pattern provides LPRM signals from all four core axial LPRM detector positions.

The APRM gain is adjusted using the instrument's front panel display or accepting the APRM gain calculated from the Percent Core Thermal Power (%CTP) downloaded from the core monitoring system. Each APRM instrument is designed to provide automatic periodic testing of the replaceable hardware modules in an APRM Channel at least every 15 minutes. The APRM firmware (or software) shall continuously cycle through a series of tests when the instrument keylock switch is in the "OPER" position. When the instrument keylock switch is in the "INOP" position, the module tests shall be performed under user control.

See Section 7.2.1.1 for a description of the APRM inputs to the RPS.

The APRM system allowable values are listed in the Technical Specifications. The APRM circuit arrangement for RPS trip input is shown in Figure 7.6-11.

APRM may be bypassed at any time. Each APRM provides a rod block output whenever the minimum number of LPRM inputs to it is not met.

The PRNM equipment receives power from 120 Vac 50/60 Hz. Each PRNM chassis (APRM or RBM chassis) is powered by redundant Low Voltage Power Supply (LVPS) modules contained with a single Quad Low Voltage Power Supply (QLVPS) chassis. One LVPS module is connected to RPS power bus A and the other LVPS module connected to RPS power bus B. Thus, APRM Channels 1, 2, 3, and 4 are powered from the bus used for trip system A and B of the RPS. The AC buses that power an APRM channel also supply power to its associated LPRMs.

7.6.1.4.4 Oscillation Power Range Monitor

7.6.1.4.4.1 Function. The digital-based OPRM detects and suppresses reactor core power instabilities using the Option III approach described in NEDO-31960. The OPRM provides independent oscillation trip signals to the RPS when one of the instability algorithms (Period based, Amplitude based, or Growth based) for an operable OPRM cell has detected an instability condition.

7.6.1.4.4.2 Operation. The OPRM upscale function monitors LPRMs combined into “cells” of 4 LPRMs each. The OPRM system consists of four independent channels capable of detecting thermal hydraulic instability by monitoring the neutron flux within the reactor core. The OPRM function combines the signals from each LPRM in an OPRM cell and evaluates that combined cell signal using the OPRM algorithms to detect thermal-hydraulic instabilities. An OPRM upscale trip output is generated from an APRM channel when the period based detection algorithm in that channel detects oscillatory changes in the neutron flux, indicated by the combined signals for the LPRM detectors in a cell, with the period confirmations and relative cell amplitude exceeding specific setpoints. One or more cells in a channel exceeding the trip conditions will result in a channel trip. An OPRM upscale trip is also issued from any APRM channel is either the growth rate or amplitude based algorithms detect growing oscillatory changes in the neutron flux from one or more cells in that channel. The OPRM upscale trip output is automatically enabled (not-bypassed) when the APRM Simulated Thermal Power is equal to or above the OPRM auto-enable power setpoint and recirculation flow is equal to or below the OPRM auto-enable flow setpoint. The OPRM upscale trip output is automatically bypassed when Simulated Thermal Power and recirculation flow are not within the OPRM trip enabled region. The OPRM upscale trip is active only when the reactor mode switch is in the RUN position.

At least two unbypassed APRM channels must be in the APRM upscale trip or inoperative trip state to cause an APRM/Inop RPS trip output from the ARPM 2-Out-of-4-Voter channels. Similarly, at least two unbypassed APRM channels must be in the OPRM upscale trip state or

inoperative state to cause an OPRM Upscale RPS trip output from the ARPM 2-Out-of-4-Voter channels. The APRM Upscale/Inop and OPRM Upscale/Inop trips are combined and input to the 2-Out-of-4-Voter channels. All four voter channels will provide RPS trip output, two to each RPS trip system. If only one unbypassed APRM channel is providing a trip output, each the four APRM 2-Out-of-4-Voter channels will have a half-trip, but no trip signals will be sent to the RPS. Removing voltage to a relay coil transmits trip outputs to RPS, so loss of power results in actuating the RPS trips. Loss of a 2-Out-of-4-Voter channel results in an RPS half-scram.

The OPRM protection system provides the following control board annunciator outputs to the control room operator:

- OPRM TRIP ENABLED (reactor has reached the operating region where instability can occur and oscillation trip output has been enabled),
- OPRM ALARM (when one of the instability algorithms (Period based, Amplitude based, or Growth based) for an operable OPRM cell has exceeded user defined setpoints),
- OPRM TRIP (provides trip signal to RPS when one of the instability algorithms (Period based, Amplitude based, or Growth based) for an operable cell has detected an instability condition), and
- OPRM INOP (when the quantity of operable OPRM cells is less than the required 25 out of 30 OPRM cells for each of the four OPRM channels.

7.6.1.5 Recirculation Pump Trip System

7.6.1.5.1 Function

The function of the RPT is to mitigate the thermal consequences of the turbine trip and generator trip transients by tripping the recirculation pumps early in the event, producing rapid pump flow coastdown and additional core voiding, which results in a core reactivity reduction. This system is linked to the RPS such that both a scram and a pump trip occur when the turbine stop valves start to close and when turbine governor valve fast closure occurs. Both scram and RPT are bypassed at low thermal power levels.

The RPT system is required to trip both recirculation pumps from their normal power source within 200 msec after a turbine/generator trip or load rejection event occurs with reactor power level greater than 29.5% of rated thermal power. This trip cannot be prevented or caused by any single component failure in the system.

7.6.1.5.2 Operation

The RPT logic is derived from relays in the RPS which are activated by turbine stop valve limit switches and turbine control valve oil pressure switches. Contacts from these relays are arranged in a logic scheme so that deenergizing various combinations of the relays will energize the RPT trip coil in each of two main power source circuit breakers provided for each recirculation pump (see Figures 7.6-12 and 7.6-13).

Each main circuit breaker has two trip coils. One trip coil is activated by an RPT signal only. The other trip coil is activated by all other breaker trip functions. The dual trip coils serve to separate the breaker safety function from its non-safety functions.

Turbine governor valve fast closure signals to the RPT system from the RPS are derived from oil line pressure switches located on each of the four fast-acting control valve hydraulic mechanisms (see Figure 7.6-14).

Turbine stop valve closure signals to the RPT system from the RPS are derived from valve stem position switches mounted on the four turbine stop valves. The switches open before the valve is more than 10% closed to provide the earliest positive indication of valve closure (see Figure 7.6-15).

Turbine first-stage pressure signals to the RPT system from the RPS are derived from four pressure switches. The pressure switches trip at a pressure setpoint corresponding to 29.5% power to bypass the turbine stop valve and turbine control valve fast closure trips below this value (see Figure 7.6-14).

The RPT, when initiated, completes the recirculation pumps circuit breakers trip. Restarting the pumps for normal power operation requires deliberate operator actions.

Channel and logic relays are fast-response, high-reliability relays from the RPS. The relays are selected so that the continuous load will not exceed 50% of the continuous duty rating. The total response time from start of the turbine control valve fast closure signal or the turbine stop valve closure signal to complete suppression of the electric arc between the fully open contacts of the pump motor circuit breaker is less than 200 msec on a 60 Hz basis. With the adjustable speed drive (ASD) installation, this time delay varies from 185 to 200 msec.

The RPT logic is illustrated in Figure 7.6-13. The system is arranged as two separately powered trip systems. Each logic trip system has at least two channels of the monitored variable. Either of the two automatic trip systems will trip both of the two recirculation pump motors.

Table 7.6-4 provides a summary of the recirculation system trip functions and actions.

7.6.1.5.2.1 Bypasses and Interlocks. With the reactor power under 29.5%, the RPT is automatically bypassed by four pressure switches associated with the turbine first stage. Any one of the four channels in a bypass state initiates main control room annunciation. A manual key-locked bypass switch is provided for each of the two RPT systems, located on the relay panels, for logic testing. Placing the manual switch in bypass position initiates a control room annunciator. The RPT is not inhibited, since the redundant system is operable.

The RPT system initiation logic is composed of contact from the RPS sensor channel relays. The interlock is performed using separate relay contacts so that no failure in the RPT system can prevent an RPS scram.

7.6.1.5.2.2 Redundancy. The RPT is divided into two divisions. Each division duplicates the function of the other to the extent that either system performs the pump motor power supply trip regardless of the state of operation or failure of the other trip system. The turbine stop valve closure and turbine governor fast valve closure signals are diverse inputs to the RPT for pump motor trip. Each pump motor is provided with two circuit breakers in series tripped from redundant division logic.

7.6.1.5.2.3 Testability. The RPT system logic can be tested during reactor operation without pumps trip and without inhibiting the pumps trip function by the redundant system.

A key-locked bypass switch for system circuit testing is provided for each system located at the RPS relay cabinets.

Since the RPT system logic consists of relay contacts actuated in the RPS, the RPS surveillance tests will include the testing of the RPT logic system. See Section 7.2 for RPS testing.

7.6.1.5.2.4 Environmental Considerations. The electrical equipment and devices of the RPT system are located in the control building and in the electrical equipment rooms. These areas have a controlled environment isolated from an accident environment ensuring reliable operation. The logic channel sensors located at the turbine-generator are discussed in Section 7.2.

7.6.1.5.2.5 Operational Considerations. The sensor channel logic relays are normally energized with contacts open in the RPT system logic. Loss of both RPS MG buses or sensor variables out of tolerance will cause RPT.

The RPT system has no manual trip feature. The pump motor power supply circuit breakers have their normal manual control switches at the control room panels for normal pump start and stop operation. These controls are isolated from the RPT circuits. Circuit breaker status indications for the operator consist of a green pilot light for breaker open position and one red pilot light for breaker closed.

7.6.1.6 Spent Fuel Pool Cooling and Cleanup System

7.6.1.6.1 Function

The function of the FPC system is to remove decay heat from the spent fuel storage pool to ensure adequate cooling of irradiated stored fuel assemblies. The FPC system also purifies the

storage pool water, maintains water clarity for fuel handling operations, and fills and drains the fuel transfer canal. See Section 9.1.3.

7.6.1.6.2 Operation

Schematic arrangement of the FPC system mechanical equipment is shown in Figure 9.1-5. The FPC system component control logic is shown in Figures 7.6-16 through 7.6-26. Instruments are listed in Table 7.6-5. Operator information displays are shown in Figure 9.1-5 and Figures 7.6-16 through 7.6-26.

The FPC system consists of two redundant cooling loops. System operation is discussed in Section 8.1.3.

Instrumentation is provided to monitor the pool temperature, pool level, pump discharge pressures, and water conductivity to allow the control room operator to assess system operation. Channels provided versus channels required for protective action completion are listed in Table 7.6-6.

7.6.1.7 Suppression Pool Temperature Monitoring System

7.6.1.7.1 Function

The SPTM system is designed to monitor suppression pool water temperature and alert the plant operator to the potentially hazardous condition of elevated pool water temperature.

The instrumentation for the SPTM system is shown in Figure 5.4-11 and Figure 9.4-8.1. Instruments are identified in Table 7.6-7.

7.6.1.7.2 Operation

The SPTM system consists of two separate divisions, each with 12 dual element thermocouples and multipoint recorder. The 24 channels are at eight locations evenly spaced around the perimeter of the pool. Sixteen channels are arranged in an upper ring at el. 465 ft 5.75 in. The remaining eight channels are mounted at el. 447 ft 10.25 in. Each quadrant contains four upper level and two lower level thermocouples. This arrangement was chosen to track stratification. Average suppression pool temperature is recorded in the control room using data from eight channels, one per division per quadrant. Temperature indication from all 24 channels is available at the control room. Additionally, a separate indicator is available for direct readout of suppression pool average temperature (Division 1 only).

The time constant for the thermocouples is no greater than 15 sec. The time from thermocouple signal input to initiation of alarm is no greater than 60 sec.

Each division of the SPTM system is provided with a multipen recorder for individual thermocouple temperature recording, a microprocessor for averaging the thermocouple outputs of both divisions and providing an average bulk suppression pool temperature, a recorder for recording the average bulk temperature, and audiovisual annunciators which alarm on abnormally high suppression pool temperature outputs of each division and of the bulk temperature averaging system.

7.6.1.8 Design Basis

The safety-related systems described in this section are designed to provide timely protective action inputs to other safety systems to protect against the onset and consequences of conditions that threaten the integrity of the fuel barrier and the RCPB. Chapter 15 identifies and evaluates events that jeopardize the fuel barrier and RCPB. The methods of assessing barrier damage and radioactive material releases, along with the methods by which abnormal events are identified, are also presented in Chapter 15.

The station conditions which require protective actions are described in Chapter 15.

7.6.1.8.1 Variables Monitored to Provide Protective Actions

The following variables are monitored to provide protective action inputs:

a. High pressure/low pressure system interlocks - reactor pressure;

b. LDS

1. RCIC area temperatures - differential and ambient,

2. RCIC steam line flow rate,

3. RCIC turbine exhaust diaphragm pressure,

4. RCIC steam line pressure,

5. RHR area temperatures - differential and ambient,

6. RHR shutdown cooling suction flow (not credited in the Columbia Generating Station [CGS] accident analysis),

7. RWCU area temperatures - differential and ambient,

8. RWCU differential flow (not credited in the CGS accident analysis),

9. RWCU blowdown line flow,

10. Identified and unidentified leakage from the drywell floor and equipment drain sumps,

11. Drywell atmosphere radiation monitor,

12. Main steam pipe tunnel area temperatures - differential and ambient,

13. Auxiliary steam line area temperature,

14. Reactor building floor drain and equipment drain sumps level,

15. Emergency core cooling systems (ECCS) pump room level;

c. NMS

1. IRM neutron flux,
2. APRM neutron flux;

d. RPT system

1. Turbine throttle valve closure,
2. Turbine governor valve fast closure;

e. Spent FPC system; and

f. Suppression pool temperature monitoring system

The plant conditions which require protective action involving the safety-related systems discussed in this section are described in Chapter 15.

7.6.1.8.2 Location and Minimum Number of Sensors

See the Technical Specifications for the minimum number of sensors required to monitor safety-related variables. The IRM and LPRM detectors are the only sensors which have spatial dependence.

7.6.1.8.3 Prudent Operational Limits

Prudent operational limits for each safety-related variable trip setting are selected to be far enough above or below normal operating levels so that a spurious safety system initiation is avoided. It is then verified by analysis that the release of radioactive materials, following

postulated gross failures of the fuel or nuclear system process barrier, is kept within acceptable bounds.

7.6.1.8.4 Margin

The margin between operational limits and the limiting conditions of operation of the safety-related systems are addressed in the Technical Specifications.

7.6.1.8.5 Levels

Levels requiring protective action are established in the Technical Specifications.

7.6.1.8.6 Range of Transient, Steady State, and Environmental Conditions

See Section 3.11 for environmental conditions. See Sections 8.2.1 and 8.3.1 for the maximum and minimum range of energy supply to the safety-related instrumentation and controls of the systems described in this section. All safety-related instrumentation and controls are specified and purchased to withstand the effects of energy supply ranges.

Environmental conditions for proper operation of the systems described in this section are discussed in Sections 3.10 and 3.11.

7.6.1.8.7 Malfunctions, Accidents, and Other Unusual Events Which Could Cause Damage to Safety Systems

Chapters 3, 6, 9, 15, and Appendix F describe the following credible accidents and events: floods, storms, tornadoes, earthquakes, fires, LOCA, pipe break outside containment, and missiles.

7.6.1.8.7.1 Floods. The buildings containing safety-related components have been designed to meet the probable maximum flood (PMF) at the site location. See Section 2.4. Therefore, none of the functions are affected by external flooding. For a discussion of internal flooding protection see Sections 3.4 and 3.6.

7.6.1.8.7.2 Storms and Tornadoes. The buildings containing safety-related components have been designed to withstand all credible meteorological events and tornadoes as described in Section 3.3.

7.6.1.8.7.3 Earthquakes. The structures containing safety-related system components have been seismically qualified as described in Sections 3.7 and 3.8 and will remain functional during and following a safe shutdown earthquake (SSE).

7.6.1.8.7.4 Fires. To protect the safety systems in the event of a postulated fire, the components have been separated by distance, electrical separation barriers, and/or fire barriers. The use of separation and barriers ensures that even though some portion of the system may be affected the safety function will not be prevented.

Within the control room power generation control complex (PGCC) (underfloor cable routing ducts) heat detectors and products of combustion detectors are provided to initiate a Halon fire suppression system.

7.6.1.8.7.5 Loss-of-Coolant Accident. The safety-related systems components described in this section and functionally required during and/or following a LOCA have been environmentally qualified to remain functional as discussed in Section 3.11.

7.6.1.8.7.6 Pipe Break Outside Containment. Protection for these components is described in Section 3.6.

7.6.1.8.7.7 Missiles. Protection for safety-related components is described in Section 3.5.

7.6.1.8.8 Minimum Performance Requirements

Minimum performance requirements for safety-related systems instrumentation and controls are provided in the Technical Specifications and the Licensee Controlled Specifications (LCS).

7.6.1.9 Final System Drawings

Functional and architectural design difference between the PSAR and FSAR are listed in Table 1.3-8.

7.6.2 ANALYSIS

7.6.2.1 Safety-Related Systems - Instrumentation and Controls

Chapter 15 evaluates the individual and combined capabilities of the safety-related systems described in this section.

The safety-related systems described in this section are designed such that a loss of instrument air, a plant load rejection, or a turbine trip will not prevent the completion of the safety function.

7.6.2.2 Conformance to 10 CFR 50, Appendix A - General Design Criteria

The following is a discussion of conformance to those General Design Criteria (GDC) which apply specifically to the safety-related systems described in this section. See Section 3.1 for a discussion of GDC which apply equally to all safety-related systems.

The GDC for the NMS and process radiation monitoring system are discussed in Sections 7.2.2.1 and 7.3.2.1.1.

GDC 12 - Suppression of Reactor Power Oscillations

The NMS provides protective actions to the RPS to ensure that fuel design limits are not exceeded.

GDC 13 - Instrumentation and Control

The safety-related instrumentation and controls monitor variables over their anticipated ranges for normal operation, anticipated occurrences, and accident conditions and initiate protective actions to limit or prevent fuel damage and maintain the integrity of the RCPB and the primary containment.

GDC 15 - Reactor Coolant System Design

The safety-related systems provide sufficient margin to ensure that the design conditions of the RCPB are not exceeded during any condition of normal operation, including anticipated operational occurrences. If the monitored variables exceed their predetermined settings, automatic safety actions are provided.

GDC 30, 34, 35, 38, and 40

The LDS provides means for detecting the source of reactor coolant leakage.

GDC 61, 62, and 63

The FPC system provides reliable fuel pool RHR capability.

7.6.2.3 Conformance to IEEE Standards

The following is a discussion of conformance to IEEE 279-1971, Criteria for Protection Systems for Nuclear Power Generating Stations, that applies specifically to the safety-related systems described in this section. See Section 7.1.2.3 for a discussion of IEEE standards which apply equally to all safety-related systems.

General Functional Requirement (IEEE 279-1971, paragraph 4.1)

The safety-related systems described in this section automatically initiate protective actions or provide information to the operator when a condition monitored reaches a preset level for all conditions described in Section 7.6.1. For example, the LDS initiates containment isolation by closure of containment isolation valves when area temperatures exceed preset limits.

Single Failure Criterion (IEEE 279-1971, paragraph 4.2)

The safety-related systems described in this section are not required to meet single failure criteria on an individual system basis. However, on a network basis, the single failure criteria does apply to ensure the completion of a protective function. Redundant sensors, wiring, logic, and actuated devices are physically and electrically separated such that a single failure will not prevent the protective function. See Section 8.3.1.4 for a discussion of the CGS separation criteria.

The RPT meets the single failure criterion. Sensors are electrically and physically separated with conduit provided to the RPS cabinets. The RPT signals to recirculation pump motor circuit breaker trip coils are separated into Division 1 and Division 2 and circuit breaker to pump motors are divisionally separated.

Quality of Components and Modules (IEEE 279-1971, paragraph 4.3)

See Section 3.11 for a discussion of safety system component quality.

Equipment Qualification (IEEE 279-1971, paragraph 4.4)

Vendor certification verifies that the sensors associated with each of the systems required for safety trip variables, manual switches, and trip logic components located in mild environments perform in accordance with the requirements listed on the purchase specification as well as in the intended application. This certification, in conjunction with the existing field experience with these components in this application, will serve to qualify these components.

See Sections 3.10 and 3.11 for a discussion of seismic and harsh environment structure, system, and component qualification.

For a complete discussion of equipment qualification for the safety-related systems described in this section, see Sections 3.5, 3.6, 3.10, and 3.11.

Channel Integrity (IEEE 279-1971, paragraph 4.5)

For a discussion of channel integrity for the safety-related systems described in this section under all extremes of conditions described in Section 7.6.1.8.6 see Sections 3.10, 3.11, 8.2.1, and 8.3.1.

Channel Independence (IEEE 279-1971, paragraph 4.6)

System channel independence is maintained by application of the CGS separation criteria as described in Section 8.3.1.4.

Control and Protection System Interaction (IEEE 279-1971, paragraph 4.7)

There are no control and protection system interactions for the systems described in this section.

Derivation of System Inputs (IEEE 279-1971, paragraph 4.8)

The variables discussed in this section are direct measures of the desired variables indicating the need for protective action.

Capability for Sensor Checks (IEEE 279-1971, paragraph 4.9)

For a discussion of sensor checks for the safety-related systems described in this section, see Regulatory Guide 1.22 in Section 7.6.2.4.

Capability for Test and Calibration (IEEE 279-1971, paragraph 4.10)

For a discussion of the test and calibration capability of the safety-related systems described in this section, see Regulatory Guide 1.22 in Section 7.6.2.4.

Channel Bypass or Removal from Operation (IEEE 279-1971, paragraph 4.11)

During periodic testing, any one sensor of the safety-related systems described in this section may be valved-out-of-service and returned-to-service under administrative control procedures. Since only one sensor is valved-out-of-service at any given time during the test interval, protective action capability for the safety-related variables is maintained through the remaining redundant instrument channels.

A sufficient number of IRM channels has been provided to permit any one IRM channel in a given trip system to be manually bypassed and still ensure that the remaining operable IRM channels comply with the single failure criterion.

One IRM manual bypass switch has been provided for each RPS trip system. The mechanical characteristics of this switch permit only one of the four IRM channels of that trip system to be bypassed at any time. To accommodate a single failure of this bypass switch, electrical interlocks have also been incorporated into the bypass logic to prevent bypassing of more than one IRM in that trip system at any time. Consequently, with any IRM bypassed in a given trip system, three IRM channels remain in operation to satisfy the protection system requirements.

The APRM system is designed so that only one APRM may be bypassed at any given time. The bypass switch is a five-position center locking joystick that mechanically switches four fiber optic signals. The bypass switch is optically isolated. When the switch is in one of the four bypass positions, light from only one of the four fiber optic signals (corresponding to the switch position) shall be allowed to pass through the switch. With an APRM bypassed, a trip of two or more APRM channels out of three will result in a trip output from all four-voter channels. The voter channels cannot be bypassed.

The LDS logic is provided with a bypass/test switch for the purpose of testing temperature sensors without initiating associated system isolation. Operation of one switch at a time will not prevent the remaining redundant isolation logic from providing system isolation if required.

The RPT system meets this design requirement as described in Section 7.6.1.5.2.1.

Operating Bypasses (IEEE 279-1971, paragraph 4.12)

There are no operating bypasses for any of the safety-related systems described in this section except for the RPT system.

The recirculation pump motors are not required to trip below 29.5% of rated power. The trip operating bypasses are automatically reinstated above 29.5% power.

Indication of Bypasses (IEEE 279-1971, paragraph 4.13)

For a discussion of automatic bypass indication for the safety-related systems described in this section see Section 7.1.2.4, Regulatory Guide 1.47.

Access to Means for Bypassing (IEEE 279-1971, paragraph 4.14)

Access to means for bypassing any safety action or safety function is under the administrative control of the control room supervisor/shift manager. Other approved methods of controlling access to bypasses are also used. These include key locks with administrative control of the access to keys, procedurally controlled equipment lineups, e.g., locked valve checklists, and the use of mechanical locking devices and annunciators and other indications, e.g., BISI (Regulatory Guide 1.47, Bypass and Inoperable Status Indication for Nuclear Power Plant Safety Systems, described in Section 7.1.2.4). These additional methods help to prevent inadvertent bypasses or to alert the plant operators to safety function bypasses occurring either

from equipment failures or from manually induced bypasses that result as part of testing, maintenance, or equipment repair activities.

Key-locked control switches that provide a means of controlling the access to a safety function bypass are designed to allow key removal only in the "safe" or "accident" positions. Access to the associated keys is procedurally controlled. When not in use, keys are under the administrative control of the control room supervisor/shift manager and stored in a key locker. The keys are audited once per day by the control room supervisor/shift manager. When operation of a key-locked control switch is required to be immediate, such as in the case of the reactor mode switch, the key may be left in the lock during normal plant operation to ensure timely actuation.

Multiple Set Points (IEEE 279-1971, paragraph 4.15)

There are no multiple setpoints within the safety-related systems described in this section.

Completion of Protective Action Once it is Initiated (IEEE 279-1971, paragraph 4.16)

Initiation control logic for the safety-related systems described in this section seals in electrically and remains energized or deenergized. After initial conditions return to normal deliberate operator action is required to return (reset) the safety system logic to normal.

The FPC system is initiated manually for continuous pool cooling when the pool contains spent fuel.

Manual Initiation (IEEE 279-1971, paragraph 4.17)

For a discussion of the manual initiation capability for the safety-related systems described in this section, see Regulatory Guide 1.62 in Section 7.6.2.4.

Access to Set Point Adjustments, Calibration, and Test Points (IEEE 279-1971, paragraph 4.18)

During reactor operation access to setpoint adjustments, calibration controls, and test points for the safety-related systems variables described in this section is under administrative control of the control room operator.

Identification of Protective Actions (IEEE 2791971, paragraph 4.19)

When a safety-related system protective action sensor described in this section exceeds its predetermined setpoint, a control room annunciator is initiated to identify that variable and a typed record is available from the process computer and transient data acquisition system.

Information Readout (IEEE 279-1971, paragraph 4.20)

The safety-related systems described in this section are designed to provide the operator with accurate and timely information pertinent to their status. This information does not give anomalous indications confusing to the operator.

System Repair (IEEE 279-1971, paragraph 4.21)

During periodic testing of the safety-related systems described in this section (except as noted) the operator can determine defective components and replace them during plant operation.

Replacement of IRM and LPRM detectors must be accomplished during plant shutdown. Repair of the remaining portions of the NMS may be accomplished during plant operation by appropriate bypassing of the defective instrument channel. The design of the system facilitates rapid diagnosis and repair.

The RPT system components are designed to facilitate maintenance with the exception of the turbine stop valve limit switches. The redundancy of the eight switches permits plant operation with a defective switch until access can be gained to the switches for repair.

Identification of Protection Systems (IEEE 279-1971, paragraph 4.22)

Each cabinet containing safety system components is labeled with the system designation and the particular redundant portion is listed on a distinctively colored marker plate. Cabling outside the cabinets is identified specifically as belonging to a particular safety system. See Section 8.3.1.3. Redundant racks are identified by the identification marker plates.

7.6.2.4 Conformance to Regulatory Guides

The following is a discussion of conformance to those Regulatory Guides which apply specifically to the safety-related systems discussed in this section. See Section 7.1.2.4 for a discussion of Regulatory Guides which apply equally to all safety-related systems.

Regulatory Guide 1.22 (February 1972)

The APRMs are calibrated to reactor power by using reactor heat balance and the traversing in-core probe (TIP) system to establish the relative local flux profile. LPRM gain settings are determined from the local flux profiles measured by the TIP system once the total reactor heat balance has been determined.

The gain-adjustment-factors for the LPRMs are produced as a result of the process computer nuclear calculations involving the reactor heat balance and the TIP flux distributions. These

adjustments when incorporated into the LPRMs permit the nuclear calculations to be completed for the next operating interval and establish the APRM calibration relative to reactor power.

The IRMs are calibrated by comparison with the APRMs.

The proper operation of the sensors and the logic associated with the LDS is verified during the LDS surveillance tests that are provided for the various components during plant operation. Each temperature monitor channel, for both ambient and differential which provide isolation signals, is connected to one element of a dual thermocouple(s).

Each temperature monitor indicates when the temperature exceeds the setpoint. To verify the thermocouple (sensor) input, a comparison of the redundant sensor readings, one from the trip channel, and the recorded channel is made. The recorded channel monitors the second element of the dual thermocouple. The first element is part of the trip channel. To test the temperature trips a simulated trip level signal is inputted to the monitor from an external source. In addition, key lock test switches are provided so that instrument and logic channels can be tested without sending an isolation signal to the system involved. Thus, a complete system check can be confirmed by checking actuation of the trip logic relay associated with each temperature monitor.

The RWCU differential flow leak detection alarm units are tested by inputting an electrical signal to simulate a high differential flow. Alarm and indicator lights monitor the status of the trip circuit.

The RPT system is testable up to but not including actual RPT circuit breaker during periodic testing of the sensor channels and logic systems. The pump trip circuit breaker testing is performed during the refueling outage.

The turbine stop valves are tested individually by closing a stop valve and verifying RPT relay operation before the control room lights indicate the valve is closed. Calibration of the limit switches is possible only during shutdown and by physical observation. The turbine governor valve closure pressure switches may be valved out, tested, and calibrated during periodic testing.

All other system instrumentation is tested and calibrated during normal reactor operation by valving out the instrumentation and supplying a test pressure source.

Regulatory Guide 1.45 (May 1973)

The leakage to the primary reactor containment from identified sources such as recirculation pump seal, fuel storage pool, head seal, etc., is separated so that flow rates are monitored separately from unidentified leakage and total flow rate can be established and monitored. The leakage from the main steam line safety/relief valves (SRVs) is identified leakage because of

the location of the sensors which detect this leakage, but the leakage is not completely separated from unidentified sources.

Separation of this leakage is not required since any leak from the main steam line SRVs would not be from a crack or break in the line so there would be no identified leakage from the SRV lines during plant operation which necessitates separation from unidentified leakage. The leakage to the reactor containment from unidentified sources is collected and this flow rate is monitored with an accuracy of better than 1 gal/minute.

The leak detection methods used to monitor unidentified leakage include sump flow monitoring, airborne particulate radioactivity monitoring, and airborne gaseous radioactivity monitoring.

Provisions are made to monitor systems connected to the RCPB for signs of intersystem leakage, including radioactivity monitoring of process fluids (process radiation system) and reactor vessel water level monitoring [nuclear steam supply system (NSSS)].

The sensitivity and response time of each system for detection of unidentified leakage is 1 gal/minute in less than 1 hr, except for the airborne particulate radioactivity and airborne gaseous activity monitoring channels, which have sensitivities of 1E-9 microcuries/cc and 1E-6 microcuries/cc respectively, which are consistent with the sensitivities suggested for these channels by Regulatory Guide 1.45. Design calculations demonstrate that the particulate monitors are capable of detecting a 1 gpm leak in 1 hour or gaseous monitors are capable of detecting 1 gpm leak in 10 hours against a background of design leakage.

The specific conditions in the design calculations under which the stated capabilities can be met are as follows:

Variable	Particulate Monitors	Gaseous Monitors
Radioisotope concentration in reactor coolant	Table 5 of ANS-18.1, Source Term Specification N237, reduced by a factor of 100	GE Specification 22A2703F Rev. 3
Background leakage rate	2.1 gpm and 5.5 gpm	2.1 gpm
Duration of background leakage	1 day and 100 days	1 day

The leakage detection system instruments listed in Table 7.6-2 have been evaluated and shown to be available for operation following an operating basis earthquake (OBE). The particulate radioactivity monitoring channel is available for operation following an SSE.

The drywell floor drain and equipment drain sumps, piping to the sumps, and the equipment drain cooler are seismically supported such that they will continue to pass leakage flow following an OBE.

The level switches are used to monitor leakage from reactor building drains to the respective sumps.

Indicators and alarms for each leakage detection system are provided in the main control room. At the site, procedures for converting various indications (e.g., temperature, Δt, and pressure) to a flow rate measurement will be provided by means of conversion curves whenever meaningful.

Major components within the drywell that by nature of their design are sources of leakage (e.g., pump seals) are contained and piped to an equipment drain sump and thereby identified.

Equipment associated with systems within the drywell (e.g., vessels, piping, fittings) share a common free volume, therefore, their leakage detection systems are common. Steam or water leaks from such equipment are collected ultimately in an area drain sump.

Each of the sumps are protected against overflowing leaks from one source masking those from another.

As added backup to the unidentified leakage drain system, the main steam lines within the steam tunnel are monitored by temperature detectors within the tunnel.

Regulatory Guide 1.53 (June 1973)

See Section 7.6.2.3 (IEEE 279-1971, paragraph 4.2).

Regulatory Guide 1.62 (October 1973)

The FPC system is manually initiated from the main control room by actuation of system pump and valve controls.

Events

1. Suction or discharge block valve less than 90% open.
2. Loss of one ASD channel.
3. Turbine control valve fast closure or stop valve $<$90% open.
4. Trip of one or two operating recirculation pumps.
5. Trip of both operating recirculation pumps.
6. Loss of one feedwater pump plus vessel low level (L4).
7. Temperature difference between the steam dome and the recirculation pump suction temperature less than 10.7°F.
8. Pump motor electrical protection logic is activated.
9. Vessel low level (level 3).
10. Vessel low-low level (level 2) or vessel high pressure (ATWS).

Actions

A. Trip of pump motor 6.9-kV power supply.
B. "Runback" to 15 Hz.
C. "Runback" or limit speed of impacted loop to single channel capability.
D. "Runback" or limit speed to a speed determined within the capability of the remaining feed pump.
E. Trip of RPT breakers (ASD output).

RHR HIGH FLOW LEAK DETECTION

AREA LEAK DETECTION FOR REACTOR WATER CLEAN-UP SYSTEM

NOTES:

1. REMOVED.
2. REMOVED.
3. TYPICAL ARRANGEMENT SHOWN ON STEAM LINE "A". FOR STEAM LINES B,C & D THE dPIS'S ARE NUMBERED N009A,B,C,D N010A,B,C,D & N011A,B,C,D RESPECTIVELY.
4. FOUR TEMPERATURE ELEMENTS SHALL BE EQUALLY SPACED IN THE VERTICAL DIRECTION OF THE DRYWELL.
5. INSTRUMENT LINE VALVING MUST COMPLY WITH INSTRUMENT PIPING STANDARD REF. 14.
6. FOR LOCATION AND IDENTIFICATION OF INSTRUMENTS SEE INSTRUMENT DATA SHEETS REF 15
7. ALL ALARMS SHALL BE LOCATED IN MAIN CONTROL ROOM ON LEAK DETECTION PANEL.
8. ONE tIS IS USED TO MEASURE SUMP FILLUP TIME AND THE SECOND tIS IS MONITORING SUMP PUMPOUT TIME.
9. DELAY TIMER SHALL BE PROVIDED TO OVERRIDE THE ISOLATION SIGNAL DURING THE SYSTEM SHOCK (e.g. PUMP STARTUP OR FILTER DEMINERALIZER OPERATION, ETC).
10. PROVISIONS FOR CONTAINMENT INSTRUMENTATION LINES ISOLATION BY CUSTOMER.
11. IT IS RECOMMENDED THAT THE SUMP BE SIZED SO THAT EACH 5 TO 10 GALLONS RAISES THE LEVEL 1 INCH.
12. AE SHALL PROVIDE DRAIN SEAL LOOP TO SEPARATE DRYWELL ATMOSPHERE FROM REACTOR BUILDING. THE SEAL DESIGN SHALL CONSIDER ISOLATION SIGNAL, DRYWELL PRESSURE RISE, AND ISOLATION VALVES RESPONSE TIME.
13. AE SHALL PROVIDE MEANS OF COOLING THE CONTENTS OF THE DRYWELL EQUIPMENT DRAIN SUMP BASED ON 25 GPM LEAKAGE.
14. PRESSURE INTEGRITY CLASSIFICATION OF LEAK-OFF LINE SHOULD CORRESPOND TO THE CLASSIFICATION OF THE LEAK-OFF VALVE AND CO WITH SUPP. DOC. -3.
15. TEMPERATURE ELEMENTS SHALL BE PLACED ALONG THE MAIN STEAM LIN APPROXIMATELY 36 INCHES ABOVE THE STEAM LINE. TEMPERATURE DET SHALL BE LOCATED OR SHIELDED SO THAT THE DETECTOR IS SENSITIV THE AIR TEMPERATURE AND NOT THE RADIATED HEAT FROM HOT EQUIPM
16. DELETE

7.7 CONTROL SYSTEMS NOT REQUIRED FOR SAFETY

7.7.1 DESCRIPTION

This section describes instrumentation and controls of major plant control systems whose functions are not essential for the safety of the plant. This section also describes instrumentation and controls not essential for the safety of the plant, which are not discussed in any other FSAR section. The systems include

a. Reactor vessel instrumentation,

b. Reactor manual control system (RMCS),

c. Recirculation flow control system,

d. Feedwater control system,

e. Digital Electro-Hydraulic (DEH) control system,

f. Neutron monitoring system (NMS) - traversing in-core probe (TIP), source range monitor (SRM), rod block monitor (RBM),

g. Process computer system and rod worth minimizer function (RWM),

h. Loose parts detection system (LPDS), Retired

i. Refueling interlocks,

j. Safety/relief valve (SRV) relief function, and

k. Transient data acquisition system (TDAS).

See Tables 7.7-1 and 7.7-2 for system design and supply responsibility and similarity to licensed reactors, respectively.

7.7.1.1 Reactor Vessel

Figure 10.3-2 shows the arrangements of the sensors and sensing equipment used to monitor reactor vessel conditions.

7.7.1.1.1 Function

The purpose of the reactor vessel instrumentation is to monitor key reactor vessel variables to provide the operator with information during normal plant operation, startup, and shutdown.

7.7.1.1.2 Operation

The following is a discussion of each reactor vessel variable monitored:

7.7.1.1.2.1 Reactor Vessel Temperature. The reactor vessel temperature is determined on the basis of reactor coolant temperature. Temperatures needed for operation and for compliance with the Technical Specifications operating limits are obtained from one of several sources, depending on the operating condition. During normal operation, either reactor pressure and/or the inlet temperature of the coolant in the recirculation loops can be used to determine the vessel temperature. The recirculation suction temperature (via thermocouples) is the primary temperature measurement when less than 100 psig. When greater than 100 psig, vessel pressure converted to saturation temperature is the primary measurement. During normal operation, vessel thermal transients are limited via operational constraints on parameters other than temperature.

7.7.1.1.2.2 Reactor Vessel Water Level. Figure 7.7-1 shows the water level range and the reactor vessel tap location for each water level range. The instruments that sense the water level are differential pressure devices with a condensate reference leg calibrated to be accurate at a specific vessel pressure and liquid temperature condition. During operation, a continuous flow of gas-free water at a flow rate of about 0.12 to 0.48 gal/hr is also maintained through each reference leg to the reference leg condensing chamber to minimize the transport of dissolved noncondensable gases down the reference leg. The following is a description of each water level range shown in Figure 7.7-1:

a. Shutdown water level range: This range is used to monitor the reactor water level during reactor shutdown conditions when the reactor system is flooded for maintenance and head removal. The vessel pressure and temperature conditions that are used for the calibration are 0 psig and 120°F water in the vessel. The two vessel instrument tap elevations used for this water level measurement are located at the top of the reactor vessel head and the instrument tap just below the bottom of the dryer skirt.

b. Upset water level range: This range is used to monitor the reactor water level above the narrow range scale (see item c below). The design and vessel taps are the same as outlined above. The vessel pressure and temperature condition for accurate indication is at the normal power operating point. The upset water level is continuously indicated by a recorder in the control room. The upset range upper limit is higher than the narrow range upper limit. Therefore, when

the indication is upscale on the narrow range recorder, water level indication may be read immediately from the upset range recorder. See Section 7.7.1.4.

c. Narrow water level range: This range uses reactor vessel taps at the elevation near the top of the dryer skirt and the taps at an elevation near the bottom of the dryer skirt. The zero of the instrument is the bottom of the dryer skirt and the instruments are calibrated to be accurate at the normal power operating point. The feedwater control system uses this range for its water level control and indication inputs. See Section 7.7.1.4.

d. Wide water level range: This range uses reactor vessel taps at the elevation near the top of the dryer skirt and the taps at an elevation near the top of the active fuel. The zero of the instrument is the bottom of the dryer skirt (527.5 in. above the vessel bottom inside) and the instruments are calibrated to be accurate at the normal power operating point. See Section 7.5 for the safety-related features of this range.

e. Fuel zone water level range: This range uses reactor vessel taps at the elevation near the top of the dryer skirt and the taps at the jet pump diffuser skirt. The zero of the instrument is the bottom of the dryer skirt (527.5 in. above the vessel bottom inside) and the instruments are calibrated to be accurate at 0 psig and saturated conditions. See Section 7.5 for the safety-related features of this range.

To decouple the change in measured water level with changes in drywell temperature, the elevation drop from reactor vessel penetration to the drywell penetration remains uniform for the narrow-range and wide-range water level instrument lines.

7.7.1.1.2.3 Reactor Core Hydraulics. A differential pressure transmitter indicates core plate pressure drop by measuring the pressure difference between the core inlet plenum and the space just above the core support assembly. The instrument sensing line used to determine the pressure below the core support assembly attaches to the reactor vessel nozzle N-11. An instrument sensing line is provided for measuring pressure above the core support assembly. The differential pressure of the core plate is recorded in the main control room.

Another differential pressure device indicates the jet pump developed head by measuring the pressure difference between the pressure above the core and the pressure below the core plate. This is indicated locally and in the main control room.

7.7.1.1.2.4 Reactor Vessel Pressure. Pressure switches, indicators, and transmitters detect reactor vessel internal pressure from the same instrument lines used for measuring reactor vessel water level.

7.7.1.2 Reactor Manual Control System

7.7.1.2.1 Function

The RMCS provides the operator with the means to make changes in nuclear reactivity by the operator manipulating control rods so that reactor power level and power distribution can be controlled.

This system includes the interlocks that inhibit rod movement (rod block) under certain conditions. The RMCS does not include any of the circuitry or devices used to automatically or manually scram the reactor; these devices are discussed in Section 7.2. In addition, the mechanical devices of the control rod drives (CRD) and the CRD hydraulic system are not included in the RMCS. The latter mechanical components are described in Section 4.1.3.

7.7.1.2.2 Operation

The RMCS includes the following:

a. Rod drive control system,
b. Rod block trip system,
c. Rod position probes, and
d. Position indication electronics.

Figure 4.6-5 show the layout of the CRD hydraulic system. Figure 7.7-2 shows the functional arrangement of devices for the control of components in the CRD hydraulic system. The logic diagram for the RMCS is shown in Figure 7.7-3. Although the figure also shows the arrangement of scram devices, these devices are not part of the RMCS. Three modes of control rod operation are used: insert, withdraw, and settle. Four solenoid-operated valves are associated with each control rod to accomplish these actions.

7.7.1.2.2.1 Rod Drive Control System. When the operator selects a control rod for motion and operates the rod insert or withdraw control switch, independent messages are formulated in the A and B portions of the rod drive control system (RDCS). A comparison test is made of these two messages, and identical results confirmed; then a serial message in the form of electrical pulses is transmitted to all hydraulic control units (HCU). The message contains two portions: (1) the identity or "address" of the selected HCU and (2) operation data on the action to be executed. Only one HCU responds to this message and it proceeds to execute the rod movement commands.

On receipt of the transmitted signal the responding HCU transmits three portions of a message back to the control room for comparison with the original message:

a. Hard-wire identity "address,"

b. Operations currently being executed, and

c. Status indications of valve positions, accumulator conditions, and test switch positions.

In either rod motion direction, the A and B messages are formulated and compared each millisecond and, if they agree, the A message is transmitted to the HCU selected by the operator.

Continued rod motion depends on receipt of a train of sequential messages because the HCU insert, withdraw, and settle valve control circuits are ac coupled. The system must operate in a dynamic manner to effect rod motion.

Any disagreement between the A and B formulated messages or the responding echo message will prevent rod motion. Electrical noise disruptions will have only a momentary effect on system operation. Correct operation of the system will resume when the noise source ceases.

In Figure 7.7-4, the three modes of the solid-state RMCS are shown:

a. Operator control mode: This mode (0.0002-sec duration) services the control rod selected by the operator to transmit action commands and receive status indications, i.e., presence of rod blocks.

b. Scan mode: This mode (0.045-sec duration) continuously monitors the other control rods in the reactor, one at a time, to update their status display.

c. Self test mode: This mode (on the order of 20 to 100-sec duration) automatically exercises one HCU at a time to ensure correct execution of actions commanded. This provides for a continuous, periodic self-test of the entire RMCS.

In the event that any discrepancy is detected in one of these three modes of operation, a rod motion inhibit is applied. This situation is alarmed and annunciated on the reactor control console as an “activity disagree” condition. The CRD control system is also designed to produce a rod motion inhibit condition should any failure of the system occur.

The cause of the discrepancy or failure must be corrected before rod movement can proceed. Note, however, that this system cannot affect normal shutdown capability via the reactor protection system (RPS).

The rod selection circuitry is arranged so that a rod selection is sustained until either another rod is selected or separate action is taken to revert the selection circuitry to a no-rod selection

condition. Initiating movement of the selected rod prevents the selection of any other rod until the movement cycle of the selected rod has been completed. Reversion to the no-rod selected condition is not possible (except for loss of control circuit power) until any moving rod has completed the movement cycle.

The direction in which the selected rod moves is determined by the position of four switches located on the reactor control panel. These four switches, "insert," "withdraw," "continuous insert," and "continuous withdraw" are push buttons which return by spring action to an off position.

The following is a description of the operation of the RMCS during an insert cycle. The cycle is described in terms of the insert, withdraw, and settle commands from the RMCS.

> With a control rod selected for movement, depressing the "insert" switch and then releasing the switch energizes the insert command for a limited time. Just as the insert command is removed, the settle command is automatically energized and remains energized for a limited time. The insert command time setting and the rate of drive water flow provided by the CRD hydraulic system determine the distance traveled by a rod. The time setting results in a one-notch (6-in.) insertion of the selected rod for each momentary application of a rod-in signal from the rod movement switch. Continuous insertion of a selected control rod is possible by holding the "insert" switch.

A second switch can be used to affect insertion of a selected control rod. This switch is the "continuous insert" switch. By holding this switch "in," the unit maintains the insert command in a continuous, energized state to cause continuous insertion of the selected control rod. When released, the "insert valves" close immediately and no settle function is available so rod motion stops via leakage past the seals.

The following is a description of the operation of the RMCS during a withdraw cycle. The cycle is described in terms of the insert, withdraw, and settle commands.

> With a control rod selected for movement, depressing the "withdrawal" switch energizes the insert valves at the beginning of the withdrawal cycle to allow the collet fingers to disengage the index tube. When the insert valves are deenergized, the withdraw and settle valves are energized for a controlled period of time. The withdraw valve is deenergized before motion is complete; the drive then settles until the collet fingers engage. The settle valve is then deenergized, completing the withdraw cycle. This withdraw cycle is the same whether the withdraw switch is held continuously or momentarily depressed position. The timers that control the withdraw cycle are set so that the rod travels one notch (6-in.) per cycle. Provisions are included to prevent further control rod motion in the event of timer failure.

A selected control rod can be continuously withdrawn if the "withdraw" switch is held in the depressed position at the same time that the "continuous withdraw" switch is held in the depressed position. With both switches held in these positions, the insert valves energize momentarily and then the withdraw valves are continuously energized. Upon releasing the switches the settle function will start.

7.7.1.2.2.2 Rod Block Trip System. This portion of the RMCS on receipt of input signals from other systems inhibits movement or selection of control rods.

a. Grouping of channels

The same grouping of neutron monitoring equipment [SRM, intermediate range monitor (IRM), average power range monitor (APRM), and RBM] that is used in the RPS is also used in the rod block circuitry.

Half of the total monitors [SRM, IRM, APRM, RBM, reactor recirculation control (RRC) flow units, flow comparator, and scram discharge volume high level] provide inputs to one of the RMCS rod block logic circuits and the remaining half provide inputs to the other RMCS rod block logic circuit.

The rod withdrawal block from the RWM trip affects only one RMCS rod block logic. The rod insert block from the RWM function prevents both notch insertion and continuous insertion.

The APRM and RBM (see Section 7.7.1.8) rod block settings are varied as a function of recirculation flow. Analyses show that the selected settings are sufficient to avoid both RPS action and local fuel damage as a result of a single control rod withdrawal error. Mechanical switches in the SRM and IRM detector drive systems provide the position signals used to indicate that a detector is not fully inserted. Additional discussion of the NMS is in Sections 7.7.1.6, 7.7.1.7, and 7.7.1.8. The rod block from scram discharge volume high water level uses two nonindicating transmitter/level switches installed on the scram discharge volume. These two transmitter/level switches provide a control room annunciation of increasing level below the level at which a rod block occurs.

b. Rod block functions

The following discussion describes the various rod block functions and explains the intent of each function. The instruments used to sense the conditions for which a rod block is provided are discussed in the following sections. The rod

block functions provided specifically for refueling situations are described in Section 7.7.1.13.

Figures 7.7-3 and 7.6-3 show the rod block interlocks used in the RMCS. Figure 7.7-3 shows the general functional arrangement of the interlocks, and Figure 7.6-3 shows the rod blocking functions that originate in the NMS.

1. With the mode switch in the SHUTDOWN position, no control rod can be withdrawn. This enforces compliance with the intent of the shutdown mode.

2. The circuitry is arranged to initiate a rod block regardless of the position of the mode switch for the following conditions:

   (a) Any APRM upscale rod block alarm. The purpose of this rod block function is to avoid conditions that would require RPS action if allowed to proceed. The APRM upscale rod block alarm setting is selected to initiate a rod block before the APRM high neutron flux scram setting is reached.

   (b) Any APRM inoperative alarm. This ensures that no control rod is withdrawn unless the average power range neutron monitoring channels are either in service or correctly bypassed.

   (c) Scram discharge volume high water level. This ensures that no control rod is withdrawn unless enough capacity is available in the scram discharge volume to accommodate a scram. The setting is selected to initiate a rod block earlier than the scram that is initiated on scram discharge volume high water level.

   (d) Scram discharge volume high water level scram trip bypassed. This ensures that no control rod is withdrawn while the scram discharge volume high water level scram function is out of service.

   (e) The RWM can initiate a rod insert block and a rod withdrawal block. The purpose of these functions is to reinforce procedural controls that limit the reactivity worth of control rods under lower power conditions. The rod block trip settings are based on the allowable control rod worth limits established for the design basis rod drop accident. Adherence to prescribed control rod patterns is the normal method by which this reactivity restriction is observed.

Additional information on the RWM function is in Section 7.7.1.10.

(f) Rod position information system (RPIS) malfunction. This ensures that no control rod can be withdrawn unless the RPIS is in service.

(g) Either RBM upscale alarm. This function is provided to stop the erroneous withdrawal of a control rod so that local fuel damage does not result. Although local fuel damage poses no significant threat in terms of radioactive material released from the nuclear system, the trip setting is selected so that no local fuel damage results from a single control rod withdrawal error during power range operation.

(h) Either RBM inoperative alarm. This ensures that no control rod is withdrawn unless the RBM channels are in service or correctly bypassed.

3. With the reactor mode switch in the RUN position, any of the following conditions initiates a rod block.

(a) Any APRM downscale alarm. This ensures that no control rod will be withdrawn during power range operation unless the average power range neutron monitoring channels are operating correctly or are correctly bypassed. All unbypassed APRMs must be on scale during reactor operations in the RUN mode.

(b) Either RBM downscale alarm. This ensures that no control rod is withdrawn during power range operation unless the RBM channels are operating correctly or are correctly bypassed. Unbypassed RBMs must be on scale during reactor operations in the RUN mode.

(c) Any recirculation flow unit upscale, inoperative, or comparator alarm. This ensures that no control rod is withdrawn unless the flow channels are operable, the difference between flow units is within limits, and the flow rate is not unusually high.

4. With the mode switch in the STARTUP or REFUEL position, any of the following conditions initiates a rod block:

(a) Any SRM detector not fully inserted into the core when the SRM count level is below the retract permit level and any IRM range switch on either of the two lowest ranges. This ensures that no control rod is withdrawn unless all SRM detectors are correctly inserted when they must be relied on to provide the operator with neutron flux level information.

(b) Any SRM upscale level alarm. This ensures that no control rod is withdrawn unless the SRM detectors are correctly retracted during a reactor startup. The rod block setting is selected at the upper end of the range over which the SRM is designed to detect and measure neutron flux.

(c) Any SRM downscale alarm. This ensures that no control rod is withdrawn unless the SRM count rate is above the minimum prescribed for low neutron flux level monitoring.

(d) Any SRM inoperative alarm. This ensures that no control rod is withdrawn during low neutron flux level operations unless neutron monitoring capability is available.

(e) Any IRM detector not fully inserted into the core. This ensures that no control rod is withdrawn during low neutron flux level operations unless proper neutron monitoring capability is available.

(f) Any IRM upscale alarm. This ensures that no control rod is withdrawn unless the intermediate range neutron monitoring equipment is correctly upranged during a reactor startup. This rod block also provided a means to stop rod withdrawal in time to avoid conditions requiring RPS action (scram) in the event that a rod withdrawal error is made during low neutron flux level operations.

(g) Any IRM downscale alarm except when range switch is on the lowest range. This ensures that no control rod is withdrawn during low neutron flux level operations unless the neutron flux is being correctly monitored. This rod block prevents the continuation of a reactor startup if the operator upranges the IRM too far for the existing flux level. Thus, the rod block ensures that the IRM is on scale if control rods are to be withdrawn.

(h) Any IRM inoperative alarm. This ensures that no control rod is withdrawn during low neutron flux level operations unless neutron monitoring capability is available.

c. Rod block bypasses

To permit continued power operation during repair or calibration of equipment for selected functions that provide rod block interlocks, a limited number of manual bypasses are permitted as follows:

1. One SRM channel,
2. Two IRM channels (1 on either RPS bus A or bus B),
3. One APRM channel, and
4. One RBM channel.

The IRMs are arranged as two groups of equal numbers of channels. One manual bypass is allowed in each group. The groups are chosen so that adequate monitoring of the core is maintained with one channel bypassed in each group.

These bypasses are affected by positioning switches in the control room. A light in the control room indicates the bypassed condition.

An automatic bypass of the SRM detector position rod block is effected as the neutron flux increases beyond a preset low level on the SRM instrumentation. The bypass allows the detectors to be partially or completely withdrawn as a reactor startup is continued.

An automatic bypass of the RBM rod block occurs when the power level is below a preselected level (less than 30% power) or when a peripheral control rod is selected. Either condition indicates that local fuel damage is not threatened and that RBM action is not required.

The RWM rod block function is automatically bypassed when reactor power increases above a preselected value in the power range. The RWM can be manually bypassed for maintenance when not required by procedure.

7.7.1.2.2.3 Rod Position Probes. The position probe is a long cylindrical assembly that fits inside the CRD. It includes 53 magnetically operated reed switches, located along the length of the probe and operated by a permanent magnet fixed to the moving part of the hydraulic drive mechanism. As the drive, and with it the control rod blade, moves along its length, the magnet causes reed switches to close as it passes over the switch locations. The particular switch closed then indicates where the CRD, and hence the rod itself is positioned.

The switches are located as follows: one at each of 25 notch (even) positions, one at each of 24 mid-notch (odd) positions, one at the fully inserted position (approximately the same location as the "00" notch), one at the fully withdrawn position (approximately the same location as the "48" notch position), one at the overtravel full out (decoupled position), and one at the overtravel full in position.

All of the mid-notch or odd switches are wired in parallel and treated as one switch (for purposes of external connections), and the fully inserted and overtravel full-in switches are wired in parallel and treated as one switch. These and the remaining switches are wired in a 5 x 6 array (the switches short the intersections) and routed out in an 11-wire cable to the processing electronics (the probe also includes a thermocouple which is wired out separate from the 5 x 6 array). See Figure 7.7-5.

7.7.1.2.2.4 Position Indication Electronics. The electronics consist of a set of probe multiplexer cards (one per four-rod group where the four-rod group is the same as the display grouping described later in this section), a set of file control cards (one per 11 multiplexer cards), and one set of master control and processing cards serving the whole system. All probe multiplexer cards are the same except that each has a pair of plug-in daughter cards containing the identity code of one four-rod group (the probes for the corresponding four rods are connected to the probe multiplexer card). The system operates on a continuous scanning basis with a complete cycle every 45 msec.

The control logic generates the identity code of one rod in the set and transmits it using time multiplexing to all of the file control cards. These in turn transmit the identity with timing signals to all of the probe multiplexer cards. The one multiplexer card with the matching rod identity will respond and transmit its identity (locally generated) plus the raw probe data for that rod back through the file control card to the master control and processing logic. The processing logic does several checks on the returning data. First a check is made to verify that an answer was received. Next the identity of the answering data is checked against that which was sent. Finally the format of the data is checked for legitimacy. Only a single even position or, full-in plus position "00," or full-out plus position "48," or odd, or overtravel, or blank (no switch closed) are legitimate. Any other combination of switches is flagged as a fault.

If the data passes all of these tests, it is (a) decoded and transmitted in multiplexed form to the displays in the main control panel and (b) loaded into a memory to be read by the computer as required.

As soon as data for one rod is processed, the identity for the next rod is generated and processed and so on for all of the rods. When data for all rods has been gathered, the cycle repeats.

A rod information display on the reactor control panel is patterned after a top view of the reactor core. The display allows the operator to acquire information rapidly by scanning.

Colored windows provide an overall indication of rod pattern and allow the operator to quickly identify an abnormal indication. The following information for each control rod is presented in the display:

a. Rod fully inserted (green),
b. Rod fully withdrawn (red),
c. Selected rod identification (coordinate position, white),
d. Accumulator trouble (amber),
e. Rod scram (blue), and
f. Rod drift (red).

LPRM low flux levels and LPRM high flux levels are displayed on the Operator Display Assemblies (ODA) located below the display.

Another display shows the positions of the control rod selected for movement and the other rods in the rod group. For display purposes the control rods are considered in groups of four adjacent rods (a four-rod group) centered around a common core volume monitored by four LPRM strings. Rod groups at the periphery of the core may have less than four rods. The four-rod display shows the positions, in digital form, of the rods in the group to which the selected rod belongs. A lighted background on the digital display indicates which of the four rods is selected for movement.

The four-rod display allows the operator to focus attention on the portion of the core where rod motion is occurring. A full core rod position display would tend to be confusing and difficult to read. The ODA's permit the operator to monitor the core reactivity during rod motion. In addition, on demand by the operator, the process computer will provide a print out of all rod positions.

During startup or shutdown all rods of a given sequence are either fully withdrawn or fully inserted. These patterns are indicated on the full core display with the full-in or full-out lights.

In addition to the whole core display, a drifting rod is indicated by an alarm and red light in the control room. The rod drift condition is also monitored by the process computer.

An indication is also provided for rod trend beyond the limits of normal rod movement. If the rod drive piston moves to the overtravel position, an alarm is sounded in the control room. The overtravel alarm provides a means to verify that the drive-to-rod coupling is intact because

with the coupling in its normal condition the drive cannot be physically withdrawn to the overtravel position. Coupling integrity can be checked by attempting to withdraw the drive to the overtravel position.

For the displays above the selected rod identification, accumulator trouble and rod scram indicators are provided by the RDCS. The ODA LPRM high and low flux level readings are provided by the power range monitor system. The remaining information to the displays and the position information for the process computer (via the RWM) are provided by the rod position information subsystem.

The following main control room lights are provided to allow the operator to know the conditions of the CRD hydraulic system and the control circuitry:

a. Stabilizer valve selector switch position,
b. Insert command energized,
c. Withdraw command energized,
d. Settle command energized,
e. Withdrawal not permissive,
f. Continuous withdrawal,
g. Pressure control valve position,
h. Flow control valve position,
i. Drive water pump low suction pressure (alarm and pump trip),
j. Drive water filter high differential pressure (alarm only),
k. Charging water (to accumulator) high pressure (alarm only),
l. Scram discharge volume not drained (alarm only), and
m. Scram valve pilot air header high/low pressure (alarm only).

7.7.1.3 Recirculation Flow Control System

7.7.1.3.1 Function

The recirculation flow control function is to control reactor power level, over a limited range, by controlling the flow rate of the reactor recirculating water using recirculation pump speed. The recirculation flow control system is not required for safety purposes, nor required to operate during or after the design-basis accident. The system is required to operate in the normal plant environment for power-generation purposes only.

7.7.1.3.2 Operation

Reactor circulation flow is varied by controlling the recirculation pump speed. By adjusting recirculation pump speed the change in recirculation flow will automatically change the reactor power level. Each recirculation pump has its individual manual control system as well as the capability of being controlled in unison or ganged by the master setpoint station.

Figure 7.7-6 shows a simplified control scheme for the reactor recirculation flow control system and its relationship to other nuclear steam supply system (NSSS) control schemes.

The reactor power change resulting from change in recirculation flow causes the turbine digital electrohydraulic (DEH) control system to reposition the turbine control valves. The turbine responds to the change in reactor power level by adjusting the control valves, and hence its power output, until the load/speed error signal is reduced to zero.

Operator Information

Indication and alarms are provided to keep the operator informed of the status of the system and equipment and allow the operator to quickly determine the location of malfunctioning equipment.

Instrumentation provides loop flow, pump speed, and controller output and input deviation meters. Alarms are provided to alert the operator of malfunctioning control signals and increasing temperatures of cooling water. In most cases, alarms are supplemented by light indicators to more closely define the problem area.

Indicating lights are provided to indicate the status of the pump/motor control breakers. Alarms are provided to alert the operator of automatic trips and transfers of the pump/motor, malfunctions, and availability of automatic control circuitry.

The GE-FANUC reactor flow control system (RFCS) provides manual control of the RRC pump speed. The GE-FANUC is a programmable logic controller (PLC) located in panel H13-P634 in the main control room. It consists of digital control design which provides operator manual control for the RRC pump speed demand, permissive logic for starting the RRC pump motor, and runback limiter logic functions.

The operator sets the RRC pump speed from a manual ganged or individual loop control setpoint station located in panel H13-P602 in the main control room. The control station provides an adjustable speed drive (ASD) speed reference demand signal to adjust the supply frequency over the range 15 Hz to 63 Hz, which adjusts the speed of the RRC pump drive motors over the range 25% to 105% and in turn controls the recirculation flow rate. Figure 7.7-7 shows a simplified version of the control system major functions. The individual

loop manual setpoint/bias station also has the ability to trim (bias) each loop speed to allow for dissimilarities in performance of the pumps.

The GE-FANUC PLC consists of redundant central processing units (CPU) redundant data communication buses, and redundant genius input/output, (I/O) blocks.

A single video display terminal (VDT) is located on the control benchboard, H13-P602, to provide operating status. Major component group alarms are also provided via the backlit annunciator windows located on the vertical section of H13-P602.

The ASD speed demand reference signal is set by the operator. The GE-FANUC PLC conditions the speed demand signal for each loop for an acceptable ramp rate and for runback limiters, where required. The speed demand reference signal is routed from the control room to the ASD local communication panel via redundant data communication buses. At the ASD local communication panel, redundant genius I/O blocks transmit the speed demand reference signals (2-10-V dc) to the appropriate ASD loop/channel controls. The operator monitors the performance of the RRC using the indicators located on the vertical section of the benchboard H13-P602.

The ASD runs at the lowest speed demand of either the limiter signal or the speed demand setpoint signal. On initiation of a limiter or development of an alarm or fault in the RFCS or ASD channel, a main control room annunciator alarms and the individual loop setpoint bias stations at H13-P602 are transferred from the ganged control to the individual loop control.

Recirculation Pump Flow Measurement

The recirculation loop elbow tap differential pressure is used to provide indirect core flow indication for the flow-biased simulated thermal power scram and to indicate pump performance and jet pump drive flow. In general these functions do not require high measurement accuracy, although repeatability is required. The flow-biased simulated thermal power scram requires a signal that is proportional to pump flow. The signal is used as an indicator of core flow. The proportionality constant (calibration coefficient - pressure drop versus flow) is unimportant as long as that constant does not change; that is, the element is repeatable.

Control Interlocks

Operating conditions have been identified that could result in cavitation of the recirculation pumps and/or jet pumps. Operating procedures require the plant operator to avoid these conditions. In the event that due to operator error these conditions are not avoided, automatic interlocks exist which will prevent operation at these conditions.

Cavitation Protection

The cavitation characteristics (thermal power level at which cavitation will occur for a given flow) of the jet pumps and recirculation pump are similar to a BWR/3 and BWR/4 except that jet pump cavitation occurs at higher thermal power levels. Protection is provided by measuring the available subcooling and reducing the pumps to 25% speed when there is inadequate subcooling. Temperature elements in the loop suction line and steam dome pressure transmitters measure the amount of subcooling available to the system.

For the pump suction temperature an RTD is used. For the discharge measurement, steam dome pressure is used. With GE-FANUC digital capability a programmed "look up" table converts pressure to temperature and hence a differential temperature interlock is provided for the measurement of subcooling. If the minimum differential temperature becomes less than a predetermined value, the control logic will provide a time delayed command and run its output down to 15 Hz; hence the dual channel ASD output will reduce to 15 Hz and each recirculation pump motor will run back to 25% speed.

Feedwater Pump Trip Runback

The recirculation pump(s) will runback to a specific speed setpoint in response to the combination of a feedwater turbine trip and a low reactor pressure vessel (RPV) water level (L4). If the recirculation pump(s) were operating at or below the specified speed setpoint, a change in speed will not incur. This runback feature prevents a scram from a low level condition caused by one feedwater pump trip from rated conditions based on testing results.

High Loop Flow Mismatch

Mismatch of the flow in one loop to the other loop of greater than 50% is known to create abnormal conditions in the jet pumps having the lower flow. Such operation is normally precluded by operating procedures. Following a trip of one of two operating pumps, the tripped pump coasts down to zero.

Loop Suction and Discharge Isolation Valve Position

The pump is tripped at less than 90% open position of either valve to prevent pump damage from no flow if isolation valve closure is initiated while the pumps are running.

Trip to 25% Speed

The pumps are tripped to 25% speed in specific cases to avoid scram recovery delays due to vessel bottom head fluid stratification.

Startup Interlocks

Interlocks ensure that the following conditions are established before the recirculation pump will start:

a. The ASD is ready for operation,

b. The suction and discharge block valves are greater than 90% open,

c. The electrical protection "lock out" relay is reset,

d. The pump motor breakers, end-of-cycle recirculation pump trip (EOC-RPT) breakers, and ASD source and load breakers are racked in place and closed,

e. The RPT function is reset, and

f. The operator manual control station is set to minimum pump speed demand.

The flow control system has been designed to limit the maximum demand signal to the ASD at a rate of less than 10% of rated pump speed/sec. This is to ensure that the RPS will not initiate scram. Interlocks are installed to ensure that this limit is not exceeded.

Recirculation Pump Speed Rate of Change

Single failures can result in a recirculation pump speed maximum rate of change in both recirculation pumps of 10% of rated pump speed/sec, which may result in RPS activation. This value is the average continuous rate used in the transient analysis for the two loop controller failure event. For a one loop controller failure event, a higher than maximum rate of 25%/sec was assumed in the analysis.

The worst single failure would be an ASD control circuit failure which provides a high voltage/frequency power source to the motor.

Scram Avoidance Provisions

a. One pump trip-pump inertia is greater than 21,500 lb_m-ft^2 to allow coastdown without an RPS trip,

b. Recirculation pump speed runback if there is a trip of one feedwater pump and vessel low level from rated conditions based on testing results.

Reliability

The reliability of the ASD system and its GE-FANUC controls have been evaluated in NEDC-32232-P, "WNP-2 Reactor Recirculation Adjustable Speed Drive (ASD) System Reliability Analysis," August 1993. This reliability evaluation concludes that no credible failure modes were found that could affect safety assumptions for the loss-of-coolant (LOCA), anticipated transient without scram (ATWS), transient, and stability analyses.

7.7.1.4 Feedwater Control System

7.7.1.4.1 Function

The feedwater control system controls the flow of feedwater into the reactor vessel to maintain the vessel water level within predetermined limits during all normal plant operating modes. The range of water level is based on the requirements of the steam separators. The feedwater control system uses vessel water level, steam flow, and feedwater flow as a three-element control.

Normally, the signal from the feedwater flow is approximately equal to the steam flow signal; thus, if a change in the steam flow occurs, the feedwater flow follows. The steam flow signal provides anticipation of the change in water level that will result from change in load. The level signal provides a correction for any mismatch between the steam and feedwater flow which causes the level of the water in the reactor vessel to rise or fall accordingly. Single-element control is also available based on water level only.

7.7.1.4.2 Operation

During normal plant operation, the feedwater control system automatically regulates feedwater flow into the reactor vessel. The system can also be manually operated (see Figure 7.7-8).

The feedwater flow control instrumentation measures the water level in the reactor vessel, the feedwater flow rate into the reactor vessel, and the steam flow rate from the reactor vessel.

The optimum reactor vessel water level is determined by the requirements of the steam separators. The separators limit water carry-over in the steam going to the turbines and limit steam carry-under in water returning to the core. The water level in the reactor vessel is maintained within ± 2 in. of the setpoint value during normal operation and within the high and low level trip setpoints during normal plant maneuvering transients. This control capability is achieved during plant load changes by balancing the mass flow rate of feedwater to the reactor vessel with the steam flow from the reactor vessel. The feedwater flow is regulated by controlling the speed of the turbine-driven feedwater pumps to deliver the required flow to the reactor vessel.

The following is a discussion of the variables sensed for system operation.

7.7.1.4.2.1 Reactor Vessel Water Level. Reactor vessel narrow range water level is measured by three identical, independent sensing systems. For each channel, a differential pressure transmitter senses the difference between the pressure caused by a constant reference column of water and the pressure caused by the variable height of water in the reactor vessel. The differential pressure transmitter is installed on lines that serve other systems (see Section 7.7.1.1). Two of the differential pressure signals are used for indication and control and the third for indication only. The narrow-range level signal from one of the two control channels can be selected by the operator as the signal to be used for feedwater flow control. A third-narrow range level sensing channel is used in conjunction with the two control channels to provide high water level trips of the main turbine and feed pump turbines. All three narrow-range reactor level signals and reactor pressure are indicated in the main control room. A fourth level sensing system (upset range) provides level information beyond the span of the narrow range devices. The selected narrow-range water level and upset range water level signals are continually recorded in the main control room.

7.7.1.4.2.2 Main Steam Line Steam Flow. Steam flow is sensed at each main steam line flow restrictor by a differential pressure transmitter. A signal proportional to the true mass steam flow rate is linearized and indicated in the main control room. The signals are summed to produce a total steam flow signal for indication and feedwater flow control. The total steam flow signal is recorded in the main control room.

Alarms on steam flow are provided for use in the RWM logic. Interlocks from steam flow and feedwater flow are used to initiate insertion of the RWM block. An alarm on low steam flow indicates that the above RWM insertion interlock setpoint is being approached. Alarms are also provided for (1) high and low water level and (2) reactor high pressure. Interlocks will trip the plant turbine and feedwater pumps in event of reactor high water level.

7.7.1.4.2.3 Feedwater Flow. Feedwater is delivered to the reactor vessel through turbine-driven feedwater pumps, which are arranged in parallel. The feedwater control system sends a flow demand signal to the master level setpoint station and to the turbine governor control system. The turbine governor control system converts the flow demand signal to a turbine speed signal. On either system failure, the turbine speed signal is maintained at the steady value by each turbine operator control station, until the operator takes manual control. Both systems share data via a communications bus, and any transfer of control signal is bumpless. On reactor SCRAM, level setpoint setdown is performed in the feedwater control system. This immediately demands a low flow value, thus rapidly reducing feedwater flow and the likelihood of carryover.

Feedwater flow is sensed at a flow element in each feedwater line by differential pressure transmitters. Each feedwater signal is linearized and then summed to provide a total mass flow signal which is sent to the feedwater control system and recorded in the control room.

Three modes of feedwater flow control and thus level control are provided.

a. Startup automatic level control,
b. Run mode automatic flow control, and
c. Manual control.

Four level controllers are provided for startup valve control and automatic feed pump control. The master level setpoint station and startup valve control station contain, as a minimum, level setpoint digital display, signal output display, manual output control, manual/automatic switching capability, and manual setpoint adjustment. The two feed pump operator control stations contain turbine speed and pump discharge pressure displays, pump speed bias and signal output displays, manual output control, and manual/automatic switching capability. Each of these manual/automatic stations are software configured for its specific function. In the startup level control mode, measured level is compared to level setpoint within the controller. The resulting signal is conditioned by the proportional plus integral controller circuits and transmitted to the startup level control valves.

During normal operation three element automatic control is provided. The total steam flow/feed flow signal, modified by the conditioned level error signal, provides a flow demand signal to the feedwater flow control loop. The demanded flow is converted to a speed demand which is compared to actual speed for each active pump. The resulting speed error signal changes the turbine speed, zeroing the error signal.

Manual control is available by selecting manual on the controller manual/automatic stations. Flow change is accomplished by depressing the raise button or lower button depending on the desired flow change.

The level control system also provides interlocks and control functions to other systems. If the recirculation pumps are running at a speed greater than the single feed turbine capability setpoint, loss of one of the reactor feed pumps and coincident or subsequent low water level, recirculation flow is reduced to within the power capabilities of the remaining reactor feed pump. This reduction aids in avoiding a low level scram by reducing the steaming rate from rated conditions based on testing results.

7.7.1.5 Digital Electro-Hydraulic Control System

7.7.1.5.1 Function

The function of turbine pressure regulation and control is performed by the DEH system. As a direct cycle boiling water reactor the turbine is slaved to the reactor in that all (except steam to the moisture separator reheaters) steam generated by the reactor is normally accepted by the turbine. The operation of the reactor requires pressure regulation to maintain a constant

(within the range of the DEH proportional controller setting) turbine inlet pressure with load following ability accomplished by variation of reactor power.

The DEH control system normally controls the turbine governor valves to maintain this constant turbine inlet pressure. In addition, the DEH control system also operates the steam bypass valves such that a portion of nuclear boiler flow can be bypassed when operating at steam generation levels that exceed the turbine load limits as well as during the startup and shutdown phase.

The overall turbine DEH control system accomplishes the following:

a. Control turbine speed and turbine acceleration,

b. Control the steam bypass system to keep reactor pressure within limits, and avoid large power transients, and

c. Control turbine inlet pressure within the DEH proportional controller range.

7.7.1.5.2 Operation

Pressure control is accomplished by controlling main steam pressure immediately upstream of the main turbine throttle and governor valves through modulation of the turbine-governor or steam bypass valves. Command signals to these valves are generated by the DEH control system which receives input from three redundant turbine inlet pressure sensors, as shown in Figure 7.7-9. For normal operation, the turbine governor valves regulate steam pressure. The plant ability to change turbine generator output is enabled by adjusting reactor power level, by varying reactor recirculation flow and by manually moving control rods. In response to the resulting steam production changes, the DEH control system adjusts the turbine governor valves to accept the steam output change, thereby regulating steam pressure and changing turbine generator power output.

7.7.1.5.2.1 Steam Pressure Control. During normal plant operation, steam pressure is controlled by the main turbine governor valves, positioned in response to the pressure demand signal (see Figure 7.7-9). The steam bypass valves are normally closed.

The DEH control system selects from three redundant pressure transmitters to control steam pressure. Separate pressure taps for each transmitter are provided at the turbine inlet. A median selector is used by the DEH control system to determine which throttle pressure transmitter is controlling. In addition, if one throttle pressure transmitter fails, the DEH control system will automatically select the higher value of the two remaining transmitters for control.

The total steam flow (pressure demand) signal is limited, after passage through the low value gate (as shown in Figure 7.7-9), to that required for full power operation of the turbine (plus a deadband) or the load setpoint. Thus, if the DEH control system senses additional steam flow is needed to control reactor pressure when the governor valves have reached the load setpoint (plus a deadband) or the governor valve (position) demand limit, the control signal error to the bypass valves will increase and cause bypass valve actuation.

Control for the turbine governor valves is designed so that the valves will close upon loss of control system electric power or loss of hydraulic system pressure.

7.7.1.5.2.2 Steam Bypass System. The steam bypass equipment is designed to control steam pressure when reactor steam generation exceeds turbine requirements such as during startup (pressure control, speed ramping, and synchronizing), sudden load reduction, and shutdown.

The bypass capacity of the system is approximately 25% of NSSS rated steam flow; sudden load reductions of up to the capacity of the steam bypass can be accommodated without reactor scram.

Normally, the bypass valves are held closed and the DEH control system controls the turbine governor valves, directing all steam flow to the turbine. If the speed/load demand limiter restricts steam flow to the turbine, the DEH controls system pressure by opening the bypass valves. If the capacity of the bypass valves is exceeded while the turbine cannot accept an increase in steam flow, the main steam pressure will rise and RPS action will cause shutdown of the reactor.

The bypass valves are an automatically operated, regulating type which are proportionally controlled by the turbine DEH control system.

The turbine DEH control system provides a signal to the bypass valves corresponding to the error between the turbine governor valve opening required by the pressure demand signal by the output of the low value gate circuit and the turbine governor valve position flow limit (see Figure 7.7-9). A bias signal is provided to maintain the bypass valves closed for momentary differences during normal operational transients.

7.7.1.5.2.3 Turbine Control System Variables. The turbine DEH control system is designed to receive input parameters of turbine throttle inlet pressure, governor and bypass valve position, and turbine speed to process the following signals in turbine modes 3 and 4:

a. The pressure setpoint signal varies the turbine inlet pressure operating point,

b. The pressure demand signal varies governor valve position corresponding to a steam flow from 0% to 100%,

c. The combined turbine and bypass valve steam flow limiter signal range adjusts valve position limits to limit steam flow from 90% to 150%; however it is set equal to or less than 130% of 15.013 Mlb/hr steam flow, which is the fuel analysis limit, and

d. The governor valve position (load) demand signal varies to close or open the valves. The governor valve position limiter limits the governor valve position demand signal so that it does not exceed the value corresponding to valves fully open. The load demand and pressure demand signals are compared and the bypass valves are opened when high steam pressure causes the pressure demand signal to be higher than the load demand signal.

7.7.1.5.2.4 Turbine Speed/Load Control Interfaces.

a. Normal control functions

The DEH control system performs three major functions: a monitoring function (Tricon 1 module), a control function (Tricon 3 module), and a trip function (Tricon 2 module). The control function can also initiate a turbine overspeed trip through the Tricon 2 module.

b. Normal modes of operation

The DEH control system (Tricon 3) has five turbine control modes. The modes are based on a system of steps that control the operation of the turbine. These modes are normally automatically entered depending on the current operating conditions. Each mode is tightly interlocked, so the next mode is only entered when the conditions are correct. This ensures an orderly progression through the steps and appropriate actions in the event of malfunctions. The five modes are Reactor Start, Speed Control, Load Control, Turbine Follow Reactor and Overspeed Test (numbered Mode 1 through Mode 5, respectively).

1. Turbine Mode 1: Reactor start

In Mode 1, the turbine throttle and bypass valves are controlled to allow the turbine to be latched and proceed to the speed control mode. Throttle pressure controller output demand selection only allows for control of the bypass valves to maintain throttle pressure. After a successful latch of the turbine, the sequence automatically enters Speed Control (Mode 2).

2. Turbine Mode 2: Speed control

In Mode 2, the turbine speed is ramped up to near synchronous speed by using the turbine throttle valves to control turbine speed and the bypass valves to control reactor pressure. The turbine valve control is transferred from the throttle valves to the governor valves when near synchronous speed. When speed measurement reaches approximately 20 rpm below target, the throttle valve minimum limit is ramped to 100%, opening the valves fully. As the throttle valves open, the governor valve speed controller is enabled to control speed.

Overspeed Protection Controller (OPC) logic is active in this mode. If nominal turbine speed is ≥103% speed, the OPC solenoids are energized which will close the governor and intercept valves. When turbine speed is reduced to less than 101%, the OPC solenoids close and return the DEH control system to Speed Control Mode.

The sequence will proceed to Load Control (Mode 3) if the generator breaker is detected closed or Overspeed Test (Mode 5) if Overspeed Test is selected.

3. Turbine Mode 3: Load (limit) control

Mode 3 is entered from Speed Control (Mode 2) when control is transferred to the governor valves and the generator output breaker is closed upon synchronizing with the grid. Mode 3 is also entered from Turbine Follow Reactor (Mode 4), when the throttle pressure controller output demand is equal to the governor valve load demand signal and when throttle pressure controller output demand is equal to the scaled valve position limit signal. See Figure 7.7-9.

When entering this mode, a load reference is set along with a ramp rate providing an initial electrical load on the generator by ramping the governor valves open increasing measured electrical load. During this initial operating condition, any increase or decrease in throttle pressure results in the bypass valves operating to maintain pressure.

During Mode 3, OPC remains enabled.

4. Turbine Mode 4: Turbine follow reactor

Mode 4 is entered from Load Control (Mode 3) when the throttle pressure controller output demand is lower than the governor valve load

demand signal. This is an indication that the throttle pressure controller is controlling pressure by modulating the governor valves. During Mode 4, as in the Load Control Mode, a load reference is set and the throttle pressure controller sets the governor and bypass valve flow demands, provided the demand is not restrained by the flow, load, or valve position limiters.

Sequential and Optimized valve management may also be selected in this Mode. In Sequential valve operation, governor valves two and three are modulated together following the same demand vs. position schedule; similarly, valves one and four are modulated together following a different schedule. Sequential valve selection is the only available selection during turbine startup and when operating below 95% electrical measured load. Optimized valve selection can only be entered if operating ≥95% electrical load. In Optimized valve operation, governor valves two and three follow the same schedule as if operating in Sequential valve. Valves one and four each have their own schedule.

This mode allows testing the throttle valves, governor valves, reheat/intercept valve pairs, and bypass valves to meet technical specification surveillance requirements. Only one valve may be tested at a time in this mode.

5. Turbine Mode 5: Overspeed/OPC test

The sequence enters Mode 5 from Mode 2, Speed Control, when the Overspeed Test Mode is selected. This Mode allows for the overspeed logic in the Control Tricon, the Trip Tricon, and each of the OPC solenoids to be tested without overspeeding the turbine. This is accomplished by ramping down the trip point to the operating speed range to initiate a trip. When the Overspeed Test select is returned to normal, the trip point automatically returns to its original setting.

c. Turbine shutdown or turbine generator trip

During turbine shutdown or turbine generator trip conditions, the main turbine throttle valves and governor valves are or will be closed. Reactor steam flow will then be passed through the steam bypass valves under steam pressure control, and through the reactor SRVs, as needed. See Section 10.2.2 for a complete description of the turbine generator protective and overspeed trips.

d. Steam bypass operation

The main turbine bypass system is designed to control steam pressure when reactor steam generation exceeds turbine requirements during plant startup, sudden load reduction, and cooldown. It allows excess steam flow from the reactor to the condenser without going through the turbine.

The technical specifications require the main turbine bypass system to be operable at greater than or equal to 25% reactor thermal power (RTP). To ensure this limit is met, the bypass valve logic is set to be armed based on generator load when the reactor is approximately 20% RTP during plant startup. This accounts for any thermal losses from the reactor and the turbine generator.

Fast opening of the steam bypass valves during a turbine trip, a generator load rejection, or an OPC actuation requires coordinated action with the turbine control system. When the turbine governor valves are under pressure control, no bypass steam flow is demanded. During turbine or generator trip events, fast-closure of the turbine throttle or governor valves occurs. The bypass valves fully open until load drops below 20% load, plus a 3-5 sec delay and then modulate under pressure control. The turbine governor valve demand is immediately tripped to zero as an anticipatory response, causing the bypass steam flow demand to equal the pressure regulation demand.

During an OPC actuation, fast closure of the governor and intercept valves occurs. If operating at or above approximately 20% RTP, the bypass valves will fast open.

e. Loss of turbine control system power

Turbine controls and valves are designed so that the turbine throttle and governor valves will close on loss of control system power or hydraulic pressure.

f. Operator information

The control interface and indications for the DEH control system are via soft control on two touch screen monitors mounted on the turbine generator section of the main control board. All controls and indications for the DEH control system during the various turbine generator operational modes (such as reactor start, speed control, load control, turbine follow reactor, or overspeed/OPC test) are available to the operator from the two Human Machine Interface (HMI) touch screens.

The DEH control system is self-diagnostic, therefore in the event of a component or control malfunction, an alarm will activate to indicate the failure to the operator. Also, the DEH control system is fault tolerant and redundant, so any single failed active component can be replaced on-line without impact to power operations.

The DEH control system (load demand) receives input from three independent pressure transmitters in the main steam line upstream of the main turbine throttle valves. The pressure setpoint can be set by the operator from the HMI stations.

The DEH control system has the following controls and information displayed in the main control room from the HMI stations:

1. Main steam throttle pressure transmitter A,
2. Main steam throttle pressure transmitter B,
3. Main steam throttle pressure transmitter C,
4. Main steam pressure setpoint,
5. Bypass valve position indication and controls, and
6. Main steam throttle, governor, reheat stop, and intercept valve position indication, and controls.

g. Protection system interface

The DEH control system is designed as a fail-safe, fault tolerant, redundant digital electro-hydraulic control system. The control system is designed to fail in a manner that is within the protection system capability for coping. See Section 3.5.1.3 for turbine missile protection and Section 10.2 for overspeed protection features.

7.7.1.6 Neutron Monitoring System - Traversing In-Core Probe

7.7.1.6.1 Function

Flux readings along the axial length of the core are obtained by fully inserting the traversing ion chamber into one of the calibration guide tubes, then taking data as the chamber is withdrawn. The analog data is available for driving a recorder and for use by the process computer. One traversing ion chamber and its associated drive mechanism is provided for each group of seven to nine fixed in-core assemblies.

7.7.1.6.2 Operation

The number of TIP machines is indicated in Figure 7.6-10. The TIP machines have the following components:

a. One TIP detector,
b. One drive mechanism,
c. One indexing mechanism, and
d. Up to 10 in-core guide tubes.

The system allows calibration of LPRM signals by correlating TIP signals to LPRM signals as the TIP is positioned in various radial and axial locations in the core. The guide tubes inside the reactor are divided into groups. Each group has its own associated TIP machine.

A TIP drive mechanism uses a fission chamber attached to a flexible drive cable (Figure 7.7-11). The cable is driven from outside the drywell by a gearbox assembly. The flexible cable is contained by guide tubes that penetrate the reactor core. The guide tubes are a part of the LPRM detector assembly. The indexing mechanism allows the use of a single detector in any one of 10 different tube paths. The tenth tube is used for TIP cross calibration with the other TIP machines. The control system provides for both manual and semiautomatic operation. Electronics of the TIP panel amplify and provide the TIP signal. Core position versus neutron flux may be recorded on the X-Y recorder in the main control room and is provided to the process computer. A block diagram of the drive system is shown in Figure 7.6-10. Actual operating experience has shown the system to reproduce within approximately 1.0% of full scale in a sequence of tests.

A valve system is provided with a valve on each guide tube entering the drywell. A ball valve and a cable shearing valve are mounted in the guide tubing just outside the drywell. The ball valves are closed except when the TIP is in operation. They maintain the leaktightness integrity of the drywell. A valve is also provided for a nitrogen gas purge line to the indexing mechanisms. A guide tube ball valve opens only when the TIP is being inserted. The shear valve is used only if containment isolation is required and the ball valve cannot be isolated. The shear valve, which is controlled by a manually operated key lock switch, can cut the cable and close off the guide tube. The shear valves are actuated by explosive squibs.

The continuity of the squib circuits is monitored by indicator lights in the main control room. On receipt of containment isolation command from the NSSS, all detectors which are not withdrawn into the shield are withdrawn at full speed, removing the TIP detector from the containment and allowing the ball valves to close. The purge valve is also closed at this time.

7.7.1.7 Neutron Monitoring System - Source Range Monitor

7.7.1.7.1 Function

The SRM provides neutron flux information during reactor startup and low flux level operations.

7.7.1.7.2 Operation

There are four SRM channels. Each includes one detector that can be physically positioned in the core from the control room (see Figures 7.6-8 and 7.7-10).

The detectors are inserted into the core for a reactor startup. They can be withdrawn if the indicated count rate is between preset limits or if the IRM is on the third range or above (see Figure 7.6-10).

During initial fuel load neutron flux was monitored by source range neutron monitoring channels, providing a scram signal when the preset flux level of any channel has been reached. The logic was removed from the scram circuitry after initial fueling by the installation of "shorting links."

The "shorting links" may be periodically removed from the RPS circuitry during control rod withdrawal to perform a shutdown margin demonstration. See Section 7.2.1.1 for the verification requirement for "shorting links" removal.

Each detector assembly consists of a miniature fission chamber and a low-noise, quartz-fiber-insulated transmission cable. The sensitivity of the detector is 1.2×10^{-3} cps/nv nominal, 5.0×10^{-4} cps/nv minimum, and 2.5×10^{-3} cps/nv maximum. The detector cable is connected underneath the reactor vessel to the multiple-shielded coaxial cable. This shielded cable carries the pulses of a pulse current preamplifier located outside the drywell.

The detector and cable are located inside the reactor vessel in a dry tube sealed against reactor vessel pressure. A remote controlled detector drive system moves the detector along the dry tube. Vertical positioning of the chamber is possible from above the centerline of the active length of fuel to 30 in. below the reactor fuel region (see Figures 7.6-6 and 7.6-5). When a detector arrives at a travel end point, detector motion is automatically stopped. The SRM/IRM drive control arrangement and logic are presented in Figures 7.6-6 and 7.6-3. The electronics for the SRMs, their trips, and their bypasses are located in four cabinets. Source range signal conditioning equipment is designed so that it can also be used for open vessel experiments.

A current pulse preamplifier provides amplification and impedance matching for the signal conditioning electronics (Figure 7.7-10).

The signal conditioning equipment converts the current pulses to analog dc currents and voltages that correspond to the logarithm of the count rate (LCR). The equipment also derives the period. The output is displayed on front panel meters and is provided to remote meters and recorders. The LCR meter displays the rate of occurrence of the input current pulses. The period meter displays the time in seconds for the count rate to change by a factor of 2.7. In addition, the equipment contains integral test and calibration circuits, trip circuits, power supplies, and selector circuits.

The trip outputs of the SRM operate in the fail-safe mode. Loss of power to the SRM causes the associated outputs to become tripped.

The SRM provides signals indicating SRM upscale, downscale, inoperative, and incorrect detector position to the RMCS to block rod withdrawal under certain conditions. Any SRM channel can initiate a rod block. These rod blocking functions are discussed in Section 7.7.1.2.2.

One of the four SRM channels can be bypassed at any one time by the operation of a switch on the operator's control panel.

Inspection and testing are performed as required on the SRM detector drive mechanism; the mechanism can be checked for full insertion and retraction capability. The various combinations of SRM trips can be introduced to ensure the operability of the rod blocking functions.

7.7.1.8 Neutron Monitoring System - Rod Block Monitor

7.7.1.8.1 Function

The purpose of the RBM is to limit control rod withdrawal if localized neutron flux exceeds a predetermined setpoint during operator control rod manipulations.

7.7.1.8.2 Operation

The RBM has two channels. Each channel uses input signals from a number of LPRM channels. A trip signal from either RBM channel initiates a rod block. One RBM channel can be bypassed at any time without loss of subsystem function. The minimum number of LPRM inputs required for each RBM channel to prevent an instrument inoperative alarm is four when using four LPRM assemblies, three when using three LPRM assemblies, and two when using two LPRM assemblies, see Figures 7.7-12 and 7.6-3.

The RBM signal is generated by averaging a set of LPRM signals. The LPRM signals used depends on the control rod selected. Upon selection of a rod for withdrawal or insertion, the

conditioned signals from the LPRMs around that rod will be automatically selected by the two RBM channels. For a typical non-edge rod, each RBM channel averages LPRM inputs from two of the four B-level and D-level detectors, and all four of the C-level detectors. A-level LPRM detectors are not included in the RBM averages, but are displayed to the operator. If a detector has been bypassed in the LPRM system, that detector is automatically deleted from the RBM processing and the averaging logic is adjusted to average only the remaining unbypassed detectors.

After selection of a control rod, each RBM channel calculates the average of the related LPRM detectors and calculates a gain factor that adjusts the average to 100. Thereafter, until another rod is selected, the gain factor is applied to the LPRM average to obtain the RBM signal value. The RBM signal value is compared to RBM trip setpoints.

When a peripheral rod is selected or the RBMs associated Reference APRM power signal is below the automatic bypass level, the RBM function is automatically bypassed, the rod block outputs are set to "permissive", and the RBM average is set to zero.

If the Reference APRM is bypassed, the APRM power signal is automatically provided by a second APRM. In the operating range, the RBM signal is accurate to approximately 1% of full-scale.

The RBM has three upscale trip levels and one downscale trip level. Figure 7.7-17 illustrates the trip setpoints. The percent rated power input used to automatically select the applicable RBM trip is provided in the form of simulated thermal power from the RBM channel's Reference APRM.

With increasing or decreasing power, the RBM setpoint automatically changes to the higher or lower rod block setpoint line based on the APRM simulated thermal power input. No operator action is required.

7.7.1.9 Process Computer System

7.7.1.9.1 Function

The function of the process computer is to provide a real time plant data collection, processing, and output system that is designed to support the following:

a. Input of real time plant data simultaneously from both TDAS and PPCRS multiple sources,

b. Processing of plant input data parameters to produce results in "engineering units,"

c. Compare plant inputs against alarm ranges,

d. Output alarm information and other pertinent information to the real time HMI displays,

e. Historical archiving of monitored plant data to circular files.

7.7.1.9.2 Operation

The process computer is half of an integrated dual processor telemetry processing system that provides redundant PPCRS and TDAS functions. With the exception of the data acquisition hardware, the software and hardware is identical between the PPCRS and TDAS system. This duplication provides manual failover capability in the event of a failure on either system. The configuration of the process computer, since redundant to TDAS, is described in Section 7.7.1.15.3 and shown in Figure 7.7-16.

The Human Machine Interface (HMI) is provided through redundant computer work stations. These workstations, as shown in Figure 7.7-16, consist of a Data Acquisition Control Module, Calculation Module and Real Time Display Module. The user (Control Room personnel) accesses these modules by a menu system.

The Data Acquisition Control Module provides the user the capability of stopping and starting the receipt of data from different sources and the transmission of data to other receiving processes. Each source deposits its specific data in the Current Value Table (CVT) for use by other modules. These sources include the RWM, TIP, Alarm, Core Monitoring System Code, and the data acquisition preprocessor. Data can only be sent to PDIS. Sending data to PDIS can be started or stopped by the Data Acquisition Control Module. Screens are provided to monitor the health/status of each function.

The Calculation Module derives information (Plant Data) from the CVT, performs predefined calculations and deposits the results back into the CVT at prescribed frequencies. These calculations include core thermal power, corrected flows, and time averages. The results are then available in the CVT and to the Real Time Display Module.

The Real Time Display Module provides the capability to examine data from all the data sources via the CVT and present them in various formats. These displays are in the form of strip charts, alphanumeric scrolling, and non-scrolling and mimic displays.

The process computer monitors and alarm checks each analog variable at a selectable rate of up to 20 times/sec. Each digital plant input to the process computer can be monitored and alarm checked at up to 250 times/sec. For all analog inputs two types of limit checking and alarming are available: process alarm high/low limits and high/low instrument range limits. Both printed and historical disk storage are provided for analog and digital system alarms.

All alarms logs are printed on the alarm printing device informing the control room personnel of computer system malfunctions, system operation exceeding acceptable limits, and potential unreasonable, off normal, or failed input sensors.

7.7.1.10 Rod Worth Minimizer Function

7.7.1.10.1 Function

The RWM functions to assist and supplement the operator with an effective backup control rod monitoring routine that enforces adherence to established startup, shutdown, and low power level control rod sequences. The RWM computer prevents the operator from establishing control rod patterns that are not consistent with the pre-stored RWM sequence by initiating appropriate rod withdrawal block, and rod insert block interlock signals to the RMCS rod block circuitry (see Figure 7.7-3). The RWM sequence stored in the computer memory are based on control rod withdrawal procedures designed to limit (and thereby minimize) individual control rod worths to acceptable levels as determined by the design basis rod drop accident.

7.7.1.10.2 Operation

The RWM function does not interfere with normal reactor operation, and in the event of a failure does not itself cause rod patterns to be established. The RWM will not function on loss of offsite power. The RWM function can be bypassed and its block function can be disabled only by specific procedural control initiated by the operator.

For the operator to bypass the RWM

a. Plant management approval is required,

b. A second operator or technically qualified plant staff member, with no other duties, is required to verify the first operator's actions while the first operator is performing rod movements,

c. The startup and shutdown sequences with their respective signoff sheets are provided to the second operator for verification of each step rod movement made by the first operator, and

d. The startup and shutdown sequences follow the same control rod patterns that the RWM enforces if it were not bypassed.

The following operator and sensor inputs are used by the RWM:

a. Rod test. In selecting this input, the operator is permitted to withdraw and reinsert one control rod at a time while all other control rods are maintained in the fully inserted position;

b. Normal/bypass mode. A key lock switch permits the operator to apply permissives to RWM rod block functions at any time during plant operation;

c. System start/reset. This input is initiated by the operator to start or restart the RWM programs and system at any time during plant operation;

d. Control rod select. Binary coded identification of the control rod selected by the operator;

e. Control rod position. Binary coded identification of the selected control rod position;

f. Control rod drive selected and driving. The RWM program uses this input as a logic diagnostic verification of the integrity of the rod select input data;

g. Control rod drift. The RWM program recognizes a position change of any control rod using the control rod drift signal input;

h. Reactor power level. Flow signals are used to implement two digital inputs to permit program control of the RWM function. These two inputs, the low power setpoint (LPSP) and the low power alarm setpoint, are used to disable/alarm the RWM function at power levels above the intended service range of the RWM function;

i. Permissive echoes. Rod withdraw and rod insert permissive echo inputs are used by the RWM as a verification "echo" feedback to the system hardware to ensure proper response of an RWM output; and

j. Diagnostic inputs. The RWM uses selected diagnostic inputs to verify the integrity and performance of the processor.

Isolated contact outputs to plant instrumentation provide RWM rod block functions to the RMCS to permit or inhibit withdrawal or insertion of a control rod. These actions do not affect any normal instrumentation displays associated with the selection of a control rod.

The RWM control panel provides the following indication:

a. Insert error. Control rod coordinate identification for as many as two insert errors;

b. Withdrawal error. Control rod coordinate identification for one withdrawal error;

c. Latch group identification of the RWM sequence group number currently enforced by the computer;

d. Rod test select indicates that the rod test function test selected by the operator was honored by the RWM Program;

e. RWM bypass - indicates that the RWM is manually bypassed;

f. Select error - indicates a control rod selection error;

g. Rod blocks - indication that a withdrawal block or insertion block is in effect for all control rods;

h. Out of sequence indication that the actual rod patterns is out of sequence;

i. Below LPSP. Indication that the reactor core power is below the LPSP;

j. Below low power alarm point (LPAP). Indication that the reactor core power is below the LPAP; and

k. Rod drift. Indication that a rod drift condition is detected.

DELETED

DELETED

7.7.1.12 Loose Parts Detection System

The LPDS has been deactivated and spared-in-place (retired). The System mainframe panel (LPDS-PNL-1) remains installed on the 522 ft. level of the Reactor Building. The accelerometer charge-converters (pre-amps) remain installed inside containment, except those posing interference. All power to the system has been disconnected and the cables "spared."

7.7.1.13 Refueling Interlocks

7.7.1.13.1 Function

The purpose of the refueling interlocks is to restrict the movement of control rods and the operation of the refueling platform. Refueling interlocks are shown in Table 7.7-3. This reinforces operational procedures that prevent the reactor from becoming critical during refueling operations.

7.7.1.13.2 Operation

The refueling interlocks circuitry senses the condition of the refueling platform and the control rods to prevent the movement of the refueling platform or withdrawal of control rods (rod block). Redundant circuitry is provided to sense the following conditions:

a. All rods inserted,

b. Refueling platform positioned near or over the core,

c. Refueling platform hoists fuel loaded (main - fuel grapple, auxiliary - frame mounted hoist, monorail - trolley mounted hoist), and

d. Reactor mode switch in "refuel" position.

The indicated conditions are combined in logic circuits to satisfy all restrictions on refueling equipment operations and control rod movement (Figure 7.7-2). The rod-in condition for each rod is established by the closure of a magnetically operated reed switch in the rod position indicator probe.

The rod-in switch must be closed for each rod before the all-rods-in signal is generated. Loss of "all-rods-in" signal will remove grapple control power, if the refueling platform is over the core.

During refueling operations, no more than one control rod is permitted to be withdrawn; this is enforced by a redundant logic circuit that uses the all-rods-in signal and a rod selection signal from the RMCS to prevent the selection of a second rod for movement. The simultaneous selection of two control rods is prevented by the interconnection arrangement of the select push buttons. With the mode switch in the refuel position, the circuitry prevents the withdrawal of more than one control rod and the movement of the loaded refueling platform over the core with any control rod withdrawn.

Operation of refueling equipment is prevented by interrupting the power supply to the equipment. The refueling platform is provided with two mechanical switches attached to the platform, which are tripped open by a long, stationary ramp mounted adjacent to the platform rail. The switches open before the platform or any of its hoists are physically located over the reactor vessel to indicate the approach of the platform toward its position over the core.

In addition to the non-safety-related rod block interlocks provided by the RMCS, and as a safety-related backup, the IRMs provide a rod scram signal during refueling when neutron flux exceeds a preset flux level. The scram signal will provide a control room alarm and will insert any control rod that is withdrawn. The IRMs are required to be operable anytime a control rod is withdrawn in a fueled cell during refueling operations.

Load cell readout is provided for all hoists. The main hoist load is displayed on the flat panel display on the main trolley. The auxiliary frame hoist and the monorail hoist load displays are on the frame pendant and monorail pendant, respectively. Load sensing is via electronic load cells and strain gauge transmitters. The load for the main hoist and frame hoist are inputs to the PLC in the control center on the main trolley. Associated interlock and load functions for the main hoist and auxiliary frame hoist are performed by the PLC. Setpoint modules provide associated interlock and load functions for the monorail hoist.

The three hoists on the refueling platform are provided with switches that open when the hoists are fuel loaded. The switches open at a load weight that is lighter than that of a single fuel assembly. This indicates when fuel is loaded on any hoist.

A bypass plug for the previously installed service platform hoist load interlock is provided which completes the circuit, preventing a false indication that the nonexistent hoist is loaded. Loaded hoist indication prevents control rod withdrawal with the mode switch in the startup or refuel positions. The bypass plug allows control rod movement in this situation. The bypass plug is physically arranged to prevent the connection of any power plug unless the bypass plug is removed.

The rod block interlocks and refueling platform interlocks provide two independent levels of interlock action. The interlocks which restrict operation of the refueling platform hoist and grapple provide a third level of interlock action since they would be required only after a failure of a rod block and refueling platform interlock.

In the refueling mode, the control room operator has an indicator light for "refueling mode select permissive" whenever all control rods are fully inserted. He can compare this indication with control rod position data from the computer as well as control rod in-out status on the full core status display. Whenever a control rod withdrawal block situation occurs, the operator receives annunciation and computer logs of the rod block. The operator can compare these outputs with the status of the variable providing the rod block condition. Both channels of the control rod withdrawal interlocks must agree that permissive conditions exist to move control rods; otherwise, a control rod withdrawal block occurs. Failure of one channel may initiate a rod withdrawal block, and will not prevent application of a valid control rod withdrawal block from the remaining operable channel (see Figure 7.7-2).

Refueling platform interlock indication and main hoist load are displayed to the operator on the flat panel display mounted on the trolley cable. In addition, the bridge, trolley, and main hoist positions displays are on the flat panel display.

The auxiliary frame hoist load and the monorail hoist load are displayed on digital displays on the frame pendant and monorail pendant, respectively. Individual push button and control switches are provided for local control of the platform and its hoists. The platform operator can immediately determine whether the platform and hoists are responding to his local instructions, and can, in conjunction with the control room operator, verify proper operation of each of the three categories of interlocks listed previously.

7.7.1.14 Safety/Relief Valves - Relief Function

7.7.1.14.1 Function

The relief function of the SRVs is to relieve high pressure conditions in the nuclear system that could lead to the failure of the RCPB. The system activates the SRVs to vent steam to the suppression pool and reduce reactor pressure. See Section 5.2.2. Also, see Section 7.3.1.1.1.2 for the ADS function of selected SRVs.

7.7.1.14.2 Operation

Schematic arrangement of system mechanical equipment is shown in Figure 10.3-2. The SRV component control logic is shown in Figure 7.3-8.

The relief function of the SRVs is initiated by pressure switches, one per relief valve. These pressure switches are set to energize the relief valve solenoids in five groups at five respective trip settings. The relief valves will open in groups, the lowest setpoint group first, followed by groups of SRVs at progressively higher setpoints. This feature automatically adjusts the relief capacity to the magnitude of the over pressure condition. The reclose pressure for each SRV is based on the deadband (reset) of the associated pressure switches. Adequate deadband is provided to eliminate rapid open/close operation and minimize system stresses.

To manually open each SRV, remote manual switches are installed in the control room. Lights on the control room panel indicate when the SRVs are open. This monitoring is in accordance with NUREG-0737, Item II.D.3 (see Section 7.5.1.9).

7.7.1.15 Transient Data Acquisition System

To meet the data acquisition and analysis needs during the operation of Columbia Generating Station, and to support emergency response facility functions, a plant data center, referred to as the Plant Data Information System (PDIS), is installed at Columbia Generating Station. The PDIS configuration is shown in Figure 7.7-16. The TDAS, the front end of PDIS, collects and multiplexes plant analog and digital data to a central location for storage and emergency response facility functions such as the graphic display system (GDS) described in Section 7.5.1.22, and the emergency response data system (ERDS), which provides direct electronic data transmission of the required plant parameters from the TDAS computer to the NRC Operations Center. The plant ERDS computer receives data from the TDAS and the process computer system described in Section 7.7.1.9 and transmits it to the Operations Center via secure Internet-based communication protocol. The ERDS was added in response to Generic Letter 89-15, Emergency Response Data System.

7.7.1.15.1 Function

The purpose of the TDAS is to provide a data control center for the acquisition, monitoring, recording, and transfer of data to a computer for analysis and presentation for plant monitoring, testing and emergency response facility functions for selected plant parameters.

7.7.1.15.2 Description

The basis and criteria for the TDAS input signal selection is as follows:

Basis	Criteria
Startup testing requirement	Regulatory Guide 1.68 SRP Section 3.9.2 FSAR Section 3.9.2
Emergency response facility requirement	Regulatory Guide 1.23 Regulatory Guide 1.97 NUREG-0737, Supplement 1 FSAR Section 7.1.1

Signals monitored may be either analog or digital (bilevel). The majority of the signals originate from existing equipment in the control room. Signals are hard-wired from the control room to TDAS remote modules (multiplexers). The remote modules provide the following:

a. Electrical isolation,
b. Signal conditioning,
c. Analog to digital conversion,
d. Multiplexing of the input data, and
e. Interface to fiber-optic cables.

The signal output from the remote modules is transmitted through fiber-optic cables to the TDAS central control unit (CCU). The fiber-optic cables provide electrical separation between remote module output signals.

The TDAS CCU controls the monitoring, recording, engineering unit conversion, alarming, and transfer functions. Discs are used for high speed storage of historical data.

Data is transferred from the TDAS CCU to a computer for data reduction, analysis, and display. A system console connected directly to TDAS is provided for operator interface.

7.7.1.15.3 Operation

TDAS automatically records data from all input points on disc. Data is continuously overlaid on the disc such that in excess of three days of data exists at all times.

A secondary file can be created and archived from the history disk to preserve the data. The data contained in the secondary file can subsequently be displayed and printed.

Three data transfer interfaces are provided by the TDAS CCU. One link is dedicated for the transfer of data to the computer to support the control room GDS displays. The second link transfers TDAS real time data to the Process Computer work stations as user interface. The third link transfers data to the corporate network for use in ERDS and other data reporting services. As noted in Section 7.7.1.9.2, the TDAS hardware (excluding signal interface) software is identical in function and configuration to the Process Computer. This provides total computer redundancy.

7.7.1.15.4 Conformance to NRC Regulatory Guides

7.7.1.15.4.1 Regulatory Guide 1.75, Revision 2, Physical Independence of Electric Systems. Regulatory Guide 1.75 is not applicable to Columbia Generating Station. However, based on commitment to the NRC the TDAS isolator design used the guidance provided in Regulatory Guide 1.75, Revision 2.

The TDAS is a non-safety-related, non-Class 1E system which interfaces with many safety-related components. To ensure that the safety-related components are protected from TDAS equipment failures, the following was implemented in the TDAS design:

a. All TDAS input circuits within raceways are identified and routed to Class 1E requirements up to a remote isolation device. From the isolation device to the remote multiplexer the circuits are considered to be non-Class 1E;

b. Remote multiplexer outputs are transmitted to the computer via a fiber optic cable which is inherently an isolation device. The fiber optic cable, therefore, can be routed in any raceway without regard to separation criteria; and

c. Transient data acquisition system Class 1E input isolators are supplied from non-Class 1E 24-V dc current limiting power supplies. The power source to these power supplies is Class 1E and is provided with a Class 1E current interrupting device. The circuit to the power supply is routed as prime (see Section 8.3.1.4) for Division 1 and 2 isolators and as Class 1E for the Division 3 isolator. The power supply section of the isolator unit is internally isolated from the Class 1E signal input circuit. Downstream of the power supply, the circuits are treated as non-Class 1E.

   All Class 1E components of the TDAS are qualified according to the requirements of Regulatory Guide 1.100 as clarified in Section 1.8.3. All components which interface with Class 1E circuitry (isolation devices) to extract signals are qualified (if applicable) according to the requirements of Regulatory Guide 1.89, Revision 1 as clarified in Section 1.8.3.

7.7.1.15.4.2 NUREG-0737, Supplement 1, Clarification of TMI Action Plan Requirements: Requirements for Emergency Response Capabilities. Parameters identified in Regulatory Guide 1.97, Revision 2, and Regulatory Guide 1.23 are hard-wired to the TDAS. The TDAS components are designed in a modular fashion with spare capacity. The system design allows the capability to expand. Physical separation or isolation devices prevent failures in the TDAS from interfering with safety-related or sensitive control functions. The TDAS components are powered from a highly reliable uninterruptible power source to ensure system availability and that power fluctuations will not result in the loss of software or stored data.

The TDAS provides the equipment needed to gather, store, and transfer data helpful in assessing plant conditions. The system provides in excess of three days of pre-event data and the capability of recording post-event data. Data storage and retrieval functions are performed without interrupting real time data transfer. Data scan rates are more than sufficient to record transient events and determine the sequence of events.

The TDAS has been designed to provide a high degree of reliability and redundancy with the Process Computer. Emergency and preventive maintenance procedures have been established. Spare parts or redundant processing is provided for critical components. Tests are performed to verify that the hardware and software meet performance requirements. Hardware and software modifications are performed in accordance with applicable procedures.

7.7.1.16 Design Differences

See Table 7.7-2 for a list of system designs and their similarity of designs of other nuclear power plants.

7.7.2 ANALYSIS

See the safety evaluations in Chapter 15. Chapter 15 shows that the systems described in this section are not used to provide any design basis accident safety function. Safety functions are provided by other systems.

Chapter 15 also evaluates all credible control system failure modes, the effects of those failures on plant functions, and the response of various safety-related systems to those failures.

The major plant control systems described above have no direct interface with any safety-related systems and, thus control system failures other than those described in Chapter 15 have no effect on the safety-related systems.

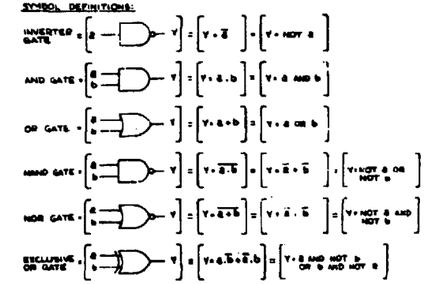
LEGEND:

- ⊖ = SWITCHGEAR DEVICE FUNCTION NUMBER ANSI SPEC C37.2
- RWM = ROD WORTH MINIMIZER
- RPIS = ROD POSITION INFORMATION SYSTEM
- NMS = NEUTRON MONITORING SYSTEM
- PRM = POWER RANGE MONITOR
- RBM = ROD BLOCK MONITOR
- SRI = SELECT ROD INSERT
- RMS = REMOTE MANUAL SWITCH

NOTES:



1. EACH CONTROL ROD, AS IT TRAVELS UP (INSERTED) OR DOWN (WITHDRAWN) PASSES A NUMBER OF SWITCHES. THE TOP TWO POSITION SWITCHES ARE CALLED "OVERTRAVEL" AND THE BOTTOM TWO POSITIONS ARE CALLED "WITHDRAWN" (BACKSEAT & DISCONNECT). SWITCHES IN BETWEEN ARE DIVIDED INTO ODD (DRIFT) AND EVEN (LATCH) POSITIONS. AS THE ROD TRAVELS OVER ANY SWITCH AN INDICATING SIGNAL IS ACTUATED. ANY EVEN SWITCH WILL INDICATE NUMERIC POSITION (eg. 00, 02....48) AND ANY ODD SWITCH WILL INDICATE "ODD".
2. WIRING FROM HCU (SCRAM VALVES AND ACCUMULATOR) TO CONTROL ROOM FOR ANNUNCIATION SHALL BE IN SERIAL CONNECTION FOR ALL HCU'S.
3. WIRING FROM HCU (ROD SCRAM TEST SWITCH IN TEST POSITION AND DISPLAY OF THOSE CONTROL RODS CHOSEN FOR "SELECT ROD INSERT FUNCTION.") SHALL BE IN SERIAL CONNECTION FOR ALL HCU'S.
4. EACH ACCUMULATOR FAILURE WILL INITIATE AN ANNUNCIATION (ANNUNCIATOR HORN & FLASHING ANNUNCIATOR WINDOW) AND AN INDIVIDUAL FLASHING INDICATOR (PART OF THE WHOLE CORE DISPLAY). OPERATION OF THE "ACCUMULATOR TROUBLE ACKNOWLEDGE" SWITCH WILL CLEAR THE INPUT TO THE ANNUNCIATOR AND CHANGE THE INDIVIDUAL INDICATOR FROM FLASHING TO STEADY. CLEARING THE ACCUMULATOR TROUBLE WILL CLEAR THE INDIVIDUAL INDICATORS.
5. SEE REF 12 FOR DEFINITIONS OF VARIABLES APPEARING ON THIS FCD.
6. A LOGICAL "1" INDICATES A FAILED COMPARISON

ELECTRIC POWER

8.1 INTRODUCTION

8.1.1 UTILITY GRID DESCRIPTION

Columbia Generating Station plant power output is connected to the Bonneville Power Administration (BPA) 500-kV transmission system. The two sources of offsite power are provided by connections to the BPA 230-kV and 115-kV transmission systems.

The BPA has an installed hydroelectric generating capacity of over 15.7 million kW. The BPA transmission facilities include over 15,012 miles of 115-kV to 500-kV ac and 1000-kV dc transmission lines and over 300 substations. These transmission facilities together with the hydroelectric generators mentioned above comprise the Federal Columbia River Power System.

The federal Columbia River Power System is interconnected at more than 100 locations with 17 other transmission systems, including major interconnections with other regions. Three high-voltage transmission line interconnections (two 500-kV ac, one 1000-kV dc) of the Pacific Northwest-Pacific Southwest Intertie are in operation.

Two 500-kV ac lines interconnect the federal Columbia River Power System with British Columbia, Canada. Several 230-kV ac lines interconnect the eastern portion of the system with utilities in the mountain states and adjacent Canadian provinces. These interconnections provide, in addition to mutual support in the event of a breakdown or emergency, the means for mutually beneficial exchange of peaking capacity and energy between the Pacific Northwest and other regions.

8.1.2 OFFSITE ELECTRICAL POWER SYSTEM DESCRIPTION

The offsite power system consists of the BPA grid; the step-up main transformer bank, and the 500-kV tie line to the BPA grid; the startup transformer and 230-kV tie line to the BPA grid; and the backup transformer and 115-kV tie line to the BPA grid.

The 1230 MVA main generator output is fed into the BPA grid at the BPA Ashe Switchyard 500-kV bus via the step-up main transformer bank and a 3000-ft long 500-kV tie line. The arrangements of the tie line and BPA 500-kV bus at Ashe Switchyard are shown in Figure 8.1-1. When the main generator is on the line, the Class 1E and non-Class 1E switchgear buses receive power from the main generator via a normal auxiliary transformer as shown in Figure 8.1-2. This source has sufficient capacity to carry both the plant normal auxiliary loads and the plant engineered safety feature (ESF) loads.

Two immediately available sources of power from the BPA grid are provided to supply offsite power, one from the BPA 230-kV grid and one from the BPA 115-kV grid. The 230-kV source is from the 230-kV bus at the BPA Ashe Switchyard via a 3000-ft long 230-kV tie line, through the startup transformer, to the 4.16-kV non-Class 1E switchgear buses to the Class 1E switchgear buses and the 6.9-kV switchgear buses. The arrangements of the BPA 230-kV grid at Ashe Switchyard and the 230-kV tie line to the plant are shown in Figure 8.1-3. The startup transformer and non-Class 1E switchgear bus arrangement is shown in Figure 8.1-2. An automatic fast transfer system is provided to transfer the 4.16-kV and 6.9-kV non-Class 1E buses from the normal auxiliary transformer to the startup transformer if the generator source is lost. This 230-kV source has sufficient thermal capacity to carry both the plant normal auxiliary loads and the plant ESF loads.

The 115-kV source is from the BPA 115-kV Benton Switchyard via a 4-mile long 115-kV tie line and the backup transformer to the Class 1E switchgear buses. The arrangement of the BPA Benton Switchyard and the 115-kV tie line to the plant is shown in Figure 8.1-4. The connections from the backup transformer to the 4.16-kV Class 1E switchgear buses are shown in Figure 8.1-2. If power is not available from the generator source and the 230-kV source, Class 1E buses SM-7 and SM-8 will be automatically transferred to the 115-kV system source. This 115-kV source has sufficient capacity to carry the Division 1 and 2 ESF loads only; the tie breakers between the 4.16-kV Class 1E and non-Class 1E buses are therefore automatically opened prior to the backup source breakers closing.

A communication system is provided between Columbia Generating Station and the BPA Ashe Switchyard for remotely controlling the 500-kV power circuit breakers, for synchronizing, for interlocking with the plant step-up main transformer bank, for equipment protection, and for communication. Columbia Generating Station has a Fiber Optic Transfer Trip (FOTT) system, consisting of communications, control, and annunciation equipment associated with the 230 kV and the 500 kV network interconnections between CGS and BPA's Ashe substation. The FOTT system is used to transmit critical trip, control, and indication signals for transmission line protection, breaker supervisory control and indication where the 500 kV FOTT will also transmit a backup ASHE 500 kV complete loss of bus protection signal as well as the 500 kV power circuit breaker position interlocks to the DEH/Turbine Control system. Various signals travel in both directions along fiber optic tele-communication channels for protection and operation of the 500 kV interconnections providing power to the network from the CGS generator and for protection of the 230 kV line interconnection providing station service to CGS.

The locations of the switchyard and electric power distribution system equipment appear in Figures 1.2-1 and 8.1-5. The layout arrangement of the 230-kV and 115-kV auxiliary power equipment appear in Figure 8.1-5.

8.1.3 ONSITE ELECTRICAL POWER SYSTEM DESCRIPTION

The plant onsite electrical power system consists of the main generator and the normal auxiliary transformers, standby ac power system, high-pressure core spray (HPCS) power system, 4.16-kV, 6.9-kV, and 480-V ac power distribution systems, 125-V and 250-V dc power distribution systems, ±24-V dc power distribution system, the 120/208 and 120/240-V ac instrumentation and uninterruptible power systems, and the 120-V ac reactor protection system (RPS) power system. These systems provide a diversity of dependable power sources which are physically isolated from one another.

The normal auxiliary transformers provide power to all plant auxiliaries and become the normal plant ac power source when the main generator is operating. One of the normal auxiliary transformers is a dual secondary type with both windings stepping down the generator voltage to 4.16-kV for supply of 4.16-kV non-Class 1E switchgear buses. The other normal auxiliary transformer steps down the generator voltage to 6.9-kV for supply of 6.9-kV non-Class 1E switchgear buses. Both transformers supply the switchgear buses via nonsegregated phase bus with main circuit breakers located in the switchgear. Removable links are provided in each of the transformer primary isolated phase bus ducts for isolation of the transformers.

The startup transformer (as described in Section 8.1.2) is a dual secondary type, stepping down the 230-kV line voltage to 4.16-kV and 6.9-kV. The 4.16-kV and 6.9-kV secondaries can supply power to the same 4.16-kV and 6.9-kV non-Class 1E switchgear buses supplied by the normal auxiliary transformers. Connections to the buses are also via nonsegregated phase bus with main circuit breakers located in the switchgear.

The backup transformer (as described in Section 8.1.2) steps down incoming 115-kV voltage to 4.16-kV and can supply backup power to two 4.16-kV Class 1E switchgear buses. All connections to the 4.16-kV switchgear buses are via cable to main circuit breakers located in the switchgear.

The standby ac power system provides an onsite power source for all ESF loads when the normal, preferred (startup), and backup offsite power supplies are not available.

The Division 1 and 2 standby ac power sources consist of two independent 4.16-kV Class 1E diesel generators, each connected to one of the two 4.16-kV Class 1E switchgear buses via two main circuit breakers. One breaker is located near the diesel generating unit; the other is located in the 4.16-kV Class 1E switchgear.

The Division 3 standby ac power source, which is supplied for the HPCS system and support auxiliaries, consists of one independent 4.16-kV Class 1E diesel generator connected to its own 4.16-kV Class 1E switchgear bus via a main circuit breaker located in the switchgear. Under the specific conditions described in Section 8.3.1.1.7.2.1, this standby power source has the

capability to be cross connected to the Division 1 or Division 2 buses via permanently installed cables. It does not have as high a capacity as the Division 1 or 2 standby sources; however, it is capable of providing power to critical Division 1 or 2 components required to maintain safe shutdown conditions.

The standby ac power system is sized to provide the required power to safely shut down the reactor, maintain safe shutdown condition, and operate ESF auxiliaries necessary for plant safety during and after shutdown.

The plant 480-V ac auxiliary power system distributes ac power necessary for normal auxiliary and ESF 480-V plant loads. All non-ESF elements of this distribution system are capable of being supplied from the normal auxiliary power source or from the startup power source via the 4.16-kV non-Class 1E switchgear. The ESF portions of the 480-V distribution system are supplied via the 4.16-kV Class 1E switchgear and therefore are capable of being supplied by either the normal, startup, backup, or standby sources (except that the HPCS power system cannot be supplied by the backup source).

The Division 1 and 2 plant 125-V dc power distribution systems provide two independent onsite sources of power for normal operation and ESF dc loads. A separate 125-V dc power system is also provided for the HPCS system.

A 250-V dc power system provides a reliable onsite source of power for the turbine auxiliary oil pumps and for RCIC pumps and valves.

The $\pm$24-V dc power system provides a reliable onsite source of power for process radiation monitoring instrumentation and nuclear instrumentation.

The 120/240-V uninterruptible ac power system provides for non-ESF plant communications, computer, and controls and instrumentation.

The 120/208-V non-Class 1E instrumentation ac power system provides power for non-ESF control and instrumentation loads. However, the system is supplied via the 480-V Class 1E motor control centers.

The 120/240-V critical (Class 1E) instrumentation ac power system provides power for ESF plant controls and vital instrumentation in the main control room. The system is separated into Division 1 and Division 2 portions with separate distribution panels, static switches, inverters, and ac and dc sources fed from their respective divisional sources.

The RPS power system, including the RPS motor generator (MG) sets, supplies power to the logic system that operates the RPS. The power system contains sufficient stored energy to remain available throughout switching transients. The safe failure characteristics of the RPS exempt the power system from being classified essential. However, redundancy is provided to

avoid an unnecessary plant shutdown on interruption of power to one RPS bus. The system is also grounded, preventing unsafe failures that might occur from multiple grounds.

A supervisory (multiplexing) system is provided between the main plant and the standby service water (SW) pump house, makeup water pump house, cooling tower, and meteorological tower areas to monitor and control operation of equipment at these locations from the main control room. There are no safety-related control functions performed by the supervisory systems.

The main one-line diagram appears in Figure 8.1-2. The electrical symbol designators are shown in Figure 8.1-6.

Compliance with Regulatory Guides 1.81, 1.89, and 1.93 is addressed in Section 1.8.

8.1.4 SAFETY LOADS

The principal ESF subsystem device loads requiring electric power to perform safety functions are included in Tables 8.3-1, 8.3-2, and 8.3-3. Tables 8.3-1 and 8.3-2 indicate the redundant (Divisions 1 and 2) loads associated with safe shutdown systems. Table 8.3-3 indicates loads associated with the HPCS power system (Division 3). Table 8.1-1 indicates the safety functions performed and the type of power source used by each of the ESF systems.

8.1.5 DESIGN BASES

8.1.5.1 Offsite Electrical Power System

The offsite power system is designed to provide reliable offsite power sources to plant auxiliary systems during plant startup and shutdown or any time that power is unavailable from the main generator.

To minimize the possibility of line failures from such causes as wind, ice loading, temperature, lightning, and flooding the transmission lines interconnecting the plant with the utility systems are designed and constructed in accordance with the industry standards for environmental conditions prevalent in the area.

The 500-kV plant output and 230-kV plant startup lines originating at the Ashe Switchyard located 3000 ft north of the plant site run parallel to each other on separate rights-of-way.

The backup 115-kV line from Benton Switchyard, geographically isolated from the 500-kV and 230-kV lines, approaches the plant site from a southeasterly direction and does not run parallel to or cross the other lines. It is physically independent of the 500-kV and 230-kV lines and provides another power source for ESF loads. Its physical separation from the 500-kV and 230-kV lines minimizes the likelihood of a simultaneous outage of all offsite sources.

The normal power supply to plant auxiliary loads is provided through the normal auxiliary transformers connected to the generator bus. On trip of the generator, the auxiliary loads are automatically fast transferred (simultaneous open/close) to the startup transformer for supply of offsite power.

Normally only one power supply breaker to a bus is closed. During manually initiated transfer after startup, during shutdown, or when removing a transformer for maintenance, the closing of one circuit breaker initiates the trip of the other, allowing only momentary paralleling of two sources.

Operation of undervoltage relays on the 4.16-kV Class 1E buses is designed to start the associated diesel generators and initiate load shedding and sequencing control as described in Sections 8.3.1.1.7.1.7 and 8.3.1.1.7.2.7.

Station blackout is addressed in Appendix 8A.

The offsite power system is designed in accordance with the applicable portions of the following criteria, with a level of implementation as described in Section 8.2.2.4. Specific data regarding the use of alternate approaches in instances of nonconformance are discussed therein.

a. General Design Criterion (GDC) 17 - Electric Power Systems

b. GDC 18 - Inspection and Testing of Electric Power Systems

c. GDC 33 - Reactor Coolant Makeup

d. GDC 34 - Residual Heat Removal

e. GDC 35 - Emergency Core Cooling

f. GDC 38 - Containment Heat Removal

g. GDC 41 - Containment Atmosphere Cleanup

h. GDC 44 - Cooling Water

i. IEEE 308-1974 - Class 1E Electrical Systems for Nuclear Power Generating Stations

j. Regulatory Guide 1.32, Revision 2 - Use of IEEE 308-1974

Fiber Optic Transfer Trip (FOTT) system consists of communications, controls, and annunciation equipment transmitting signals between CGS and the ASHE substation for 230 kV and 500 kV transmission line protection, backup ASHE 500 kV complete loss of bus protection, supervisory control and indication of the 500 kV bus tie breakers, and 500 kV breaker position indication inputs to the DEH/Turbine Control System protection logic.

CGS FOTT system is based on the concept of "quad redundancy," or two sets of redundant systems. This design eliminates single point vulnerability. This redundancy allows for on-line maintenance, so maintenance can be done more frequently.

This system includes digital, tele-communication components. It uses bi-directional SONET Ring configuration which provides multiple transmission paths for the information between CGS and Ashe Substation. This increases the reliability of the system.

The response time for the system does not add unnecessary time delay to the clearing or operating times of the protection scheme. FOTT signal transit time is approximately one cycle (16 ms).

There is a Sequence of Events Recorder (SER) in the CGS Communication Room (RW 525) that provides a time tagged record of alarms in the case of a plant FOTT initiated plant trip, or other FOTT equipment problems during plant operations that are visible to PBA dispatch control centers. The SER processes signals from both ends of the FOTT system from Ashe or CGS that also that also drives two trouble alarm annunciator windows in the CGS Main Control Room for either the 230 kV FOTT or the 500 kV FOTT system.

8.1.5.2 Onsite Electrical Power System

The onsite power system is designed to supply the power requirements of all auxiliary plant loads during normal operation and to ESF loads when required. Sufficient instrumentation and protective control devices are provided to maximize operational reliability and availability of the supply system.

Those portions of the onsite power system required for the distribution of power to ESF electrical components are designed to provide reliable availability of power essential to shut down and maintain the unit in a safe condition and/or limit the release of radioactivity to the environment following a design basis accident (DBA). The physical events that accompany such an accident will not interfere with the ability of the system to mitigate the consequences of that accident within the acceptable limits, even assuming a single, simultaneous failure in the electrical system.

Two immediate access (offsite) power sources are provided for the Division 1 and Division 2 ESF systems; one immediate access (offsite) power source is provided for the Division 3 (HPCS) system. One additional offsite power source is available to each (Division 1, 2, and 3)

division by disconnecting the main generator bus links and backfeeding the safety-related buses from the 500 kV network. Additionally, one independent Class 1E 4.16-kV diesel generator and one independent Class 1E 125-V dc system are provided for each division load group.

The redundant ESF electrical load groups (Divisions 1 and 2) are provided with separate onsite standby power sources, electrical buses, distribution cables, controls, relays, and other electrical devices. Redundant parts of the system are physically independent to the extent that no single credible event, including a single electrical failure, will cause loss of power to both redundant load groups. An independent raceway system is provided to meet load group cable separation requirements for each of these divisions, as well as for the HPCS (Division 3) and RPS (Division 4, 5, 6, and 7) divisions.

Each Division 1 and 2 standby power source has sufficient capacity to provide power to all its required divisional loads. In the event of loss of the normal and offsite power sources (as detected by 4.16-kV Class 1E bus undervoltage) or receipt of LOCA signals, these standby sources are designed to start and, if an undervoltage condition exists, connect automatically. This is accomplished in sufficient time to maintain the reactor in a safe condition, safely shut down the reactor, or limit the consequences of a DBA to acceptable limits.

The standby electrical system 4.16-kV Division 1 or 2 switchgear buses and associated diesel generators, 480-V ac auxiliary distribution systems, 120/208-V ac, 120/240-V ac, and 125-V and 250-V dc power and control systems all conform to Seismic Category I requirements and are housed in Seismic Category I structures. Detailed descriptions of equipment seismic design and capability are contained in Section 3.10.

The Division 3 HPCS standby power source is designed to supply all power required for emergency core cooling (water spray) in the event of a LOCA. The system consists of the 4.16-kV HPCS switchgear bus, HPCS pump motor and diesel generator, and the associated 480-V HPCS auxiliary distribution system supplying motor-operated valves, engine cooling water pumps, and miscellaneous engine auxiliary loads. The system is capable of performing its function when subjected to the effects of prevalent natural phenomena at the plant site and is designed in accordance with Class 1E requirements. All HPCS system equipment is housed in a Seismic Category I structure. The system is self-contained, except for access to the normal and offsite sources of power (by connection through the plant ac power distribution system) and for instrumentation connection to the LOCA start signal. Isolated operation independent of electrical connections to other power sources is accomplished by use of direct connection to the 4.16-kV HPCS diesel-generator. Auxiliary equipment such as heater, air compressor, and battery charger are supplied from the same power source as the HPCS pump motor.

In the event that offsite power is unavailable, the HPCS diesel generator (standby power source) can furnish onsite power in sufficient time to provide all power for startup and operation of the HPCS pump motor compatible with accident mitigation. The diesel generator

starts automatically on receipt of 4.16-kV HPCS bus (SM-4) undervoltage or plant LOCA signals. Under the condition of bus SM-4 undervoltage, the diesel generator unit is also connected to the bus automatically. The HPCS diesel generator has an electrical cross connect capability to allow it to energize selected Division 1 or Division 2 equipment by feeding from the HPCS bus to the associated Division 1 or Division 2 buses. The HPCS diesel generator does not have the capacity to assume all the Division 1 or 2 loads, however, it can energize selected loads during an extended station blackout or a non-DBA loss of offsite power as described in Section 8.3.1.1.7.2.1.

Manual controls are provided for all diesel generators to permit the plant operator to select the most suitable source to supply power to loads. An automatic start signal will override the test mode. Provision is made for control from both the main control room and from the diesel generator building local control panel.

The RPS power system is designed to serve as a continuous, dependable source of power for the RPS logic. The system supplies power from two independent MG set sources, each capable of sustaining output voltage and frequency where momentary loss of input power occurs (e.g., due to switching). The system is classified as nonessential (Division A and B) since loss of output power due to open, short, or ground causes the reactor to trip.

The onsite power system is designed in accordance with the applicable portions of the following criteria, with a level of implementation as described in Sections 8.3.1.2 and 8.3.2.2. Specific data regarding the use of alternative approaches in instances of nonconformance, and information regarding conformance to differing revisions of the criteria indicated below, are discussed therein.

8.2 OFFSITE POWER SYSTEM

8.2.1 DESCRIPTION

The offsite power system consists of the following elements and the connections between them.

a. The Bonneville Power Administration (BPA) utility grid,
b. The 500-kV and 230-kV tie lines from the plant to the BPA Ashe Switchyard,
c. The 115-kV tie line from the plant to the BPA Benton Switchyard,
d. The plant main generators step-up main transformer bank, and
e. The plant startup and backup transformers.

See Section 8.2.2 for a discussion of conformance to applicable regulatory guides and standards.

8.2.1.1 Utility Grid Arrangement

The plant output 500-kV tie line is connected to the BPA utility grid at the Ashe Switchyard located 3000 ft north of the plant. Figure 8.1-1 shows the BPA Ashe 500-kV Switchyard arrangement and the connection of the plant 500-kV tie line.

The BPA 500-kV bus at the Ashe Switchyard is a double bus-double breaker arrangement. The Ashe 500-kV bus is tied into the BPA 500-kV network by four 500-kV lines that connect to the Hanford, Slatt, Lower Monumental, and Marion 500-kV Switchyards.

The BPA line from Ashe to Hanford is 18 miles long and the BPA line from Ashe to Lower Monumental is 41 miles long. The BPA line from Ashe to Marion is 224 miles long. The BPA line from Ashe to Slatt is 72 miles long. Each line has a thermal load capacity of about 3000 MW.

The protective relaying for the 500-kV lines and 500-kV bus protection consists of redundant microprocessor relays and transfer trips. The Hanford, Lower Monumental, and Slatt lines are equipped with single pole switching and high-speed reclosing for single line to ground faults. A breaker failure scheme is provided so that in the event of a breaker failure to trip on a fault, only the bus sections adjacent to the failed breaker are lost. For complete loss of the ASHE 500-kV bus when the generator is synchronized to the network where primary relaying has failed to isolate a bus section (north or south bus sections), backup protection that clears all remaining power circuit breakers will initiate a transfer trip signal via the Fiber Optic Transfer Trip (FOTT) communication link to the station's unit protection lockout relays that enable interlocks to trip the turbine generator, SCRAM the reactor and trip plant auxiliary distribution system breakers. For this condition, a complete loss of the ASHE 500-kV bus that separates the generating unit from the 500-kV network, the generating unit protection system will also initiate fast transfer of auxiliary plant loads to the startup transformer to support unit shutdown.

The BPA network 230-kV bus arrangement at the Ashe Switchyard is shown in Figure 8.1-3. The 230-kV bus is a main bus-transfer bus type configuration. The BPA 230-kV line from the Ashe Switchyard to the DOE 230-kV loop is 9.5 miles long and the BPA 230-kV line from Ashe Switchyard to the BPA White Bluffs Substation is 5 miles long. Each line has a capacity of about 350 MW. The 230-kV line from Ashe to the DOE 230-kV loop is equipped with redundant protective relays for line fault protection with a three terminal line transfer trip scheme. The protective relaying for the 230-kV line to the White Bluffs Switchyard consists of redundant protective relays. Both lines are provided with a local breaker failure trip.

The BPA network arrangement at Benton Switchyard is shown in Figure 8.1-4. Benton Switchyard is located 3 miles east-southeast of Columbia Generating Station (CGS). The BPA 115-kV bus at Benton has a main bus-transfer bus configuration. The network connections that can supply power to the Benton Switchyard are the two lines to Midway Switchyard (29 miles long), the two lines to Franklin Substation (21 miles long), and the two lines to White Bluffs (11 miles long). Each of these lines has a capacity of over 100 MW. The lines out of the BPA Benton Switchyard are equipped with redundant microprocessor protective relays for line fault protection. All lines are equipped with breaker failure relays to provide local breaker failure backup.

8.2.1.2 Offsite Power Transmission Lines

The 500-kV transmission lines involved in this area are predominantly two or three bundle conductor designs. The isokeraunic level is five, i.e., an average of five thunderstorm days per year occur in the area of the station, which is reasonably low. Most existing lines east of the Cascades have continuous overhead ground wires. All future 500-kV lines east of the Cascades will also have continuous overhead ground wires for their entire length.

The 500-kV plant output transmission line originates at the CGS step-up main transformer bank and extends 3000 ft to the 500-kV Ashe Switchyard. Connection at the step-up main transformer bank is made via flexible conductors from each transformer HV bushing connection to the ground mounted (post type) overhead 500kV hard bus that in turn uses flexible conductors from the hard bus below the A-frame connection point onto the CGS side of this 500kV transmission line providing plant output over to the Ashe 500kV bus.

The line is a horizontal flat spaced configuration using triple bundle cable. Each phase conductor consists of three aluminum cable steel-reinforced “bunting” subconductors maintained at constant spacing by fixed spacers. Standard Stockbridge dampers are used to damp aeolian vibration if needed. Subconductor twisting has not been a problem on existing lines and it is not anticipated that this problem will occur on this line. Accumulation of dust on insulators is a problem only when transmission lines cross areas where intensive farming activities occur. Since the 500-kV line is not traversing cultivated areas, this problem is not expected to occur. With the use of continuous overhead ground wires and an isokeraunic level

of five, it is anticipated that lightning caused outages will not be a problem. Conductors and towers are designed for 0.5 in. (uniform distribution) ice loading and 8 psf wind loading. Since ice storms produce nonuniform coatings of ice of density between 14 and 27 lb/ft^3, and the design basis covers ice at 57 lb/ft^3, the towers and conductors should be capable of withstanding an asymmetrical ice loading of approximately 2 in. thickness. The type of storm required to deposit this much ice is unlikely to occur east of the Cascade Mountains where the plant is located.

The 230-kV preferred plant startup and safe shutdown transmission line is 3000 ft long, originating at the 230-kV Ashe Switchyard and connecting to the CGS startup transformer. The 115-kV backup plant safe shutdown transmission line is 4 miles long. It originates at the Benton Switchyard and connects to the CGS backup transformer via a circuit breaker, and a BPA owned and operated 115kV disconnect switch, B599, located east of the transformer yard.

All incoming and outgoing lines have lightning arresters connected at the transformer terminals.

Figures 1.2-1 and 8.1-5 show the relative physical locations of the generating plant buildings, step-up main transformer bank, normal auxiliary transformers, startup and backup transformers, transmission lines, and distribution equipment.

8.2.1.3 Main Generator and Step-Up Main Transformer Bank

The turbine generator is rated at 25-kV, 1230 MVA, 0.975 power factor and has a hydrogen-cooled rotor and water-cooled stator. The generator neutral is grounded through a transformer with a secondary resistor. The brushless excitation system consists of a permanent magnet-pilot exciter, ac main exciter, and rotating rectifier assembly connected to the generator shaft. Current transformers are provided in the main leads for relaying and metering. Main generator data is given in Table 8.2-1.

The generator is connected to the step-up main transformer bank with a forced-air-cooled, isolated phase bus duct. Potential transformers for relaying, metering, and voltage regulation are provided and connected to the isolated phase bus duct. Separate isolated phase bus ducts are tapped from the main bus to supply power to the normal auxiliary transformers.

The main transformer bank, stepping up generator output from 25-kV to 500-kV, consists of four single phase transformers (one transformer is spare). The bank is delta connected on the primary (low voltage) side, and wye connected on the secondary (high voltage) side with a solidly grounded neutral.

The location of the generator step-up main transformer bank is outdoors on the north side of the turbine generator building.

The generator stator winding is protected against internal faults by high-speed differential relays. Stator ground fault protection is provided by a neutral ground overvoltage relay in the high impedance grounding circuit. An instantaneous overvoltage relay is also furnished in the circuit to provide ground fault protection during turbine generator warm-up.

The generator rotor is protected against excessive heating due to asynchronous operation by loss of field relays. Protection from excessive heating due to unbalanced stator winding currents is provided by negative sequence current relays. The steam turbine is protected against excessive heating caused by motoring of the generator during periods of a low or zero steam flow by differential pressure anti-motoring devices. Directional power relays are provided to back up the antimotoring devices. In addition, an instantaneous overcurrent relay is provided to give backup protection when the 500-kV breakers are open.

Under frequency relays are provided for protection of the turbine.

The step-up main transformer bank is protected against faults by high-speed differential relays and by sudden pressure relays.

Relay signals from any of the generator or step-up main transformer bank protective devices previously described will trip the generator field, trip the 500-kV Ashe Switchyard power circuit breakers, and trip appropriate plant auxiliary distribution system breakers. Fast transfer to the plant startup transformer would also be initiated automatically by the generating unit trip system (see Section 8.2.1.4).

In addition to the primary level of fault protection described above, there is a secondary level of protection provided by unit overall differential relays. The zone for these relays includes the generator, isolated phase generator bus, the normal auxiliary transformers, and generator step-up main transformer bank.

Step-up main transformer bank oil levels, oil temperature, and winding hot-spot temperatures are also monitored and annunciated, but the associated relays do not initiate tripping.

8.2.1.4 Normal Auxiliary, Startup, and Backup Transformers and Buses

The two normal auxiliary transformers (TR-N1, TR-N2), the startup transformer (TR-S), and the backup transformer (TR-B) are located outdoors at the north side of the turbine generator building. The TR-N1, TR-N2, and TR-S are connected to the ac distribution system by nonsegregated phase bus ducts. The TR-B is connected by cable.

All transformers are three-phase, outdoor, oil-filled type with wye connected secondary (low-voltage) windings individually resistance grounded (transformers TR-N1 and TR-S are dual secondary winding type). The normal auxiliary transformers and backup transformer have ratings at both 55°C and 65°C temperature rise; the startup transformer is rated at 65°C temperature rise.

The normal auxiliary transformers together have the capability of supplying all plant operating loads. Transformer primary (high-voltage) windings of each are delta connected. The 25/4.16/4.16-kV dual secondary transformer (TR-N1) is rated 24/32/40 MVA at 55°C temperature rise, OA/FA/FA cooled. The secondary windings are rated 9.6/12.8/16 MVA and 14.4/19.2/24 MVA. The ratings at 65°C are approximately 12% higher. The 25/6.9-kV transformer (TR-N2) is rated 16.2/23.63/31.25 MVA at 55°C temperature rise, OA/FA/FA cooled. The 65°C rating is approximately 31.7 MVA.

The startup transformer (TR-S) has the capacity to supply full startup, normal running, and engineered safety feature (ESF) shutdown loads for Divisions 1, 2, and 3. Transformer primary (high-voltage) winding is wye connected with a solid connection to ground. An intermediate delta connected winding is provided between the single wye connected primary and dual wye connected secondary windings. This 230/6.9/4.16-kV transformer is rated 42/56/68.66 MVA at 65°C temperature rise OA/FA/FA cooled. The 6.9-kV secondary winding is rated 18/24/28.66 MVA and the 4.16-kV secondary winding is rated 24/32/40 MVA.

The backup transformer (TR-B) has the capability of supplying the full power requirements of the ESF systems for both Division 1 and Division 2. Transformer primary (high-voltage) winding is wye connected with a solid connection to ground. An intermediate delta connected winding is provided between the wye connected primary and secondary winding. This 115/4.16-kV transformer is rated 10/12.5 MVA at 55°C temperature rise, OA/FA cooled, and 11.2/14 MVA at 65°C, OA/FA cooled.

Figure 8.1-5 is a representation of the physical layout of the supply circuitry which connects the startup transformer and the backup transformer to their respective transmission lines.

Protective relaying provided for each transformer includes differential current and sudden pressure relays to sense internal transformer faults, and primary overcurrent relays to provide backup for secondary faults. These relays in turn actuate the affected transformer lockout relay.

Additionally, separate open phase protection features are provided to detect an open phase condition in both the 230kV offsite power transmission line connection to TR-S and in the 115kV offsite power tie line to TR-B.

The purpose of the Open Phase Detection System (OPDS) is to augment legacy high voltage line protection and transformer neutral overcurrent protection schemes to increase overall capability to detect and where necessary trip and isolate degraded offsite power sources at the network interconnection to TR-S or TR-B for a larger spectrum of fault conditions that would encompass open circuits with or without ground fault impedance (i.e., high impedance faults).

These open phase protection features help ensure objectives for qualified network sources to transmit necessary three phase power to the on-site AC power distribution systems are met. Each open phase protection scheme monitors the TR-S and TR-B high voltage interconnections during all plant loading conditions from standby (no load) to full load of the transformer. A main control room alarm is provided if an open phase fault is detected on the energized network connection when the transformers are in service from standby to full load operation. If the offsite power circuits are degraded due to open phase conditions when plant auxiliary loads are aligned to the TR-S or TR-B high voltage network sources, then an alarm is provided in the main control room and the affected transformer lockout relays are actuated by the OPDS to de-energize the affected degraded network connection.

Should the OPDS operate the TR-S (or TR-B) lockout relay circuit with offsite power supplying plant auxiliary loads and aligned to the 4.16kV ESF switchgear buses (i.e., station auxiliary power to the downstream 4.16kV ESF switchgear bus is not supplied by the main generator), isolation of the startup (or backup) transformer offsite power circuit will result in subsequent loss of preferred (of backup) power to downstream connected 4.16kV ESF switchgear buses. This power system operating condition in turn initiates existing Class-1E 4.16kV bus loss of voltage relays that will: (i) perform load shedding of the affected 4.16kV safety buses and (ii) actuate bus source selection transfer logic to align the next available source of AC power to the affected Class-1E 4.16kV ESF switchgear buses to restore reliable power to plant safety systems (FSAR 8.3.1.1.1).

The plant startup and backup transformers are also provided with overcurrent relays in the primary winding ground connection.

Protective relay signals from the normal auxiliary transformers will trip the generator field, and trip and lock out the 500-kV Ashe Switchyard power circuit breakers and appropriate plant auxiliary distribution system breakers. Transfer to the plant startup transformer would also be initiated automatically through lockout relays.

Protective relay signals from the startup transformer will trip and lock out the 230-kV Ashe Switchyard circuit breaker and appropriate plant auxiliary distribution system breakers. In the event the main generating unit is synchronized with the 500-kV system and plant auxiliaries are operating from the startup transformer and a loss of the startup transformer occurs, then a unit lockout condition will open the 500-kV Ashe Switchyard power circuit breaker, open the startup breakers (the normal breakers are already open), and trip the main turbine.

Protective relay signals from the backup transformer will trip and lock out the 115-kV circuit breaker located in the plant switchyard and the transformer secondary circuit breakers.

Undervoltage relays monitor the startup and back up transformer secondaries and trip the transformer secondary circuit breakers for loss of voltage.

In addition to the protective devices described above, all transformer secondary windings are provided with ground sensor relays which will alarm but do not initiate tripping. Reverse power relays on the startup and backup transformers will alarm if backfeed to the 230-kV or 115-kV system occurs.

8.2.1.5 Power System Communications

A communication system, including telephone facilities dedicated for electrical utility service, is provided between Columbia Generating Station and the BPA Ashe Switchyard. The system is an extension of the existing communication system owned and maintained by BPA.

The power source for the solid state communication equipment located at Columbia Generating Station is the non-Class 1E 125-V dc plant battery (see Figure 8.3-5.1).

The communication circuits also provide for the following functions:

a. Protective relaying,

b. Telemetering of net plant megawatts and megavars to Dittmer Control Center at Vancouver, Washington,

c. Transmission of turbine trip signal and other data to Dittmer Control Center, and

d. Control of the power circuit breakers associated with the plant 500-kV transmission line (from Columbia Generating Station and Dittmer) and the plant 230-kV transmission line (Dittmer only).

For additional discussion of both the Columbia Generating Station communication system and other (commercial, UHF radio) available plant communication systems, see Section 9.5.2.

8.3 ONSITE POWER SYSTEMS

8.3.1 ALTERNATING CURRENT POWER SYSTEMS

8.3.1.1 Description

Principal elements of the Columbia Generating Station (CGS) auxiliary ac electrical systems are illustrated in Figure 8.1-2. Four auxiliary transformers are provided.

Normal auxiliary power is provided by two normal auxiliary transformer fed from the main generator 25-kV isolated phase bus. The startup transformer is connected to the Bonneville Power Administration (BPA) 230-kV H. J. Ashe Switchyard. These auxiliary systems each have the capacity to carry the full plant auxiliary load. A backup transformer is provided to supply all Divisions 1 and 2 plant engineered safety feature (ESF) loads. This transformer is supplied from the BPA Benton Switchyard via a 115-kV line to the plant. The transformer steps down the 115-kV supply to 4.16-kV and is connected by cables through circuit breakers to the 4.16-kV Class 1E switchgear buses SM-7 and SM-8.

8.3.1.1.1 4.16-kV and 6.9-kV Distribution System

The auxiliary transformers step down the available voltage as required to supply the 4.16-kV and 6.9-kV auxiliary switchgear buses. During normal operation, all load is carried by the normal auxiliary transformers. The startup transformer is used while the 25-kV main generator is being started and synchronized with the system. When this is accomplished, all auxiliary load is transferred (live load transfer) to the normal auxiliary transformers. The startup transformer remains energized from the 230-kV offsite power line to permit the auxiliary load to be automatically transferred back to it if power from either normal auxiliary transformer is lost. It is possible to operate the plant with auxiliary loads carried by the startup transformer.

The 4.16-kV non-Class 1E switchgear buses SM-1, SM-2, and SM-3 are fed from the secondary windings of the dual secondary winding normal auxiliary transformer (TR-N1) or from the 4.16-kV "Y" winding of the dual secondary winding startup transformer (TR-S). These buses supply the large non-Class 1E auxiliary motors and substations, and the Class 1E switchgear buses SM-4, SM-7, and SM-8. Permanently installed, locked open electrical cross connects between SM-2 and SM-1 and SM-3 allow for powering Division 1 or 2 equipment from SM-4 when plant conditions allow (see Section 8.3.1.1.7.2.1). The cross connect breakers are not installed in the switchgear. They must be installed and racked in prior to use. Use of the cross connect feature is controlled per plant procedures by administratively maintaining the source breakers open to prevent inadvertent paralleling of standby sources.

The 6.9-kV non-Class 1E switchgear buses are fed from the single secondary winding normal auxiliary transformer (TR-N2) or from the 6.9-kV "X" winding of the dual secondary winding

startup transformer (TR-S). These buses supply the non-Class 1E reactor recirculation pump adjustable speed drives (ASDs), cooling tower substations, and auxiliary substations.

The 6.9-kV and 4.16-kV auxiliary switchgear buses are arranged for distribution of power through a switchgear assembly of circuit breakers. The switchgear is of metal-clad, indoor design and has three-pole circuit breakers (draw-out type) with stored energy mechanisms fed from the plant dc systems.

Normal source power failure is detected by relays in the unit trip protective system and by undervoltage relays. Automatic transfer facilities are provided so that failure of normal supply causes immediate tripping of the normal supply circuit breakers and simultaneous closing of the startup transformer supply circuit breakers. This provides virtually continuous feed to the Class 1E and non-Class 1E switchgear buses of all divisions.

On loss of both normal and startup sources, or if the startup source is lost when the main generator is out of service, the tie breakers between the 4.16-kV Class 1E and the 4.16-kV non-Class 1E switchgear buses are automatically opened, thereby shedding all loads supplied via the 4.16-kV non-Class 1E buses. The 4.16-kV Class 1E bus undervoltage signals cause trips of all 4.16-kV feeder breakers except those breakers supplying 480-V substations. The Divisions 1 and 2 4.16-kV Class 1E buses (SM-7, 8) are then automatically transferred to the 115/4.16-kV backup transformer for supply of load. In the event this source is also unavailable, these buses would be automatically transferred to the onsite standby sources (Divisions 1 and 2 diesel generators). Reapplication of load is on a time priority basis. The loading sequence for buses SM-7 and SM-8, as shown in Tables 8.3-1 and 8.3-2 and Figures 8.3-1 and 8.3-2, is accomplished through the use of electromechanical time delay relays. The Division 3 [high-pressure core spray (HPCS)] 4.16-kV Class 1E bus (SM-4) cannot be connected to the backup source; loss of the normal/startup sources causes automatic transfer of this load, as shown in Table 8.3-3, to the Division 3 onsite standby source (Division 3 diesel generator). Load shedding and load sequencing are not required in this division. Permanently installed, electrical cross connect cables between SM-2 and SM-1 and SM-3 allow cross connecting Division 3 to Divisions 1 or 2 under conditions described in Section 8.3.1.1.7.2.1. This allows Division 3 to power selected Division 1 or 2 loads.

The 4.16-kV Class 1E buses SM-7 and SM-8 provide power to the 4.16-kV emergency core cooling system (ECCS) loads, control rod drive pumps, and (via stepdown transformers) the 480-V Class 1E buses SL-71, SL-73, SL-81, and SL-83. The 4.16-kV Class 1E bus SM-4 provides power to the 4.16-kV HPCS pump and (via stepdown transformer) the 480-V Class 1E motor control center (MCC) MC-4A (HPCS auxiliaries). Buses SM-7 and SM-8 can be fed from any of three sources, namely (1) normal auxiliary switchgear which receives power from either the normal auxiliary transformers or the startup transformer, (2) the backup transformer, or (3) standby diesel generators. Bus SM-4 can be fed from either of two sources, namely, (1) normal auxiliary switchgear which receives power from either the normal auxiliary transformers or the startup transformer, or (2) a standby diesel generator.

As shown in Figure 8.1-2.2, bus SM-7 supplies 4.16-kV Division 1 ESF loads and non-ESF control rod drive pump (CRD-P-1A). Subbus SM-75 supplies other 4.16-kV non-ESF loads, including the plant service water pump (TSW-P-1A). Class 1E breaker CRD-CB-P1A (SM-7 supply to CRD-P-1A) is automatically tripped on loss of offsite power (LOOP), and Class 1E breaker E-CB-7/75/1 (SM-7 supply to SM-75) is automatically tripped on a loss-of-coolant accident (LOCA) with LOOP to prevent overloading of DG1. This arrangement allows the plant service water pump to be supplied from Division 1 bus SM-7 during a LOCA when an offsite source is available. Division 2 loads are treated in a similar manner on buses SM-8 and SM-85.

Time delays are provided with timers to extend the intervals between auto starts of ECCS pumps on LOCA initiation with the TR-S supply. This prevents second level undervoltage relay operation due to excessive voltage drops and longer starting time resulting from simultaneous or overlapping starts of large motors. To improve bus voltages during LOCA (1) buses SM-72 and SM-82 are shed automatically on LOCA initiation, and (2) an electrical interlock prevents starting the second plant service water (TSW) pump during a LOCA.

The combined ECCS and TSW loads in Divisions 1 and 2 exceed the rated capacity of their respective diesels. Hence, feeder breakers 7-75/land 8-85/1 supplying buses SM-75 and SM-85, respectively, are tripped automatically on a LOCA with LOOP. Breakers 7-75/1 and 8-85/1 remain closed on LOOP without a LOCA, and the TSW pumps are started automatically to provide water for drywell cooling to ensure a controlled shutdown.

Two circulating water pumps, CW-P-1B and CW-P-1C, are tripped automatically on LOCA initiation leaving the third circulating water pump, CW-P-1A, operating during a LOCA. Starting of CW-P-1A under minimum grid voltage (230-kV) and maximum loading conditions during a LOCA is avoided by administrative procedure.

Manual live transfer of power between normal auxiliary and startup sources is possible either way by the main control room operator on the 4.16-kV non-Class 1E switchgear buses SM-1, 2, and 3. Likewise, manual live transfer of power between normal/startup and backup transformer sources is possible on the 4.16-kV Class 1E switchgear buses SM-7 or 8, although the startup source is the preferred offsite power source. Manual live transfer of power between the normal/start or the backup power source and the Division 1 or 2 standby power source is possible. This facilitates diesel generator testing without dropping loads or the return of loads from the diesel generator to the offsite power source on recovery of the offsite source following a total loss. However, synchronizing of any diesel generator with the normal auxiliary transformer is avoided by administrative procedures.

The primary undervoltage sensing scheme for the 4.16-kV Class 1E distribution system utilizes instantaneous undervoltage relays to start the Divisions 1 and 2 standby diesel generators immediately on loss of voltage at their associated 4.16-kV Class 1E switchgear buses. These

relays also energize timers which allow the system to attempt to establish supply from the startup source (if the plant is operating from the normal source at the time) or verify that voltage loss is maintained (if the plant is operating from the startup source initially).

In the event that voltage loss is maintained for 3.5 sec, the Division 1 and/or 2 timers trip the Class 1E bus normal/startup source breakers, institute load shedding, and energize additional 2-sec and 4-sec timers. The 2-sec timer is utilized to attempt closing of the backup source breakers; backup transformer undervoltage relays will inhibit breaker closure in the event of backup source undervoltage. The 4-sec timers are used to inhibit closure of the diesel generator breakers until the system has had time to attempt reestablishment of supply via the backup source.

When 4.16-kV Class 1E Division 1 and/or 2 buses are supplied from 115-kV backup source, a loss of the backup source initiates a timer. The timer trips the backup source breaker B-7 (B-8) after a 3.5-sec delay. This allows coordination of the backup source undervoltage relay with the associated incoming line and branch circuit overcurrent protection.

The primary undervoltage scheme for the 4.16-kV Division 3 Class 1E bus utilizes instantaneous undervoltage relays which energize a 2-sec timer. In the event that voltage loss is maintained for 2 sec, this timer trips the preferred source breaker and energize an additional 1-sec timer. The second timer, after timing out, starts the HPCS diesel generator and annunciates the loss of voltage in the control room. The diesel generator supply breaker will then close after the diesel has reached rated frequency.

See Sections 8.3.1.1.7.1.7 and 8.3.1.1.7.2.7 for additional discussion of the standby diesel generator starting and loading systems.

A second level of undervoltage protection is provided to protect against the effects of prolonged degraded voltage which could adversely affect the operation of Class 1E electric motors requiring at least 90% of the nameplate voltage for continuous operation (see Table 8.3-4). For this reason, Class 1E bus SM-4, SM-7, and SM-8 voltages are monitored by an additional set of Class 1E undervoltage relays. Three static type undervoltage relays are provided for Divisions 1, 2 and 3 and are connected to monitor all three line voltages (i.e., phases AB, BC, and CA). The arrangement utilizes a two-out-of-three logic to preclude the possibility of spurious voltage loss signal and facilitate testing.

In the event of sustained bus undervoltage (approximately 89.4% of nominal bus voltage lasting more than approximately 8 sec), the second level of undervoltage protection automatically trips the feeder breaker connecting the normal/startup sources to their respective 4.16-kV Class 1E buses. For Divisions 1 and 2, this action results in loss of bus voltage, thereby starting the diesel generators, initiating load shedding and energizing two of the

three bus transfer timers mentioned in the primary undervoltage scheme above. In this case the first 3.5-sec timer is bypassed. The 2-sec timer permits closing of the backup source breaker and the 4-sec timer permits closing of the diesel generator breaker assuming a failure of the backup source breaker to close. Closure of the backup source and diesel generator breakers is permitted if the source voltage is at least 94% of normal.

Should the degraded voltage condition exist on the backup power source while the source is supplying the load, the second level undervoltage relays would then isolate that source, again initiating the sequence of events described for the secondary undervoltage sensing scheme above. However, closing of backup feeder breakers, as part of that sequence of events, is blocked.

For Division 3, the second level undervoltage protection trips the normal/startup source breaker, thereby causing a loss of bus voltage. This energizes the second timer which results in diesel start and subsequent supply to Division 3 from the diesel generator.

The setpoints and allowable values for the 4.16-kV emergency bus loss of power instrumentation are as follows:

Type	Setpoint (Volts)	Allowable Value (Volts)
Loss of Voltage (Divisions 1, 2, and 3)		
4160 V basis	2782.5-2957.5	2450-3135
120 V basis	79.5-84.5	70.0-89.57
Undervoltage (Divisions 1, 2, and 3)		
4160 V basis	3711.8-3729.2	3685-3755
120 V basis	106.05-106.55	105.29-107.28

A blown P.T. fuse on the bus SM-7 or SM-8 would result in a spurious voltage loss signal for the primary and second level undervoltage relays. The primary undervoltage relays will trip the normal/startup source breaker and initiate auto transfer to the backup source. The second level undervoltage protection for the backup source is blocked in this event, in order to prevent cycling of the backup source breaker. The primary undervoltage protection for the backup source will be unaffected since the back-up source primary undervoltage relay is connected to a separate P.T. as shown in Figures 8.3-1 and 8.3-2. In this event, the ESF load breakers of the affected bus will trip and will not be available until the blown P.T. fuse is replaced. However, the ESF loads on the other two unaffected Class 1E buses will be available during this time for safe shutdown, if required.

When the Class 1E buses SM-7 and SM-8 are being fed from the turbine generator, the possibility of sustained undervoltage is not considered credible due to response characteristics of the voltage regulator and protection equipment for the unit.

The scheme described ensures a power source within the acceptable voltage limits for the Class 1E loads at all times. Circuit design allows for testing of the individual relays, one at a time, without disrupting the protective function. There are no bypasses of the protective action for this system.

The load shedding of these emergency buses, SM-7 and SM-8, due to under voltage during motor starting will not occur once the diesel generator is supplying power to the emergency bus. The minimum voltage on the emergency buses SM-7 and SM-8 as a result of motor starting when the associated diesel generator is supplying the bus is 80% or greater of the rated bus voltage. Since the Class 1E bus primary undervoltage relays are set at 69% of nominal bus voltage, reinstitution of load shedding as a result of voltage dip due to motor starting will not occur.

Technical Specifications for CGS include a test requirement to verify that on interruption of offsite power the loads are shed from the emergency buses and the loading of the onsite sources is sequenced by time delay relays in the motor start controls.

8.3.1.1.2 480-Volt Distribution System

Power for 480-V auxiliaries is supplied from unit substations consisting of 6.9-kV/480-V or 4.16-kV/480-V transformers and associated metal clad switchgear. Non-Class 1E 4.16-kV buses SM-1, 2 and 3, supply separate 480-V substations, each with its own power transformer and switchgear.

Class 1E 480-V substations supplying ESF loads are arranged as independent radial systems with each 480-V bus fed by its own power transformer. Each 480-V Class 1E bus is independent of the other 480-V buses; there are no cross ties. The 480-V auxiliaries required during emergency conditions are supplied from 480-V Class 1E buses SL-71 and SL-73 (Division 1) and SL-81 and SL-83 (Division 2). The HPCS 480-V auxiliaries are supplied from an independent transformer and Class 1E bus MC-4A (Division 3). Power supplies to all Class 1E auxiliary systems are arranged so that alternate or redundant auxiliary systems are supplied from 4.16-kV switchgear buses of separate Class 1E divisions.

The 480-V substations, in general, supply 460-V motor loads larger than 100 hp and all MCC loads. Switchgear for 480-V substations is of the indoor metal clad type with draw-out circuit breakers operated from the plant dc system, with the exception of SL-54 which is equipped with molded case circuit breakers. Phase to ground fault currents are limited to a maximum of 10 amp by use of neutral ground resistors in all substation transformer neutral ground

connections. All substation transformer neutral ground connections and switchgear branch feeder circuits are equipped with ground detection devices and alarms.

The 480-V MCCs feed motors 100 hp and less (in general), control power transformers, heaters, motor-operated valves (MOVs), all other small electrically operated auxiliaries, and all lighting. Control centers are isolated in separate load groups corresponding to divisions established by the 480-V substation units. Branch circuit protection for all loads is provided by fused disconnect switches equipped with current limiting fuses or molded-case circuit breakers. The fuses for the MC-8BA subfeed also provide backup overcurrent protection for containment penetration circuits in accordance with Regulatory Guide 1.63.

Class 1E MCCs are shown on the auxiliary one-line diagram (Figure 8.3-4).

8.3.1.1.3 120/240-Volt (Non-Class 1E) Plant Uninterruptible Power System

The non-Class 1E plant uninterruptible power system supplies 120/240-V ac to station services where uninterruptible power is required, such as for plant computer and plant instrumentation [e.g., digital electrohydraulic control system (DEH) cabinet]. This source of power is necessary for plant operational loads, but does not supply ESF loads. Power is distributed via a single phase, three-wire, grounded neutral system.

Failure of the non-Class 1E uninterruptible power system has no adverse effect on station safety since no ESF loads are supplied from this system.

The plant uninterruptible power system receives its power from a static inverter-static switch arrangement fed both from a 250-V dc station battery (float source) and from a 480-V ac Class 1E MCC (preferred source) as shown in Figure 8.3-5.1. During faults on the uninterruptible power system the static switch will automatically transfer loads to a regulated alternate source, which supplies sufficient fault current to blow the circuit fuse and clear the fault.

Manual bypass switches are also provided to bypass the plants uninterruptible power systems and transfer load to a regulated bypass source. This will allow for maintenance and inspection of the system.

8.3.1.1.4 120/208-Volt Non-Class 1E Instrumentation Power System

Power is supplied to non-Class 1E plant instrumentation at 120/208-V ac via a three-phase, four-wire, grounded neutral distribution system. This distribution system supplies power to the 115-V ac transversing in-core probe (TIP) of the neutron monitoring system and other non-Class 1E instrumentation loads.

Failure of the noncritical instrumentation power system has no adverse effect on station safety since no ESF loads are supplied from this system.

Alarm and fault detection equipment is provided to alert the operator of possible trouble. All equipment associated with the 120/208-V non-Class 1E instrumentation power system is readily accessible for inspection and maintenance on a routine basis in accordance with the manufacturer's recommendation.

8.3.1.1.5 Divisions 1 and 2 120/240-Volt Critical (Class 1E) Instrumentation Power System

Power is supplied to critical plant instrumentation at 120/240-V ac via two single-phase, three-wire, grounded neutral distribution systems as shown in Figure 8.3-5.1. The ac power is normally fed into the systems from 15-kVA static inverter-static switch arrangements supplied from both the 125-V dc battery systems (primary sources) and the critical ac distribution panels (alternate sources). The static switches immediately transfer from the inverter sources to separate ac sources on loss of inverter output or when the inverter output sensing circuit detects a 120% overload is present. The critical instrumentation power system is divided into Divisions 1 and 2 redundant circuits with separate inverters and static switches feeding into separate distribution panels (E-P-7AA and E-PP-8AA) in the main control room for service to ESF circuits in the nuclear steam supply system (NSSS). This system maintains the 120/240 Volt critical instrumentation, control and protection system power sources available from the associated inverter backed 125 VDC station battery even during the short interval when offsite power has been lost and standby power has not yet been applied to the Class 1E 4.16kV and 480 V AC buses (including the alternate AC power sources to each of the divisional inverter-static switch arrangements shown on Figure 8.3-5.1). Each 120/240 Volt Class 1E instrumentation power system division has two, full capacity, 15-kVA static inverters (E-IN-3A and E-IN-3B for Division 1 and E-IN-2A and E-IN-2B for Division 2). One inverter in each division will be the on-line unit supplying power to their associated vital instrument bus and the other will normally be available as an installed spare unit for use if the on-line inverter fails or has to be removed from service.

8.3.1.1.6 Reactor Protection System Power System

The reactor protection system (RPS) power system is designed to provide 120-V ac power to the logic and/or system components that are part of the RPS, the containment isolation system, the neutron monitoring system, and the process radiation monitoring system. It is designed to prevent inadvertent reactor trip or isolation due to a transient loss of power to the trip logic. See also Section 7.2.1.1.

The principal elements of the RPS power system are shown in Figure 8.3-5.2. The system consists of two high inertia, ac, motor generator (MG) sets.

Each of these high inertia MG sets has a voltage regulator which is designed to respond to a step load change of 50% of rated load with an output voltage change of not more than 15% and

keep the normal voltage limits to within ±10% of rated. The MG sets do not require manual operation or adjustment during coastdown or acceleration.

High inertia is provided by a flywheel. The inertia is sufficient to maintain the voltage and frequency of generated voltage within -5% of the rated values for at least 1 sec following a loss of power to the drive motor. However, prototype tests show that an RPS trip does not occur until approximately 4 to 5 sec after the loss of MG set power supply.

The 120-V ac power is supplied from two sources. The primary source of power is the MG sets previously described. The alternate source is from a non-Class 1E distribution panel which is powered from the main generator or the startup transformer. The MG sets themselves are supplied from separate Class 1E 480-V (Divisions 1 and 2) MCCs. Indicating lights are provided in the main control room to monitor the status of both the MG sets and the alternate feed.

To protect the RPS trip system from the unacceptable effects of sustained over/under voltage or under frequency from the non-Class 1E power sources, two series redundant Class 1E circuit breakers are provided between the RPS distribution panel and each of the non-Class 1E power sources, namely, the two RPS MG sets and the common alternate source. Each circuit breaker is provided with an independent set of Class 1E over/under voltage and underfrequency sensing relays. See Figure 8.3-5.2.

During operation, the RPS buses are energized by their respective MG sets. Either MG set can be taken out of service by manually operating the RPS transfer contactor which takes one MG set out and connects that RPS bus to the alternate power source. Provision is made to prevent connection of both RPS buses to the alternate source at the same time. A loss of power to either MG set is monitored in the main control room where the operator on detecting such a condition can switch to the alternate source. A complete, sustained loss of electrical power to both buses is required to cause a scram and containment isolation.

Equipment associated with the RPS power system is located in separate rooms where routine maintenance can be conducted. Motor generator sets can be inspected, serviced, and tested individually while using the alternate feed from the aforementioned distribution panel.

The electrical protective assembly (EPA) consisting of Class 1E protective circuitry is installed between the RPS and each of the power sources. The EPA provides redundant protection to the RPS and other systems which receive power from the RPS buses by acting to disconnect the RPS from the power source circuits.

The EPA consists of a circuit breaker with a trip coil driven by logic circuitry which senses line voltage and frequency and trips the circuit breaker open on the conditions of overvoltage, undervoltage, and underfrequency. Provision is made for setpoint verification, calibration, and adjustment under administrative control. After tripping, the circuit breaker must be reset manually. Trip setpoints are based on providing 115-V ac, 60-Hz power at the RPS logic

cabinets. The protective circuit functional range is ±10% of nominal ac voltage and -5% of nominal frequency.

The EPA assemblies are packaged in an enclosure designed to be wall mounted. The enclosures are mounted on a Seismic Category I structure separately from the MG sets and separate from each other. Two EPAs are installed in series between each of the two RPS MG sets and the RPS buses, and between the auxiliary power source and the RPS buses. The block diagram in Figure 7.2-11 provides an overview of the EPA units and their connections between the power sources and the RPS buses. The EPA is designed as a Class 1E electrical component to meet the environmental qualification requirements of IEEE 323-1974 (see Section 3.11) and the seismic qualifications requirements of IEEE 344-1975 (see Section 3.10). It is designed and fabricated to meet the quality assurance requirements of 10 CFR 50, Appendix B.

The enclosure dimensions are approximately 16 x 24 x 8 in. and accommodate power cable sizes from 6 AWG to 250 MCM.

8.3.1.1.7 Standby Alternating Current Power System

The standby ac power source for the plant consists of three diesel generator sets, each one serving ESF loads in its associated division (1, 2, 3), their attendant air starting and fuel supply systems, and automatic control circuitry. The diesel generator sets supply power to those electrical loads which are required to achieve safe cold shutdown of the plant and/or mitigate the consequences of a design basis event coincident with a loss of all offsite ac power. Tables 8.3-1, 8.3-2, and 8.3-3 list the equipment and loads supplied by each generator for both cases.

Each diesel generator (with its auxiliaries) is housed in a separate room as shown in Figure 1.2-22. The separating walls are designed as 3-hr fire barriers and will provide missile protection in the event of explosion or failure of rotating equipment. Each room is provided with its own ventilation and lighting systems. Design provisions ensure that flooding in one diesel generator room does not jeopardize the operation of the other diesel generators. The power, instrumentation, and control cabling associated with the diesel generators is contained in cable trays and conduits which meet the separation criteria detailed in Section 8.3.1.4. All equipment for these systems is identified as indicated in Section 8.3.1.3.

8.3.1.1.7.1 Redundant (Division 1 and Division 2) Standby Alternating Current Power Supplies.

8.3.1.1.7.1.1 General. The dual drive diesel generators comprising the Divisions 1 and 2 standby ac power supplies are designed to quickly restore onsite power to their respective Class 1E distribution system divisions in the event of coincident loss of all offsite ac power. Figure 8.1-2 shows the interconnections between the preferred power system and the Divisions 1 and 2 standby diesel generating units.

The dual drive engines utilized are medium weight, fabricated, main frame engines capable of rapid starting and quick acceptance of the electrical loads. Selection of the type of diesel engine utilized is based upon the advantages offered by the class of unit: the ability to start and accept rated load rapidly and repeatedly with enough dead load pickup capability to assume substantial incremental motor load additions.

8.3.1.1.7.1.2 Unit Ratings and Capability. The diesel generator sets for Divisions 1 and 2 each have a continuous service rating of 4400 kW. Diesel generator set short-term ratings are 4650 kW for 2000 hr, 4900 kW for 7 days, and 5150 kW for 30 minutes. The continuous rating of each diesel generator is based on an accident condition load which is larger than that required for a safe plant shutdown. The generators are rated 5812-kVA at 0.8 pf, which is sufficient to carry the 4650 kW short-term ratings at 0.8 pf. At higher kW outputs, the diesel generator sets would have to operate at a higher power factor.

The size of each of the diesel generators serving Divisions 1 and 2 satisfies the requirements of Regulatory Guide 1.9, Revision 0, and conforms to the following criteria:

a. The continuous (8000 hr/year) nameplate rating of each set exceeds the maximum required load indicated in Tables 8.3-1 and 8.3-2 under rated conditions. Engine brake horsepower required to supply calculated steady state load is also within each diesel engine's 8000 hr/year rated capability with an air inlet temperature of 115°F;

b. Each diesel generator is capable of starting, accelerating, and supplying its loads in the sequence shown on Tables 8.3-1 and 8.3-2 without exceeding 5% frequency drop (maximum). The units are capable of recovery to 98% of normal frequency in less than 2 sec;

c. Each diesel generator is capable of starting, accelerating, and supplying its load in their proper sequence without exceeding 20% voltage drop at its terminals (maximum). The units are capable of recovery to 90% of normal voltage is less than 2 sec;

d. Each diesel generator is capable of starting, accelerating, and running its largest motor at any time after the automatic loading sequence is completed, assuming that the motor had failed to start immediately;

e. Each diesel generator is capable of reaching full speed and voltage within 15 sec after receiving a signal to start, and can be fully loaded within 30 sec following the start signal; and

f. The speed of each diesel generator does not exceed 75% of the difference between nominal speed and the overspeed trip setpoint, or 115% of nominal

speed, whichever is lower, during recovery from transients caused by disconnection of the largest single load.

Each governor control system includes manual engine idle capability. Manually operating engines at a reduced speed for "warm up" or a "cool down" run prior to shutdown is recommended by manufacturer to minimize mechanical stress and wear. If a 4.16-kV Class 1E bus (SM-7, 8) primary undervoltage relay signal is received when operating engines at reduced rpm (idle speed), manual control is automatically bypassed. The engines are accelerated to rated speed and generator excitation (field flash) is initiated. The diesel generator is automatically brought to rated frequency and voltage attaining a ready-to-load condition within 15 sec.

8.3.1.1.7.1.3 Cooling Water Systems. Each engine in each diesel generator set has a closed cooling system consisting of a forced circulation cooling water system which cools the engine directly and a heat exchanger connected to the respective standby service water system. The cooling water pumps are driven directly from the engine crankshaft. The engine cooling water system incorporates provision for heat to maintain the engine jacket at a steady temperature when the engine is not running to ensure quick starts. The diesel generator cooling water systems are discussed in Section 9.5.5.

8.3.1.1.7.1.4 Lubrication Systems. The engines of each diesel generator set have self-contained lubrication oil systems consisting of lubrication sumps located at the base of each engine, lubrication oil pumps, piping, and heat exchangers. The lube oil heat exchanger is served by the diesel generator cooling water system. When the engine is not running, the temperature of the lube oil is maintained at a steady level with heaters and temperature controls to ensure quick starts. The diesel generator lubrication systems are discussed in Section 9.5.7.

8.3.1.1.7.1.5 Air Starting Systems. Diesel generators 1 and 2 have independent redundant air starting systems as discussed in Section 9.5.6; diesel generator 3 has redundant equipment, but not redundant independent systems.

8.3.1.1.7.1.6 Fuel Oil Systems. The diesel generator fuel oil storage and transfer systems are discussed in Section 9.5.4.

8.3.1.1.7.1.7 Automatic Starting and Loading Systems. In the event of loss of offsite sources of power to the onsite power bus, each diesel generator set is automatically started and loaded by independent control and circuitry. The starting circuitry and control power is provided by separate 125-V dc station batteries for Divisions 1 and 2 (see Section 8.3.2.1.1). The diesel generator starting logic and starting signals (shown in Figures 8.3-1, 8.3-2, and 8.3-7 through 8.3-10) are described as follows:

a. Each diesel generator starts immediately upon receipt of a 4.16-kV Class 1E bus (SM-7, 8) primary undervoltage relay signal or LOCA signals (reactor low water level and/or high drywell pressure);

b. On sustained loss of 4.16-kV Class 1E bus voltage, the bus is automatically isolated from the upstream non-Class 1E system. All loads on the bus are tripped, except for those small loads shown in Tables 8.3-1 and 8.3-2 as part of the initial load block fed by the 480-V unit substation;

c. After each diesel generator has attained approximately normal frequency and voltage, its breaker closes (if 4.16-kV Class 1E bus voltage has not been reestablished via the offsite system sources) thus immediately starting all loads belonging to the first block for which "starting required" signals are available for ESF actuation signals;

d. The starting of subsequent load blocks are delayed by time relays in accordance with Tables 8.3-1 and 8.3-2. Diesel generator capacity is such that units are capable of maintaining all required loads established by the loading schedules;

e. Limitation of diesel generator loading is maintained during the entire period the units are operate, since the Class 1E loads capable of being connected to the units exceed unit capability. However, as indicated in the loading schedules Tables 8.3-1 and 8.3-2, the maximum loads automatically connected to the Divisions 1 and 2 diesel generating units do not exceed individual diesel generator unit ratings (4400 kW each). Loading beyond the automatically applied load would require positive operator action to manually apply loads;

f. The minimum voltage projected to occur on the Class 1E buses (SM-7, 8) as a result of motor starting during periods when emergency plant load is being supplied by the diesel generators is greater than 80% of nominal bus voltage. The duration of voltage dip is expected to be very short lived in the order of 2 to 5 sec. Since the Class 1E bus primary undervoltage relays are set at approximately 69% of nominal bus voltage, initiation of load shedding as a result of voltage dip due to motor starting will not occur. Since the Class 1E bus secondary undervoltage relays are set at approximately 89.4% of nominal bus voltage (approximately 93% of motor nominal voltage) with a definite time delay of approximately 8 sec, they will not initiate any undesirable tripping action. If bus voltage were to dip below approximately 89.4% of nominal for more than approximately 8 sec, load shedding would be initiated;

g. If offsite power is still present, and the diesel generator is started by a LOCA signal, the diesel generator breaker will not close. However, the unit will continue to run at rated frequency and voltage until manually shut down; and

h. Means are provided for periodic exercising of each diesel generator under load. To accomplish this, supply of the 4.16-kV Class 1E bus associated with the diesel generator to be tested is transferred to the startup source. Under this condition the diesel generator to be tested is synchronized to the 230-kV startup source and loaded via manual adjustment of the unit speed controls. During periodic testing of a diesel generator, if a safety-injection actuation signal occurs, the diesel generator in test mode is disconnected from parallel operation with the offsite power system and maintained in the emergency standby mode. The diesel generator can automatically provide acceptable voltage and frequency for subsequent unit operation within requirements set by Regulatory Guide 1.9, Revision 0. See unit ratings and capability discussion in 8.3.1.1.7.1.2. In the event of a loss of voltage to the critical medium voltage bus, the associated diesel generator would be ready to accept load. Administrative procedures are used to prevent paralleling of the diesel generator with the normal auxiliary transformer so that the switchgear short circuit capability is not exceeded.

The control circuits for automatic start are provided with means for manual testing during normal plant operation and conform to criteria detailed in IEEE 279-1971. Means are provided to permit applying selected non-ESF loads in the plant to the diesel generator sets within their capabilities. However, this is a manual operation under the operator's full control. Under LOCA conditions, application of the non-ESF loads can only be accomplished after the LOCA parameters have been reduced below LOCA sensing instrumentation setpoints.

8.3.1.1.7.1.8 Protective Trips. The diesel generator protection system is designed such that on accident signal (low reactor water level, high drywell pressure) only the following diesel generator trips are effective:

a. Engine overspeed,
b. Generator differential relay action,
c. Incomplete sequence, and
d. Emergency stop push button.

During nonemergency operation of the diesel generator sets (such as testing) the engine is shut down and the generator breaker tripped under the following conditions:

a. Engine overspeed,
b. Generator differential relay action,
c. Incomplete sequence,
d. Emergency stop push button,
e. Generator loss of excitation,
f. Reverse current,
g. Generator overcurrent,

h. Generator overvoltage,
i. High jacket water temperature, and
j. Low lube oil pressure.

During a synchronizing test, the diesel generator is protected from overcurrent resulting from the non-Class 1E loads connected to the upstream buses, in the event of a loss of startup transformer power. The overcurrent protection results in isolation of the diesel generator emergency bus from the upstream non-Class 1E loads without disconnecting the diesel generator from the emergency bus.

The Divisions 1 and 2 standby diesel generator control circuits are shown in Figure 8.3-11 through 8.3-22.

The diesel generator incomplete sequence (fail to start) relay (K4) indicated in Figures 8.3-15 and 8.3-21 is designed to shut the generating unit down and lock it out in the event the normal starting cycle is not completed within a predetermined time. The relay is actuated if speed sensing instrumentation indicates that the unit requires in excess of 10 sec to accelerate to 150 rpm (regardless of the cause), or on failure of the cranking motors to disconnect when the unit is running.

8.3.1.1.7.1.9 Surveillance. Surveillance instrumentation is provided to monitor the status of the standby diesel generating system. Provisions for surveillance are an essential requirement in the design, manufacturing, installation, testing, operation, and maintenance of the diesel generators. Such surveillance not only provides continuous monitoring of the status of the standby diesel generating system, so as to indicate readiness to perform intended functions, but also serves to facilitate testing and maintenance of the equipment. Periodic surveillance procedures are also implemented to check setpoints of protective relays to ensure a reliable operation. Annunciation is provided both locally (diesel generator control panels) and in the main control room. Table 8.3-5 indicates the annunciation furnished for the Divisions 1 and 2 diesel generating systems.

When operating in the standby mode, conditions rendering the diesel generating units incapable of responding to emergency start signals are intentionally limited, as indicated in Section 8.3.1.1.7.1.8. Table 8.3-5, items 1 through 7 (inclusive), indicates all conditions which render the units incapable of responding, including both diesel generating unit and distribution system problems. Local, disabling diesel generator incomplete sequence and differential current conditions are annunciated indirectly (and distinctly from any nondisabling alarms) via the unit lockout (item 6) and fail to start (item 9) alarms. Item 21 indicates that the unit has been started automatically on receipt of emergency start signals. The remaining items indicate nondisabling diesel generator problems which do not cause unit trip.

During test mode operation, an expanded set of disabling conditions are permitted to prevent unit start or initiate unit trip as indicated in Section 8.3.1.1.7.1.8. However, in the event of

receipt of emergency start signals while the units are in the test mode, those signals not permitted to disable the unit in the standby mode are eliminated from the trip circuitry. In the event of receipt of a LOCA signal when a diesel is parallel to an offsite source, the diesel generator breaker will trip. With the diesel generator disconnected from parallel operation with the offsite power system during test mode operation, the diesel generator can automatically provide acceptable voltage and frequency for subsequent unit operation within requirements set by Regulatory Guide 1.9, Revision 0 if called upon. The diesel will keep running until shutdown by operator action. The maintenance lockout key lock switch and the emergency stop lockout features are verified to prevent the diesel generator from starting only when required no less than once every 30 months.

Main control room annunciation is designed to permit the control room operator to accurately monitor the status of the standby diesel generating system at all times and during all modes of operation. Any condition which renders the diesel generators incapable of operation is annunciated via Table 8.3-5, Items 1 through 9. The difference between the standby mode and all other modes is that the number of unit tripping signals permitted to actually operate (via the unit lockout relay) is limited in the standby mode.

Diesel generating unit controls reset automatically (time delayed) following nonemergency manual stops initiated at the local control stations.

8.3.1.1.7.1.10 Instrumentation and Control Systems. Power supply source for the instrumentation and control systems for each diesel generator is independent in accordance with the divisional separation criteria detailed in Sections 8.3.1.4 and 8.3.2.4. Each diesel generator set includes the following instrumentation:

a. Voltmeter,
b. Ammeter,
c. Wattmeter,
d. Varmeter,
e. Field ammeter,
f. Annunciator panel,
g. Synchroscope, synchronizing switches and lights,
h. Frequency meter,
i. Elapsed time meter,
j. Generator breaker status lights, and
k. Bus-tie breaker status lights.

The diesel generator sets are capable of being started or stopped manually from the main control room or from local control panels, and all Class 1E instrumentation is capable of being monitored both in the main control room and locally.

8.3.1.1.7.1.11 Light or No Load Operation. Light loading of the diesel generators for extended periods may lead to accumulation of oil in the exhaust system and create a potential for fire which could damage the turbo-charger and exhaust system. The HPCS diesel generator (3) when started will be loaded, except when offsite power is available as described in Section 8.3.1.1.7.2.7. The diesel generators (units 1 and 2) start when offsite power is not available to the Class 1E 4.16-kV switchgear buses or when LOCA signal is received. Partial LOOP does not cause connection of a diesel generator onto its 4.16-kV switchgear bus. Once offsite power to the bus is reestablished via transfer to a remaining offsite source, closure of the diesel generator breaker is blocked. In such a case, the units run unloaded. Also, during testing and maintenance/repairs, periods of unloaded operation are also expected to occur.

The Divisions 1 and 2 diesel generating units are capable of running for 4 hr in the unloaded or lightly loaded condition at rated speed. Operating restrictions are employed to avoid the potential for fire if the diesels are run for more than 4 hr at less than 50% loading at rated speed. After 4 hr of loading at less than 50% the engines are run for a minimum of 30 minutes at greater than 50% loading before being shut down. The engines may be run unloaded at idle speed for extended periods.

8.3.1.1.7.2 High-Pressure Core Spray (Division 3) Standby Alternating Current Power Supply.

8.3.1.1.7.2.1 General. The single drive HPCS standby diesel generator is used to supply power to the HPCS system in the absence of the normal/startup power sources. Figure 8.1-2 shows the interconnections between the preferred power system, the HPCS diesel generator unit, and the HPCS pump and 225-kVA auxiliary transformer. The HPCS auxiliary loads appear in Figure 8.3-4.

The HPCS system is self-contained except for connection to LOCA start signals and for access to the preferred source of offsite power through the plant ac power distribution system. It is operable as an isolated system independent of electrical connection to any other system through its use of the dedicated HPCS diesel generator. The standby auxiliary equipment such as heaters, air compressor, and battery charger are supplied from the same power source as the HPCS motor when the diesel generator is not running.

The HPCS diesel generator has the capability to quickly restore onsite power to the HPCS pump motor in the event offsite power is unavailable and to provide all required power for the startup and operation of the HPCS pump motor in a manner compatible with safe shutdown of the plant. The HPCS diesel generator starts automatically on a signal from the plant protection system; the unit is both started and connected to the bus automatically upon receipt of a bus undervoltage signal. The failure of this unit does not negate the capability of other power sources.

The HPCS diesel generator may also be cross connected to either Division 1 or to Division 2. These cross connects are only allowed under the following two scenarios:

(1) Extended Station Blackout (ESBO): A station blackout that may extend beyond the analyzed 4 hour coping time in which adequate core cooling can be assured without continuous HPCS system operation. (Reference 8.3-6).

(2) Non-Design Basis Accident (DBA) LOOP: A LOOP in which adequate core cooling can be assured without continuous HPCS system operation.

Under these conditions, the HPCS diesel generator may be used to energize selected Division 1 or Division 2 equipment by back-feeding from the HPCS bus to the Division 1 or Division 2 buses. The HPCS diesel generator does not have sufficient capacity to assume all the Division 1 or 2 ESBO or non-DBA LOOP loads. However, the HPCS diesel generator can energize selected loads during an ESBO or non-DBA LOOP. The cross connect breakers are not normally installed in their associated switchgear cubicle.

8.3.1.1.7.2.2 Unit Rating and Capability. The diesel generator set for Division 3 (HPCS) has a continuous service rating of 2600 kW. Diesel generator set short-term ratings are 2850 kW for 2000 hr and 3026 kW for 30 minutes. The generator is rated 3560 kVA at 0.8 pf, which is sufficient to carry the 2850 kW short-term rating at 0.8 pf. At higher kW outputs, the diesel generator set would have to operate at a higher power factor.

The generator is rated to have sufficient capacity to start and supply the HPCS induction motor for the HPCS pump and (via stepdown auxiliary transformer) 460-V induction motors which drive the engine cooling water pump, valve operator motors, and miscellaneous HPCS auxiliaries. The valve motors operate for short times and do not impose a significant load on the generator. The HPCS pump motor has a nameplate rating of 3000 hp at 4000-V. Table 8.3-3 lists the principal loads on Division 3 (HPCS). The diesel generator unit has the capacity to start and supply the loads required by the HPCS system within the time requirements described in Chapter 6. Table 8.3-3 lists the sequence of starting loads for the HPCS system.

The size of the diesel generator serving Division 3 (HPCS) satisfies the requirements of Regulatory Guide 1.9, Revision 0, except for voltage and frequency limitations, and conforms to the following criteria:

a. The (2000 hr/year) nameplate rating of the unit exceeds the maximum required load indicated in Table 8.3-3 under rated conditions. Engine brake horsepower

required to supply calculated steady state load is within the diesel engine's 2000-hr/year rated capability with an air inlet temperature of 115°F;

b. The unit is capable of starting, accelerating, and running its largest motor at any time;

c. The unit is capable of reaching full speed and voltage within 15 sec after receiving a signal to start, and can be fully loaded within 30 sec following the start signal; and

d. The unit demonstrates a torque margin in excess of the starting period requirements.

See Section 8.3.1.2.1.4 for a discussion of the nonconformance to Regulatory Guide 1.9, Revision 0, voltage and frequency limitations.

The governor control system includes manual engine idle capability. Manually operating the engine at a reduced speed for a "warm up" or a "cool down" run prior to shutdown is recommended by the manufacturer to minimize mechanical stress and wear. If a HPCS auto initiation or E-SM-4 undervoltage signal is received when operating the engine at reduced rpm (idle speed), manual control is automatically bypassed and the engine is accelerated to rated speed.

The HPCS power system electrical apparatus is sized on the basis of the most severe conditions it will be subject to in either a continuous or intermittent basis in any mode of operation. Intermittent loads are factored in on the basis of heating (e.g., short time peaks are not added directly to determine total continuous load imposed). Adverse environmental conditions have been taken into consideration (e.g., derating of cable for temperatures higher than the basic rated values and use of multipliers on actual service hours for motors operated at higher than normal rated temperatures).

8.3.1.1.7.2.3 Cooling Water System. The HPCS diesel engine is provided with a closed cooling system containing immersion heaters to maintain the engine coolant temperature, an expansion tank, a temperature regulating valve, and a lube oil cooler. The immersion heater is thermostatically controlled and, in conjunction with the temperature regulating valve, will maintain the jacket water at a steady temperature. During engine shutdown condition, jacket water heated by the immersion heater will circulate through the lube oil cooler by thermosyphon action to warm the lubricating oil circulated by an ac motor-driven pump. This "keep warm" feature will provide the engine with the capability of quick start and load acceptance after a shut down. The engine low temperature condition will be annunciated in the main control room. See Section 9.5.5 for additional details of the cooling water system.

8.3.1.1.7.2.4 Lubrication System. The lubricating oil system schematic is shown in Figure 9.5-6. The lube oil system is provided with a suction-strainer full-flow filter with bypass relief valves, a lube oil cooler/heater, and a lube oil sump pan of sufficient capacity to

hold usable lube oil for 7 days operating without adding makeup lube oil. High crankcase pressure is annunciated for operator action. See Section 9.5.7 for additional details of the lubrication system.

8.3.1.1.7.2.5 Air Starting System. The air starting system is shown in Figure 9.5-1. To ensure positive starting, both solenoids are energized simultaneously and both banks of dual starting motors crank the engine. The air supply system contains two receivers. One of the air compressors is electric-motor driven and the other is diesel-engine driven. The motor-driven air compressor is powered from MCC MC-6B. Running either air compressor will charge both receivers.

The volume of the receiver allows sufficient time for moisture and oil to precipitate in the bottom of the tank. The connection to the engine start system is located far enough above the bottom so that the moisture in the bottom will not get carried in the air being supplied to the air start motors. Blowdown valves are provided in the bottom of the air receivers to drain any moisture that might have collected in the bottom. The blowdown valves are opened periodically on a maintenance schedule to blow moisture out of the tank.

Wye strainers are provided in the air start system piping to filter any particulate carryover. Inspection and cleaning of the system components were made after the initial trail runs during installation. After the initial trial runs, all loose particles were either collected or blown out. As an extra precaution against moisture carryover, a dryer was added between the air compressors and air receivers.

See Section 9.5.6 for additional details of the air starting system.

8.3.1.1.7.2.6 Fuel Oil System. The fuel oil system consists of two fuel oil systems external to the engine fuel manifolds, either of which is capable of supplying fuel oil to the engine. One of the fuel oil pumps is mechanically driven by the engine, and the other by a 120-V dc motor. The systems contain the following components from the day tank: fuel supply lines, strainers, fuel oil pumps, duplex filters, relief and check valves. The two systems join together at the manifold for the duplex filter of the engine driven fuel oil pump and share that duplex filter, a pressure gage, fuel lines and manifolds to the injectors, injectors, and a return line to the day tank.

See Section 9.5.4 for additional details of the fuel oil system.

8.3.1.1.7.2.7 Automatic Starting and Loading System. In the event of loss of offsite sources of power to the onsite power system, the HPCS diesel generator set is automatically started and loaded by controls and circuitry which are independent of those used to start and load the Divisions 1 and 2 units. Control power for the diesel generator unit is supplied from its own 125-V dc system which consists of a battery with its own battery charger (see Section 8.3.2.1.2).

The diesel generator starting logic and starting signals (shown in Figures 8.3-23 and 8.3-24) are described as follows:

a. The diesel generator starts immediately upon receipt of LOCA signals (reactor low water level and/or high drywell pressure);

b. Upon sustained loss of bus SM-4 voltage the bus is automatically isolated from the upstream non-Class 1E system, and the diesel generator started;

c. After the diesel generator has attained approximately normal frequency, its breaker automatically closes (if unit start was initiated by bus SM-4 undervoltage), picking up loads as indicated in Table 8.3-3. LOCA signals do not initiate automatic breaker closure;

d. Diesel generator capacity (2850 kW) is such that the unit is capable of supplying the entire Division 3 load per the load schedule shown in Table 8.3-3 on a 2000-hr/year basis. There is no load shedding in Division 3;

e. If offsite power is still present and the unit is started by a LOCA signal, the diesel generator breaker will not close. However, the unit will continue to run at rated frequency and voltage until manually shut down; and

f. Means are provided for periodic exercising of the diesel generator under load. To accomplish this, supply of 4.16-kV Class 1E bus SM-4 is transferred to the startup source. Under this condition, the diesel generator is synchronized to the 230-kV startup source and loaded via manual adjustment of the unit speed controls. Administrative procedures are used to prevent paralleling of the diesel generator with the normal auxiliary transformer so that the short circuit capability of the switchgear is not exceeded.

Means are also provided to periodically test the entire chain of HPCS system elements from sensing devices through driven equipment to ensure that equipment is functioning in accordance with design requirements. The drawout feature of protective relays allows a replacement relay to be installed while the relay that was removed can be bench tested and calibrated. Startup of the diesel generator can be effected by simulation of signals for LOCA or bus SM-4 undervoltage.

8.3.1.1.7.2.8 Protective Trips. The HPCS diesel generator protection system is designed such that on accident signal (low reactor water level, high drywell pressure) only the following diesel generator trips are effective:

a. Engine overspeed,
b. Generator differential relay action,

c. Incomplete sequence, and
d. Emergency stop push button.

The trips are annunciated in the main control room. Other normal protective relays and devices such as loss of excitation, antimotoring (reverse power), overcurrent (with voltage restraint), high jacket water temperature, high crankcase pressure, and low lube oil pressures are used to protect the machine when it is operating during periodic tests. These relays are automatically blocked from the tripping circuits under accident conditions.

In addition to these protective relays, a normal time delay overcurrent relay senses a generator overload and causes an alarm in the main control room. The generator differential relays and overspeed trip device are retained under emergency conditions to protect against what could be major faults which would cause immediate system failure and major damage. All the necessary bypassed trip devices alarm in the control room and provide the operator with sufficient information to take the necessary corrective action. Since the diesel generator is performing a safety-related core cooling function during accident conditions, these trip devices cannot be permitted to interrupt the diesel generator's operation. The capability of the diesel to operate under these abnormal conditions is left to the operator.

During a synchronizing test, the diesel generator is protected from overcurrent resulting from non-Class 1E loads connected to the upstream buses, in the event of a loss of startup transformer power. The overcurrent protection results in the tripping of the offsite source breaker without tripping the generator breaker.

8.3.1.1.7.2.9 Surveillance. Surveillance instrumentation is provided to monitor the status of the standby diesel generating system. Provisions for surveillance are an essential requirement in the design, manufacture, installation, testing, and maintenance of the diesel generator. Such surveillance not only provides continuous monitoring of the status of the standby diesel generating system, so as to indicate readiness to perform intended functions, but also serves to facilitate testing and maintenance of the equipment. Protective surveillance procedures are also implemented to check setpoints of protective relays to ensure a reliable operation. Annunciation is provided both locally (diesel generator panel) and in the main control room.

An alarm "HPCS not ready for auto start," which operates during one of the following conditions, is provided in the control room.

a. Voltage regulator not in auto position,
b. Engine generator lockout operated,
c. Engine in maintenance position,
d. Diesel generator breaker racked out, and
e. HPCS pump motor breaker racked out.

In addition, the following alarms in the control room pertaining to the diesel generator aid the operator in determining the status of the unit.

a. Diesel engine in maintenance or test position,
b. Generator trip lockout,
c. 125-V dc power failure,
d. Diesel engine overspeed,
e. Diesel engine running, and
f. Diesel generator local panel alarm.

The diesel generator local panel alarm indicated above is actuated by any one of the following alarms (which are annunciated locally in the diesel generator panel).

a. Low lube oil pressure,
b. High lube oil temperature,
c. Low air pressure,
d. Overspeed trip,
e. Low jacket water temperature,
f. High jacket water temperature,
g. Low water pressure,
h. Unit lockout,
i. Blown fuse,
j. Lube oil relief valve open (lube oil system fault),
k. Fuel system fault,
l. Fail to start,
m. Fail to run,
n. Not ready for auto start,
o. Engine running,
p. Charger input power failure,
q. Generator RTD high temperature,
r. Low lube oil temperature,
s. Low circulating lube oil pressure,
t. High crankcase pressure,
u. Low water level, and
v. Low lube oil sump level.

When the engine selector switch is in the “local manual” position, the air compressor switch is in the “not in auto” position, or the voltage regulator switch is in the “off” position, the engine will not be prevented from starting automatically.

A manual stop signal does not prevent the engine from starting in the automatic mode; however, the emergency manual stop signal prevents the engine from starting unless reset. In this case, it is annunciated in the control room as “HPCS not ready for automatic start.”

8.3.1.1.7.2.10 Instrumentation and Control System. The power supply source for Division 3 controls and instrumentation is independent of the power sources for controls and instrumentation of other divisions, in accordance with the separation criteria described in Sections 8.3.1.4 and 8.3.2.4.

The diesel generator set includes the following instrumentation:

a. Voltmeter,
b. Ammeter,
c. Wattmeter,
d. Watthour meter,
e. Varmeter,
f. Field voltmeter,
g. Field ammeter,
h. Synchroscope, synchronizing switches and lights,
i. Frequency meter, and
j. Generator breaker status lights.

See Figure 8.1-2 for protection and surveillance devices for the HPCS power system. Some control and monitoring instruments are located on the diesel generator skid and have been qualified for engine vibration.

Additional information is provided in Section 7.3.1.1.1.1.

8.3.1.1.7.2.11 Light Load Operation. Light load operating capability of the HPCS (Division 3) diesel generating unit, and administratively controlled operating procedures for this operating mode, are identical to those described for the Divisions 1 and 2 diesel generating units. See Section 8.3.1.1.7.1.11.

8.3.1.1.8 Electrical Equipment Tests

Components of the onsite ac power system are factory tested in accordance with industry and manufacturer's standards. For Seismic Category I components, the manufacturer submits dynamic tests, analysis, or combination of both which substantiate the ability of the equipment to function under safe shutdown earthquake (SSE) loads (see Section 3.10). Tests and inspection of the onsite ac power system are discussed further in Section 8.3.1.2.2.

The standby diesel generators for Divisions 1 and 2 are of a type not previously used nor qualified for standby power service at a nuclear plant. Therefore, the diesel generators were shop tested to demonstrate starting reliability. The starting test requirements included the following:

a. Shop tests which confirmed a starting reliability of 0.99 with a confidence level of 0.95. One of the diesel generators was started 300 times with a failure rate not in excess of one per 100 starts;

b. Bringing the set to full speed and voltage automatically within 15 sec;

c. Loading of the generator to at least 95% of continuous rating in four steps at 5 sec intervals immediately after each successful start and maintaining this load until thermal equilibrium is attained;

d. 90% "cold" starts and 10% "hot" starts; and

e. Monitoring of operating conditions throughout the duration of test with significant parameters such as voltage frequency, operating temperature, acceleration times, and other pertinent functions being recorded.

Failures considered were limited to those caused by malfunctions of the diesel generator set only. Failures caused by malfunctions in the test equipment, external circuitry, or loads were not considered attributable to the reliability of the diesel generator set. Provisions were made in the testing procedure to determine the cause of any malfunction or excess wear and to classify it as a valid failure of the equipment being tested or an external nonvalid failure. Such determination of cause and classification of failure or excess wear was fully supported by documentation. At the completion of the tests, a thorough inspection was performed on the diesel generator unit.

A prototype test was made for the standby diesel generator selected for Division 3 (HPCS) to establish the adequacy of the diesel generator unit to successfully accelerate the bulk HPCS pump loads. The test consisted of starting the actual HPCS pump motor depicting as closely as possible the actual HPCS pump loop (HPCS system in condensate to condensate test mode) and auxiliary loads. A topical report on HPCS power system unit (NEDO-10905-3) describes and shows theoretical and experimental evidence as to the adequacy of the design.

8.3.1.1.9 Equipment Criteria

8.3.1.1.9.1 Motor Size. The criterion for Class 1E motor size is that the safety-related motor develop sufficient horsepower to drive the mechanical load under runout or maximum expected flow and pressure, whichever is greater. Class 1E motors are sized in accordance with NEMA standards and manufacturers ratings to be at least large enough to produce the starting, pull-up, and breakdown torque calculated to be needed for the particular application, and to permit the driven equipment to develop its specified capacity without exceeding the temperature rise rating of the motor when operated at the duty cycle of the driven equipment.

Motors are initially tested in accordance with NEMA-MG-1.

The motor and the associated driven equipment are preoperationally tested to verify that the system requirements are met.

8.3.1.1.9.2 Motor Thermal Overloads. Motor thermal overloads for miscellaneous Class 1E motors having a 1.0 or 1.15 service factor are selected from manufacturer's table for 1.15 service factor motors. Overloads so selected give 125% of motor full load current protection.

Motor thermal overloads for Class 1E MOVs are selected two sizes larger than the normally selected thermal overload (this approximates 140% of motor FLA). Selection of overloads in this range permits Class 1E MOVs to operate for extended periods of time at moderate overloads; tripping occurs just prior to motor damage. Class 1E MCCs are located in environmentally controlled rooms such that overload ambient temperature variation is not a significant factor. Periodic surveillance procedures are provided to check setpoint drift of the thermal overload devices.

8.3.1.1.9.3 Minimum Voltage. In general, Class 1E motors are designed to start and run at full load with a minimum 80% of rated voltage at the motor terminals. Deviation from the 80% voltage requirement is permitted provided an analysis is performed and documented to demonstrate that the motor can perform its safety function with the minimum voltage supplied.

The HPCS pump motor is designed to accelerate its load with only 75% voltage applied to the motor terminals.

8.3.1.1.9.4 Motor Starting Torque. Class 1E motors are designed for full voltage starting and to be capable of accelerating the driven equipment to its required speed without exceeding the thermal capability of the motor under all expected conditions of ambient temperature, voltage, and frequency.

8.3.1.1.9.5 Minimum Torque. The minimum motor torque through the accelerating period, for Class 1E motors, is based on the following criteria:

a. The brake horsepower does not exceed the guaranteed motor rating over the entire range of the driven equipment, and

b. The driven equipment is capable of attaining required speed under normal voltage conditions within 5 sec and under degraded voltage conditions within 8 sec.

In general, motors are sized such that no portion of a motor's service factor above 1.0 is used in continuous operation of the motor. Specified minimum values of motor torque over equipment torque are, therefore, not required.

For the HPCS pump motor, the minimum difference between the motor torque and the pump torque at any given speed during acceleration is 10% of motor rated torque.

8.3.1.1.9.6 Motor Insulation. The criteria for determining insulation for Class 1E motors are as follows:

a. The insulation for continuous rated motors has a 40-year life expectancy for the duty cycle and the ambient conditions of temperature and radiation at which they are required to operate. Intermittent duty motors are similarly rated for the number of duty cycles expected over the 40-year life of the plant; and

b. For Class 1E motors, which are required to operate during or subsequent to accidents, insulation is provided to withstand the expected environmental conditions of ambient pressure, temperature, and radiation dosage.

All motors are provided with either class B, F, or H insulation. The insulation temperature ratings are greater than the sum of the motor temperature rise, the ambient temperature at the motor location, and the hot spot temperature allowance.

During the license renewal review, the service life of the HPCS system components that provide an intended function for license renewal were evaluated for 60 years.

8.3.1.1.9.7 Temperature Monitoring Devices. Motors 300 hp in size and larger are provided with one or more copper-constantan thermocouples in each bearing.

The HPCS, low-pressure core spray (LPCS), residual heat removal (RHR), and standby service water pump motors are provided with six single element copper-constantan thermocouples imbedded in stator windings, two per phase, where the highest operating temperatures are expected.

The output from the thermocouples is wired to the station computer for scanning and alarm in the main control room.

8.3.1.1.9.8 Interrupting Capacity. Class 1E switchgear, load centers, control centers, and distribution panels are sized for interrupting capacity based on maximum short circuit availability at their location. Switchgear is applied within its interrupting close and latch ratings in accordance with ANSI C37.010-1972, Application Guide for Alternating Current High Voltage Circuit Breakers.

The calculations to document this application take into account the fault contributions of all rotating machines and source transformers and make proper allowance for system X/R ratio at the point of fault. Transformer impedance is selected to limit short circuit currents at 4.16-kV switchgear. Low voltage metal enclosed breakers at load centers and molded-case breakers at MCCs are adequately sized for the maximum available short circuit currents.

8.3.1.1.9.9 Electric Circuit Protection. Equipment and settings are provided to carry out relaying as listed below. The basic coordination for the 4.16-kV and 480-V systems for Class 1E buses is as follows:

a. A faulted piece of equipment is cleared by isolating the smallest possible portion of the system;

b. A faulted piece of equipment is cleared as quickly as possible to minimize damage to that equipment and the effects on the remainder of the system; and

c. In the event that the primary protective device fails to clear the fault, a backup device operates to clear it after a suitable coordination interval. Operation of a backup device usually results in deenergizing a larger portion of this system than the operation of a primary device.

The one line diagrams, Figure 8.1-2 shows the relay protection schemes.

The incoming supply feeders are included in the differential zone of the normal auxiliary, startup, and backup transformers; hence the primary protection for these feeders consists of harmonically restrained differential relays. The overcurrent relays on the incoming supply breaker are coordinated with the maximum feeder setting on the bus.

The 6.9-kV and 4.16-kV systems are high resistance grounded to minimize damages by limiting ground fault currents to 12.5 amps (maximum). An overcurrent relay is connected to a current transformer in the neutral of the resistance grounded, wye-connected secondary of the supply transformer for ground indication, and each feeder is equipped with a ground sensor.

The 480-V system is also high resistance grounded to limit ground fault currents to 10 amps (maximum). Ground faults are detected at all diesel generator neutrals, transformer secondary neutrals, or 480-V switchgear feeders.

Circuit protection of the NSSS vendor supplied HPCS bus is coordinated with the design of the overall protection system for the plant auxiliary system. Simplicity in load grouping is employed to achieve simplicity in conventional protective relaying practice for isolation of fault. There is no load shedding or sequencing in the HPCS power system. Emphasis is given in preserving function and limiting loss of Class 1E equipment function in situations of power loss and equipment failure. Normal overload relays for HPCS pump motor and diesel generator give alarm indication only. Faults are isolated by instantaneous relaying.

8.3.1.1.9.10 4.16-kV Motor Feeder. Each Class 1E 4.16-kV motor feeder is protected by two relays, each having a long time overcurrent unit, a high dropout instantaneous unit, and an indicating instantaneous trip unit. The relays are set to provide: (1) an overload alarm at

114% to 160% of the motor nameplate full load current, (2) a breaker trip on locked rotor current within the safe stall time of the motor, and (3) an instantaneous trip of the breaker for short circuit currents above the motor locked rotor current including adjustments for DC offset and voltage variation. The motor relays are coordinated with the three sets of incoming bus breaker time overcurrent relays. Ground fault indication is provided by a ground sensor relay activated by a doughnut current transformer. The 4.16-kV HPCS pump motor feeder is also tripped on motor feeder over frequency.

8.3.1.1.9.11 Transformer Feeders. Each 480-V load center unit substation or MCC transformer feeder on the 4.16-kV buses has two time overcurrent relays with instantaneous overcurrent elements or high speed transformer differential protection for fault protection. These relays are coordinated with the maximum protective device settings on the 480-V Class 1E equipment buses fed by the transformers. Ground fault indication is provided by the ground sensor system.

8.3.1.1.9.12 Diesel Generator. The primary protection for the diesel generator connected to each 4.16-kV Class 1E bus consists of differential relaying and overspeed trip (see Sections 8.3.1.1.7.1.8 and 8.3.1.1.7.2.8).

8.3.1.1.9.13 480-Volt Motor Feeder Fed From Switchgear Bus. The overcurrent fault protection on each 480-V motor feeder is a low-voltage power circuit breaker, containing a solid state trip device with adjustable long time delay and instantaneous trips. Ground sensors provide ground fault detection.

8.3.1.1.9.14 Motor Control Center Feeder Fed From 480-Volt Switchgear Bus. The overcurrent fault protection for each 480-V MCC feeder (except HPCS MCC MC-4A) is a low voltage power circuit breaker with a solid state trip device having both adjustable long time and adjustable short time trips. The long time device is coordinated with the maximum overload device setting in the MCC. The short time device is coordinated with the maximum instantaneous device setting in the MCC. Motor control center MC-4A is protected by the 4.16-kV feeder circuit breaker. Ground sensors provide ground fault detection.

8.3.1.1.9.15 Feeders From 480-Volt Motor Control Centers. Motors fed from the 480-V MCCs are generally 100 hp or less. Circuit protection, which includes molded-case circuit breakers or dual element time delay fuses, is provided for high interrupting capacity and short circuit protection. Motor running overcurrent protection is provided by overload relays in each motor starter. Non motor MCC loads are generally provided short circuit and overload protection by dual element time delay fuses. Subfeeders to other MCCs are provided short circuit and overload protection by molded-case circuit breakers or dual element time delay fuses.

8.3.1.1.9.16 Electrical Penetration Assemblies in Containment Structures. CGS design is in compliance with Regulatory Guide 1.63, Revision 0. All circuits which enter penetrations and

are subject to I^2T heating due to fault currents are provided with two protective devices (primary and backup). In the event the primary protective devices fail to clear faults, the backup protective devices are designed to limit the I^2T levels experienced by the penetration conductors to values below the conductor I^2T ratings.

Electrical Calculation E/I-02-93-04 presents an analysis of overcurrent protection of primary containment electrical penetrations.

8.3.1.1.9.17 Raceway Systems. The cable tray system utilizes open ladder type trays, with the exception of RPS and instrumentation trays which are totally enclosed type (see Figures 8.3-25 through 8.3-30 and Figures 8.3-33 through 8.3-38). Cable trays are constructed of galvanized steel, except for aluminum cable trays installed in and adjacent to the building for the non-Class 1E reactor recirculation pump ASD.

All conduit, except for conduits for lighting, communication, security, and fire detection systems which may utilize EMT thinwall, are full weight rigid galvanized steel. Sleeves also utilize full weight conduit.

Conduit and sleeve fill is generally in accordance with National Electric Code criteria.

Flexible metallic conduit is utilized for final connections to vibrating or rotating equipment, cabling within the area below the reactor pressure vessel, cabling within the power generation control room complex (PGCC) periphery, cabling for fail safe, fire protection, and control/utility power circuits within the PGCC, short extensions of rigid conduit which require numerous direction changes, short connections between cable tray and panels or devices, and between different structures or buildings which experience differential movement.

8.3.1.1.9.18 Grounding Requirements. The design criteria for grounding are

a. Equipment hardware, exposed surfaces, and potential induced voltage hazards are adequately grounded to ensure that no danger exists for plant personnel;

b. A high resistance ground return path is provided to facilitate the operation of ground fault detection devices in the event of ground fault or insulation failure on any electrical load or current. Ground fault currents are thereby limited to 12.5 amps (maximum) in the 6.9-kV and 4.16-kV systems, and to 10 amps (maximum) in the 480-V system. The 120/208-V system is solidly grounded; and

c. A separate and independent grounding system for instruments and instrument wire shield is provided.

The design basis for grounding requirements is

a. All major electrical equipment is connected directly to the grounding grid by cable ties. A fault current return path is provided for 6.9-kV and 4.16-kV switchgear, 480-V switchgear, MCCs, and other equipment. This fault return path consists of bare #4/0 copper cables installed on all power cable trays, in duct banks and in loops along the building walls. Motors and electrical equipment operating at 150 V (to ground) and above, or carrying currents of 60 amps or more, have direct cable or strap connections to the ground grid. Alternately, the #4/0 AWG grounding cable alongside the trays may be tapped for grounding motors, panels and other equipment, if the distance is not greater than from the grounding loop indicated on contract drawings, and the equipment does not require larger cable than #4/0. Motors and electrical equipment operating at less than 150 V (to ground) or carrying currents less than 60 amps are grounded via the connecting conduit system and the ground cable in trays;

b. The cable trays are solidly grounded to the station grounding grid or building steel work. Electrical connections between individual tray sections are made by mechanical connector plates. In addition, a bare ground cable is attached to trays supporting power cables and to flexible conduits external to the PGCC. All flexible conduits containing fail-safe circuits which are routed in the PGCC modular floor are grounded;

c. The station ground grid is routed into primary containment via two penetrations suitable for the purpose; and

d. The station grounding grid is designed to maintain the station area at an effective ground potential during a worst-case ground fault of any installed electrical equipment, including transmission facilities and unit main generator, as well as lightning effects. An effective ground is considered to be the maintenance of voltage potentials below "safe touch-and-step potential" levels for plant personnel.

8.3.1.1.9.19 Vital Inverter Instrumentation Power System Protection Requirements.

The design of the 120/240VAC Class 1E inverter, static switch and alternate power supply to the vital instrument buses E-PP-7AA and E-PP-8AA as shown in Figure 8.3-5.1 is in compliance with IEEE 308-1974.

8.3.1.1.10 Class 1E Electrical Equipment Arrangement

The Class 1E electrical equipment arrangement for major components of the three separate power divisions is shown in Figures 1.2-14 and 1.2-22.

8.3.1.2 Analysis

8.3.1.2.1 Compliance to Criteria

8.3.1.2.1.1 General. Compliance with General Design Criterion (GDC) 17 is ensured for the onsite power systems by having sufficient independence, redundancy, and testability to perform the required safety functions assuming a single failure. Independence is discussed in Section 8.3.1.4 and testability is covered in Section 8.3.1.2.2. Redundancy in the onsite auxiliary ac power system is provided via the formation of redundant safety-related (Class 1E) electrical load groups (Divisions 1 and 2) in conformance with GDC 17, IEEE308-1974, and Regulatory Guide 1.6, Revision 0. This redundancy extends from the onsite standby power sources through 4.16-kV buses, station service transformers, 480-V buses, MCCs, distribution cables, switchgear, and protective devices.

The Division 3 power system is a separate and independent safety-related (Class 1E) power system serving the HPCS system. The Division 3 power system may be connected to either Division 1 or Division 2 in conformance with GDC 17, IEEE 308-1974, and Regulatory Guide 1.6, Revision 0 as described in Section 8.3.1.1.7.2.1.

The DG3 cross connect is in compliance with GDC 17 in that no single failure can inhibit the design independence, redundancy, and testing features. This is ensured by the multiple breakers that separate the divisions within the non-safety related switchgear. The DG3 cross connect decreases the probability of losing power to plant power systems due to the defense in depth features that it provides.

The DG3 cross connect is in compliance with IEEE 308-1974 since the cross connect is performed manually and the breaker positions are administratively controlled.

The DG3 cross connect is in compliance with Regulatory Guide 1.6, Revision 0 as explained in Section 8.3.1.2.1.4.

No essential electrical component of one Class 1E electrical division is dependent for its emergency power supply on electrical equipment or devices which are common to the power supply of another division. The onsite auxiliary ac power system standby sources consist of three diesel generator sets. Each of the diesel generators feeds one of the Class 1E divisions. The onsite auxiliary power system redundancy is based on the capability of either of the two redundant (Divisions 1 and 2) onsite power sources and their associated load groups, in conjunction with the Division 3 onsite power source and associated load group, to bring the reactor to a safe cold shutdown condition and/or to mitigate the consequences of a DBA.

The electrical separation and independence of redundant (Divisions 1 and 2) portions of the safety-related auxiliary power systems conform to IEEE 308-1974, GDC 17 and Regulatory Guide 1.6, Revision 0, except that these diesel generators have tandem diesel engines.

Reliability equivalent to a single diesel engine generator set is achieved, as shown by prototype testing (see Section 8.3.1.1.8).

The 4.16-kV Class 1E buses (SM-7, 8, and 4 respectively) for Divisions 1, 2, and 3 are normally supplied from separate 4.16-kV non-Class 1E buses (SM-1, 3, and 2 respectively) as indicated in Figure 8.1-2. Class 1E circuit breakers which automatically open on a LOOP are provided on the 4.16-kV tie lines between the Class 1E and non-Class 1E buses.

As protection against failures of the redundant standby ac power sources due to a single event, there are no electrical interconnections between the circuits needed to start, load, and maintain operation of each standby diesel generator.

All principal power circuits have both overload and short circuit protection provided by protective relays circuit breakers or by fuses.

Physical separation is provided between the independent electrical divisions as described in Section 8.3.1.4.

Design of the onsite power systems is not in strict accordance with Regulatory Guide 1.75, Revision 0, since the CGS Construction Permit issue date precedes the regulatory guide issue date. However, CGS design does provide independence between equipment and circuits of redundant Class 1E electrical divisions and between Class 1E and non-Class 1E equipment and circuits where practicable in satisfaction of 10 CFR 50 requirements.

Non-Class 1E loads required to operate during a LOOP are connected to the Class 1E power supplies. These connections do not degrade the Class 1E power supplies, based on the following:

a. Connection of non-Class 1E loads to Class 1E power supplies is via Class 1E isolation devices. These devices are either a circuit breaker shunt tripped on LOCA or one or two overcurrent devices in series such as fuses or circuit breakers. The overcurrent devices trip on overload currents (except for 4-kV motor circuits), line-to-line and three-phase faults and line-to-ground faults for solidly grounded systems. All overcurrent devices trip on overloads with the exception of those used in 4-kV motor circuits;

   The power source shall supply the necessary fault current to ensure proper coordination of the circuit's Class 1E isolation device without loss of function of Class 1E loads;

b. Wiring to the non-Class 1E loads from the Class 1E power supplies are designated as prime circuits and are routed in accordance with the separation criteria of Section 8.3.1.4;

c. Periodic surveillance of isolation devices ensure maintenance of the trip setpoints within the limits for proper coordination with the main supply circuit protective devices; and

d. The Class 1E power supplies are adequately sized to handle all the Class 1E and non-Class 1E loads.

See Sections 8.3.1.3 and 8.3.2.3 for specific details of equipment and circuit identification for plant ac and dc systems respectively.

See Sections 8.3.1.4 and 8.3.2.4 for specific details of equipment and circuit separation for plant ac and dc systems respectively.

8.3.1.2.1.2 Reactor Protection System Power System. The RPS power system is not an ESF, component, or system. The system itself fails in a fail-safe mode. That is, it deenergizes and thus causes a shutdown action. In addition, redundant electrical protection devices are utilized for isolation as indicated in Section 8.3.1.1.6. However, design considerations are taken to ensure power supply availability commensurate with the needs of the equipment serviced by it. Redundancy of equipment ensures a high degree of availability.

8.3.1.2.1.3 Redundant (Division 1 and Division 2) Standby Alternating Current Power Supplies. On loss of normal and offsite sources of power to the 4.16-kV switchgear buses, the 4.16-kV Class 1E portion of the auxiliary ac power system is automatically isolated. All 4.0-kV motor and selected 460-V motor loads are automatically shed from their respective buses to allow for the sequential loading of the standby diesel generators (see Section 8.3.1.1.1).

The diesel generators start automatically and are automatically connected to the Class 1E 4.16-kV buses. Electrical loads necessary for an emergency reactor shutdown or shutdown in the event of a LOCA are automatically and sequentially reconnected to these safety-related buses. The automatic diesel starting and loading sequence is designed to provide power to ESF components required in the event of a DBA within the time period specified for their operation in Chapter 15.

The two diesel generators supplying power to Divisions 1 and 2 ESF components are sized and designed in accordance with Regulatory Guide 1.9, Revision 0. Their ratings are based on the 2000 hr/year load rating greater than the sum of the loads requiring power at any one time.

The sequencing of large loads at 5 sec (or more) intervals ensures that diesel generator voltage and frequency limits (80% and 95%, respectively) are maintained. Also, engine overspeed settings and other design parameters remain in accordance with Regulatory Guide 1.9, Revision 0, as discussed in Section 8.3.1.1.7.1.

The Divisions 1 and 2 portions of the onsite ac power system also satisfy Regulatory Guide 1.32, Revision 2, not only in their adherence to IEEE 308-1974, but also as follows:

a. Offsite power is available from either offsite source within a few seconds if the plant main generator source is lost,

b. Electrical and physical independence of standby power sources is in accordance with Regulatory Guide 1.6 as described in Section 8.3.1.1.7.1, and

c. The selection of the diesel generator capacities has been made in accordance with Regulatory Guide 1.9 as further described in Section 8.3.1.1.7.1.

8.3.1.2.1.4 High-Pressure Core Spray (Division 3) Standby Alternating Current Power Supply.

Compliance With GDC 17

The HPCS ac power supply is Class 1E and is designed with sufficient capacity and independence to ensure that core cooling, containment integrity, and other vital functions are maintained in the event of a postulated accident. The design of the onsite and offsite electrical power systems provides compatible independence and redundancy to ensure high availability of power supply to the ECCS, even assuming a single failure.

Electrical power from the transmission network to the HPCS bus SM-4 is provided via the 230-kV startup auxiliary transformer. A loss of normal voltage at 4.16-kV bus SM-4 results in automatic starting of the HPCS diesel generator, tripping of the normal supply breaker and closing of the generator breaker as described in Section 8.3.1.1.7.2.7.

Compliance With GDC 18

The auxiliary electrical system is designed to permit inspection and testing of all important areas and features, especially those that have a safety function and whose operation is not normally required. As described in the Technical Specifications, periodic component tests will be supplemented by extensive functional tests during the refueling outage, the latter based on simulation of actual accident conditions. These tests demonstrate the operability of diesel generator, battery system components, and logic systems and thereby verify the continuity of the systems and the operation of the components.

Because the diesel generator is a standby unit, readiness is of prime importance. Readiness is demonstrated by periodic testing. The testing program is designed to test the ability to start the HPCS loads as well as to run under load long enough to bring all components of the system into equilibrium conditions. This ensures that cooling and lubrication are adequate for

extended periods of operation. Full functional tests of the automatic control circuitry will be conducted on a periodic basis to demonstrate correct operation.

Conformance With Regulatory Guide 1.6, Revision 0

The HPCS diesel generator unit supplies power for the HPCS pump and its auxiliaries; failure of any single component of the HPCS diesel generator does not prevent the startup and operation of any other standby power supply and thus meets the requirements of Regulatory Guide 1.6, Revision 0.

The system conforms to Position 1 of the guide in that each Class 1E load is assigned to a division of the load groups. The assignment is determined by the nuclear safety functional redundancy of the load such that the loss of any one division of the load group does not prevent the minimum safety functions from being performed.

The system conforms to Position 2 of the guide in that the HPCS ac loads have a supply from the startup auxiliary transformer as the preferred (offsite) power source, as well as from the HPCS diesel generator as the standby (onsite) power source (see Figure 8.1-2).

The HPCS diesel generator breaker will close automatically if the normal source breaker to HPCS bus SM-4 is open and the diesel generator has reached rated frequency.

The system conforms to Position 3 of the guide in that there is no automatic connection of the HPCS system to any other load group.

The system conforms to Position 4 of the guide as follows:

a. The diesel generator connected to any division of a load group cannot be automatically paralleled with a diesel generator that is connected to another division of the load group;

b. Each of the diesel generators is connected to one independent division of load group. No means exist for automatically connecting different load groups with each other;

c. No means are provided for automatically transferring loads between the diesel generators; and

d. An exception is taken to Regulatory Guide 1.6, Position 4d as follows. As described in Section 8.3.1.1.7.2.1, the HPCS diesel generator may be manually cross connected to either Division 1 or Division 2. This is performed without an interlock as specified by Position 4, Item d. However, Generic Letter 91-11: Resolution of Generic Issues 48 clarifies this requirement by stating that “the

staff concludes that if proper administrative controls that provide assurance that these breakers are normally open are placed on the operation of the tie breakers, then the addition of interlocks need not be pursued."

To comply with the requirements of Position 5 of the guide, the following start and load reliability test as described in NEDO-10905-3 (Reference 8.3-1) was successfully performed.

a. A series of tests were conducted to establish the capability of a prototype HPCS diesel generator unit to consistently start and load within the required time;

b. The prototype diesel generator is of the same model as the unit used for CGS except for the generator. Comparative data shown in Table 8.3-6 indicates that the CGS generator is at least equivalent to the prototype unit;

c. The start and load reliability test satisfied the following requirements: A total of 69 valid start and loading tests with no failure or 128 valid start and loading tests with a single failure have been performed. The start and load test was conducted as follows:

1. Engine cranking was started on receipt of the start signal, and the diesel generator set accelerated to specified frequency and voltage within the required time interval;

2. Immediately following, the diesel generator set accepted a single step load consisting of the main HPCS pump motor load (fully loaded) or larger motor load (fully loaded) and additional loads (inductive and/or resistive) as required to total at least 100% of the continuous rating of the diesel generator unit;

3. At least 90% of these tests were performed with the diesel generator set initially at "warm standby," based on jacket water and lube oil temperatures at or below values recommended by the engine manufacturer. After load was applied, the diesel generator set continued to operate until jacket water and lube oil temperatures were within ±10°F (5.5°C) of the normal engine operating temperatures for the corresponding load; and

4. The other 10% of these tests were performed with the engine initially at normal operating temperature equilibrium (defined as jacket water and lube oil temperature within ±10°F (5.5°C) of normal operating temperatures as established by the engine manufacturer for the corresponding load).

If the cause for failure to start or accept load in accordance with the preceding sequence fell under any of the categories listed below, that particular test was disregarded, and the test sequence resumed without penalty following identification of the cause for the unsuccessful attempt.

1. Unsuccessful start attempts which can definitely be attributed to operator error including setting of alignment control switches, rheostats, potentiometers, or other adjustments that may have been changed inadvertently prior to that particular start test;

2. A starting and/or loading test performed for verification of a schedule maintenance procedure required during this series of tests. This maintenance procedure was defined prior to conducting the start and load acceptance qualification tests and then became part of the normal maintenance schedule after installation;

3. Failure of any of the temporary service systems such as dc power source, output circuit breaker, load, interconnecting piping, and any other temporary setup which was not part of the permanent installation; and

4. Failure to carry load which was definitely attributed to loadings in excess of required loading.

Conformance With Regulatory Guide 1.9, Revision 0

The HPCS system diesel generating unit conforms to the requirements of Regulatory Guide 1.9, Revision 0, with the exception of voltage and frequency limits, as described below.

The unit conforms to Position 2 of the guide in that the 2000-hr (2850-kW) and 90% of the 30-minute (2727-kW) ratings both exceed the maximum coincidental load indicated in Table 8.3-3. Intermittent loads such as MOVs are not considered for long-term loads.

The unit conforms to Position 3 of the guide in that the load requirements will be verified by preoperational tests. The HPCS diesel generator unit is considered as a justifiable departure from strict conformance to Position 4 of the guide regarding voltage and frequency limits during the initial loading transient. The HPCS system consists of one large pump and motor combination which represents more than 90% of the total load; consequently, limiting the momentary voltage drop to 25% and the momentary frequency drop to 5% would not significantly enhance the reliability of HPCS operation. To meet these regulatory guide requirements, a diesel generator unit approximately two to three times as large as that required to carry the continuous rated load would be necessary. However, the frequency and voltage overshoot requirements of Regulatory Guide 1.9, Revision 0, are met. A prototype testing

program on an installed unit, as described in Section 8.3.1.2.1.4, has verified the following functions:

a. System fast-start capabilities,

b. Load carrying capability,

c. Load rejection capability,

d. Ability of the system to accept and carry the required loads, and

e. The mechanical integrity of the diesel engine generator unit and all of the major system auxiliaries.

The design of the HPCS diesel generator conforms with the applicable sections of IEEE criteria for Class 1E Electrical Systems for Nuclear Power Generation Station, IEEE 308-1971.

The generator has the capability of providing power to start the required loads with operationally acceptable voltage and frequency recovery characteristics. A partial or complete load rejection will not cause the diesel engine to trip on overspeed.

Reference 8.3-1 describes the prototype and reliability test requirements.

The calculated HPCS diesel generator transient response is indicated in Figure 8.3-31. Reference 8.3-1 provides an analysis showing the conservatism of calculated response compared to that obtained from actual tests.

Conformance With Regulatory Guide 1.29

The HPCS power supply system is capable of performing its function when subjected to the effects of design bases natural phenomena at its location. In particular, it is designed in accordance with the Seismic Category I criteria and housed in a safety class structure.

Conformance With Regulatory Guide 1.32

The design of the HPCS diesel generator conforms with the applicable sections of IEEE criteria for Class 1E, Electrical Systems for Nuclear Power Generation Stations, IEEE 308-1971.

Conformance With Regulatory Guide 1.47

See Section 7.1.

Conformance With Regulatory Guide 1.62

Manual controls are provided to permit the operator to select the most suitable distribution path from the power supply to the load. An automatic start signal will override the test mode. Provision is made for control of the system from the control room as well as from an external location.

Conformance With IEEE 279-1971

See Section 7.3.2.1.2 for a discussion of compliance of the HPCS with IEEE 279-1971.

Conformance With IEEE 308-1971

The HPCS electrical system components supplying power to the Class 1E electrical equipment are designed to meet their functional requirements under the conditions produced by the design basis events. Equipment of different divisions is physically separated to maintain independence and to minimize the possibility of a common-mode failure. The HPCS Class 1E equipment is located in Seismic Category I structures.

Surveillance of the HPCS Class 1E electrical system is in compliance with the standard.

Conformance With IEEE 344-1971 and 1975

The HPCS power supply unit components are seismically qualified to IEEE 344-1971 or 1975 as applicable. See Section 3.10.1.2.

Conformance to IEEE 387-1972

The HPCS power supply unit is completely independent from other standby power supply units and meets the applicable requirements of IEEE 387-1972.

The HPCS diesel generator unit is designed to

a. Operate in its service environment during and after any design basis event without support from the preferred power supply;

b. Start, accelerate, and be loaded with the design load within an acceptable time:

1. From the normal standby condition,

2. With no cooling available, for a time equivalent to that required to bring the cooling equipment into service with energy from the diesel generator unit, and

3. On a restart with an initial engine temperature equal to the continuous rating, full load engine temperature;

c. Carry the design load for 2000 hr;

d. Maintain voltage and frequency within limits that will not degrade the performance of any of the loads composing the design load below their minimum requirements, including the duration of transients caused by load application or load removal; and

e. Withstand any anticipated vibration and overspeed conditions. There is no flywheel coupled with the HPCS diesel generator. The generator and exciter are designed to withstand 25% overspeed without damage.

The HPCS diesel generator has continuous and short-term ratings consistent with the requirements of Section 5.1 of IEEE 387-1972.

Mechanical and electrical system interactions between the HPCS diesel generator unit and other units of the standby power supply, the nuclear plant, the conventional plant, and the Class 1E electrical systems are coordinated so that the HPCS diesel generator units' design function and capability are realized for any design basis event except failure of the HPCS diesel generator unit.

Environmental qualification of the HPCS diesel generator is not required since it is located in a mild environment.

8.3.1.2.2 Tests and Inspection

The auxiliary ac power system is designed to permit periodic testing and inspection of the system as a whole and of the operability and functional performance of the components in accordance with GDC 18. Preoperational testing, as described in Section 14.2, was performed to verify that all components, automatic and manual controls, and sequences of operation of the standby power system function as required. Preoperational testing of redundant portions of the onsite electrical power system to verify proper load group assignments was performed in accordance with Regulatory Guide 1.41, Revision 0. Voltage values at Class 1E high and low

voltage buses were measured and compared to the design values, to demonstrate correct transformer tap settings, during the preoperational testing phase of the plant.

Description of Division 3 Test:

To accomplish this test, supply of 4.16-kV Class 1E bus SM-4 was transferred to the startup source. Under this condition, the diesel generator was synchronized to the 230-kV startup source and loaded via manual adjustment of the unit speed controls to at least 50% of continuous rating and operated to this level for at least 1 hr. Sixty-nine such tests have been accomplished with no failures. In addition, five tests have involved loading the diesel with the existing bus loads including the HPCS pump motor.

Significant parameters such as voltage, frequency, operating temperature, acceleration times, and other pertinent functions were monitored throughout the duration of the test and recorded.

At periodic intervals when the reactor is not at power operation, tests simulating Class 1E bus undervoltage, LOCA, undervoltage and LOCA simultaneously, or manual start signals will be performed to demonstrate the capability of the power sources to meet the starting and loading sequencing requirements. Periodic testing will verify the diesel generator being tested is aligned to provide standby power to the associated emergency buses. Testing procedures during these times are described in the Technical Specifications.

Periodically during plant operation, each diesel generator is manually started and loaded. Each (Divisions 1, 2, and 3) unit is separately synchronized to the 230-kV startup offsite power source and loaded.

During diesel generator test mode, a LOCA signal received when a diesel is parallel to an offsite source will cause the diesel generator breaker to trip. The diesel will then remain running in standby mode until shutdown by operator action.

Prior to operation of the standby diesel generators, there are checks to ensure correct valve lineup as well as switch position confirmation as identified in the diesel generator operating procedure. Among these are the normal prestart checks including expansion tank water level, diesel starting air compressor oil level, air start motor in line lubricator oil level, engine crank case oil level, using both the gauge and the dipstick, generator bearing oil level, and the woodward governor oil level. Periodic inspections of the diesel generators will be conducted

in accordance with plant procedures prepared in conjunction with the manufacturer's recommendations.

The testing program is designed to test the ability of each diesel generator to start as well as to run under load long enough to bring all components of the system into equilibrium condition. During the start and load run surveillance, the generator voltage and frequency is verified to be 4160 V (+240, -250) and 60 (+1.2, -1.2) Hz for DG-1, DG-2, and DG-3. The steady-state generator voltage and frequency is verified to be maintained within the above voltage and frequency limits during this test. This ensures that cooling and lubrication are adequate for extended periods of operation. Functional testing of the automatic control circuitry is conducted on a periodic basis to demonstrate proper operation.

Sufficient testability, alarms, and fault detection equipment are provided to comply with the criteria indicated above. Thus assurance is given that the standby power sources are capable of performing their safety functions with adequate reliability at all times.

For periodic testing, the surveillance requirements for demonstrating the operability of the diesel generators are consistent with the recommendations of Regulatory Guide 1.9 Revision 3 as described in the Bases for Technical Specification B 3.8.1. Additionally, periodic testing of all diesel generators is accomplished at intervals specified in the Technical Specifications (TS) which are controlled under the Surveillance Frequency Control Program (SFCP).

8.3.1.2.3 Service Environment

In addition to the effects of operation in normal service environment, all components of the emergency portion of the auxiliary ac power system essential to limiting the consequences of a LOCA are designed to operate in the postaccident environment expected in the area in which they are located. See Section 3.11 for discussion of environmental design and analysis of safety-related (Class 1E) electrical components for postaccident conditions. Section 3.11 also identifies safety-related equipment that must operate in a harsh environment and provides information on the conditions under which the equipment must operate. Section 3.10 identifies Seismic Category I electrical equipment and describes the criteria, design and testing of electrical equipment in compliance with IEEE 344-1971 for seismic qualification.

All cables for Class 1E systems and associated circuits are moisture and radiation resistant, are highly flame retardant and emit negligible amounts of corrosive gas when subject to heat or flame. Certified proof tests are performed on cable samples by thermal aging, to prove radiation resistance by exposure of aged specimen to integrated dosage of 5×10^7 rads, mechanical/electrical tests of previously exposed cable to 340°F and 45 psig steam, to prove flame resistance by the vertical tray, 70,000-Btu/hr flame test for 8 minutes, minimum, and finally, to show acceptable levels of gas by an acid gas generation test. See Section 8.3.3.1.

8.3.1.2.4 Offsite Power System Degradation

8.3.1.2.4.1 General. The CGS auxiliary ac power system is normally supplied by the 25-kV plant main generator (via the normal auxiliary transformers TR-N1 and TR-N2). During this time, the main generating unit is generally synchronized with and furnishes power to the 500-kV BPA grid via the plant main transformer.

During plant startup, shutdown, or sudden loss of the main generating unit, the 230-kV startup offsite power source is capable of supplying all required, steady state, plant auxiliary ac power system loads via the startup auxiliary transformer TR-S.

In the event that both the 25-kV normal source and the 230-kV startup source are unavailable, the 115-kV backup offsite power source supplies (via the backup auxiliary transformer TR-B) the Divisions 1 and 2 Class 1E loads required for safe shutdown.

See Section 8.2 for a detailed description of the CGS offsite power sources. See Section 8.3.1 for a detailed description of the auxiliary ac power system.

Based on previous industry operating experience with BWRs of a similar type, it is estimated that CGS plant availability will be approximately 0.75. When the plant is shut down, auxiliary ac power system loads are supplied by either the 230-kV startup offsite power source, the 115-kV offsite power source, or the 500-kV backfeed with the generator links removed.

8.3.1.2.4.2 Class 1E Auxiliary Alternating Current Distribution System Voltages.

8.3.1.2.4.2.1 Voltage Criteria. The auxiliary ac distribution system is designed to maintain system voltages within acceptable ranges at all levels of the plant distribution system, whether incoming supply is from the plant main generator or from the BPA grid system. Table 8.3-7 indicates the acceptable voltage ranges for the major Class 1E portions of the system, based upon consideration of motor-operating voltage ranges as determining system voltage acceptability. Table 8.3-4 indicates the voltage range over which Class 1E and non-Class 1E motors and motor starters are capable of operating.

Load tap changing capability is not provided on the power transformers utilized at CGS. All power transformers are furnished with no-load type tap changers on the primary side only.

8.3.1.2.4.2.2 Expected Voltages - 25-kV Main Generating Unit Supply. Main generating unit output voltage range is 23.8 kV to 26.3 kV, corresponding to an output voltage variation of ±5% of generator nameplate voltage. This range is based upon the use of a unit automatic voltage regulator designed to maintain generator output voltage between 0.95 pu and 1.05 pu.

The expected voltages in the Class 1E portions of the auxiliary ac distribution system, when supplied from the 25-kV plant main generating unit, are within the acceptable ranges of Tables 8.3-7 and 8.3-4.

Higher bus voltages are expected during shutdown light load conditions when ac distribution system is supplied from the 230-kV grid system.

8.3.1.2.4.2.3 Expected Voltages - 230-kV Grid Supply. The preferred offsite power source grid system voltage has a nominal rating of 230 kV. Minimum and maximum loaded values of grid voltage are 230 kV and 242 kV, respectively.

The expected voltages in the Class 1E portions of the auxiliary ac distribution system, when supplied from the 230-kV grid system, are within the acceptable ranges of Tables 8.3-7 and 8.3-4.

8.3.1.2.4.2.4 Expected Voltages - 115 kV Grid Supply. The backup offsite power source grid voltage has a nominal rating of 115 kV. Minimum and maximum loaded values of grid voltage are 115 kV and 121 kV, respectively.

The expected voltages in the Class 1E portions of the auxiliary ac distribution system, when supplied from 115-kV grid system, are within the acceptable ranges of Tables 8.3-7 and 8.3-4.

8.3.1.2.4.3 Class 1E Auxiliary Alternating Current Distribution System Voltage Sensing.

8.3.1.2.4.3.1 Primary Undervoltage Sensing. High speed, instantaneous undervoltage relays located in each of the 4.16-kV Class 1E switchgear units are utilized for detection of undervoltage at the switchgear buses.

The trip setpoint of each relay is set at 2870 V, corresponding to 69% of nominal bus voltage. Trip setpoint selection is based upon overriding minimum bus voltage during motor starting, with an allowance (10% below minimum motor starting voltage) to compensate for relay setting tolerances.

8.3.1.2.4.3.2 Secondary Undervoltage Sensing. Static Class 1E undervoltage relays with definite time delay located in each of the redundant 4.16-kV Class 1E Divisions 1 and 2 switchgear units are utilized for detection of sustained degraded voltage in the offsite power system. This protection scheme is designed to compliment the primary undervoltage scheme described above, by ensuring ESF motors fed from critical 480-V and 4160-V buses do not operate continuously connected to a degraded voltage source exceeding the motor (NEMA MG-1) design tolerance of $\pm$10% of nameplate, unless a deviation has been analyzed and documented (see Table 8.3-4).

The trip setpoint selection is normally based upon ensuring 90% of motor nominal voltage at the motor terminals, including allowance for feeder (and branch circuit) voltage drop and relay error tolerances. Any deviations are analyzed and documented (see Table 8.3-4). The relay automatically resets when the bus voltage exceeds the 1% differential between dropout (trip) and pickup (reset) settings.

The approximately 8-sec time delay will override the voltage dips associated with motor starting loads under normal operating practice and under normal source voltage.

The relays operate to isolate the degraded source and initiate the sequence of events to select the next available source. Circuit design precludes spurious voltage loss signal and allows for testing of the individual relay, one at a time, without disrupting the protective function.

During a LOCA, the output breaker close permissive for Divisions 1 and 2 diesel generators is satisfied 12 sec after the sustained degraded grid voltage condition is sensed at the emergency bus. This time delay is derived from the approximately 8-sec delay prior to the offsite breaker trip plus an approximately 4-sec delay. The above time delay is acceptable since, during a concurrent LOCA, the ECCS coolant injection time requirements as specified in Table 6.3-2c are met.

See Figures 8.3-1 and 8.3-2 for the logic diagrams of Divisions 1 and 2 secondary undervoltage protection and nominal time delay setpoints.

Similar voltage trip and time delay setpoints are used for the Division 3 secondary undervoltage relays. For Division 3, however, the diesel generator output breaker close permissive is satisfied approximately 9 sec after a coincident occurrence of a LOCA and a degraded grid condition. This time delay is equal to the approximately 8-sec delay prior to the offsite breaker trip plus an approximately 1-sec delay.

See Figure 8.3-32 for the Division 3 secondary undervoltage protection logic diagram and nominal time delay setpoints. The HPCS injection time requirement of Table 6.3-2c are also met.

Assume that during an accident when the emergency motor loads are running a subsequent degradation of offsite grid voltage occurs assuming further that the degraded voltage is anywhere between 69% and approximately 90% of the bus nominal voltage. The following analysis shows that the motor loads remain adequately protected and ready for a restart as soon as the power supply has been restored to normal. Under the above condition the emergency motors would be exposed to terminal voltage between 72% and 90% (approximately) of nameplate value. For terminal voltages between 80% (or 75% for the HPCS pump motor) and 90%, the motor will continue to run overloaded up to 125% (133% for the HPCS pump motor) of full load current. The motors can safely carry this overload for 8 sec. For voltages less

than 80% (75% for the HPCS pump motor), the motor torque could be less than the load torque, thus resulting in deceleration and eventual stalling.

At rated voltage and cold start conditions the motors are protected against locked rotor currents by a relay which trips and locks out within 15 sec. However, for a degraded voltage condition which could cause motor stalling, the secondary undervoltage relaying is set to trip the offsite source breaker approximately 8 sec after the undervoltage condition develops and the locked rotor protective relay will not trip. Load shedding after 8 sec trips the motors without locking them out. A subsequent motor restart when power supply is restored will expose the motor to locked rotor currents for another 5 sec as a maximum (based on maximum motor starting time of 5 sec at rated voltage). The total stall time is therefore equal to approximately 13 sec. This is less than the designed motor safe stall time of 14 sec at 80°C winding temperature. Since the voltage at the motor is assumed to be less than 90% of the rated value, resulting in lower locked rotor currents it follows that there is sufficient margin between the motor stall time under the above worst case conditions and the designed motor safe stall time.

It should be noted that critical (Class 1E) plant controls and vital instrumentation are supplied by redundant (Divisions 1 and 2) divisions of the 120/240-V ac Class 1E uninterruptible power supply (UPS) system. This system supplies loads via inverters with static transfer to an alternate AC supply in case of circuit faults or loss of inverter voltage. The on-line static inverter provides regulated output voltage within ±2% of nominal to the vital instrument bus loads. From rated output to overcurrent overloads up to approximately 125% of the continuous rating the inverter will continue to maintain a nominal voltage. When the ferro-resonant inverter experiences higher overloads it will go into current limit mode at which time output voltage from the inverter will begin to collapse. At 120% current overload the inverter will engage the static transfer feature from the inverter to the alternate AC supply before the inverter goes into final current limit and before voltage supply drops off so the voltage supply to the vital instrument bus load remains unaffected. This automatic transfer sensed as an inverter overload is inhibited when the alternate AC supply to the vital instrument bus is not available.

The alternate supply line voltage is regulated within ±10% of normal in accordance with the NSSS vendor's requirements. A manual bypass switch is provided for maintenance of the inverter or static switch.

Table 8.3-8 indicates the various monitors and alarms (annunciators/computer) provided to monitor system voltages.

8.3.1.3 Physical Identification of Safety-Related (Class 1E) Equipment

Each safety-related electrical component or cable is tagged with an identification number. In addition, a color-coded separation marker is provided along with the identification number which indicates the assignment to one of seven divisions (Division 1, 2, 3, 4, 5, 6, or 7). This division marker is inscribed with color-coded characters on a color-coded background as

described in Reference 8.3-2, which was submitted to the NRC. Assignment of equipment to the seven divisions is given in Reference 8.3-2.

Cable routing information is provided in Reference 8.3-2. This illustrates the computer program used for identification and routing of cables in trays. Routing information for cables in conduits is provided in raceway layout drawings. Reference 8.3-2 also contains sample cable routing schedules. Actual cable tray drawings for the diesel generator, reactor and radwaste/control buildings are shown in Figures 8.3-6, 8.3-25 through 8.3-30, and 8.3-33 through 8.3-38.

A list of Class 1E components and equipment is provided to facilitate identification of safety-related components and their circuits.

8.3.1.3.1 Class 1E Raceways, Cables, Equipment (Panels and Racks), and Enclosures

See Reference 8.3-2.

In addition to the discussion provided in Reference 8.3-2, circuits that have been upgraded from non-Class 1E to Class 1E and are already installed in raceways are identified with a Class 1E color coded marker at terminations, pull boxes, and entrances and exits to raceways. Upgraded cables are routed in Class 1E raceways. Cable installation records are reviewed to provide assurance that these cables are routed in Class 1E raceways and installed to Class 1E requirements (cable installation parameters). Otherwise, megger and continuity tests shall be performed, termination and routing reinspected to Class 1E requirements, and documentation prepared verifying the upgrade.

8.3.1.3.2 Prime and Associated by Proximity Circuit Raceways, Cables, Equipment, and Enclosures

See Reference 8.3-2.

8.3.1.3.3 Non-Class 1E Raceways, Cables, Equipment, and Enclosures

See Reference 8.3-2.

8.3.1.4 Independence of Redundant Systems

The physical independence of electrical systems complies with the requirements of IEEE 279-1971, IEEE 308-1974 (IEEE 308-1971 for the HPCS system), GDC 3 and 17, and Regulatory Guide 1.6, Revision 0. See Table 7.1-3 for a matrix of the applicability of codes and standards to the various safety-related systems. The physical separation of mechanical equipment including piping and instrumentation tubing is not included in this section. However, sufficient separation between redundant plant protection system equipment is provided such that the capability of the protection systems to mitigate the consequences of any DBA and bring the reactor to a cold shutdown condition is ensured. See Section 3.1.

8.3.1.4.1 Definitions

See Reference 8.3-2.

8.3.1.4.2 General Separation Criteria

The criteria in this section provides sufficient physical independence of Class 1E electrical systems so safety-related systems can perform their engineered safety function during any DBA and bring the reactor to a cold shutdown condition.

8.3.1.4.2.1 Cable Separation. Cable separation is achieved by segregating electrical circuits by voltage level and service it performs (such as power, control, or signal) by engineered system designations, by power supply and divisional separation categories, and by routing as described in Reference 8.3-2.

Power cables of different voltage ratings are routed in different cable trays except as follows: (1) common tray is permitted for 480 V, 120/208 V ac, 125 V and 250 V dc of compatible divisions, and (2) common tray is permitted for 4160-V and 6900-V power cables of compatible divisions; 480-V, 4160-V, and 6900-V power cables are not to be installed in cable trays in the spreading area beneath the control room. If a run through this area is unavoidable, the power cable is installed in conduit.

Power cables are installed in raceways separate from control cables and low level signal cables and where vertically stacked, the power cables are placed in the tray with the highest position in the tray tier. Stacking of multiple power trays are such that the voltage levels decrease sequentially from the top of the bottom tray in the stack.

In addition to the discussion provided in Reference 8.3-2, control circuits are low energy circuits for the following reasons: the largest protective devices for control circuit fuses (35 amp) are found only in 4-kV switchgear breaker trip circuits; the majority of the control circuits are intermittent with circuit protective device having 5- to 20-amp ratings; the circuit protective device ratings are chosen to accept initial momentary in-rush currents; and the actual circuit normal operating current is generally in the 0.1 to 2 amp range.

In addition to the discussion provided in Reference 8.3-2, associated cables are procured to the same requirements as Class 1E. When not bulk pulled with Class 1E cables they are installed to the same installation parameters as Class 1E cables except that verification documentation for sidewall pressure, pull tension, and minimum bend radius may not be available. Associated cables comply with at least one of the following requirements:

a. Where installed in cable trays, raceways, and PGCC floor ducts,

   1. They are uniquely identified as associated or as Class 1E circuits and remain with, or are physically separated the same as, those Class 1E circuits with which they are associated;

2. They are identified in accordance with item 1 above from the Class 1E equipment up to and including an isolation device. Beyond the isolation device, such a circuit is not considered an associated circuit and does not conform to item 1 above, provided it does not again become associated with a Class 1E system; or

3. They are analyzed or tested to demonstrate that Class 1E circuits are not degraded below an acceptable level.

b. Where installed in enclosures and equipment, external to trays, raceways, and PGCC floor ducts (item a above), associated circuits which become associated due to sharing of enclosures with Class 1E circuits are not separated; they are analyzed to show that the Class 1E circuits are not degraded below an acceptable level.

In addition to the discussion provided in Reference 8.3-2, non-Class 1E (non-associated) cable numbers are prefixed by "A" or "B" and are routed in non-Class 1E raceways. They are procured to the same requirements and installed to the same installation parameters as Class 1E cables, except for a few vendor supplied cables designated in the computerized cable schedule as Type Z.

The isolation of non-Class 1E circuits from Class 1E circuits or associated circuits is achieved by complying with at least one of the following requirements:

a. Non-Class 1E circuits are physically separated from Class 1E circuits and associated circuits by the minimum separation requirements specified for redundant Class 1E divisions or they become associated circuits; or

b. Non-Class 1E circuits are electrically isolated from Class 1E circuits and associated circuits by the use of isolation devices, shielding and wiring techniques, physical separation, or an appropriate combination, or they become associated circuits; or

c. The effects of lesser separation or the absence of isolation between the non-Class 1E circuits and the Class 1E circuits or associated circuits are analyzed to demonstrate that Class 1E circuits are not degraded below an acceptable level or they become associated circuits; or

d. Non-Class 1E low energy (instrumentation and control) circuits are not required to be physically separated or isolated from associated circuits provided: (1) the non-Class 1E circuits are not routed with associated cables of a redundant division; or (2) they are analyzed to demonstrate that Class 1E circuits are not

degraded below an acceptable level. As part of the analysis, consideration is given to potential energy and identification of the circuits involved.

Since power circuits are not considered to be low energy, the analysis applied to non-Class 1E-to-Class 1E/associated separation described above does not totally apply. Non-Class 1E power cables routed in open raceways (trays) dedicated to non-Class 1E power cables are physically separated from all Class 1E/associated cable trays with the same requirements specified for physical separation of redundant Class 1E cable trays. For other than open raceways, additional information is provided in Section 8.3.1.4.4.

8.3.1.4.2.2 Cable Routing. In addition to the discussion provided in Reference 8.3-2, the routing of cables in raceways is in accordance with the following:

a. Cable splices are not normally designed into the cable system (except for cables entering containment at electrical penetrations). If required, they are not permitted in cable trays, but are made in conduit fittings or metallic electrical boxes;

b. All cabling for use in Class 1E systems, and for associated circuits, is designed to resist combustion as described in Section 8.3.3. Cable flame retardance characteristics and routing arrangement eliminate (insofar as practical) the potential for fire damage to cables and the spread of fire between redundant divisions;

c. Power cable ampacities are based on NEMA publication number WC51-1975 for cables routed in trays and ICEA publications P46-426 for cables routed in conduit including underground conduits (ducts). Additional cable ampacity derating factors have been used for fire rated barrier material on raceways, covered trays, conduit clusters, and ambient air temperatures above 40°C. Power trays can be filled to 40% of the cross-sectional area, which is based on a 4-in. deep tray. The cable ampacity is determined from the calculated cable depth;

d. In general, hazardous areas are avoided to limit circuit failures to failures or faults internal to the electric equipment or cables. Where hazardous areas cannot be avoided an analysis is provided;

e. In the cable spreading and main control room areas, 120-V ac (or below) and 125-V dc (or below) branch circuits from distribution panels to the control boards and terminal cabinets are routed in conduit. The only power cables in these areas are the 460-V ac feeders to the control room emergency lighting panel step-down transformers; these cables are routed in conduit; and

f. In addition to the discussion provided in Reference 8.3-2, underground cables for Class 1E systems comply with GDC 1, 2, 3, 4, and 17, as well as IEEE 308-1974 and the following:

1. Underground cables between manholes are run in concrete encased plastic ducts for non-Class 1E systems and in reinforced concrete encased steel ducts for Class 1E systems; and

2. Underground ducts for Class 1E cables are Quality Class I and Seismic Category I. Cables are fire retardant type, and where splices are necessary in manholes because of the length of pull, waterproofing is used.

8.3.1.4.2.3 Physical Separation Criteria. Physical separation as a protection against single failures of redundant Class 1E power, control, and instrumentation systems (Divisions 1 to 7) is provided. Where the use of separate safety class structures is not feasible, spatial separation is the preferred method of achieving separation. Methods of maintaining physical separation are as follows:

a. Non-safety-related equipment, components, or piping are not installed above safety equipment. Where installation above safety equipment cannot be avoided, the supports are installed to Seismic Category I requirements or analysis is made to demonstrate that failure will not impair the overall function of the safety system;

b. Where Class 1E equipment or cabling is located or routed in areas where there is a potential for internally generated missiles, pipe whip, or flood, a protective barrier is provided or an analysis is performed to ensure that a loss of plant capability to mitigate the consequences of an accident and/or to bring it to a safe shutdown condition cannot occur;

c. Fire-rated fire stops, fire barriers, and/or electrical separation barriers are provided between redundant electrical equipment including raceways whenever the physical separation distances required in Reference 8.3-2, are not met. Acceptable barriers are noted in the above referenced document.

Raceways penetrating fire-rated walls, floors, or ceilings are sealed with a fire-rated fire stop; and

d. Raceways penetrating pressure boundaries are sealed to maintain the pressure rating. See Appendix F for compliance with 10 CFR 50 Appendix R.

8.3.1.4.2.4 Administrative Controls for Ensuring Separation Criteria. The quality assurance procedures described in IEEE 336-1971 are employed during the design and installation of the cable system to ensure compliance with the design criteria. Design drawings and cable lists are prepared, reviewed, and approved for installations. Each cable and raceway is identified in the computer program, and the identification includes the applicable separation classification. Cable routing programs ensure that cables or particular separation groups are routed through the appropriate raceways. Cables are installed in accordance with written procedures which specify quality requirements, inspection, and documentation requirements for all cable pulls.

In some cases it has been necessary to upgrade certain cables from a non-Class 1E status to either a Class 1E or prime cable status. Postinstallation procedures exist to upgrade such cables. These cables are evaluated on an individual basis and allowed to deviate from the normal installation procedures.

The following briefly describes the upgrading procedure for various categories of cables:

a. Non-Class 1E cables upgraded to Class 1E

1. Cable identification tags are revised at all terminations, pullpoints, entrance, and exits to raceways; and

2. Cable installation records are reviewed to provide assurance that these cables are routed in Class 1E raceways and installed to Class 1E requirements. Otherwise, megger and continuity tests are performed, termination and routing is reinspected to Class 1E requirements, and documentation is prepared verifying the upgrade;

b. Non-Class 1E cables upgraded to prime cables

1. Same upgrade as a.1 above; and

2. Routing and termination is reinspected to Class 1E requirements and documentation is prepared verifying the upgrade.

8.3.1.4.2.5 Separation For Fail-Safe Systems. See Reference 8.3-2.

8.3.1.4.2.6 Equipment and Circuits Requiring Separation. Equipment and circuits requiring separation are identified on documents and drawings in a distinctive manner.

8.3.1.4.2.7 Compliance to Regulatory Guide 1.75, Revision 1. This regulatory guide is not applicable to CGS since the CGS Construction Permit date precedes the regulatory guide issue date. However, the actual plant design does provide a technically acceptable alternative to the

requirements of the guide. Independence between equipment and circuits of redundant Class 1E electrical divisions is provided to satisfy 10 CFR 50 requirements.

Deviations to the guide are listed below:

a. Paragraph C.1 of Regulatory Guide 1.75, Revision 1, excludes the use of fault current actuated circuit interrupting devices as an isolation device;

CGS uses overcurrent actuated circuit breakers and fuses. Justification for this deviation is provided in Sections 8.3.1.2.1.1 and 8.3.2.2.1.1;

b. Paragraph 4.5 of IEEE 384, as endorsed by Regulatory Guide 1.75, Revision 1, Paragraph C.4, states that associated circuits should meet all the same requirements as those placed on Class 1E circuits. Some CGS cables, which are associated by the IEEE 384 definitions may be partially routed in non-Class 1E raceways as well as Class 1E raceways. These cables, when routed in the non-Class 1E trays, are not considered associated based on analysis. They meet all the pull/termination documentation requirements placed on Class 1E cables when they are bulk pulled with Class 1E cables. When they are not bulk pulled with Class 1E cables, they are installed to the same installation parameters as Class 1E by procedure, except that verification documentation for sidewall pressure, pulling tension, and minimum bend radius may not be available;

c. Paragraphs 4.6.1 and 4.6.2 of IEEE 384 as endorsed by Regulatory Guide 1.75, Revision 1, require that non-Class 1E circuits be separated from Class 1E/ associated circuits by the same minimum separation required between redundant Class 1E circuits, unless the non-Class 1E circuits are classified as associated. As discussed in (b) above, some circuits that would be classified as “associated” by the IEEE 384 definition are partially routed in non-Class 1E raceways and, therefore, are not separated from non-Class 1E circuits. Class 1E physical separation is not necessarily maintained between the non-Class 1E and Class 1E raceways, except for power trays as noted in Section 8.3.1.4.2.1.

Inside enclosures, non-Class 1E circuits are not separated from Class 1E circuits and thus would be termed “associated” by Regulatory Guide 1.75. These circuits are Category 1C and treated as non-Class 1E, except for prime circuits which do meet Class 1E separation requirements. Justification for this deviation is described in Section 8.3.1.4.4.1.3;

d. Paragraphs 5.1.3 and 5.1.4 of IEEE 384 as endorsed by Regulatory Guide 1.75, Revision 1, required a minimum separation of 1-in. between enclosed raceways of redundant divisions. This requirement is not met in CGS though the raceways are not physically touching. Justification for this deviation is based on

Wyle Lab tests No. 56719 and No. 56669 for the Susquehanna Steam Electric Station. These tests demonstrate that rigid steel conduits and some specific heat-resistant sleeving materials qualify as barriers against potential damage due to an electrical fault in one of the circuits requiring separation; and

e. Paragraph 5.6.3 of IEEE 384 as endorsed by Regulatory Guide 1.75, Revision 1, requires identification of internal wiring to distinguish between redundant Class 1E wiring and between Class 1E and non-Class 1E wiring. At CGS the panel or enclosure is assigned to a given Class 1E division if the majority of the contained wiring belongs to this division. Circuits compatible with this division and non-Class 1E wiring in the panel are not identified. However, if Class 1E wiring for a redundant division or wiring associated by connection to the redundant division are also present in the same panel, then these wires are identified by color coded tags as shown in Reference 8.3-2.

8.3.1.4.3 Physical And Spatial Separation Details

See Reference 8.3-2.

Structures are designed to provide protection from the effects of wind loadings, tornadoes, external missiles, flooding, and earthquakes. All Class 1E equipment, components, and raceways, and their supports, are designed to Seismic Category I requirements (see Section 3.10 for discussion of seismic capability).

8.3.1.4.3.1 Standby Generating Units and Auxiliaries. The standby diesel generator sets are located in separate equipment rooms in the diesel generator building. Auxiliaries and local controls for each diesel generator set, separated the same as the units themselves, are also located in this building. Each unit is provided with an independent air supply.

8.3.1.4.3.2 Direct Current Power Systems. The Class 1E dc power systems include batteries, chargers, and associated equipment. Equipment for redundant systems is located in separate rooms. For further description see Section 8.3.2.

8.3.1.4.3.3 Switchgear. Separate electrical equipment rooms are provided in the radwaste/ control building for redundant 4.16-kV and 480-V Class 1E Divisions 1 and 2 switchgear as shown in Figure 1.2-14. The Division 3 4.16-kV Class 1E switchgear and 480-V Class 1E MCCs are located in the diesel generator building.

8.3.1.4.3.4 Motor Control Centers and Distribution Panels. The MCCs, distribution panels, and miscellaneous electrical equipment of redundant divisions are either spatially separated or are located in separate rooms of safety class structures.

8.3.1.4.3.5 Containment Electrical Penetrations. There are 24 electrical penetrations which provide electrical power to equipment inside the primary containment as described in Section 3.8.6.1.4. Redundant Class 1E circuits for loads located inside primary containment are routed through separate penetrations with the exception of HPCS cabling. HPCS (Division 3) cabling is routed through a Division 2 penetration in a separate sleeve.

8.3.1.4.3.6 Power Generation Control Complex. The PGCC is defined in Reference 8.3-2. PGCC is a modular design concept which allows the fabrication, installation, and testing in a quality controlled environment in accordance with the requirements of 10 CFR 50, Appendix B (see Figures 8.3-39 and 8.3-40). The PGCC forms an interface between the field cables and the control panels and consists of three different subassemblies: termination cabinets (T/C), modular floor sections, and cable assemblies.

8.3.1.4.3.6.1 Termination Cabinets. Termination cabinets provide the interface with the field cables (see Figures 8.3-41 and 8.3-42) and consists of three different subassemblies: termination modules, connector plates (including connectors), and junction boxes for flexible conduit terminations (see Figure 8.3-43). The T/C enclosures are constructed of 3/16-in. steel plate welded to 3/8-in. steel corner angles and use swing and stationary steel barriers for fire separation between redundant system cables. Seismic and fire tests have been conducted on these units as reported in the licensing report NEDO-10466A (Reference 8.3-3). The fire tests demonstrated the adequacy of the stationary steel barriers. In addition to the overall structural fire protection design of the PGCC (see Figure 8.3-44), products of combustion detectors are located at the top of each termination cabinet. These detectors are monitored on each module fire control panel and on the main control room fire control panel. Additional defense in depth measures include the installation of fire stops and penetration seals at all cable entrances to the cabinet, and the use of fire retardant materials, and the use of unlocked cabinet doors to allow rapid use of hand-held extinguishers (see Figure 8.3-45).

8.3.1.4.3.6.2 Modular Floor Sections. The modular floor section is a latticed floor constructed of steel "I" beams and rectangular steel tubes forming longitudinal and lateral ducts. These ducts interconnect the control panel modules (which are bolted on the modular floor section) and the termination cabinet (see Figures 8.3-40 and 8.3-46). The network, including transition and extension ducts, provides divisional separation with the use of vertical and/or horizontal barriers and fire stops. Miniducts (Figure 8.3-47) are for divisional separation within the longitudinal ducts. Cables in the miniducts are routed in flexible metallic conduit or wrapped in Haveg Siltemp tape.

When it is necessary to route cables between PGCC sections which are not directly connected by floor ducts, it is permissible to route these cables through the cable spreading room; see Reference 8.3-2.

Fire protection is provided in accordance with the PGCC Licensing Topical Report, NEDO-10466A (Reference 8.3-3) and Appendix F. Products of combustion and thermal

detectors are provided in the floor section longitudinal ducts. These detectors are monitored on the respective PGCC module fire control panel and on the main control room fire control panel where zoned alarms are grouped by floor section. Products of combustion detectors will prealarm to allow a manual response through quickly removable floor plates. Thermal detectors will automatically release Halon 1301 through a distribution system into each of the floor sections longitudinal cable ducts. Fire stops and penetration seals are located in the ducts that access the termination cabling and in the ducts that access the control panels (see Figure 8.3-48). Floor plates consist of an aluminum honeycomb core, 1-1/16 in. thick.

8.3.1.4.3.6.3 Power Generation Control Complex Cable Assembly and Routing. The cable assembly within the PGCC is designed around the following variables: engineered system designation, circuit signal classification, PGCC separation classification based on power supply, and finally, the origination/destination which provides the routing and length (see Figure 8.3-49). (See Reference 8.3-2.) Each PGCC cable is precut, assembled (with lugs and connectors at either end as required), and installed in the panel/floor module shipping section. Special cable and routing requirements are identified in Reference 8.3-2. The cable jacket and conductor insulation for the cables within the PGCC is either Raychem Flamtrol, General Electric Vulkene/Geoprene, Teflon, or Tefzel. The fire suppression system has been provided to limit a cable fire and resulting offgasing/smoke.

Cable routing consists of two categories: field interface terminations (FITS) and system interface terminations (SITS). FITS cables are routed between termination cabinets and PGCC control panels, while SITS cables are routed between PGCC control panels and do not interface with balance-of-plant (BOP) field cable (see Figure 8.3-39).

8.3.1.4.3.7 Separation Within Enclosures and Equipment. See Reference 8.3-2.

Within equipment and enclosures it may be necessary for a single device such as a relay to be connected to wiring from redundant safety divisions. In such cases the intruding division wiring is routed immediately away from the device to attain the required 6-in. separation or to the extent where a barrier can be installed.

Where relays are used for isolation coil-to-contact separation is provided except as described below for fail-safe circuits. General Electric types HMA, HFA, and CR105, and Agastat type GP relays are used. The relays are used for 125-V dc or less applications. The justification for this type configuration is the following:

Contact-to-contact separation between redundant divisions within relay isolation devices is acceptable when utilized within fail-safe system (RPS and containment isolation) logic. Justification is as follows:

a. Logic circuits are fail-safe, i.e., loss of power from faults results in safety system actuation;

b. Logic is arranged in a one-out-of-two twice network such that contacts utilized in redundant logics are reversed in order in each logic. This arrangement allows the logic to always function in a fail-safe manner irrespective of hot shorts or ground fault combinations;

c. Intruder circuits to the relay contacts are separated from residing wiring by 6 in. or an approved barrier which is installed, as practicable, between redundant division wiring as near to the device as possible;

d. The circuits are all control circuits which are low energy;

e. Wire insulation is fire retardant complying with the requirements of IEEE 383-1974 or equivalent;

f. Each circuit is provided with Class 1E overcurrent protective devices to isolate faults;

g. These circuits are not allowed to bridge directly between redundant Class 1E raceways;

h. Fire loading inside panels is a minimum; and

i. Wire insulation within these relays is rated at 600-V minimum Type Class A or H while the control circuit voltage carried by this wiring is 125-V dc maximum.

As described in Reference 8.3-2, within enclosures/equipment it is acceptable to have secondary bridging between redundant division wiring by non-Class 1E control and instrumentation (low energy). Wiring secondary bridging is not allowed by non-Class 1E power cables unless supported by analysis. The following analysis is provided to justify the power cable secondary bridge(s) which exist within the CGS design:

a. Power cables upstream of the Class 1E 4160-V ac buses are part of the offsite power source scheme and are exempted from the bridging requirement; and

b. A single 6900-V ac circuit from the ASD providing power to the reactor recirculation pump(s) is routed between a Division 1 and a Division 2 circuit breaker enclosure and comes in proximity to both Divisions 1 and 2 breaker control 125-V dc circuits. These breakers are provided to ensure that the reactor recirculation pump(s) will trip when a main turbine generator trip occurs. This ensures adequate reactivity shutdown margin at control rod end of cycle. These breakers are Class 1E but not required to respond to a LOCA or a high-energy line break (HELB). Each control circuit is located in a separate and

independent cabinet and protected by Class 1E protective devices (fuses). Any faults occurring in the 6900-V ac circuits will be cleared by the overcurrent trips provided with these Class 1E circuit breakers.

8.3.1.4.3.8 Spatial Separation Between Raceways. See Reference 8.3-2.

8.3.1.4.3.9 Spatial Separation of 120/240 VAC Critical (Class 1E) Instrument Power System.

Redundant Division 1 and Division 2 instrument power systems, with separate inverters and static switches are located in separate rooms in the Radwaste/Control building vital island (seismic category 1 structure) supplying power to separate distribution panels E-PP-7AA (and E-PP-8AA) located on opposite sides of the Main Control Room.

8.3.1.4.4 Associated Circuit Analysis

Non-Class 1E control and instrumentation cables as discussed in Reference 8.3-2 illustrates the various circuit configurations that result in associated circuits within the designed cable and raceway systems. These non-Class 1E cables which become associated by connection or proximity to a Class 1E circuit are representative of the definition of associated circuits in Reference 8.3-2. Associated cables described in Reference 8.3-2 are routed in compatible divisional trays. These cables are uniquely identified and while routed with Class 1E cables are physically separated the same as those Class 1E circuits with which they are associated except inside enclosures.

8.3.1.4.4.1 Categories of Associated Circuits Treated as Non-Class 1E. The following categories of circuits are treated as non-Class 1E circuits. Justification is provided in Sections 8.3.1.4.4.1.1 to 8.3.1.4.4.1.8.

Category 1A: Non-Class 1E instrumentation and control cables/wires that are not supplied Class 1E power and are routed in non-Class 1E raceways, but have a continuing section in Class 1E raceways or enclosures. See Figure 8.3-50.

Category 1B: Non-Class 1E instrumentation and control cables/wires that are supplied Class 1E power and are routed in non-Class 1E raceways, but have a continuing section in Class 1E raceways or enclosures. See Figure 8.3-50.

Category 1C: Non-Class 1E instrumentation and control cables/wires that are not supplied Class 1E power, but are associated by proximity inside an enclosure. See Figure 8.3-50.

Category 2A: Non-Class 1E power cables/wires that are not supplied Class 1E power and are routed in non-Class 1E raceways, but have a continuing section in Class 1E raceways or enclosures. See Figure 8.3-50.

Category 2B:	Non-Class 1E power cables/wires that are connected to Class 1E power and are routed in non-Class 1E raceways, but have a continuing section in Class 1E raceways or enclosures. See Figure 8.3-50.
Category 3A:	Non-Class 1E instrumentation circuits that are connected to Class 1E circuits and utilize current limiting isolation devices. See Figure 8.3-50.
Category 3B:	Non-Class 1E power cables/wires that are connected to Class 1E power through a series of two Class 1E circuit breakers or fuses.
Category 3C:	Non-Class 1E power cables/wires that are supplied Class 1E power through other than two Class 1E isolation devices.

8.3.1.4.4.1.1 Analysis for Category 1A Non-Class 1E Circuits. The postulated events for this category of non-Class 1E instrumentation and control cables (non-Class 1E powered, but a continuing section associated by proximity with Class 1E cables/wires) are mechanical, structural, or electrical failures in the non-Class 1E raceway or equipment during seismic or other degrading events, e.g., missiles. Failure of non-Class 1E raceways and equipment may result in short circuits manifesting as overcurrents in the non-Class 1E cable section routed with Class 1E cables. Class 1E cables can only be effected by these failures if circuit protective devices in the non-Class 1E circuits fail to clear the short circuit and sufficient electrical energy exists to cause localized fires or cable insulation failures of Class 1E cables in the Class 1E raceway sections. This condition must occur simultaneously in two redundant division raceways and involve cables having redundant safety functions before plant safety is degraded. The following design features are provided to demonstrate that even with the unlikely events listed above, the effects on safety-related systems are minimized:

a. Overcurrent protective devices (including current limiting) are provided to isolate the cables or wires carrying abnormal currents and limit the effects on the Class 1E cables. In many cases non-Class 1E circuits routed with Class 1E circuits are protected by Class 1E overcurrent circuit protective devices. Those devices which are not Class 1E are highly reliable industrial grade equipment and, in general, are the same models as those which are qualified to Class 1E requirements;

b. The cable insulation and jacketing are fire retardant per IEEE 383-1974 or equivalent (see Section 8.3.3). Cable types are selected and routed according to their voltage level and application;

c. Fire stops are provided at or near the penetration of all fire-rated barriers, seismic gaps, and entrances to PGCC panels (including termination cabinets). Penetrations of pressure boundaries are sealed to maintain the pressure rating;

d. The cables routed in instrumentation and control raceways are low energy circuits and, as such localized fires or insulation failures are not expected;

e. Non-Class 1E cables are not allowed to bridge directly between redundant Class 1E raceways (except as allowed by Reference 8.3-2), thus preventing single cable faults from affecting two redundant Class 1E divisions; and

f. Pipe whip/jet impingement and missile studies provide structural barriers and/or restraints where required to prevent impact on redundant ESF required to mitigate the consequences of these events and safely shutdown the plant.

8.3.1.4.4.1.2 Analysis for Category 1B Non-Class 1E Circuits. This category of non-Class 1E circuits are instrumentation and control cables/wires that are supplied Class 1E power and have continuing sections routed in Class 1E raceways. The postulated failures and results are the same as those of Category 1A.

The following design features are provided to minimize the occurrence of this hazard.

a. Those listed under Category 1A-b, c, d, e, and f;

b. Class 1E coordinated overcurrent protective devices have been provided for all Category 1B non-Class 1E circuits to protect Class 1E buses from failures in non-Class 1E loads. These devices may be current-limiting fuses or circuit breakers. See Sections 8.3.1.2.1.1 and 8.3.2.2.1.1;

c. These circuits have been designated "prime" downstream of the circuit isolation device and adhere to the same physical separation requirements imposed on Class 1E circuits. Barriers used to comply with Class 1E separation requirements are provided between Division A and Division B raceways that contain redundant prime cables where design constraints prevent adequate physical separation of these raceways; and

d. Prime cables are separated the same as Class 1E cables within enclosures. An A prime 1 (A'1) cable is treated like a Division 1 cable and a B'2 cable is treated like a Division 2 cable.

8.3.1.4.4.1.3 Analysis for Category 1C Non-Class 1E Circuits. This category of non-Class 1E circuits are non-Class 1E powered instrumentation and control circuits that become associated by proximity to Class 1E cables inside enclosures. The analysis for Category 1C is similar to Category 1A. See Section 8.3.1.4.4.1.1.

8.3.1.4.4.1.4 Analysis for Category 2A Non-Class 1E Circuits. This category of non-Class 1E cables consists of power cables that are not supplied power from a Class 1E source and are routed in non-Class 1E raceways, but have a continuing section in Class 1E raceways or enclosures. The analysis for this category is identical to Category 1A except that these circuits are not low energy circuits and under short circuit conditions may provide

sufficient energy to cause localized cable failures in the Class 1E raceway sections. See Section 8.3.1.4.4.1.1. The justifications for these circuits are as follows:

a. Those as listed under Category 1A-a, b, c, e, and f;

b. A safe shutdown analysis was performed for this category of cables with the following assumptions, guidelines, and results:

   1. Non-Class 1E power cables analyzed were those which had a portion of their route with Class 1E power cables;

   2. A single non-Class 1E power cable was assumed to fault. A worst case single failure was assumed in addition to the failures of the Class 1E cables routed with the faulted non-Class 1E cable. Circuit overcurrent interrupting devices (fuses/breakers) were assumed to clear the fault without damage if the devices were Class 1E;

   3. Those non-Class 1E power cables whose failure resulted in the loss of ability to safely shutdown the plant were identified; and

   4. The identified cables were either rerouted or provided with Class 1E circuit protective devices.

c. The 480-V system is high resistance grounded to limit ground fault currents to 10 amps maximum (see Section 8.3.1.1.9). Phase-to-phase faults are not limited;

d. The 6.9-kV and 4.16-kV systems are high resistance grounded to limit ground fault currents to 12.5 amps maximum. Phase-to-phase faults are not limited;

e. For cable loading in power trays see Section 8.3.1.4.2.2;

f. Non-Class 1E 480-V combination motor starters in MCCs are provided current limiting fuses and thermal overload relays which are designed to operate at 1.25 times full load current;

g. Since power circuits are not considered to be low energy non-Class 1E power cables routed in open raceways (trays) dedicated to non-Class 1E power cables are physically separated from all Class 1E associated cable trays with the same requirements specified for physical separation of redundant Class 1E cable trays; and

h. Certain non-Class 1E loads which are normally supplied from a Class 1E source but have no useful postaccident function are shunt tripped from the Class 1E bus by providing a LOCA trip signal to a Class 1E breaker in the non-Class 1E circuit. Those loads that are not tripped are assumed to be energized and included in the appropriate bus loading calculation. See Section 8.3.1.4.4.1.7. This removes the potential for Class 1E circuit damage from failures in these non-Class 1E loads during and following these accidents.

8.3.1.4.4.1.5 Analysis for Category 2B Non-Class 1E Circuits. These circuits are non-Class 1E power cables that are supplied power from a Class 1E source, are routed in non-Class 1E raceways, and have a continuing section in Class 1E raceways or enclosures. Justification for these circuits are as follows:

a. Those listed under Category 2A, and
b. Those listed under Category 1B-b, c, and d.

8.3.1.4.4.1.6 Analysis for Category 3A Non-Class 1E Circuits. The cables in this category consist of data logging and display type instrumentation circuits such as inputs to the analog process computer. These circuits are low energy circuits that are connected to Class 1E signal circuits through current limiting resistance units or current limiting power supplies such that a fault in the non-Class 1E portion of the circuit does not affect operation of the Class 1E circuit. These circuits are not identified or separated as prime circuits downstream of the current limiting units. Downstream of the current limiting units these circuits are reviewed to ensure that direct bridging between redundant division raceways does not occur except as allowed by Reference 8.3-2. Additionally, the justifications for Category 1A apply.

8.3.1.4.4.1.7 Analysis for Category 3B Non-Class 1E Circuits. The non-Class 1E cables in this category are connected to Class 1E power supplies and supply power to important non-Class 1E loads such as: emergency lighting, obstruction lighting, main control room normal lighting, synchronization circuits, portions of the standby liquid control system, portions of the source range monitor (SRM) and intermediate range monitor (IRM) systems, TIP system feeders, meteorological tower supervisory, fire protection circuits, diesel generator building welding outlets, power panel E-PP-7AZ, power panel E-PP-8AZ, the UPS inverters (IN-1 and IN-4) breaker control circuits for accident tripped breakers RCC-CB-P/1A, RCC-CB-P/1B, RCC-CB-P/1C, ROA-CB-FN/1A, ROA-CB-FN/1B, REA-CB-FN/1A, REA-CB-FN/1B, and welding receptacles. To prevent failures in the non-Class 1E loads from effecting the Class 1E power supplies, two-series Class 1E circuit protective devices are provided for these circuits. Downstream of the circuit protective devices the circuits need not be identified or separated as Prime, but may be identified as non-Class 1E. As in Category 3A above, these circuits are reviewed to ensure that direct bridging between redundant division raceways does not occur. Additionally, justifications a, b, c, and f, of Category 1A apply.

8.3.1.4.4.1.8 Analysis for Category 3C Non-Class 1E Circuits. The non-Class 1E cables in this category connect to non-Class 1E loads to Class 1E power supplies by means other than two-series Class 1E isolation devices. Description and justification are as follows:

a. The TDAS UPS Inverter (IN-5) which supplies power to the non-Class 1E TDAS loads (computer, remote multiplexers, etc.) is connected to the Class 1E power supply through a single Class 1E circuit breaker and a cable which is identified and routed as Prime to the input of the non-Class 1E inverter. Downstream of the inverter these TDAS circuits are routed as non-Class 1E and not Prime. This design is justifiable since the TDAS Inverter has inherent design features which limit inverter output current. Current limiting is provided by multiple, inverter internal series circuit protective devices and an overcurrent sensing network which limits the unit output current to 125% of rated with a downstream fault;

b. The following normally open manual transfer switches connect alternate Class 1E power supplies to non-Class 1E buses whose downstream circuits are non-Class 1E.

1. Inverter IN-1 alternate supply is identified and routed as Prime to the transfer switch and as non-Class 1E downstream of the switch;

2. 480-V ac bus MC-8A-2C alternate power supply is identified and routed as Prime to the transfer switch; downstream circuits are routed is non-Class 1E; and

3. 480-V ac alternate supply from MC-7AA to the backup transformer for the cooling water cooling fan is identified and routed as Prime to the transfer switch; downstream the circuit is identified and routed as non-Class 1E.

Since the above described Prime circuits are isolated by manual transfer switches which are, by procedure normally open and thus assumed to be open during an accident, it is justifiable to allow downstream circuits to be identified and routed as non-Class 1E, and not Prime; and

c. The security system's critical power comes from a Class 1E source for reliability. The power supply is routed as Prime from a Class 1E circuit protective device at the Class 1E bus to a non-Class 1E bus, E-DP-SS/SL81 with two non-Class 1E breakers. Downstream of E-DP-SS/SL81, the cables are all non-Class 1E security circuits routed in security raceways that contain no Class 1E circuits. Similarly the Technical Support Center (TSC) receives its power supply from a Class 1E source for reliability. The power supply circuit

is routed as Prime from a Class 1E circuit protective device at the Class 1E bus to a non-Class 1E incoming breaker at the TSC MCC. Downstream of the TSC incoming breaker the circuits are identified and routed as non-Class 1E. In that the TSC received its power from a single Class 1E supply, the design serves, by itself, as a means of separation of TSC circuits from redundant division circuits. The routing and identification of the circuits downstream of the TSC incoming breaker need only comply with non-Class 1E separation criteria, i.e., no redundant division circuits are within the TSC. As in 3A above, these circuits are reviewed to ensure that direct bridging between redundant division raceways does not occur. Additionally, justifications a, b, c, and f of Category 1A apply.

8.3.1.4.4.2 Categories of Associated Circuits Treated as Class 1E. The following categories of associated circuits exist and are illustrated in Figure 8.3-51.

Category 4A: Associated instrumentation and control circuits that are connected to non-Class 1E power and routed in Class 1E raceways and/or enclosures and may have a continuing section in a non-Class 1E raceway (Category 1A).

Category 4B: Associated power circuits that are connected to non-Class 1E power and routed in Class 1E raceways and/or enclosures and may have a continuing section in a non-Class 1E raceway (Category 2A).

Category 4C: Associated instrumentation and control circuits that are supplied Class 1E power are routed in Class 1E raceways, are not isolated on accident signal, and may have a continuing section in a non-Class 1E raceway (Category 1B).

Category 4D: Associated power circuits that are connected to Class 1E power, are routed in Class 1E raceways, are not isolated on accident signal and may have a continuing section in a non-Class 1E raceway (Category 2B).

The design features of all associated circuits are in accordance with Section 8.3.1.4.2.1. The non-associated circuit portions of the cable routes are analyzed in Section 8.3.1.4.4.1.

8.3.1.4.4.3 Specific Deviations to Separation Criteria - Reactor Protection System Power Supply. See Reference 8.3-2.

8.3.2 DIRECT CURRENT POWER SYSTEMS

8.3.2.1 Description

The principal elements of the Class 1E dc power systems are shown in Figure 8.3-52. The systems consist of three electrically independent and separate 125-V batteries (Divisions 1, 2, and 3), two ±24-V batteries (Divisions 1 and 2), one 250-V battery (Division 1) and associated auxiliary equipment.

One non-Class 1E 125-V dc power supply system is provided in the radwaste building to supply non-Class 1E power, control, and instrumentation loads.

Two non-Class 1E 125-V dc (Divisions A and B) power supply systems are located at the makeup water pump house to provide local control power.

One non-Class 1E 405-V dc power supply system is provided in building 62 for the security system.

All non-Class 1E loads supplied by the Class 1E dc power systems are connected to Class 1E dc power supplies through Class 1E isolation devices. Any overcurrent conditions that could occur in the non-Class 1E portions of the system are isolated by the Class 1E devices without affecting the availability of the power supply. These Class 1E protective devices are discussed further in Section 8.3.2.2.1.1. Wiring to the non-Class 1E loads from the Class 1E power supplies are designated as prime circuits and are routed in accordance with separation criteria defined in Section 8.3.1.4.

An analysis of the consequences of a total loss of dc buses (Class 1E) S1-1, S1-2, or S2-1 for operating and shutdown modes is addressed in Chapter 15 accident analyses. The conclusion of this analysis is that previously reported limits of minimum critical power ratio (MCPR), peak vessel and main steam line pressures, and peak fuel cladding temperature for the expected operational occurrence category of events would not be exceeded as a result of common power source failures. Furthermore no situation exists where a single bus power failure would prevent plant personnel from achieving a reactor cold shutdown condition. This conclusion is based primarily on the analysis results which delineate that no single bus supplies power to all three shutdown paths. In most cases, single buses are active in only one shutdown path.

Table 8.3-9 indicates the switchgear and MCCs which are supplied with dc control power by the various dc power systems.

The battery chargers for the Divisions 1 and 2 (Class 1E) dc power systems will remain stable while supplying the load even if the batteries are disconnected. The load on the charger has to be more than 10% of its rating under this condition. When the battery is disconnected from the charger, there is a possibility that the ripple in the charger output is more than 100 mV.

There are no normal modes of plant operation where the battery will be disconnected from the charger and load. The charger and the battery will be connected for applying equalizing charges.

During service and performance tests of the batteries which are normally performed during refueling outage, the batteries for 250-V and 125-V systems are disconnected from the charger and load. For the 24-V system, the charger is shut down for service and performance tests of the batteries. During this period, the 24-V battery carries the load.

Plant maintenance procedures require that the chargers be disconnected from their respective batteries and loads during maintenance checks of the charger low and high voltage level alarms and the high level shunt trip. The chargers for 250-V and 125-V Divisions 1 and 2 dc systems remain stable under this condition but additional capacitive load is connected to the output of the 24-V charger to stabilize the output.

The design of the battery chargers provides assurance that safety-related equipment will be protected from damaging overvoltages as a result of faulty charger voltage regulation or operator error by alarms and a high voltage shutdown feature. Normal system float voltage is 2.25 V per cell. Should the voltage increase approximately 5 to 8%, a high voltage alarm is sounded. At approximately 10-12% above float voltage, the high voltage shutdown relay trips the charger output breaker, disconnecting the charger from its respective bus, thus protecting the equipment from further voltage increase. The controls for these alarm/trips are located inside the respective battery charger cabinet precluding inadvertent operator error.

Table 8.3-10 is a summary of the Class 1E battery duty cycles based on anticipated operations required during LOOP with coincident LOCA conditions.

8.3.2.1.1 125-Volt Direct Current Divisions 1 and 2 Systems

8.3.2.1.1.1 General. Two separate and independent Class 1E, 125-V dc systems are provided to power the safety-related (ESF) load groups of Divisions 1 and 2. Each of the batteries has two, full capacity, battery chargers sized to carry normal and postaccident steady dc loads, while simultaneously recharging the battery from its discharged state (1.81-V per cell) to its fully charged state (charging current has stabilized) within 24 hr. The battery chargers receive 480-V ac input power from their respective Divisions 1 and 2 480-V MCCs. For each division, one charger will be on line while the other will normally be available for service if the on-line charger fails or has to be removed from service.

8.3.2.1.1.2 Batteries. In the event of a loss or interruption of charger 125-V dc output, the station batteries will maintain power to their respective dc systems. The ampere-hour capacity and short time rating of all batteries are in accordance with IEEE 308-1974. They are capable

of supplying, (based on duty cycle calculations for a simultaneous LOOP and LOCA), dc power required to safely shut down the plant. The battery is conservatively sized based on the charger not being available for 2 hr even though this condition is not a requirement for any analyzed DBE at CGS.

The capability of the 125-V Divisions 1 and 2 batteries to supply SBO loads for a 4-hr coping period is discussed in Appendix 8A.

The 125-V dc, station batteries E-B1-1 (Division 1) and E-B1-2 (Division 2) each consist of 58 cells.

The capacity of batteries E-B1-1 and E-B1-2 is 1190 ampere-hours (based on an 8-hr discharge to 1.81 V per cell) which is equivalent to a battery terminal voltage of 105 V dc.

The nominal "float-voltage" for these batteries is 2.25 V per cell, and the "end-of-discharge" voltage is 1.81 V per cell.

8.3.2.1.1.3 Chargers. The chargers for each Divisions 1 and 2 125-V dc load group are supplied from separate 480-V ac MCCs associated with each division. Each charger is capable of carrying the largest combined demand of the various steady state dc loads for its division while simultaneously recharging the battery from its discharged state (1.81 V per cell) to its fully charged state (charging current has stabilized) in 24 hr. The charger size and instrumentation conform to the requirements of IEEE 308-1974 and Regulatory Guide 1.32, Revision 2. The chargers are capable of supplying the 125-V dc power requirements during all modes of plant operation. The Divisions 1 and 2 battery chargers (chargers C1-1A and 1B and C1-2A and 2B, respectively) are rated 200 amps dc output. The old 125 V dc charger E-C1-1, (formally Division 1) is disconnected and spared in place for use as temporary power.

8.3.2.1.2 High-Pressure Core Spray (Division 3) 125-Volt Direct Current System

8.3.2.1.2.1 General. The objective of the HPCS 125-V dc (Division 3) system is to provide a reliable, continuous, and independent 125-V dc power source of control and motive power as required for the HPCS system logic, HPCS diesel generator set control and protection, and all Division 3 related control. Figure 8.3-52 shows the 125-V dc one-line diagram. The system is classified as Class 1E. The Division 3 125-V dc system is independent of all other divisional batteries and there is no manual or automatic connection to any other battery. The battery is not shared with any other unit. The 125-V dc power is required for HPCS diesel generator field flashing, control logic, control, and switching functions of 4.16-kV breakers.

8.3.2.1.2.2 Battery and Charger. The 125-V dc system for the HPCS power supply has a 58-cell 125-V dc battery, one battery charger, and a distribution panel.

The 125-V dc system is designed as Class 1E equipment in accordance with applicable clauses of IEEE 308-1974. It is designed so that no single failure in the 125-V dc system will result in conditions that prevent safe shutdown of the plant. The plant design and circuit layout from these dc systems provide physical separation of the equipment, cabling, and instrumentation essential to plant safety.

The 125-V dc battery and its charger and distribution panel are shown in Figure 8.3-52. All components of the system are located in the HPCS diesel generating area of the diesel generator building.

8.3.2.1.2.3 Battery Capacity. The ampere-hour capacity (96 AH at 8 hr) and short time rating of the battery are in accordance with criteria given in IEEE 308-1974 and are adequate to supply all electrical loads required until ac power is restored for the operation of the battery chargers. The battery is conservatively sized based on the charger not being available for 2 hr even though this condition is not a requirement for any analyzed DBE at CGS. See SBO discussion in Appendix 8A. Capacity is large enough to cope with LOCA conditions or any other emergency shutdown. Each distribution circuit is capable of transmitting sufficient energy to start and operate all required loads in that circuit. The 125-V battery is sized in accordance with the principles set out in IEEE 308-1974.

8.3.2.1.2.4 Charger. The charger for the 125-V dc system is supplied by the 480-V HPCS MCC (via the engine generator control panel). It is rated 50 amp dc and is capable of carrying the largest combined demand of the various direct current system loads while simultaneously recharging the battery from its discharged state (1.81 V per cell which is equivalent to a battery terminal voltage of 105 V dc) to a fully charged state (charging current has stabilized) within 24 hr.

During an ESBO scenario that extends beyond the 4 hour coping time of a SBO or during a non-DBA LOOP scenario, the Class 1E 125-V Division 1 and Division 2 battery chargers may be supplied by alternative sources. 1) The Division 3 HPCS diesel generator may be cross connected from SM-2 to either Division 1 through SM-1 or Division 2 through SM-3. 2) The opposite division may be connected to a 400 kW diesel generator connected to either the Division 1 or the Division 2 480V safety bus.

8.3.2.1.3 ±24-Volt Direct Current (Divisions 1 and 2) Systems

8.3.2.1.3.1 General. Two separate and independent Class 1E, ±24-V dc systems are provided to power the Divisions 1 and 2 main control room equipment as indicated in Figure 8.3-52. Each ±24-V battery has two 12-cell 24-V banks connected in series with

common point grounded. Each bank is provided with a solid-state battery charger which receives 120-V ac input power from its respective Division 1 or 2 120-V ac vital power panel.

8.3.2.1.3.2 Batteries. In the event of a loss or interruption of charger 24-V dc (plus or minus) output, the batteries will maintain power to their respective dc systems for at least 2 hr. The ampere-hour capacity of each battery is 150 AH at 8 hr. This exceeds the NSSS vendor's requirements for units sized 60 AH at 4 hr. Circuit loads are indicated in Figure 8.3-52, dc one line diagram.

8.3.2.1.3.3 Chargers. The chargers for each ±24-V dc load group (four chargers total) are supplied from 120-V ac vital power panels associated with each division. Each charger is capable of carrying the largest combined demand of the various steady state dc loads while simultaneously restoring the battery from its discharged state (1.75 V per cell which is equivalent to a battery terminal voltage of 21 V dc) to its fully charged state (charging current has stability) in 24 hr. The charger size and instrumentation conform to the requirements of IEEE 308-1974 and Regulatory Guide 1.32, Revision 2. The ±24-V dc Division 1 (CO-1A, CO-1B) and Division 2 (CO-2A, CO-2B) chargers are rated 25 amps dc output.

8.3.2.1.4 250-Volt Direct Current (Division 1) System

8.3.2.1.4.1 General. One Class 1E 250-V dc system is provided to supply 120/240-V ac power on an uninterruptible basis to plant controls, instrumentation, computer and communication equipment via a solid state inverter. It also supplies 250-V dc power directly to reactor core isolation cooling (RCIC), selected RHR and reactor water cleanup (RWCU) system MOVs and the main and feedwater turbines auxiliary oil pumps. See Figures 8.3-5 and 8.3-52.

The cabling to the main 250-V dc distribution panel, the panel, battery, charger, and incoming 480-V ac normal source are Class 1E (Division 1).

8.3.2.1.4.2 Battery. In the event of a loss or interruption of charger 250-V dc output, the battery will maintain power to its dc system loads. The amp rating and short time rating of the battery is in accordance with IEEE 308-1974. The battery is capable of supplying (based on duty cycle calculations for a simultaneous LOOP and LOCA) dc power required to safely shut down the plant. The battery is conservatively sized based on the charger not being available for 2 hr even though this condition is not a requirement for any analyzed DBE at CGS.

The battery consists of two parallel strings of 116 cells (total of 232 cells) and has a capacity of 2380 AH (based on an 8 hr discharge to 1.81 V per cell which is equivalent to a battery terminal voltage of 210 V dc).

8.3.2.1.4.3 Charger. The charger for the 250-V dc system is supplied from a Class 1E 480-V ac MCC and is capable of carrying the largest combined demand of the various steady-state loads while simultaneously restoring the battery from its discharged state (1.81 V per cell) to its fully charged state in 24 hr. The charger size and instrumentation conform to the requirements of IEEE 308-1974 and Regulatory Guide 1.32, Revision 2. The active charger (C2-1) is rated at 400 amps output.

During an ESBO scenario that extends beyond the 4 hour coping time of a SBO or during a non-DBA LOOP scenario, the Class 1E 250-V Division 1 battery charger may be supplied by alternative sources. The Division 3 HPCS diesel generator may be cross connected from SM-2 to Division 1 through SM-1 or a 400 kW diesel generator connected to the Division 1 480V safety bus.

8.3.2.1.5 Non-Class 1E Direct Current Systems

8.3.2.1.5.1 Main Plant 125-Volt Direct Current (Non-Class 1E) System.

8.3.2.1.5.1.1 General. The main plant non-Class 1E 125-V dc system is designed to supply the majority of the plant non-Class 1E 125-V dc loads. Selected 125-V dc non-Class 1E loads are supplied by one or the other of two Class 1E 125-V dc batteries through isolation devices. The battery is provided a solid-state battery charger which is fed from a non-Class 1E 480-V ac source. During an ESBO or a non-DBA LOOP, its source power may be transferred from its normal power source to a Division 2 power source.

8.3.2.1.5.1.1.1 Battery (B1-7). The battery has 58 cells which are floated to 2.25 V per cell. It is rated at 1190 amp hr at an 8-hr discharge rate down to 1.81 V per cell.

8.3.2.1.5.1.1.2 Charger (C1-7). The battery charger is a three phase, thyristor controlled, constant potential battery charger. It is unique in that it has two separate power supply sources. It is normally powered from MC-6B. However, during an ESBO or a non-DBA LOOP, its source power may be transferred from MC-6B to MC-8A. This transfer is accomplished by repositioning two locked, manual transfer switches located near the battery charger. The keys for the locked manual transfer switches are administratively controlled.

8.3.2.1.5.2 Makeup Pump House 125-Volt Direct Current (Non-Class 1E) System.

8.3.2.1.5.2.1 General. The Divisions A and B 125-V dc non-Class 1E loads of the makeup water pump house are fed from two non-Class 1E batteries.

B1-3 and B1-4. Each battery is provided with a charger which is fed from a 480/120-V transformer connected to an MCC of a compatible division.

8.3.2.1.5.2.2 Batteries (B1-3 and B1-4). The batteries are rated for 94 amp-hr based on an 8-hr discharge rate of 1.81 V per cell.

8.3.2.1.5.2.3 Chargers (C1-3 and C1-4). The battery chargers are each sized 25 amps at 125 V dc.

8.3.2.1.5.3 405-Volt Direct Current (Non-Class 1E) System.

8.3.2.1.5.3.1 General. The 405-V dc system is located in building 62. It is provided with an inverter/charger (IN-4) which is supplied from a Class 1E 480-V ac source.

8.3.2.1.5.3.2 Battery (B1-6). The battery is made up of 180 cells in series and floated at 2.25 V per cell. Its 1-hr discharge rate is 601.3 amps down to a minimum voltage of 1.75 V per cell. This discharge rate supports the 1-hr emergency load cycle for this battery.

8.3.2.1.5.3.3 Charger. The battery charger portion of the security system inverter (IN-4) is sized to supply the emergency and normal loads and at the same time charge the battery from its minimum charge of 1.75 V per cell to its fully charged state in 24 hr.

8.3.2.1.6 Ventilation

Batteries for Divisions 1 and 2 are located in separate rooms within the radwaste/control building. The battery for Division 3 is located in the diesel generator building. Each room is ventilated by separate exhaust fans to remove gases produced during the battery charging cycle. Battery rooms have no common ventilation ducts. Failure of the HVAC system of each battery room is annunciated. A portable exhaust fan is provided to service a battery room with a failed ventilation system.

8.3.2.1.7 Testing and Maintenance

8.3.2.1.7.1 Periodic Maintenance Testing. Periodic maintenance tests will be performed in accordance with IEEE 308-1974, 450-2002, with the exception noted in Section 8.3.2.1.7.2, 8.3.2.1.7.3, and Regulatory Guide 1.32, Revision 2, on all components of the dc systems to determine the condition of each individual subsystem. Battery and battery chargers will be tested and inspected in accordance with Technical Specifications requirements. The following tests/inspections shall be made:

a. Visual inspection of system and electrical connections;

b. Liquid level of each cell;

c. Voltage and temperature of the pilot cell of each battery;

d. The voltage and specific gravity of each cell, and the temperature of selected cells; and

e. Performance discharge and service tests will be performed in accordance with IEEE 450-2002. The voltage of each cell will be taken and logged after discharge.

For Class 1E dc system components, the manufacturer has either performed operational tests or calculated data which substantiate the capability of the equipment to carry their dc postaccident (worst case) loads. Seismic and environmental qualification is discussed in Sections 3.10 and 3.11.

Preoperational testing, as described in Section 14.2, was performed to verify that all components, automatic and manual controls, and functions of the dc power systems perform as required.

8.3.2.1.7.2 Exceptions to Institute of Electrical and Electronics Engineers Standards. The following exceptions are taken to the requirements listed in Table 2 of IEEE 308-1974:

a. Battery float charging current will be measured in lieu of pilot cell specific gravity. Charging current and pilot cell voltage will be measured quarterly versus every week as recommended in the standard;

b. The cell voltage of all the cells will be measured quarterly versus every month as recommended in the standard;

c. Specific gravity of all cells will be measured annually versus every month as recommended in the standard;

d. A visual inspection will be performed quarterly versus every week as recommended in the standard;

e. A performance test will be performed at least once every 5 years versus every 3 years as recommended in the standard; and

f. Battery float charging current and voltage will be measured and logged on a monthly basis versus every week as recommended in the standard.

8.3.2.1.7.3 The following exceptions are taken to the requirements listed in IEEE 450-2002.

a. When any cell electrolyte reaches the low-level line, water will be added to bring the cells to the middle of high-low mark versus to bring the cells to the high-level line as recommended by Section 5.3.1.a of IEEE 450-2002; and

b. Section 5.2.1 of IEEE 450-2002 – Monthly inspections of the battery on a regularly scheduled basis will be performed quarterly versus monthly as recommended in the standard for the following:

1) Float voltage measured at battery terminals
2) General appearance and cleanliness of the battery
3) Charger output current and voltage
4) Electrolyte levels
5) Cracks in cells or evidence of electrolyte leakage
6) Any evidence of corrosion at terminals, connectors, racks, or cabinets
7) Ambient temperature and ventilation
8) Pilot-cells (if used) voltage and electrolyte temperature
9) Battery float charging current or pilot cell specific gravity.

8.3.2.2 Analysis

8.3.2.2.1 Compliance to Criteria

8.3.2.2.1.1 General. In accordance with GDC 17, IEEE 308-1974, and Regulatory Guide 1.6, Revision 0, redundancy and independence of dc power sources and distribution equipment are provided by the separate Divisions 1 and 2 (Class 1E) battery systems. Each dc system has sufficient capacity to supply the dc power requirements of the redundant (Divisions 1 and 2) load groups for at least 2 hr following loss of power to the charger coincident with a DBA. This redundancy extends from the batteries and battery chargers through distribution panels, cabling, switchgear, and protective devices.

The HPCS dc power system is a separate and independent safety-related (Class 1E) system comprising Division 3. The Division 3 dc loads serve a separate safety function not provided by Division 1 or 2 directly. However, the automatic depressurization system (ADS), working with the LPCS, or low-pressure coolant injection (LPCI) systems supplied via Divisions 1 and 2, can compensate for the loss of the entire Division 3 system.

There are no electrical connections between the dc buses for Division 1, 2, and 3, and there is no automatic or manual transfer of load between divisions. The elimination of ties between dc systems prevents a single failure from affecting more than one division.

Selected non-Class 1E loads are connected to the Class 1E power supplies. This does not degrade the Class 1E power supplies based on the following:

a. All non-Class 1E loads are connected to Class 1E power supplies through Class 1E isolation devices. Any overcurrent condition that could occur in the non-Class 1E portions of the system are isolated by these Class 1E devices without affecting the availability of the power supply. These Class 1E protective devices are either a circuit breaker shunt, tripped on a LOCA signal, or one or two series overcurrent devices such as fuses or circuit breakers. The overcurrent devices trip on overloads, line-to-line and double line-to-ground faults on all dc systems. They also trip on single line, line-to-line ground faults on solidly grounded systems;

   The power source shall supply the necessary fault current to ensure proper coordination of the circuit's Class 1E isolation device without loss of function of Class 1E loads;

b. Periodic surveillance procedures ensure protective device trip setpoints to be within acceptable limits for proper coordination with the main circuit protective device;

c. Wiring to the non-Class 1E loads from the Class 1E power supplies is designated as prime circuits, and is routed in accordance with separation criteria defined in Section 8.3.1.4; and

d. The Class 1E power supplies are sized adequately to supply all Class 1E and non-Class 1E loads connected to them.

8.3.2.2.1.2 Divisions 1 and 2 125-Volt, ±24-Volt, and 250-Volt Direct Current Systems. The Divisions 1 and 2 dc power systems have been designed in compliance with IEEE 308-1974. Components of the systems are located in the radwaste/control building, a Seismic Category I structure. This ensures that any design basis event as listed in IEEE 308-1974, Table I, will not cause loss of dc power and jeopardize the safety of the reactor or cause damage to the reactor coolant system. The dc buses and the associated equipment are located such that redundant counterparts are physically separated from each other. There are no dc ties between redundant ESF equipment such as switchgear or motors. Therefore, no single failure of any dc component can adversely affect the operation of the redundant dc systems.

The chargers are on diesel generator supplied buses so that during LOOP, with diesel generators operating, the batteries will be required to carry their loads for short periods only. Alarms are provided in the main control room for low dc bus voltage on the 125-V and 250-V buses.

Low ±24-V dc alarms are communicated via the main control room computer.

The Divisions 1 and 2 dc power systems satisfy the requirements of Regulatory Guide 1.32, Revision 2, not only in their adherence to IEEE 308-1974 but also as follows:

a. The battery chargers are sized as described in Section 8.3.2.1 to meet load and recharging requirements, and

b. Battery performance discharge tests and battery service tests are scheduled in accordance with IEEE 450-2002.

The dc power systems are designed to permit periodic inspection and test of important areas such as wiring, insulation, connections, and switchboards, and thus comply with GDC 18.

Control room instrumentation and alarms are provided for each battery and battery charger to monitor the status of each power supply in accordance with IEEE 308-1974 and Regulatory Guide 1.47. This instrumentation includes indication of the main bus voltage, battery current (charge and discharge), and battery charger current. Alarms through the control room annunciator and computer are provided for the following abnormal conditions: bus undervoltage, dc system ground fault (for ungrounded systems), battery fuse blown, battery charger over/undervoltage, and battery charger ac failure. Charger and battery disconnect switches are provided with position indication and group alarm in the control room.

Battery high discharge rate is not separately alarmed. In the absence of an electrical fault and with battery charger available, all normal and emergency steady state loads are carried by the battery charger. For the 125-Volt and 250-Volt Direct Current Systems, the battery charger operates in a current-limiting mode of 115% of its full load rating and any overcurrent in excess is supplied by the battery. For the 24-Volt Direct Current Systems, the battery charger operates in a current-limiting mode between 110% to 125% of its full load rating and any overcurrent in excess is supplied by the battery. However, the feeder circuit fuses are sized to trip on overcurrents of this magnitude, thereby preventing battery high discharge current to continue to the point of degrading the system. Annunciation of the isolated Class 1E circuit is made for each connected load. Failure of the battery charger also causes a battery high discharge as discussed above.

8.3.2.2.1.3 High-Pressure Core Spray (Division 3) 125-Volt Direct Current System. The 480-V ac feed to the HPCS battery charger is from the HPCS MCC via the engine generator control panel. Separation between Division 3 and other independent systems is maintained and the power provided to the chargers can be from either offsite or onsite sources. The HPCS dc system is arranged so that the probability of a system failure resulting in loss of dc power is extremely low. Important system components are either self-alarming on failure or capable of being tested during service to detect faults. All abnormal conditions of selected system parameters important to surveillance of the system annunciate in the main control room. Cross connections with other independent 125-V dc systems do not exist.

Control room instrumentation and alarms for the HPCS are similar to those of the Divisions 1 and 2 dc systems as discussed in Section 8.3.2.2.1.2.

Components of the system are located in the diesel generator building, a Seismic Category I structure.

The dc power supply to switchgear circuit breakers in the Division 3 load group is from the Division 3 battery. There are no connections between dc systems of different divisions, thereby ensuring that no single failure in one dc system can affect power systems of other divisions.

8.3.2.2.1.4 Non-Class 1E Direct Current Systems. There are no specific safety design requirements for the non-Class 1E dc systems other than those required for a reliable operation and for good system operability and maintainability.

8.3.2.2.2 Service Environment

All components of Class 1E dc systems, with the exception of some distribution and control cables and control devices, are located outside of primary containment.

Components located in normally air conditioned areas are either designed to continue operating in the event of loss of air conditioning or a Class 1E air conditioning system is provided (see Section 3.11.4).

See Section 3.11 for discussion of environmental design and analysis of Class 1E electrical components for postaccident conditions and to Section 3.10 for seismic conditions.

8.3.2.3 Physical Identification of Safety-Related (Class 1E) Equipment

The safety-related equipment for each division of the Class 1E dc power system is discussed in Section 8.3.1.3.

8.3.2.4 Independence of Electrical Divisions

Spatial separation and/or placement of physical barriers between different divisions of the dc power system is used as a protection against loss of the redundant dc load groups from a single event. Electrical separation is provided as described in Section 8.3.1.4.

The Class 1E batteries and battery chargers of redundant divisions are located separately from one another in Seismic Category I rooms with no common ventilation connections. Redundant dc distribution panels and 480-V MCCs are located at sufficient distance apart to prevent any single credible event from causing the loss of more than one panel or MCC. Cable trays,

cables, and control circuitry for the three divisions (1, 2, and 3) are also separated as described in Section 8.3.1.4.

8.3.3 FIRE PROTECTION FOR CABLE SYSTEMS

8.3.3.1 Resistance of Cables to Combustion

See Section F.3.

8.3.3.2 Localization of Fires

See Section F.3.

8.3.3.3 Detection and Protection Systems

See Section F.3.

				Total automatically applied 3823.7				*Total automatically applied 4381.4*			

( ) kW figures in parenthesis are for manually applied loads not added to total automatically applied loads.

[a] Time to start after bus voltage frequency have been established. Maximum time after signal to start generator for voltage to be established is 15 sec.
[b] Intermittent loads not included as long-term loading.
[c] Motors stop automatically when valve action is completed.
[d] Items are non-Class 1E.
[e] Start and/or stop manually.
[f] Start and/or stop automatically with associated pump or diesel, pressure, temperature switch, or flow.
[g] SW start time (after bus energization) is the sum of SW start timer (20 sec) and SW return valve open time to actuate the limit switch permissive.
[h] Load can be manually applied after the operator determines there is sufficient generator capacity.
[i] Operates automatically on chilled water demand.

			Total 197.0 kW				*Total 2514.3 kW*			

[a] *Time to start after bus voltage frequency have been established. Maximum time after signal to start generator for voltage to be established is 15 sec.*

[b] *Start and/or stop manually.*

[c] *Intermittent loads not included as long-term loading.*

[d] *Start and/or stop automatically with associated pump or diesel, pressure, temperature switch, or flow.*

[e] *Due to heat dissipation from the diesel, the room temperature exceeds 70°F (thermostat settings for DMA-EHC-32 and DRA-EUH-31 are 70°F and 50°F, respectively) within a few minutes. Hence, DMA-EHC-32 and DRA-EUH-31 are switched off within a few minutes. Therefore, these heaters are short-term load. However, for a conservative approach, these heater loads are included in the diesel loading.*

[f] *Non-Class 1E.*

Table 8.3-4

Motor and Motor Starter Voltage Requirements

Equipment	Nameplate Voltage	Minimum Requirement		Maximum Capability	
		Voltage	% NPV	Voltage	% NPV
6.9-kV motors (continuous operation)	6600 V	5940	90	7260	110
4.16-kV motors (continuous operation)	4000 V	3600	90	4400	110
480-V motors (continuous operation)	460 V	414	90	506	110
480-V starters (pickup)	480 V	341-408[a]	71-85	528	110
480-V starters (holding)	480 V	264	55	---	---

[a] Minimum pickup voltage varies between different manufacturers and model types.

Notes:

1. NPV indicates nameplate voltage of motors or starters for the particular voltage level.

2. Deviation from the minimum voltage requirements is permitted for Class 1E motors provided an analysis is performed and documented, to demonstrate that the motors can perform their safety function with the voltage supplied.

38.	Diesel generator No. 1 (No. 2) improper paralleling	---	X

[a] Independent drops are provided for Division 1 and Division 2 annunciators. Drop titles for the Division 2 annunciators are indicated by parentheses.

[b] Main control room - Board "C" (Panel P800).

[c] This function inputs into a BISI alarm that indicates the breaker is out of service.

[d] Diesel generating unit incomplete sequence and differential current signals trip the units via the unit lockout relays (item 6).

[e] All abnormal signals detected at the local diesel generator control panels provide input to the general (item 22) alarm.

Table 8.3-6

The italicized information is historical and was provided to support the application for an operating license.

Comparison of High-Pressure Core Spray Diesel Generators

Component	*Data*	
	LaSalle	*Columbia Generating Station*
Engine:		
Model	*EMD-20-645E4*	*EMD-20-645E4*
hp	*3600*	*3600*
Speed (rpm)	*900*	*900*
Generator:		
Model	*Ideal Electric-CO-SAB*	*GE - 264 x 730*
kVA	*3560*	*3560*
Volts	*3400/4160Y*	*2400/4160Y*
Hertz	*60*	*60*
Insulation	*Class B*	*Class B*
Moment of inertia (#-ft^2)	*36,000*	*32,450*[a]
Reactance (%)		
Subtransient (X"$_d$)	*7.1*	*10.9*[b]
Transient (X'$_d$)	*14.3*	*16.5*
Synchronous (X$_d$)	*112.0*	*82.0*
Time const (sec)		
T$_d$" (S-C)	*0.021*	*0.01*
T'$_{d+}$(O-C)	*3.5*	*2.87*
Regulator type	*Solid state*	*Solid state*
Exciter type	*Brushless rotary*	*Static with field flashing*
Governor		
Model	*Woodward UG-8*	*Woodward EGB-10*
Speed sensor	*Mechanical*	*Electronic*[c]
Error	*±1%*	*±0.25%*
Loads		
HPCS pump	*3000 hp* *1800 rpm* *373 FLA*	*3000 hp* *1800 rpm* *373 FLA*
Auxiliary loads	*220 kW*	*220 kW*

[a] *Columbia Generating Station overall diesel generator moment of inertia is lower than LaSalle. Hence, diesel generator starting time may be less for Columbia Generating Station than for LaSalle.*

[b] *The higher transient and subtransient reactance for Columbia Generating Station is compensated by the use of a static exciter which provides faster voltage recovery during voltage dips.*

[c] *Electronic sensing together with hydraulic actuation result in faster and more accurate response.*

Table 8.3-7

Class 1E Auxiliary Alternating Current Distribution System - Acceptable Voltage Range

	Voltages		Voltage Ranges	
System Level	System Nominal	Motor Nameplate	Normal Operation[a]	Starting[b]
4.16-kV switchgear	4.16 kV	4.0 kV	3.6-4.4 kV	3.2-4.4 kV
480-V switchgear	480 V	460 V	414-506 V	368-506 V
480-V MCC	480 V	460 V	414-506 V	368-506 V

[a] Minimum and maximum voltages indicated correspond to 90% and 110% (respectively) of motor nameplate voltage for the particular voltage level.

[b] Minimum and maximum voltages indicated correspond to 80% and 110% (respectively) of motor nameplate voltage for the particular voltage level.

Note:

Deviation from the minimum voltage requirements is permitted for Class 1E motors provided an analysis is performed, and documented to demonstrate that the motors can perform their safety function with the voltage supplied.

Table 8.3-8

System Bus Voltage Monitoring Alarms

System Level	Monitoring Device	Location	Undervoltage Alarms[a]	
			Annunciator	Computer
500-kV grid	Voltmeter	Main control room	---	---
230-kV grid	Voltmeter	Main control room	---	---
115-kV grid	Voltmeter	Main control room	X	---
4.16-kV switchgear	Voltmeter	Main control room	X	X
480-V switchgear	Voltmeter	Main control room	---	---
480-V MCC	---	---	---	---

[a] Located in main control room.

MC-S2-1A	250-V dc	1	DP-S1-1D	1
MC-S2-1B	250-V dc	A	DP-S1-1C-1	A

[a] Voltage is ac, unless otherwise noted.

[b] See Figure 8.3-52.

[c] Switchgear contains manually operated breakers. All indication is remote powered via the non-Class 1E supervisory system.

Note:

Control power for 480-V-ac motor control centers is obtained from control power transformers located in the units.

NOTE: The italicized information below is historical and is no longer updated in the FSAR. For Division 1 and 2 duty cycles refer to calculation 2.05.01 and its outstanding Calculation Modification Records (CMRs). For the Division 3 duty cycles refer to calculation E/I-02-85-02 and its outstanding CMRs.

Table 8.3-10

Battery Design Duty Cycles (Amperes vs. Time)

Division 3 Battery Duty Cycle

Battery[2]	*Seconds*					*Minutes*	
	0≤t<2	*2≤t<4*	*4≤t<8*	*8≤t<12*	*12≤t<60*	*1≤t<60*	*60≤t<120*
E-B1-HPCS	*31.49*	*31.49*	*44.89*	*22.79*	*11.99*	*11.99*	*12.19*

Notes:

*Table 8.3-11**

Division 1 125-Volt Direct Current Battery Design Duty Cycle

**The italicized information is historical and was provided to support the application for an operating license. It is no longer updated in the FSAR.*

	Seconds			*Minutes*			
Equipment	*0-6*	*6-18*	*18-60*	*1-2*	*2-60*	*60-119*	*119-120*
MC-S1-1D	*138*	*77*	*40*	*26*	*18*	*18*	*18*
Switchgear control[a]	---	---	---	---	---	---	---
Inverter IN-3A or 3B (PP-7A-A)	*85*	*85*	*85*	*85*	*85*	*85*	*85*
Distribution panels (DP-S1-1A) (DP-S1-1D) (DP-S1-1E) (DP-S1-1F)	*137*	*131*	*55*	*53*	*53*	*53*	*111*
Contingency (future)	*10*	*10*	*5*	*5*	*5*	*5*	*5*
Total amperes[b]	*370*	*303*	*182*	*169*	*161*	*161*	*219*

[a] *The switchgear control power loads are included in the distribution panels.*

[b] *The total values include margin and are rounded up from the maximum amps occurring at any second within the above time intervals. Not all loads listed within the 0-60 second interval are concurrent.*

Notes:

1 This duty cycle is based on calculation 2.05.01.

2. The duty cycle is based on loss of offsite power (LOOP) with a coincident loss-of-coolant accident (LOCA) at time = 0.

3. The load increase during the last minute (time = 120 minutes) is the result of adding momentary loads that occur while returning safety systems to their standby mode. The most limiting condition is for these operator controlled loads to occur at the end of the duty cycle.

*Table 8.3-12**

Division 2 125-Volt Direct Current Battery Design Duty Cycle

**The italicized information is historical and was provided to support the application for an operating license. It is no longer updated in the FSAR.*

	Seconds			*Minutes*			
Equipment	*0-6*	*6-18*	*18-60*	*1-2*	*2-60*	*60-119*	*119-120*
MC-S1-2D	*76*	*40*	*36*	*22*	*22*	*22*	*22*

Inverter IN-2A or 2B (PP-8A-A)	*70*	*70*	*70*	*70*	*70*	*70*	*70*
Distribution panels (DP-S1-2A) (DP-S1-2D) (DP-S1-2E)	*153*	*141*	*63*	*63*	*63*	*63*	*121*
Contingency (future)	*5*	*5*	*5*	*5*	*5*	*5*	*5*
Total amperes[b]	*304*	*255*	*174*	*160*	*160*	*160*	*218*

[a] *The switchgear control power loads are included in the distribution panels.*

[b] *The total values include margin and are rounded up from the maximum amps occurring at any second within the above time intervals. Not all loads listed within the 0-60 second intervals are concurrent.*

Notes:

1. *This battery duty cycle is based on calculation 2.05.01.*

2. *The load profile is based on loss of offsite power (LOOP) with a coincident loss of coolant accident (LOCA) at time = 0.*

3. *The load increase during the last minute (time = 120 minutes) is the result of adding momentary loads that occur while returning safety systems to their standby mode. The most limiting condition is for these operator controlled loads to occur at the end of the 2-hr duty cycle.*

*Table 8.3-13**

Division 3 (HPCS) 125-Volt Direct Current Battery Design Duty Cycle
HPCS-B1-DG3[a]

**The italicized information is historical and was provided to support the application for an operating license. It is no longer updated in the FSAR.*

	Seconds			*Minutes*	
Description	*0-13*	*13-20*	*20-60*	*1-60*	*60-120*
HPCS system control[b]	*6.5*	*6.5*	*6.5*	*6.5*	*6.5*
Field flashing	*22*	---	---	---	---
Two air-start solenoid valves	*2.0*	---	---	---	---
Switchgear (one breaker trip)	*6.0*	---	---	---	---
Switchgear (two breakers close)	*6.0*	*6.0*	---	---	---
Diesel generator standby fuel pump (DO-P-6)	*16.7*	*5.2*	*5.2*	*5.2*	*5.4*
Diesel generator lube oil pump (DLO-P-10)	*10.9*	*4.8*	---	---	---
Total amperes[c]	*50.0*	*50.0*	*15.0*	*15.0*	*15.0*

[a] Battery duty cycle is based on loss of ac power with a coincident HPCS system actuation.

[b] High-pressure core spray system control components consist of DG protective and auxiliary relays, DG control relays, time delay relays, a local annuciator panel, HPCS valve position indicators, control relays for HPCS process control logic, etc.

[c] The total values include margin and are rounded up from the maximum amps occurring at any second within the above time intervals. Not all loads listed within the 0-13 second interval are concurrent.

*Table 8.3-14**

Appendix 8A

STATION BLACKOUT

8A.1 INTRODUCTION

The complete loss of ac electrical power to the essential and nonessential switchgear buses is referred to as "station blackout" (SBO). It does not include the loss of ac power as supplied by the station batteries through inverter or the loss of ac power that is available from an "alternate ac" source as defined below. Station blackout also does not assume a concurrent single failure or a design basis accident (10 CFR 50.2 and Reference 8A-1, Appendix A).

NUREG-0933 states that SBO was resolved on a generic basis by publication of the station blackout rule (10 CFR 50.63) and Regulatory Guide 1.155. The regulatory guide provides guidance acceptable to the Staff for use of NUMARC 87-00 to satisfy the requirements of 50.63 (Reference 8A-1, Appendix K). The regulatory guide shows that NUMARC 87-00 provides guidance for meeting all aspects of the rule with the exception of the quality assurance requirements to be applied to SBO response equipment that is not safety-related and the potential need for changes to the Technical Specifications (Reference 8A-1, Appendix I, Q/A 1).

Contained within NUMARC 87-00 are five initiatives approved by the NUMARC Board of Directors to address the more important contributors to SBO risk. The initiatives are

a. Initiative 1A - Risk Reduction

   Each utility will review their site(s) against the criteria specified in the revised draft SBO Regulatory Guide, and if the site(s) fall into the category of an 8-hr or 16-hr site after utilizing all power sources available, the utility will take actions to reduce the site(s) contribution to the overall risk of station blackout. Nonhardware changes will be made within 1 year. Hardware changes will be made within a reasonable time thereafter.

b. Initiative 2 - Procedures

   Each utility will implement procedures at each of its site(s) for

   1. Coping with a station blackout,

   2. Restoration of ac power following a station blackout event, and

3. Preparing the plant for severe weather conditions (e.g., hurricanes) to reduce the likelihood and consequences of a loss of offsite power and to reduce the overall risk of a station blackout event.

c. Initiative 3 - Cold Starts

Each utility will, if applicable, reduce or eliminate cold fast-starts of emergency diesel generators for testing through changes to technical specifications or other appropriate means.

d. Initiative 4 - Alternating Current Power Availability

Each utility will monitor emergency ac power unavailability, utilizing data provided to INPO on a regular basis.

e. Initiative 5A - Coping Assessment/Emergency Diesel Generator (EDG) Performance

Each utility will assess the ability of its plant(s) to cope with a station blackout. Plants utilizing alternate ac power for station blackout response which can be shown by test to be available to power the shutdown buses within 10 minutes of the onset of station blackout do not need to perform any coping assessment. Remaining alternate ac plants will assess their ability to cope for 1 hr. Plants not utilizing an alternate ac source will assess their ability to cope for 4 hr. Factors identified which prevent demonstrating the capability to cope for the appropriate duration will be addressed through hardware and/or procedural changes so that successful demonstration is possible.

As part of the coping assessment, utilities are required to choose an EDG target reliability (0.95 or 0.975) and are required to maintain that chosen reliability. Accordingly, each utility will employ the following exceedance trigger values (on a plant unit basis) as the mechanism for monitoring EDG target reliability and to support closure of Generic Issues B-56.

Selected EDG Target Reliability	Failures in 20 Demands	Failures in 50 Demands	Failures in 100 Demands
0.95	3	5	8
0.975	3	4	5

Additionally, each utility, in response to an individual EDG experiencing four or more failures in the last 25 demands, will demonstrate restored EDG performance by conducting seven consecutive failure free start and load-run tests. This form of accelerated testing shall be conducted at a frequency of no

less than 24 hr and of no more than 7 days between each demand. Each utility will, if applicable, address this reduction in accelerated testing through changes to Technical Specifications or other appropriate means.

Columbia Generating Station implementation of these initiatives is discussed in Section 8A.2.

The SBO rule requires that a SBO coping period be established through appropriate coping analysis. It is required that during the established SBO coping period core cooling and containment integrity are maintained [10 CFR 50.63(a)(2)].

The discussion in Section 8A.2 shows Columbia Generating Station to be in compliance to the SBO rule by comparison with the requirements of NUMARC 87-00. Additional discussions relative to station blackout quality assurance and Technical Specifications are provided in Sections 8A.2.6 and 8A.2.7.

Two approaches are available to licensees for compliance to the SBO rule. They are use of

Alternate ac. This is a power source that is (1) connectable to but not normally connected to the offsite or onsite emergency ac power systems, (2) has minimum potential for common-mode failure with offsite power or the onsite emergency ac power sources, (3) is available in a timely manner after the onset of SBO, and (4) has sufficient capacity and reliability for operation of all systems required for coping with SBO and for the time required to bring and maintain the plant in safe shutdown (non-design-basis accident) (10 CFR 50.2 and Reference 8A-1, Appendix A).

Columbia Generating Station, along with some other BWRs, proposed the use of the high-pressure core spray (HPCS) diesel generator as alternate ac (Reference 8A-2) as this third diesel generator is in excess of the number required to meet the minimum redundancy requirements (i.e., single failure for safe shutdown) (Reference 8A-1, Appendix I, Q/A 105). While HPCS could provide decay heat removal during an SBO, it could not provide power to an emergency bus. Therefore, it was proposed that coping analyses would also be performed to address instrumentation, battery capacities, air supply, and loss of heating, ventilating, and air conditioning (HVAC). This approach has been found to be acceptable to the NRC although they disagreed that the HPCS diesel generator should be classified as alternate ac (Reference 8A-3).

ac-Independent. For this approach the plant relies on available process steam, dc power, and compressed air to operate equipment necessary to achieve safe shutdown conditions until offsite or emergency ac power is restored (Reference 8A-1).

The RCIC system is considered the backup to HPCS during SBO. Columbia Generating Station's coping analysis includes battery voltage profiles for both the 125 V dc and 250 V dc batteries that provide power to RCIC system equipment. These

battery profiles assume that RCIC is providing sole mitigation for the SBO event. Although the RCIC system is not credited for SBO event mitigation, it is the preferred SBO mitigation system and will be maintained available to respond to an SBO event. (Reference 8A-16).

RCIC uses reactor steam and dc power to operate during SBO. The system's keepfill pump, RCIC-P-3, is ac powered and assumed unavailable. Upon loss of keepfill, the system experiences a gradual decay in pressure while in the standby mode. The RCIC system remains available for use until the low pressure alarm of RCIC-PIS-34, which alerts the operator to the loss of margin to void formation in the discharge header.

8A.2 EVALUATION TO NUMARC 87-00

Chapters 3 through 7 of NUMARC 87-00 contain guidance which, if implemented, would serve to satisfy the five NUMARC SBO initiatives and obtain compliance with the SBO rule, with the exception of quality assurance and Technical Specifications considerations. The following sections address the content of these chapters.

8A.2.1 REQUIRED COPING DURATION

Using the data listed in Table 8A-1 and the methodology provided in Chapter 3 of NUMARC 87-00, the coping period for Columbia Generating Station was determined to be 4 hr.

8A.2.2 RESPONSE PROCEDURES

NUMARC 87-00 required procedure changes to deal with

a. SBO response. Changes in this category included; requiring priority efforts to restore ac power with site specific instructions on how this is to be accomplished, providing for core cooling and containment isolation, dealing with the loss of HVAC (e.g., the opening of control room cabinet doors), and the need to strip battery loads if necessary to conserve dc power.

b. Alternating current power restoration. These changes provided guidance to operations and the load dispatcher concerning the course of actions to be taken to restore ac power.

c. Severe weather guidelines. These changes provided guidance for operators to determine the proper course of action due to the onset of severe weather; in particular hurricanes.

The Columbia Generating Station SBO emergency response procedure provides guidance for responding to an SBO including specific instructions for (1) providing for core cooling if HPCS and/or reactor core isolation cooling (RCIC) are available, (2) dealing with the loss of

HVAC (e.g., the opening of control room cabinet doors and actions to prevent RCIC isolation on high temperature), (3) notifying BPA to give priority to restoration of power to Columbia Generating Station, and (4) checking closed containment isolation valves that might have been open prior to the onset of the SBO. For Columbia Generating Station response to the SBO rule, only the B1-1 and B1-2 batteries are required. As there is no need to provide for load stripping of these batteries, this is not provided for in the SBO procedure (Reference 8A-1, Appendix I, Q/A 77).

In addition to the instructions in the SBO response procedure for giving priority to restoration of power to Columbia Generating Station, the loss of all offsite power procedure was revised to provide this guidance and the BPA System Restoration Plan was revised to identify the need for prompt restoration of offsite power to Columbia Generating Station and the actions to be taken to achieve this.

As Columbia Generating Station was not evaluated for a hurricane during initial plant licensing and as no credit was taken for hurricane procedures in the coping analysis, no procedure changes were required to deal with the threat of hurricanes (Reference 8A-1, Appendix I, Q/As 12 and 52). In Reference 8A-4 Energy Northwest proposed to the NRC that with the Columbia Generating Station site having a very low risk for tornadoes, no special site inspections for potential missiles were necessary. Also, it was explained that restoration of important plant systems and components did not require special procedures with the exception of tornado damage to the ultimate heat sink spray ponds which was covered by existing procedures.

8A.2.3 COLD STARTS

This requires that each plant ensure that emergency diesel generator tests are performed in a prewarmed and prelubed condition except during the Technical Specifications demand test required approximately once each scheduled refueling outage unless the emergency diesel generator is normally prewarmed and prelubed.

No action was required for this item as the Columbia Generating Station diesels have prewarm (see Section 9.5.5.2) and prelube (see Section 9.5.7.2) systems that are normally in operation.

8A.2.4 EMERGENCY ALTERNATING CURRENT POWER AVAILABILITY

This item implements NUMARC SBO Initiative 4 which requires monitoring of plant emergency generator unavailability. Appendix D of the NUMARC document provides a suggested diesel generator reliability program.

In Reference 8A-5 Energy Northwest stated that procedures had been revised to implement Appendix D of NUMARC 87-00 and the five elements listed in Regulatory Guide 1.155, Position 2.

8A.2.5 COPING WITH A STATION BLACKOUT EVENT

Chapter 7 of NUMARC 87-00 provides a simplified assessment procedure for establishing the ability to cope with an SBO. There are five steps to the procedure, addressing the following topics:

a. Condensate inventory for decay heat removal,
b. Assessing the Class 1E battery capacity,
c. Compressed air,
d. Effects of loss of ventilation, and
e. Containment isolation.

8A.2.5.1 Condensate Inventory

The required condensate is to be determined from

B = A*(X gal/MWt) + C + RCS leakage

Where:

A = licensed output - MWt,

X = 22.12 for a 4-hr coping period, and

C = amount of water to support cooldown if cooldown is required to limit pump seal leakage or to maintain decay heat removal - gallons.

The reactor coolant system (RCS) leakage term is the coping period inventory loss due to (1) an assumed pump seal failure leakage term of 25 gpm/pump (later changed by the NRC to 18 gpm/pump for BWRs, Reference 8A-1, Appendix J, Q/A 2.1), and (2) the maximum allowable Technical Specifications RCS leakage. For Columbia Generating Station, A is 3544 MWt and C is 31,568 gal resulting in a required inventory of 109,962 gal.

Reference 8A-6 discusses the administrative controls and plant feature that proved assurance that this quantity of water will be available in the condensate storage tanks (CST) (the Technical Specifications do not control CST quantity while in Mode 1).

8A.2.5.2 Class 1E Battery Capacity

The B1-1 and B1-2 125-V batteries have adequate capacity for a 4-hr SBO coping period without load shedding (Reference 8A-4 through 8A-7). The battery load calculations assume an electrolyte temperature of 74°F. This was found to be acceptable to the NRC by Reference 8A-8 provided that administrative controls are in place to ensure that this value

would be the lowest temperature anticipated during normal operating conditions as required by Reference 8A-1, Section 7.2.2. The supplemental SER (SSER) (Reference 8A-8) did require the revisions to the calculations to account for changes to inverter efficiency and load currents. The calculations have been revised.

The B2-1 battery is not required for compliance to the SBO rule (Reference 8A-5).

8A.2.5.3 Compressed Air

Compressed air is addressed to ensure that air operated valves required for decay heat removal have sufficient reserve air or can be manually operated under station blackout conditions for the established coping duration.

In Reference 8A-4 Energy Northwest stated that (1) no air-operated valves are relied on to cope with an SBO of 4 hr, and (2) the safety/relief valves (SRVs), which together with the HPCS provide for decay heat transfer to the suppression pool, have an adequate nitrogen supply for 4 hr of SRV operation.

8A.2.5.4 Effects of Loss of Ventilation

To address the impact of a loss of ventilation during the SBO, the 4-hr (final) steady-state temperatures are determined for dominant areas of concern (DAC). Dominant areas of concern are those that (1) contain equipment that is needed to function early in an SBO (within 1 hr) to remove decay heat, (2) have significant heat generation sources after ac power is lost, relative to the free air volume of the room, and (3) unless the operator takes action, the capability to remove heat is lost during an SBO (Reference 8A-1, Appendix I, Q/A 4).

With the SBO temperatures determined, reasonable assurance of operability (RAO) of SBO coping equipment located in the areas is then established per the requirements of NUMARC 87-00, Appendix F.

For the Columbia Generating Station SBO response, the dominant areas of concern are (1) the control room, and (2) primary containment.

The SBO temperature for switchgear room 2 was determined as it contains breakers required for the restoration of ac power; its major heat source is inverter IN-5 which is not required for compliance to the SBO rule. A primary containment thermal hydraulic analysis was performed to determine the SBO drywell and wetwell temperatures.

The steam tunnel was also analyzed for SBO although it was found to not contain SBO coping equipment (References 8A-5, 8A-9, and 8A-10). The following rooms contain SBO coping equipment but maintain ventilation during a SBO and thus do not need to be evaluated as dominant areas of concern (Reference 8A-1, Section 7.1.2): (1) HPCS pump room, (2) HPCS

diesel/electrical equipment room, and (3) service water pump house A. The HVAC calculations for these rooms were reviewed to confirm RAO of SBO equipment located in these areas although this is not a requirement of the SBO rule (Reference 8A-1, Appendix I, Q/A 137).

The SBO final temperatures for the rooms listed below were derived from calculations based on selected initial temperatures as appropriate:

Room	Final (°F)	Initial (°F)	Doors
SW pump house A	113	N/A	Closed
HPCS diesel/equipment room	104	N/A	Closed
HPCS pump room	123	N/A	Closed
RPS-1 room (IN-3A and 3B)	127	104	Closed
RPS-2 room (IN-2A and 2B)	119	104	Closed
Switchgear room 2	113	104	Closed
Control room	119.7	78	Closed
Steam tunnel	193	140	Closed
Drywell	229	135	N/A
Wetwell air	179	150	N/A
Wetwell water	209	90	N/A

In Reference 8A-5 the use of the initial temperatures of 78°F for the control room was justified based on the addition of administrative controls to ensure that the room temperature would not be exceeded or corrective action would be taken to restore them. This was accepted by the NRC in Reference 8A-8.

The HPCS diesel/equipment and HPCS pump rooms and SW pump house A are not considered as dominant areas of concern as ventilation is maintained during an SBO. For the remaining areas RAO has been established for the SBO coping equipment located in these rooms. For those areas with a temperature of less than or equal to 120°F, RAO can be assumed without further analysis (Reference 8A-1, Appendix J, Q/A 2.2). The SBO coping equipment located in other areas was previously designated as safety-related for non-SBO considerations for which the environmental qualification requirements of 50.49 establish RAO.

8A.2.5.5 Containment Isolation

Containment isolation valves must be reviewed to ensure that appropriate containment integrity can be provided during an SBO should core damage become imminent (Reference 8A-1, Appendix I, Q/A 102).

Valves that do not need to be considered for SBO closure considerations are those that meet one of the following criteria:

a. Valves normally locked closed during operation,

b. Valves that fail closed on loss of ac power or air,

c. Valve is a check valve,

d. Valves in nonradioactive closed loop systems not expected to be breached in a SBO (with the exception of lines that communicate directly with the containment atmosphere), or

e. All valves less than 3 in. nominal diameter.

In addition, as the objective is to protect the penetration and additional single failures do not need to be applied for SBO coping, valves that have an in-series valve that satisfies one of the above criteria can also be excluded (Reference 8A-1, Appendix I, Q/A 101).

In References 8A-5 and 8A-9 Energy Northwest proposed to add the following exclusion criteria:

a. Valves for which interlocks exist that prevent opening of one or both in-series valves during power operation;

b. Valves that are associated with containment penetrations that use single isolation valves and satisfy General Design Criterion 56 by taking credit for the closed loop system outside containment as a second isolation barrier. This is often the case for those lines for which the suppression pool serves as a loop seal; and

c. Valves that are procedurally controlled to be closed during normal power operation. It is acceptable for such valves to be opened to support surveillance testing. However, exclusion of valves associated with more frequent operation, e.g., suppression pool cooling, is not appropriate.

These exclusion criteria were found acceptable by the Staff in Reference 8A-8.

The result of this evaluation is provided in Table 6.2-16. The SBO emergency response procedure has been revised to provide guidance for closure of those valves that were not excluded by this evaluation. For these valves it has been confirmed that (1) position indication is provided (by means other than observation of the stem position), (2) local manual closure capability exists, and (3) access would be available during an SBO. This confirmation was also made for those valves that were excluded by the fact that they are procedurally controlled to be closed during normal operation.

8A.2.6 QUALITY ASSURANCE CONSIDERATIONS

Regulatory Guide 1.155, Section 3.5, requires that the quality assurance requirements of Appendixes A and B of the guide be applied to that non-safety-related equipment used to meet the requirements of the SBO rule that are not already covered by existing quality assurance requirements of 10 CFR 50 Appendixes B or R.

In Reference 8A-5 Energy Northwest stated that SBO instrumentation coping equipment that is identified as QC II+ and is also required by Regulatory Guide 1.97 conforms to the quality assurance requirements of Regulatory Guide 1.97 for Category 2 equipment. As such, any additional quality assurance requirements of Regulatory Guide 1.155 are not applied to the equipment. Also, the reference explains that with the exception of the CST, SBO quality assurance is not applied to passive equipment (e.g., piping and structural supports). Other SBO coping equipment will conform to the requirements of Appendix R or Regulatory Guide 1.155.

These positions were accepted by the NRC in the SSER (Reference 8A-8); however Reference 8A-10 was submitted to the NRC to correct the words in the SSER relative to the quality assurance provided for passive equipment.

Reference 8A-5 also explained that SBO coping equipment has been identified as that equipment required to cope with an SBO and that failure of other equipment during an SBO was not postulated simply because it had not been assigned safety-related or SBO quality assurance requirements.

In Reference 8A-7 Energy Northwest stated that with regard to SBO recovery (not coping) equipment, SBO quality assurance requirements would only apply to SBO recovery equipment that is not in service during normal operation

8A.2.7 TECHNICAL SPECIFICATIONS CONSIDERATIONS

The basis for the Columbia Generating Station response to the SBO rule is use of HPCS which is safety related and already adequately covered in the Technical Specifications. No SBO Technical Specifications changes are required for Columbia Generating Station. Use of HPCS for SBO coping does not place any additional design or operating considerations on the HPCS system.

8A.2.8 VERIFICATION OF NUMARC 87-00 BASELINE ASSUMPTIONS

Section 1.3 of NUMARC 87-00 states that utilities are expected to ensure that the baseline assumptions of the document are applicable to their plants. Utilities are, however, not expected to perform rigorous analyses or evaluations in verifying these assumptions (Reference 8A-1, Appendix I, Q.A 3). The analyses are to be available for NRC review.

Table 8A-2 documents the evaluation of the baseline assumptions as applied to Columbia Generating Station. The table shows that where the assumptions were found to be invalid, alternative methods confirmed Columbia Generating Station compliance to the SBO rule. In all cases where a baseline assumption was found to be invalid, it was not because of a Columbia Generating Station unique feature, but rather because the assumption was not applicable to a large class of plants.

Table 8A-2

Validation of NUMARC 87-00 Assumptions

NUMARC	Assumption	Comment
NUMARC 87-00, Rev. 1, Appendix J.9 Considerations		
2.4.1(1)	Confirm dc power for EDG field flashing and breaker closure.	These considerations are included in the battery capacity calculations (Reference 8A-7).
2.5.2	BWRs should consider RRC pump seal leakage.	Seal leakage is included in the required inventory calculation (see Section 8A.2.5.1).
2.7.1	LOCA and HELB temperatures may not be conservative for SBO.	A plant specific SBO primary containment heatup calculation has been performed for Columbia Generating Station, and the SBO temperatures are bounded by the LOCA analysis temperatures. The DAC area outside containment is not susceptible to HELB conditions. (see Section 8A.2.5.4).
2.7.1(2)(a)	Confirm control room temperatures do not exceed 120°F.	This assumption was confirmed for Columbia Generating Station by a plant-specific control room heatup calculation (Reference 8A-7).
2.7.1(2)(a)1 2.7.1(2)(a)2	Initial and average wall temperatures assumptions should be verified by plant data.	The use of 104°F for RPS rooms and switchgear room 2 is valid as these rooms are controlled to below this temperature per the Licensee Controlled Specifications.

Table 8A-2

Validation of NUMARC 87-00 Assumptions (Continued)

NUMARC	Assumption	Comment
		The heatup calculations for the control room used an alternate methodology for which the temperature of adjacent rooms was properly accounted for. The temperatures of the rooms adjacent to the control room were conservatively assumed to be 104°F with the exception of the communication room which may have SBO heat loads and was assumed to be at 120°F. The control room model does not use the basic NUMARC 87-00 assumption that wall temperature remains basically constant during the SBO. Rather it models the wall as several nodes (typically 10) for which time dependent heat conduction and convection are accounted for.
		The primary containment model used the maximum temperature allowed by the Technical Specifications for the drywell and suppression pool as the initial temperatures for the appropriate portions of the containment shell and internal structures. These temperatures are higher than those that would be expected for the adjacent areas outside primary containment (i.e., within the Reactor Building).

Table 8A-2

Validation of NUMARC 87-00 Assumptions (Continued)

NUMARC	Assumption	Comment
2.7.1(2)(a)(3) 2.7.1(2)(a)(4)	Drop ceilings and walls that are not poured concrete cannot be modeled by NUMARC 87-00 methodology. If either are to be modeled, an alternate methodology must be used and this should be identified to the NRC.	The control room has a drop ceiling and walls that have facia board paneling. The drop ceiling was modeled by a method identified to the NRC in Reference 8A-7. The control room model has two volumes; the main portion of the room and the volume above the drop ceiling. Walls with facia board panel were not credited as heat sinks.
2.7.1(2)(a)(5)	In order to take credit for opening doors, the adjacent room must be large relative to the DAC and at a lower temperature.	The opening of doors is not required for SBO Rule compliance.
2.7.1.(2)(b)	Loss of heating in the battery room is assumed not to affect battery capacity. Provided battery capacity calculations used the lowest electrolyte temperature anticipated under normal operating conditions, further consideration of loss of battery capacity is not required.	The battery rooms have no walls that are exterior walls of the building and some of the adjacent rooms will have SBO heat loads. As such, there will not be significant cooling of the rooms during the coping period. Also, as the I^2R heat generation within the batteries will be greater than the heat loss due to the endothermic discharge reaction (Reference 8A-12), it is likely that the electrolyte temperature will increase even with a slight decrease in room temperature.

Table 8A-2

Validation of NUMARC 87-00 Assumptions (Continued)

NUMARC	Assumption	Comment
Other Considerations		
2.3.1	Specific consideration was not given in NUMARC 87-00 for a grid related LOOP due to volcanic activity.	The eruptions of Mt. St. Helens in 1980 did not result in significant disturbance to the BPA system. Also, the probability of volcanic activity that could significantly impact the BPA system is low relative to severe weather events that could do the same. Columbia Generating Station has made procedure and design provisions to ensure continuous EDG operations during volcanic activity (see Section 9.2.5.3 and Reference 8A-13).
2.7.1.(2)(a)	RAO only needs to be established for areas that lose normal ventilation.	RAO was confirmed for those areas that contain SBO coping equipment for which ventilation is maintained (Section 8A.2.5.4).
2.7.1.(2)(a)	For a temperature ≤ 120°F, it is likely no specific actions to ensure RAO are required.	Analysis has confirmed that all equipment important to station blackout is capable of functioning at temperatures ≤ 120°F (≤ 129°F for the RPS-1 room) with no specific action required to ensure RAO.
2.7.1.(2)(a)	The DACs for BWRs are the HPCI/HPCS and RCIC rooms and the main steam tunnel.	For Columbia Generating Station, the control room and primary containment are considered as DACs.

Table 8A-2

Validation of NUMARC 87-00 Assumptions (Continued)

NUMARC	Assumption	Comment
Appendix I, Q/A 95	Plants that relied on GE HELB analysis or a plant specific analysis which bounds the GE analysis, need not address the drywell temperature.	This assumption was validated for Columbia Generating Station using a plant-specific primary containment heatup analysis that modeled the drywell, wetwell air space, and suppression pool.

9.1 FUEL STORAGE AND HANDLING

9.1.1 NEW FUEL STORAGE

9.1.1.1 Design Bases

9.1.1.1.1 Safety Design Bases

9.1.1.1.1.1 Safety Design Bases - Structural.

a. The new fuel storage racks containing a full complement of fuel assemblies are designed to withstand all credible static and dynamic loadings, to prevent damage to the structure of the racks and the contained fuel, and to minimize distortion of the rack arrangement [see Table 3.9-2(s)],

b. The racks are designed to protect the fuel assemblies from excessive physical damage so as to prevent the release of radioactive materials in excess of 10 CFR 20 limits under normal or abnormal conditions,

c. The racks are constructed in accordance with the Quality Assurance Requirements of 10 CFR Part 50, Appendix B,

d. The new fuel storage racks are categorized as Safety Class 2 and Seismic Category I, and

e. The new fuel storage vault is located within secondary containment in the reactor building and therefore complies with the objectives set forth in Regulatory Guide 1.13, and General Design Criteria (GDC) 2, 3, 4, 5, 61, 62 and 63 of 10 CFR Part 50, Appendix A.

9.1.1.1.1.2 Safety Design Bases - Nuclear.

a. The new fuel storage racks are designed and maintained with sufficient spacing between the new fuel assemblies to ensure that the array shall be subcritical by at least 5% Δk, including allowance for calculation biases and uncertainties.

Calculations were performed to ensure that $k_{eff} \leq 0.95$ for all water mist densities up to 1.0 gm/cm^3 in and around the fuel. The new fuel storage vault was modeled using the KENO

computer code (Reference 9.1-1). GE14 and GNF2 fuel bundles were modeled using the MCNP01A (GEH's version of MCNP4A) computer code (Reference 9.1-10).

The biases between the calculated results and experimental results, as well as the uncertainty involved in the calculations, are taken into account as part of the calculation procedure to ensure that the specified K_{eff} limits are met.

b. Columbia has chosen to comply with 10 CFR 50.68, "Criticality Accident Requirements".

9.1.1.1.2 Power Generation Design Bases

a. New fuel storage racks provide for approximately 8% of the full core fuel load, and

b. New fuel storage racks are designed and arranged so that the fuel assemblies can be handled efficiently during refueling operations.

9.1.1.2 Facilities Description

The new fuel storage vault containing the new fuel storage racks is a concrete structure adjacent to the spent fuel pool at the refueling floor level of the reactor building (see Figure 1.2-10). The reactor building is built to Seismic Category I requirements and is further discussed in Section 3.2. The new fuel rack design features are as follows:

a. The new fuel storage vault contains 24 sets of castings, with each casting containing 10 possible storage locations. A maximum of 60 fuel storage positions will be used. The remaining storage locations will be blocked with a positive physical barrier, such that no fuel can be placed in the blocked positions. Figure 9.1-1 shows the locations where fuel will be stored;

b. There are three tiers of castings positioned by fixed box beams. The castings hold the fuel assemblies in a vertical position; the fuel assemblies are supported at the lower tie plate, with additional lateral support;

c. The lower casting is designed to support the weight of the fuel assembly and restrict lateral movement when used in the as-built configuration. To facilitate the assembly of ABB type fuel, a stub tube rests in the bottom casting to raise the fuel approximately 30 in. The center and top castings restrict only lateral movement of the fuel assembly;

d. The new fuel storage racks are made from aluminum. Materials used for construction are specified in accordance with the latest issue of applicable ASTM specifications. The material choice is based on a consideration of the susceptibility of various metal combinations to electrochemical reaction. When

considering the susceptibility of metals to galvanic corrosion, aluminum and stainless steel are similar insofar as their coupled potential is concerned. The use of stainless steel fasteners in aluminum to avoid detrimental galvanic corrosion is a recommended practice and has been used successfully for many years by the aluminum industry. The stub tubes are used when assembling Westinghouse type fuel, are made of stainless steel and are not directly fastened to lower casting;

e. Lead-in and lead-out of the casting provide guidance of the fuel assembly during insertion or withdrawal; and

f. The nominal center-to-center spacing with rows is 7 in. and between rows is 12 in. However, as shown in Figure 9.1-1, face adjacent locations are not used. The fuel assembly center-to-center spacing is a multiple of the above dimensions.

The fuel assemblies are loaded into the rack through the top. Each hole for a fuel assembly has adequate clearance for inserting or withdrawing the assembly channeled or unchanneled. Sufficient guidance is provided to preclude damage to the fuel assemblies. The design of the racks and the blocking devices prevent accidental insertion of the fuel assembly into a position not intended for the fuel. The only spaces in the racks are those into which it is intended to insert fuel. The weight of the fuel assembly is supported by the lower tie plate which is seated in a chamfered hole or stub tube in the base casting.

The floor of the new fuel storage vault is sloped towards a drain located at the low point. This removes any water that may be accidentally and unknowingly introduced into the vault. The drain is part of the floor drain subsystem of the liquid radwaste system.

The radiation monitoring equipment for the new fuel storage area is described in Section 12.3.4.

9.1.1.3 Safety Evaluation

9.1.1.3.1 Criticality Control

The calculations of k_{eff} are based on the geometrical arrangements of the fuel array, and that subcriticality does not depend on the presence of neutron absorbing materials. To meet the requirements of GDC 62, geometrically safe configurations of fuel stored in the new fuel array are used to ensure that k_{eff} will not exceed 0.95 if fuel is stored in the dry condition or in an abnormal mist condition with water densities up to 1.0 g/cm^3.

The new fuel storage vault has concrete covers with rubber seals.

The fuel storage rack is designed using noncombustible materials. New fuel storage vault covers prevent optimum moderation in the new fuel vault (water density between 0 and 1 g/cc).

The GE14 fuel assembly is a 10 x 10 fuel rod array with 2 internal water channels offset in the center of the assembly (displacing 8 fuel rod locations). The GE14 nominal design parameters are listed in Reference 9.1-14, Table 2-1. The GE14 new fuel storage vault model makes several key assumptions:

a. New fuel assemblies are assumed to contain the highest enriched unexposed lattice for the entire length of the assembly and are associated with a beginning-of-life reactivity of 1.31 with benchmark uncertainties included.

b. The GE14 analysis assumes infinite fuel in the axial direction (no axial reflector) for normal dry storage conditions and fully flooded abnormal conditions. Neutron absorption in fuel structural components is neglected.

c. The GE14 analysis assumes a finite geometry for a single new fuel vault loaded in accordance with the loading pattern shown in Figure 9.1-1. Neutron leakage is assumed on all sides, top, and bottom for optimally moderated abnormal conditions. Neutron absorption in fuel structural components is neglected with the exception of the concrete walls of the new fuel storage vault.

d. Up to 3 GE14 bundles can be safely handled in the spent fuel pool, outside of the spent fuel rack, in any configuration.

e. The results of the analysis include a statistical rollup of all significant manufacturing and calculational uncertainties and abnormal storage condition biases.

f. An infinitely long fuel bundle is modeled to lie horizontally at 1 cm above the active fuel region of the rack.

g. An abnormal condition that evaluates a misplaced fuel bundle that is loaded in addition to the fully loaded fuel loading pattern, shown in Figure 9.1-1, in a position that yields the optimum reactivity for the scenario.

The GNF2 fuel assembly is a 10 x 10 fuel rod array with 2 internal water channels offset in the center of the assembly. The GNF2 nominal parameters are listed in Reference 9.1-14, Table 2-1. The GNF2 new fuel storage vault model is consistent with the model described for GE14 (Reference 9.1-13).

9.1.1.3.2 New Fuel Rack Structural Design

The new fuel storage racks are designed to meet Seismic Category I requirements.

The maximum stress in the fully load rack in a faulted condition is 16.5 kips. This is significantly lower than the allowable stress.

The storage rack is designed to withstand horizontal combined loads up to 222,000 lb, well in excess of expected loads.

The storage rack is designed to withstand the pull-up force of 4000 lb and a horizontal force of 1000 lb. There are no readily available forces in excess of 1000 lb. The racks are designed with lead outs to prevent sticking. However, in the event of a stuck fuel bundle, the upward force on the racks is limited to the 1000 lb load limit of the jib crane (MT-CRA-9A or 9B) used to handle new fuel.

The storage rack structure (Figure 9.1-2) is designed to withstand the impact resulting from a falling weight. Tests using a simulated fuel bundle have been conducted to verify that the rack casting can withstand the impact from a bundle dropped from above the array. During testing the lowest drop to cause the rack casting to exceed ultimate stress was a drop of 6.17 ft (4314 ft/lb) made at mid span.

Therefore, procedural requirements dictate that no more than one bundle at a time can be handled over the storage array. These requirements ensure that the racks cannot be displaced in a manner causing critical spacing as a result of impact from a dropped fuel assembly. Since the 125-ton reactor building crane can traverse the full length of the refueling floor, administrative controls will prohibit carrying loads over the new fuel.

9.1.1.3.3 New Fuel Handling

New fuel is carried to the new fuel vault and placed in the storage rack with jib crane MT-CRA-9A or 9B or the reactor building crane auxiliary hoist. To handle the new fuel, rigging controlled by plant procedures is used, which interfaces with the lifting device at the upper end and the fuel bundle bail at the lower end.

During the positioning of a new fuel assembly into the new fuel rack, the rigging is always above the upper fuel rack casting. The rigging interfaces only with the fuel bundle bail, thus precluding engagement of the fuel rack. The transfer devices used for new fuel handling to the new fuel vault, therefore, cannot impose uplift loads on the rack castings. See Section 9.1.4.2.10.1 for further discussion of new fuel handling.

9.1.1.3.4 Other New Fuel Storage Design Factors

The new fuel racks are designed to be restrained by holddown bolts to ensure that rack spacing does not vary during the safe shutdown earthquake (SSE).

The storage rack structure is so designed that the height of the rack is less than the length of the fuel bundle. Therefore, the upper tie plate of the bundle cannot pass below the top cross member of the rack. Also, the fuel bundle insertion spaces in the top casting of the rack have

a lead in chamfer on the upper and lower surfaces. These design features prevent any tendency of the fuel bundle to jam during insertion into or removal from the rack.

The new fuel storage rack castings are made from aluminum and are secured by stainless steel fasteners. Materials used for construction are specified in accordance with ASTM Specifications B108, B179, B209, B211, and B221 dated January 1971.

The new fuel storage racks do not require any periodic special testing or inspection for nuclear safety purposes.

9.1.2 SPENT FUEL STORAGE

9.1.2.1 Design Bases

9.1.2.1.1 Safety Design Bases

9.1.2.1.1.1 Safety Design Bases - Structural.

a. The spent fuel storage racks are designed to withstand the affects of the SSE and remain functional and maintain subcriticality. The racks are also designed to withstand the impact of a dropped fuel assembly or the upward force of a stuck assembly without loss of function. The racks are designed and fabricated to meet seismic and quality class requirements per 10 CFR 50, Appendix B;

b. The spent fuel storage facility is located so that no missiles can enter the fuel pool with the necessary energy to cause any damage to the fuel; and

c. The reactor building containing the spent fuel storage facility provides the capability for limiting the potential offsite exposures in accordance with 10 CFR Part 100 in the event of significant release of radioactivity from the stored fuel.

9.1.2.1.1.2 Safety Design Bases - Nuclear.

a. The center-to-center spacing between stored fuel assemblies in a fully loaded rack is sufficient to maintain a k_{eff} less than 0.95 at a conservative water temperature.

b. The spent fuel storage rack design precludes storage of a fuel assembly other than where intended at a nominal 6.5 in. center to center distance between fuel assembly placed in the storage rack.

c. The spent fuel storage racks are designed to allow adequate cooling of the stored spent fuel assemblies; and

d. Shielding for the spent fuel storage arrangement is sufficient to protect plant personnel from exposure to radiation in excess of 10 CFR Part 20 limits.

e. Columbia has chosen to comply with 10 CFR 50.68, "Criticality Accident Requirements".

9.1.2.1.2 Power Generation Design Bases

a. Spent fuel storage space in the fuel storage pool is for 2658 fuel assemblies, and

b. Spent fuel storage racks are designed and arranged so that fuel assemblies can be handled efficiently during refueling operations.

9.1.2.2 Facilities Description

9.1.2.2.1 Spent Fuel Storage Racks

Spent fuel storage racks provide a place in the fuel pool for storing the spent fuel discharged from the reactor vessel. They are top entry racks, designed to maintain the spent fuel in a space geometry that precludes the possibility of criticality under both normal and abnormal conditions. This is accomplished with the aid of neutron absorbing plates. The location of the spent fuel pool within the plant is shown in Figures 1.2-10 and 1.2-11.

The spent fuel storage rack design, shown in Figure 9.1-3, consists of fuel storage cells which are square stainless steel tubes with neutron absorbing B_4C plates between them. A stainless steel plate grid at the top and the bottom of the tubes, to which the tubes are welded, form the tubes into racks and maintain center-to-center spacing between the tubes at 6.5 in. The racks are welded together into modules which are held firmly in place by seismic restraints attached between the rack modules and the pool wall. The storage racks are made of stainless steel. The square tube storage cells are 1/8 in. thick.

The neutron absorber plates have nominal dimensions of 19 in. long, 5.88 in. wide, and 0.2 in. thick. They are composed of B_4C granular material bonded together to form a plate of uniform properties. They have a nominal B-10 loading of 0.0959 g/cm^2 of plate and a plate density of 0.05 lb/in^3. The plate has been shown by tests to have negligible corrosion in water and thermally stable over the range of pool water temperatures that can occur. The plates are seal welded in a stainless steel cavity to prevent water intrusion and are vented at the pool curb through sampling valves.

There are no load bearing requirements for the plates. Based on the results of the Modulus of Rupture tests, the plates will withstand approximately two times the calculated stresses caused by a postulated seismic event. Plate integrity and mechanical properties have been verified by

comprehensive tests. These tests included Modulus of Rupture and Modulus of Elasticity tests. The Modulus of Rupture testing was performed using a three point support method and was done on specimens at temperatures varying from ambient to 300°F, specimens soaked in water, and irradiated specimens. The modulus of elasticity was performed using a resonance procedure and was done at varying temperatures and after the plate had been immersed in water. The tests showed no swelling, cracking, or dimensional changes and provided verification of the plate mechanical properties required for the rack design.

To prevent distortion of the spent fuel rack cavities and binding of spent fuel assemblies due to pressure buildup, the enclosures are vented through an arrangement of tubing and sampling valves to above the storage pool water surface at the pool curb. Monitoring for offgas pressure, sampling of offgas, and venting to relieve pressure are provided for.

Different rack sizes are used (12 x 16, 12 x 13, 8 x 13, 7 x 18, and 11 x 16 arrays) to take full advantage of the fuel storage space in the pool (see Figure 9.1-4). The upper rack structures are welded to an elevated base plate which, in turn, is supported by a system of welded beams and stiffeners. The base serves to support the weight of the fuel assemblies and to distribute the load to the pool floor. The base plate contains an opening at each fuel assembly storage location which accommodates the fuel assembly lower nozzle. Natural circulation of pool water flows upward through the lower nozzle and the fuel assembly to remove decay heat. The storage cells are designed to provide lateral support for the storage assemblies

The minimum edge-to-edge distance of the assembly array from adjacent concrete walls is 16.75 in. between the edge of the C-14 storage rack and the shipping cask storage area wall.

The seismic restraints are stainless steel turnbuckles located between the pool walls and the racks around the periphery of the pool (Figure 9.1-4). They are located at both the top and bottom of the rack and will transmit the seismic forces of the operating basis earthquake (OBE) and the SSE between the racks and the walls and remain functional. The turnbuckles are connected at the wall to stainless steel bands which are embedded in the concrete wall and seal welded to the pool liner.

9.1.2.2.2 Spent Fuel Storage Pool

The spent fuel storage pool is designed to withstand earthquake loadings as a Seismic Category I structure. It is a reinforced-concrete structure completely lined with stainless steel, which provides a leakproof membrane that is resistant to abrasion and damage during normal and refueling operations. The stainless steel liner plates are seamwelded together and are anchored to the surrounding concrete by concrete anchors in the walls and structural members in the floor welded to the liner plates. Each liner weld seam is backed up by a drainage monitoring channel. These channels form a series of interconnecting systems designed to provide the following:

a. Detection, measurement, and location of any liner leakage,

b. Prevention of pressure buildup behind the liner plates due to leakage, and

c. Prevention of uncontrolled loss of contaminated pool water to other relatively clean locations within the secondary containment.

This network of drainage monitoring channels is embedded in the concrete behind the liners and is designed to permit free gravity drainage to the radioactive drain system, the flow of which is monitored.

The refueling canal connecting the spent fuel storage pool to the reactor well is provided with two gates in series, with a monitor drain between them. This arrangement permits monitoring for any leaks and facilitates repair of a gate or seal, if required.

A gamma scan collimator port is located 15 ft 11 in. from the bottom of the fuel pool and extends through the side of the pool. Through this port, gamma scanning of radioactive reactor components and spent fuel assemblies can be performed. This nondestructive method of analysis by the measurement of the gamma radiation being emitted by a material can indicate fuel enrichment, reactor power distribution, or fission product content of the component being analyzed.

The water supply to the spent fuel pool is provided and level maintained as described in Section 9.1.3.

9.1.2.3 Safety Evaluation

9.1.2.3.1 Criticality Control

9.1.2.3.1.1 8 x 8 Fuel. The design of the spent fuel storage racks provides for a subcritical multiplication factor (k_{eff}) of ≤ 0.95 for both normal and abnormal storage conditions. Normal conditions exist when the fuel storage racks are covered with a normal depth of water (about 23 ft above the active fuel) for radiation shielding, and with the maximum number of fuel assemblies or bundles in their design storage position. An abnormal condition may result from damage caused by accidental drop of a fuel assembly or stuck fuel assembly during attempted withdrawal.

The criticality analyses of the normal condition included several conservative assumptions as well as the effect of uncertainties in calculation method and geometric and material variations of the fuel storage rack. The following conservative assumptions were used in the calculation:

a. Fresh fuel of 3.25 wt % ^{235}U enrichment.

Initially the maximum enrichment will be much lower than this, but could approach this value if an 18-month fuel cycle is used. The enrichment selected is higher than the average enrichment of any fuel expected to be stored in the spent fuel pool. It was chosen because the fully loaded rack of fuel with this enrichment gives a more reactive condition than any presently foreseen;

b. Uniform planar array of 3.25 wt % enrichment fuel. Calculations have shown that this is conservative compared to the realistic, planar distributed enrichments within an assembly;

c. Spent fuel pool bulk water temperature 68°F. This is considerably lower than expected. Nevertheless, a calculation was done to determine the increase in reactivity due to a decrease in pool temperature to 32°F. The results showed the effect to be negligible;

d. Fuel racks are infinite in three dimensions; and

e. Fixed neutron poisons in the fuel assembly are neglected.

The majority of the calculations were performed with methods commonly used in light water reactor design; i.e., four-group diffusion theory cell calculations using PDQ-7 (Reference 9.1-2). Cross sections for these calculations are generated with NUMICE-2 (Reference 9.1-3), the NUS Corporation version of the Westinghouse LEOPARD code. This code uses the same cross section library tape and calculational techniques as LEOPARD. Selected cases were checked and the final design multiplication factors were verified with Monte Carlo calculations using KENO-IV (Reference 9.1-4), with a 123-group cross section library generated from a basic GAM-THERMOS library using two subroutines, NITAWL and XSDRNPM, in the AMPX1 (Reference 9.1-5) code package. Both the PDQ-7 and the KENO-IV calculation methods, as described above, have been benchmarked. These calculation methods, as described, were used for the Columbia Generating Station (CGS) calculation and do not contain any significant modifications.

Under normal conditions, for a center-to-center spacing of 6.5 in. between fuel assemblies with B_4C plates surrounding each stored fuel assembly, the k_{eff}, as determined using KENO, is 0.851. With the void space between the B_4C plates and the stainless steel box flooded with water, the KENO calculation yielded a lower k_{eff}. Calculation uncertainties were determined from comparison between calculation and experiments using KENO and a statistical evaluation of Monte Carlo runs. The results indicated a calculational uncertainty for the former of 0.013 Δk and for the latter 0.010 Δk at a 95% confidence level; this represents a total calculation uncertainty of 0.023 Δk. Mechanical spacing and tolerances acting in a direction close to the water gaps between adjacent racks result in a slight reactivity increase of 0.002 Δk. Production tolerances of B_4C plates result in a reactivity increase of 0.003 Δk.

To determine the effect of reduced or missing neutron absorbing material, it was assumed that one out of every 25 neutron absorber plates was missing. This case is extremely unlikely but shows poison variation sensitivity. The results of the calculation was an increase in reactivity of 0.015 Δk. A temperature decrease in pool water temperature of 32°F was included, i.e., 0.004 Δk. Adding the total calculational uncertainties of 0.023 Δk and the total geometric and material uncertainties of 0.024 Δk to the nominal k_{eff} results in a k_{eff} of 0.897 with a confidence level of 95%. This is well below the design basis of $\leq$0.95% for the normal wet condition.

Two abnormal conditions were also considered. They are (a) a dropped assembly assumed to lay across the top of a fuel rack and (b) a fuel assembly in transport in a vertical position, accidentally dropped into the water channels between racks. Of these two, the second condition is more severe. For the first condition, the end fittings on the top of the BWR assembly prohibits a spacing between the dropped assembly and the active fuel in the storage racks of less than 11.6 in. Using the same techniques, assumptions, and uncertainties previously discussed, the second case resulted in a k_{eff} of 0.903. This is only slightly different from the conservative normal condition and within the design basis k_{eff} of $\leq$0.95.

9.1.2.3.1.2 9 x 9 and 10 x 10 Fuel. The criticality safety of the spent fuel storage rack with 9 x 9-9X, SVEA-96 (10 x 10), ATRIUM-10 (10 x 10), GE14 (10 x 10) and GNF2 (10 x 10) fuel is assessed in accordance with NUREG 0800 and ANSI/ANS 57.2 (References 9.1-7, 9.1-8, 9.1-9, 9.1-11 and 9.1-13). The spent fuel storage rack meets the applicable criticality safety criteria subject to the conditions given below:

a. Fuel design - As specified below with a maximum enrichment of 4.0 wt % ^{235}U for 9 x 9-9X fuel.

b. For SVEA-96 fuel - Enrichment above 3.77 wt % ^{235}U is allowed in the spent fuel pool by determining the reactivity equivalency. Reactivity equivalency is predicated on the reduction in reactivity associated with the combination of fuel depletion and gadolinia burnable absorbers (Reference 9.1-8). The reactivity equivalency is checked for each SVEA assembly design for each reload. Any significant deviation from the fuel assembly geometry specified by this design will require additional analysis as specified in Westinghouse methodology (CE NPSD-786-P, Revision 1).

c. For ATRIUM-10 fuel, the maximum enriched lattice zone is ≤4.6 wt % ^{235}U with ≥10 gadolinia rods at ≥2.0 wt % Gd_2O_3. Any significant deviation from the fuel assembly geometry specified by this design will require additional analysis as specified in AREVA NP methodology (Reference 9.1-9).

d. The CGS spent fuel fuel storage racks were analyzed for the storage of GE14 fuel bundles. The analyses were performed with the MCNP01A (GEH's version of MCNP4A) Monte Carlo neutron transport program (Reference 9.1-

10). The GE14 spent fuel design basis bundle was analyzed in rack with an infinite lattice geometry and uniform 4.9w% U-235 enrichment, using both full and part length fuel rods with initial distributed fissile inventories, burnable absorber, and evaluated at its respective cold, uncontrolled, exposure-dependent reactivity statepoints. Representative placement and numbers of Gadolinium rods were used to model a peak in-core eigenvalue (k_∞) of 1.33 using the TGBLA06A production lattice physics code with benchmark uncertainties included. Any fuel meeting a k_∞ of 1.33 and the established in-core calculated benchmark uncertainties of the GE14 analysis are also bounded by the results of the GE14 analysis. No further evaluation is required.

e. The CGS spent fuel storage racks were analyzed for the storage of GNF2 fuel bundles. The GNF2 spent fuel storage rack model is consistent with the model described for GE14. Reference 9.1-13 provides additional details about the GNF2 fuel storage analysis.

f. When stored, the fuel assemblies must be inserted into the fuel storage boxes such that no fully enriched fuel protrudes above the B_4C absorber plates to a maximum fuel assembly protrusion of less than six in. (i.e., no more than 11.4 in. from the top of the bail handle to the top of the storage rack).

g. B_4C content in the absorber plates is constant over time; and

h. The B_4C plates contain no significant gaps.

The key assembly design parameters used in these calculations are listed in Table 9.1-1. The 9 x 9 assembly has 72 enriched uranium fuel rods. An internal water channel is located in the central portion of the assembly.

The SVEA-96 assembly has 96 fuel rods in a 10 x 10 array with four central rods missing. An internal cruciform water channel separates the 96 rods into four subassemblies of 24 rods each.

a. The neutron multiplication factors were calculated using KENO V.a,

b. Specular reflection was used with all models which means that no credit is taken for neutron leakage. In other words, k_∞ and k_{eff} are identical for the models used in this analysis, and

c. All codes and cross sections have been benchmarked against critical experiment data.

The major assumptions made in this analysis are as follows:

a. Fuel enrichment is the bundle average in all rod locations,

b. Fuel contains no burnable poisons,

c. No soluble poisons are present in the water,

d. Spent fuel pool bulk water temperature 68°F including a temperature decrease to 32°F,

e. B_4C content in the absorber plates is constant over time, and

f. The B_4C plates contain no significant gaps.

The first four assumptions make the analysis conservative. The last two are limiting conditions.

The ATRIUM-10 fuel assembly is a 10 x 10 fuel rod array with an internal water channel offset in the center of the assembly (displacing nine fuel rod locations). The assembly contains part length fuel rods constituting a "top" lattice (above the part length fuel rods) and a "bottom" lattice (below the part length fuel rods). The ATRIUM-10 nominal design parameters are listed in Table 9.1-1.

The following conservative assumptions are made:

a. The results are based on a moderator temperature of 4°C (39°F), which gives the highest reactivity for the fuel pool racks;

b. Fuel assemblies are assumed to contain the highest enriched lattice (highest reactive lattice) for the entire length of the assembly;

c. Each fuel assembly in the array is assumed to be at the peak reactivity of its lifetime;

d. Analyses assumes infinite fuel in the axial direction (no axial reflector);

e. Neutron absorption in fuel structural components is neglected; and

f. The maximum reactivity values include all significant manufacturing and calculational uncertainties.

The GNF2 and GE14 fuel assemblies are a 10 x 10 fuel rod array with 2 internal water rods offset in the center of the assembly (displacing 8 fuel rod locations). The GNF2 and GE14 nominal design parameters are listed in Table 2-1 of Reference 9.1-14.

The GNF2 and GE14 analysis 12 x 16 spent fuel storage rack model assumes several key assumptions:

a. Fuel assemblies are assumed to contain the highest enriched lattice for the entire length of the assembly and are associated with a peak in-core reactivity of 1.33 with benchmark uncertainties included.

b. The analysis assumes infinite fuel in the axial direction (no axial reflector).

c. Neutron absorption in fuel structural components is neglected.

d. The outer sides of the 12 x 16 storage rack array (Figures 9.1-3 and 9.1-4) contain no boron carbide absorber plates. Boron carbide absorber plates are only located along the inner walls of the spent fuel rack lattice structure. The 12 x 16 infinite array model is bounding for the actual spacing and rack configurations in the spent fuel pool with mixed adjacent 12 x 16 and 12 x 11 fuel arrays.

e. Up to three GNF2 and GE14 bundles can be safely handled in the spent fuel pool, outside of the spent fuel rack, in any configuration.

f. The results of the analysis include a statistical rollup of all significant manufacturing and calculation uncertainties and abnormal storage condition biases.

g. The following abnormal conditions have been evaluated as part of this analysis and have been accounted for within the bias of the maximum k-effective result:

    i. Four damaged fuel bundles surround the non-borated intersection of the four 12 x 16 array spent fuel storage racks. This model approximates the damage to the bundles by optimizing the fuel rod pitch of the design basis bundle within the fuel box without consideration of the bundle channel. The fuel rod arrays in each of the four fuel boxes are placed as close to the intersection of the four 12 x 16 arrays as possible. This model does not consider damage to the storage rack.

ii. Misplaced/dropped fuel bundle in between storage rack modules.

iii. An infinitely long fuel bundle is modeled to lie horizontally at 1 cm above the active fuel region of the rack.

iv. A single bundle protruding from the top of the borated region of the spent fuel rack by a maximum distance of 6 in.

All normal and credible abnormal conditions are found to have an acceptable reactivity, (k_{eff}) of ≤ 0.95 after adding the calculational uncertainty. The assumption that the entire fuel storage rack contains 9 x 9-9X fuel with up to 4.0 wt % ^{235}U, SVEA-96 fuel with up to 3.77 wt % ^{235}U, ATRIUM-10 fuel with each lattice zone ≤4.6 wt % ^{235}U with ≥10 gadolinia rods at ≥2 wt % Gd_2O_3 and GE14 and GNF2 fuel with ≤ 4.9 wt% ^{235}U and a Gd_2O_3 loading that corresponds to an in-core reactivity of 1.33 conservatively accounts for the presence and potential intermixing of older and lower enriched 8 x 8 fuel bundles.

9.1.2.3.2 Spent Fuel Storage Rack Structural Design

In accordance with Regulatory Guide 1.13, Revision 1, the spent fuel storage racks are designed to Seismic Category I requirements. Structural integrity of the racks when subject to normal and abnormal loads, as well as seismic loads, is demonstrated in accordance with the load requirements and acceptance criteria of Standard Review Plan Section 3.8.4. The loads considered are

a. Dead loads which are the dead weight of the rack and fuel assemblies and hydrostatic loads,

b. Live loads, i.e., the effect of lifting empty racks during installation,

c. Thermal loads, which include the uniform thermal expansion of the racks due to increases in average pool temperature, and a thermal gradient between adjacent storage locations,

d. The seismic forces of the OBE and SSE,

e. Accidental drop of a fuel assembly from the maximum possible height consistent with fuel handling operations, which is 4 ft above the top of fuel rack, and

f. Postulated stuck fuel assembly causing an upward force of 1200 lb, equal to the fuel grapple load limit to be exerted on the assembly upon attempted withdrawal.

The spent fuel storage racks were analyzed for six combinations of these loads using elastic working stress design methods. The combinations are

a. Dead loads plus live loads,
b. Dead loads plus OBE,
c. Dead loads plus thermal loads plus OBE,
d. Dead loads plus thermal loads plus SSE,
e. Dead loads plus thermal loads plus fuel assembly drop, and
f. Dead loads plus thermal loads plus stuck fuel assembly.

Live loads are not included in load combinations b through f. The only live load on the rack is that due to lifting of the racks which is performed with the racks empty. In all cases the loads were below the strength limits, which were determined from Part I of the AISC "Specification for the Design, Fabrication and Reaction of Structural Steel for Buildings," February 12, 1969, and Supplements 1, 2, and 3. (Supplement 3 was effective June 12, 1974.)

Individual fuel racks are welded into either 1 x 2 or 2 x 2 rack arrays or "super modules." These super modules are then attached to the fuel pool walls at two elevations by adjustable seismic restraints which are essentially large turnbuckles. These restraints are designed and positioned to eliminate any significant thermal growth loads on the walls.

The fundamental frequency of lateral vibration of the welded rack array yielding the lowest frequency was determined using the STARDYNE3 (Reference 9.1-6) computer program. The model, consisting of beam and plate elements and lumped masses, represents a three-dimensional 2 x 2 rack array. The model has an array of beams, representing fuel storage cans, connecting the upper and lower grids, and resting on a base grid which is held off the pool floor by support feet. The rack is restrained laterally by two levels springs, representing the seismic restraints. The stiffnesses of the fuel assemblies and B_4C neutron absorber plates conservatively were neglected. However, the mass of the fuel assemblies, as well as the mass of the B_4C plates and an effective mass of water was considered to be uniformly distributed over the height of the fuel boxes. The results of the STARDYNE analysis showed a lateral natural frequency of 14.7 Hz. A dynamic analysis was performed using the horizontal floor response spectra (damping 0.5% of critical).

The fundamental frequency of vertical vibration of the rack was also determined using the STARDYNE computer program. The same model replacing lateral mass with vertical mass was utilized. In this case, since the fuel rests on the base frame, the entire mass of the fuel was lumped at the base grid. Since the calculated frequency was 50.9 Hz and the vertical floor response spectra (damping 0.5% of critical) showed constant acceleration at frequencies in excess of 18 Hz, the effects of the vertical accelerations were considered using the zero-period acceleration in a static analysis. The lateral and vertical loads were considered to be acting simultaneously.

In the general seismic/structural analysis of the fuel racks, the mass of a fuel assembly is assumed to be uniformly distributed along the length of each of the fuel storage cans. Since a maximum gap on the order of 3/8 in. exists between the side of a fuel assembly and the can (when the fuel is not encased in a channel), the fuel will actually move within the can during a seismic event and cause impact loads to be transmitted to the fuel rack restraints. The effects of this fuel can interaction are determined using a simplified finite element model of the rack and fuel. A nonlinear dynamic analysis is performed using the ANSYS computer program. Details of this analysis are given in NUS Corporation Technical Report 2060, entitled "Fuel-Can Interaction Analysis," October 1977.

Using the given loads, load combinations, and analytical methods, stresses were calculated at critical sections of the rack and compared to the structural acceptance criteria. In all cases, the calculated stress did not exceed the allowable stress.

To ensure the integrity of the spent fuel storage racks in the event that water has leaked into the racks, specially designed control samples, consisting of B_4C plates in vented (to pool water) canisters, are placed in a readily accessible position in the spent fuel pool. These samples are subjected to periodic examinations to check for possible deterioration and they are also analyzed to ensure that the boron has not leached from the plates.

Section 15.7.4 presents an analysis (for radiological considerations) of fuel handling accidents.

The high density fuel rack designer, NUS Corporation, analyzed the fuel racks from both a structural and criticality standpoint concerning a 1510-lb object dropped from the surface of the fuel pool. The results indicated that none of the fuel rack damage that might occur in this situation would lead to a criticality problem. Details of these analyses are given in NUS Corporation Technical Reports 5326-FA-01 and G-RA-17 entitled, "Structural Analysis of the CGS Rack and Fuel Assemblies for an Accidental Object Drop Loading Condition," and "Criticality Analysis of Dropped Object Accident for WNP-2 Spent Fuel Storage Racks," respectively.

Similarly, independent analysis of GNF2 and GE14 fuel indicates that none of the fuel rack damage that might occur would result in increased reactivity that could exceed the 0.95 safety limit. This evaluation is based the guidance of NUREG-0612 and includes damage to the four

fuel bundles that surround the non-borated intersection of the four 12 x 16 array spent fuel storage racks (Figures 9.1-3 and 9.1-4). The 12 x 16 infinite array model is bounding for the actual spacing and rack configurations in the spent fuel pool with mixed adjacent 12 x 16 and 12 x 11 fuel arrays. This model approximates the damage to the bundles by optimizing the fuel rod pitch of the design basis bundle within the fuel box without consideration of the bundle channel. The fuel rod arrays in each of the four fuel boxes are placed as close to the intersection of the four 12 x 16 arrays as possible. The model does not consider damage to the storage rack.

During shutdown, crane operations over the spent fuel storage pool (when fuel assemblies are stored within) are suspended when operability of less than the required number of onsite and offsite power sources occurs, as defined in the Technical Specifications.

9.1.2.3.3 Spent Fuel and Cask Handling

The 125-ton reactor building crane traverses the full length of the refueling floor level of the reactor building. The design of the refueling floor provides aisles on both sides of the fuel pool for moving components past (and not over) the fuel storage pool. Interlocks on the reactor building crane prevent travel over the spent fuel racks. The interlock-controlled restricted area for crane travel is shown in Figure 9.1-5. The interlocks are bypassed only when it is necessary to operate the crane in the fuel pool area in conjunction with activities associated with fuel handling and storage. During these rare occasions when the interlocks are bypassed, administrative controls are used to prevent the crane from carrying loads that are not necessary for fuel handling or storage and which are in excess of the rack design drop load (one fuel assembly at 4 ft above the top of the fuel rack). See Section 9.1.2.3.2.

Transfer of fuel assemblies between the reactor well and the spent fuel pool is performed with the refueling platform (see Section 9.1.4.2.10.2). The fuel grapple or the auxiliary fuel hoist may be used, depending on the transfer operation.

The grapple and hoists are provided with load sensing and limiting devices designed to the following limits:

	NF-500 Fuel Grapple (lb)	Auxiliary Hoists (lb)
Load limiting switch NF500	1700	1000
Load sensing switch Auxiliary Hoist		535
Load sensing switch NF500	750	
Stall torque for hoist system	3000	3000

The load limiting features of the refueling platform grapple and auxiliary fuel hoist will prevent damage to the fuel racks if a fuel assembly accidentally engages a rack while being lifted.

These load limits provide a redundant safety feature since the fuel handling grapple is not lowered below the upper fuel rack and is designed to interface only with the fuel bail. Thus, the possibility of inadvertent direct lifting of the racks with the grapple is precluded.

Guard rails around the spent fuel pool prevent the falling of fuel handling area machinery into the pool. Other objects that could conceivably fall into the pool will not transfer energy amounts exceeding the specified limits of the fuel racks.

The preclusion of accidental dropping of the spent fuel cask on the spent fuel racks is accomplished by incorporating a separate cask storage area in the spent fuel pool, by interlocks on the reactor building crane, and by designing the path of the spent fuel cask to avoid passing over the spent fuel racks. The pool cask storage area is separated from the spent fuel racks by a wall over which the spent fuel is transferred.

For removal of spent fuel from the plant, a spent fuel cask is lowered into the cask area. Transfer of fuel to the cask is made over the wall between the spent fuel racks and the cask storage area. When the main hook of the reactor building crane removes the cask from the cask area, it follows the travel path shown in Figure 9.1-5. In addition, sufficient redundancy is provided in the reactor building crane such that no credible postulated failure of any crane component will result in the dropping of the fuel cask. See Section 9.1.4.2.2.

Failure of the gates between the reactor well and the spent fuel storage pool is improbable. However, in the event of this failure, the loss of water from the storage pool into the reactor well would not uncover the stored spent fuel due to the elevation of the weir wall under the gates. This elevation ensures that sufficient water is retained in the pool to cover the spent fuel.

To avoid unintentional draining of the spent fuel storage pool to levels below that required for adequate shielding of the spent fuel, no inlets, outlets, or drains that would normally permit the pool to be drained are provided. Discharge lines extending below the pool water level are designed to prevent any siphon back flow. Two skimmer surge tanks are provided and are sized to accommodate water displacement due to large items being placed into or removed from the spent fuel storage pool.

See Section 9.1.3 for additional evaluation of continuous cooling capabilities of the spent fuel pool cooling and cleanup (FPC) system.

9.1.2.3.4 Spent Fuel Rack Design Features

The rack, rack modules, and restraints are all stainless steel, as is the spent fuel pool liner, to minimize the potential for galvanic corrosion. Stainless steel has also been shown to be compatible with spent fuel pool water and the stored assemblies.

The fuel rack base is elevated above the floor to ensure adequate flow under the rack in each fuel assembly. Analyses have been performed and show that sufficient flow is induced by natural convection to preclude local boiling in the hottest storage location.

The analyses were based on the following assumptions:

a. The fuel element inlet temperature is the mixed hot design temperature of the pool,

b. A hot assembly peaking factor of 1.74 is applied to the core average assembly energy release rate of 5.3×10^4 Btu/hr,

c. The maximum local peaking factor is 2.49, giving a maximum local heat flux of 1334 Btu/hr-ft^2,

d. A film coefficient of 31 Btu/hr-ft^2-°F is based on pure conduction through a stagnant boundary layer at the fuel rod surface,

e. The downcomer region feeds 12 assemblies in a row, each assumed to be generating the maximum heat rate defined in assumption b, and

f. One dimensional fluid flow analysis applies.

During full core offload with the bulk pool temperature at a design value of 150°F, the mixed temperature of the water exiting from the hottest storage location is less than 181°F. This is 58°F below the local saturation temperature of 239°F, indicating that adequate margin to bulk boiling exists. Under normal operating conditions, the fuel rod surface temperature calculated on the basis of the heat flux and film coefficient defined above is more than 14°F below the local saturation temperature. Local boiling is thus precluded.

The fuel racks are designed, constructed, and fabricated with a high degree of reliability and integrity. A list of the industry design codes and standards used for the spent fuel storage racks is given below.

Design Codes

a. AISC Manual of Steel Construction, 7th Edition, 1970,

b. ASME Boiler and Pressure Vessel Code Section III-1971, Nuclear Power Plant Components. (Tables I-2.2, I-5.0, and I-6.0 are used for yield strength values, coefficients of thermal expansion, and moduli of elasticity),

c. AISC Specification for the Design, Fabrication, and Erection of Structural Steel for Buildings, February 12, 1969 and Supplements 1, 2, and 3 (Supplement 3 effective 6/12/74),

d. ASTM Specification A 240-75a, Specification for Heat-Resisting Chromium and Chromium-Nickel Stainless Steel Plate Sheet and Strip for Fusion-Welded Unfired Pressure Vessels,

e. ASTM Specification A 320-74, Specification for Alloy Steel Bolting Materials for Low-Temperature Service,

f. AWS A 5.9, Corrosion Resisting Chromium and Chromium-Nickel Steel Welding Rods and Bare Electrodes, and

g. ASME Boiler and Pressure Vessel Code Section IX-1974, Welding and Brazing Qualification.

9.1.2.3.5 Spent Fuel Storage Facilities Design

The spent fuel storage pool is designed to Seismic Category I requirements to prevent earthquake damage to the stored fuel. The exterior walls and roof of the reactor building are designed as low-leakage barriers to confine potential airborne radiation (contamination) within the reactor building and the exhaust air treatment systems.

Release of radioactive products from damaged or failed fuel in the spent fuel pool will be detected by a high level gamma radiation monitor located in the fuel pool vicinity. This instrument has a range of 100 to 10^6 mrem/hr with remote readout and alarm in the main control room. Backup detection provided by high radioactivity monitors in the reactor building ventilation system exhaust plenum (see Section 9.4.2) will initiate reactor building ventilation system isolation and operation of the standby gas treatment system (see Section 6.5.1) to block potential leakage of contaminated air to the environment. See Chapter 15 for radiological considerations.

The spent fuel storage pool contains a minimum water depth of 22 ft above the top of the irradiated fuel assemblies seated in the spent fuel storage racks. A low water level alarm is provided in the control room in the event of loss of pool water. As a backup, flow alarms are provided in the drain lines to detect leakage in the reactor vessel to drywell seal, drywell to concrete seal, and fuel pool gate. An adequate fuel pool water level can be maintained, even in the unlikely event of a pipe break between the skimmer surge tanks and the FPC system pumps, since fuel pool discharge to the skimmer surge tanks is by overflow only. A pipe break would drain the skimmer surge tank but would not reduce the spent fuel storage level. A check valve in each supply pipe from the FPC system prevents siphon back flow to the cleanup system. Provision is also made so that standby service water (SW) can be used as

backup for fuel pool makeup upon failure of the normal makeup system. This connection is capable of supplying enough water to prevent the uncovering of the spent fuel. By use of the standby SW as makeup, the fuel pool will be cooled by evaporation of the pool water. The residual heat removal (RHR) system can be operated in parallel with the fuel pool cooling system, to remove abnormal heat loads in the fuel pool. See Section 9.1.3 for details.

The reactor building below the refueling floor is designed to be tornado proof. Tornado missiles below this elevation cannot impair the structural integrity of the pool. Missiles which could reach the pool from above are small enough that they could not impair the structural integrity of the pool. Metal siding above the refueling floor blows out during a tornado. All large objects on the refueling floor are secured so that they cannot be carried into the fuel pool. See Section 3.3 and GE Topical Report, APED-5696, Tornado Protection for the Spent Fuel Storage Pool.

Leak detection channels are provided on the concrete sides of the spent fuel storage pool liner. Surveillance of flow indications from these leak channels permits early determination and localization of any leakage.

9.1.2.3.6 Radiological Considerations

9.1.2.3.6.1 Normal Operation. Three sources of exposure to personnel in the area of the spent fuel storage pool are considered:

a. Direct dose from the stored fuel,
b. Dose from the radionuclides in the spent fuel pool water, and
c. Dose from airborne tritium.

Direct dose from the stored fuel is negligible due to the height of water above the storage positions. Calculations indicate a direct dose from stored fuel of less than 1×10^{-5} mrem/hr.

Most of the personnel exposure in the area of the spent fuel storage pool comes from the radionuclide inventory in the water. Estimates of the dose from this source were calculated to be 3.5 mrem/hr during the first refueling, increasing to 6.9 mrem/hr during the eleventh refueling. These calculated values are given in Table 9.1-2.

The dose from airborne tritium is limited by spent fuel storage pool water temperature limitations as described in Section 9.1.3 and by the fuel pool exhaust ventilation described in Section 9.4.2.

9.1.2.3.6.2 Radiological Consequences of Accidents. See Chapter 15.

The storage racks, storage pool and associated equipment, and the reactor building in which the pool is located, are designed to remain functional through and after an SSE.

The impact of heavy objects on the racks has been considered in the design. The reactor building below the refueling floor is tornado proof and tornado missiles that could reach the pool from above this level are small enough that the structural integrity of the pool (and racks therein) could not be impaired. The drop of a spent fuel shipping cask is precluded by redundancy features of the crane and other design features discussed in Section 9.1.2.3.3.

9.1.2.3.7 Conclusions

From the foregoing analyses, it is concluded that the spent fuel storage arrangement and design comply with the objectives in Regulatory Guide 1.13, Revision 1.

9.1.3 SPENT FUEL POOL COOLING AND CLEANUP SYSTEM

9.1.3.1 Design Bases

The FPC system has been designed to comply with the objectives in Regulatory Guides 1.13, Revision 1, and 1.26, Revision 3, to the extent specified in the following subsections. The system and equipment are designed to the classifications given in Tables 3.2-1 and 9.1-3.

During normal reactor operation the system is designed to remove decay heat released from the stored spent fuel elements and maintain a specified fuel pool water temperature, water clarity, and water level by accomplishing the following:

a. Minimizing corrosion product buildup and controlling fuel pool water clarity so that fuel assemblies can be efficiently handled underwater,

b. Minimizing fission product concentration in the fuel pool water thereby minimizing the release of fission products from the pool to the reactor building environment,

c. Monitoring surge tank water level to thereby maintain a pool water level above the fuel sufficient to provide shielding for normal building occupancy and to control makeup flow rate from the condensate transfer system, and

d. Maintaining the fuel pool water temperature below 125°F under normal (nonrefueling) operating conditions. The maximum heat load in the fuel pool occurs during refueling. The magnitude of this heat load will vary for each refueling based on the number of irradiated fuel assemblies moved from the reactor core to the fuel pool, the burnup of each fuel assembly, and the decay time of each fuel assembly.

Additionally, the system also provides cleanup for purity and clarity control to the reactor well, dryer-separator pool, and the suppression pool.

During shutdown conditions, the RHR system may be operated to remove the decay heat load. However, the RHR assist mode may only be credited for spent fuel pool cooling during a full core offload.

In Section 1.3.2 it was indicated that a significant change was made in the fuel pool cooling system between the time of the PSAR and FSAR. The design basis originally relied on fuel pool boiling following a severe seismic event and provided for safety grade makeup from the standby SW system. In the final design, the design basis of the fuel pool cooling portion of the system was changed to Seismic Category I. Following a seismic event or major plant disturbance, the system is designed to prevent fuel pool boiling and maintain adequate water level in the spent fuel pool by means of the following:

a. Automatic isolation on low fuel pool water level of the Seismic Category I cooling portion of the system from the Seismic Category II cleanup portion of the system,

b. Remote-manual startup from the control room of redundant, active components of the fuel pool cooling portion of the system, and initiation of safety grade cooling water from the standby SW system, to the fuel pool cooling heat exchangers,

c. Remote valve operation, from the control room, to initiate SW cooling to the FPC heat exchangers, and

d. Redundant SW system makeup to the fuel pool (see Section 3.1.2.6.2) and fuel pool level monitoring from the control room.

9.1.3.2 System Description

The FPC system must operate in a variety of conditions. During normal reactor operations the FPC provides for cooling and cleaning of the spent fuel pool containing discharged fuel assemblies. During refueling outages, the FPC system may be required to provide additional decay heat removal. The spent fuel pool cooling function can be provided by operating both trains of FPC. The RHR B loop may only be credited for FPC assist during a full core offload. The RHR B loop may be operated, but not credited, to provide supplemental cooling as required. The RHR B loop can be cross connected to the FPC system. In addition, with the reactor cavity flooded and fuel pool gates removed, RHR A or B may be lined up to take suction from the surge tanks and discharge to the RPV.

The FPC system flow diagram is shown in Figures 9.1-6.1 and 9.1-6.2.

System performance data are summarized in Table 9.1-5. Major components of the system are summarized in Table 9.1-3. The system is designed to dissipate the fuel pool heat load during normal operation and refueling conditions.

The FPC system consists of two separate trains, each containing a circulating pump and a heat exchanger. The system also contains two filter demineralizers and two skimmer surge tanks, as well as the required piping, valves, and instrumentation. Except for the pumps, heat exchangers and filter demineralizers, common piping headers are used. The FPC pumps normally circulate the pool water in a closed loop, taking suction from the surge tanks, circulating the water through a heat exchanger and a filter demineralizer, and discharging it through the diffusers at the bottom of the fuel pool. During refueling, pool water is discharged through the fuel pool diffusers or through diffusers in the reactor well. The water flows from the pool surface through skimmer weirs to the surge tanks. Makeup water for the system is normally transferred from the condensate storage tank to a skimmer surge tank to make up pool water losses. The fuel pool pumps and heat exchangers are located in an enclosed room on the 548-ft level of the reactor building beneath the fuel pool.

Instrumentation is provided for both automatic and remote manual operation. Indication is provided in the control room. Surge tank high and low water level switches are provided. Control of flow to or from the reactor well can be accomplished during refueling. A fuel pool high/low water level switch sounds an alarm in the control room whenever the level is either too high or too low. The alarm points are fixed at the bottom of the weirs (low) and 1-1/8 in. above the normal water level (high).

The pumps are controlled from instrument racks on the 522 ft el. and the control room. Pump low suction pressure automatically shuts down the operating pump(s). A pump low discharge pressure alarm annunciates in the control room and starts the standby pump.

A high rate of leakage through the reactor drywell refueling bellows assembly, drywell to reactor well seal, or the fuel pool gates is indicated locally and is alarmed in the control room.

Failure of the reactor closed cooling water system (RCC), RHR, or a loss of inventory, are addressed in procedures. The FPC system operation and RHR/FPC assist modes of operation are each discussed in the following sections in more detail.

9.1.3.2.1 System Operation

9.1.3.2.1.1 FPC System Cooling Function

The system normally cools the fuel pool by transferring the spent fuel decay heat from the tube side of the two fuel pool cooling heat exchangers to the RCC. Standby SW can be manually aligned as the alternate heat sink for the heat exchangers (see Section 9.1.3.2.3 for additional

details). The fuel pool is maintained at or below 125°F during normal plant operations. The fuel pool temperature may rise above this value during refueling activities or during an anticipated operational transient of the loss of one train of the FPC system. The RHR system can also be manually aligned into several configurations to provide supplemental cooling of the fuel pool. One of these RHR configurations is the RHR/FPC assist mode of RHR (see Section 9.1.3.2.2 for additional details).

The maximum heat load is present in the spent fuel pool during refueling activities when recently irradiated fuel bundles are discharged from the reactor core to the fuel pool. The magnitude of this heat load is contingent upon the cycle-specific refueling activities, i.e., the number of the bundles discharged, the burnup of the discharged bundles, and the decay time of each bundle when it is placed in the fuel pool. The heat load associated with a planned discharge can be calculated with the ORIGEN-ARP computer code assuming a .34% thermal power uncertainty or other acceptable means to account for code bias and uncertainties. During refueling activities, the fuel pool temperature is managed by controlling the number and schedule of fuel assemblies discharged, controlling the number of heat removal systems in service, and controlling the temperatures of the systems (RCC or SW) used to remove the heat from the FPC heat exchangers.

The fuel pool cooling system was originally designed to maintain the pool at a temperature of less than or equal to 125°F during refueling activities with both trains of fuel pool cooling in operation and RCC cooling water at 95°F. The decay heat load assumed for the original design basis (normal offload) was based on the original licensed power of 3323 MW-thermal, a one-year fuel cycle, and a quarter core offload with a 20-day decay period.

Since the original design, the licensed power was increased to 3544 MW-thermal and the operating cycle was revised from a one-year cycle to a two-year cycle. These changes resulted in an increased heat load in the fuel pool, particularly during refueling outages. For the current design (3544 MW-thermal and a two-year cycle), a 150°F fuel pool temperature limit (see Table 9.1-6) applies to normal refueling activities for the scenario of both trains of fuel pool cooling in operation.

The FPC system is also designed to provide sufficient cooling for an anticipated operational transient of the loss of one train of the FPC system. For this transient, the maximum bulk fuel pool water temperature is limited to 175°F. This limit applies to both normal operation and normal refueling activities (i.e., excluding a full core offload).

The system's ability to satisfy these temperature limits could be challenged based on outage-specific plans or activities. Outage-specific calculations are performed, as needed, to ensure acceptance criteria limits are maintained and adequate decay heat removal capability exists. Management of the rate and magnitude of the heat load added to the fuel pool during refueling activities and the temperature of the credited heat sink (i.e., RCC or SW) are considered.

Energy Northwest does not routinely perform full core offloads at Columbia and as such, a full core offload is considered a non-routine evolution. If performing a full core offload, supplemental RHR cooling (RHR/FPC assist mode) is required to maintain fuel pool temperatures below 145°F. The limit for this scenario is 175°F. A single failure scenario involving the loss of one train of the FPC is not postulated for a full core offload. This exemption from a single failure is reasonable based on the expected infrequent performance of a full core offload.

During normal plant operations, the heat load in the fuel pool will be less than the heat load experienced during refueling activities. There are three fundamental operational scenarios considered in the design and licensing basis of the FPC. These scenarios are: 1) normal operations with both FPC trains available; 2) normal operations with an anticipated operational transient of the loss of one train of the FPC system; and 3) a design basis LOCA condition. The fuel pool temperature limits for each of these scenarios are presented in Table 9.1-6.

The FPC system is not credited for mitigating the consequences of a design basis event. For a postulated LOOP/LOCA event, RCC will be lost (automatically load sheds in response to an F or A signal) and one train of the FPC system is lost as the result of an assumed single failure. Standby SW can be manually aligned from the control room to replace the lost RCC. Prior to the postulated LOCA, the SW is maintained at a temperature of less than or equal to 77°F in accordance with the Technical Specifications. During the mitigation of the design basis LOCA, the SW will rise to approximately 90°F. The heat up of the fuel pool following a design basis LOCA has been evaluated using a heat load of approximately 10.1 MBTUs/hr and the peak temperature is within the acceptance criteria of 175°F. This temperature is consistent with the design limits of the FPC system.

9.1.3.2.1.2 FPC System Clean-Up Functions

Water purity and clarity in the storage pool, reactor well, and dryer-separator pool are maintained by filtering and demineralizing the pool water through the FPC system filter demineralizers. In addition to fuel pool water demineralization, the system may be used to mix and demineralize the suppression pool water. The suppression pool cleanup portion of the FPC may also be used to periodically let down suppression pool water inventory.

To establish a circulating pattern of flow in the reactor well and fuel storage pool, the diffusers and skimmer drains are placed to sweep particles dislodged during refueling operations away from the work area and out of the pool.

Particulate material is removed from the water by the pressure precoat filter demineralizer units. The finely divided disposable filter medium is replaced when the pressure drop is excessive or the ion exchange resin is depleted. The spent filter medium is backwashed to the waste sludge phase separator tank for processing in the solid radwaste handling system. New filter medium is mixed in a precoat tank and is transferred as a slurry by a precoat pump where

the solids deposit on the filter elements. The holding pump connected to each filter demineralizer maintains circulation through the filter in the interval between the precoating operation and the return to normal system operation. A strainer is provided in the effluent stream of the filter demineralizers to limit the migration of the filter material.

The two filter demineralizer units are located separately in shielded cells in the radwaste building. Sufficient clearance is provided in the cells to permit removal of the filter elements from the vessels. Each cell contains only the filter demineralizer and its associated piping. All valves are located on the outside of one shielding wall of the cell, together with necessary piping and headers, instrument elements, and controls. The FPC cleaning portion of the system is controlled from the radwaste control room.

The flow rate through the filter demineralizers is given by a flow indicator in the radwaste control room located on the demineralizer control panel.

Differential pressure and conductivity instrumentation is provided for each unit to indicate when backwash is required. Suitable alarms, differential pressure indicators, and flow indicators are provided to monitor the condition of the filter demineralizers.

There are two sampling points: SP-25A&B, at the effluent from the fuel pool filter demineralizers, FPC-DM-1A&B. There are also sample points: SP-69, at the fuel pool return line, and SP-24, at common inlet header to the demineralizers. All four sample points are piped to the sample room. All four sample points continuously transmit conductivity measurements to a 4-point recorder and also provide grab samples at the nearby associated fume hood.

Weekly fuel pool analyses is performed to ensure that the water quality specifications for the fuel pool are maintained. The water quality parameters are as follows:

Conductivity	3 µS/cm at 25°C
Chloride	0.5 ppm
pH	5.3-7.5 at 25°C
Total insolubles	1 ppm
Heavy metals	0.1 ppm

Weekly gamma analyses are performed following fuel load or when irradiated fuel is stored in the pool. Special tests on iodine or other significant radionuclide removal by the fuel pool filter demineralizers will be performed when gross gamma activity levels in the fuel pool exceed 10^{-3} mCi/cm^3 during normal power operation.

Continuous influent and effluent conductivity for the fuel pool demineralizers are monitored and recorded. A high conductivity effluent alarm setpoint of 1.5 µS/cm is chosen to reflect marginal performance of the demineralizer since they will eventually saturate with air saturated

water at an equilibrium level of about 1.1 μS/cm. Differential pressure drop is continuously monitored across the filter demineralizers and at a pressure alarm setpoint of 10.5 psid, the units are removed from service and re-precoated with a combined filtration/ion exchange media.

9.1.3.2.2 Residual Heat Removal/Fuel Pool Cooling Cleanup Assist Mode Operation

As discussed in Section 9.1.3.2.1, the RHR loop B may be operated to assist the FPC system, however, the RHR system may only be credited for the decay heat removal function during a full core offload.

The cross connect between RHR and FPC is provided by two flanged spool pieces. The installation and removal of the spool pieces is administratively controlled. However, design evaluation of the system found it acceptable to leave them permanently installed. Procedures direct initiation and operation of the RHR/FPC assist mode and provide guidance to mitigate the consequences in the event of the loss of this mode.

The supplementary cooling provided by RHR/FPC assist is not required the majority of the time. The separation of the two systems is maintained by system operating procedures and administrative controls on the valves needed to isolate the spool pieces. The two valves on the discharge side of RHR-P-2B (RHR-V-104 and FPC-V-119) are maintained as locked closed valves. The suction side isolation is provided by the locked closed FPC-V-141 and RHR-V-261 and locked open FPC-V-101 and the check valve, RHR-V-105. The initiation of the RHR/FPC assist mode is not a routine evolution. The installation, testing, and operation of this mode will require an evaluation of plant conditions and requirements. While operating in RHR/FPC assist mode, the RHR B loop will not be able to provide the low-pressure coolant injection (LPCI), shutdown cooling (SDC), or containment spray functions without local manual operations.

While in RHR/FPC assist, RHR and FPC take a suction on the skimmer surge tanks. Water directed to RHR B loop is cooled by SW and the FPC system provides for cleaning of the fuel pool water. As in normal FPC operation, the water is directed to the surge tank by skimmers near the top of the spent fuel pool. The cooled and cleaned water is returned to the pool through the 8-in. diffusers normally used by the FPC system. To limit RHR flow rates while operating in FPC assist, two restricting orifices are installed in the FPC system. While in the FPC assist mode, an optional, additional return path for the RHR B discharge is into the reactor cavity through the line normally providing RPV head spray (Section 5.4.7.2.1). During refueling outage conditions the head spray line is disconnected at a flange in the cavity and removed with the reactor head insulation package. Normally this flange is then blanked off. However, for the additional cooling, the blank can be left off providing the additional flow path of RHR to the cavity, with a rate of up to 1000 gpm.

9.1.3.2.3 Fuel Pool Cooling System Operation Following a Seismic Event or Major Plant Disturbance

The portion of the FPC system that is required for cooling the fuel pool is located within the reactor building and is designed to Seismic Category I criteria. The portion of the FPC system which is used for fuel pool cleanup is located within the radwaste building and is isolable from the reactor building by means of two Seismic Category I isolation valves per line located within the reactor building. The isolation valves are either check valves or motor-operated gate valves. The motor-operated valves close automatically on a fuel pool low water level condition.

The redundant, active components required for fuel pool cooling are powered from Division 1 and 2 power sources. Following a loss of offsite power, these components can be energized from onsite emergency power. On a loss of RCC to the fuel pool heat exchangers, the RCC supply lines to the heat exchangers can be isolated by redundant Seismic Category I motor-operated gate and check valves and the return lines by redundant Seismic Category I motor-operated gate valves. Standby SW can be supplied to the heat exchangers through motor-operated valves which are normally key locked closed. Radiation detectors are located on the SW return lines. The SW system can also be used to mitigate inventory reduction.

To preclude leakage of service water into the spent fuel pool during operation of the SW system or leakage of fuel pool cooling water into the SW system when the SW system is not operating, the manual valves (SW-V-75AA and SW-V-75BB) and the motor-operated valves (SW-V-75A and SW-V-75B) are kept normally closed when spent fuel pool temperatures are below 138°F. If during normal plant operations the spent fuel pool temperature rises above 138°F, the manual valves will be maintained open. The manual valves are located on the west side of the 522-ft el. of the reactor building and are accessible and can be opened if necessary following a LOCA prior to spent fuel pool temperatures exceeding 175°F. The access route to these manual valves is shown in Appendix J. Once the manual valve(s) are opened, spent fuel pool level can be maintained using the remote-manual valves from the main control room.

Operation and monitoring of fuel pool cooling portion of the FPC system can be done entirely from the control room.

All components required for fuel pool cooling are qualified to the reactor building accident environment. The fuel pool equipment room located on the 548 ft el. is provided with redundant Seismic Category I room coolers with one each on Division 1 and 2 power sources.

9.1.3.3 Safety Evaluation

The maximum heat load is the decay heat of one full core load of the fuel plus the remaining decay heat of previously discharged fuel assemblies. The RHR B loop is operated in parallel with the FPC system during this condition or other events which require supplemental cooling.

To permit this use of the RHR system, normally locked closed valves interconnecting the RHR system to the FPC system are opened after verification of the installation of the flanged spool pieces. A full core offload is a non-routine evolution. A single failure is not postulated to occur during this evolution and credit for RHR/FPC assist is allowed. During this evolution, sufficient cooling should be provided to maintain the fuel pool temperature at less than 145°F. The licensing basis limit is 175°F.

The fuel pool heat exchangers are normally cooled by the RCC system to contain released radioactivity in the event of a fuel pool heat exchanger tube failure. During normal operations, the system maintains the fuel pool water temperature below 125°F when removing the nominal heat load from the fuel pool. During normal refueling outage conditions, the system is evaluated to ensure it has the capability to maintain the fuel pool water temperature below 150°F. This limit applies to core offloads up to, but not including a full core offload, and is based on the assumption of 2 FPC trains in service. The system maintains fuel pool water temperature below 175°F in the event that only one pump and one heat exchanger are available. Depending on the heat load in the pool during refueling activities, RCC or SW temperature is controlled to ensure the FPC system can perform its design functions within the acceptance criteria shown in Table 9.1-6.

Following a seismic event or major plant disturbance the SW system is available to cool the fuel pool (by means of FPC or RHR-B heat exchangers) to preclude boiling of the fuel pool water. The SW pressure is higher than the fuel pool pressure; thus, any leakage will be into the fuel pool system. In addition, radiation monitors of the SW return line detect any gross failure in the heat exchangers.

The fuel pool design precludes any condition which could allow the fuel pool to be drained below the pool gate between the reactor well and the fuel pool. Two diffusers are placed in both the reactor well and the fuel pool to distribute cooled return water efficiently. Diffusers are placed to minimize stratification of either temperature or contamination. Valving is provided to prevent water from being siphoned out of the pool. All piping connected to the fuel pool and reactor well, except for drains and liner drains, are Seismic Category I, including any normally closed manual or normally open automatic valves that provide isolation from the Seismic Category II portion of the system. Drain and liner drain piping connected to the fuel pool, reactor well, and dryer separator pool are Seismic Category II supported to Seismic Category I requirements. Since the fuel pool system is at low temperature and pressure (moderate energy system) postulated breaks in the Seismic Category I portion are limited to cracks.

Fuel pool cooling can be established and monitored from the control room following a design basis LOCA. One of the two FPC trains is adequate to prevent fuel pool boiling by a large margin. However, during normal plant operation, one or both trains operate to maintain 125°F pool water. Should one of the trains be unavailable, the second train operates to maintain pool water temperature below 175°F. The 175°F value is applicable for an

anticipated operational transient involving the loss of one FPC loop. If the fuel pool heat load is such that the resulting temperature transient exceeds 125°F, procedural guidance is in place to restore the fuel pool temperature to < 125°F. Due to the large thermal capacity of the fuel pool sufficient operator time is available for the operator to take necessary corrective action to supplement cooling.

A makeup water valve controlled by skimmer surge tank level switches supplies water from the condensate transfer system to the fuel pool to replace losses. The backup source of makeup water is from the Seismic Category I, safety class 3 SW system. This source supplies makeup for long-term pool water losses.

Each filter demineralizer is capable of continuous operation at a normal fuel pool water flow rate of 575 gpm or a maximum fuel pool water flow rate of 1100 gpm and will maintain water conditions as specified in Section 9.1.3.2.

A radiological evaluation of the cleanup system is presented in Chapter 12.

From the foregoing analysis, it is concluded that the FPC system meets its design basis and satisfies the requirements of Regulatory Guide 1.13, Revision 1.

9.1.3.4 Testing and Inspection Requirements

Special testing is not required for the system except as noted below because, when fuel is stored in the pool, at least one pump, heat exchanger, and filter demineralizer are routinely in operation.

Routine, periodic visual inspection of system components, instrumentation, and alarms are adequate to verify system operability. Likewise, the interconnecting valves between the FPC system and the RCC, SW, and RHR systems are periodically inspected to verify their operability.

9.1.4 FUEL HANDLING SYSTEM

9.1.4.1 Design Bases

The fuel handling system is designed to provide a safe and effective means for transporting and handling fuel from the time it reaches the plant until it leaves the plant after postirradiation cooling. Safe handling of fuel includes design considerations for maintaining occupational radiation exposures as low as reasonably achievable during transportation and handling.

Design classification criteria for major fuel handling system equipment is provided in Table 3.2-1 which lists the safety class, quality class, quality group, and seismic category for the equipment.

The cask storage area in the spent fuel pool and the cask handling facilities are designed to accommodate a spent fuel cask of 125 tons. The reactor building crane is designed to transport the spent fuel cask between the cask receiving area, the cask storage area in the spent fuel pool, and the cask washdown area without inducing a permanent deformation of any crane element. Adequate safety features are designed into the reactor building crane system and controls to ensure that no credible postulated failure of any crane component will result in the dropping of the fuel cask.

The transfer of new fuel assemblies between the uncrating area and the new fuel inspection stand and/or the new fuel storage vault is accomplished using the jib crane or the reactor building crane auxiliary hoist.

The refueling floor jib cranes are used to transfer new fuel from the new fuel vault to the fuel storage pool. From this point on, the fuel will be handled by the telescoping grapple on the refueling platform.

The refueling platform is General Class G and Seismic Category 1M from a structural standpoint in accordance with 10 CFR Part 50, Appendixes A and B. Allowable stress due to SSE loading is 120% of yield or 70% of ultimate, whichever is less. A dynamic analysis is performed on the structures using the response spectrum method with load contributions resulting from each of three components earthquake motion being combined by the RMS procedure.

Working loads of the platform structures are in accordance with the AISC Manual of Steel Construction. All parts of the hoist systems are designed to have a safety factor of five, based on the ultimate strength of the material. A redundant load path is incorporated in the fuel hoists so that no single component failure could result in a fuel bundle drop. Maximum deflection limitations are imposed on the main structures to maintain relative stiffness of the platform. Welding of the platform is in accordance with AWS D14-1. Gears and bearings meet AGMA Gear Classification Manual and ANSI B3.5. Materials used in construction of load bearing members are to ASTM specifications. For personnel safety, OSHA Part 1910-179 is applied. Electrical equipment and controls meet ANSI-ANS C1, National Electric Code, and NEMA Publications No. IC1 and MG1.

The general purpose grapples and the main telescoping fuel grapples have redundant hooks. The main telescoping fuel grapple has an indicator which confirms positive grapple engagement.

The fuel grapple is used for lifting and transporting fuel bundles. It is designed as a telescoping grapple that can extend to the proper work level and in its fully retracted state still maintains adequate water shielding over fuel.

In addition to redundant electrical interlocks to preclude the possibility of raising radioactive material out of the water, the cables on the auxiliary hoists incorporate an adjustable, removal stop that will jam the hoist cable against the platform structure to prevent hoisting when the free end of the cable is at a preset distance below water level.

Sufficient redundancy is provided in the reactor building crane such that no credible postulated failure of any crane component will result in dropping of the fuel cask and rupturing the fuel storage pool. Furthermore, limitation of the travel of the crane handling the cask will preclude transporting the cask over any fuel storage rack. See Chapter 15 for accident considerations.

9.1.4.2 System Description

Table 9.1-7 is a listing of typical tools and servicing equipment supplied with the nuclear system. The following paragraphs describe the use of some of the major tools and servicing equipment and address safety aspects of the design, where applicable.

9.1.4.2.1 Spent Fuel Cask

The designs of cask storage and dry cask handling facilities are based on a design cask weighing approximately 125 tons and being approximately 17 ft long by 8 ft in diameter.

The following description of the spent fuel cask is based on the licensed Holtec HI-STORM 100 System. That system includes a canister that contains the fuel and a transfer cask that contains the canister. The canister confines the fuel. The transfer cask provides shielding and structural protection of the canister during canister loading or movement.

Overland offsite transportation of the cask will conform to transportation rules and regulations, 49 CFR Part 173.

9.1.4.2.2 Reactor Building Crane

9.1.4.2.2.1 Description. The main purpose of the reactor building crane is to handle the spent fuel cask between the cask receiving area, the cask loading area in the spent fuel pool, and the cask decontamination washdown area. Secondary purposes of the crane include servicing and refueling the reactor pressure vessel, and handling of equipment or parts thereof received or shipped through the loading facility in the reactor building.

The reactor building crane is a single-trolley top-running electric overhead traveling crane with a 125-ton capacity main hoist, and a span of approximately 126 ft. The general arrangement

of the crane in the reactor building is shown in Figures 1.2-11 and 1.2-12. The crane is Class A1 as defined for nuclear fuel handling by the Crane Manufacturers Association of America Specification No. 70 for Electric Overhead Traveling Cranes, (CMAA No. 70). The reactor building crane is designed, fabricated, installed, and tested in accordance with ANSI Standard B30.2, Safety Code for Cranes, Derricks and Hoists, and CMAA Specification No. 70. The crane is Seismic Category I.

Operation of the reactor building crane is from the cab or from the floor by radio control. The crane radio control system uses crystals highly tuned to a narrow frequency band, thereby precluding interferences from other signaling systems. Control at any one time is from one point only.

The structure of the crane bridge consists of welded box type girders with truck saddles and truck frames of welded-steel construction. The trolley side frames, sheave frames, and truck frames are of structural steel-welded construction.

The rated full-load capacities, lifts, and full-load speeds are as follows:

Main Hook

Rated full-load capacity, tons	125
Hook travel, ft	190 ft 0 in.
Hoisting speed, fpm at full load	5.5

Auxiliary Hook

Rated full-load capacity, tons	15
Hook travel, ft	199 ft 8 in.
Hoisting speed, fpm at full load	20

Travel Speeds

Trolley, fpm at full load	40
Bridge, fpm at full load	50

The crane is capable of raising, lowering, holding, and transporting a test work load at 125% of rated load without damage to any parts and without inducing a permanent deformation of any crane element.

Structural members not covered by the CMAA Specification No. 70 are designed in accordance with the AISC Specification for the Design, Fabrication, and Erection of Structural Steel for Buildings (September 1972).

All parts of the crane are designed to resist the maximum stresses caused by loading combinations called for in the CMAA Specification No. 70 and for the following loading combinations:

a. Dead load + trolley weight and rated load + SSE, not to exceed 90% of the yield strength,

b. Dead load + weight of unloaded trolley + tornado loading, not to exceed 90% of the yield strength, and

c. Rated breakdown torque of the motors, not to exceed allowable stresses.

The lateral loads on the crane runway, in the normal operating condition, are taken as 10% of the sum of the weights of the hook load and the crane trolley, plus the seismic load of the crane dead load, acting simultaneously at the top of each rail in either direction normal to the runway rails.

Safety factors for the main hoist cables are discussed in Section 9.1.4.2.2.2. The main hook and auxiliary hook are capable of sustaining the full-rated load with a design safety factor of five.

9.1.4.2.2.2 Safety Features. The single hoist motor drives two separate shafts. The motor has two centrifugally tripped limit switches, one outboard of each hoist input pinion at each end of the motor shaft assembly. These provide an automatic safety shutdown and protection from any control or motor malfunction which might result in a runaway condition of the load. Each motor driven shaft passes through a 150% capacity solenoid-actuated brake. A failure of either the motor shaft, the connecting shafts, or the shaft couplings would not result in a load drop since the redundant dual solenoid actuated brakes would be effective in holding the load. On loss of power to the motor, both brakes engage. They can also be engaged by the operator. Additionally, there is a 90% capacity eddy current brake to limit the rate of load lowering.

After the brake, each motor shaft enters its own gear reducer. If a component of one gear case (gear teeth, shafts, bearings, or structural component) should fail, the other gear reducer will hold the load with its brake. The brake is designed with a safety factor of five.

Each gear case is fitted on its output end with a pinion meshing with the drum gear. A failure of a pinion, drum gear, pinion shaft, or pinion bearing will result in the load being carried by the other similar set of parts on the other end of the drum. Each functioning part is designed with a safety factor of five. In each of the main hoist gear cases, there is a mechanical load brake with cooling of the gear case oil to offer additional safety in loading handling.

In the event of failure of the drum shaft, drum bearing, or drum bearing bracket, the drum flange will drop a fraction of an inch onto structural seats so located that the drum is

supported. The remaining pinion and gear will stay in mesh to restrain the load. Again, a safety factor of five is incorporated into the design of these parts.

Two separate wire ropes are led from the main hoist drum, each being reeved through a set of sheaves, upper and lower (block sheaves), and back to an equalizer bar arranged for equal division of the load between the two ropes. The individual wire rope safety factors for maximum static load and static plus inertia load (dynamic) are 9.7 and 9.0 respectively. The equalizer bar is fitted with double acting springs to minimize the shock when the entire load is transferred to one rope. Therefore, load drop is precluded. To protect against overloading of the cables and to provide indication of load balancing, a load sensing system consisting of tension type load cells is installed in each of the hoist cables at its connection to the equalizer bar assembly under the trolley.

All sheaves, both upper and block sheaves, are contained in heavy structural casings which usually carry a negligible load. In the event of a sheave pin failure, the sheaves would rise to the top of the block or drop to the base of the upper sheave housing and stop at those points. Thus a load drop is precluded. The block assembly contains two 100% capacity load carrying devices consisting of a sister hook and an eye hook. This redundancy, in attachment to lifting assembly and in load carrying capability, is such that a single failure will not cause load drop. Additional non-destructive examination (NDE) (ultrasonic and magnaflux testing for the load block swivel and the sheave shafts of the upper assembly) provide further assurance that this crane is of a quality suitable for nuclear services. Sufficient electrical circuitry is provided such that no single credible electrical component failure will cause the load to drop.

To preclude any dislodgement of the crane bridge girder and trolley system during seismic or tornado excitation, the following is provided:

a. From the bridge trucks, lugs or brackets are attached to the truck frame to limit total crane drop to 1 in. or less should a wheel or axle break, and

b. The trolley is provided with latches to engage racks attached to the bridge girder; the bridge trucks are provided with latches to engage racks attached to the crane runway girders. The latches and racks ensure that the trolley is rigidly attached to the crane runway girders. These provisions are used when the crane is not operational.

9.1.4.2.3 Fuel Servicing Equipment

The major fuel servicing equipment described below has been designed in accordance with the classification criteria listed in Table 3.2-1.

9.1.4.2.3.1 Fuel Preparation Machine. The fuel preparation machine, Figure 9.1-7, is mounted on the wall of the fuel storage pool and is used for stripping reusable channels from

the spent fuel and for rechanneling of the new fuel. The machine is also used with the fuel inspection fixture to provide an underwater inspection capability, and with the defective fuel storage container to contain a defective fuel assembly for stripping of the channel.

The fuel preparation machine consists of a work platform, a frame, and a movable carriage. The frame and movable carriage are located below the normal water level in the fuel storage pool, thus providing a water shield for the fuel assemblies being handled. The fuel preparation machine carriage has an up-travel-stop to prevent raising fuel above the safe water shield level. The movable carriage is operated by a foot pedal controlled air hoist.

9.1.4.2.3.2 New Fuel Inspection Stand. The new fuel inspection stand, Figure 9.1-8, serves as a support for the new fuel bundles undergoing receiving inspection and provides a working platform for technicians engaged in performing the inspection.

The new fuel inspection stand consists of a vertical guide column, a lift unit to position the work platform at any desired level, bearing seats and upper clamps to hold the fuel bundles in position.

9.1.4.2.3.3 Channel Bolt Wrench. The channel bolt wrench, Figure 9.1-9, is a manually operated device approximately 12 ft in overall length. The wrench is used for removing and installing the channel fastener assembly while the fuel assembly is held in the fuel preparation machine.

The channel bolt wrench has a socket which mates and captures the channel fastener capscrew.

9.1.4.2.3.4 Channel Handling Tool. The channel handling tool, Figure 9.1-10, is used in conjunction with the fuel preparation machine to remove, install, and transport box fuel channels in the fuel storage pool.

The tool is composed of a handling bail, a lock/release knob, extension shaft, angle guides, and clamp arms which engage the fuel channel. The clamps are actuated (extended or retracted) by manually rotating lock/release knob.

The channel handling tool is suspended by its bail from a spring balancer on the channel handling boom located on the fuel pool periphery.

Similar tooling is provided as appropriate by the current reload fuel vendor.

9.1.4.2.3.5 Fuel Pool Sipper. The originally supplied equipment is not used. Any fuel sipping is performed by the refueling vendor using their own equipment and procedures. Fuel sipping heads, panels, and containers are separate pieces of equipment used for out-of-core wet sipping at any time. They are used to isolate a fuel bundle while circulating water through the

fuel bundle in a closed system. The containers cannot be used for transporting a fuel bundle. The bail on the container head is designed not to fit into any of the grapples.

9.1.4.2.3.6 Fuel Inspection Fixture. The fuel inspection fixture, Figure 9.1-11, is used in conjunction with the fuel preparation machine to permit remote inspection of fuel elements. The fixture consists of two parts: (1) a lower bearing assembly, and (2) a guide assembly at the upper end of the carriage. The fuel inspection fixture permits the rotation of the fuel assembly in the carriage, and, in conjunction with the vertical movement of the carriage, provides complete access for inspection.

9.1.4.2.3.7 Channel Gauging Fixture. The originally supplied equipment is not used. Any channel gauging is performed by the refueling vendor using their own equipment and procedures.

9.1.4.2.3.8 General Purpose Grapple. The general purpose grapple, Figure 9.1-12, is a handling tool used generally with the fuel. The grapple can be attached to the jib crane and the auxiliary hoists on the refueling platforms. The general purpose grapple or other rigging controlled by plant procedures may be used to remove new fuel from the fuel container, place it in the inspection stand or vault, and transfer it to the fuel pool. It can be used to handle new fuel during channeling.

9.1.4.2.4 Servicing Aids

General area underwater lights are provided with a suitable reflector for illumination. Suitable light support brackets are furnished to support the lights in the reactor vessel and to allow the light to be positioned over the area being serviced independent of the platform. Local area underwater lights are small diameter lights for additional illumination. Drop lights are used for illumination where needed.

A radiation hardened designed portable underwater closed circuit television camera is provided. The camera may be lowered into the reactor vessel and/or fuel storage pool to assist in the inspection and/or maintenance of these areas. The camera is also equipped with a right angle lens to allow viewing at 90 degrees.

A general purpose, plastic viewing aid is provided to float on the water surface to permit better visibility. The sides of the viewing aid are brightly colored to allow the operator to observe it in the event of filling with water and sinking. A portable, submersible type, underwater vacuum cleaner is provided to assist in removing crud and miscellaneous particulate matter from the pool floors, or the reactor vessel. The pump and the filter unit are completely submersible for extended periods. The filter “package” is capable of being remotely changed, and the filters will fit into a standard shipping container for offsite burial. Fuel pool tool accessories are also provided to meet servicing requirements.

9.1.4.2.5 Reactor Vessel Servicing Equipment

The following is a description of the equipment designs.

9.1.4.2.5.1 Reactor Vessel Service Tools. These tools are used when the reactor is shut down and the reactor vessel head is being removed or reinstalled. Tools in this group are

a. Stud handling tool,
b. Stud wrench,
c. Nut runner,
d. Stud thread protectors,
e. Thread protector mandrel,
f. Bushing wrench,
g. Seal surface protector,
h. Stud elongation measuring rods, and
i. Head guide cap.

These tools are designed for a specified environment. Lifting tools are designed for a safety factor of five or better with respect to the ultimate strength of the material used. When carbon steel is used, it is either hard chrome plated, parkerized, or coated with an acceptable paint.

9.1.4.2.5.2 Steam Line Plug. The steam line plugs are used during reactor refueling or servicing; they are inserted in the steam outlet nozzles from inside of the reactor vessel to prevent a flow of water from the reactor well into the main steam lines during servicing of safety/relief valves, main steam isolation valves, or other components of the main steam lines. (The reactor water level is raised to the refueling level during servicing.)

The steam line plug design provides two seals of different types. Each one is independently capable of holding full head pressure. The equipment is constructed of noncorrosive materials. All calculated safety factors are five or greater.

9.1.4.2.5.3 Shroud Head Bolt Wrench. This is a hand held tool for operation of shroud head bolts. It is made of aluminum to be easy to handle and to resist corrosion. Testing has been performed to confirm the design.

9.1.4.2.5.4 Head Holding Pedestal. Three pedestals are provided for mounting the reactor vessel head on the refueling floor. The pedestals have studs which engage three evenly spaced stud holes in the head flange. The flange surface rests on replaceable wear pads made of aluminum. When resting on the pedestals, the head flange is approximately 3 ft above the floor to allow access to the seal surface for inspection and O-ring replacement.

The pedestal structure is a carbon steel weldment, coated with an approved paint. It has a base with bolt holes for mounting it to the concrete floor. The structure is designed in accordance with "The Manual of Steel Construction" by AISC.

9.1.4.2.5.5 Head Nut and Washer Racks. The RPV head nut and washer racks are used for transporting and storing up to six nuts and washers. The rack is a box-shaped aluminum structure with dividers to provide individual compartments for each nut and washer. Each corner has a lug and shackle for attaching a four-leg lifting sling.

The racks are designed in accordance with the "Aluminum Construction Manual" by the Aluminum Associations and for a safety factor of five.

9.1.4.2.5.6 Head Stud Racks. The head stud racks are used for transporting and storage of up to six reactor pressure vessel studs. They are suspended from the auxiliary building crane hook when lifting studs from the reactor well to the operating floor.

The racks are made of aluminum to resist corrosion.

9.1.4.2.5.7 Dryer and Separator Slings. The dryer and separator slings are lifting device assemblies used for transporting the steam dryer or the steam separator between the reactor vessel and the equipment pool. Each sling assembly consists of a cruciform shaped structure which has been designed such that one hook pin and one main beam of the cruciform is capable of carrying the total load and so that no single component failure will cause the load to drop or swing uncontrollably out of an essentially level attitude.

The safety factor of the lifting members is five or better in reference to the ultimate breaking strength of the material. The structure is designed in accordance with "The Manual of Steel Construction" by AISC. The completed assembly is proof tested at 125% or greater of rated load and all structural welds are magnetic particle inspected after load test.

9.1.4.2.5.8 Head Strongback. The RPV head strongback is used for lifting both the pressure vessel head and the drywell head. It is a cruciform shape with four equally spaced lifting points on the ends of the arms. In the center it has a hook box which engages with two pins to the reactor service crane sister hook and one pin to the hook lifting eye.

The strongback is designed such that one leg of the cruciform will support the rated load and such that no single component failure will cause the load to drop or swing uncontrollably out of an essentially level attitude. The structure is designed in accordance with "The Manual of

Steel Construction" by AISC. All welding is in accordance with the ASME Boiler and Pressure Vessel (B&PV) Code Section IX. A safety factor of five or greater in reference to the ultimate material strength is used for the design. The completed assembly is proof tested at 125% rated load. After the load test, all structural welds are magnetic particle inspected.

9.1.4.2.5.9 Steam Line Plug Installation Tool. The steam line plug installation tool is suspended from the building crane auxiliary hook or refueling platform monorail or auxiliary hoist for transporting and installing the steam line plugs in the steam line nozzles of the reactor vessel. This tool is designed for a safety factor of five.

9.1.4.2.5.10 Auxiliary Work Platform. The auxiliary work platform provides an alternate work space over the reactor cavity and equipment pool for maintenance work. The platform spans the reactor cavity and travels on the same rails as the refueling platform. The platform is equipped with two jib cranes, two electrically operated jib hoists, three jib crane support pedestals, and is driven by electric motors. To increase accessibility for maintenance work above the cavity, the center floor section of the platform is removable.

Positioning of the platform over the reactor cavity is controlled by administrative procedures.

The auxiliary work platform is designed structurally to meet Seismic Category I requirements. The structural design is in accordance with "The Manual of Steel Construction" by AISC. Materials are in accordance with ASTM Standards. The structure is coated with an approved paint.

The cranes are exempted from the NUREG 0612 requirement because the definition of heavy loads at CGS is 1200 lb. Each 500 lb hoist is equipped with a load limiting device to prevent lifting fuel bundles or unauthorized heavy loads. Interlocks on the platform or hoists are not provided since the hoists and platform are controlled administratively and will not be used for reactivity manipulation.

9.1.4.2.5.11 Cavity In-Vessel Service Platform (CISP). The CISP, Figures 9.1-17 and 9.1-18, serves as a circular H-shaped platform with an inside diameter equal to that of the reactor vessel. The CISP has an opening which may be aligned with the transfer canal (cattle chute). The CISP is used to allow personnel access over the reactor vessel annulus, between the vessel wall and the core shroud, while core alterations are in process using the refueling platform. The CISP can be oriented to allow access to either the spent fuel pool or the dryer-separator pit. The CISP is attached to three support frame legs which rest on the upper cavity shield block ledge. The platform is partially submerged with the walkway floor at a depth of approximately 16 in. when the cavity is flooded up for refueling operations. The CISP also has a 750 lb capacity electric hoist which may be positioned around the inside diameter of the CISP.

The CISP was designed and constructed to Seismic I criteria and all lifting components meet NUREG 0612 requirements for a single failure proof lift. The platform is designed to meet the requirements of the AISC Manual of Steel Construction and the NUREG 0800, Standard Review Plan (SRP) Section 3.8.4. It may be installed in the reactor cavity after the steam separator is removed from the vessel, the cavity is flooded up to normal refueling level and the fuel pool gates are removed. The CISP is removed from the cavity prior to the commencement of vessel restoration.

During movement of the CISP to and from the temporary lay-down area (north of the spent fuel pool), a small portion of the CISP must pass over the spent fuel pool in order to clear the stack monitoring equipment along the center of the refueling floor north wall. The lifting of the CISP is accomplished by the single failure proof reactor building crane, and with NUREG 0612 compliant rigging and handling equipment. Therefore drop of the CISP into the spent fuel pool is not a credible accident. In addition the distance that the CISP can extend over the spent fuel pool is administratively controlled such that only a small portion of the CISP passes over the spent fuel pool and the center of gravity of the CISP is at least 7.5 ft north of the spent fuel pool north curb.

9.1.4.2.5.12 Head Stud Tensioner Carousel/Strongback. The RPV head stud tensioner carousel/strongback is a lifting device that provides an alternate means to remove and install the RPV head. It combines the functions of the original stud tensioner handling frame, RPV head lifting strongback, and head nut and washer racks. The design allows the carousel/strongback to be released from the reactor building crane once it has been mounted onto the four lifting lugs of the RPV head. The head stud tensioners, which ride on the carousel/strongback's integral monorail, are positioned to effect head stud nut removal and reinstallation. The nuts and washers for all 76 of the RPV head studs can be stowed on the carousel/strongback's head stud nut storage ring. The RPV head, head stud nuts and washers, and carousel/strongback (with the RPV head attached) are together lifted by the reactor building crane.

The head stud tensioner carousel/strongback was designed, fabricated, and tested to meet the requirements of NUREG-0612, "Control of Heavy Loads at Nuclear Power Plants" and the guidelines of ANSI N14.6, "American National Standard for Special Lifting Devices for Shipping Containers Weighing 10,000 Pounds (4500 kg) or More for Nuclear Materials."

9.1.4.2.6 In-Vessel Servicing Equipment

The instrument strongback attached to the reactor building crane auxiliary hoist is used for servicing neutron monitor dry tubes should they require replacement. The strongback initially supports the dry tubes into the vessel. The in-core dry tube is then decoupled from the strongback and is guided into place while being supported by the instrument handling tool. Final in-core insertion is accomplished from below the reactor vessel. The instrument handling tool is attached to the refueling platform monorail hoist and is used for removing and

installing fixed in-core dry tubes as well as handling neutrons source holders and the source range monitor/intermediate range monitor dry tubes.

Each in-core instrumentation guide tube seals by metal-to-metal contact with the guide tube flange seal. In the event that the seal needs replacing, an in-core guide tube seal tool is provided. The tool is inserted into an empty guide tube and sits on the beveled guide tube entry in the vessel. When the drain on the water seal cap is opened, hydrostatic pressure seats the tool. The flange can then be removed for seal replacement.

The auxiliary hoists on the refueling platform are used with appropriate grapples to handle control rods, fuel support pieces, double blade guides, flux monitor dry tubes, sources, and other internals of the reactor. Interlocks on the fuel grapple hoist and both auxiliary hoists are provided for safety purposes; the refueling interlocks are described and evaluated in Section 7.7.1.13.

The Westinghouse Multi-Lift Tool (MLT) is used exclusively with the Monorail Auxiliary Hoist. The MLT is used to remove and replace a control rod blade with its associated fuel support piece and double blade guide. The MLT may also be used for uncoupling the control rod drive mechanism from the control rod blade to be removed. The monorail hoist backup emergency stop block position is procedurally controlled to accommodate the length of the MLT and grappled components.

9.1.4.2.7 Refueling Equipment

Fuel movement and reactor servicing operations are performed from a platform which spans the refueling, servicing, and storage cavities.

9.1.4.2.7.1 Refueling Platform. The refueling platform is a gantry crane that is used to transport fuel and reactor components to and from pool storage and the reactor vessel. The platform spans the fuel storage and vessel pools on rails bedded in the refueling floor. A telescoping mast and grapple suspended from a trolley system is used to transport and orient fuel bundles for core, storage rack, or spent fuel cask placement. Control of the platform is from an operator station on the main trolley with a position indicating system provided to position the grapple over core locations. The platform control system includes interlocks to verify hook engagement and grapple load, prevent unsafe operation over the vessel during control rod movements, and limit vertical travel of the grapple. Two 1000-lb capacity auxiliary hoists, one main trolley mounted and one auxiliary trolley mounted, are provided for servicing such as local power range monitor (LPRM) replacement, fuel support replacement, jet pump servicing, and control rod replacement. The grapple in its normal up position provides 7 ft 6 in. minimum water shielding over the active fuel during transit.

9.1.4.2.8 Storage Equipment

Specific storage equipment is used for new, used, or spent fuel, for control rods, and for other core components.

Specially designed fuel storage racks are provided in the spent fuel pool and in the new fuel vault. Additional storage equipment is listed in Table 9.1-7. For fuel storage racks description and fuel arrangement, see Sections 9.1.1 and 9.1.2.

9.1.4.2.9 Under Reactor Vessel Servicing Equipment

The primary functions of the under reactor vessel servicing equipment are to (a) remove and install control rod drives, (b) service thermal sleeve and control rod guide tube, and (c) install and remove the neutron detectors. Table 9.1-7 lists the equipment and tools required for servicing. Of the equipment listed, the equipment handling platform and the control rod drive handling equipment are powered electrically.

The control rod drive handling equipment is used for the removal and installation of the control rod drives from their housings. This equipment is designed in accordance with the requirements of National Electrical Manufacturers Association (NEMA, MG1: Motor and Generator Standards), American National Standards Institute Standards (ANSI C1, National Electric Code), Occupational Safety and Health Administration (OSHA, 1910.179), and American Institute of Steel Construction (AICS, Manual of Steel Construction). All lifting components are equipped with adequate brakes or gearing to prevent uncontrolled movement on loss of power or component failure.

The equipment handling platform provides a working surface for equipment and personnel performing work in the under vessel area. It is a polar platform capable of 360 degree rotation. This equipment is designed in accordance with the applicable requirements of OSHA (Vol. 37, No. 202, Part 191 ON), AISC, and ANSI C1 (National Electric Code).

The spring reel is designed to be used to pull the in-core guide tube seal or in-core detector into the in-core tube during in-core servicing.

The thermal sleeve installation tool locks, unlocks, and lowers the thermal sleeve from the control rod drive guide tube.

In-core flange seal test plug is used to determine the pressure integrity of the in-core flange seal. It is constructed of noncorrosive material. The key bender is designed to install and remove the antirotation key that is used on the thermal sleeve.

9.1.4.2.10 Description of Fuel Transfer

The fuel handling system provides a safe and effective means for transporting and handling fuel from the time it reaches the plant until it leaves the plant after postirradiation cooling. The previous subsection has described the equipment and methods used in fuel handling. The following paragraphs describe the integrated fuel handling system that ensures the design bases of the fuel handling system is satisfied.

9.1.4.2.10.1 Arrival of Fuel on Site. The new fuel arrives at the site in either one of two types of special shipping containers. The one type of container, designated the "RA Series," has space for two fuel bundles and the other type of container, designated "927 Series," has space for four fuel bundles.

The RA Series container consists of a metal inner container positioned by means of cushioning materials within an outer container. These containers with their contents meet all NRC requirements. Both inner and outer containers are reusable.

The 927 Series container is a steel unit with a removable cover. The fuel bundles are secured in the interior by a series of steel brackets. These containers also meet all NRC requirements.

After arrival of the fuel shipment the containers are visually inspected for evidence of damage during shipping. If there are indications of rough handling or damages, further investigation, for possible damage to fuel bundles, will be performed. With the RA Series the inner metal container is then removed from the outer container with appropriate lifting equipment. The containers are then taken to the refuel floor using lifting rigging designed for the task and the container is placed in a horizontal position. The covers are then removed to expose the fuel bundles. The fuel is then visually inspected for any obvious damage and a radiation survey for contamination is made.

Bundle restraints will be installed on the metal container in preparation for raising it to the vertical position. The container is then raised to the vertical position and secured using the reactor building auxiliary hoist with rigging designed for the task.

New fuel may also be shipped with channels already installed, in which case channel installation will not occur in the inspection stand or the fuel pool.

9.1.4.2.10.2 Refueling Procedure. Fuel handling procedures are described below and shown visually in Figure 9.1-13 through Figure 9.1-16.

The refueling floor layout is shown in Figure 9.1-5 and component drawings of the principal fuel handling equipment are shown in Figures 9.1-7 through 9.1-12.

During core alterations (except movement of control rods with their normal drive system), direct communication is maintained between the control room and refueling platform personnel. Direct communication is demonstrated within 1 hr prior to the start of and no less than once per 15 hr during core alterations (with the exceptions noted above). When direct communication cannot be maintained, core alterations (with the exceptions noted above) are immediately suspended.

The fuel handling process takes place primarily on the refueling floor above the reactor. The principal locations and equipment are shown on Figure 9.1-13. The reactor and fuel pool are connected to each other by slot (A) which is open during reactor refueling. At other times the slot is closed by means of blocks and gates, which make watertight barriers.

Since provisions for portable shielding are not provided in the drywell, administrative control is used during refueling operations to avoid overexposure of personnel as the result of a postulated fuel drop accident such as a drop occurring on the reactor seal plate.

New fuel in shipping containers is brought up to the refueling floor through the hatches.

The handling of new fuel on the refueling floor is illustrated in Figure 9.1-14. The transfer of the bundles between the fuel container (C), and the new fuel inspection stand (D), the new fuel storage vault (E) and the fuel pool storage racks (F) is accomplished using the reactor building crane auxiliary hoist or jib crane.

The jib crane is also used to transfer new fuel from the new fuel vault or inspection stand to the fuel prep machine in the spent fuel pool. From this point on the fuel is handled by the telescoping grapple on the refueling platform.

The storage racks in both the vault and the fuel pool hold the fuel bundles or assemblies vertical, in an array which is subcritical under all possible conditions.

The new fuel inspection stand holds one or two bundles in vertical position. The inspector(s) ride up and down on a platform, and the bundles are manually rotated on their axes. Thus the inspectors can see all visible surfaces on the bundles.

The refueling platform uses a grapple on the telescoping mast for lifting and transporting fuel bundles or assemblies. The telescoping mast can extend to the proper work level, and, in its normal up position, maintains adequate water shielding over the fuel being handled.

The reactor refueling procedure is shown schematically in Figure 9.1-15. The refueling platform moves over the fuel pool, lowers the grapple on the telescoping mast (H), and engages the bail on a new fuel assembly which is in the fuel storage rack. The assembly is lifted clear of the rack and moved through slot (A) and over the appropriate empty fuel

location in the core (J). The mast then lowers the assembly into the location, and the grapple releases the bail.

The operator then moves the platform until the grapple is over a spent fuel assembly which is to be discharged from the core. The assembly is grappled, lifted, and moved through slot (A) to the fuel pool.

To preclude the possibility of raising radioactive material out of the water, redundant electrical limit switches are incorporated in the hoist and interlocked to prevent hoisting above the preset limit. In addition, the cables on the auxiliary hoists incorporate adjustable stops that will jam the hoist cable against the hoist structure, which prevents hoisting if the limit switch interlock system should fail. Prior to moving irradiated fuel in the reactor pressure vessel, the reactor is verified to have been subcritical for at least 24 hr. This is consistent with fuel handling accident assumptions described in Section 15.7.4.5.

When spent fuel is to be transferred, it is placed in a cask, as shown in Figure 9.1-16. The refueling platform grapples a fuel bundle from the storage rack in the fuel pools, lifts it, carries it to the transfer cask area of the pool, and lowers it into the canister within cask (M). When the canister is loaded, the building crane sets the cover on the canister, and then lifts the cask out of the pool. The cask is then decontaminated and lowered through the open hatchways (P) to the cask transport system at near grade level.

9.1.4.2.10.2.1 New Fuel Preparation.

9.1.4.2.10.2.1.1 Receipt and Inspection of New Fuel. The incoming new fuel shipping container will be visually inspected for shipping damage as the containers are offloaded from the transport vehicle. The fuel is also visually inspected upon opening the container on the refuel floor.

Incoming fuel is inspected as governed by plant procedures prior to being placed in the reactor vessel. Preferably, the inspection will be done before the fuel is stored. However, depending on specific plans for the initial fueling and/or subsequent refueling, fuel may be stored until a more desirable time for inspection.

Inspections may be performed onsite or at the vendor facilities. Onsite inspections are performed with the fuel bundles secured in the fuel inspection stand. Inspections are performed, by qualified inspectors, in accordance with plant approved procedures.

If a fuel bundle fails inspection, discrepancies are noted and action will be taken to repair the fuel bundle or it will be set aside for disposition by the fuel manufacturer.

After satisfactory inspection, the fuel bundle is then transferred to a storage rack in the new fuel vault or to a storage rack in the spent fuel storage pool. The fuel bundle may or may not be channeled prior to storage.

9.1.4.2.10.2.1.2 Channeling New Fuel (Non Westinghouse Fuel). New fuel is channeled with new channels after the fuel is inspected in the inspection stand. The channels are visually inspected for defects prior to installing on the fuel. The inspected channel is then attached to lifting rigging and installed on the fuel while in the inspection stand.

The fuel can also be channeled in the spent fuel pool. For a channel located in the channel rack in the pool, the channel handling tool (fastened to the channel jib crane) is attached to the channel and raised manually with the assistance of the channel jib crane then positioned over the bundle to be channeled. The bundle is then raised into the channel and the channel fastener is installed with the channel bolt wrench.

9.1.4.2.10.2.1.3 Channeling New Fuel (Westinghouse Fuel Only). Westinghouse Fuel (SVEA-96 type) requires the fuel bundle to be inserted into the combination fuel channel/lower tie plate. The new channels will be received up on the refueling floor and inspected then installed into the new fuel storage vault or the fuel prep machine. The Westinghouse fuel is inspected in the inspection stand then moved to the storage vault or fuel prep machine by use of the jib crane. The bundle is positioned over the channel and the temporary lower tie plate, installed for shipping purposes, if not removed earlier, is then removed and the four mini bundle assemblies are inserted into the channel. With the bundle seated, the rigging is removed, the temporary upper bale handle is removed and the permanent bail handle is installed and torqued. The bundle, if channeled in the new fuel storage vault, is then ready to be transferred to the spent fuel pool prep machine.

9.1.4.2.10.2.1.4 Equipment Preparation. Prior to use for refueling, refueling equipment will be placed in readiness. All tools, grapples, slings, strongbacks, stud tensioners, etc. will be given a thorough check and any defective (or well worn) parts will be replaced. Air hoses on the main grapples will be routinely leak tested. Crane cables will be routinely inspected. All necessary maintenance and interlock checks will be performed to ensure no extended outage due to equipment failure.

The channeled new fuel will be ready in the storage pool.

9.1.4.2.10.2.2 Reactor Shutdown. The reactor is shut down according to a prescribed procedure. During cooldown the reactor pressure vessel is vented. The reactor well shield plugs are removed using the reactor building crane and the supplied slings.

This operation can be immediately followed by removal of the canal plugs. These activities are covered in Sections 9.1.4.2.10.2.3.3 and 9.1.4.2.10.2.4.

9.1.4.2.10.2.2.1 Drywell Head Removal. Immediately after removal of the reactor well shield plugs, the work to unbolt the drywell head can begin. The drywell head is attached by removable bolts. The bolts are unscrewed and together with their nuts are removed and stored.

The head strongback is attached to the unbolted drywell head and lifted by the overhead reactor building crane to its appointed storage space on the refueling floor.

9.1.4.2.10.2.2.2 Reactor Well Servicing. When the drywell head has been removed, an array of piping is exposed that must be serviced. Various vent piping penetrations through the reactor well must be removed and the penetrations made watertight. Vessel head piping and head insulation must be removed and transported to storage on the refueling floor.

Water level in the vessel is now adjusted in preparation for head removal.

9.1.4.2.10.2.3 Reactor Vessel Opening.

9.1.4.2.10.2.3.1 Vessel Head Removal. The stud tensioners are transported by the reactor building crane and positioned on the reactor vessel head. Each stud is tensioned and its nut loosened in a prescribed manner to uniformly detension the head. When the nuts are loose, they are backed off using a nut runner until only a few threads remain engaged. The vessel nut handling tool is engaged in the upper part of the nut and the nut is rotated free from the stud. The nuts and washers are placed in the racks provided for them and transported to the refueling floor for storage. With the nuts and washers removed, the vessel stud protectors and vessel head guide caps are installed.

The head strongback, transported by the reactor building crane, is attached to the vessel head and the head transported to the head holding pedestals on the refueling floor. The head holding pedestals keep the vessel head elevated to facilitate inspection and O-ring replacement.

Alternatively, the reactor vessel head can be removed using the RPV head stud tensioner carousel/strongback, a tool that combines the functions of the stud tensioner handling frame and the head lifting strongback. The carousel/strongback, with the stud tensioners suspended from its integral monorail, is transported by the reactor building crane and attached to the RPV head. Using the stud tensioners, the nuts are removed from the RPV head studs in the manner previously described, the nuts placed in a circular nut storage transporting rack, also integral to the carousel/strongback. When all the head stud nuts are removed, the RPV head stud tensioner carousel/strongback, with the RPV head attached and all head stud nuts stowed in the integral nut rack, is transported by the reactor building crane to the head holding pedestals on the refueling floor.

The studs in line with the fuel transfer canal are removed from the vessel flange and placed in the rack provided. The loaded rack is transported to the refueling floor for storage.

9.1.4.2.10.2.3.2 Dryer Removal. The dryer sling assembly is lowered by the reactor building crane and attached to the dryer lifting lugs. The dryer is lifted from the reactor vessel and transported to its storage location in the dryer-separator storage pool adjacent to the reactor well. The dryer is sprayed with water to control the spread of contamination during transfer and until water level in reactor well and dryer-separator pool cover the dryer.

9.1.4.2.10.2.3.3 Separator Removal. The four main steam lines are plugged from inside the vessel using the furnished plugs for this duty. Servicing of the safety and relief valves can thus be accomplished without adding to the critical refueling path time. The separator is unbolted using the shroud head bolt wrenches furnished. The fuel pool slot plugs are then removed.

The separator sling assembly is lowered into the vessel and attached to the separator lifting lugs. The water in the reactor well and in the dryer-separator storage is raised to fuel pool water level, and the separator is transferred to its allotted storage place in the equipment pool.

9.1.4.2.10.2.3.4 Fuel Bundle Sampling. During reactor operation, the core offgas radiation level is monitored. If a rise in offgas activity indicating a fuel failure has been noted, the reactor core will be sampled during a refueling outage to locate any leaking fuel assemblies.

9.1.4.2.10.2.4 Refueling and Reactor Servicing. The gates isolating the fuel pool from the reactor well are now removed thereby interconnecting the fuel pool, the reactor well, and the dryer-separator storage pool. The actual refueling of the reactor can now begin.

9.1.4.2.10.2.4.1 Refueling. The refueling pattern will depend on various factors such as fuel performance, plant loading, and fuel design.

Detailed procedures will be developed for various refueling tasks such as fuel receipt, fuel inspection, fuel transfer from vault to pool, fuel movements within the pool, fuel movements within the reactor, or between the spent fuel pool and the reactor, as well as procedures for handling of other core components.

During a normal equilibrium outage, approximately 33% of the fuel is removed from the reactor vessel, 33% of the fuel is shuffled in the core (generally from center to peripheral locations), and 33% new fuel is installed. The actual fuel handling is done with the fuel grapple which is an integral part of the refueling platform. The platform runs on rails over the fuel pool and the reactor well. In addition to the fuel grapple, the refueling platform is equipped with two auxiliary hoists which can be used with various grapples to service other reactor internals.

To move fuel, the fuel grapple is aligned over the fuel assembly, lowered and attached to the fuel bundle bail. The fuel bundle is raised out of the core, moved through the refueling slot to

the fuel pool, positioned over the storage rack and lowered to storage. Fuel is shuffled and new fuel is moved from the storage pool to the reactor vessel in the same manner.

9.1.4.2.10.2.5 Vessel Closure. The following steps, when performed, will return the reactor to operating condition. The procedures are the reverse of those described in the proceeding sections. Many steps are performed in parallel and not in the sequences listed.

a. Core verification. The core position of each fuel assembly must be verified to ensure the desired core configuration has been attained;

b. Control rod drive tests. The control rod drive timing, friction and scram tests are performed;

c. Install inner fuel pool gate;

d. Replace separator and drain dryer-separator storage pool and reactor well;

e. Bolt separator and remove the four steam line plugs;

f. Replace steam dryer;

g. Install reactor vessel head;

h. Decontaminate reactor well;

i. Open drywell vents, install vent piping;

j. Replace slot plugs;

k. Replace vessel studs;

l. Install vessel head piping and insulation;

m. Replace dryer-separator canal plugs;

n. Hydrotest vessel, if necessary;

o. Install drywell head;

p. Install reactor well shield plugs; and

q. Startup tests. The reactor is returned to full power operation. Power is increased gradually in a series of steps until the reactor is operating at rated

power. At specific steps during the approach to power, the in-core flux monitors are calibrated.

9.1.4.2.10.3 Departure of Spent Fuel From the Reactor Building. Spent fuel is removed from the Reactor Building in an NRC licensed shielded cask. The reactor building and cask handling facilities (see Section 9.1.4.2.2 for a description of the crane) are designed to handle casks up to 125 tons.

The following description of the spent fuel departure is based on the licensed Holtec HI-STORM 100 System which includes a transfer cask of 125 tons maximum weight with a capacity of 68 BWR fuel bundles.

After the cask has been inspected and prepared for lifting, it is transferred to the reactor operating floor and placed onto the cask decontamination pad where it is prepared for placement into the spent fuel cask loading area. The cask provides shielding for a canister contained within the cask. The canister, when sealed, is a confinement for the fuel.

The cask is next raised and transferred into the spent fuel cask loading area. The cask lifting yoke is lowered until it is disengaged from the cask trunnions.

Spent fuel is transferred under water from storage in the fuel pool to the cask using the telescoping fuel grapple mounted on the refueling platform. When the cask is filled with spent fuel, the canister closure head is placed on the cask and the lift yoke engaged with the cask trunnions. The loaded cask is raised and transferred to the cask decontamination pad.

The cask is checked by health physics personnel and decontamination is performed with high pressure water sprays, chemicals, and hand scrubbing, as required, to clean the cask. The canister is sealed, dewatered and inerted. The cask lid is installed and the cask prepared for lifting.

The sealed canister is then transferred to a storage cask. The storage cask and canister are moved to the spent fuel storage area.

9.1.4.3 Fuel Handling Safety Evaluation

Stresses in all structural and mechanical parts of the reactor building crane system are far below the endurance limits for infinite life of the various materials for both the rated crane capacity and the test load of 125% of rated load. All loads to be handled are below rated crane capacity. Therefore, stresses should never reach allowable working stresses. Loads on the structural parts vary but do not reverse. The only critical parts with stress reversals are the rotating parts, and these are provided with single failure protection. Since the crane is to operate under normal temperature conditions and since the stress levels are below the

endurance limits for infinite life, testing of the crane to 125% of rated capacity provides reasonable assurance that the crane will not fail while handling a spent fuel cask.

As described in Section 9.1.4.2.2.2, sufficient redundancy is provided in the reactor building crane so that no credible postulated failure of any crane component will result in the dropping of the fuel cask. Therefore, the consequences of a cask drop accident are precluded. In addition, crane travel over the spent fuel pool is controlled by travel path (Figure 9.1-5) and interlocks that prohibit the crane from traveling over the spent fuel racks. At no time while being transported does the cask pass over any safe shutdown items. The objectives of Regulatory Guide 1.13 are met. Furthermore, when the crane is carrying the cask over the refueling floor area, the clear distance between the bottom of the cask and the refueling floor is minimized by good operating practice. Should any crane failure occur while the crane is moving the cask over the refueling floor area, the crane drop of less than one inch described in Section 9.1.4.2.2.2 prevents the cask from physically contacting the floor. See Section 9.1.4.2.2.2 for safety features which ensure crane stability during tornado and seismic excitation.

Jib cranes MT-CRA-9A and 9B are designed and equipped to meet the Class A1 (standby) service requirements of CMAA Specification #70. Each crane is capable of raising, lowering, holding, and transporting a test work load of 125% of rated work load without damage to or excessive deflection in a part and without inducing permanent deformation in any crane element. Cables are of the nonrotating type to prevent rotation of load during raising or lowering operations.

The following factors of safety are used in design and are based on the maximum stress produced by worst load combinations and the average ultimate strength of the material, unless otherwise stated herein:

a. All load carrying components except structural members and hoisting ropes are designed to have a minimum safety factor of five;

b. All mechanical parts subject to dynamic strains, such as gears, shafts, drums, blocks, and other integral parts, have a minimum safety factor of five;

c. All hoisting ropes are designed to have a minimum safety factor of five based on the published breaking strength of the rope;

d. Components of the jib cranes are adequately proportioned to limit the overall deflections of the crane to safe limits under any position of the loaded trolley hoist. Maximum vertical static deflection of the boom with nameplate rated hook load is less than 0.6 in.; and

e. Structural members/shapes not covered by the above safety factors are designed in accordance with CMAA Specification No. 70, and if not covered by CMAA Specification No. 70, in accordance with the AISC Specification for the design, fabrication, and erection of structural steel for buildings except that the allowable stress shall not exceed 80% of the AISC allowable design stress.

Jib cranes MT-CRA-9A and 9B are designed to Seismic Category I requirements (with lifted load).

The cranes are equipped with switches to limit their lifted load to 1000 lb.

The cranes are exempted from the NUREG 0612 requirement because the definition of "Heavy Loads" at CGS is 1200 lb. The cranes are also not required to hold their lifted load during a seismic event since the maximum load of 1000 lb (or 1200 lb) is enveloped by analysis that indicates the high density spent fuel storage racks can withstand a drop (both from a structural and criticality standpoint) of 1510 lb from the height of the fuel pool water surface. Licensee Controlled Specifications limit the loads over spent fuel in the spent fuel pool to 1500 lb whenever irradiated fuel assemblies are in the spent fuel storage pool. Crane operations with loads will be suspended in the spent fuel storage pool area if there is less than 22 ft of water over the top of fuel assemblies seated in the storage racks. Based on the analysis presented in Section 15.7, the radiological consequences of a fuel bundle (with or without a channel) dropped by the jib crane are bounded by the fuel handling analysis which assumed a bundle dropped from 34 ft into the reactor core. This resulted in a much higher kinetic energy level. In comparing the jib crane drop to the reactor core drop, it is not possible to cause the release of more fission gases from the damaged fuel than assumed in the Section 15.7 analysis due to the shorter drop distance and resulting lower kinetic energy.

The cranes are designed so as to be capable of operating within the following tolerances:

a. With all brakes adjusted for normal operation, it is possible to control the vertical movement to within 0.25 in. under all conditions of loading,

b. Cranes operate through full hook lift without noticeable rotation of load, and

c. With hook carrying 100% of rated load and lowering at full speed, the motor does not exceed 125% of synchronous speed.

Since jib cranes MT-CRA-9A and 9B are to be used on and around the fuel pool for handling new and spent fuel and other components in the work area, the following safety features are provided:

The hoist is motorized with a motorized boom and jib. To preclude the possibility of inadvertently raising radioactive materials out of the water, a specially prepared sling or

handling tool will be used when handling materials not intended to be raised out of the water. The length of the sling or tool will be administratively controlled such that with the crane at full mechanical up travel the top of the active fuel will be at a minimum of 7 ft 6 in. below water level.

The unit is equipped with two full capacity brakes. A mechanical force gauge is supplied to automatically stop the hoist on an overload signal of 1000 +50 lb. Two additional microswitches are wired in parallel and the three leads are brought out with the power leads for connection to a platform receptacle. The two additional switches are designed to open at 400 ±50 lb (these switches are not normally used for any function).

Safety aspects (evaluation) of the fuel servicing equipment are discussed in Section 9.1.4.2.3 and safety aspects of the refueling equipment are discussed throughout Section 9.1.4.2.7. A description of fuel transfer, including appropriate safety features, is provided in Section 9.1.4.2.10. In addition, the following summary safety evaluation of the fuel handling system is provided below.

The fuel prep machine can remove and install channels with all parts remaining under water. Mechanical stops in use when handling irradiated fuel prevent the carriage from lifting the fuel bundle or assembly to a height where water shielding for the active fuel is less than 7.5 ft. Irradiated channels, as well as small parts, such as bolts and springs, are stored underwater. The spaces in the channel storage rack have center posts which prevent the loading of fuel bundles into this rack.

There are no nuclear safety problems associated with the handling of new fuel bundles, singly or in pairs. Equipment and procedures prevent an accumulation of more than two bundles in any location.

The refueling platform is designed to prevent it from toppling into the pools during a SSE. The refueling mast has normal up limit switches to prevent raising the top of active fuel to a height of less than 7.5 ft below the water surface. The grapple is hoisted by redundant cables inside the mast and is lowered by gravity. A digital readout is displayed to the operator, showing him the exact coordinates of the grapple over the core.

The mast is suspended and gimbaled from the trolley, near its top, so that the mast can be swung about the axis of platform travel to remove the grapple from the water for servicing and storage.

The grapple has two mechanically coupled hooks, operated by a single air cylinder. Engagement is indicated to the operator.

In addition to the main hoist on the trolley, there is an auxiliary hoist on the trolley, and another hoist on its own monorail. These three hoists are precluded from operating simultaneously because control power is available to only one of them at a time.

The two auxiliary hoists have electrical interlocks which will prevent lifting the top of the active fuel on lifted fuel assemblies higher than 7.5 ft under water. Adjustable mechanical jam-stops on the cables back up these interlocks.

In summary, the fuel handling system complies with Regulatory Guide 1.13, Revision 1, GDC 2, 3, 4, 5, 61, 62, and 63, and applicable portions of 10 CFR Part 50.

The safety evaluation of the new and spent fuel storage is presented in Sections 9.1.1.3 and 9.1.2.3.

9.1.4.4 Testing and Inspection Requirements

9.1.4.4.1 Testing and Inspection of Cranes

The main and auxiliary hooks of the reactor building crane are proof tested in the vertical, direction with a total uniformly applied load equal to 150% of their rated capacity. Tests on the main hook are made with a load suspended. After the load tests, the hooks are checked by magnetic particle inspection and for any dimensional change. When completely assembled, the crane components (except for wire ropes), are operated to ensure the accuracy of fabrication and the quality of workmanship.

After erection in the reactor building, the crane is statically tested to 125% of rated capacity (156.25 tons for the main hoist and 18.75 tons for the auxiliary hoist). The tests are performed in accordance with written procedures which include movement in all positions of hoisting, lowering and trolley and bridge travel. After completion of the static test, a full performance test with 100% of the design rated load is performed.

Operational tests and visual inspections are made at periodic intervals during the life of the crane to demonstrate its ability to safely perform its functions. The crane hooks are to be inspected by the magnetic particle or liquid penetrant methods as applicable. These inspections and tests will be scheduled to precede major fuel handling activities.

Jib crane hooks (9A and 9B) shall be either magnetic particle inspected in accordance with ASTM E-109 (July, 1975) or liquid penetrant inspected in accordance with ASTM E-165 (July, 1975). Standard shop tests shall be performed on all equipment. Field tests shall be performed upon each piece of equipment, after completion of erection and installation, in order to verify the overall performance of the equipment against requirements and to check the mechanical performance of the equipment with regard to applicable specification requirements.

Periodic operational tests and inspection will be performed on the jib cranes to demonstrate their ability to perform their safety function.

9.1.4.4.2 Inspection and Testing Requirements of Refueling and Servicing Equipment

9.1.4.4.2.1 Inspection. Refueling and servicing equipment is subject to the strict controls of quality assurance, incorporating the requirements of 10 CFR Part 50, Appendix B. Components defined as important to safety, such as the fuel storage racks and refueling platform, have an additional set of engineering specified "quality requirements" that identify safety-related features which require specific quality assurance verification of compliance to drawing requirements.

For components classified as ASME Section III, the shop operation must secure and maintain an ASME "N" stamp, which requires the submittal of an acceptable ASME quality plan and a corresponding procedural manual.

Additionally, the shop operation must submit to frequent ASME audits and component inspections by resident state code inspectors.

Prior to shipment, every component inspection item is reviewed by quality assurance supervisory personnel and combined into a summary product quality checklist (PQL). By issuance of the PQL, verification is made that all quality requirements have been confirmed and are on record in the product's historical file.

9.1.4.4.2.2 Testing. Qualification testing is performed on refueling and servicing equipment prior to multiunit production. Test specifications are defined by the responsible design engineer and may include; sequence of operations, load capacity and life cycles tests. These test activities are performed by an independent test engineering group and, in many cases, a full design review of the product is conducted before and after the qualification testing cycle. Any design changes affecting function, that are made after the completion of qualification testing, are requalified by test or calculation.

Functional tests are performed in the shop prior to the shipment of production units and include electrical tests, leak tests and sequence of operations tests.

When the unit is received at the site, it is inspected to insure no damage has occurred, during transit or storage. Prior to use and at periodic intervals, each piece of equipment is again tested to ensure the electrical and/or mechanical functions are operational.

Passive units, such as the fuel storage racks are visually inspected prior to use.

There is an operation and maintenance instruction manual for each tool that additionally requires a series of functional checks each time the unit is operated for reactor refueling or servicing.

Fuel handling and vessel servicing equipment preoperational tests are described in Section 14.2.12.1.12.

9.1.4.5 Instrumentation Requirements

9.1.4.5.1 Instrument Requirements - Cranes

Operation of the reactor building crane is from the cab or from the floor by radio control. Control at any one time is from one point only. Sufficient electrical circuitry in the system is provided such that no single credible electrical component failure will cause the load to drop. The reactor building crane and its safety features are described in Section 9.1.4.2.2.

The refueling platform contains a position-indicating system that indicates the position of the fuel grapple over the core. Interlocks on both the fuel grapple hoist and the auxiliary hoists are provided for safety purposes. The refueling interlocks are described and evaluated in Section 7.7.1.13.

For a description of jib crane safety-related interlocks, see Section 9.1.4.3. Except for jib cranes MT-CRA-9A and MT-CRA-9B, limit switches are provided for all electrically operated hoists to prevent overhoisting. Pushbutton pendant controls are provided with stepped controls for multispeed motions.

9.1.4.5.2 Instrumentation Requirements - Refueling and Servicing Equipment

The majority of the refueling and servicing equipment is manually operated and controlled by the operator's visual observations. This type of operation does not necessitate the need for a dynamic instrumentation system.

However, there are several components that are essential to prudent operation that do have instrumentation and control systems.

The refueling platform has a non-safety-related X-Y-Z position indicator system that informs the operator which core fuel cell the fuel grapple is accessing. Interlocks and control room monitor are provided to prevent the fuel grapple from operating in a fuel cell where the control rod is not in the proper orientation for refueling. Refer to Section 7.7.1.13 for discussion of refueling interlocks.

Additionally, a programmable logic controller (PLC), which is a part of the refueling platform control system, provides indications to the operator for grapple limits, hoist load conditions, and confirmation that the grapple hook is either engaged or released.

The load for the main hoist, auxiliary frame hoist, and monorail hoist is determined by electronic load cells and strain gauge transmitters. The load for the main hoist and auxiliary frame hoist is input to the PLC. The PLC provides hoist loaded and hoist overload signals for both the main hoist and auxiliary frame hoist, and provides slack cable signal for the main hoist. Setpoint modules monitor the monorail hoist load and provide hoist loaded and hoist overload interlock signals. Automatic shutdown occurs whenever threshold limits are exceeded on either the main hoist, the auxiliary frame hoist, or the monorail hoist.

9.1.4.5.3 Fuel Support Grapple

Although the fuel support piece grapple is not important to safety, it has an instrumentation system consisting of mechanical switches and indicator lights. This system provides the operator with a positive indication that the grapple is properly aligned and oriented and that the grappling mechanism is either extended or retracted.

The Westinghouse MLT, also used to grapple and remove fuel support pieces, is designated Safety Class 3. The instrumentation system for the MLT consists of flag-type indicators directly linked to each grapple mechanism to show when the grapple is engaged to the fuel support piece. The MLT also incorporates internal guide tubes for underwater cameras, allowing the MLT operator to view and verify proper seating and alignment of the fuel support piece on its guide pin.

9.1.4.5.4 Other

See Table 9.1-7 for additional refueling and servicing equipment.

9.1.4.5.5 Radiation Monitoring

The radiation monitoring equipment for the refueling and servicing area is discussed in Sections 11.5.2.1.2 and 12.3.4.

9.1.5 CONTROL OF HEAVY LOADS

9.1.5.1 Introduction/Licensing Background

Columbia Generating Station controls heavy load lifts by implementing NUREG-0612 recommended guidelines in its plant procedures. Columbia's heavy loads program procedures focus on areas where a load drop could impact stored spent fuel, fuel in the reactor core, or equipment that may be required to achieve safe shutdown or permit continued decay heat

removal. Columbia reduces the likelihood of dropping heavy loads by implementing criteria for establishing safe load paths, procedures for load handling operations, training of crane operators, design, testing, inspection, and maintenance of cranes and lifting devices, and analyses of the impact of heavy load drops. Columbia also mitigates the consequences of a heavy load drop with the use of a single-failure-proof crane in certain applications for increased handling system reliability. In other areas where a single-failure-proof crane is not used, load drop and consequence analyses are performed for assessing the impact of dropped loads on plant safety and operations.

9.1.5.2 Safety Basis

The recommended guidelines established in NUREG-0612 are the safety basis that provides a defense-in-depth approach to controlling the handling of heavy loads near spent fuel and safe shutdown equipment. These guidelines are reflected in Columbia's heavy loads handling procedures. These procedures incorporate NUREG-0612 requirements except for those deviations approved by the NRC. Columbia's heavy loads handling procedures ensure that the risk associated with load handling failures is acceptably low, based on meeting requirements of Phase 1 of NUREG-0612, Section 5.1.1, and based on increasing the handling system reliability by meeting NUREG-0612 Phase II guidelines with the utilization of a single-failure-proof crane where a load drop could impact on stored spent fuel and fuel in the reactor core. An exception to NUREG-0612 Phase I, Section 5.1.1(1) was approved to not require load paths marked on the floor for monorail hoists because the single available path cannot vary. Additionally, load paths for the Reactor Building Crane loads are not required to be permanently marked on the refueling floor because the multiple paths would overlap in places and would be difficult to follow. Furthermore, protective coverings on the refueling floor would cover the paths for many lifts. The main Reactor Building crane (MT-CRA-2) has been approved as single-failure-proof crane that meets the criteria established in either NUREG-0554 or NUREG-0612 Appendix C. Additional defense-in-depth analyses and evaluations are performed for heavy load lifts not associated with the use of a single-failure-proof crane in areas where a load drop could impact equipment that may be required to achieve safe shutdown or permit continued decay heat removal.

9.1.5.3 Scope of Overhead Heavy Load Handling Systems

At CGS, overhead handling systems are used to handle heavy loads in the area of the reactor vessel or spent fuel in the spent fuel pool. Additionally, loads are handled in other areas where their accidental drop may damage safe shutdown systems or systems that permit continued decay heat removal. The following is the committed heavy lifts along with their associated cranes/hoists.

Committed Heavy Lifts

	Committed Heavy Load Lift		Committed Heavy Load Lift
1	Vessel Cavity Shield Plug (MT-CRA-2)	21	MPC Lid (MT-CRA-2)
2	Dry/Separator Pool Plugs Top (MT-CRA-2)	22	HI-STORM Lid (MT-CRA-2)
3	Dry/Separator Pool Plugs Bottom (MT-CRA-2)	23	MPC with contents (MT-CRA-2)
4	Spent Fuel Gates (MT-CRA-2)	24	MPC without contents (MT-CRA-2)
5	Fuel Pool Shield (Slot) Plugs (MT-CRA-2)	25	Sea Van Container & other loads during plant operation (MT-CRA-1)
6	"Cattle" Chute (MT-CRA-2)	26	Standby Service Water Pumps (MT-CRA-6A & 6B)
7	Space Frame (w/head insulation) (MT-CRA-2)	27	RHR A&B Shield Blocks (MT-HOI-6)
8	Drywell Head (MT-CRA-2)	28	RHR A&B Pumps (MT-HOI-6)
9	Reactor Head (MT-CRA-2)	29	RHR C Shield Blocks (MT-HOI-8)
10	Steam Dryer (MT-CRA-2)	30	RHR C Pumps (MT-HOI-8)
11	Moisture Separator (MT-CRA-2)	31	RCIC Shield Blocks (MT-HOI-7)
12	Reactor Vessel Service Platform (MT-CRA-2)	32	RCIC Pump & Turbine (MT-HOI-7)
13	RHR HX Floor Plugs (MT-CRA-2)	33	LPCS Shield Blocks (MT-HOI-9)
14	New Fuel Pit Floor Plugs (MT-CRA-2)	34	LPCS Pump/Motor (MT-HOI-9)
15	FPC Skimmer Surge Tank Plugs (MT-CRA-2)	35	HPCS Shield Blocks (MT-HOI-10)
16	Refueling Basket (MT-CRA-2)	36	HPCS Pump (MT-HOI-10)
17	RPV Head Stud Tension/Carousel (MT-CRA-2)	37	RRC Motors (MT-HOI-16)
18	Mating Device (MT-CRA-2)	38	Steam (Pipe) Tunnel Shield Blocks (MT-HOI-18)
19	HI-TRAC Cask with or without MPC, lid, etc. (MT-CRA-2)		
20	HI-TRAC Top Lid (MT-CRA-2)		

9.1.5.4 Control of Heavy Loads Program

Columbia's Control of Heavy Loads Program consists of the following:

1. Commitments to NUREG-0612, Phase I General Requirements.

2. Commitments to NUREG-0612, Phase II with the utilization of a single-failure-proof crane for Reactor Pressure Vessel Head (RPVH) lifts and for spent fuel cask lifts over the spent fuel pool. Additional defense-in-depth analyses and evaluations are performed for heavy load lifts not associated with the use of a single-failure-proof crane in areas where a load drop could impact equipment that may be required to achieve safe shutdown or permit continued decay heat removal.

9.1.5.4.1 Columbia Generating Station Commitments in Response to NUREG-0612 Section 5.1.1, Phase I Guidelines

9.1.5.4.1.1 Safe Load Path. Safe load paths are defined in Columbia's heavy load lifting procedures and some temporary paths may be marked when it can help assure safe load handling. A person in charge, other than the operator, is responsible for inspecting the load path for potential interferences. Load paths are not marked on the floor for monorail hoists because the single available path can not vary. Load paths for the Reactor Building Crane loads are not permanently marked on the refueling floor because the multiple paths would overlap in places and would be difficult to follow. Protective coverings on the refueling floor would cover the paths for many lifts. The above exceptions are approved NRC deviations.

9.1.5.4.1.2 Procedures. Procedures are implemented to prevent personnel errors consistent with the requirements of Section 5.1.1(2) of NUREG-0612.

9.1.5.4.1.3 Crane and Hoist Operators. Plant-wide training and qualification procedures have been implemented and meet the requirement found in Section 5.1.1(3) of NUREG-0612.

9.1.5.4.1.4 Special Lifting Devices. Special lifting devices satisfy the guidelines of ANSI N14.6-1978 are identified, maintained and controlled by plant procedures. These requirements are consistent with Section 5.1.1(4) of NUREG-0612. Dynamic loads determined as a percentage of static loads are added to the static load to obtain the design load.

9.1.5.4.1.5 Lifting Devices that are not Specially Designed. Lifting devices that are not specially designed are used in accordance with ANSI B30.9-1971. Usage is restricted to properly trained and qualified site rigging personnel consistent with the requirements found in Section 5.1.1(5) of NUREG-0612. Dynamic loads determined as a percentage of static loads are added to the static load to obtain the design load.

9.1.5.4.1.6 Crane Inspection, Testing and Maintenance. Cranes are inspected, tested, and maintained in accordance with the guidance in Chapter 2-2 of ANSI B30.2-1976 by inspection, maintenance and testing procedures. This is consistent with the requirements found in Section 5.1.1(6) of NUREG-0612.

9.1.5.4.1.7 Hoist and Crane Design

9.1.5.4.1.7.1 Hoist Design. In the absence of specific guidance from NUREG-0612, hoists are designed to applicable requirements of industry standards CMAA 74, ANSI B30.11 and ANSI B30.16.

9.1.5.4.1.7.2 Crane Design. Cranes are designed according to applicable criteria and guidelines of Chapter 2-1 of ANSI B30.2-1976. These crane requirements are consistent with Section 5.1.1(7) of NUREG-0612.

9.1.5.4.2 Reactor Pressure Vessel Head Lifting Procedures

Columbia Generating Station RPV handling procedures are used to control the lift and replacement of the reactor pressure vessel head. These procedures rely on the use of the main Reactor Building Crane (MT-CRA-2) which is a single-failure-proof crane.

9.1.5.4.3 Single-Failure-Proof Cranes for Spent Fuel Casks

The Spent Fuel Casks lifts and movements are controlled by CGS procedures. These procedures rely on the use of the main Reactor Building Crane (MT-CRA-2) which is a single-failure-proof crane.

9.1.5.4.4 Other Analyses

Additional defense-in-depth analyses and evaluations are performed for heavy load lifts not associated with the use of a single-failure-proof crane in areas where a load drop could impact equipment that may be required to achieve safe shutdown or permit continued decay heat removal.

9.1.5.5 Safety Evaluation

The heavy loads handling activities at CGS are controlled in a manner consistent with the requirements of Phase I of NUREG-0612, except as allowed by the NRC, and with industry standards to ensure defense-in-depth is maintained during heavy load movements. A single-failure-proof crane is used for Reactor Pressure Vessel Head and Spent Fuel Cask movements. Evaluations are performed for heavy load lifts not associated with the use of a single-failure-proof crane and appropriate measures are implemented as necessary to ensure adequate safety

is maintained. Risks associated with heavy load lifting are identified, assessed and managed through usage of CGS lifting procedures.

Performance Data

Design heat load, Btu/hr	8.0×10^6
Maximum heat load, Btu/hr	44.3×10^6 (see note)
System design pressure, psig	150
System design temperature, °F	150 normal, 175 maximum
Fuel pool water volume, gal	350,000
Dryer-separator pool water volume, gal	293,600
Reactor well water volume, gal	210,000

NOTE: The maximum heat load is the decay heat of one full core load of the fuel plus the remaining decay heat of previously discharged fuel assemblies. The heat load and the fuel pool cooling system will be controlled such that the temperature limits shown in Table 9.1-6 are maintained.

Table 9.1-6

Bounding Fuel Pool Cooling Events

Fuel Pool Heat Load/Scenario	Fuel Cycle Length (Months)	FPC Loops		RHR Loops in FPC Assist Mode		Acceptance Criteria[a] (°F)
		Available	Credited	Available	Credited	
Normal refueling[b] (non-transient condition)	24	2	2	1	0	150
Normal refueling[c] (anticipated operational transient condition)	24	1	1	1	0	175
Full core offload refueling[d]	24	2	0	1	1	145/175
Normal Operations[e] (non-transient/non-accident condition)	24	2	2	0	0	125
Normal Operations[f] (anticipated operational transient condition)	24	1	1	0	0	175
Normal Operations[g] (design basis LOCA condition)	24	2	1	0	0	125 (pre-accident) 175 (post-accident)

Table 9.1-6

Bounding Fuel Pool Cooling Events (Continued)
Performance Data

Table Notes:

[a] Outage-specific/Cycle-specific calculations are performed, as needed, to ensure acceptance criteria limits are maintained.

[b] A normal refueling does not involve a full core offload. The normal refueling temperature limits go into effect upon placing the plant in cold shutdown and remain in effect until plant start-up. The 150°F acceptance criterion is applicable for the case of both FPC loops available.

[c] A normal refueling does not involve a full core offload. The 175°F acceptance criterion is applicable for an anticipated operational transient of the loss of one FPC loop.

[d] A full core offload is a non-routine evolution. Although no single failure is postulated to occur during this evolution, only credit for RHR/FPC assist is taken. During this evolution, sufficient cooling is provided to maintain the fuel pool temperature at less than 145°F. The licensing basis limit is 175°F.

[e] Normal Operations is defined as any plant condition other than a refueling outage. The normal operation temperature limits become applicable upon plant start-up following a refueling outage. The 125°F value supports the initial (i.e., pre-accident) fuel pool temperature assumption in the design basis LOCA analysis.

[f] Normal Operations is defined as any plant condition other than a refueling outage. The 175°F value is applicable for an anticipated operational transient involving the loss of one FPC loop. If the fuel pool heat load is such that the resulting temperature transient exceeds 125°F, procedural guidance is in place to restore the fuel pool temperature to < 125°F.

[g] Normal Operations is defined as any plant condition other than a refueling outage. The 125°F and 175°F values support the initial fuel pool temperature assumption and the calculated peak fuel pool temperatures, respectively, in the design basis LOCA analysis. For this event, RCC is assumed to be lost and SW is manually aligned to the FPC system heat exchangers. An equilibrium temperature of 90°F is assumed for the SW.

9.2 WATER SYSTEMS

9.2.1 PLANT SERVICE WATER SYSTEM

9.2.1.1 Design Bases

a. The plant service water (TSW) system is designed to provide cooling water for removal of heat rejected from auxiliary (nonessential) equipment, including turbine generator and reactor auxiliaries located throughout the plant, and

b. The plant service water system is designed to remove the maximum expected heat load of the equipment under normal operating conditions.

9.2.1.2 System Description

The plant service water system consists of two 100% capacity pumps (TSW-P-1A, TSW-P-1B) taking suction from the circulating water intake structure and supplying cooling water to equipment located throughout the plant (see Figure 9.2-1).

Plant service water is returned to the circulating water tunnel for heat removal by the circulating water system cooling towers.

The plant service water system is designed to function continuously during all modes of operation except during loss-of-coolant accident (LOCA) with loss of offsite power. Following loss of power under nonLOCA conditions, the plant service water pumps will be supplied from standby power buses (see Section 8.3.1.1.1). The plant service water radiation monitor is continuously recorded in the control room and will alarm if the water becomes contaminated except during loss of offsite power when plant service water will be manually monitored for radiation. The circulating water system blowdown line radiation monitor serves as backup (see Figure 10.4-4). On detecting radiation in the blowdown line, it automatically isolates the blowdown to the river except during plant outages as described in Section 11.5.2.2.2.4.

In addition to the biocide treated circulating water supply utilized by the plant service water system, the plant service water system is equipped with a biocide treatment system to retard biological growth. Additional chemical treatment capability is provided to minimize silt deposition, scale formation, corrosion, and consequent fouling of heat transfer surfaces.

Required makeup to the plant service water system is included as part of the overall circulating water system makeup requirements. The makeup flow can be directed in to the circulating water bay or to one or both of the plant service water pump suctions. This is accomplished by means of a weir box and sluice gate arrangement in the circulating water mixing bay (see Section 10.4.5).

Water for plant service water (TSW) pump 1B (TSW-P-1B) bearing lubrication and for both TSW pumps 1A and 1B (TSW-P-1A and TSW-P-1B) motor cooling is supplied from the plant service water pump during operation of the pump. This water is filtered before being injected to lubricate the bearings. The Fire Protection system provides TSW pump bearing lubrication water for initial system startup for TSW pump 1B (TSW-P-1B). The Fire Protection system also provides water for motor cooling of both TSW pumps 1A and 1B (TSW-P-1A and TSW-P-1B) during initial TSW system startup after both pumps have been secured (or tripped) (see F.2, Section F.2.4.1).

The plant service water system piping is designed in accordance with ANSI B31.1. The two service water pumps are designed in accordance with the Standards of the Hydraulic Institute, Centrifugal Pump Section.

9.2.1.3 Safety Evaluation

The operation of the plant service water system is not required to ensure any of the following conditions:

a. The integrity of the reactor coolant pressure boundary (RCPB),

b. The capability to shut down the reactor and maintain it in a safe shutdown condition, or

c. The ability to prevent or mitigate the consequences of accidents which could result in potential offsite exposures in excess of the guideline exposures of 10 CFR Part 100.

A single-failure analysis has not been provided for the plant service water system since this system serves only nonessential systems and is not required to perform a safety function. See Section 3.6 for a discussion of piping failures. The system, however, incorporates features that ensure continuity and reliability of operation. Plant service water pumps will be alternately operated to minimize wear, and the standby pump is available as a replacement during maintenance of the normally operating pump.

All piping, valves, and associated components of the plant service water system are classified Seismic Category II except in the reactor building and control building where system hangers are designed for Seismic Category I loads (seismic 1M).

9.2.1.4 Testing and Inspection Requirements

The components used in this system were tested and inspected at the manufacturer's plant for conformance with specifications. After installation, major components were checked and the system hydrostatically tested to ensure leak tightness prior to plant startup. Preoperational testing included testing of automatic controls for actuation at the proper setpoints, calibration

of instruments and alarms. Routine visual inspection of system components, instrumentation, and trouble alarms verify system operability and performance.

9.2.1.5 Instrumentation Requirements

Suitable alarms and indicators are provided to monitor and control the system throughout the system to allow the control room operator to take corrective action as required.

Each pump is manually started from the main control room. The standby pump is automatically started by actuation of a low pressure switch in the operating pump discharge line. The pressure at the discharge of each pump is indicated locally and also in the main control room. A pressure switch provides annunciation in the main control room on low pump discharge pressure signal.

9.2.2 REACTOR BUILDING CLOSED COOLING WATER SYSTEM

9.2.2.1 Design Bases

a. The RCC is designed to provide adequate cooling water to auxiliary plant equipment in the reactor and radwaste buildings during all normal modes of operation, and

b. The RCC is designed to provide a closed cooling water loop between nonessential systems which are potentially contaminated and the plant service water which is used for cooling. This loop provides an additional barrier between the potentially contaminated systems and the plant service water discharged to the circulating water system.

9.2.2.2 System Description

The RCC is a closed loop system which provides parallel-flow cooling to auxiliary equipment in the primary containment, the reactor building, and radwaste building. The system consists of pumps, heat exchangers, tanks, piping, valves, and instrumentation as shown in Figure 9.2-2. Each of the three pumps and three heat exchangers are half capacity based on maximum normal cooling requirements. Heat is removed from the RCC system by the plant service water system. The plant service water is passed through the tube side of the RCC heat exchangers and the closed-loop water is passed through the shell side. A 550-gal surge tanks accommodates volume changes from thermal expansion and contraction. Makeup water to the system is supplied to the surge tank by the demineralized water system.

The RCC cools the following equipment:

a. Reactor recirculation pumps,
b. Drywell fan unit cooling coils,
c. Drywell equipment drain condenser,

d. Reactor water cleanup (RWCU) nonregenerative heat exchangers,
e. Reactor building equipment drain heat exchanger,
f. Control rod drive pumps,
g. Fuel pool heat exchangers,
h. RWCU recirculating pumps, and
i. Offgas glycol refrigeration machines.

The RCC piping inside primary containment is constructed in accordance with ASME Section III, Class 3, and Seismic Category II requirements. The RCC piping outside of primary containment is constructed in accordance with ANSI B31.1. In the reactor building and inside primary containment, RCC piping is supported to Seismic Category I. In the radwaste building, RCC piping is supported to Seismic Category II requirements. System primary containment penetrations and isolation valves are constructed to Seismic Category I, and ASME Code Section III, Class 2, requirements. The RCC pumps are constructed to Seismic Category II, and RCC heat exchangers are constructed to ASME Code Section VIII and the Standards of the Tubular Exchanger Manufacturers Association, Class R. The system design pressure is 195 psig. The design temperature is 150°F for all piping except the RWCU nonregenerative heat exchanger discharge piping. The piping from the RWCU heat exchanger to the 18-in. return line has a design temperature of 175°F. The system operates at pressures and temperatures below the stated design values.

Equipment Design Parameters

Closed Cooling Water Pumps (RCC-P-1A, RCC-P-1B, RCC-P-1C)

Quantity	3
Driver	200 hp motor - ac
Design capacity	2500 gpm
Head	200 ft
Speed, rpm	1775

Closed Cooling Water Heat Exchangers (RCC-HX-1A, RCC-HX-1B, RCC-HX-1C)

Quantity	3
Heat duty	25×10^6 Btu/hr

	Shell side	Tube side
Flow rate	2500 gpm	3333 gpm
Inlet temperature	115°F	85°F
Outlet temperature	95°F	100°F
Pressure drop	11.2 psig	5.0 psig

A chemical addition tank (RCC-TK-2) and metering pump (RCC-P-2) were included in the original design for the addition of corrosion inhibiting chemicals if required. This chemical addition equipment is not normally used.

The RCC pumps supply water to the specified auxiliary plant equipment during all modes of operation except under LOCA conditions. Following loss of normal power and under nonLOCA conditions, the RCC pumps are supplied from standby power.

9.2.2.3 Safety Evaluation

The RCC provides a barrier between nonessential, potentially contaminated systems, and the plant service water discharged to the circulating water system. A radiation monitor is provided in the RCC to detect inleakage to this system from any contaminated system. Leakage is also detected by pressure instrumentation in the system supply headers or by monitoring system surge tank level.

Portions of the RCC which penetrate the primary containment are provided with containment isolation valves which can be remotely actuated by the operator in the main control room and close automatically on the high drywell pressure (F) and the reactor vessel low water level (A) containment isolation signals.

A pressure bypass line exists around the inboard isolation valve on the return line to prevent overpressurization of the piping between the inboard and outboard isolation valve. The bypass line has a check valve that acts as an inboard isolation valve in parallel with the normal inboard isolation valve.

A single-failure analysis has not been provided for the RCC since this system serves only nonessential systems and is not required to perform a safety function. See Section 3.6 for a discussion of piping failures.

9.2.2.4 Testing and Inspection Requirements

Pumps in the RCC are proven operable by their continuous use during normal plant operation. The motor-operated isolation valves are tested to ensure that they are capable of opening and closing by operating manual switches in the main control room and observing the position lights. The check valve in the bypass line across the inboard isolation valve on the return line is tested to ensure that it is capable of opening and closing by manual means during an outage. Routine visual inspection of the system components, instrumentation, and trouble alarms is adequate to verify system operability.

9.2.2.5 Instrumentation Requirements

The RCC is a balanced constant-flow system. Local pressure and temperature gauges and test points are provided throughout the system. Temperature in the primary containment is transmitted to the main control room, as is pressure downstream of the closed cooling water heat exchangers. A temperature switch downstream of the heat exchangers actuates an alarm in the main control room on high water temperature. When an operating pump trips, the standby pump is automatically brought on line. Alarms are actuated in the main control room following a decrease in pressure sensed by pressure switches on each pump discharge.

The system water volume is maintained from the plant demineralized water system by a level control valve actuated by level switches in the surge tank.

9.2.3 PLANT MAKEUP WATER TREATMENT AND DEMINERALIZED WATER SYSTEMS

9.2.3.1 Design Basis

a. The plant potable water system provides the supply water for the plant makeup water treatment system. A vendor furnished and maintained trailer-mounted demineralizer provides the purified water to the demineralized water system using the potable water source.

b. The demineralized water system is designed to utilize the demineralized effluent from the plant makeup water treatment system to provide demineralized water to the condensate storage tanks and to distribute demineralized water throughout the plant.

9.2.3.2 System Description

9.2.3.2.1 Plant Makeup Water Treatment System

The plant makeup water treatment system is shown in Figure 9.2-3. Raw water is normally supplied from the Columbia River through a branch line of the tower makeup system (TMU). From this line a branch is routed to the service building basement and is isolated. Another branch line continues to pump house 3, where raw water is processed into potable water. Here the water is chemically deflocculated and transferred to a 300,000-gal potable water storage tank. Sodium hypochlorite is injected into the potable storage tank influent line. In case the TMU is temporarily not in service, water is supplied from a cross tie with the WNP-1 potable water system.

The trailer-mounted demineralizer is supplied with water from the potable water pump PWC-P-103 which runs continuously. Demineralized water is pumped from the trailer demineralizer to tank DW-TK-1 in the basement of the service building through a tank level control valve.

Demineralized water is stored in a 50,000-gal epoxy-lined carbon steel demineralized water storage tank (see Figure 9.2-4 and Section 9.2.3.2.2).

The effluent from the trailer-mounted demineralizer is continuously recorded with associated alarms.

9.2.3.2.2 Demineralized Water System

The demineralized water system shown in Figure 9.2-4 consists of a 50,000-gal steel, epoxy-lined storage tank (DW-TK-1) with two 200-gpm transfer pumps with a 265-ft head (DW-P-1A, DW-P-1B). Among the components being supplied by the pumps are the following:

a. Condensate storage tanks,
b. RCC surge tank,
c. Diesel generator expansion tanks,
d. Auxiliary boiler condensate return tanks,
e. Chemical addition tanks,
f. Stator cooling makeup,
g. Refueling floor service boxes,
h. Decontamination facilities,
i. Flushing and washdown services,
j. Sealing water,
k. Laboratory water,
l. Reactor containment services,

m. Instrument flushing water, and
n. CJW surge pipe.

During operation one demineralized water transfer pump runs continuously to keep the system headers pressurized to supply demineralized water on demand. The operating pump recirculates a minimum flow back to the storage tank to prevent damage to the pump under low flow conditions.

9.2.3.3 Safety Evaluation

The demineralized water and plant makeup treatment systems are not required for a safe shutdown of the plant and are therefore, not safety related. A failure of these systems will not affect the operation of systems that are vital to safe shutdown of the plant. Alarmed instrumentation is provided to prevent delivery of out-of-specification water to safety-related systems or components. The piping associated with the demineralized water and plant makeup water treatment systems is designed in accordance with ANSI B31.1 except for piping that penetrates containment is designed ASME III, Class 2. All demineralized water and plant makeup water treatment system piping is classified Seismic Category II except that piping penetrating or routed inside primary containment, which is classified Seismic Category I. In the reactor and diesel generator buildings and inside primary containment, piping is supported to Seismic Category I requirements.

9.2.3.4 Testing and Inspection Requirements

The demineralized water and plant makeup water treatment systems are in daily use and as such do not require periodic testing to ensure operability. Grab samples are periodically tested in the laboratory to verify filter and demineralizer performance and to ascertain stored water quality. Periodic visual inspection and preventive maintenance are conducted.

The major components of these systems were subject to manufacturer shop tests including performance and hydrostatic tests.

Prior to initial operation the piping systems were subject to a hydrotest in accordance with their respective code groups. In addition, the completed systems were subjected to acceptance testing during plant startup as discussed in Section 14.2.

9.2.3.5 Instrumentation Requirements

Instrumentation and controls for the plant makeup water treatment and demineralized water systems are provided to control and monitor the operation of each of the subsystems.

Level controls in the demineralized water storage tank maintain the tank at the proper level by opening and closing a valve in the makeup demineralizer discharge piping.

9.2.4 POTABLE WATER AND SANITARY DRAIN SYSTEMS

9.2.4.1 Design Bases

The function of the potable water system is to supply potable water throughout the plant, provide supply water to the plant makeup water treatment system, and can be used to supply makeup water to the spray ponds.

The potable water system is designed to provide cold and/or hot water to the points of potable water usage such as lavatories, urinals, toilets, showers, eyewashes, sinks, electric drinking water coolers located in the various plant buildings, and site grounds irrigation.

The sanitary waste system is designed to drain the noncontaminated sanitary waste from the various buildings served.

All system fixtures, piping, and component material, as well as the fabrication, erection, and testing comply with applicable sections of appropriate codes and standards.

The potable water storage tank is designed and constructed in accordance with ASME Section VIII and Seismic Category II requirements.

9.2.4.2 System Description

9.2.4.2.1 Potable Water System

The potable water system is shown in Figure 9.2-5. Water is supplied to the potable water storage tank (PWC-TK-1). The makeup water treatment system is described in Section 9.2.3. The potable water tank is located in the basement of the service building from which potable water is pumped to all buildings serviced.

Potable hot water is provided to the various plant buildings by individual electric hot water heaters.

9.2.4.2.2 Sanitary Drain System

The plant sanitary waste system is shown in Figure 9.2-6. All noncontaminated sanitary waste from all buildings is directed into this system. Potentially contaminated drainage, such as that from the radiochemical laboratory sinks, is routed to the radioactive drainage system as described in Section 11.2.

All sanitary drains in the plant are collected into a main 6-in. sewage header which leaves the plant building complex, below grade, from the service building. All waste lines are vented to

the atmosphere via roof vents in accordance with applicable codes except those in the reactor building, which are vented to the main reactor building exhaust system (see Section 9.4.6) and in the main control room are vented to the main control room exhaust system.

All sanitary lines drain by gravity flow into the main 6-in. sewage pipe which connects to an 8-in. line leading to a centrally located sanitary waste treatment facility (SWTF) serving WNP-1, Columbia Generating Station (CGS), WNP-4, the Kootenai Building (Plant Support Facility), and the Department of Energy's 400 Area (FFTF facility). Low levels of radioactive materials, particularly tritium from the 400 Area, are expected to be present in the treatment facility as a result of processing these waste streams. The SWTF is permitted and regulated by the State of Washington and is not part of the CGS licensing basis. Therefore, the radioactive material from FFTF is not considered to be licensed material.

9.2.4.3 Safety Evaluation

The potable water and sanitary drain systems are of conventional design and have no safety function. All contaminated drains are routed to the liquid radwaste system as discussed in Section 11.2. All system piping except that in the reactor building and control building is Seismic Category II as defined in Section 3.2.1. The piping in the reactor building and control building is Seismic Category I.

9.2.4.4 Testing and Inspection Requirements

Routine monitoring during normal operation verifies the system is performing acceptably.

9.2.4.5 Instrumentation Requirements

The system is provided with sufficient instrumentation and controls to monitor and operate the system to meet the normal operating requirements of the facility.

9.2.5 ULTIMATE HEAT SINK

9.2.5.1 Design Bases

a. The ultimate heat sink (UHS), a spray pond system, supplies cooling water to remove heat from all nuclear plant equipment that is essential for a safe and orderly shutdown of the reactor and to maintain it in a safe condition;

b. The UHS is capable of accomplishing its safety function for a normal cooldown or an emergency cooldown following a LOCA without the availability of offsite power. The sink provides this cooling capability for a period of 30 days without outside makeup (except following a tornado). Provisions are made for replenishment of the sink to allow continued cooling capability beyond the initial 30-day period. The sink will accomplish its safety function despite the

occurrence of the most severe site-related natural events including earthquake, tornado, flood, or drought; and

c. Regulatory Guide 1.27 compliance is described in Section 1.8.

9.2.5.2 System Description

During all normal operating conditions, including normal shutdown as well as emergency conditions, waste heat from the reactor auxiliaries is transferred to the UHS by the standby service water (SW) system.

The UHS consists of two concrete ponds. The concrete ponds provide suction and discharge points for the redundant pumping and spray facilities of the SW system. The pond and pump house arrangements are shown in Figure 9.2-7. The ponds and pump houses are designed to Seismic Category I requirements. Standby service water loop A draws water from pond A, cools the Division 1 equipment required for safe shutdown, and discharges through a spray ring into pond B for heat dissipation. Similarly, SW loop B draws water from pond B, cools Division 2 equipment, and discharges through a spray ring into pond A. The high-pressure core spray (HPCS) SW system draws water from pond A, cools Division 3, and discharges without spray into pond A. A siphon between the ponds allows for water flow from one pond to the other.

The spray system illustrated in Figure 9.2-7 consists of two annuli of spray trees, one for each of the SW subsystems. Each annulus is 140.0 ft in diameter and contains 32 spray trees equally spaced (13.75 ft between vertical centerlines) on the circumference. The vertical trees are serviced by the annulus water pipe, 20 in. in diameter, mounted above the water level. The annulus pipe is fed by the main header from each respective pump house. Each spray tree consists of a vertical riser pipe or trunk 8 in. in diameter and horizontal limbs of 1.5-in. pipe. The limbs are attached to the riser at 2 ft-8 in. intervals of heights and are rotated at 90 degree subsequent angles from each other so that the arms resemble a counterclockwise helix with increasing height. The arms radial to the annulus are 4 ft-6-7/16 in. long. The lowermost arm is a tangent arm. The arms tangent to the annulus pipe are 3 ft-6 in. long. Spray nozzles are located at the end of each arm and are connected by fittings. The orientation of every nozzle is radially inward with an angle of 55 degrees upward from horizontal. The nozzles are 1-1/2-CX-27-55 Whirljet nozzles supplied by Spraying Systems Company. Since each tree nozzle is located at a different elevation, each nozzle pressure is different. The uppermost nozzle water pressure is approximately 17 psig, and the total water flow from a tree is approximately 300 gpm.

The HPCS SW flow is treated as a straight heat dump in the thermal analyses.

The combined water volume of the spray ponds is adequate to provide cooling water for 30 days without makeup. Although the ponds are not routinely used for cooling during normal

operation, some small losses are to be expected due to normal evaporation from the surface, minor leakage from the ponds, and occasional blowdown needed to maintain water chemistry. A gravity makeup line is provided from the circulating water pump house to the spray ponds; however, the required pond level will normally be maintained by makeup directly from the TMU water pumps (see Section 10.4.5) or directly from the potable water system. The TMU is the makeup source credited in the event of water loss due to a tornado. Design parameters for the spray pond are given in Tables 9.2-1 and 9.2-2.

An SW pump is located in each spray pond pump house along with its associated equipment so that an accident, such as a fire or pipe break associated with one pump, would not affect the operation of the redundant pump.

The bottom of the pump sump is depressed below the pond bottom. This ensures that there is still sufficient submergence for the pumps at the lowest possible water level in the pond. A sand trap and screen precede the pump sump to prevent heavy debris from entering the pump sump area. A skimmer wall and fixed screen prevent floating debris from entering the pumps.

A spray ring bypass is provided that allows water to be returned directly to the pond through use of manually operated dump and spray ring isolation valves. This allows pond temperature to be controlled during cold weather operations, mixing of the pond volumes, minimization of drift losses, and other situations where bypass of the spray rings is desirable. If the spray ring header is bypassed, it will be realigned to allow spray mode of operation before pond temperature exceeds 70°F. Analysis demonstrates that at pond temperatures less than or equal to 70°F, sufficient time is available under accident conditions to permit realignment to the spray mode prior to pond temperature exceeding 77°F.

To prevent adverse operation during freezing weather, all SW piping and components are either below the frost line, within heated buildings, heat traced or drained when not in use.

To allow for infrequent maintenance of the spray pond piping and piping supports, a cross connection, consisting of a removable spool piece and two isolation valves, is available between the two redundant loops of SW. A removable siphon plug is available to prevent one pond siphoning to the drained pond. The cross connecting spool piece and siphon plug are normally not installed and are only used while the plant is shut down for refueling. This cross connection allows water to be pumped back directly to the pond from which it was removed, thus allowing for the other pond to be drained.

9.2.5.3 Safety Evaluation

An oriented spray cooling system (OSCS) is utilized for cooling the water inventory of the UHS. The OSCS was developed as a result of intensive analytical studies and experimental verification over a period of more than 6 years. Details of the OSCS experimental and

analytical developmental efforts are described in Topical Report, Oriented Spray Cooling System (OSCS) for Ultimate Heat Sink Application (UHS), I-R 100, which has been submitted for Nuclear Regulatory Commission staff review.

The thermal performance model is based on the correlation of the Canadys test data described in Section 3.1 of the Topical Report, I-R 100. The resulting KAV/L for this application is 2.66. This includes a 10% derate of the KAV/L to cover conservatively the data scatter experienced at Canadys. Since the KAV/L represents the performance of the specified geometry and nozzle pressure, the KAV/L combined with the meteorological data are sufficient to determine the system cooling performance. The performance predicted by this model is modified as shown below.

$$CR = (-0.761 + 0.009 \times TWB) + (0.2677 + 0.004029 \times TWB) \times CP + (0.001179 - 7.14 \times 10^{-6} TWB) \times CP^2$$

CR = cooling range
TWB = wet bulb temperature
CP = cooling potential

The system model for both the thermal performance analysis and the mass loss analysis was based on the following assumptions:

a. The pond contains total inventory upon onset of LOCA less 0.5 ft for sedimentation of the pond basin;

b. Water losses result only from drift, leakage, evaporation of the sprayed droplets and evaporation due to heat rejection on the pond surface;

c. All the heat transfer is accomplished by evaporation, none of the heat transfer is accomplished by sensible heat transfer;

d. The first 3 days of the thermal performance analysis assume the worst single day of record conditions (Table 9.2-3). It was found that repeating the worst day conditions for 3 days resulted in the maximum peak. The 4 through 30 days are the average meteorological conditions of the worst 30-day period of record (Table 9.2-3). For conservatism, the root mean square (RMS) average wind speed during each period is used rather than the diurnal variation;

e. The 1 through 30 days of the mass loss analysis are the average meteorological conditions of the worst 30-day period of record (see Section 2.3.1.2 and Table 9.2-3). The analysis assumes a mass loss due to drift of 1.02% of the spray flow. This value is an upper bound obtained from results of tests

performed on the spray ponds. Its conservatism was confirmed by testing reported in Reference 2 and shown in Figure 9.2-8;

f. For the design basis mass loss case evaluation, the spray flow is continuous for one spray ring for the first 3 days, with one SW pump in operation. The sprays are cycled on and off for the 4 through 30 days depending on pond temperature. The sprays are turned on when the SW temperature in the suction pond reaches 85°F and are turned off when the temperature drops below 80°F. This method of operation resulted in one cycle on and off per day;

g. Minor leakage was observed in testing of the spray ponds, so test results were used to establish a leakage rate of 3.94 gpm total for both ponds (170,000 gal per 30 days);

h. While not a design basis case, mass loss was also evaluated assuming two spray rings in continuous operation for 2 days, followed by one spray ring in cyclic mode described in item f;

i. The design basis fuel pool cooling heat load is included;

j. For design basis analysis, offsite power is lost and Division 2 diesel fails to start, resulting in a loss of the pond A spray header. (Division 1 heat loads are slightly higher); and

k. The major heat loads considered are reactor core decay heat, sensible heat from both the coolant and the reactor, fuel pool decay heat, pump work, and the heat removed from the station auxiliaries. These heat loads are listed in Table 9.2-4 (using the calculated heat load values) and Table 9.2-5. The fuel pool decay heat generation rate, listed in Table 9.2-4 as variable, is found in Table 9.2-5. No credit was taken for heat sinks in the primary containment other than the suppression pool volume.

The RMS average wind speed during the selected 30-day period for the mass loss analysis was 6.91 mph. The drift loss was based on the calculated drift value at the RMS wind speed. The mass loss analysis thus demonstrates that the spray ponds contain sufficient water inventory to meet drift losses significantly higher than expected. Figure 9.2-8 shows the conservatism demonstrated in confirmatory drift loss testing.

The analyses assume an initial temperature of 77°F. This is approximately the highest monthly average temperature expected if the sprays are not operated. To maintain the pond temperature below this limit, the spray headers will be operated and/or river water makeup to the cooling towers will be diverted through the spray ponds. Analyses were performed which demonstrate that the above operations can maintain the spray pond below 77°F.

An analysis was conducted which verified failure of Division 1 or Division 2 power results in the most severe service water transient. If the failure was postulated in Division 3 (HPCS) instead of Division 1 or 2, the peak pond temperature is lower. The HPCS SW flow is a straight heat dump; therefore, inasmuch as the spray pond is concerned, it raises rather than lowers the temperature transient.

The resulting peak spray pond temperature, 89.6°F, predicted by the "worst case" analysis is below the 90°F service water temperature assumed in the analysis performed in Section 6.2.1 for containment heat removal, adding further conservatism to the containment temperature and pressure transients therein presented. The service water temperature, however, exceeds the design basis temperature, 85°F, for short periods of time as shown in Figure 9.2-9.
A temperature of 90°F has been evaluated for those rooms served by emergency heating, ventilating, and air conditioning (HVAC) equipment, and room temperatures remain within the design limit.

A sensitivity study was performed to determine the effect of the RHR heat exchanger effectiveness on the spray pond temperature transient. The RHR heat exchanger effectiveness varies with the amount of fouling and with the flow rates. The RHR heat exchanger flows different from the rated values in Table 6.2-2 are anticipated only if the operator delays or fails to close the RHR heat exchanger shell side bypass valve as discussed in Section 6.2.2.3. Anticipated variations in fouling were determined to have essentially no affect on the spray pond temperature transient following a design basis LOCA. However, the combination of low SW to RHR cooling flow, low overall SW flow, design RHR HX fouling and no containment spray does adversely affect peak pond temperature. For this reason the temperature case uses low flow/design fouling while the mass loss case uses high flow/clean heat exchangers.

The results of the design basis mass loss analysis assuming an unfouled heat exchanger is shown in Figure 9.2-10 and is tabulated in Table 9.2-6.

Drift losses following loss of makeup to the ponds may be controlled during two spray ring operations by bypassing the spray header on one pond whenever spray pond temperatures drop below approximately 80°F. Continuous, simultaneous operation of both spray rings is not required after a LOCA. Since the two SW loops are redundant to each other, operators will be able to secure any redundant safe shutdown equipment when they determine that the peak temperatures have been passed.

Table 9.2-7 lists the available sources of makeup water to provide continued cooling beyond the initial 30-day period. This table assumes that offsite power is restored within the 30 days. No credit is taken for the water stored in the cooling tower basins. However, it is expected that this water will not be instantaneously lost and may flow to the pond for the same period of time. Table 9.2-7 also summarizes the effects of natural phenomena and of a LOCA on the water supplies to the spray pond.

The possibility of a tornado passing over the spray pond and removing a significant amount of water is considered a credible event. For this reason, the makeup water pump house is designed to be tornado proof, with all piping and electrical power supply between the plant and the pump house underground with adequate soil cover to provide protection from tornado-generated missiles. Since it is not credible to assume an earthquake coincident with a tornado, this system need not be Seismic Category I. Two 12,500-gpm tower makeup water pumps are provided, one powered from each emergency diesel generator. Should pond water be lost due to a tornado, one of these pumps will be started to provide makeup. If the spray headers are damaged by a tornado-generated missile, cooling is provided by a feed-and-bleed mode of operation. In the feed-and-bleed mode, cooling water is supplied to the spray ponds from the makeup water pump house. The service water system takes suction from the spray ponds to provide cooling to safe shutdown equipment. The cooling water is then routed to tornado-protected underground circulating water piping and discharged to the circulating water basin.

The design basis of the UHS includes a 6-in. sedimentation allowance for water inventory considerations. This allowance includes all forms of accumulation, such as dust, silt, or volcanic ash. The design basis ashfall is 3 in. which bounds the Mount St. Helens eruption of May 18, 1980. When sedimentation levels reach 3 inches, an administrative requirement to clean the spray ponds has been incorporated into plant procedures. This ensures adequate water supply even in the event of a design basis ashfall.

With regard to SW pump operation following a design basis ashfall, experience has shown that there may be some increased seal leakage as a result of ashfall. An evaluation was performed which concludes that the pumps would remain operable during a volcanic ashfall condition. Bearing life could be shortened, and bearings would be examined for wear when possible following a significant ashfall.

While the plant is shut down it may be necessary to drain one spray pond for maintenance using the cross connecting spool piece and siphon plug to provide a flow path back to the same pond from which the water was pumped. For this infrequently used mode, there is less than a 30-day supply of water available in one pond without makeup. However, with the reactor vessel depressurized, flooded up to 22 ft or greater above the reactor flange, the fuel pool gates removed, and the reactor at a relatively low temperature (less than about 140°F) prior to removal of a pond from service, the risk to public safety is very small. Alternative makeup water sources for the UHS can be made readily available. Experience has shown that temporary pipe lines can be run from the river in about 3 days. Even in the unlikely event of a loss of the siphon plug, the water inventory would not be lost and the system would remain operable. In that event, water in the inactive pond could be transferred back to the operating pond via portable pumps.

9.2.5.4 Testing and Inspection Requirements

Availability is ensured by periodic functional tests and inspections as required by the Technical Specifications.

9.2.5.5 Instrumentation Requirements

The spray pond is equipped with redundant level and temperature sensors which are alarmed and indicated in the main control room.

In the event that the spray pond level falls below the minimum level required for 30 days of cooling, an alarm is sounded and makeup to the spray ponds is provided using the TMU.

High and low temperature alarms are provided. If the pond water temperature approaches the upper design limit, the spray system is manually initiated to lower the temperature. On a low water temperature signal, return water is dumped directly into the ponds to prevent spray trees and spray headers from icing.

9.2.6 CONDENSATE SUPPLY SYSTEM

9.2.6.1 Design Bases

The condensate supply system (COND) is designed to:

a. Store and provide a condensate supply to the reactor core isolation cooling (RCIC) system, the HPCS system, and the RHR loops;

b. Maintain an adequate level of condensate in the condenser hotwell;

c. Provide a condensate supply for the control rod drive pumps;

d. Provide makeup water to the spent fuel pool;

e. Provide condensate for various radwaste processes;

f. Facilitate testing and/or flushing of the HPCS, low-pressure core spray (LPCS), RHR, and the RCIC;

g. Receive and accommodate a surge volume for condensate returned to the storage tanks after treatment in the liquid radwaste system; and

h. System piping is constructed to ANSI B31.1. Condensate storage tanks are constructed to ASME Section III, Class 3 requirements. System piping inside

the reactor building is Seismic Category II, supported to Seismic Category I requirements. All other piping and system pumps are designed to Seismic Category II requirements. The radwaste building condensate supply pump and the condensate filter demineralizer backwash pump are constructed to ASME Code Section III, Class 3. The reactor building condensate supply pump is designed to the Standards of the Hydraulic Institute.

9.2.6.2 System Description

The demineralized water system and the liquid radwaste system are the primary sources of makeup water to the condensate storage tanks.

The COND is shown in Figure 9.2-11. The system consists of two storage tanks (COND-TK-1A, COND-TK-1B) each with a nominal capacity of 400,000 gal and equipped with electric heaters, a reactor building condensate supply pump (COND-P-3), a radwaste building condensate supply pump (COND-P-4), a condensate filter demineralizer backwash pump (COND-P-5), and necessary piping and instrumentation. The tanks are manufactured with a design pressure of atmospheric plus full static head and maximum design temperature of 140°F. Minimum operating temperature of the tanks is 40°F. The tanks are designed to withstand a wind load of 20 psf on the vertical projected area of the tank and a snow load of 20 psf.

The radwaste building condensate supply pump and the condensate filter demineralizer backwash pump each are designed to supply 1535 gpm at 185 ft total head. The radwaste condensate supply pump has a secondary operating point of 500 gpm at 220 ft total head. The reactor building condensate supply pump is designed to supply 200 gpm at 220 ft total head.

A minimum inventory of 135,000 gal in the condensate storage tanks is reserved for the RCIC and HPCS pumps. This ensures the immediate availability of a sufficient quantity of condensate for emergency core cooling, and reactor shutdown, as discussed in Section 9.2.6.3 and Station Blackout as discussed in Appendix 8A.

Makeup for the condenser hotwell is gravity fed from the storage tank. Bleedoff water from the condensate system is returned to the storage tanks from the discharge of the condensate demineralizer.

A separate line is provided to supply the control rod drive pumps with condensate. Condensate is supplied for various reactor building services, including fuel pool makeup by the reactor building condensate supply pump. The condensate storage tank can be drained to the condenser hotwell. Inadvertent overflow of the tanks is collected in the concrete retaining basin surrounding the tanks. This water can be drained to the radwaste system for processing if sampling indicates that the water is radioactively contaminated. Rain water collected in the retaining basin can be drained to the radwaste system for processing.

9.2.6.3 Safety Evaluation

The condensate storage facilities are not required to ensure any of the following:

a. The integrity of the RCPB,

b. The ability to shut down the reactor and maintain it in a safe shutdown condition, or

c. The ability to prevent or mitigate the consequences of accidents which could result in potential offsite exposures in excess of the guideline exposure of 10 CFR Part 100.

Although a minimum of 135,000 gal is maintained in the condensate storage tanks as a source of water for the RCIC and HPCS pumps, the supply of water in the suppression pool is the emergency source of water for these pumps. The reserve of water is maintained by monitoring the level in the condensate storage tank and by preventing condensate transfer when this reserve level is reached. The RCIC and HPCS pumps are gravity fed from the condensate storage tanks.

The condensate storage tanks are Seismic Category II; however, they are located inside a Seismic Category I concrete dike which is designed to retain the condensate from both tanks. Drainage from the dike is routed to the radwaste system for processing. During precipitation, drainage from the dike is sampled and analyzed for radioactivity before being discharged to a Turbine Building sump and processed in the radwaste system.

The evaluation of radiological considerations for the COND is presented in Section 2.4.13.3. Since the dike is designed to contain any condensate from a postulated tank rupture in conjunction with the heaviest recorded precipitation, the resulting offsite dose rate from this occurrence would be no greater than the value presented in Section 2.4.13.3.

For corrosion protection, the tanks are made of carbon steel with a 1/16-in. corrosion allowance and lined with a modified phenolic coating. Quality control for the application of the coating was in accordance with ANSI N101.4. The interior surfaces of the tanks were blasted to white metal in accordance with SSPC-SP-5 prior to the application of a minimum of 10 mils dry film thickness of Plasite 7155. Coating repairs are made with a compatible amine cured epoxy coating.

9.2.6.4 Testing and Inspection Requirements

The components were inspected and cleaned prior to installation into the system. The condensate storage tanks side wall, side wall to bottom, and nozzle joints were examined in

accordance with ASME Section III, Subsection NC-5000. The tank thickness was tested by magnetic means in accordance with ASTM E376. Underground portions of the HPCS and RCIC piping welds were 100% radiographed to ensure the integrity of the piping.

Periodic functional tests and inspections as required by the Technical Specifications ensure system availability for nonroutine functions. Routine monitoring during normal operation verifies satisfactory system operation to support plant requirements for normal operation.

9.2.6.5 Instrumentation Requirements

Condensate storage tank level is monitored in the main control room. High- and low-level alarms are provided to prevent overflow and to prevent the water level from dropping below the required reserve level for reactor pressure vessel (RPV) makeup. Level switches provide low-low annunciation and interlock with the HPCS and RCIC systems. Building condensate supply pumps are provided with manual controls for maintaining condensate supply pressure in the system headers so that condensate is available for system process services, based on demand.

The following parameters apply to the condensate storage tanks.

Reserve capacity for RPV makeup is provided between the setpoints of the low-level switch and the low-low-level switch. The elevation differential provides a reserve capacity of approximately 67,500 gal per tank.

Thermostatically controlled tank heaters are provided to maintain water temperature in the tanks at or above a nominal 40°F at all times. All above-ground piping that contains water is heat traced to prevent freezing.

System logic diagrams are given in Chapter 7.

9.2.7 STANDBY SERVICE WATER SYSTEM

9.2.7.1 Design Bases

a. The SW system is designed to remove heat from plant systems that are required for a safe reactor shutdown following a LOCA;

b. The system is designed to remove reactor decay heat from the residual heat removal system during normal plant shutdown;

c. The system is designed to perform its required cooling water function following a LOCA, assuming a single active failure;

d. The system is designed to provide a means of flooding the vessel and containment, if required during the post-LOCA period;

e. The system is designed to provide a long-term cooling and makeup source to the fuel pool cooling system following a loss of the RCC system which is the normal source of cooling to fuel pool cooling and cleanup (FPC); and

f. The system is constructed to Seismic Category I and ASME Code Section III, Class 3, requirements with the exception of that portion to and from the plant cooling towers, which is constructed to ANSI B31.1 and Seismic Category II requirements; the spray bypass line discharge orifice and mating flange, which are also constructed to ANSI B31.1 and supported Seismic Category I, the keep full subsystem located in the pump house which is constructed to ANSI B31.1 and supported Seismic Category I, and the spray pond crossover piping which is constructed to ANSI B31.1 and supported Seismic Category I.

9.2.7.2 System Description

The SW system includes vertical service water pumps located adjacent to the two spray ponds in two separate pump houses designed to Seismic Category I criteria. The pumps discharge to three independent piping systems which serve emergency core cooling system (ECCS) equipment, auxiliary plant equipment, and reactor shutdown cooling equipment (see Figures 9.2-7, 9.2-12 through 9.2-14).

The SW pumps consist of two independent 100% capacity pumps each supplying normal and emergency shutdown cooling equipment as shown in Table 9.2-4. A third 100% capacity HPCS service water pump (housed in pump house A) supplies the HPCS system cooling equipment as shown in Table 9.2-4.

Each of the three SW pumps receives its power from independent electrical buses. Each bus is powered from the offsite power supply or its own diesel generator.

During the normal and emergency shutdown modes of operation, water is circulated from the spray ponds to the equipment requiring cooling, and returned to the ponds. The two SW systems return via the spray rings prior to recycle. The HPCS service water returns directly to pond A with no sprays. Spray pond operation and a description of its ability to dissipate waste heat from the plant during normal, shutdown, and accident conditions are provided in Section 9.2.5.

The system is designed such that on receipt of an ECCS start signal, all three pumps are started automatically.

The two spray ponds are sized to have a combined equivalent storage for at least 30 days of operation, assuming no makeup and maximum evaporation and drift losses (see Section 9.2.5).

The SW system is chemically treated to control biological growth and to minimize corrosion.

A small keep-full subsystem is attached to the SW system piping. The keep-full subsystem was originally designed to provide back pressure on the pump discharge valve so that maintenance repairs on the valve could be minimized (i.e., the keep-full subsystem was never intended to keep the system piping completely full). The pump discharge valve design and the system start sequence were changed so that back pressure on the pump discharge valve during the start sequence was no longer necessary. The SW system is able to start from a partially drained condition without damage to system components. The keep-full subsystem has been deactivated and spared in place because it no longer provides a useful function.

The spray ponds are provided with makeup water by the TMU system or the potable water system. The makeup water system supplies Columbia River water to the cooling towers or spray pond to replace water lost during normal operation due to evaporation and drift. The potable water system replaces normal spray pond evaporation and drift losses. In addition, the makeup system is designed to replace spray pond water lost during a tornado. To ensure system availability for this mode of operation, the makeup system is designed to withstand a design basis tornado coincident with a loss of offsite power (see Section 9.2.5.2).

The SW system piping is carbon steel designed to 309 psig (some 150 psig), 150°F, and with a corrosion allowance of 0.080 in. Where SW piping degradation due to erosion/corrosion or other degradation mechanisms occurs, stainless steel material may be substituted to prevent future recurrence.

Standby makeup water to the fuel pool system can be supplied through normally closed Seismic Category I, Quality Class 1, isolation valves by remote manual operation from the control room for SW-V-75A and SW-V-75B and by manual operation for SW-V-75AA and SW-V-75BB (see Section 9.1.3.2.3).

EQUIPMENT DESIGN PARAMETERS

Standby Service Water Pumps (SW-P-1A, SW-P-1B)

Quantity	2
Driver	Motor - ac
Design Capacity	10,300 gpm
Head	500 ft

HPCS Service Water Pump (HPCS-P-2)	
Quantity	1
Driver	Motor - ac
Design Capacity	1200 gpm
Head	123 ft

9.2.7.3 Safety Evaluation

The SW system provides cooling for plant equipment that is essential to a safe reactor shutdown following a design basis LOCA.

System failure mode and effects analyses of passive and active components of the SW system is presented in Table 9.2-8. Any of the assumed failures of the SW system is detected in the main control room by indications and/or alarmed from the various system instruments.

The SW is routed through the tube side of the RHR heat exchanger, through the shell side of the FPC heat exchangers, and through the shell side of the RHR pump seal coolers. The RHR heat exchanger, the FPC heat exchanger, and the RHR pump seal coolers are the only potential sources of radioactive leakage into the standby water system.

A restricting orifice and bypass valve is installed on return lines of loops A and B to maintain sufficient back pressure to ensure flow to all components and to maintain the pressure in the system at a level such that tube leakage in the RHR heat exchanger or pump seal cooler is from the service water system into the RHR system after the reactor is depressurized following shutdown or after a LOCA. Liquid effluent radiation monitors are provided in each of the two RHR heat exchangers outlet lines of the service water system to detect radioactivity resulting from a tube leak in one of the RHR heat exchangers. This condition can occur only for a short time when the RHR system is operated in the shutdown cooling mode in which the service water system pressure may be lower than the RHR system pressure. On detection of radioactive leakage in one of the subsystems, that subsystem is isolated by operator action in the main control room and the cooling requirements are met by the redundant train.* Per the CGS emergency procedures the operators are directed to utilize the alternate shutdown cooling mode when a degraded core condition has been identified. The alternate shutdown cooling mode does not have the potential for radiation leakage into the SW system due to the lower RHR pressure. Consequently, radioactivity released to the spray ponds and/or cooling tower basins is minimized.

Under emergency conditions, i.e., loss of RCC system, the SW system can be routed through the shell side of the FPC heat exchangers to provide long-term cooling. The SW system

* Note that the Safety Evaluation Report for CGS (NUREG – 0892) states in 5.2.5 that automatic isolation is provided. The response for CGS has always been by operator action.

pressure is higher than the FPC system pressure, so that any leakage will be into the FPC system.

An intertie with the RHR system is provided from the SW system supply header B which contains two remote manually operated isolation valves. These valves can be opened from the main control room in the event primary containment flooding is required following a LOCA.

An atmospheric syphon is provided to allow the transfer of water between the two spray ponds. In addition, the SW pumps are provided with double valved, normally closed bypass connections for transferring water from one pond to another.

Temperature/pressure controlled and/or manually operated throttle valves are located on the return side of all SW serviced coolers and heat exchangers. The system is balanced for optimum operation and the throttle valves left in that position. The RHR heat exchanger service water outlet valve, while open during normal standby lineup, is interlocked to open on starting of an SW pump to prevent excess flow conditions in other portions of the system.

Normal SW return is to the spray pond, with normally closed redundant isolation valves on the SW return line to the cooling towers. These valves are mechanically and electrically prevented from opening to preclude returning SW to the cooling towers during normal system operation. This is to ensure that the spray ponds always maintain the capability to meet the system requirements described in Section 9.2.5 and allows control of water chemistry by minimizing dilution.

The non-safety-related SW keep-full subsystem cannot inhibit the ability of the SW system to meet its safety function. Keep-full piping is small and any break in that piping would result in a flow change to SW that is insignificant. The potential flooding of the valve pit area has been evaluated to ensure continued system performance should a break occur in the deactivated keep-full system.

An orifice is installed on the discharge of each spray bypass line where it enters the spray pond. The purpose of the orifice is to mitigate cavitation damage that has occurred in the past due to the higher flow rate of the system in the spray bypass mode of operation. The orifice balances the flow in the bypass mode so it is approximately the same as that in the spray mode. The orifice and its mating flange serve no safety-related function and serve to reduce the potential for long-term effects of cavitation. Failure of the orifice cannot affect the ability of the SW system to fulfill its safety function. The elbow to which the orifice is attached directs the return water into the pond after it passes through SW-V-165A/B, and failure of the orifice would not obstruct or limit flow of return water to the spray pond.

During normal plant operation, the SW pumps are not operating. If a LOCA occurs, the diesel generators and respective SW pumps start automatically. Consequently, no operator action is

required following a LOCA to start the SW system and put the system into its LOCA operating mode.

9.2.7.4 Testing and Inspection Requirements

The SW system is designed to permit periodic inspection of all active system components to ensure the integrity and capability of the system. For inservice inspection see Section 6.6.

The SW system is periodically tested as required by the Technical Specifications to ensure system availability and capability to perform its required design functions.

Requirements for monitoring of heat exchangers cooled by SW are discussed in Generic Letter 89-13. Energy Northwest response to Generic Letter 89-13 outlines compliance with these requirements.

9.2.7.5 Instrumentation Requirements

Each of the SW discharge lines from the RHR heat exchangers contains radiation monitors to detect any radioactivity resulting from a tube leak in the RHR heat exchanger.

Flow indicators and/or switches are provided for most serviced components to indicate low flow. The radiation monitors have transmitters but no indicators due to the use of gravity flow. There are no permanently installed flow instruments for the control room chilled water (CCH) since service water flow through the chiller condensers is controlled by pressure control valves. Temperature indicators, temperature switches, pressure indicators, and/or pressure switches are located in each system to determine pump, individual cooling coil, cooler, or heat exchanger performance.

To avoid excessive system surge pressures, SW pumps SW-P-1A and SW-P-1B are started only if the associated pump discharge valve is closed. HPCS-P-2 can auto start with its discharge valve open, in order to minimize running the HPCS DG without service water cooling (see Section 9.5.5 for discussion of the diesel generator cooling water systems). All three pumps start automatically when the associated diesel generator is started. For each of the three pumps, the pump discharge valve automatically opens when the associated pump is running and the pump discharge pressure is greater than 50 psig. The system instrumentation is shown in Figure 9.2-12.

9.2.8 COMPRESSOR JACKET WATER SYSTEM

9.2.8.1 Design Bases

a. The CJW system is designed to circulate clean water to remove heat from the control air system compressor oil coolers and aftercoolers,

b. The CJW system provides clean water to remove heat from the control air system refrigerated dryer condensers, and

c. Heat is rejected from the CJW system to the plant service water system (TSW).

The CJW system piping and valves are designed in accordance with the ANSI B31.1 Power Piping Code, using design conditions of 125 psig and 200°F, except for the fill and makeup supply piping at the surge pipe, which is designed to 150 psig and 150°F, the same as the demineralized water system. The CJW system is open to the atmosphere at the surge pipe, and the maximum system pressure at the pump discharge is less than design pressure. The heat exchangers are designed and constructed to the ASME Boiler and Pressure Vessel (B&PV) Code Section VIII for design conditions of 150 psig and 200°F.

9.2.8.2 System Description

The CJW system is shown diagrammatically in Figure 9.2-15. Fill and makeup water is supplied from the demineralized water system to the surge pipe through a float operated valve (CJW-LCV-1). An overflow line allows expansion volume to drain to an equipment drain. The surge pipe is connected to the circulating coolant return header at a high point and is open to the atmosphere to vent free air released from the heated water. A positive suction head of approximately 20 ft is provided at the circulating pump suction by the water level in the surge pipe.

Two full-capacity centrifugal pumps (CJW-P-1A and CJW-P-1B) are provided, permitting the system to remain in operation while one pump is isolated for servicing or repair. The operating pump draws water through the return header from the outlets of the compressor(s) and refrigerated dryers(s) in service at that time. This heated water is discharged from the pump toward two full-capacity plate and frame heat exchangers.

The heat exchangers (CJW-HX-1A and CJW-HX-1B) are designed for one to be in operation while the other is isolated. Heat is rejected from the CJW system to the plant service water system. The plant service water is essentially river water which may contain considerable amounts of particulate solids. The CJW to TSW heat exchangers are of the plate and frame type that maintain water velocities high through the passes on both sides, and are readily opened to clean the plate surfaces without disturbing the connecting piping. In the event a heat exchanger becomes fouled, it may be isolated and cleaned while both the CJW and TSW systems remain in operation. The cooled water from the heat exchangers is piped to the compressor and refrigerated dryer supply header. Coolant flow to the compressors and dryers is controlled by temperature control valves in each unit. The dryers will provide a minimal flow path so the CJW pumps do not deadhead because the dryers are designed for continuous operation.

Cooling water at each compressor and refrigerated dryer may be manually isolated when a compressor or dryer is taken out of service for repair, and the coolant may be drained, without disturbing coolant flow at the other compressors and dryers.

9.2.8.3 Safety Evaluation

Operation of the CJW system is not required for the initiation of any engineered safety feature system, or for safe shutdown of the reactor. However, plant availability depends on an adequate supply of compressed control air to operate nonnuclear plant systems, and the CJW system includes redundant components to ensure operability of the system under most conditions.

9.2.8.4 Testing and Inspection Requirements

Routine surveillance inspections while in operation will discover conditions requiring correction before functional failure of the system will occur.

9.2.8.5 Instrumentation Requirements

Sufficient instruments and controls are provided for system operation to support normal facility requirements.

Table 9.2-1

Ultimate Heat Sink Spray Cooling
Pond Design

Parameter	Quantity
Pond configuration	Square (250 ft x 250 ft)
Surface area (two ponds)	125,000 ft^2
Normal water elevation (above msl)	433 ft 6 in.
Maximum operating water elevation (above msl)	433 ft 9 in.
Overflow water elevation (above msl)	434 ft 6 in.
Pond bottom elevation (above msl)	420 ft 0 in.
Pump sump bottom elevation (above msl)	408 ft 3 in.
Freeboard above normal water level	1 ft 0 in.
Sedimentation allowance	6 in.
Normal pond capacity (two ponds at el. 433 ft 6 in.)	12,620,000 gal
Minimum pond capacity (two ponds at el. 432 ft 9 in.)	11,920,000 gal

Table 9.2-2

Spray System Design

Parameter	Quantity
Number of systems	2
Number of trees per system	32
Diameter of the ring headers	140 ft 0 in.
Circumferential spacing between trees	13 ft 9 in.
Number of horizontal arms per riser	7
Pressure at top nozzle	17.3[a] psig
Pressure at interface (flange)	24.5[a] psig
Flow rate per tree at design pressure	321.9[a] gpm
Total flow rate per system	10,300[a] gpm
Nozzle type	Spraying Systems Company 1-1/2-CX-27-55
Height of vertical riser	17 ft 9 in.
Spacing between arms	32 in.
Height of bottom nozzle elevation from system interface (flange) riser pipe diameter	6-11/16 in.
Riser pipe	8 in., Schedule 80
Horizontal branch arm pipe	1.5 in., Schedule 80

[a] Flow rates and pressures are for final design with fuel pool cooling system upgraded (see Section 9.1.3). Prior to completion of fuel pool cooling upgrade, total flow is approximately 9750 gpm.

[a] Information in this table is data input into the thermal analysis of the UHS calculation. The thermal analysis is constructed to provide the peak pond temperature for a LOCA. As such, the data in this table was chosen to conservatively bound the conditions in the field and, therefore, does not necessarily represent exact plant conditions.

Table 9.2-5

Heat Load Rates Used in Ultimate Heat Sink Analysis

I. Core decay heat load[a]

Calculated using BTP ASB 9-2 data.

II. Reactor coolant sensible heat load[a]

The energy (414 x 10^6 Btu referenced to 32°F) of the reactor coolant is accounted for by starting the suppression pool at 150°F).

		Time (hr)	Rate (10^6 Btu/hr)
III.	Reactor vessel, piping, and core sensible heat load[a]	$t \leq 24$ $t > 24$	8.14 Negligible
IV.	Metal-water reaction heat load[a]	$t \leq 1$ $t > 1$	0.47 Negligible
V.	ECCS pump work load[a,b,c]	$t \leq 8$ $t > 8$	13.35857 5.534
VI.	HPCS (division 3) service water system heat load[c,d]	$t \leq 8$ $t > 8$	8.623 0
VII.	Constant division 1 service water system heat load[e,f]	$t \geq 0$	20.04
VIII.	Fuel pool heat load	$t \geq 0$	8.2[g]

[a] Rejected initially to the suppression pool and subsequently transferred by the RHR heat exchangers to the UHS.

[b] RHR pump 2.16277 x 10^6 Btu/hr
LPCS pump 3.5623 x 10^6 Btu/hr
HPCS pump 7.6335 x 10^6 Btu/hr

[c] HPCS system and HPCS SW system shut down after 8 hr.
LPCS system and RHR loop A maintain long-term cooling.

Table 9.2-5

Heat Load Rates Used in
Ultimate Heat Sink Analysis (Continued)

[d]	HPCS service water pump work	0.132314×10^6 Btu/hr
	HPCS coolers (Table 9.2-4)	8.49×10^6 Btu/hr
	Does not include HPCS diesel building coolers.	
[e]	Division 1 service water pump work	4.198315×10^6 Btu/hr
	Division 1 diesel generator, Coolers and misc. equipment (Table 9.2-4)	15.84175×10^6 Btu/hr

[f] Excludes fuel pool, RHR heat exchanger, and diesel generator building "A" coolers.

[g] This heat load is treated as a constant.

Table 9.2-6

Spray Pond Water Losses and Content
(30 days after design basis LOCA event)

Analysis	Quantity (gal)
Drift losses[a]	3.0606 x 10^6
Spray evaporation[b]	5.5690 x 10^6
Surface evaporation	0.6471 x 10^6
Deleted	
Leakage	0.1728 x 10^6
TOTAL	9.4495 x 10^6
Remaining inventory	2.4705 x 10^6
Minimum volume required for system operation	2.26 x 10^6

[a] Based on conservative RHR heat exchanger flow rate of 7400 gpm and fuel pool cooling at 575 gpm.

[b] Based on inclusion of design basis fuel pool cooling heat load.

Table 9.2-8

Standby Service Water System
Failure Analysis

Single Active Failure	Analysis
Loss of power on one emergency bus due to failure of a diesel generator to start or loss of offsite power.	The service water pump powered by the redundant emergency bus will be automatically started to provide the necessary cooling water.
Failure of pump to automatically start.	Same analysis as above.
Failure of an isolation valve in the service water piping to the cooling tower.	Redundant valve is operated to perform the isolation function.
Failure of ECCS pump room air cooling.	Essential plant cooling requirements met by the redundant ECCS subsystems which have their own independently cooled pump rooms.
Failure of a single service water pump during operation.	Essential plant cooling requirements met by the remaining operable redundant ECCS subsystems.
Failure of system return isolation valve.	Essential plant cooling requirements met by the remaining intact ECCS subsystem which includes its own independent return service water headers.
Failure of a pump discharge or RHR outlet isolation valve to open.	Essential plant cooling requirements met by the remaining operable redundant emergency core cooling subsystems.

Table 9.2-8

Standby Service Water System
Failure Analysis (Continued)

Single Active Failure	Analysis
Failure of any supply or return piping.	Essential plant cooling requirements met by the remaining intact ECCS subsystem which includes its own independent supply and return service water headers. Passive failures, i.e., pipe whip, missiles, jet loads are discussed in Sections 3.5 and 3.6.1. The SW system is a moderate-energy fluid system since it is operated at less than 275 psig and 200°F.
Failure of RHR heat exchanger.	Essential plant cooling requirements met by the remaining intact redundant RHR subsystem which includes its own 100% capacity heat exchanger.
Fire	All credible fires and their consequences were evaluated in Appendix F. Because of physical separation, redundancy, and low inventories of combustibles, there are no credible fires which could impede the SW from performing its function.
Failures of equipment by missile.	The HVAC equipment in the SW pump house is arranged in such a manner that would preclude any postulated missile from preventing the plant to be brought to a safe shutdown. External missiles are discussed in Section 3.5.

Table 9.2-9

Integrated Heat Data - Ultimate Heat Sink Reanalysis (Continued)

[a] Q Decay	Integrated core decay heat suppression pool.
[b] Q Sensible	Integrated sensible heat rejected by the reactor vessel, piping, and core to the suppression pool.
[c] Q Auxiliary I	Integrated heat from ECCS pump work rejected to the suppression pool.
[d] Q Auxiliary 2	Integrated heat from auxiliary systems rejected to division 1 SW system. This heat includes all sources of heat into division 1 SW system except for the RHR heat exchanger. The RHR heat exchanger transfers heat from the suppression pool to division 1 SW system.
[e] Q Auxiliary 3	Integrated heat from HPCS SW system. This heat is a straight heat dump into spray pond A.
[f] Q Total	Sum of Q Decay, Q Sensible, Q Auxiliary 1, Q Auxiliary 2, and Q Auxiliary 3.
[g] Q Service	Sum of Q Auxiliary 2 and the heat rejected by the RHR heat exchanger into division 1 SW system, i.e, the sum of the heat rejected through the spray nozzles.

[h] The RHR heat exchangers provide suppression pool cooling from 10 minutes through to the end of an accident (30 days). No heat exchanger cooling is assumed for the first 10 minutes of an accident. See Sections 6.2.2.2 and 6.3.2.8 for further information on containment cooling.

NOTES:

1. FOR NOTES & LEGEND SEE M508-1.
2. WIRELESS TRANSMISSION TO RFW-RCVR-2W & TSW-TT-1, FROM TT-1, 902 TO 928 MHZ FHSS, 31 mW MAX. RF POWER OUTPUT. ANTENNA GAIN IS 0.44 DBI. BASE RADIO SHALL HAVE AN EXCLUSION DISTANCE OF 1'-0" MIN. TO ELECTRICAL COMPONENTS.

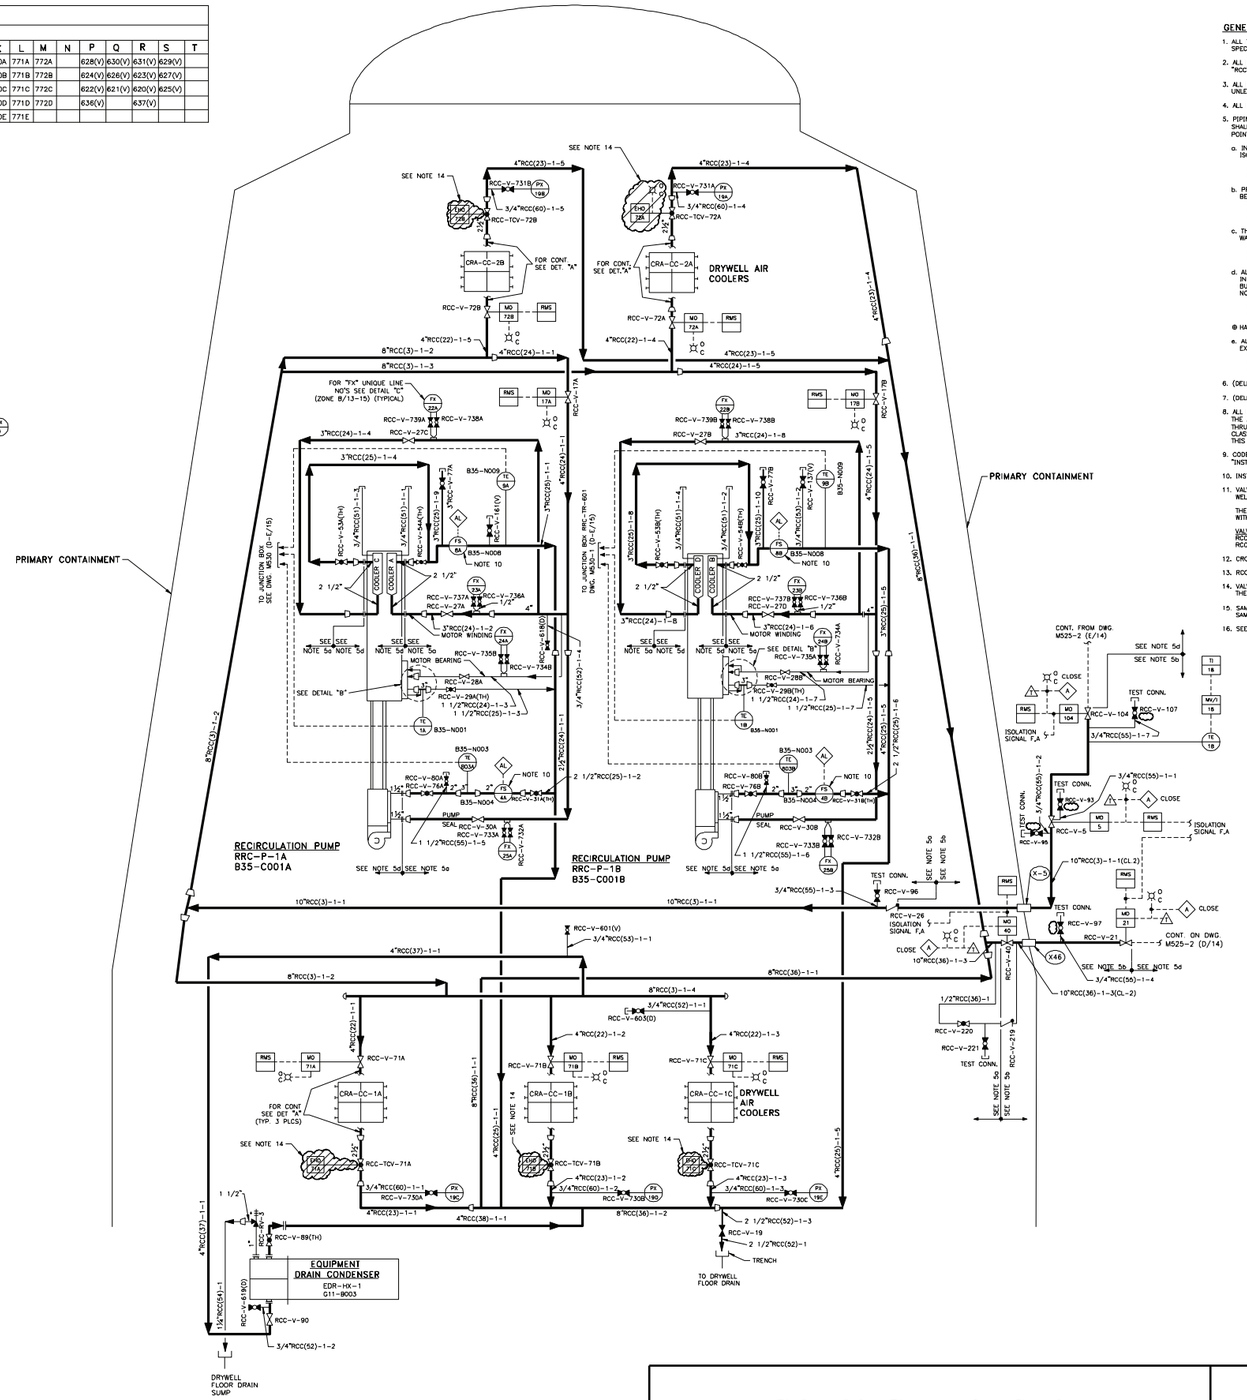
DETAIL "A"

TYPICAL DETAIL FOR COOLING COIL BANKS CRA-CC-1A, 1B, 1C, 2A, 2B.

NOTE:

FOR THE REMAINING UNITS, CHANGE THE INITIAL DIGIT OF THE UNIQUE LINE NUMBER TO CORRESPOND TO THE FOLLOWING: IF UNIT 1A (SHOWN) INDENTIFIES -1,-11-12, ETC. THEN THE UNIT 1B WILL BE: -2,-21-22, ETC; UNIT 1C: -3,-31-32, ETC; UNIT 2A: -4,-41,-42, ETC, AND UNIT 2B: -5,-51,-52, ETC.



DETAIL "B"

(ZONE F/6,8)

LINE NUMBERS IN PARENTHESES DENOTE PUMP 1B SYSTEM IDENTIFICATION

DETAIL "C"

DETAIL "C"

GENERAL NOTES:

1. ALL TEMPERATURE WELL CONNECTION TO BE 1 1/2" NPT UNLESS SPECIFICALLY NOTED OTHERWISE.
2. ALL INSTRUMENTATION ON THIS DRAWING TO BE INDENTIFIED BY PREFIX "RCC" UNLESS SPECIFICALLY NOTED OTHERWISE.
3. ALL INSTRUMENT ROOT VALVES NOT LABELED WILL BE 3/4" GLOBE VALVES UNLESS SPECIFICALLY NOTED OTHERWISE.
4. ALL ITEMS MARKED * ARE FURNISHED WITH ASSOCIATED EQUIPMENT.
5. PIPING, VALVES, AND ASSOCIATED COMPONENTS ON THIS DRAWING SHALL BE CLASSIFIED AS FOLLOWS, EXCEPT AS STATED IN NOTE 8. (BREAK POINTS ARE INDICATED ON THE FLOW DIAGRAM):
   a. INSIDE PRIMARY CONTAINMENT BEYOND THE INNERMOST CONTAINMENT ISOLATION VALVES:
      SEISMIC CATEGORY II @
      QUALITY CLASS II
      CODE GROUP C
   b. PRIMARY CONTAINMENT ISOLATION VALVES AND ALL PIPING AND VALVES BETWEEN THESE ISOLATION VALVES:
      SEISMIC CATEGORY I
      QUALITY CLASS I
      CODE GROUP B
   c. THE RADWASTE BLDG. STARTING FROM THE RADWASTE BUILDING EAST WALL:
      SEISMIC CATEGORY II
      QUALITY CLASS II
      CODE GROUP D
   d. ALL PIPING, VALVES, AND ASSOCIATED COMPONENTS ON THIS DRAWING IN THE RCC SYSTEM, IN THE REACTOR BUILDING, AND THE RADWASTE BUILDING CORRIDOR SHALL BE CLASSIFIED AS FOLLOWS, EXCEPT AS NOTED:
      SEISMIC CATEGORY II @
      QUALITY CLASS II
      CODE GROUP D
   @ HANGERS TO BE DESIGNED TO SEISMIC CATEGORY I LOADS.
   e. ALL PIPING, VALVES, AND ASSOCIATED COMPONENTS ON THIS DRAWING EXCEPT AS NOTED ABOVE:
      SEISMIC CATEGORY I
      QUALITY CLASS I
      CODE GROUP C
6. (DELETED)
7. (DELETED)
8. ALL PIPING DOWNSTREAM OF THE LAST ISOLATION VALVE AND OPEN TO THE ATMOSPHERE WITH THE SUBSYSTEM DESIGNATION "SYSTEM" (50) THRU (59) SHALL BE CLASSIFIED AS CODE GROUP D WITH QUALITY CLASS AND SEISMIC CATEGORY PROVIDED BY THE APPLICABLE NOTES ON THIS DRAWING.
9. CODE BREAK DEFINITIONS FOR THERMOWELLS ARE SHOWN ON M610, "INSTALLATION OF THERMOWELLS AND SAMPLE PROBES."
10. INSTRUMENTATION SO NOTED SHALL BE CODE GROUP E.
11. VALVE IS NOT ASME III CLASS 3, IT IS CONSIDERED SA105 MATERIAL WELDED TO THE SYSTEM.

    THE FOLLOWING WASHINGTON STATE SPECIAL NUMBERS ARE IDENTIFIED WITH THE CORRESPONDING VALVES:

VALVE TAG NUMBER	WASHINGTON STATE SPECIAL NUMBER
RCC-V-133A	WS-22-83W
RCC-V-133B	WS-25-83W

12. CROSS-HATCHED AND SCOPED EQUIPMENT IS NON-OPERATIONAL.
13. RCC-V-36A & RCC-V-36B HAVE BEEN GAGGED CLOSED.
14. VALVE OPERATOR HAS BEEN DEACTIVATED. VALVE IS IN THE OPEN POSITION AND FLUID DRAINED FROM OPERATOR.
15. SAMPLE POINT IS NO LONGER FUNCTIONAL. ALTERNATE METHOD OF SAMPLING IS DONE PER APPLICABLE PPM.
16. SEE DWG M501 FOR FLOW DIAGRAM LEGENDS, SYMBOLS AND ABBREVIATIONS.

LEGEND:

1. ALL VALVES (EXCEPT THOSE ON INSTRUMENT LINES) SUFFIXED WITH A (V) DENOTE A 3/4" VENT VALVE, EXCEPT AS NOTED.
2. ALL VALVES (EXCEPT THOSE ON INSTRUMENT LINES) SUFFIXED WITH A (D) DENOTE A 3/4" DRAIN VALVE.
3. ALL VALVES SUFFIXED WITH A (TH) DENOTE A THROTTLED VALVE.

SEISMIC CATEGORY	I
QUALITY CLASS	II
CODE GROUP	D

⊕ HANGERS TO BE DESIGNED TO SEISMIC CATEGORY I LOADS

35. SW-SV-918 IS INTERLOCKED WITH SW-V-12B SUCH THAT IT IS OPEN ONLY WHEN SW-P-1B IS RUNNING (SEE NOTE 14)

36. SW-V-69B HAS A MOTOR OPERATOR INSTALLED BUT HAS NO ELECTRICAL POWER AND CAN ONLY BE OPERATED MANUALLY. SW-V-70B HAS ITS MOTOR CONTROL CENTER COMPARTMENT LOCKED IN THE "OFF" POSITION. THESE VALVES ARE MECHANICALLY LOCKED CLOSED TO MAINTAIN PROPER WATER CHEMISTRY AND TO MAINTAIN SPRAY POND INVENTORY DURING AN ACCIDENT. THEY MAY BE OPENED IN CONJUNCTION WITH THE CLOSURE OF SW-V-12B TO PROVIDE ONCE THROUGH COOLING DURING A TORNADO EVENT.

37. "SPARED IN PLACE" SW-SPV-38A & SW-SPV-38B CONTROLLED AIR TO SW-PCV-38A & SW-PCV-38B. SW-PCV-38A & SW-PCV-38B ARE LOCKED OPEN. THIS ELIMINATES THE NEED FOR SW-SPV-38A & SW-SPV-38B WHICH HAVE BEEN DISCONNECTED.

38. THE KEEPFULL SYSTEM IS NOT REQUIRED AND HAS BEEN DEACTIVATED AND SPARED IN PLACE.

39. VALVE MOTOR AND OPERATOR "SPARED IN PLACE". CABLES DE-TERMINATED.

40. MAKEUP WATER SUPPLY FROM THE POTABLE WATER SYSTEM. SEE P541 (G/13).

41. DELETED

42. SW-M-P/1A AND SW-M-P/1B 1/2" COOLING WATER SUPPLY/RETURN PIPING SHALL BE CLASSIFIED AS FOLLOWS:

SEISMIC CATEGORY	I
QUALITY CLASS	I
CODE GROUP	D

43. FOR PERIODIC THERMAL PERFORMANCE TESTING OF RHR-HX-1A, FOUR THERMISTORS ARE INSTALLED ON THE SERVICE WATER INLET SIDE OF RHR-HX-1A AND EIGHT THERMISTORS ARE INSTALLED ON THE SERVICE WATER OUTLET SIDE OF RHR-HX-1A. THESE ARE MOUNTED QCII+, SC IM.

44. FOR PERIODIC THERMAL PERFORMANCE TESTING OF RHR-HX-1B, FOUR THERMISTORS ARE INSTALLED ON THE SERVICE WATER INLET SIDE OF RHR-HX-1B AND EIGHT THERMISTORS ARE INSTALLED ON THE SERVICE WATER OUTLET SIDE OF RHR-HX-1B. THESE ARE MOUNTED QCII+, SC IM.

45. FOR SERVICE WATER CHEMICAL FEED (SWCF) ADDITION INTO SERVICE WATER PONDS "A" AND "B" SEE CVI 897-00,1 FOR DETAILS.

46. FOR PERIODIC THERMAL PERFORMANCE TESTING OF PRA-FC-1B, FOUR THERMOCOUPLES ARE INSTALLED ON THE SW INLET AND TWO THERMOCOUPLES ARE INSTALLED ON THE SW OUTLET OF PRA-CC-1B. THESE ARE MOUNTED QC II+ SC 1M.

47. SEE DWG M501 FOR FLOW DIAGRAM LEGENDS, SYMBOLS AND ABBREVIATIONS.

48. FOR PERIODIC THERMAL PERFORMANCE TESTING OF PRA-FC-1A, FOUR THERMOCOUPLES ARE INSTALLED ON THE SW INLET AND TWO THERMOCOUPLES ARE INSTALLED ON THE SW OUTLET OF PRA-CC-1A. THESE ARE MOUNTED QC II+ SC 1M.

Flow Diagram - Compressor Jacket Water System
Turbine Generator Building

Draw No. M942	Rev. 8	Figure 9.2-15

9.3 PROCESS AUXILIARIES

9.3.1 COMPRESSED AIR SYSTEMS

The compressed air systems consist of the control and service air systems (CAS and SA) and the containment instrument air (CIA) system.

9.3.1.1 Design Bases

9.3.1.1.1 Control and Service Air Systems

The CAS and the SA system are supplied with oil-free compressed air from three rotary screw compressors, two refrigerated dryers, two sets of filters, and three air receivers located in the turbine generator building and by one rotary screw compressor and refrigerated filtered dryer in the radwaste building. The CAS receivers are maintained at a pressure between 110 psig and 120 psig by the compression loading control devices. Normally, the SA compressor and one CAS compressor will meet the plant demand for compressed air. Should the air pressure in the three CAS air receivers, which are interconnected, drop to less than the running CAS compressor setpoint, a second and if necessary, a third CAS compressor will start. If pressure in the CAS supply header drops to less than 80 psig, the SA system will be automatically isolated from the CAS air receivers to conserve air for use in the CAS.

The CAS provides instrument quality air, oil-free, maximum particle size of 1 micron, and dried to an atmospheric dewpoint of -40°F, throughout the plant for pneumatic instrumentation, controls and actuators. Air is drawn from the air receivers, is passed through prefilters, a desiccant dryer and afterfilters, to distribution piping.

A complete loss of control air will result in a plant shutdown, but none of the reactor systems require control air to achieve and maintain a safe shutdown condition.

The SA system provides oil-free compressed air from the CAS air receivers and/or from the SA receiver in the radwaste building, for use in process functions such as backwashing filters or demineralizers, for general services and maintenance uses throughout the plant, and as a source of breathing air.

The CAS and SA system are generally designed to Safety Class G, Seismic Category II requirements; however, piping and equipment in the reactor building, diesel generator building, and the standby service water (SW) pump houses are supported to Seismic Category I requirements. Pressure vessels are designed and constructed in accordance with the American Society of Mechanical Engineers (ASME) Boiler and Pressure Vessel (B&PV) Code Section VIII. Piping and valves are designed and constructed in accordance with the ANSI B31.1 Power Piping Code, except for piping or valves performing a primary containment function and the local control piping at the outer main steam isolation valves (MSIV). These

portions of the piping are Quality Class I, Seismic Category I, and are designed and constructed in accordance with ASME B&PV Code Section III, Class 2 and Class 3, respectively.

9.3.1.1.2 Containment Instrument Air System

The CIA system is designed to deliver clean, dry, compressed gas, nitrogen or air, to the following valve actuator accumulators and valve pilot controls inside primary containment. Seven individual accumulators for the seven main steam relief valves (MSRV) dedicated to the automatic depressurization system (ADS) function are supplied with gas through two separate isolable headers at a nominal pressure of 180 psig. The four inboard MSIV actuator accumulators, 18 MSRV actuator accumulators for the power-assisted pressure relief function, and two reactor recirculation cooling (RRC) pump seal staging drain valve pilot control valves are supplied with gas at a reduced nominal pressure of 100 psig. The CIA system also provides nitrogen to the set pressure verification device (SPVD) system. For normal plant operation, nitrogen is supplied from the containment nitrogen (CN) system cryogenic storage vessel which is also the source of nitrogen for inerting the primary containment atmosphere. Should the normal nitrogen supply become unavailable, the gas supply piping to the ADS function accumulators will automatically isolate from the cryogenic nitrogen supply, and the ADS accumulator backup compressed gas manifold subsystems will provide a nominal pressure of 180 psig nitrogen from banks of high pressure compressed nitrogen cylinders. The designed pneumatic supply to the ADS accumulator is such that, following a failure of the safety-related pneumatic supply to the accumulator, at least two valve actuations can occur with the drywell at 70% of design pressure.

The 100 psig line does not have an automatic backup supply, but provision has been made for supplying air from the CAS system through the CIA dryer and filters via manually actuated intertie valves in lieu of the normal CN supply.

The piping for normal supply of compressed nitrogen or air, that is outboard of the primary containment isolation valves, is designed to the ANSI B31.1 Power Piping Code, and pressure vessels are constructed to the rules of the ASME B&PV Code Section VIII. Piping penetrating primary containment and inside of primary containment, from the outermost containment isolation valves to the point of use valve connections, is constructed to Safety Class 2, ASME B&PV Code Section III, Class 2, Seismic Category I, requirements; except that the flexible connectors at the four inboard MSIV actuator supply valves are equivalent to but are not ASME Section III stamped items. Piping located in the reactor building and the diesel generator building is supported by Seismic Category I supports, although most of the non-ADS piping itself is designed to Seismic Category II loadings. The ADS function accumulator backup compressed nitrogen supply subsystems, from the normal supply isolation valves and from the outboard containment isolation valves, to, but not including, the compressed nitrogen cylinders, pressure regulators and overpressure relief valves, are constructed to ASME B&PV Code Section III Class 3 rules including Seismic Category I load conditions. An exception to this

ASME statement occurs at the pressure control valve stations in the diesel generator building corridor, where the sections of line containing the pressure control valve in each station is non-ASME (due to the unavailability of ASME pressure control valves), but is isolable and bypassable via ASME manually operable valves. The compressed gas cylinders are U.S. Department of Transportation approved commercial shipping containers. The cylinder valves, connectors, pressure regulators, and overpressure relief valves are approved by the Compressed Gas Association. The supports for the compressed gas cylinders, cylinder valves, connectors, pressure regulators, and overpressure relief valves are designed to Seismic Category I requirements.

9.3.1.2 System Description

9.3.1.2.1 Control and Service Air System

The CAS and SA system are shown schematically in Figure 9.3-1. Three compressors and three interconnected CAS air receivers in addition to one SA compressor and SA air receiver supply both control and SA requirements.

Each CAS compressor has a run-standby-stop local selector switch. When the selector switch is set in the run position, the compressor runs continuously and loads and unloads to maintain receiver pressure. When the selector switch is in standby position, the standby CAS compressor will automatically start when the CAS supply header pressure falls below the running CAS compressor setpoint. Normally one CAS and the SA compressor are running with at least one CAS compressor on standby.

The CAS compressors take suction from the room through 10 μ filters. The air is filtered down to 0.1 μ before entering the air receivers. The CAS compressors are cooled by the compressor jacket water (CJW) system. The CJW system is a closed loop system that transfers heat from the CAS system to the plant SW system.

The SA compressor takes suction from the outside to ensure that the air, which can be used for breathing purposes, is free from contaminants. The use of SA for breathing air is permissible with the use of local air filtration and local monitoring for carbon monoxide. System-level monitoring for carbon monoxide does not provide sufficient assurance of detection and mitigation of an adverse condition. The use of local filtration and monitoring enables the entire SA system to be used for breathing air.

The CAS and SA compressors pump an air/oil mixture to an internal air receiver/oil separator and then the air enters an internal aftercooler for cooling and moisture separation. The air is then discharged to a refrigerated dryer for further moisture removal. The air then enters a series of filters to remove any remaining particles and oil vapor from the air before entering the main air receivers.

Control air for station instrumentation and controls is processed through a refrigerated air dryer, a filter array, one of two 100%-capacity air dryer skids. Each skid has two 100% capacity prefilters and after filters arranged in parallel pairs to allow for replacement of the filter cartridge without interruption of air flow. The dryer on each skid is a heatless regenerative twin tower desiccant type which dries through one tower while the other is regenerating. A timer switches between towers and a purge economizer allows reduction in purge usage when the dryer is not operated at full capacity. There are two parallel refrigerated dryer and filter arrays, one or both of which may be operating at a given time.

Service air is distributed from the header to quick-disconnect hose connections where it is used for pneumatic service equipment and maintenance throughout the plant. Service air is also distributed for plant services such as demineralizer resin mixing and filter and demineralizer backwashing (see Figure 9.3-1).

Table 9.3-1 presents the major characteristics of the air compressors, receivers, and the air dryer for the control and SA.

9.3.1.2.2 Containment Instrument Air System

The CIA system is primarily a pressurized nitrogen system as shown in Figure 9.3-2. The location of components in this system in the Seismic Category I reactor building is shown in Figures 1.2-7, 1.2-8 and 1.2-9. During normal reactor operation, the CN system, discussed in Section 6.2.5.7, supplies pressurized nitrogen from an 11,000-gal (approximately 1 million-scf) cryogenic storage tank to meet the requirements of the following valves inside primary containment:

a. Full supply pressure (180 psig nominal) loads,

   1. Seven ADS function MSRVs and their individual ADS accumulators,

b. Reduced pressure (100 psig nominal) loads,

   1. Four inboard MSIV accumulators,

   2. Eighteen main steam safety/relief valves (SRVs) and their individual accumulators to be used for the power assisted pressure relief function, and

   3. Two RRC pump seal staging drain valve pilot control valves.

For a discussion of the function and operation of the ADS, see Sections 6.3 and 7.3. In case the cryogenic nitrogen source does not maintain supply pressure to the ADS accumulator supply headers, two backup nitrogen cylinder bank subsystems are provided to automatically

supply a nominal pressure of 180 psig nitrogen. A bank of 15 nitrogen cylinders supplies three of the ADS function accumulators, and a separate bank of 19 nitrogen cylinders supplies the other four ADS function accumulators (see Figure 9.3-2). Of these backup subsystems, only 14 nitrogen bottles for three ADS accumulators and 17 nitrogen bottles for the four ADS accumulators are necessary to provide a 30-day supply of nitrogen for the ADS function during a postulated loss-of-coolant accident (LOCA) condition. The backup subsystems also provide for manual SRV operation during station blackout (Appendix 8A). A remote nitrogen cylinder connection is provided to each subsystem to permit supplementing the cylinder banks through manual connection of portable nitrogen cylinders, and thus maintain the ADS function for at least 100 days following a postulated LOCA event. The remote cylinder connections are located in the diesel generator building corridor, adjacent to the reactor building, outside the secondary containment boundary, permitting personnel access to the connections under postaccident conditions.

Remote pressure control stations, each consisting of a bypassable pressure control valve, are schematically located downstream of the junction of the backup nitrogen cylinders supply with the remote backup nitrogen cylinder supply, and are physically located in the diesel generator building corridor. Thus, any problems with the pressure control valve could be accommodated by isolating it, to allow maintenance to be performed, while the ADS function header pressure was being maintained with the manual bypass valve. The pressure control valve allows the cylinder regulators to be set at a higher, but broad range, pressure.

The backup nitrogen cylinder banks are located in the reactor building vehicle air lock (railroad bay) and are accessible during normal reactor operation. Cylinders are valved to the supply piping in a sequential manner by a pressure-controlled programmer for each bank, so that only the number of cylinders necessary to maintain pressure in the ADS accumulator supply lines are drawn on. During normal reactor operation, minimum cylinder pressure is maintained as required by the Technical Specifications. The gas cylinders used may only be charged to 3000 psig, a limitation imposed by the system piping.

Once opened, the ADS valves are not expected to be cycled during the postaccident period; nevertheless, the air supply was conservatively sized to allow for extra cycles, since they may be used for alternate shutdown cooling.

In the event the cryogenic nitrogen source totally fails to supply the system requirements, the backup nitrogen cylinder banks will supply their respective ADS supply headers as described above and the headers will be automatically isolated from the common CIA supply line. The reduced pressure loads will then be without a source of pressurized gas until the CAS intertie valves are opened. A normally open vent between the two in-line series block valves could then be closed (the vent is there to guarantee no backleakage from CIA to CAS, which could lower the oxygen content of CAS/SA and result in an adverse condition should a breathing-air tap be in use). The relatively low pressure CAS supply would still be inadequate for the ADS headers, though, and they would still automatically be supplied as discussed above.

9.3.1.3 Safety Evaluation

9.3.1.3.1 Control and Service Air System

Operation of the CAS and SA systems are not required for the initiation of any engineered safety feature systems or for safe shutdown of the reactor.

A complete loss of the CAS system during power operation results in a plant shutdown with the following expected to occur: The SA system is automatically isolated as the CAS system pressure decreases. Control rods drift into the core as the control rod drive (CRD) scram outlet valves begin to slowly open. The outboard MSIVs close causing an automatic reactor scram. Operator actions based on CAS failure would be taken in accordance with plant procedures to scram the rector, control reactor pressure vessel (RPV) pressure/water level, and to mitigate the effects of individual air-operated valve failure modes.

9.3.1.3.2 Containment Instrument Air System

Since each of the two backup nitrogen cylinder banks and the cryogenic nitrogen supply are independent of each other, a single component failure in one will not affect the operational function of the other. The two ADS header tie line isolation valves are each powered from a different division of the critical power supply.

During normal operation, the cryogenic nitrogen supply will maintain pressure in the inboard MSIV, the power-assisted MSRV, and the ADS function accumulators. The cryogenic nitrogen supply piping and the CAS supply piping are not assumed to be serviceable under accident conditions. In such an event, the local accumulators at the MSIVs and MSRVs provide a short-term source of pressure for actuating these valves. Further discussion of the effects of loss of pressure to the MSIVs and the normal function MSRVs is presented in Sections 5.2.2.4, 5.4.5, and 7.3.1.1.10. The backup nitrogen cylinder bank subsystems will supply operating nitrogen pressure to the ADS MSRV accumulators at any time the normal supply does not function.

The solenoid valves on the ADS function MSRVs could be pressurized to a pressure greater than their qualified pressure under certain accident conditions if the ADS header pressure were allowed to approach the piping design pressure; therefore, the ASME relief valves are set at a lower pressure to preclude this possibility. They are located in the diesel generator building to provide access (post-LOCA) should one open and stick open.

9.3.1.4 Testing and Inspection Requirements

A channel functional test of the ADS accumulator backup compressed gas system alarm with a channel calibration verifies an alarm setpoint of greater than or equal to 135 psig (decreasing).

At a frequency no less than once per 22.5 months, the nitrogen capacity in at least two accumulator bottles per division within the backup compressed gas system is verified.

The backup compressed gas pressure instrumentation is periodically tested and calibrated as required by the Technical Specifications.

Instrument air sampling and testing is performed periodically to ensure that the air quality meets system design requirements. Routine maintenance and inspection along with operator observation during operation ensures the system is functioning properly to support normal plant operations.

9.3.1.5 Instrumentation Requirements

9.3.1.5.1 Control and Service Air Systems

Instrumentation and controls are provided in the main control room to control and monitor the operation of the systems. Low receiver air pressure, high air temperature, high filter differential pressure, and other system operating parameters (see Figure 9.3-1) are alarmed in the control room.

An air-operated control valve isolates the SA when its header pressure drops to 80 psig to enable sufficient air flow to the CAS. Nonlubricated control valves, a solid state timer, and a purge economizer regulate the air drying cycle.

9.3.1.5.2 Containment Instrument Air System

The instrumentation provided in the CIA system is shown in Figure 9.3-2. Pressure switches and alarms are provided in this system to regulate the nitrogen supply from the 15 nitrogen bottles in one bank and the 19 bottles in the second bank. Pressure switches in the tie lines between the CIA distribution header, which is itself supplied by either the CN system or the CAS system, and the ADS function lines monitor the supply pressure and cause tie line isolation valves to independently close if the tie line pressure should drop below the switch setpoint for a time period greater than 3 minutes. A pressure switch on each ADS function header then causes the nitrogen bottles to begin supplying their respective headers after the tie-line isolation valves actually close. A redundant pressure switch on each ADS function header set at a slightly lower pressure than the tie-line isolation setpoint, acts as a backup to either the isolation valve closed position switch, or the other pressure switch on the same ADS function header, to initiate supply from the nitrogen bottles. The redundant pressure switch also initiates an alarm in the control room to alert the operators to a low-pressure condition in the ADS function header.

In addition to the low pressure switches, each ADS function header has a pressure switch that provides control room annunciation to alert the operators to a high-pressure condition.

Local pressure indication is provided just downstream of each pressure control valve station should the station require isolation and the ADS function header pressure require regulation via the manual bypass valve.

9.3.2 PROCESS SAMPLING SYSTEM

9.3.2.1 Design Bases

The plant process sampling system is designed to provide representative samples, under controlled conditions, of plant process streams. Provisions for continuous monitoring of selected systems provide a means of analytical surveillance of system trends and performance during plant operations. Laboratory samples are taken to provide (a) comprehensive analytical information on plant operations, (b) a check on continuous monitoring instrumentation, and (c) regular reports on critical plant systems to ensure safe and proper operation.

The sample system is designed to the following criteria:

a. To ensure that the samples of the process stream are representative of the conditions that exist at the sample tap, the following design practices have been implemented:

1. The shortest practical line length and smallest practical line diameter is used to reduce time lag and sample line plate-out;

2. Sample lines are routed to prevent dead legs and are assembled to avoid traps and dips;

3. Certain sample lines have a continuous purge flow of sufficient velocity to inhibit deposition of suspended solids and to satisfy the requirements of analytical instrumentation;

4. To ensure representative sampling of gaseous effluents, special sampling probes are employed which consider the process line size, flow conditions, and flow direction. Where appropriate, isokinetic probes are used to ensure representative sampling of the particulates;

5. Where precision measurements are to be made of high purity (low conductivity) water, the process sample flow stream is conditioned by constant temperature baths before in-line conductivity measurement to maintain the internal temperature compensation within the valid range.

Hot process fluids are cooled by heat exchangers before entering grab sample hoods or analysis equipment to avoid measurement errors and the potential for injury; and

6. Sample line pressures are reduced at sample racks to protect in-line instruments and minimize the potential for personnel injury. Pressure regulators with relief valves are used to control and limit sample pressure.

7. Where tubing samples are taken from high temperature and pressure lines, flow will be isolated and the temperature allowed to decay to ambient before the system is depressurized, drained and then the sample removed.

b. In addition to limiting sample temperatures and pressures, the following safety precautions are taken:

1. The sample lines are made of stainless steel tubing with a minimum of joints or connections, and

2. Process sample lines containing highly radioactive fluids are routed to minimize personal radioactive exposure.

9.3.2.2 System Description

The sampling system consists of continuous flow in-line analytical instruments, plus numerous grab sample points which are either local or routed to a centralized sampling station. The sampling system is shown in Figures 9.3-3, 9.3-4, 9.3-5 and 9.3-17.

A sample station typically consists of a sample rack and a fume hood. Process fluids enter the conditioning rack and, where necessary, pass through one or more heat exchangers to reduce temperatures to 105°F or less. Pressure is reduced, where necessary, to limit sample pressure to 40 psig or less. If sampling criteria does not allow the temperature and pressure to be reduced at a sample rack, the flow will be isolated and the system brought to a safe temperature and pressure before sample removal to minimize the potential for injury to personnel. After conditioning, the process fluid is routed to the chemical fume hood where grab samples are taken. In the case of continuously monitored process streams, a portion of the fluid is diverted through a constant temperature bath, through conductivity cells and rotameters, and then to a drain line. Selected process fluids are continuously monitored by sample line sensors for conductivity and other parameters. Electric outputs of the sensors go to monitors and continuous recorders. Electrodes located in RWCU piping and inside of the RPV provide electro-chemical potential (ECP) signals to continuous recorders on PSR-CAB-1. Liquid effluents from the sample racks and chemical fume hoods are routed through closed drains to the liquid radwaste system.

The systems that require intermittent or continuous analytical sampling are arranged to permit sampling during normal and shutdown conditions. Many of the sample lines flow continuously. For those that do not, written procedures specify the flow rate and time required for sample line purge before taking the sample. This ensures that representative samples are obtained.

9.3.2.2.1 Sample Locations

The available process liquid sampling system points are described in Table 9.3-2 (not all available sample points are used). The sampling system for radiation monitoring equipment is described in Section 11.5.

9.3.2.2.2 Liquid Sample Taps and Probes

Sample line connections are, where possible, located after a straight run of pipe. Since process piping is designed for turbulent flow conditions, sample taps for nominal line sizes 3 in. and less can be taken from tees or welded-pipe connections. For nominal pipe sizes 4 in. and larger, sample probes are installed into the pipe line. Sample connections to process pipes are a minimum of 0.75 in. and have the root valves as close to process lines as possible. The root valve and connection are the same quality and code group as that of the process pipe.

The sample probes are fabricated in accordance with Figures 9.3-6, 9.3-7, and 9.3-8 and are designed to avoid failure through vibration or wear.

Sampling taps, where possible, are located at the sides of horizontal process lines rather than at the top or bottom.

9.3.2.2.3 Steam Samples

Two sample taps for main steam are installed, one of which is a spare.

The sample line is stainless steel tubing of sufficient total length (from sample point to sample rack) to allow for decay of ^{16}N to minimize radiation dose rate at the sample station. The steam sample is condensed near the process line tap and the resultant condensate is piped to the sample rack.

9.3.2.2.4 Sample Piping Design

The sample piping, from the root valve at the process tap to the sample conditioning rack in a sample room, is small diameter heavy wall stainless steel tubing to minimize corrosion or contamination of the sample. The small diameter also provides a passive flow restriction in the event of a sample line break.

Sample lines are sized to ensure turbulent flow conditions at the required flow rate. This turbulence alleviates stratification or plate-out of particles in the sample line.

Continuous flow lines containing fluids over 150°F are insulated to protect personnel. When warranted by high anticipated radiation levels, sample lines containing radioactive fluids are routed or shielded as described in Section 12.3.

9.3.2.2.5 Fume Hood Design and Grab Samples

All liquid sample lines entering the sample rooms have provisions for grab sampling. Each fume hood is an enclosed sheet metal structure (stainless steel) with manual grab sample valves positioned over a stainless steel sink, all located within the hood. The face of the hood has a transparent sash opening for hood access. Ambient air enters the opening to remove any gases or droplets released from the liquid sample. Air is exhausted from the top of the hood into the building ventilation exhaust system. The hood sink collects the sample liquids not collected in the grab sample and pipes the effluent to a closed drain system. A demineralized water faucet and a compressed air nozzle is located near the sink in the hood to flush and clean sampling apparatus.

9.3.2.3 Safety Evaluation

The process sampling system has no direct process control functions. Each continuously monitored sample line is provided with local indication and annunciation. This includes a high alarm, a low alarm where appropriate, and a continuous recorder. Remote indication is provided on certain samples.

Components of the process sampling system which form part of the reactor coolant pressure boundary (RCPB) or containment isolation system are designed in accordance with Seismic Category I requirements and other code and quality requirements as described in Section 3.2. Sample lines which form part of the containment isolation are provided with automatic fail-closed isolation valves both inside and outside of containment. The components of the process sampling system that do not form part of the RCPB or containment isolation system and are not in the reactor building are not designed to Seismic Category I requirements since they are not necessary to ensure any of the following:

a. The integrity of the RCPB,

b. The capability to shut down the reactor, and

c. The capability to prevent or mitigate the consequence of accidents which could result in potential offsite exposure in excess of the limits of 10 CFR 50.67.

The operation of the liquid sampling system is not necessary for plant safety. Therefore, in the unlikely event of an accident, all sample lines which pass through the containment are automatically isolated by fail-closed valves. Electrical power for the sampling subsystem is from a nonessential bus.

The routing of high temperature and high pressure sample lines outside the containment is not considered hazardous because of limited flow and limited stored energy as discussed in Section 3.6. The location of sample temperature and pressure reduction equipment outside the containment allows maintenance during plant operation.

The sample station is a closed system with grab samples taken under the safety of a chemical fume hood to minimize radiological hazard. The hood maintains a constant air velocity of approximately 100 ft/minute through the working face to ensure that airborne contamination will not enter the room.

Pressure control valves are installed in high-pressure sample lines so that operators will not be exposed to high sample pressure when obtaining grab samples.

At PSR-SR-49 sample rack, tubing samples are taken from high temperature and pressure lines that will utilize double isolation valves to protect the worker from harm due to the operating conditions of the high-energy line. This sample rack will be isolated then cooled to ambient temperature and then depressurized. The rack is then drained before the tubing sample is removed. This rack is located in the RWCU heat exchanger room, which minimizes exposure or contamination of personnel and maintains contamination control in case of a spill.

9.3.2.4 Tests and Inspections

The sample nozzles and associated piping, tubing, fittings, and valves are tested and inspected in accordance with the requirements of the main process pipes from which the samples are taken.

The process sampling system is proved operable by its use during normal plant operation. Grab sampling is provided for laboratory analysis for verification of proper operation and calibration of continuous analyzers.

9.3.2.5 Instrument Requirements

Continuous analyzers and associated recorders monitor conductivity and dissolved oxygen at selected points in the sampling system. Alarms annunciate in the main control room or the radwaste control room when the variables are out of specification to alert the control room operator that corrective action is required.

9.3.3 EQUIPMENT AND FLOOR DRAINAGE SYSTEMS

9.3.3.1 Design Bases

The equipment and floor drainage systems are designed to collect and convey the various operational waste liquids from their points of origin to their points of ultimate disposal under controlled conditions. The following design bases are used to ensure the system integrity during normal plant operation and preclude any danger to the health and safety of plant personnel, the environs, and the general public.

Drainage systems which carry radioactive waste are isolated from drainage systems which do not carry radioactive waste. Radioactive wastes are collected separately in tanks or sumps, based on their classification as floor drainage (low purity), equipment drainage (high purity), chemical drainage (nonneutral) and detergent drainage, to facilitate their treatment in the radwaste building.

Floor and equipment drains in the diesel generator building, service building, isolated areas of the turbine building, and storm water drainage are not intended to be operated as radioactive systems.

The majority of radioactive drainage piping 1-in. and above is of butt-welded construction to avoid the collection of radioactive solids, see Section 12.3.1.3.2. Drain lines are sloped to ensure complete drainage of piping. Appropriate shielding is used in locations which could result in increased radiation exposure. Cover plates are an integral part of all floor drains to prevent solids from entering drain piping and causing subsequent clogging.

9.3.3.2 System Description

Equipment and floor drainage systems are provided to handle radioactive and nonradioactive wastes in separate systems. Radioactive wastes are collected in the building sumps and transferred to the radwaste system (see Section 11.2) for treatment, sampling, and disposal or reuse within the plant. Roof drains are drained by gravity or pumped to the storm drain system.

9.3.3.2.1 Radioactive Equipment Drainage System

9.3.3.2.1.1 Reactor Building Drains. Reactor building equipment drains are collected in two separate subsystems (see Figure 9.3-9). One subsystem handles drainage from all equipment drains located in the primary containment. The other handles drainage from equipment drains located in remaining portions of the reactor building.

The primary containment equipment drain subsystem starts at funnel drains located at pieces of equipment, collects in branch lines, and discharges to the drywell equipment drain sump. The

drywell equipment drain sump is the collecting point for valve leakoffs, the inner refueling bellows seal support drains, reactor recirculation pump seal leakoffs, and equipment vents and drains within the drywell.

The drywell equipment drain sump is drained through a 3-in. line penetrating the containment wall to the reactor building equipment drain sump. This drain line includes two isolation valves located outside the drywell and a flow meter for monitoring of the leakage into the drywell sump during reactor operation. Leakage into the drywell equipment drain sump is considered identified leakage (see Section 5.2.5.2). This drain line is provided with a loop seal to prevent gas flow between the drywell and the reactor building during normal operation.

The containment isolation valves in the drywell sump drain line will close on a high pressure signal in the drywell to prevent blowing out the water seals. All equipment drainage piping in the drywell has been designed to Seismic Category 1M requirements. The drywell equipment sump drain line is Seismic Category I and is constructed to ASME Section III Class 2 requirements from the sump outlet to the second containment isolation valve.

The equipment drains for the remainder of the reactor building start at funnel drains located at pieces of equipment, collect in branch lines, and discharge to the reactor building equipment drain sump. The reactor building equipment drain sump collects drainage and leakage from the following major sources:

a. Fuel pool gate drainage,

b. Residual heat removal system equipment,

c. Fuel pool cooling system equipment,

d. CRD system equipment,

e. Reactor water cleanup system equipment,

f. High-pressure core spray (HPCS) system equipment,

g. Low-pressure core spray system equipment,

h. Reactor core isolation cooling system equipment,

i. Condensate filter demineralizer backwash pump and auxiliary condensate pumps, and

j. Drywell equipment drain sump.

Two sump pumps are installed in the reactor building equipment drain sump to transfer the collected water to the selected collector tank located in the radwaste building. Only one pump is in service at a time. A manual selector switch is located near the pumps to select the active pump.

A level switch in the sump starts and stops the active pump and timers monitor the fill and pump out rate and energize an alarm(s) in the control room if the settings on the fill and pump out timers are exceeded. A temperature sensor in the sump starts the active sump pump and directs the sump water through a heat exchanger to cool the water prior to being pumped to the radwaste system. All drainage piping in the reactor building has been designed to Seismic Category 1M requirements.

To minimize the release of radioactive contaminants, the reactor building equipment drain sump and drain headers are maintained at a negative pressure and vented through a filter system (see Section 9.4.2).

9.3.3.2.1.2 Turbine Building Drains. The turbine building equipment drain sumps serve as the collection point for equipment drains from all floors of the building (see Figure 9.3-10).

The equipment drains start at funnel drains located at pieces of equipment, collect in branch lines, and discharge to one of two turbine building equipment drain sumps. The turbine building equipment drain sumps collect drainage and leakage collection includes the following major sources:

a. Low-pressure feedwater heaters,
b. High-pressure feedwater heaters,
c. Gland steam evaporators,
d. Reactor feed pumps,
e. Instrument racks,
f. Steam jet air ejector condensers,
g. Mechanical vacuum pumps, and
h. Main condenser.

Two sump pumps are installed in each turbine building equipment drain sump since the pumps are not accessible during plant operation due to their location in a high radiation area. These pumps transfer the collected water to the waste collector tank located in the radwaste building. Level switches are provided in each sump to start and stop the sump pumps at predetermined levels. Drainage piping in this system is designed to Seismic Category II requirements.

9.3.3.2.1.3 Radwaste Building Drains. The radwaste building equipment drainage is collected in a separate equipment drain sump (see Figure 9.3-11). The subsystem collects drainage from components containing high purity water. The sump contains a sump pump which transfers the

water collected to the waste collector tank. The pump is controlled by a level switch in the sump.

To minimize the release of radioactive contaminants, the radwaste building equipment drain sump and drain header are maintained at a negative pressure and vented to the radwaste building ventilation system (see Section 9.4.3).

The radwaste building chemical waste sump collects wastes from equipment drains and floor drains associated with the chemical waste system (see Section 11.2.2) in a separate sump (see Figure 9.3-11). These wastes are collected and pumped to the chemical waste tank. The pump is controlled by a level switch located in the sump.

Drainage piping in these systems is designed to Seismic Category II requirements.

9.3.3.2.2 Radioactive Floor Drainage Subsystem

9.3.3.2.2.1 Reactor Building Floor Drains. Reactor building floor drainage is collected in two separate systems (see Figure 9.3-12). One handles drainage from the drywell which collects leakage from piping and equipment. The other handles drainage from all floor drains located in the remaining portions of the reactor building.

The drywell floor drains subsystem collects leakage in the drywell from piping, valves, and equipment in the drywell floor drain sump. In addition, drains from the drywell coolers are routed to this sump.

The floor drain sump system is a gravity flow feed from the drywell floor drain into one of the reactor building floor drain sumps. The floor drain sump geometry is such that the gravity feed is connected to a perforated standpipe in the center of the sump. Approximately 50 gal of liquid is required to fill a completely dry sump to the first row of holes in the perforated pipe outlet. A flow transmitter continuously measures flow from the drywell floor drain and supplies this flow information to a flow totalizer in the control room. Drywell floor drain flow is also provided to a recorder whose function is to actuate a control room alarm if flow exceeds a pre-established limit.

The drywell floor drain sump is drained through a 3-in. line penetrating the containment wall to one of the reactor building floor drain sumps. This drain line includes two isolation valves located outside the containment and an in-line flow meter for monitoring the flow from the drywell sump during reactor operation. Leakage into the drywell floor drain sump is considered unidentified leakage (see Section 5.2.5.2). The drain line is provided with a loop seal to prevent gas flow between the drywell and the reactor building during normal operation.

The containment isolation valves in the drywell sump drain line will close on a high-pressure signal in the drywell to prevent blowing out the water seal.

All floor drainage piping in the drywell has been designed to Seismic Category 1M requirements. The drywell floor drain sump piping is Seismic Category I and is constructed to ASME Section III Class 2 requirements from the sump out to the second containment isolation valve except 3 ft of 2-in. piping from the diaphragm floor seal, which does not require hydrotest or code stamp.

The floor drain system for the remainder of the reactor building contains four independent sumps. Each sump is located near one of the four corners of the building and collects drainage from roughly one quarter of the building.

The four sumps collect water from the following typical sources:

a. Floor drains throughout the building;

b. Drains from electrical trenches, refueling services boxes, valve boxes, cable reel pit and track drains on the refueling floor, pool liner drains, and the new fuel storage vault; and

c. Equipment drains from equipment containing low-purity water, such as reactor building closed cooling water system and standby gas treatment system.

As shown in Figure 9.3-12, the floor drain piping in the reactor building drains to one of four sumps listed below.

Floor Drain Sump	Room Locations	Rooms Served
FDR-SUMP-R1	RHR A pump room	RCIC RHR A
FDR-SUMP-R2	RHR B pump room	RHR B
FDR-SUMP-R3	HPCS pump room	HPCS CRD
FDR-SUMP-R4	RHR C pump room	LPCS RHR C

Each sump is equipped with level instrumentation which (a) controls the sump pumps, (b) alarms in the control room (on high sump level), and (c) initiates closure of the isolation valves in the piping between interconnected rooms. Class 1E level instrumentation is installed

just above floor level in each emergency core cooling system (ECCS) pump room. This instrumentation alarms in the control room.

The floor drain system is analyzed against potential sources of flooding as described in Section 3.6.

The effects of passive failures in the ECCS during post-LOCA long term cooling is addressed in Section 6.3.

Two of the reactor building floor drain sumps are provided with one sump pump (FD-SUMP-R4 and FD-SUMP-R2). The other two sumps have two pumps, one of which is for backup. The two sumps (FD-SUMP-R3 and FD-SUMP-R1) which have a backup pump, serve rooms containing the reactor core isolation system, residual heat removal system loop A pumps, and the CRD pump, condensate supply pumps, and the HPCS pump.

Floor drain sump FDR-SUMP-R3 also receives the leakage from the drywell floor drain sump. Each FDR sump draining more than one pump room has an isolation valve installed in the drain header between the connected pump rooms. The valve will close on high water level signal from the sump. Thus, except for the sump valve, room doors and piping/cable penetrations, drainage in any pump room, exceeding the capacity of the sump pump, will be confined to that room with the exception of RCIC and CRD pump rooms which are connected by an unisolable sump pipe.

The reactor building floor drain pumps transfer the collected water to the floor drain collector tank located in the radwaste building. Level switches are provided in each sump to start and stop the sump pumps at predetermined levels. A timing switch in each sump monitors the fill-up rate in the sump. Abnormal sump fill-up rate is alarmed in the main control room.

In addition, wall-mounted level sensing instrumentation is provided in each ECCS pump room to detect passive failures in the ECCS during post-LOCA long-term cooling and to alarm in the control room. As discussed in Section 6.3.2.5, ample operator time is available after detection of the leak to identify and isolate the source before the leak has any adverse effect on the ECCS.

To minimize the release of radioactive contaminants the reactor building floor drain sumps and drain headers are maintained at a negative pressure and vented through a filter system (see Section 9.4.2).

9.3.3.2.2.2 Turbine Building Floor Drains. Turbine building radioactive floor drains are collected in two sumps located in the turbine building (see Figure 9.3-10). Each sump is equipped with two sump pumps. Floor drain water collected in these sumps is pumped to the floor drain collector tank in the radwaste building for processing.

Level switches are provided in each sump to start and stop the sump pumps at predetermined levels. A mechanical alternator installed in each sump alternates the operation of each pump.

Drainage piping in this system is designed to Seismic Category II requirements.

9.3.3.2.2.3 Radwaste Building Floor Drains. Three sumps collect radioactive floor drains and equipment drains and overflows from equipment containing water of low purity (see Figure 9.3-11). Two of these sumps pump to the floor drain collector tank. The remaining sump, which collects drainage from the solid waste handling area, discharges to the waste sludge phase separator.

Level switches are provided in each sump to start and stop the pump at predetermined levels.

Drainage piping in this system is designed to Seismic Category II requirements and supported to Seismic Category I requirements.

9.3.3.2.3 Nonradioactive Water Drainage System

9.3.3.2.3.1 Turbine and Service Buildings. Equipment and floor drains from normally uncontaminated areas of the turbine building are collected in three sumps (see Figure 9.3-13). All these sumps are routed to the radwaste system for processing (see Section 11.2).

Level switches are provided in each sump to start and stop the pumps at predetermined levels.

Area floor drains and equipment drains collected by this system are as follows:

a. Operating floor (el. 501 ft 0 in.)

Air handling units (equipment drains)
Air handling wash pumps (equipment drains)
Instrument panels (equipment drains)
Air washers (equipment drains)
Clean area drains

b. Mezzanine floor (el. 471 ft.0 in.)

Clean area drains
Turbine oil coolers (cooling water drains)
HP fluid reservoir (cooling water drains)

c. Ground floor (el. 441 ft 0 in.)

Clean area drains
H_2 seal oil unit (cooling water drains)
Stator cooling water unit (equipment drain)
Main condenser water box (equipment drain)
Elevator pit drain
Auxiliary boiler blowdown tank (equipment drain)
Auxiliary condensate tank (equipment drain)
Service and instrument air compressors (equipment drain)

Equipment and floor drains in the service building are collected in a single sump containing two sump pumps. Water collected in the service building floor drain sump is pumped to the storm water drainage system.

Equipment and floor drains in the diesel generator building are routed to the storm water drainage system. Building roof drains are collected in branch lines which empty into a header prior to discharge to the storm water system.

Water collected by the storm water drainage system is conveyed by a concrete pipe to a point approximately 1500 ft northeast of the plant. The pipe discharges to lined evaporation ponds. Grab samples of the discharge are analyzed as part of the radiological environmental monitoring program (REMP). A composite water sampler was installed in late 1992.

9.3.3.2.3.2 Miscellaneous Drainage System. Liquid waste from curbed oil equipment areas are directed to separate oil sumps for collection and disposal. These areas are as follows:

a. Turbine lube oil storage and conditioning area, and
b. H_2 seal oil room.

Curbs are provided around fuel oil tanks, auxiliary boiler, and other equipment to contain spillage and prevent oil from entering drainage systems.

9.3.3.3 Safety Evaluation

Each of the sumps in the reactor, radwaste, turbine generator, and service buildings are provided with high-high level alarm signals. The sump pump starts operating on actuation of the high water level switch and shuts down on actuation of the low level switch. On sumps containing two pumps the standby pump is started when a high-high water level switch is actuated and an alarm is actuated. Both pumps shut down on actuation of the low level switch.

Sumps in the reactor building are provided with timers which initiate an alarm when the fill-up rate of a sump exceeds a preset value. These sumps serve as leakage monitors for the CRD

seals, the drywell equipment, the RCIC system, ECCS system, and other systems that support and protect the nuclear steam supply system.

Containment integrity is maintained in the transfer of liquid waste from the drywell sumps to the reactor building sump by a loop seal and isolation valves located outside the containment. These valves close on high containment pressure or low reactor vessel water level. In the reactor building, floor drain sumps that serve more than one ECCS equipment room isolate the rooms from one another on a high-high level sump signal that closes sump influent isolation valves.

In addition, if failure of the normal sump level detection and isolation system in the ECCS pump rooms should occur, a Class 1E leak detection system is installed (see Section 6.3).

9.3.3.4 Testing and Inspection Requirements

The equipment and floor drainage systems are in daily use and as such do not require periodic testing to ensure operability. Testing and calibration of the leak detection system components are discussed in Section 5.2.5.

9.3.3.5 Instrumentation Requirements

Sump pumps are equipped with run lights and elapsed time meters located on the radwaste control panel. High-high level alarms for the turbine and radwaste building sumps are also annunciated in the radwaste control room. Reactor building equipment drain sump temperature and reactor building sump level are monitored in the main control room.

9.3.4 CHEMICAL AND VOLUME CONTROL SYSTEM

Not applicable to BWRs.

9.3.5 STANDBY LIQUID CONTROL SYSTEM

9.3.5.1 Design Bases

The standby liquid control (SLC) system meets the following design bases:

a. Backup capability for reactivity control is provided, independent of normal reactivity control provisions in the nuclear reactor, to shut down the reactor if the normal control ever becomes inoperable. The SLC system equipment essential for injection of neutron absorber solution into the reactor is designed to Seismic Category I requirements (see Section 3.7). The system piping and

equipment are designed in accordance with the requirements stated in Sections 3.2 and 3.9;

b. The system has the capacity for controlling the reactivity difference between the steady-state operating condition of the reactor with voids and the cold shutdown condition, including shutdown margin, to ensure complete shutdown from the most reactive condition at any time in core life;

c. The system has the capability to inject sodium pentaborate solution into the RPV in response to a LOCA to control the pH in the suppression pool. Re-evolution of iodine from the suppression pool water can be minimized by maintaining the suppression pool pH level greater than 7.0.

d. The system meets the requirements of 10 CFR 50.62 for response to anticipated transients without scram (ATWS). System modifications have been done in conformance with the criteria presented in the BWR Owner's Group ATWS Licensing Topical Report, NEDE-31096-P, and in Generic Letter 85-06;

e. The time required for actuation and effectiveness of the SLC system is consistent with the nuclear reactivity rate of change predicted between rated operating and cold shutdown condition. This system is not safety related and is not designed to provide a fast scram of the reactor or operation of fast reactivity transients;

f. The functional performance capability of the SLC system components can be verified periodically under test conditions consistent with system operating parameters. In addition, demineralized water, rather than the actual neutron absorber solution, can be injected during cold shutdown or refueling into the reactor to test the operation of all redundant components of the system;

g. The neutron absorber is dispersed within the reactor core in sufficient quantity to provide a reasonable margin for leakage or imperfect mixing; and

h. The possibility of unintentional or accidental shutdown of the reactor by this system is minimized.

9.3.5.2 System Description

The SLC system (see Figure 9.3-14) is manually initiated through two keylock switches from the main control room to pump a boron neutron absorber solution into the reactor if the operator determines the reactor cannot be shut down with the control rods or suppression pool pH control is required to mitigate the dose consequences of a LOCA. The key locked switches prevent inadvertent injection of neutron absorber by the SLC system.

The two key locked switches are provided to ensure positive action from the main control room should the need arise. Standard power plant procedural controls are applied to the operation of the key locked control room switches.

The boron solution tank, the test water tank, the two positive displacement pumps, the two explosive valves, the two motor-operated pump suction valves, and associated local valves and controls are located in the reactor building.

The solution is piped into the reactor vessel and discharged into the core via the HPCS spray header so it mixes with the cooling water (see Section 5.3). In the event of a LOCA, the mixed solution and cooling water flows to the suppression pool by flowing through the break and downcomers.

The SLC system can deliver enough sodium pentaborate solution into the reactor (see Figure 9.3-15) to ensure reactor shutdown. As well, the SLC system can inject sufficient sodium pentaborate solution to ensure the pH in the suppression pool is maintained greater than 7.0 following a LOCA. The sodium pentaborate solution is prepared in the SLC tank. The sodium pentaborate enrichment is verified prior to addition to the SLC tank by isotopic analysis. The required sodium pentaborate concentration and solution volume in the SLC tank to ensure reactor shutdown capability is included in the Technical Specifications. An air sparger is provided in the tank for mixing. To prevent system plugging, the tank outlet is raised above the bottom of the tank. Samples for analyses are taken in accordance with approved procedures.

The saturation temperature of the solution is 67°F at the maximum concentration of 15.0% (see Figure 9.3-16). An automatic electrical resistance heater system provides heat to maintain the solution temperature greater than saturation conditions for sodium pentaborate to prevent precipitation during storage. The pump suction piping from the storage tank to the pump suction valves is also electrically heat traced. Administrative controls limit the solution temperature to less than 150°F during heatup and mixing using manual temperature control.

Liquid level in the storage tank is alarmed at either high level or low level.

The positive displacement pumps are sized to inject the solution into the reactor in approximately 1 hr with both pumps operating. The system design pressure between the pump discharge and the explosive valves is 1400 psig, at which pressure the two relief valves are set. To prevent bypass flow from one pump in case of relief valve failure in the line from the other pump, a check valve is installed downstream of each relief valve line in the pump discharge pipe.

The two explosive-actuated injection valves provide assurance of opening when needed and ensure that boron will not leak into the reactor even when the pumps are being tested. Each

explosive valve is closed by a plug in the inlet chamber. The plug is circumscribed with a deep groove so the end will readily shear off when pushed with the valve plunger. This opens the inlet hole through the plug. The sheared end is pushed out of the way in the chamber, and it is shaped so it will not block the ports after release.

The shearing plunger is actuated by an explosive charge with dual ignition primers inserted in the side chamber of the valve. The two ignition circuits of each explosive valve are monitored for continuity. If either circuit opens, a bypass and inoperable status indication (BISI) display occurs in the main control room.

The SLC system is actuated by two key locked switches on the main control room console. This ensures that switching from the "off" position is a deliberate act. Operating either switch starts one of the injection pumps, actuates both of the explosive valves, opens both pump suction motor-operated valves, and closes the RWCU system outboard isolation valve to prevent loss or dilution of the boron. (This is the sole purpose of this RWCU isolation. This isolation is not related to RWCU isolation to ensure containment integrity.)

A green light in the control room indicates that power is available to the pump motor contactor and that the contactor is deenergized (pump not running). A red light indicates that the contactor is closed to energize.

Storage tank liquid level, tank outlet valve position, pump discharge pressure, flow indication, and loss of continuity on the explosive valves indicate that the system is functioning. Cross piping and check valves ensure a flow path through either pump and either explosive valve. Pump discharge pressure and system flow is indicated in the control room.

Equipment drains and tank overflow are not piped to the radwaste system but to separate containers (such as 55-gal drums) that can be removed and disposed of to prevent any trace of boron from inadvertently reaching the reactor.

Instrumentation consisting of solution temperature indication and control, solution level, and heater system status is provided locally at the storage tank. The SLC system is seismically qualified from the storage tank (including the tank) to the injection point to the HPCS piping. Seismic category and quality class are included in Table 3.2-1. Principles of system testing are discussed in Section 9.3.5.4.

9.3.5.3 Safety Evaluation

The SLC system is a reactivity control system and is maintained in an operable status whenever the reactor is critical. The SLC system may also be used to maintain suppression pool pH above 7.0 following a LOCA and is maintained operable when critical or in hot shutdown.

The system is designed to bring the reactor from rated power to a cold shutdown at any time in core life. The reactivity compensation provided will reduce reactor power from rated to zero level and allow cooling the nuclear system to below 200°F with the control rods remaining withdrawn in the rated power pattern. It includes the reactivity gains that result from complete decay of the rated power xenon inventory. It also includes the positive reactivity effects from eliminating steam voids, changing water density from hot to cold, reduced doppler effect in uranium, reducing neutron leakage from boiling to cold, and decreasing control rod worth as the moderator cools.

The minimum average concentration of natural boron in the reactor to provide adequate shutdown margin, after operation of the SLC system, is 780 ppm. Calculation of the minimum quantity of sodium pentaborate to be injected into the reactor is based on the required 780 ppm average concentration in the reactor coolant, including recirculation loops, at 70°F and reactor normal water level. The amount is increased by 25% to allow for imperfect mixing and leakage. An additional 275 ppm is provided to accommodate dilution by the RHR system in the shutdown cooling mode. This concentration is achieved when the solution is prepared as described in Section 9.3.5.2 and maintained above saturation temperature.

The saturation temperature of the maximum concentration solution is 67°F. To ensure complete solubility of the solution, a tank operating heater is provided which turns on when the temperature drops below approximately 80°F. The tank heater turns off when the temperature increases to approximately 90°F.

Cooldown of the nuclear system requires a minimum of several hours to remove the thermal energy stored in the reactor, cooling water, and associated equipment. Use of the main condenser and various shutdown cooling systems requires 10 to 24 hr to lower the reactor vessel to room temperature (70°F); this is the condition of maximum reactivity and, therefore, the condition that requires the maximum concentration of boron.

To mitigate the consequences of an ATWS, the SLC system is capable of injecting the equivalent in reactivity control of 86 gpm at 13.0% (by weight) of sodium pentaborate solution per the requirements of 10 CFR 50.62. Each SLC pump injects at not less than 41.2 gpm at 13.6% concentration which is mathematically equivalent to 86 gpm at 13.0%. At this injection rate with only one pump, the solution is injected into the reactor in approximately 2 hr which provides negative reactivity insertion considerably quicker than the reactivity increase caused by the cooldown. The SLC injection path via the HPCS spray ring provides sufficient mixing so that any power oscillations are precluded. This same amount and concentration of boron, at the flow rate of a single pump is adequate to maintain the suppression pool pH greater than 7.0, when used in a LOCA.

The SLC system has redundant electrical components requiring AC power to actuate for sodium pentaborate solution injection. These divisional components are powered by separate safety-related AC divisions that are backed by onsite emergency diesel generators.

The SLC system and pumps have sufficient pressure margin, up to the system relief valve setting of approximately 1400 psig, to ensure solution injection into the reactor above the normal pressure in the reactor. The nuclear system safety/relief valves begin to relieve pressure at approximately 1100 psig. Therefore, the SLC system positive displacement pumps cannot overpressurize the nuclear system.

The SLC system is evaluated against the applicable General Design Criteria as follows:

Criterion 2:

The SLC system is located in the area outside of the primary containment and below the refueling floor. In this location, it is protected by walls from external natural phenomena such as earthquakes, tornadoes, hurricanes, and floods and also from the effects of internal postulated accident events.

Criterion 4:

The SLC system is designed for the expected environment in the compartment in which it is located. In this compartment, it is not subject to the conditions postulated in this criterion such as missiles, whipping pipes, and discharging fluids. The SLC system components are qualified in accordance with the CGS Equipment Qualification Program to operate in a post-LOCA environment for a minimum of 24 hours.

Criterion 26:

The SLC system is a backup reactivity control system for the normal reactivity control systems.

Criterion 29:

Although GDC 29 is not a design basis, certain valves outboard of the isolation valves are redundant. Two suction valves and two injection valves are arranged and cross-tied such that operation of either one of a pair results in successful operation of the system. The SLC system also has test capability. A special test tank is supplied for providing test fluid for the injection test.

Pumping capability and suction valve operability may be tested at any time. A trickle current continuously monitors continuity of the firing mechanisms of the injection squib valves.

Regulatory Guide compliance is described in Section 1.8.

This system is used in the special plant capability demonstration events, "Reactor Shutdown and Cooldown - ATWS" and "Reactor Shutdown and Cooldown Without Control Rods." These events are extremely low probability non design basis postulated accidents. Various single failure analytical exercises can be examined to show additional capabilities to accommodate further plant system degradations. See GE Topical Report NEDO-20626, dated October 1974, Studies of BWR Design for Mitigation of ATWS.

9.3.5.4 Testing and Inspection Requirements

Operational testing of the SLC system is performed in accordance with applicable Technical Specifications. The SLC system injection train components and piping are included in the CGS Inservice Inspection (ISI) and Inservice Testing (IST) Programs. The reactor must be in mode 4 or 5 before changing from the SLC system standby mode to the injection test mode.

The concentration of the sodium pentaborate in the solution tank is determined periodically by chemical analysis using samples taken directly from the tank. The sodium pentaborate enrichment is verified prior to addition to the SLC tank by isotopic analysis.

Should the boron solution ever be injected into the reactor, either intentionally or inadvertently, the boron can be removed from the reactor coolant system by flushing, followed by operating the RWCU system. There is practically no effect on reactor operations when the boron concentration has been reduced below approximately 50 ppm.

The SLC system preoperational test is described in Section 14.2.

9.3.5.5 Instrumentation Requirements

The instrumentation and control system for the SLC system is designed to allow the injection of neutron absorber solution into the reactor and to maintain the neutron absorber solution well above the saturation temperature. A further discussion of the SLC system instrumentation is provided in Section 7.4.1.2.

NOTES:
1. PIPING, VALVES AND ASSOCIATED COMPONENTS ON THIS DRAWING SHALL BE CLASSIFIED AS FOLLOWS (BREAK POINTS ARE INDICATED ON THE FLOW DIAGRAM):
A) WITHIN PRIMARY CONTAINMENT AND OUT THROUGH THE OUTERMOST PRIMARY CONTAINMENT ISOLATION VALVES:
SEISMIC CATEGORY I
QUALITY CLASS I
CODE GROUP B
B) PIPING BEYOND OUTERMOST PRIMARY CONTAINMENT ISOLATION VALVE EXCEPT CIA (5):
SEISMIC CATEGORY II
QUALITY CLASS II
CODE GROUP D
* HANGERS TO BE DESIGNED TO SEISMIC CATEGORY I LOADS
C) EQUIPMENT BEYOND OUTERMOST PRIMARY CONTAINMENT ISOLATION VALVE EXCEPT CIA (5):
SEISMIC CATEGORY II
QUALITY CLASS II
CODE GROUP D
* HANGERS TO BE DESIGNED TO SEISMIC CATEGORY I LOADS
D) CIA (3) AS NOTED, AND CIA (5) BEYOND OUTERMOST PRIMARY CONTAINMENT ISOLATION VALVE EXCEPT NITROGEN BOTTLES AND ASSOCIATED EQUIPMENT:
SEISMIC CATEGORY II
QUALITY CLASS II
CODE GROUP D
E) NITROGEN BOTTLES AND ASSOCIATED EQUIPMENT:
SEISMIC CATEGORY II
QUALITY CLASS II
CODE GROUP D
EXCEPT AS NOTED ON M619 INSTRUMENT CONNECTION DIAGRAMS.
2. ALL ITEMS MARKED WITH * ARE FURNISHED WITH ASSOCIATED EQUIPMENT.
3. (DELETED)
4. ALL INSTRUMENTS ON THIS DRAWING TO BE IDENTIFIED BY THE PREFIX "CIA" UNLESS SPECIFICALLY NOTED OTHERWISE.
5. ALL PRESSURE AND FLOW INSTRUMENT ROOT VALVES NOT LABELED WILL BE 3/4" GLOBE VALVES UNLESS SPECIFICALLY NOTED OTHERWISE.
6. FOR UNIQUE LINE NUMBERS NOT SHOWN SEE TABLES 1 AND 2 ON DWG M556-2.
7. ALL INSTRUMENT LINES ARE DESIGNATED BY CODE AND LINE NUMBER.
EXAMPLE: LINES ORIGINATING OUTSIDE CONTAINMENT:
1/2" P(1)-ST - (R-74)-4
CODE DESIGNATION LINE NUMBER
8. ALL FLEX HOSE ASSEMBLIES REFERENCED TO THIS NOTE ON THIS DRAWING SHALL BE CLASSIFIED AS:
SEISMIC CATEGORY I
QUALITY CLASS A
CODE GROUP COMMERCIAL **
** MATERIAL CERTIFICATION TO ASME OR ASTM REQUIRED
9. THE "I" HANDLE HAS BEEN REMOVED FROM CIA-PCV-2A AND CIA-PCV-2B. AFTER REGULATOR ADJUSTMENT, A SEAL WIRE SHALL BE RUN THROUGH THE ADJUSTING SCREW, SPROLLED DOWN AROUND THE VALVE BODY AND THE ENDS FIXED TOGETHER WITH A CRIMP OR SIMILAR SEAL.
10. DELETED
11. MOISTURE INDICATING CONTROLLER FEATURE HAS BEEN DEACTIVATED.
12. ALL LOW PRESSURE GAGES HAVE BEEN REMOVED FROM THE NITROGEN BOTTLE REGULATORS, THE PORT PLUGGED, AND THE GAGES RELOCATED DOWN STREAM OF THE BLEED/SHUT-OFF VALVES.
13. SEE DWG M501 FOR FLOW DIAGRAM LEGENDS, SYMBOLS AND ABBREVIATIONS.
LEGEND

GENERAL NOTES

1. ALL PROCESS PIPING (EXCLUSIVE OF PS & PSR LINE DESIGNATION) IS BY CONTRACT 2808-215 ALL TUBING (PS & PSR DESIGNATION) IS BY CONTRACT 2808-220.
2. (DELETED)
3. ALL SAMPLE LINES TO BE 1/4" O.D. X 0.035" WALL S.S. TUBING, EXCEPT AS NOTED.
4. SAMPLE PROBES SHALL BE INSTALLED IN 4" AND ABOVE PIPING ONLY. FOR PIPING BELOW 4", A PRESSURE TAP SHALL BE USED.

5. TYPICAL CONTRACT MATCH LINE FOR SAMPLE CONN'S SHALL BE AS FOLLOWS:

6. ROUTE STEAM SAMPLE LINE FROM LINE TAP, FOR AT LEAST 14 FEET BEHIND SHIELD WALLS BEFORE SAMPLE LINE ENTERS AN ACCESSIBLE AREA.
7. 3/8" PSR(1)-4S TUBING RUN FROM PENETRATION X-77 TO SR-1 IS ABANDONED IN PLACE.
8. SEE DWG. M610 FOR STEAM PROBE INSTALLATION DETAILS.
9. INSULATE FOR PERSONNEL PROTECTION ONLY.
10. SAMPLE PIPING TO BE QUALITY CLASS II AND SEISMIC CATEGORY CLASS II (EXCEPT WHERE NOTED) HEREIN AND ON M619, INSTRUMENT CONNECTION DIAGRAMS.
11. ▭ DENOTES SAMPLE RACK SERVICE NOZZLE CONN.
12. △ DENOTES SEQUENTIAL ORDER OF SAMPLE RACK INLET AND OUTLET SAMPLE CONNECTIONS AS SHOWN ON CVI 60A-00,1B & 60A-00,2T.
13. STRAINERS PS-ST-49A, & B ARE C.S. WYE TYPE, 1/2" NPT ENDS, 100 MESH SS STRAINER, 150 LB MINIMUM RATING.
14. RELIEF VALVES PS-RV-49A, B, CS BODY, 3/8 NPT ENDS, CORROSION-RESISTANT INTERNALS, SOFT SEAT.
15. PUMPS PS-P-49A & B TO BE INSTALLED BY CONTR 215
16. PUMPS COND-P-17A, B & C HAVE BEEN REMOVED ASSOCIATED PIPING DEACTIVATED AND SPARED IN PLACE.
17. ◯ DENOTES BULKHEAD NUMBER OF SAMPLE RACK INLET AND OUTLET SAMPLE CONNECTIONS AS SHOWN ON CVI 220-01,1422,B & 220-01,1442,L2.
18. AR-V-1 HAS BEEN MECHANICALLY GAGGED OPEN. (REF DWG D-ARV1GAC-488)

REFERENCES TO CONTRACT NUMBERS, SUCH AS 215, 206, 220, FOUND IN THIS NOTES ON THIS DRAWING REFER TO ORIGINAL CONSTRUCTION DESIGN REQUIREMENTS.

CURRENT DESIGN REQUIREMENTS ARE DOCUMENTED IN THE STATION DESIGN SPECIFICATIONS AND ACTIVE CONTRACT SPECIFICATIONS WHICH STILL APPLY

9.4 HEATING, VENTILATING, AND AIR CONDITIONING SYSTEMS

The various heating, ventilating, and air conditioning (HVAC) systems serving the plant are designed to provide suitable environmental conditions throughout the plant for personnel comfort and/or equipment operation.

The following performance objectives are implemented in the design of the HVAC systems:

a. Maintain appropriate ambient temperature and humidity conditions for station operating personnel and equipment,

b. Control and monitor all potentially radioactive airborne releases from the plant so that releases are within the limits of 10 CFR Part 20,

c. Control and limit airborne radioactive contaminants within the plant structures by inducing air flow from areas of low contamination potential into areas of progressively higher contamination potential, and

d. Remove all potentially explosive gases, noxious fumes, or smoke from the plant.

In addition, a number of HVAC systems are required to ensure a safe shutdown of the reactor or to mitigate the results of the design basis accident. These systems are designed to continue operation in the event of any or all of the following events:

a. Safe shutdown earthquake (SSE),
b. Loss of offsite power,
c. Single failure of any active component, and
d. Design basis accident.

The effect of a loss of normal ventilation during a station blackout is discussed in Appendix 8A.

The following areas containing engineered safety features (ESF) equipment are serviced by critical HVAC systems:

a. Main control room/cable spreading room/critical switchgear area,
b. Diesel generator building,
c. Standby service water (SW) pump houses,
d. Reactor building emergency pump rooms,
e. Reactor building critical electrical equipment rooms, and
f. Diesel generator cable area corridor.

The balance of the plant structures are serviced by noncritical HVAC systems.

The following outdoor design conditions are used in the design of HVAC systems having ESF:

Summer:	105°F dry-bulb, 71°F wet-bulb
Winter:	0°F dry-bulb

The extreme outdoor conditions are:

Summer:	115°F dry-bulb
Winter:	-27°F

The effect of these extreme outdoor conditions on main control room/cable spreading room and critical switchgear area temperatures is negligible for the frequency and duration of these conditions since the rooms are interior rooms and the total load changes due to fresh air (maximum 5% of total air flow for control room and maximum 10% of total air flow for critical switchgear area) are within equipment capacity limits for maintaining inside design conditions. The mechanical equipment rooms housing these three systems are of extra heavy exterior wall and roof construction and the effect of extreme outside conditions is considered to be negligible for the frequency and duration of these extremes.

Extreme outside conditions have no effect on reactor building emergency pump rooms and reactor building critical electrical equipment rooms since these are interior rooms without any outdoor air supply during emergency. During normal operation the emergency pumps are not running and the critical electrical equipment is operating at a reduced load. The battery rooms are provided with room heaters to prevent excessive cooling from SW that could affect battery capacity.

The effect of extreme outdoor conditions on the diesel generator building ventilation system, diesel generator area cable cooling system, and SW pump house ventilation systems is discussed in Sections 9.4.7, 9.4.8, and 9.4.10 respectively.

9.4.1 MAIN CONTROL ROOM/CABLE SPREADING ROOM/CRITICAL SWITCHGEAR AREA

9.4.1.1 Design Bases

The critical switchgear area, cable spreading room, and main control room are located, one above the other, on three successive levels of the radwaste building, with the main control room on the top level. Each level is served by a separate HVAC system. Redundant HVAC systems are provided for the main control room and the cable spreading room. These three systems are ESF systems and all system components, except the radwaste building chilled water system (WCH) (see Section 9.4.4) to the control room, cable spreading room and critical

switchgear area systems, and the plant service water (TSW) system to the switchgear area system, are designed to operate under all emergency modes. During an emergency condition, the SW system is used as the cooling medium for the cable spreading room and switchgear area systems. The control room chilled water (CCH) system, or SW system when capable of the required heat removal, is used as the cooling medium for the control room HVAC system during emergency conditions.

The three systems are designed to satisfy the following design criteria:

a. Main control room

During normal operation the main control room ambient conditions are normally maintained at 75°F ±3° dry-bulb temperature by the radwaste chillers. In the event both radwaste chillers are inoperative (emergency condition), the control room temperature will be maintained to ensure 30 days continuous occupancy of the control room and ensure the equipment qualification temperature limit is not exceeded. The control room habitability design condition is 85ºF with a sustained occupancy of 10 persons. The equipment qualification temperature limit for equipment cooled by the control room HVAC system is 104ºF. The CCH system is the preferred cooling source to the control room HVAC system, however, SW is an acceptable alternate cooling source when evaluated as capable of maintaining the bounding 85ºF long term steady state control room temperature. The ingress of smoke or combustion vapors (due to a fire within the plant but external to the control room), or of airborne radioactive contaminants released due to the design basis accident, is minimized by pressurizing the control room. During a loss-of-coolant accident (LOCA), the control room emergency pressurization mode through the emergency filter unit maintains a positive pressure with respect to its surroundings as measured in the cable spreading room.

Three air intakes are provided from which fresh air can be drawn. One local intake is provided for normal operation and two remote intakes are provided for normal and emergency operation. Fire external to the plant and any ingress of smoke or combustion vapors are detected by smoke detectors in the control room fresh air intake ducting, which will alarm in the control room.

Isolation of the control room fresh air intakes would place the control room HVAC in an unfiltered recirculation mode. In the event of a hazardous chemical release, the control room HVAC is manually isolated into the recirculation mode without filtration through the emergency filter units by closing the normal fresh air isolation damper.

b. Cable spreading room

The cable spreading room HVAC system is designed to maintain the cable spreading room and the remote shutdown room at approximately 80°F during

normal operation and to limit the temperature below equipment operability limits during all emergency modes of operation. See Table 3.11-1.

c. Critical switchgear area

The critical switchgear area HVAC system is designed to maintain temperatures in the electrical rooms between 55°F and 104°F during normal operation and to limit the temperatures below equipment operability limits during all emergency modes of operation. See Table 3.11-1. The system is also designed to remove any combustible fumes generated by the emergency batteries.

9.4.1.2 System Description

The HVAC systems of the main control room, cable spreading room, and critical switchgear areas are shown in Figure 9.4.1-1 through 9.4.1-3. The HVAC systems for these three areas are located in equipment rooms above the main control room. These two equipment rooms are separated from each other by a missile barrier. Each equipment room houses three separate and independent systems serving the three areas. Equipment details are given in Table 9.4-1. Equipment seismic information is given in Table 3.2-1.

9.4.1.2.1 Main Control Room

Each of the main control room's 100%-capacity HVAC systems are composed of a primary air handling system and an emergency filter system. The two HVAC systems share a common outside air intake system and a common duct distribution system within the main control room. A single exhaust system, composed of a fan, shutoff damper, and ductwork, discharges air from the main control room toilet and kitchen. The exhaust fan operates continuously during normal operations.

Each primary air handling system consists of a centrifugal supply fan which blows through an air handling unit consisting of an air filter, two water cooling coils in series (one normal use coil for radwaste chilled water and one emergency use coil for control room chilled water or SW), and an electric blast coil heater and associated ductwork and dampers.

Separate return air ductwork containing a sound absorber unit is provided from the main control room to each of the primary air handling systems.

During normal operation one air handling system operates, distributing air to the main control room. The temperature is controlled by electronic controllers located in the main control room which modulate the radwaste chilled water flow to the cooling coil.

Chilled water is normally supplied to the main control room air handling systems by the WCH. The WCH, which includes two 100%-capacity chillers and two 100%-capacity pumps is not an

ESF. During emergency conditions, CCH water is supplied to the air handling unit emergency cooling coil for control room cooling. The CCH system is normally in standby alignment for emergency use and is manually initiated. The CCH system is capable of maintaining the control room below the control room habitability design condition of 85ºF which also bounds the 104ºF equipment qualification temperature limit for the control room. SW can be used as an acceptable alternate emergency cooling source when CCH is unavailable and when SW is evaluated as capable of maintaining the bounding 85ºF long term steady state control room temperature.

The two 1000-cfm capacity filter systems are normally in standby and operate in the event of an emergency (F, A, Z signal). Each of the emergency filter systems consists of an emergency filter unit, a 5-kW electric heater, bypass and recirculation control dampers, and associated ductwork. Each emergency filter unit consists of a medium efficiency prefilter, high efficiency particulate air (HEPA) filter, activated charcoal filters, and direct drive centrifugal fan, all enclosed in an all-welded sheet metal housing. A deluge water spray system is provided to soak the charcoal filters in the event of high temperatures in the charcoal beds. Check valves are provided on all drain connections from the filter unit, and the drain header is provided with a deep water seal trap to prevent inleakage of air during unit operation. The electric heater located in the fresh air duct to each emergency filter limits the relative humidity of the air entering the filter to 70%.

The medium efficiency prefilters are provided to protect and extend the life of the HEPA filters. They have an 80% to 85% dust spot efficiency by ASHRAE Standard 52.1 (MERV 13 rating by ASHRAE standard 52.2).

Regulatory Guide 1.52 compliance is described in Section 1.8.

Motor-operated outside air intake (bypass) dampers WMA-AD-51A-1 and 51B-1 are spring-loaded fail-closed type and are provided with limit switches to indicate full open and full closed positions on the main control room panel. Each damper is provided with a remote manual switch in the main control room. Dampers are automatically closed when deenergized by isolation signal or by the main control room panel-mounted switch. These dampers have a design leak rate of 0.5% of the rated flow. Main control room supply fan inlet pressure is higher than the emergency filter unit fan; therefore, when the emergency filter unit is operating, a negative pressure is developed on the inlet side of the bypass dampers preventing any contaminated air bypass of the emergency filter unit. In the event that either bypass damper does not close, an alarm will be activated in the main control room.

The three fresh air intakes (one normal and two remote) for the main control room are fitted with two butterfly isolation valves in series. The normal control room fresh air local intake valves are automatic isolation valves which isolate on an F, A, or Z signal. The normal fresh air intake valves have electrohydraulic operators which are powered from the Class 1E buses. All fresh air intakes are connected via ductwork to a common intake header from which both main control room air handling systems and both emergency filter systems draw fresh air. The isolation valves in the purge lines and the normal air intake and position indication on all fresh

air intakes, the emergency filter units, and the bypass dampers that direct fresh air through the emergency filter units are division oriented electrically.

The remote air intake valves are manual, and the design is simple and reliable enough that the valve may be manually repositioned in a short period of time.

In the event of a LOCA, the main control room is protected from potential airborne radioactivity by pressurizing the control room with air supplied via the remote air intakes. The system operates in the following manner:

The isolation valves in the normal fresh air intake are closed by any of the F, A, or Z signals. These are the same signals provided for isolating the primary and secondary containments.

Both sets of remote air intake isolation valves are normally locked open. At least one air intake must be maintained open to ensure the control room is pressurized.

The two purge exhaust systems each consists of two isolation valves in series. One purge valve is equipped with an electrohydraulic operator and is interlocked with its remote intake valve, and the other purge valve is maintained open.

Both purge exhaust systems utilize battery exhaust fans WEA-FN-53A and WEA-FN-53B (which are both ESF) to purge air from the remote intake headers.

Both battery exhaust fans provide the necessary redundancy through cross over ductwork between each set of purge exhaust valves.

The emergency filter units are energized by F, A, Z signals and all outdoor pressurizing air is automatically diverted through the filter units. The main control room kitchen exhaust fan and its isolation damper are also shut off by F, A, Z signals.

Operating in the above manner ensures that the main control room is continuously pressurized with filtered air. The details of the control room dose analysis are discussed in Sections 15.4.9, 15.6.4, 15.6.5 and 15.7.4.

9.4.1.2.2 Cable Spreading Room

The cable spreading room HVAC system consists of two 100%-capacity air-handling units, each with its own duct distribution system, common distribution system inside the cable spreading room, and one purge exhaust fan. The air handling units are similar to those servicing the main control room, i.e., filter, SW coil, chilled water coil, electric heater, and centrifugal fan in the sheet metal housing. Normally one air handling unit operates continuously on a 100% recirculation mode of operation maintaining the cable spreading room and remote shutdown room at approximately 80°F.

The cable spreading room purge exhaust fan does not normally operate. In the unlikely event of fire developing in the cable spreading room, the purge fan can be manually operated to remove any smoke from the cable spreading room prior to personnel access.

If the radwaste chilled water supply to the cable spreading room air handling units is lost, SW is supplied to the units for emergency cooling. Under this mode of operation the cable spreading room and remote shutdown room temperature is limited below equipment operability limits. See Table 3.11-1.

9.4.1.2.3 Critical Switchgear Area

The switchgear and batteries associated with the redundant emergency electric power systems are located in separate equipment rooms below the cable spreading room. A separate heating and ventilation system is provided for each set of equipment rooms. Ventilation of the emergency chiller area at the 525 ft level is also provided by this system. Each of the two heating and ventilating systems consists of an air handling unit, battery room exhaust fans and associated ductwork and controls. The air handling unit consists of a roughing filter, two water coils in series (one for WCH or plant service water, one for SW), an electric blast coil heater, and a centrifugal fan in a sheet metal housing. The two air handling units have different capacities due to heat load differences between the two sets of rooms. Electric heaters are provided in the ducts supplying air to the battery rooms to maintain temperature in those rooms above 60°F.

Both heating and ventilating systems normally operate continuously during all modes of operation. They are both partial recirculation systems with fresh air provided as makeup for the air exhausted from the battery rooms. The battery rooms are continuously exhausted (no recirculation) to prevent the possible buildup of combustible gases generated by the batteries. During normal operation, either WCH or plant service water is provided to the air handling units as the cooling medium.

Under all emergency modes of operation SW is provided to both units as the cooling medium. The critical switchgear area air handling units also provide the normal and emergency ventilation for the HVAC equipment rooms and the emergency chiller area at the 525 ft level. Temperatures in the HVAC equipment rooms are limited to a range of 55°F to 104°F during normal operation and below equipment operability limits during all emergency modes of operation. See Table 3.11-1.

9.4.1.3 Safety Evaluation

9.4.1.3.1 Main Control Room

The reliability of the HVAC system serving the main control room is achieved by providing two 100% redundant trains. Only one of the two redundant trains is required to operate to provide adequate cooling and dose mitigation. The two HVAC trains are physically separated to preclude simultaneous failure from any one incident. These HVAC trains are cooled

normally by the non-safety related Radwaste Building Chilled Water (WCH) System. During an emergency, the HVAC trains are cooled by the CCH system, or can be cooled by the SW system when CCH is unavailable and the SW is evaluated as capable of the required heat removal. All components of the two HVAC trains and the SW and CCH cooling systems are designed to withstand the effects of a SSE and are powered from emergency diesel buses. The emergency chillers are located in a general area. During initial licensing the emergency chillers were installed as directed in License Condition 2.c.(21) of the Operating License. The emergency chillers were required to be redundant, Seismic Category I, and environmentally qualified.

The CCH system is normally aligned for emergency standby service. The CCH system is manually started post-accident upon a loss of normal control room cooling. Analyses were performed to evaluate control room heat up without cooling, acceptable temperature levels/stay times for operators, and time available to bring cooling back online. The results demonstrated that temperatures would not exceed acceptable limits during manual operation. At no time will the control room exceed the 104ºF equipment qualification temperature limit. Prior to start of the CCH system, the control room may temporarily exceed the steady state habitability temperature of 85ºF but would remain below the National Institute for Occupational Safety and Health wet-bulb globe temperature for unlimited duration habitability (Reference 9.4-1).

The normal fresh air intake is provided with two division oriented valves (normally open, fail closed) in series to close in the event of an F, A, Z signal. The valves are a highly reliable butterfly-type with the disc keyed to the pivot shaft. If one of the remote air intake isolation valves should fail it may be easily repositioned or repaired. One remote intake will always remain open to ensure a pressurized control room and prevent infiltration.

The remote fresh air intakes are used to pressurize the main control room through emergency filter units. This limits infiltration of airborne radioactive contaminants and smoke due to a fire within the plant but external to the control room. Infiltration of airborne radioactivity in the main control room is discussed in Section 6.4.

The emergency filter unit starts operating in the event of a LOCA.

The main control room is maintained at 75 $\pm$3°F dry-bulb temperature under normal conditions. In the event of an emergency, the control room will be cooled by CCH. When CCH is unavailable, SW can be an acceptable alternate cooling source when evaluated as capable of maintaining the bounding 85°F long term steady state control room temperature.

9.4.1.3.2 Cable Spreading Room

The cable spreading room is provided with two 100%-capacity HVAC systems which are physically separated. All components of the two systems, except the chilled water system, are designed to operate through the SSE and are powered from emergency diesel buses. As with the control room HVAC system, SW is used as the cooling water for the cable spreading room

handling units to maintain an acceptable temperature in the cable spreading room for equipment operation in the event that the chilled water system is inoperable.

9.4.1.3.3 Critical Switchgear Area

The essential electric equipment for each of the redundant emergency diesel generators is serviced by separate heating and cooling systems. Each system is powered from a Class 1E bus which is supplied by the diesel generator it serves and is designed to operate through an SSE.

Standby service water is used as the system cooling medium whenever WCH or plant service water are not available, thus ensuring cooling during all modes of plant operation. The two systems are physically separated and arranged in such a manner that the failure of one system can affect only the diesel generator that it services.

9.4.1.4 Testing and Inspection Requirements

The performance of the HVAC systems servicing the main control room, cable spreading room, and critical switchgear areas can be verified while the systems are operating. The operability and performance of standby equipment is determined by alternating the duty of redundant systems.

The control room system ductwork was subject to leak tests during erection and was balanced for air flows in accordance with the procedures of the Associated Air Balance Control Council (AABC). All system components were subject to preoperational testing. All piping systems components were subject to hydrostatic tests during erection.

The emergency filter housings and filters were subject to both shop and field efficiency tests.

The HEPA and charcoal adsorber filters are periodically tested as required by the Technical Specifications. Charcoal samples laboratory test results are required within 31 days of removal.

9.4.1.5 Instrumentation Requirements

All essential controls for the control room, cable spreading room, and critical switchgear area HVAC systems are electric or electronic except the remote air intake isolation valves. Pneumatic controls are used only on nonessential components.

9.4.1.5.1 Main Control Room

The following controls are provided in the main control room in addition to those discussed in Section 9.4.1.2.1.

Both air handling systems serving the main control room can be started from separate selector switches located in the main control room. When an air handling unit fan is started, all

controls associated with that system are energized via electrical interlocks initiating the following operations:

a. The fresh air intake damper is opened, and

b. The electronic thermostat in the main control room modulates the radwaste valve and energizes the two stages of electric heaters, as required, to satisfy the heating/cooling requirements of the main control room. (The heater breakers are normally locked open in modes 1, 2, and 3.)

In the emergency condition (loss of radwaste building chilled water during a design basis accident), the emergency cooling coils in the HVAC air handling units are supplied from the CCH system. The CCH system is manually initiated. The HVAC air handling unit recirculation fans auto-start on a F, A, Z signal. During a LOOP event, the recirculation fan that had been running will restart upon its associated diesel generator start. The control room operator will re-establish control room cooling from the control room, however, local field operation at the CCH chiller is required to load (adjust) the chiller to obtain the required heat removal. No valve manipulations are required to initiate control room cooling using the CCH system when it is maintained in the standby emergency cooling configuration.

Use of the SW system to provide cooling, in lieu of the CCH system, and when evaluated as capable of the required heat removal, requires local valve manipulations to isolate the CCH system supply and align SW to the HVAC air handling unit emergency cooling coil. To support the use of SW, valves SW-V-104C(D) and SW-V-106C(D) on the outlet of the air handling unit emergency cooling coils will be throttled to provide a minimum 125 GPM SW flow rate through the air handling unit coils.

Control switches are provided in the main control room for all fans, local air intake isolation valves, and dampers so that all components can be controlled manually as well as automatically. The remote air intake isolation valves are manual valves.

9.4.1.5.2 Cable Spreading Room

The air handling units serving the cable spreading room are started from separate selector switches located in the main control room. When an air handling unit fan is started, an associated solenoid valve is energized permitting the air handling unit pneumatic chilled water control valve and electric heating coils to receive a pneumatic control signal from a temperature controller sensing temperature in the air return duct from the cable spreading room (the heater breakers are normally locked open in modes 1, 2, and 3). The starting of the fan also energizes the air handling automatic roll filter control circuit permitting the filter drive motor to change media at selected preset timer intervals. Redundant temperature switches located in the cable spreading room will annunciate alarms in the main control room in the event of a temperature rise to 90°F thus alerting the operator of a possible equipment

malfunction. A differential pressure switch across the air handling unit filter will alarm in the event of high differential pressure.

Smoke detectors in the cable spreading room return air ducts annunciate alarms in the main control room in the event of smoke so that the operator can activate the fire protection system (see Appendix F).

There are no control valves associated with the SW coils in the cable spreading room units. Whenever SW is on, there is full water flow through the coil. During normal operation any heat added to the space by the SW coil is compensated for by the air handling units chilled water coil.

9.4.1.5.3 Critical Switchgear Area

The two air handling units and the two battery room exhaust fans which service the critical switchgear area each have their own selector switch located in the main control room. When an air handling unit fan is started, an associated solenoid valve is energized permitting the air handling unit pneumatic plant service water valve and electric heating coils to receive a pneumatic control signal from a temperature controller sensing temperature in the supply air duct to the critical switchgear area. The temperature controller is set to maintain the temperature as described in Table 3.11-1. The starting of the fan also energizes the air handling unit automatic roll filter control circuit, permitting the filter drive motor to change media at selected preset timer intervals.

Temperature switches located in each of the electrical equipment rooms serviced by the critical switchgear system annunciate alarms in the main control room in the event of abnormally high temperatures thus alerting the operator of a possible malfunction of the cooling system. Smoke detectors in the main return air ducts to the air handling unit and in the battery room exhaust ducts will annunciate alarms in the main control room in the event of fire in the switchgear area. Differential pressure switches across each of the battery room exhaust fans and across the filter of the air handling units will annunciate alarms in the main control room in the event of low differential pressure across fan or high/low differential pressure across filter.

As with the cable spreading room air handling units, there are no control valves associated with the SW coils in the switchgear area units. Whenever SW is on, there is full water flow through the coil.

9.4.2 REACTOR BUILDING

9.4.2.1 Design Bases

The reactor building, or secondary containment, is provided with a HVAC system designed to meet the requirements for all general areas of the building, the spent fuel pool, potentially contaminated areas and the primary purge as follows.

a. To provide fresh, tempered, ventilating air to the various spaces in the reactor building in sufficient quantity to limit the temperature during all normal operating conditions and/or during loss of ac power as specified in Table 3.11-1, while providing at least one air change per hour in all areas;

b. To draw air across the surface of the spent fuel pool, reactor well, and dryer/separator pool by exhausting around their perimeters to control temperature and to maintain airborne radioactivity within acceptable levels in these spaces;

c. To provide for controlled air movement from areas of potentially low radiation to areas of potentially high radiation. This serves to isolate and segregate airborne radioactivity which may be released due to equipment failure or malfunction. The system is designed to preclude recirculation of reactor building air under normal operating conditions;

d. To maintain the reactor building during normal operation at a negative pressure of 0.25 in. w.g. with respect to atmosphere as indicated at the reactor building el. 572 ft to minimize release of airborne radioactive material. During emergency operation, the standby gas treatment (SGT) system (see Section 6.5) maintains the reactor building at a negative pressure;

e. Maintain the reactor building equipment drain sumps and headers at a negative pressure with respect to the rest of the reactor building, and provide means to filter the effluent before discharging it to the main reactor building exhaust header so that the release of radioactive contaminants is minimized;

f. Provide means to monitor all effluent from the reactor building prior to release for radioactive contamination and to isolate all ventilation openings in the building in the event that radiation levels so monitored exceed the limits defined in 10 CFR Part 20; and

g. In addition, the reactor building ventilation system is designed to provide for purging of the primary containment. Primary containment purge air is supplied and exhausted by the reactor building ventilation system.

Except for the emergency cooling system which is described in Section 9.4.9, the only portions of the reactor building heating and ventilating system which are designed as ESF are the isolation valves located in the outdoor air intake duct and the exhaust system discharge duct, and the isolation valves on the purge connections to the primary containment. The reactor building isolation valves are designed, manufactured, and N-stamped Class 3 in accordance with Section III of the ASME Boiler and Pressure Vessel (B&PV) Code. The primary containment purge isolation valves are N-stamped Class 2 in accordance with

Section III of the ASME B&PV Code. All isolation valves are Seismic Category I. The means of protecting the system vents and louvers from missiles is discussed in Section 3.5.

9.4.2.2 System Description

The reactor building heating and ventilating system is shown in Figure 9.4-2. The system is basically a "push-pull" heating and ventilation system providing once-through air flow with no recirculation and consists of the following systems:

a. Supply air,
b. Exhaust air,
c. Sump vent exhaust filter,
d. Emergency cooling (described in Section 9.4.9), and
e. Miscellaneous ventilation.

Equipment details are given in Table 9.4-2. Equipment seismic information is given in Table 3.2-1.

9.4.2.2.1 Supply Air System

The supply air consists of a heating and ventilation unit, air distribution ductwork, two isolation butterfly valves on the fresh air intake, and associated controls. The heating and ventilation unit is composed of the following elements in an insulated housing:

a. An automatic roll type prefilter,

b. Steam coils with face and bypass dampers,

c. A capillary type, evaporative cooling section with two 100%-capacity spray pumps, and

d. Two 100%-capacity vaneaxial fans with back draft dampers on the fan discharges.

During normal plant operation and shutdown, the supply air system isolation valves are open and the ventilation system operates continuously distributing tempered, 100% outdoor air throughout the building. One supply fan is normally operating with the second fan in standby. The standby fan starts automatically in the event the operating fan fails. During winter months, the steam coil in the ventilating unit heats the supply air. A second steam booster heater in the supply duct to the refueling floor heats the air to maintain the refueling floor area. (See Table 3.11-1 for temperature limitations.) During summer months, the capillary type air washer cools the incoming air by evaporative cooling. Water for this air washer is supplied from the potable water system (see Section 9.2.4).

The reactor building supply air system also provides makeup air to the primary containment during primary containment purge if needed. During purge, supply air is directed into the primary containment through the isolation valves. The purge supply air flow rate is controlled by an air operated directing damper in the supply system ductwork which is set manually from the main control room. A backdraft damper is provided in this purge line and is counterweighted so that the pressure drop across the backdraft damper in the open position, does not exceed 0.25 in. w.g.

9.4.2.2.2 Exhaust Air System

The reactor building exhaust system draws air from all areas with potential radiation contamination and discharges it to the elevated release point. There are two 100%-capacity vaneaxial fans in the system. One fan normally operates with the second fan in standby.

Approximately one-half of the reactor building exhaust air is drawn from the refueling level of the reactor building. Intake ducts to the exhaust system are embedded around the periphery of the spent fuel pool, dryer/separator pool, and reactor well to remove any potentially radioactive vapors generated in the pools. Volume control dampers in the ducts from each pool are controlled from a local panel in the reactor building to permit the operator to vary the flow over each pool during various fuel handling operations.

Primary containment purge can be performed by discharging the purge air through the reactor building exhaust system or through the SGT system (see Section 6.5). Ducts connect the primary containment drywell and suppression pool area with both systems. The reactor building exhaust system is normally used for purge after the SGT system is used for the first 24 hr. The SGT system is also used when an unacceptably high level of airborne radioactivity is present inside the primary containment.

Radiation monitors are located just outside of the air plenum on the intake side of the two reactor building exhaust fans. In the event that a preset high level limit of radioactivity is exceeded, the radiation monitors will annunciate an alarm in the main control room and transmit an isolation signal to the affected emergency safeguards systems. In the event of an F, A, or Z signal, the reactor building exhaust fans stop and the isolation valves close. All isolation signals which stop and isolate the reactor building exhaust system also start the SGT system (see Section 6.5.1).

9.4.2.2.3 Sump Vent Exhaust Filter System

All potentially radioactive leaks and/or spills in the reactor building are channeled to the equipment and/or floor drain systems. To minimize the release of radioactive contaminants from the building, the drain system sumps and drain headers are maintained at a negative pressure and vented through a filter system. The sump vent exhaust system is composed of

two, full-capacity, filter units which draw air from the sumps and drain headers and pass it through filters, a moisture separator, and electric heater before discharge to the main reactor building exhaust system upstream of the radiation monitors.

Each filter unit consists of the following elements in a sheet metal housing:

a. A moisture separator to remove entrained moisture,

b. An electric blast coil heater to limit the relative humidity of the air entering the filter to 70%,

c. A medium efficiency particulate prefilter,

d. A HEPA filter,

e. A tray type, 2-in.-thick activated charcoal filter, and

f. A centrifugal fan.

All filters in the sump vent exhaust units are designed to satisfy the same efficiency requirements as those of the control room emergency filter units outlined in Section 9.4.1.2.1. One filter unit operates continuously during normal plant operation. The standby unit is started from the main control room in the event that the fan of the operating unit fails. Neither unit operates in the event of a reactor building isolation signal. Deluge fire protection is provided for each filter unit (see Appendix F).

9.4.2.2.4 Miscellaneous Area Ventilation Systems

The following miscellaneous HVAC systems are provided to service local areas in the reactor building:

a. The main steam tunnel is serviced by three fan coil units located within the tunnel. Three fan coil units are composed of a water cooling coil supplied by the plant service water system and a direct drive centrifugal fan in a sheet metal housing. Two fan coil units normally operate continuously in the recirculation mode to remove heat generated by the steam piping in the tunnel. Two fan coil units operating has sufficient capacity to limit the temperature in the tunnel to 130°F with one fan coil unit in standby.

b. The reactor water cleanup (RWCU) sample hood is provided with an exhaust filter unit which is operated whenever a sample is taken. The hood is of the air curtain type with supply air to the hood provided from the reactor building supply air system. An electric duct heater is provided in the supply air duct to

temper the air into the hood to 70°F. The exhaust filter unit, which draws air from the hood, is composed of a medium efficiency prefilter, a HEPA filter, and a centrifugal fan in a sheet metal housing. The exhaust fan discharges air into the reactor building exhaust system upstream of the radiation monitors.

c. The vehicle air lock (railroad bay), on grade elevation, is heated and cooled by an air handling unit which operates in a 100% recirculation mode. The air handling unit is composed of a prefilter, water cooling coil, and centrifugal fan in a sheet metal housing. A 15-kW electric blast coil heater is provided in the unit discharge duct for heating. Plant service water is supplied to the water coil for cooling.

During periods when the large railroad lock door (R106) is open for operations associated with the Independent Spent Fuel Storage Installation (ISFSI), or other activities requiring the door to be open for an extended period, engineered features are available to maintain the railroad lock at temperate conditions. Eight thermostatically controlled heaters are installed near the door, and an air curtain is installed above the door. These supplemental heaters, used in conjunction with the air curtain, keep the railroad lock warm during winter conditions when the door is open.

9.4.2.3 Safety Evaluation

The following safety features are incorporated in the design of the reactor building ventilation system:

a. The air distribution within the building provides for controlled air movement from areas of potentially low radiation to areas of potentially high radiation. Under normal operating conditions, recirculation of contaminated air is precluded by system design.

b. There are only two penetrations of the reactor building associated with the building ventilation system. Two butterfly valves in series are provided in the duct connections to each of these ventilation openings. The four valves close, isolating the reactor building, and the ventilation system fans stop in the event of any of the F, A, Z isolation signals.

The redundant, fail-closed valves on each ventilation opening ensure reactor building isolation in the event of failure of any one valve.

Two fail-closed, air-operated isolation valves, in series, are also provided on all purge connections to the primary containment. These valves are open only

during primary containment purge operations and close automatically in the event of any of the above isolation signals.

c. The reactor building is maintained at a negative pressure of 0.25 in. w.g. with respect to atmosphere by differential pressure controllers which position the blade settings of the exhaust fans. This atmospheric control limits the exfiltration of radioactive contaminants from secondary containment. See Section 6.5.1 for emergency operation of the SGT system which maintains the reactor building at a negative pressure under postulated accident conditions. Each set of main supply and exhaust fans are powered from different divisions of the Class 1E power supply.

d. Radiation monitors, located just outside of the exhaust air discharge plenum, monitor exhaust air discharged from the building and transmit an isolation signal in the event that the radiation level exceeds a preset level. See Chapter 11 for further discussion of radiation monitoring.

e. The equipment drain system sumps and headers are vented through two 100%-capacity filter units. This operation minimizes the release of radioactive material during normal plant operation. Two 100%-capacity redundant filter trains ensures continuous system operation in the event of any single component failure.

f. Each ventilation header with embedded exhaust duct connections around the spent fuel pool, reactor well and dryer/separator pool is equipped with a flow transmitter and flow indicator to ensure that the designed quantity of air is being exhausted for proper airborne contamination control. See Figure 9.4-2.

9.4.2.4 Testing and Inspection Requirements

The performance of the HVAC systems servicing the reactor building can be verified while the systems are operating. The operability of standby equipment is determined by rotating the duty of the redundant components.

The performance of those portions of the exhaust system which serves the fuel pool can be verified by measuring air flow in the fuel pool exhaust system exhaust header. A damper located in the fuel pool exhaust header controls this air flow. The flow indicator and damper controller are mounted on a local panel in the reactor building.

All system ductwork was balanced for air flows in accordance with procedures of the AABC. All system components were subject to preoperational testing to verify that the system functions in accordance with the design requirements. All piping systems and components were subject to hydrostatic and/or pressure tests during erection. Primary containment purge

system isolation valves are normally closed and are leak tested in accordance with the Technical Specifications.

The sump vent exhaust system filter housings and filters were subject to both shop and field efficiency tests. The HEPA filters are given in-place DOP tests in accordance with ANSI N510-1980, "Testing of Nuclear Air Cleaning System." Filters are tested at rated flow with an acceptance limit of less than 0.05% penetration at rated flow. Charcoal adsorber filters are leak tested in accordance with ANSI N510-1980 to ensure that filter bypass is less than 0.05% of full flow.

9.4.2.5 Instrumentation Requirements

The following are the major instrumentation devices used for controlling the reactor building heating and ventilation system:

a. Isolation valve control

The isolation valves on the purge lines to the primary containment and the reactor building supply air intake and exhaust air discharge ducts are controlled by individual OPEN-AUTO-CLOSE selector switches located in the main control room. The switch springs back to AUTO from either the OPEN or CLOSE position. With the selector switch in the AUTO position, an isolation signal will deenergize the solenoid and close the isolation valve. The isolation valves are designed to fail in the closed position in the event of loss of control air.

b. Supply ventilation unit fan control

Selector switches, with indicating lights, are provided in the main control room for the two supply ventilation unit fans.

A differential pressure switch, with probes on either side of the fan/damper assembly, will automatically start the standby fan in the event of low differential pressure which is indicative of fan failure. The differential pressure switch will also annunciate an alarm in the main control room.

In the event of an isolation signal, both supply fans are stopped automatically via electric interlocks.

c. Main exhaust system fans

The two main exhaust fans are controlled by selector switches located in the main control room. When one fan is started, an associated solenoid valve is

energized causing the pneumatic, fail-closed damper on the fan discharge to receive control air and open. A differential pressure switch, with probes on either side of the fan/damper assembly, will start the standby fan in the event of low differential pressure which is indicative of fan or damper failure.

The reactor building is maintained at a negative pressure of 0.25 in. w.g. with respect to atmosphere by automatically varying the pitch of the main exhaust fan blades, thereby changing fan capacity, via a pneumatic controller. There is an electronic differential pressure sensor across each of the reactor building's four exterior walls. The lowest of the four signals is transmitted to a differential pressure controller which transmits a signal, converted to a pneumatic signal, to the pneumatic fan blade controller to maintain the lowest differential pressure at the selected setpoint.

In the event of an isolation signal, both exhaust fans are stopped via electric interlocks.

d. Primary containment purge control

When the primary containment is purged to the reactor building exhaust system, the following operations are performed:

The primary containment purge exhaust isolation valves and the valve connecting the purge exhaust header to the reactor building exhaust system are opened via individual selector switches located in the main control room.

A pneumatic volume damper in the purge line to the exhaust system is controlled by an adjustable differential pressure controller. The pressure is sensed between the ductwork connecting the primary containment and the reactor building. The differential pressure controller is located in the main control room. The primary containment is depressurized, if required, by slowly lowering the setpoint of the differential pressure controller thus gradually opening the damper. Flow indication of purge exhaust is provided in the main control room so that depressurization can be performed at a controlled rate.

Once the containment is depressurized, the isolation valves on the supply purge connection to the containment are opened via selector switches in the main control room. Pneumatic dampers in the supply system, which divert supply air into the purge supply header, are used for purge rate control. When the valve in the supply line to the supply purge header is opened, an associated solenoid valve is energized permitting the diverting damper to receive a control signal. The control signal is transmitted from an adjustable flow controller located in the main control room, which will modulate the damper as required to maintain

the purge supply rate at the controller setpoint. Purge flow is adjustable up to 10,500 cfm.

Normally the primary containment drywell and suppression pool area are purged separately by opening the appropriate isolation valves. In the event of an isolation signal during purge, all isolation valves are automatically closed.

e. Sump vent exhaust system control

Selector switches with running lights are provided for each sump vent exhaust unit. When a unit fan is started, the control circuit for the unit is energized causing the electric blast coil heater to start and a damper control solenoid valve to energize. When energized, the solenoid valve permits the pneumatic volume damper on the unit fan discharge to receive a control signal from a differential pressure controller set to maintain a flow of 1000 cfm through the unit.

The drain system main exhaust header from which the filter unit draws is maintained at a negative pressure of approximately 1.0 in. w.g. with respect to the reactor building atmosphere. A volume control damper, located between the exhaust header and reactor building atmosphere, is modulated by a differential pressure controller set to maintain that pressure differential.

In the event that the operating sump exhaust unit fails, a differential pressure switch with probes set across the unit filters will annunciate an alarm in the main control room, thus alerting the operator to start the standby unit. The differential pressure switch also deenergizes the units electric heater.

A thermocouple on the charcoal filter will annunciate an alarm in the main control room on a temperature rise to 250°F.

f. Heating control

Supply air is heated in the supply ventilation unit by a steam coil with pneumatic face and bypass dampers. The source of the heating steam (HS) is from the gland steam evaporator during turbine generator operation and from the auxiliary boiler during shutdown. The dampers are controlled by a temperature controller which senses supply air temperature downstream of the fans. The setpoint of the temperature controller is adjustable. A temperature switch with a sensor in the outdoor air intake energizes a solenoid valve, thus causing the steam shutoff valve in the feed line to the steam coil to open whenever the outdoor temperature drops below the setpoint.

The steam booster heater in the supply duct to the refueling floor is controlled in a similar manner to that of the main ventilation unit and is supplied HS from the same sources that supply the main unit. Face and bypass dampers on the booster heater are modulated by an adjustable, area mounted, temperature controller.

g. Evaporative cooler control

The supply ventilation unit evaporative cooler (air washer) section is controlled by temperature switches with sensors located in the outdoor air intake.

9.4.3 RADWASTE BUILDING

9.4.3.1 Design Bases

The radwaste building houses the solid, liquid, and gaseous radwaste treatment systems. The HVAC systems serving the radwaste building are designed to satisfy the following requirements:

a. To provide fresh tempered ventilation air to the various spaces in the radwaste building in sufficient quantity to limit the temperature as specified in Table 3.11-1, while providing at least three air changes per hour in potentially contaminated areas. Additionally, areas in which personnel will spend extended periods of time performing sensitive operations are air conditioned for personnel comfort;

b. The air distribution within the building provides for controlled air movement from areas of low radiation contamination potential to areas of progressively higher radiation contamination potential;

c. To filter the exhaust air from the building before discharging it to the atmosphere to limit the release of airborne radioactive particulates;

d. To heat the supply air as required during the winter season to maintain minimum temperatures as specified in Table 3.11-1; and

e. To maintain the lower level of the radwaste building at a negative pressure with respect to atmosphere to minimize the release of radioactivity.

9.4.3.2 System Description

The radwaste building HVAC system is shown in Figure 9.4-3. The main system is a push-pull heating and ventilating system providing once-through air flow with no recirculation.

In addition, individual air conditioning units are provided for all rooms which personnel will normally occupy for extended periods of time. Equipment details are given in Table 9.4-3. Equipment seismic information is given in Table 3.2-1.

The main radwaste building supply air system consists of a supply ventilation unit and distribution ductwork. The supply ventilation unit consists of an insulated steel cabinet housing a prefilter, steam coil with face and bypass dampers, an evaporative cooling section, and two 100%-capacity centrifugal fans. The prefilter is of the renewable roll type, automatically progressed to maintain uniform pressure drop. The steam coil is of the nonfreeze type with automatic face and bypass dampers for temperature control. The evaporative cooling section is of the capillary type with two full-capacity pumps with common suction from the washer basin and common discharge into the spray header system. Makeup water to the evaporative cooler is supplied from the plant potable water system.

During normal plant operation the supply unit operates continuously, providing tempered air throughout the building via the supply duct distribution system. The radwaste building supply system has no safety functions and will be inoperative in the event of loss of offsite power.

The radwaste building exhaust system is composed of three 50%-capacity exhaust filter units. Each exhaust unit consists of medium efficiency prefilters, HEPA filters, and a centrifugal fan in a sheet metal housing. The prefilters are of the cartridge type with a minimum Dust Spot Efficiency of 80%-85% by ASHRAE standard 52.1 (MERV 13 rating by ASHRAE standard 52.2). The HEPA filters are designed for removal of fine airborne particulates. These filters are of water repellent and fire-resistant construction for operation at temperatures up to 300°F. The HEPA filter has a minimum efficiency of 99.97% on a 0.3 m DOP test. The HEPA filters are fabricated in accordance with MIL-F-51068C, MIL-STD-282, and carry a UL label certifying compliance with UL586.

Each exhaust unit fan is provided with an automatic air-operated inlet vane for flow control. The inlet vanes are controlled by differential pressure controllers set to maintain the tank enclosures in the lower level of the radwaste building at a negative pressure with respect to atmosphere.

During normal plant operation two exhaust units operate, with the third unit in standby, drawing air from a common exhaust duct system and discharging the air above the radwaste building roof. All radwaste building exhaust air is processed by the exhaust units and monitored by radiation detectors prior to discharge. Radioactive releases to the environment are discussed in Section 11.3.3. The radiation monitoring system is discussed in Section 11.5.2.2.1.7 with arrangement details shown in Figure 11.5-7. The exhaust duct system is arranged in such a manner that all exhaust is drawn from areas with the highest radioactive contamination potential thus inducing air flow from clean areas into the potentially contaminated zones. Where applicable, automatic volume dampers are provided in ventilation openings in walls between clean and potentially contaminated areas. The volume dampers are

controlled by differential pressure controllers, with probes on either side of the vent opening, to maintain "hot zones" at a negative pressure with respect to "clean zones."

The radwaste control room, instrument shop, radiochemical laboratory, sample room, counting room, and health physics area are provided with air conditioning systems to maintain suitable conditions for personnel comfort. All areas except the radwaste control room are serviced by once-through air conditioning systems. The radwaste control room, which has no contamination potential, has a partial recirculation air conditioning system.

The air conditioning for each area is provided by air handling units which draw air from the radwaste building supply air system, pass it through filters, chilled water coils, and electric heaters, and discharge it into the rooms being conditioned. Chilled water is supplied to the coils from the WCH.

The conditioned air leaves the rooms by exfiltration to the rest of the building or, as in case of radiochemistry laboratory, hot instrument shop and sample room, through exhaust hoods which discharge into the main exhaust system. The exhaust hoods in the radiochemistry laboratory, hot instrument shop and sample room are provided with local filter units composed of prefilters, HEPA filters, and fans to remove radioactive particulates at the hoods prior to discharge into the exhaust system. These HEPA filters are similar to those in the main exhaust filter units.

Effluent from the radwaste building ventilation is continuously monitored for gaseous activity and continuously sampled for laboratory analysis of particulate radioactivity. The sampling and monitoring system is described in Section 11.5.2.2.3.

9.4.3.3 Safety Evaluation

The radwaste building HVAC system is not required for a safe shutdown of the plant; however, the following features are incorporated in its design to ensure system reliability and to minimize the uncontrolled release of airborne radioactive contaminants during normal plant operation:

a. The 50% standby capacity of the exhaust filter system ensures full system capacity with any unit inoperative due to equipment failure or maintenance outage,

b. Redundant supply fans ensure supply system operation in the event of single fan failure,

c. All exhaust air is passed through HEPA filters prior to discharge thus minimizing the release of radioactive contaminants, and

d. The potentially contaminated area is maintained at a negative pressure and all air is monitored by radiation detectors prior to discharge to ensure against release of radioactive contaminants.

9.4.3.4 Testing and Inspection Requirements

The performance of the HVAC systems servicing the radwaste building can be verified while the systems are operating. The operability and performance of standby equipment is determined by rotating the duty of redundant components. Pressure, temperature, and flow instrumentation is provided as shown in Figure 9.4-3.

The HEPA filters in the radwaste building exhaust filter units are subject to both shop and field efficiency tests. On installation, and periodically thereafter, HEPA filters are given in-place DOP tests in accordance with ANSI N510-1980, "Testing of Nuclear Air Cleaning System." Filters are field tested at rated flow with an acceptance limit of less than 0.05% penetration.

All system ductwork was balanced for air flows in accordance with the procedures of the AABC. All system components were subject to preoperational testing to verify that the system functions in accordance with the design requirements.

9.4.4 RADWASTE BUILDING CHILLED WATER SYSTEM

9.4.4.1 Design Bases

The WCH is designed to provide a reliable source of chilled water to the main control room air handling units, the cable spreading room air handling units, the switchgear area air handling units, and the air handling units serving the conditioned areas of the radwaste building (see Sections 9.4.1 and 9.4.3).

The temperature of the chilled water supplied to the air handling units is maintained between 44°F and 55°.

9.4.4.2 System Description

The WCH is shown in Figure 9.4-4. It is a closed loop system incorporating two 100%-capacity pumps and two 100%-capacity water chillers. The chillers are arranged to operate independently with bypass and shutoff valves provided for ease of maintenance. During normal operation, either chiller operates to maintain the chilled water supplied to the air handling units between 44°F and 55°F. The two chilled water pumps are arranged in parallel with one normally operating and one in standby. The liquid chillers are each rated at 150 tons refrigeration capacity. Each consists of a compressor, evaporator, water-cooled condenser, and controls. Condenser cooling water is supplied to the chillers from the plant service water system (see Section 9.2.1).

An air separator, expansion tank, chemical feed tank, and appropriate valves and piping connections are provided at the common suction to the two pumps for system control. Makeup water to the system is supplied from the plant potable water system (see Section 9.2.4).

9.4.4.3 Safety Evaluation

The WCH has no safety function; however, redundant circulating pumps and liquid chillers are incorporated in the design to ensure uninterrupted system operation during normal plant operation.

All components of the chilled water system are designed to Seismic Category II requirements.

9.4.4.4 Testing and Inspection Requirements

The performance of the WCH can be verified while the system is operating. The functionality of standby equipment is determined by rotating the duty of redundant components. Pressure, temperature, and flow instrumentation is provided as shown in Figure 9.4-4.

9.4.4.5 Instrumentation Requirements

Each of the two chilled water pumps are controlled locally. When either pump is energized, the chiller control circuit is energized via electrical interlocks. If the operating chilled water pump fails, a pressure switch on the pump discharge will start the standby pump after a delay and an alarm will be actuated in the main control room.

Each chiller has a temperature sensing element in the chilled water supply line which controls the chiller capacity to maintain the required temperature.

A single trouble alarm is actuated in the control room to alert operators upon chilled water low temperature, high condenser temperature, or high motor temperature.

9.4.5 OFFGAS CHARCOAL ADSORBER VAULT REFRIGERATION SYSTEM

The offgas charcoal adsorber vault refrigeration system has been permanently deactivated in-place.

9.4.6 TURBINE GENERATOR BUILDING

9.4.6.1 Design Bases

The turbine generator building is provided with HVAC systems designed to satisfy the following requirements.

a. Provide fresh, tempered, filtered ventilating air to the various spaces within the turbine generator building in sufficient quantity to limit the temperatures as specified in Table 3.11-1;

b. Provide for controlled air movement from areas of potentially lower airborne radiation contamination to areas of progressively higher airborne radiation contamination potential. This distribution serves to limit airborne contaminants from migrating from potentially contaminated areas into clean areas. The ventilation systems operate on a once-through basis without recirculation;

c. Monitor exhaust air from the building for radioactive contaminants, prior to discharge, to ensure that the release of contaminants does not exceed the concentration limits defined in 10 CFR 20;

d. Maintain the turbine generator building potentially radioactive areas at a negative pressure with respect to atmosphere to minimize the release of radioactive contaminants;

e. Automatically provide combustion air for the auxiliary boiler in the turbine generator building;

f. Provide ventilation air to the makeup water pump transformers in the turbine building, this portion of the ventilation system is to remain operable through a design basis tornado; and

g. Provide the sample room exhaust hood with a supply and exhaust filtration system and to provide tempered ventilation air to the sample room.

The components of the turbine generator building ventilation systems are classified Seismic Category II. The system fans are constructed and rated in accordance with the applicable AMCA standards.

9.4.6.2 System Description

The HVAC systems of the turbine generator building are shown in Figure 9.4-6. The primary system is a "push-pull" heating and ventilating system consisting of the following systems:

a. Main supply,
b. Main exhaust,
c. Auxiliary boiler room ventilation,
d. Transformer vault ventilation, and
e. Sample room air conditioning.

Equipment details are given in Table 9.4-4. Equipment seismic information is given in Table 3.2-1.

9.4.6.2.1 Main Supply System

The turbine generator building supply air system consists of four supply ventilation units and associated distribution ductwork. The units are operated in pairs, with one pair discharging into a common supply duct system servicing the west side of the building and the other pair discharging into a common supply duct system servicing the east side of the building.

Each of the four ventilation units consists of a prefilter, a steam coil with face and bypass dampers, an evaporative cooling section, and a centrifugal fan enclosed in an insulated housing. The prefilters are of the renewable roll type, automatically progressed to maintain uniform pressure drop. The steam coil is of the nonfreeze type with automatic face and bypass dampers used for temperature control. The evaporative cooling section is of the capillary air washer type with two full capacity pumps which have a common suction line from the washer basin and common discharge line into the washer spray healer system. Makeup water to the air washer is supplied from the plant potable water system.

The centrifugal fans of each ventilation unit have automatic inlet vanes for fan capacity control and are used to vary supply air flow to maintain the turbine building at a set pressure with respect to outdoors. The fan intake ducts of each pair of ventilation units are joined by means of a manual damper so that a single fan can draw air through both ventilation units in the event of failure of one fan. Automatic dampers are provided on the intake of each supply fan which can be controlled from the local panel.

9.4.6.2.2 Main Exhaust System

The main exhaust system consists of four roof-mounted centrifugal fans which draw air from a central exhaust plenum. Three of the exhaust fans normally operate continuously with one fan in standby. During the winter, if the temperature in the turbine generator building can be maintained within the design limit, two of the exhaust fans can be operated.

Almost all exhaust air is drawn from the shielded areas of the turbine building, where the potential for airborne radioactive contamination is highest, thus inducing flow from the less contaminated areas through the shielded areas. The air in the exhaust duct is monitored for radioactive contaminants by a recorder in the main control room. Radioactive releases to the environment are discussed in Section 11.3.3.

In the event that supply air to the turbine generator building is reduced, as during a plant outage, only one or two exhaust fans may be operated. Motor-operated shutoff dampers are provided in the main branches of the exhaust duct system so that exhaust can be stopped on an area-by-area basis. Automatic volume dampers are provided in the exhaust system so that full exhaust flow can be drawn from the shielded equipment vaults on the lower level of the turbine building when the exhaust system is operating at reduced capacity. These vaults house equipment with higher contamination potential such as the air ejectors and the offgas system hydrogen recombiners.

9.4.6.2.3 Auxiliary Boiler Room Ventilation System

The auxiliary boiler room, which is located in the lower level of the turbine generator building, is normally ventilated from the turbine generator building supply air system. This ventilation rate is sufficient when the boiler is not operating. However, when the boiler is operating and drawing combustion air from the room, additional ventilation is supplied to the boiler room by a separate air handling unit. This air handling unit starts automatically, via electrical interlocks, when the boiler is started and draws 100% outdoor air through a weather louver, heats it as required, and discharges it into the room. Part of this air is drawn by the boiler as combustion air, with the balance of the air leaving the boiler room via relief dampers in the exterior wall of the boiler room.

9.4.6.2.4 Transformer Vault Ventilation System

Two transformers, located in adjacent equipment vaults in the lower level of the turbine generator building, must remain operational in the event of a design basis tornado. The power feeds of the makeup water pumps, which are the source of makeup water to the emergency spray ponds, are drawn from these transformers which can be fed from the emergency diesel generator buses. Two tube-axial fans are provided for the ventilation of the vaults in the event of a tornado. The two fans exhaust air from the vaults with makeup air provided through ventilation openings in the vaults walls. Either fan has sufficient capacity to remove the heat generated by the transformers and both are powered from the emergency diesel generator buses. During normal plant operation, makeup air to the vaults is provided by the main turbine generator building supply air system with one vault ventilation fan operating and other in standby.

9.4.6.2.5 Sample Room Air Conditioning System

The turbine building sample room located on the lower level of the turbine generator building is provided with a sample hood exhaust filter system and a self-contained air conditioning system. The sample room hood is of the air curtain type with air supplied to the hood by a centrifugal fan which draws air from the corridor outside the sample room and from the room itself. Air is exhausted from the hood by a filter unit. This unit is composed of a medium efficiency prefilter, a HEPA filter, and an exhaust fan in a sheet metal housing. The filter unit discharges into the main turbine building exhaust system.

9.4.6.3 Safety Evaluation

The transformer vault ventilation system is designed to operate in the event of a design basis tornado. Two full-capacity fans powered from the emergency diesel buses are provided to ensure system operation in the event of a single active component failure. The vaults, which house the ventilation fans as well as the transformers, are designed to withstand the effects of the design basis tornado.

The following features are incorporated in the design of the turbine generator building HVAC system to ensure system reliability and to control air movement from the potentially contaminated areas:

a. Standby exhaust fan capacity is provided (three of four fans operating) to ensure full system capacity in the event of a single fan failure,

b. The supply system ventilation units are designed with cross ties between fans to minimize the effect of a fan failure on system capacity,

c. The building air is monitored by radiation monitoring system sampling from the exhaust ductwork, and

d. Exhaust air is drawn from within the shielded areas of the turbine generator building thus inducing air flow from “clean” areas to areas of potential airborne contamination.

The radiological considerations of normal system operation are evaluated in Chapters 11 and 12.

9.4.6.4 Testing and Inspection Requirements

The performance of the HVAC systems serving the turbine generator building can be verified while the systems are operating. The operability and performance of standby equipment is

determined by rotating the duty of redundant components. Pressure, temperature, and flow instrumentation is provided, as shown in Figure 9.4-6, to monitor system performance.

All system ductwork was balanced for air flows in accordance with the procedures of the AABC. All system components were subject to preoperational testing to verify that the system functions in accordance with the design requirements.

9.4.6.5 Instrumentation Requirements

Control devices for the turbine generator building HVAC system are mounted on racks in unshielded areas of the building. The following major instrumentation devices are used for the turbine generator building HVAC system:

a. Main supply system: The inlet vortex damper on each supply fan is automatically controlled by a differential pressure controller and transmitter, which sense the pressure inside the turbine building relative to outside the building. The differential pressure controller can maintain a differential pressure from approximately -0.25-in. w.g. to +0.25-in. w.g.

b. Auxiliary boiler room ventilation system: The unit is automatically started, via electrical interlocks, when the boiler is started.

c. Transformer vault ventilation system: The two transformer vault fans are controlled by locally mounted selector switches. One unit normally operates continuously with the second unit in standby. In the event of operating fan failure, a pressure switch on the fan discharge will annunciate an alarm and start the standby fan.

9.4.7 EMERGENCY DIESEL GENERATOR BUILDING

9.4.7.1 Design Bases

Each of the three diesel generator rooms is serviced by a separate HVAC system. With the exception of the fuel oil day tank room and the oil pump room exhaust fans, the function of the three systems is to maintain suitable temperatures within the rooms for equipment operation. The exhaust fans provided in each of the three oil pump rooms and in the three day tank rooms prevent the buildup of oil fumes.

All three HVAC systems operate automatically to maintain ambient temperature below equipment operability limits during all emergency modes of operation (see Table 3.11-1) for the various locations in the diesel generator building. Electric heaters are designed to maintain diesel generator rooms above the minimum required for reliable equipment operation (down to the design low of 0°F) and may be supplemented as necessary by other means (down to the

extreme low of -27°F). The high-pressure core spray (HPCS) diesel generator batteries will be maintained at a temperature of 60°F or greater by the HVAC system and supplemented as necessary by portable heaters or other means.

Since an independent and separate diesel generator HVAC system serves each diesel generator, a failure in one system will not effect the operational function of the other systems. The HVAC systems are housed in separate rooms in the Seismic Category I diesel generator building. The means of protecting system vents and louvers from missiles is discussed in Section 3.5.

All system components (except the electric unit heaters, the intake filters, the day tank room exhaust fans, and the fuel oil pump room exhaust fans) are Seismic Category I. The system fans are constructed and rated in accordance with applicable AMCA standards.

9.4.7.2 System Description

The three similar heating and ventilating systems serving the diesel generator rooms are shown in Figure 9.4-7.

Each room has a main "push-pull" ventilation system and an exhaust system for each oil day tank room. Each diesel fuel pump room is served by its own independent ventilation system. Equipment details are given in Table 9.4-5. Equipment seismic information is given in Table 3.2-1.

Each "push-pull" ventilation system is composed of two air handling units, an exhaust fan, associated ductwork, and controls. The two air handling units share a fresh air intake plenum and a common intake air filter bank. Each air handling unit has a water cooling coil (with a bypass damper) and a centrifugal fan in a sheet metal housing. The exhaust fan is a direct drive, vaneaxial fan.

Normally, the smaller of the two air handling units operates continuously to maintain proper temperatures in the diesel generator room. Heating is provided by an electric blast coil heater located in the air handling unit discharge duct. Ambient temperature control is provided by temperature regulated proportional dampers on the air handling unit intake which mix outside air and recirculated room air.

When a diesel generator is started, the larger air handling unit and the main exhaust fan automatically start, and SW is supplied to the water cooling coils in both air handling units. The exhaust fan ductwork is arranged such that the exhaust air can be discharged outside (via the pipe area) or recirculated through the two air handling units in any proportion from 0% to 100% to control supply air temperature. The water cooling coils provide additional cooling during high outdoor air temperatures.

The fuel oil day tank exhaust fans and the fuel oil pump room exhaust fans operate to purge oil fumes from the rooms. An outside air intake louver is provided in each oil pump room. The oil pump exhaust fan discharges to the atmosphere. The explosion-proof electric unit heaters in the pump rooms will maintain the temperature above 50°F.

9.4.7.3 Safety Evaluation

Components of the three emergency diesel generators are serviced by separate and independent HVAC systems. Each HVAC system is powered from a Class 1E bus which is supplied by the diesel generator it serves. All components of each system are located within the equipment room it serves and are therefore protected from all external missiles. All HVAC components required to ensure emergency diesel generator operation are Seismic Category I and Quality Class I.

The HVAC system is started automatically, via electric interlocks, whenever the associated diesel generator is started. Failure of part of any of the three systems will only effect the diesel served and will not impair the operational function of the remaining two systems. These systems are designed to operate in the event of a LOCA coincident with loss of offsite power.

9.4.7.4 Testing and Inspection Requirements

The diesel generators are normally on standby with the ventilation system equipment accessible for out-of-service inspection. All system ductwork was balanced for air flows in accordance with the procedures of AABC. All system components were subject to preoperational testing to verify that the system functions in accordance with the design requirements. All piping system components were subject to hydrostatic tests during erection.

The performance of the heating and ventilation system components are verified while the system is in operation. The performance of standby components are verified during Technical Specifications required testing of the diesel generators. Temperature and pressure instrumentation are provided as shown in Figure 9.4-7.

9.4.7.5 Instrumentation Requirements

The following is a discussion of the instrumentation provided for each of the three emergency diesel generator room HVAC systems.

The smaller air handling unit in each room is controlled by a local rack-mounted ON-OFF switch. In the ON position, the fan operates and the control circuits of all associated equipment are energized causing the following:

a. Electric duct heater control circuit is energized permitting the heater to operate, to satisfy the electric heating thermostat. (Heaters can only operate when the differential pressure switch across the air handling unit fan indicates air flow);

b. Fresh air/recirculation air damper control circuit permitting the electronic temperature controller to proportion air to maintain a proper supply air temperature (100% outdoor air supplied when outdoor temperature is above the damper motor controller setpoint). A sensor located in the supply air duct upstream of the heating unit signals the temperature of the supply air to the damper control; and

c. A motor-operated face and bypass damper on the air handling unit water cooling coil is controlled by a temperature switch located in the fresh air intake. When the fresh air temperature falls below the damper motor controller setpoint, the air is bypassed over the cooling coil to prevent the supply air temperature from dropping below the setpoint temperature.

The larger air handling unit fan and the main exhaust fan are controlled by separate local rack-mounted ON-OFF-AUTO switches. Both unit switches are normally in the AUTO position and are started automatically, via electric interlocks, whenever the associated diesel generator is started. The control circuits for the dampers associated with the larger air handling unit are energized when the fan is started and operated in the same manner as those of the smaller air handling unit.

The oil day tank room and fuel oil pump room exhaust fans are all controlled by local rack mounted ON-OFF switches. The explosion proof electric unit heaters are controlled by local ON-OFF switches. In the ON position, the heaters are cycled on and off by electric room thermostats.

Differential pressure switches are installed across all fans serving the diesel generator rooms. In the event of low differential pressure, an alarm is annunciated in the main control room and/or on local panels. Temperature sensors in the diesel generator rooms and in the exhaust ducts also annunciate alarms in the event of abnormally high or low temperatures (see Figure 9.4-7).

9.4.8 DIESEL GENERATOR AREA CABLE COOLING SYSTEM

9.4.8.1 Design Bases

The critical electric cabling which runs between the emergency diesel generators and the main control room and critical switchgear room is routed in corridors adjacent to the diesel generator building and in corridors between the reactor building and radwaste building. These corridors are normally ventilated by the turbine building and radwaste building ventilation

systems with normal ambient temperatures below 115°F (except for corridor C-121 below 104°F); however, an emergency cable cooling ventilation system is provided to ensure that ambient temperatures in the corridors do not exceed the ambient environmental temperatures for which the cables are rated, in the event of loss of offsite power. During an extreme winter outside temperature of -27°F, the incoming air is heated to a minimum temperature of 35°F.

The ventilation system is comprised of two independent and separate systems which cool Division 1 and Division 2 cable areas. A failure in one system will not effect the operational functions of the other cooling system.

The fresh air intake opening is located in the south exterior wall and is shielded by a concrete barrier which would preclude entry by a missile such as generated by a tornado. Division 1 exhaust fan discharges air into a cable chase which is not open to the atmosphere. The air is removed by the radwaste building exhaust system.

All components in the system are Seismic Category I, Quality Class I. The system fans are constructed and rated in accordance with AMCA standards.

9.4.8.2 System Description

The cable cooling system is shown in Figure 9.4-7. The system is composed of one exhaust fan powered from the Division 1 emergency power bus and one supply air handling unit powered from the Division 2 emergency power bus.

The exhaust fan, which is normally in standby, is started automatically when the Division 1 diesel generator is started. The operation of this standby exhaust fan opens the outdoor air bypass damper when outdoor air temperature is above 40°F and when the Division 2 supply fan is not running.

The Division 2 air handling unit is composed of a 30-kW electric blast coil heater and a centrifugal fan in a sheet metal housing. It is normally in standby. When the Division 2 diesel generator is started, this air handling unit is automatically started through interlocks. When this air handling unit is started, a damper in the supply air duct from the turbine building HVAC system (which is used for normal ventilation of the corridors) is automatically closed. This air handling unit then supplies tempered air to the corridors in which Division 2 cable is routed.

9.4.8.3 Safety Evaluation

All components of the cable cooling system are powered from their respective emergency diesel buses. All HVAC components in this system are Seismic Category I, Quality Class I.

The capacity of the Division 1 and Division 2 components of the HVAC system is sufficient to maintain safe ambient conditions in the event of failure of either power division. The components powered from the two divisions are independent and physically separated to preclude the possibility of any single failure damaging both systems.

9.4.8.4 Inspection and Testing Requirements

All components of the cable cooling system which are normally in standby are accessible for out-of-service inspection. All system ductwork was balanced for air flows in accordance with the procedures of AABC. All system components were subject to preoperational testing to verify that the system functions in accordance with the design requirements.

The performance of the ventilation system components are verified while the system is in operation. Temperature and pressure instrumentation is provided, as shown in Figure 9.4-7, to monitor system performance.

9.4.8.5 Instrumentation Requirements

The Division 1 standby exhaust fan and the Division 2 air handling unit are controlled by separate, local, ON-AUTO-OFF switches (spring back from OFF to AUTO). With the control switches in the AUTO position, the Division 1 standby exhaust fan starts automatically, via electric interlocks, when the Division 1 diesel generator is started.

The Division 2 air handling unit control switch is normally in the AUTO position. It automatically starts and its control circuit energizes, via electric interlocks, when the Division 2 diesel generator is started. When energized, the air handling unit's control circuits perform the following function:

The inlet mixing damper and electric blast coil heaters are controlled by electric thermostats located in the corridor. When corridor temperature is above 70°F, the damper is positioned for 100% outdoor air. When the temperature drops below a nominal 70°F, the damper is positioned for minimum outdoor air. When the temperature drops below a nominal 62°F and 54°F, respectively, the two stages of electric heater are energized.

Failure of air flow through the air handling unit fan after the fan motor is energized will trip a differential pressure switch that deenergizes the air handling unit control circuits and activates an alarm. Also, the filter bank in the air handling units is provided with a differential pressure switch which activates an alarm on high differential pressure.

The operation of the Division 1 standby exhaust fan opens the outdoor air bypass damper when outdoor air temperature is above 40°F and when the Division 2 supply fan is not running.

9.4.9 REACTOR BUILDING EMERGENCY COOLING SYSTEMS

9.4.9.1 Design Bases

All equipment located within the Seismic Category I reactor building which requires a controlled environment to operate, and which must operate in the event of a LOCA, is enclosed in individual equipment rooms. These rooms are normally heated and ventilated by the reactor building HVAC system (see Section 9.4.2); however, under emergency conditions, the rooms are automatically cooled by recirculation of room air through their respective reactor building emergency cooling system. Ambient temperatures of the following rooms are maintained below equipment operability limits during all emergency modes of operation. See Table 3.11-1.

HPCS pump room
Division 1 Low-pressure core spray (LPCS) pump room
Division 2 Reactor core isolation cooling (RCIC) pump room
Division 1 Residual heat removal (RHR) pump room
Division 2 RHR pump rooms (2 pump rooms)
Division 1 Motor control center (MCC) room (el. 522)
Division 2 MCC room (el. 522)
Division 1 dc MCC room (el. 471)
Division 1 H2 recombiner MCC room (el. 572)
Division 2 H2 recombiner MCC room (el. 572)
Fuel pool cooling (FPC) pump room

The critical MCC and FPC pump rooms emergency cooling fans auto start and the rooms are isolated from the reactor building HVAC system on an F, A, or Z signal. Although the FPC pump room is isolated from the reactor building HVAC system, the room temperature can be maintained below equipment operability limits with the reactor building HVAC dampers open. The ECCS and RCIC pump rooms emergency cooling fans auto start when their respective pump starts. SW is provided to the emergency cooling coils as described in Section 9.4.9.5.

All components of the reactor building emergency cooling system are designed Quality Class I, Seismic Category I and are powered from the same diesel generator bus as the equipment being served. Since each separate cooling system services redundant emergency equipment systems, a failure of one cooling system will not effect the operational function of the other cooling systems or the safe shutdown of the reactor. The means of protecting the system vents and louvers from missiles is discussed in Section 3.5.

All ductwork connected to the fan coil units in this system is designed to Seismic Category I requirements. The system fans are constructed and rated in accordance with the applicable AMCA standards. The water cooling coils are designed and code stamped in accordance with the requirements of the ASME Code Section III, Class 3.

9.4.9.2 System Description

The reactor building emergency cooling system is shown in Figure 9.4-2. Each of the rooms housing critical equipment is provided with an individual air handling unit (two units in the FPC pump room) which is fully enclosed within the room. Each air handling unit is comprised of a direct drive centrifugal or vane axial fan and a water cooling coil in a sheet metal housing. Water is supplied to the water coils by the SW system (see Section 9.2.7). During normal operation, these air handling units are in standby.

All units recirculate the air within the room they serve, removing the heat generated in the room via the water coil, to maintain temperatures below the design limits. Equipment details are on Table 9.4-2. Equipment seismic information is given in Table 3.2-1.

9.4.9.3 Safety Evaluation

Each of the emergency equipment rooms in the reactor building is provided with a separate, independent cooling system, all components of which are located within the room serviced. Each cooling system is powered from a Class 1E bus of the same division as the equipment it serves and is designed to withstand the effects of an SSE. A failure of one cooling system will not affect the operational function of any other system or the safe shutdown of the reactor.

With the exception of the FPC pump room the air handling units serving the pump rooms are interlocked electrically with the pumps they serve in such a manner that they start when the pump is started. The air handling units serving the FPC pump room and critical MCC rooms are started by any of the F, A, or Z isolation signals.

The FPC pump room air handling units also start on loss of offsite power.

9.4.9.4 Testing and Inspection Requirements

All components of the reactor building emergency cooling system are normally in standby and are accessible for out-of-service inspection. All piping systems were subject to hydrostatic tests during manufacture and erection.

The cooling system was subject to preoperational testing to verify that the system functions in accordance with the design requirements, and performance is verified periodically by testing during unit operation.

9.4.9.5 Instrumentation Requirements

With the exception of the FPC pump room units, the air handling units serving the pump rooms are controlled identically. Each is electrically interlocked with the pump it serves to

operate when the pump operates. Running lights for the fans are located on the MCCs. The SW system supplies the air handling unit water coil when the pump is started. A local manual switch is provided in each pump room for testing the air handling unit fan.

The controls for each of the air handling units serving the FPC pump room and the critical MCC rooms are identical. An ON-AUTO-OFF switch (spring back from OFF to AUTO) is provided for each fan unit in the main control room. Normally all switches are in the AUTO position and the fan units are in standby. In the AUTO mode, any of the three isolation signals (F, A, Z) will cause the following operations, via electric interlocks.

a. Air handling unit fans start,

b. Solenoid valves associated with the air-operated dampers in the reactor building ventilation system supply air ducts to the critical MCC and FPC pump rooms are deenergized, thus isolating these rooms from the balance of the reactor building.

For the F isolation signal, the Division 1 and 2 SW systems are auto started as described in Section 7.3.1.1.6 and provide cooling water to these unit cooling coils. For the A isolation signal, the Division 2 SW system is auto started via RCIC as described in Section 7.3.1.1.6 and the Division 1 SW system can be manually started as needed from the control room. For the Z isolation signal, the Division 1 and 2 SW systems can be manually started as needed from the control room.

In addition, the FPC pump room fan units will start on loss of offsite power when the control switch is in the AUTO position.

Room temperature indicators, alarms and/or HVAC related alarms are provided in the main control room for each of the equipment rooms as shown on Figure 9.4-2 or 9.2-12, as applicable. The alarms will annunciate in the event that temperatures exceed the design limit.

In addition, the leak detection system provides temperature indication and alarms in the main control room for Division 1 RHR A pump room, Division 2 RHR B pump room and the RCIC pump room as shown on Figure 7.6-1.

9.4.10 STANDBY SERVICE WATER PUMP HOUSE

9.4.10.1 Design Bases

The SW pump house HVAC systems are designed to remove the heat generated by operation of the SW pumps and the HPCS service water pump and to limit the temperature in the two pump houses as specified in Table 3.11-1. The ventilation systems are designed as ESF systems and are powered from a Class 1E bus of the same division as the pumps being served.

Since each HVAC system associated with the redundant SW pumps is separate and independent, a failure in one system will not affect the operational function of the other system. The means of protecting the system vents and louvers from missiles is discussed in Section 3.5.

Heating of the pump houses is provided by electric unit heaters (four in each building) sized to heat the building spaces to maintain temperatures as specified in Table 3.11-1. The unit heaters are powered from the emergency diesel-generator buses, but are classified Seismic Category II. If the pumps are required to operate following a seismic event, the heat generated from the pump motor is sufficient to maintain the building above freezing. The SW pumphouse outside air supply fans and motors are classified Seismic Category IM. These fans and motors are not required to operate to cool the safety related equipment in the pump houses under accident conditions. The remaining components, ductwork, and piping in the SW pump house ventilation systems are classified Seismic Category I.

The fan coil units and the supply fans are constructed and rated in accordance with the applicable AMCA standards. The water cooling coils are designed and code stamped in accordance with the requirements of ASME Code Section III, Class 3.

9.4.10.2 System Description

The SW pumps are located in pump houses adjacent to the emergency spray ponds. The loop A SW pump and the HPCS service water pump share one pump house and the loop B SW pump is in a second pump house. The HVAC systems serving the two pump houses are depicted in Figure 9.4-7. Each system consists of a fan coil unit composed of a sheet metal cabinet containing a direct-drive centrifugal fan and a water cooling coil, and a separate centrifugal supply fan with inlet mixing dampers.

Each fan coil unit is interlocked electrically with the associated SW pump it serves in such a manner that the unit fan starts and recirculates room air over the water cooling coil when the pump starts. Water is supplied to the unit coil from the main supply header of the SW pump. The fan coil units are normally in standby and operate only when the pump is started.

The supply ventilation fans in both pump rooms operate automatically when required. A room thermostat in the pump house starts the fan on a temperature rise to 80°F or above and stops the fan on a temperature drop to 60°F or below. When the outdoor temperature is above 40°F, 100% outdoor air is supplied to the room. When the outdoor temperature falls below 40°F, a temperature indicating switch, with its sensor in the outdoor air intake duct, positions the motor-operated intake mixing damper to a position for 4400 cfm recirculation air and 600 cfm outdoor air. Air is exhausted from the pump houses through relief dampers at a rate between 600 cfm and 5000 cfm depending on the intake of outside air.

There are four 10-kW electric unit heaters in each pump house. Each heater is controlled by a separate wall-mounted thermostat which starts the heater on a drop in room temperature to

below 40°F. Equipment details are given in Table 9.4-6. Equipment seismic information is given in Table 3.2-1.

9.4.10.3 Safety Evaluation

The following safety features are incorporated in the design of the heating and ventilating systems serving the SW pump houses:

a. Each of SW pump rooms 1A and 1B is serviced by a separate 100%-capacity fan coil unit powered from the same Class 1E bus as the pump room being serviced,

b. The HPCS service water pump is located in SW pump house 1A,

c. Both fan coil units and the HPCS supply fan start when the pump serviced starts,

d. In the event of loss of offsite power, the ventilation equipment is powered from the emergency diesel generator buses, and

e. All ESF components of the system are designed to operate in the event of an SSE.

Since each HVAC system associated with the redundant SW pumps is separate and independent, a failure in one system will not effect the operational function of the other system.

9.4.10.4 Testing and Inspection Requirements

The performance of normally operating components of the SW pump house ventilating systems can be verified while operating. All standby equipment is accessible for out-of-service inspection. All system ductwork was balanced for air flows in accordance with the procedures of AABC. All system components were subject to preoperational testing to verify that the system functions in accordance with the design requirements. All piping systems and components were subject to hydrostatic tests during erection.

9.4.10.5 Instrumentation Requirements

In addition to the instrumentation described in Section 9.4.10.3 the following devices are provided:

a. Each fan coil unit fan is provided with a local rack-mounted ON-AUTO-OFF switch (spring back to AUTO) which is used to test fan operation,

b. Each supply air fan is provided with a local rack-mounted ON-AUTO-OFF switch (spring back from OFF to AUTO) which is used to test fan operation,

c. Differential pressure switches are provided across each fan coil unit fan and each supply fan which annunciate an alarm in the main control room in the event of low differential pressure when the fan is given a start signal, and

d. Temperature switches in each pump room annunciate alarms in the main control room in the event of high or low temperatures.

9.4.11 PRIMARY CONTAINMENT

9.4.11.1 Design Bases

The primary containment is divided into two separate volumes: the drywell which houses the reactor vessel and auxiliaries, and the wetwell which housed the suppression pool. There is no heat producing equipment in the wetwell; therefore, a wetwell air cooling system is not required. The drywell, which has a high internal heat load, is provided with recirculation cooling system designed to meet the following requirements:

a. To limit during normal plant operation, the average air temperature within the primary containment drywell to Table 3.11-1 limits,

b. To provide suitable working temperatures inside the primary containment for personnel during shutdown and refueling operations, and

c. To remove the additional heat released in the event of a reactor scram, and to limit temperatures in the neutron monitoring cable area beneath the reactor to Table 3.11-1 limits.

The primary containment cooling system is not required for safe shutdown of the reactor. Essential equipment located in primary containment that is required for safe shutdown of the reactor is designed to function without the containment cooling system in operation.

All components of the primary containment cooling system are classified Seismic Category I. System fans are constructed and rated in accordance with applicable AMCA codes. The water cooling coils are designed and code stamped in accordance with the requirements of the ASME Code Section III, Class 3.

9.4.11.2 System Description

Equipment seismic information is given in Table 3.2-1. The equipment details are described in Table 9.4-2. The primary containment cooling system is shown in Figure 9.4-8. Cooling of the drywell is provided by five fan coil units which recirculate containment air through water cooling coils for heat removal. Seven recirculation fans and two head area return fans are also provided at various locations in the drywell to provide additional air turbulence to prevent pockets of hot air from developing. Each of the five fan coil units consists of two vaneaxial fans, both of which operate at the same time, and a water cooling coil in a sheet metal housing. Provisions have been made to install filters in the units, for coil protection, while the units are operated during plant construction; however, no filters are required during normal plant operation. Water is supplied to the unit cooling coils from the reactor building closed cooling water system as described in Section 9.2.2.

Three of the fan coil units are located low in the drywell and two of the units are located at a higher level.

Each of the three lower level fan coil units are provided with two vaneaxial fans one of which discharges directly into the general drywell volume, and the other discharges, via ductwork, into the neutron monitoring cable area beneath the reactor and general drywell volume.

The two upper level fan coil units are each provided with one 30,000-cfm capacity fan and one 10,000-cfm capacity fan. The larger fans discharge directly into the upper volume area. The smaller fans discharge into the containment head area above the refueling bellows. Two vaneaxial head area return fans draw air from the containment head area and discharge it below the refueling bellows. Return air to the upper fan coil units is drawn from immediately below the refueling bellows. During normal operation, one or both of the head area return fans will be running.

Three recirculating fans are located at lower level and four fans are located at upper level in the drywell to provide air circulation. During normal operation, up to three lower level fans and up to four upper level fans are operating.

In the event of a reactor scram, both of the head area return fans are started (unless already operating).

9.4.11.3 Safety Evaluation

The primary containment cooling system does not have to operate, in the event of LOCA, to ensure the safe shutdown of the reactor. Head area return fans (CRA-FN-4A and CRA-FN-4B) will operate post-LOCA to help ensure hydrogen mixing. Design of the system incorporates the following features to ensure safe operation.

a. All fan coil units, recirculation fans, and head area return fans are designed to withstand the effects of an SSE and are powered from the emergency diesel buses;

b. All containment fans have been evaluated for the normal environmental conditions in containment to ensure long term reliable operation; and

c. Those fans used for hydrogen mixing following a LOCA are identified and qualified to Class 1E requirements. Additionally, these fans are powered from Class 1E sources.

9.4.11.4 Testing and Inspection Requirements

All components of the primary containment cooling system were subject to shop and field tests prior to plant operation. System performance is verified during reactor operation when the equipment is operating at design conditions.

All system ductwork was balanced for air flows in accordance with the procedures of the AABC. All system components were subject to preoperational testing to verify that the system functions in accordance with the design requirements.

9.4.11.5 Instrumentation Requirements

The primary containment fan coil units, recirculation fans, and cooling water isolation valves are each controlled by individual selector switches with indication lights, mounted in the main control room.

Temperature sensors are located throughout the primary containment as indicated in Figure 9.4-8. These sensors continuously monitor ambient conditions inside the containment and the performance of the cooling system.

9.4.12 MAKEUP WATER PUMP HOUSE

9.4.12.1 Design Bases

The heating and ventilating system provided in the makeup water pump house is designed to maintain temperatures within the structure between 50°F and 104°F to ensure suitable conditions for equipment operation. In the event of the hypothesized dewatering of the SW spray ponds due to a tornado, the makeup water pumps may be operated to refill the spray ponds (see Sections 9.2.7 and 10.4.5).

Since the ventilation system must be operated to ensure an acceptable environment for the makeup pump motors, the system is designed with redundant equipment to ensure that a single

component failure will not interfere with the operation function of the system. In the event a tornado causes the loss of offsite power, the system is powered from the emergency diesel generator buses. The fresh air intake and exhaust air openings are located in the east exterior wall and are shielded by a concrete barrier wall which precludes entry of a missile such as a tornado-generated missile.

The makeup water pumps and auxiliaries are not required to operate in the event of an SSE; therefore, all components of the heating and ventilating system serving the pump house are designed to Seismic Category II requirements as defined in Section 3.2. The system fans are constructed and rated in accordance with applicable AMCA standards.

9.4.12.2 System Description

The makeup water pump house heating and ventilating system is shown in Figure 9.4-7. It consists of two full-capacity air handling units and two battery hood exhaust fans which service the electric equipment area, and two full-capacity fan coil units and two electric space heaters which service the pump area. Equipment details are given in Table 9.4-7. Equipment seismic information is given in Table 3.2-1.

The two air handling units serving the electric equipment area consist of an insulated sheet metal cabinet housing a replaceable roughing filter, a two-stage electric blast coil heater, a water cooling coil, and a centrifugal fan. One of the two air handling units operates at all times to maintain design temperatures in the electric equipment area. The second unit is in standby and starts in the event that the operating unit fails.

The air handling units draw air from the outside atmosphere through intake louvers. The air is discharged, via ductwork, into the electric equipment area from which it flows into the pump room. It is then released either to the outside atmosphere, via relief dampers, or is partially recirculated back through the unit. Motor-operated dampers on the unit intake ducts are so arranged that the unit can draw 100% outdoor air or recirculate air drawn from the pump area back through the unit. The damper motor is controlled by a temperature switch which senses outdoor temperature. The damper will be positioned for 100% outdoor air when the outside temperature is between 50°F and 70°F.

The fan coil units servicing the pump area consist of a centrifugal fan, a water cooling coil, and a roughing filter in a sheet metal housing. The units recirculate air in the pump room only and are interlocked electrically with the makeup water pumps to start when the pumps start. Each unit has sufficient capacity to maintain design conditions with two of the makeup water pumps operating. In the event all three pumps are operating, the second fan coil is automatically started.

Water is supplied to the electrical area air handling units and the pump area fan coil units from the discharge header of the makeup water pumps. A fail-closed, motor-operated valve is

provided in the water supply line to each unit. The valve control circuit is energized when its respective fan is energized. With the control circuit energized, the valve is controlled by a thermostat, located in the area serviced, which opens the valve on a temperature rise to 90°F or above.

The electric blast coil heaters in the electrical equipment area air handling units are controlled by separate two-stage room thermostats. Two electric unit heaters provide supplementary heating to the pump area. A temperature switch starts the heaters at the desired temperature setpoint.

Two spark resistant, battery hood exhaust fans both operate continuously to exhaust any combustible gases generated from the batteries to the atmosphere.

9.4.12.3 Safety Evaluation

The makeup water pumps are required to supply water to the SW spray ponds in the event a design basis tornado empties the ponds of their coolant (see Section 9.2.7). The pump house HVAC system is required to ensure that the operation of the makeup pumps is not diminished by extremes in temperature. The HVAC system provided in the makeup water pump house incorporates the following safety features to ensure that a single component failure will not prevent the system from performing its operational function:

a. Two full-capacity air handling units are provided for the electrical equipment area and two full-capacity fan coil units are provided for the makeup pump area; therefore, failure of any one unit will not effect system operation,

b. The redundant HVAC equipment is powered from different divisions of the emergency diesel generator buses; therefore, failure of any one bus will affect only one train of ventilating equipment, and

c. All heating and ventilating equipment is located within the pump house where it is protected from tornado missiles.

9.4.12.4 Testing and Inspection Requirements

The performance of the heating and ventilating system servicing the makeup water pump house can be verified while the systems are operating. The operability of standby equipment is determined by rotating the duty of redundant systems.

All systems ductwork was balanced for air flows in accordance with the procedures of AABC and all piping systems and components were subject to hydrostatic tests during erection.

9.4.12.5 Instrumentation Requirements

The following major instrumentation devices are used in the control and monitoring of the makeup water pump house heating and ventilating system in addition to those described in Section 9.4.12.2:

a. Three position selector switches (ON-OFF-AUTO) are provided locally for each of the two pump area fan coil units and are normally in the AUTO position. In this position, the starting of the makeup pump, powered from the same bus as the fan coil unit, will start the fan coil unit and energize its control circuit via an electric interlock. The second makeup pump start will not start the second fan coil unit. Both fan coil units operate only when all three pumps are operating. Differential pressure switches across the fan of each unit will annunciate an alarm and start the standby unit in the event of a low differential pressure;

b. Three position selector switches (ON-OFF-STANDBY) are provided locally for each of the two electrical equipment area air handling units. One unit is normally operating with the second unit in standby. Differential pressure switches across each fan, annunciate an alarm and start the standby unit in the event of low differential pressure across the operating fan;

c. Each of the two battery hood exhaust fans are provided with local selector switches and a differential pressure switch across the fan which annunciates a local alarm in the event of fan failure; and

d. Temperature switches located in the electrical equipment and pump areas annunciate alarms in the main control room on high or low ambient temperature conditions.

9.4.13 SERVICE BUILDING

9.4.13.1 Design Bases

The service building HVAC system is designed to provide a controlled environment for personnel comfort within the building. The heating and air conditioning system is of a conventional design.

9.4.13.2 System Description

The service building HVAC system is a “push-pull,” multizone system using chilled water for cooling and hot water for heating.

9.4.13.3 Safety Evaluation

The service building HVAC system has no safety function. Malfunction or failure of the HVAC system will not impair normal or emergency plant operations.

There are no potential sources of radioactive contaminants, with the exception of tritium (see Section 9.4.16.3), nor safety related equipment in the service building.

9.4.14 WATER TREATMENT AREA AND MACHINE SHOP

9.4.14.1 Design Bases

The HVAC system serving the water treatment area and machine shop, both of which are in the service building, is designed to remove noxious fumes generated in the area served and to provide tempered air for personnel comfort. The HVAC system is of a conventional design. The system is sized to provide three air changes per hour in the areas served.

9.4.14.2 System Description

The system is basically a once-through system with the facility for partial recirculation of air from the machine shop to reduce heating requirements during the winter months.

Air is supplied to the machine shop and water treatment area by a central supply air system composed of a ventilation unit and distribution ductwork.

Exhaust fans are provided to exhaust air from the machine shop and water treatment area.

9.4.14.3 Safety Evaluation

The heating and ventilating system serving the water treatment area and machine shop has no safety function. Malfunction or failure of the system will not effect reactor operation nor cause the release of radioactive materials.

There are no potential sources of radioactive contaminants, with the exception of tritium (see Section 9.4.16.3) nor safety-related equipment in the areas serviced.

9.4.15 CIRCULATING WATER PUMP HOUSE

9.4.15.1 Design Bases

The HVAC system serving the circulating pump house is designed to satisfy the following criteria:

a. Limit the maximum temperature in the circulating pump area to within 10°F of the ambient temperature when the pumps are operating,

b. Maintain the pump area at a minimum temperature of 50°F when the pumps are not operating,

c. Maintain the electrical equipment room and control room pressurized, with respect to the adjacent rooms, to prevent the ingress of noxious fumes, and maintain the room temperature between 65°F and 85°F,

d. Exhaust air from the halogen storage tank room, halogen injection pump room, and acid pump room to prevent the potential buildup of noxious fumes, and heat the halogen injection pump room to 65°F for personnel comfort during room occupancy, and

e. Continuously exhaust air to atmosphere from the diesel oil storage room to prevent the potential buildup of combustible fumes.

9.4.15.2 System Description

The HVAC systems serving the circulating water pump house are shown in Figure 9.4-7.

The pump area is ventilated by six 33,000-cfm capacity roof exhaust fans, each of which is controlled by a manual switch.

When the exhaust fans are on, air is induced into the pump area through weather louvers in the exterior walls of the structure. Heat is provided in the pump area by twelve electric unit heaters, each controlled by separate room thermostats.

The electrical equipment room and control room are serviced by an air-cooled, roof-mounted air conditioning unit. The unit has a built-in, electric blast coil heater, a roughing filter bank, an integral air-cooled condenser, and a centrifugal fan. The unit supplies air to the two rooms, drawing outdoor air to pressurize the rooms and recirculating air from the electric equipment room. The pressurizing outside air supplied to the rooms is relieved to the pump area via relief dampers in the partition wall between the rooms and the pump area.

A fiberglass roof ventilator continuously exhausts air from the halogen injection pump room, and the acid pump room. The halogen storage tank room is served by a heat pump unit, which recirculates air from this area. If needed, the fiberglass roof ventilator can be used to exhaust air from the halogen storage tank room by opening a volume damper in the exhaust duct. Makeup air is induced into the halogen injection pump room and the acid pump room through relief dampers from the pump area. An electric unit heater is provided in the halogen injection pump room for personnel comfort when the area is occupied. A motor-operated damper in the branch exhaust duct from the halogen injection pump room is controlled by a thermostat located in the halogen storage tank room in such a manner that air exhaust from the halogen injection pump room can be reduced when the outdoor temperature (as sensed in the halogen storage tank room) falls below a predetermined setpoint to minimize the halogen injection pump room heating requirements.

An explosion proof wall fan continuously exhausts air from the diesel oil tank storage room to the atmosphere to prevent the buildup of combustible gases. Air is introduced into the room from the pump area through a vent opening protected by a 3-hr rated fire damper. Air exhausted from the room is also vented through a 3-hr rated fire damper. Equipment details are given in Table 9.4-8. Equipment seismic information is given in Table 3.2-1.

9.4.15.3 Safety Evaluation

The HVAC system serving the circulating water pump house has no safety function. Malfunction or failure of the system will not impair normal or emergency operation.

9.4.15.4 Testing and Inspection Requirements

All system ductwork was balanced for air flows in accordance with the procedures of AABC. All system components were subjected to preoperational testing to verify that the system functions in accordance with the design requirements.

9.4.15.5 Instrumentation Requirements

Each electric unit heater is put in service by a local hand switch and is controlled by its own thermostat.

Each fan is put in service by an OFF-ON switch.

The electrical equipment room air conditioning unit is put in service by a local ON-OFF switch. When ON, the fan runs continuously and the unit control circuit is energized permitting a one-stage cooling, two-stage heating thermostat to cycle the unit compressor or the two-stage electric blast coil heater, as required.

Pressure switches with sensors in the exhaust duct of the chlorine exhaust fan and the supply duct of the air conditioning unit fan will annunciate alarms in the event of a fan failure.

9.4.16 PLANT HEATING STEAM SYSTEM

9.4.16.1 Design Basis

The plant HS system, in conjunction with heating coils, humidifiers, and steam unit heaters in the plant HVAC systems, discussed previously in this section, is designed to:

a. Maintain a minimum temperature of 50°F in the reactor, radwaste, and turbine generator buildings during cold weather conditions,

b. Maintain a minimum temperature of 65°F on the refueling floor of the reactor building and in the service building machine shop and water treatment areas,

c. Provide humidified air to the radwaste control room, radiochemistry laboratory, counting room, and hot instrument shop, and

d. Generate, through a hot water heat exchanger, 180°F water for perimeter heating of service building offices and laboratories.

The plant HS system is designed for 50 psig service. The source of the HS is the gland steam evaporator during turbine generator operation and the auxiliary boiler during plant shutdown. The heating condensate (HCO) system is designed as a gravity return to the auxiliary boiler condensate return tank (CO-TK-1) in the turbine generator building.

9.4.16.2 System Description

The plant HS system is depicted in Figure 9.4-9. The system originates from four pressure reducing stations (two in the turbine generator building and one each in the reactor and radwaste buildings). Steam at 200 psig pressure is supplied to these pressure reducing stations from either the auxiliary boiler or the gland steam evaporator. At the pressure reducing stations, the steam pressure is reduced to 50 psig and this steam is fed to the heating coils, humidifiers, steam unit heaters, and hot water heat exchanger.

The condensate from the HS system is returned to the auxiliary boiler condensate return tank located in the auxiliary boiler room of the turbine generator building. Condensate from the reactor building, turbine generator building, and upper level of the service building is returned to the auxiliary condensate return tank by gravity.

In the radwaste building and lower level of the service building, the condensate returns are below the level of the auxiliary condensate return tank. A condensate pump-set is, therefore,

provided in each of these areas to pump the condensate to the return tank. Equipment details are given in Table 9.4-9. Equipment seismic information is given in Table 3.2-1.

9.4.16.3 Safety Evaluation

The auxiliary boiler and associated steam systems were originally intended to be free from radiological contamination. During operation, however, the system has become contaminated with tritium. Possible sources of the tritium activity are tube leaks in the feedwater heaters or the steam evaporator. As is discussed in Section 11.1.3, all tritium produced in the reactor is eventually released to the environs. Tritium may be released from the heating system in vapor and gaseous form or in auxiliary boiler water blowdown. The boiler blowdown tank drains to a turbine building sump (see Section 9.3.3.2.3.1) which is directed to radwaste processing. The tritium contamination in the auxiliary boiler and associated steam systems is monitored and efforts are made to minimize the levels of activity. The tritium does not necessitate changes in system design or operation and will not cause significant radiological impacts.

The plant HS system has no safety function. Any rupture in HS or HCO piping does not impair safe reactor shutdown as discussed in Sections 3.6.1.15.3 and 3.6.1.18.3.6. All system piping except that in the reactor building is Seismic Category II. All system piping in the reactor building is analyzed and supported to Seismic Category I loading requirements.

9.4.16.4 Testing and Inspection Requirements

The performance of plant HS system was verified by tests prior to startup and is verified during system operation. All components in the system were tested and inspected at the manufacturers plant for conformance with specifications. After installation, the major components were checked and the system hydrostatically tested to ensure leaktightness.

9.4.16.5 Instrumentation Requirements

Adequate instrumentation is provided to monitor and control operation of the system.

Reactor Building and Primary Containment Areas
Major Components of HVAC Systems (Continued)

f. Sump vent filter units	
1. Tag number	REA-FU-2A REA-FU-2B
2. Number of units	2 (1 standby)
3. Capacity (scfm)	1000
4. Fan	Centrifugal direct drive
5. Total static pressure (in., w.g.)	9.6
6. Prefilters	
a) Type	Replaceable media
b) Efficiency	80-85%
c) Initial pressure drop (in., w.g.)	0.5
7. Heater	
a) Type	Electric resistance (3 stage)
b) Quantity	1
c) Capacity	21 kW total
8. HEPA filters	
a) Type	High efficiency
b) Media	Glass media, water repellent and fire resistant
c) Efficiency (DOP 0.3 μ particle size)	99.97%
d) Initial pressure drop (in., w.g.)	Maximum 1.0
9. Charcoal adsorber	
a) Media	Activated carbon
b) Test efficiency @ 70% RH	99.9% elemental iodine 99% methyl iodide
10. Moisture separator	
a) Type	Impingement
b) Initial pressure drop (in., w.g.)	Maximum 1.0

Reactor Building and Primary Containment Areas
Major Components of HVAC Systems (Continued)

g. Sample room fume hood exhaust filter unit

1. Tag number	REA-FU-15
2. Number of units	1
3. Capacity (scfm)	850
4. Type of fan	Centrifugal direct drive (3 hp motor)
5. Prefilter	Replaceable viscous impingement type
6. HEPA filter	Glass media, water repellent and fire resistant
7. HEPA filter efficiency (DOP 0.3 μ particle size)	99.97%
8. Total static pressure (in., w.g.)	4.5

h. Primary containment fan coil units

1. Tag number	CRA-FC-1A CRA-FC-1B CRA-FC-1C	 CRA-FC-2A CRA-FC-2B
2. Number of units	3 (1 standby)	2 (1 standby)
3. Fan type	Vaneaxial (2 per unit)	Vaneaxial (2 per unit)
4. Fan motor type	TEAO with Class RN insulation	TEAO with Class RN insulation
5. Nominal air flow (scfm)	40,000	40,000
6. Cooling capacity (sensible) at nominal air flow (Btu/hr)	1,140,000	1,140,000
7. Water supply source	Reactor building closed cooling system	Reactor building closed cooling system

Table 9.4-2

Reactor Building and Primary Containment Areas
Major Components of HVAC Systems (Continued)

i. Primary containment head area return fans	
1. Tag number	CRA-FN-4A CRA-FN-4B
2. Number of fans	2 (1 standby)
3. Fan type	Vaneaxial
4. Drive	Direct
5. Capacity (acfm)	5000
6. Total pressure (in., w.g.)	1.68 (normal condition) 5.23 (accident condition)
7. Motor type	TEAO with Class RN insulation
j. Primary containment recirculating fans	
1. Tag number	CRA-FN-3A, CRA-FN-3B, CRA-FN-3C, CRA-FN-5A, CRA-FN-5B, CRA-FN-5C, CRA-FN-5D
2. Number of fans	7 (2 standby)
3. Fan type	Vaneaxial
4. Drive	Direct
5. Capacity (acfm)	20,000
6. Total pressure (in., w.g.)	0.83
7. Motor type	TEAO with Class RN insulation

Table 9.4-3

Radwaste Building Area Major Components of HVAC Systems

a. Heating and ventilating unit (evaporative air washer)

1. Tag number	WOA-HV-1
2. Number of units	1
3. Maximum air flow (acfm)	91,304 (82,430 cfm normal)
4. Steam flow (lb/hr)	6980
5. Supply air temperature	
a) Summer	72°F DB (evaporative cooling)
b) Winter	50°F (minimum)
6. Fan type	Centrifugal SWSI V-belt drive (150 hp motor)
7. Number of fans	2 (1 standby)
8. Total static pressure (in., w.g.)	5.43

b. Air handling units

1. Tag number	WOA-AH-3	WOA-AH-4	WOA-AH-5	WMA-AH-6	WOA-AH-9
2. Number of units	1	1	1	1	1
3. Drive	V-belt (1 hp motor)	V-belt (5 hp motor)	V- belt (2 hp motor)	V-belt (5 hp motor)	V-belt (1.5 hp motor)
4. Nominal air flow (scfm)	1475	6900	3000	7000	2000
5. Cooling capacity (sensible and latent) at nominal air flow (MBtu/hr)	57	255	155	204	76
6. Total static pressure (in., w.g.)	1.9	1.9	1.77	1.9	1.7
7. Area served	Health physics area	Radio chem lab	Hot instrument shop	Radwaste control room	Counting room
8. Cooling water supply source	Chilled water	Chilled water	Chilled water	Chilled water	Chilled water

Table 9.4-3

Radwaste Building Area Major Components of HVAC Systems (Continued)

d. Fume hood filter units

1. Tag number	WEA-FU-2A WEA-FU-2B WEA-FU-2C	WEA-FU-4 WEA-FU-5	WEA-FU-6
2. Number of units	3	2	1
3. Capacity (scfm)	1850	1850	3700
4. Fan type	Centrifugal direct drive	Centrifugal direct drive	Centrifugal direct drive
5. Prefilter	Replaceable viscous impingement type	Replaceable viscous impingement type	Replaceable viscous impingement type
6. HEPA filter	Glass media, water repellent and fire resistant	Glass media, water repellent and fire resistant	Glass media, water repellent and fire resistant
7. HEPA filter efficiency (DOP 0.3 μ particle size)	99.97%	99.97%	99.97%
8. Total static pressure (in., w.g.)	4.5	4.5	4.5
9. Area served	Fume hood radio chem labs	Fume hood instrument shop	Fume hood sample room

e. Water chillers

1. Tag number	WCH-CR-51A, WCH-CR-51B
2. Number of units	2 (1 standby)
3. Nominal capacity	150 tons
4. Chilled water (gpm)	360
5. Chilled water supply temperature	44°F
6. Condenser cooling water source	Plant service water
7. Area served	Main control room, cable spreading room, health physics area, radwaste control, radio chem lab, counting room, and hot instrument shop

Table 9.4-3

Radwaste Building Area Major Components of HVAC Systems (Continued)

f. Offgas charcoal adsorber vault air handling units (spared in place)

1. Tag number	WRA-AH-7A, WRA-AH-8A, WRA-AH-7B, WRA-AH-8B
2. Number of units	4 (2 standby)
3. Drive	V-belt (15 hp motor)
4. Nominal air flow (acfm)	15,000
5. Total cooling capacity at -55°F brine (R-11) temp (MBtu/hr)	155
6. Nominal brine flow (gpm)	150
7. External static pressure (in., w.g.)	1.5

g. Brine chillers (spared in place)

1. Tag number	WRE-CR-7A, WRE-CR-7B
2. Number of units	2 (1 standby)
3. Brine	R-11
4. Brine flow range (gpm)	265
5. Brine inlet and outlet temperature	-51°F and -55°F
6. Nominal capacity (MBtu/hr)	175
7. Condenser cooling water source	Plant service water or chilled water (both physically disconnected from brine chillers)
8. Area served	Offgas charcoal adsorber vault

Table 9.4-4

Turbine Generator Building Major Components of HVAC Systems

a. Heating and ventilating unit (evaporative air washer)

1. Tag number	TOA-HV-1A TOA-HV-1B	TOA-HV-2A TOA-HV-2B
2. Number of units	2	2
3. Nominal air flow (scfm)	80,000	97,000
4. Steam flow (lb/hr)	4530	5570
5. Supply air temperature		
a) Summer	72°F DB (evaporative cooling)	72°F DB (evaporative cooling)
b) Winter	50°F	50°F
6. Fan type	Centrifugal V-belt (125 hp motor)	Centrifugal V-belt (125 hp motor)
7. Number of fans	2 (1 for each unit)	2 (1 for each unit)
8. Total static pressure (in., w.g.)	5.8	4.8

b. Exhaust fans

1. Tag number	TEA-FN-1A, TEA-FN-1B, TEA-FN-1C, TEA-FN-1D
2. Number of fans	4 (one standby)
3. Fan type	Centrifugal SWSI
4. Drive	Direct (200 hp motor)
5. Capacity (acfm)	117,000
6. Total static pressure (in., w.g.)	7.0

Table 9.4-4

Turbine Generator Building Major Components of HVAC Systems (Continued)

c. Boiler room air handling unit

1. Tag number	TOA-AH-51
2. Number of units	1
3. Drive	V-belt (15 hp motor)
4. Nominal air flow (scfm)	15,000
5. Steam flow (lb/hr)	980
6. Total static pressure (in., w.g.)	2.1
7. Area served	Boiler room

d. Local exhaust fans

1. Tag number	TEA-FN-52	TEA-FN-53	TEA-FN-2	TEA-FN-3A TEA-FN-3B
2. Number of units	1	1	1	2
3. Drive	Direct (2 hp motor)	Direct (3/4 hp motor)	Direct (1/4 hp motor)	Direct (2 hp motor)
4. Nominal air flow (scfm)	1350	810	400	9000
5. Total static pressure (in., w.g.)	4 1/2	5/8	3/4	1/4
6. Area served	Fume hood sample room	Sample room	Toilet	Transformer room

2. Unit capacity	15,000	80,000
3. Pumpset capacity (gpm)	22.5	120
4. Discharge pressure (psig)	20	25
5. Area served	Service building	Radwaste building
d. Heat transfer package		
1. Tag number	SHHW-HX-51	
2. Heating capacity (mbh)	1800	
3. Steam flow (lb/hr)	1980	
4. Water flow (gpm)	190	
5. Inlet water temperature	161°F	
6. Outlet water temperature	180°F	
7. Area served	Service building	
e. Reheat Coil		
1. Tag number	ROA-HC-2	
2. Air flow (cfm)	33,200	
3. Steam flow (lb/hr)	2560	
4. Air temperature in	50°F	
5. Air temperature out	115°F	
6. Area served	Reactor building	

NOTES:

1. ALL INSTRUMENTS ON THIS DRAWING SHALL BE IDENTIFIED BY PREFIX "WMA" UNLESS OTHERWISE NOTED. (EXAMPLE: WMA-TIC-51A)
2. ALL INSTRUMENTATION SHALL BE PROVIDED BY HVAC CONTRACTOR (CONTR. NO. 216), UNLESS SHOWN AS MOUNTED ON MAIN CONTROL ROOM PANEL OR AS LISTED BELOW.

   ▭ OR ◇

   WMA-RE-10A, 10B
3. ALL ITEMS MARKED WITH AN ASTERISK (*) ARE PROVIDED WITH ASSOCIATED EQUIPMENT.
4. FOR FLOW DIAGRAM LEGEND, SYMBOLS, AND ABBREVIATIONS SEE DWG. M501.
5. a) ALL DUCTWORK, EQUIPMENT, INSTRUMENTS, AND ASSOCIATED COMPONENTS SHOWN ON THIS DWG. SHALL BE CLASSIFIED AS FOLLOWS, UNLESS OTHERWISE NOTED:

   SEISMIC CATEGORY I
   QUALITY CLASS I

   b) UNITS WRA-AC-51 AND WRA-AC-52 ALONG WITH ALL ASSOCIATED COMPONENTS, DUCTWORK, HANGERS, AND INSTRUMENTATION SHALL BE CLASSIFIED AS FOLLOWS:

   SEISMIC CATEGORY II
   QUALITY CLASS II

   c) ALL UNIT HEATERS, ASSOCIATED COMPONENTS, AND INSTRUMENT WMA-DPI-7 SHALL BE CLASSIFIED AS FOLLOWS.

   SEISMIC CATEGORY II
   QUALITY CLASS II

   ALL SUPPORTS FOR UNIT HEATERS, ASSOCIATED COMPONENTS, INSTRUMENT WMA-DPI-7, AND ITS ASSOCIATED TUBING SHALL BE CLASSIFIED:

   SEISMIC CATEGORY I
   QUALITY CLASS II

   d) ALL CHILLED WATER SHALL BE CLASSIFIED AS FOLLOWS:

   SEISMIC CATEGORY:

   PIPING SUPPORTS I
   PIPING, VALVES, & ASSOCIATED COMP. II

   QUALITY CLASS.

   PIPING SUPPORTS II
   PIPING, VALVES, & ASSOCIATED COMP. II

   e) ALL PIPING, VALVES, AND ASSOCIATED COMPONENTS ON THIS DRAWING IN THE TSW SYSTEM IN THE REACTOR BLDG. AND CONTROL BLDG. SHALL BE CLASSIFIED AS FOLLOWS:
   QUALITY CLASS II+
   SEISMIC CATEGORY II/I*M*
   CODE GROUP D
   *HANGERS TO BE DESIGNED TO SEISMIC CATEGORY I LOADS.
6. AIR QUANTITIES INDICATED AS CFM ARE (STANDARD) SCFM. WHERE ACTUAL CFM IS INDICATED AT FAN AS ACFM, CONTRACTOR SHALL BALANCE SYSTEM TO SUIT ACFM CONDITIONS.
7. ALL TAGS FOR INSTRUMENT ROOT VALVES WILL BE FURNISHED AND INSTALLED BY OWNER.
8. INTERFACE WITH OTHER CONTRACTORS:

   a) ALL STANDBY SERVICE WATER SYSTEM, PLANT SERVICE WATER, AND FIRE PROTECTION SYSTEM PIPING (UPSTREAM OF DELUGE VALVE STATIONS) SHOWN ON THIS DRAWING SHALL BE SUPPLIED AND INSTALLED BY MECH. CONTRACTOR (NO. 215).

   b) ALL CHILLED WATER SYSTEMS, MAKE-UP WATER (POTABLE WATER SYSTEM), FIRE PROTECTION SYSTEM (FP) FROM DELUGE VALVE STATIONS TO FILTER UNITS, AND EQUIPMENT DRAIN (FROM EQUIPMENT TO EXISTING EQUIPMENT DRAINS) PIPING AND VALVES SHALL BE SUPPLIED AND INSTALLED BY HVAC CONTRACTOR (NO. 216).
9. ALL FIRE PROTECTION PIPING ON THIS DRAWING SHALL BE CLASSIFIED AS FOLLOWS.

   a) PIPING & VALVES:

   SIESMIC CATEGORY II
   QUALITY CLASS II
   CODE GROUP D

   b) PIPING SUPPORTS:

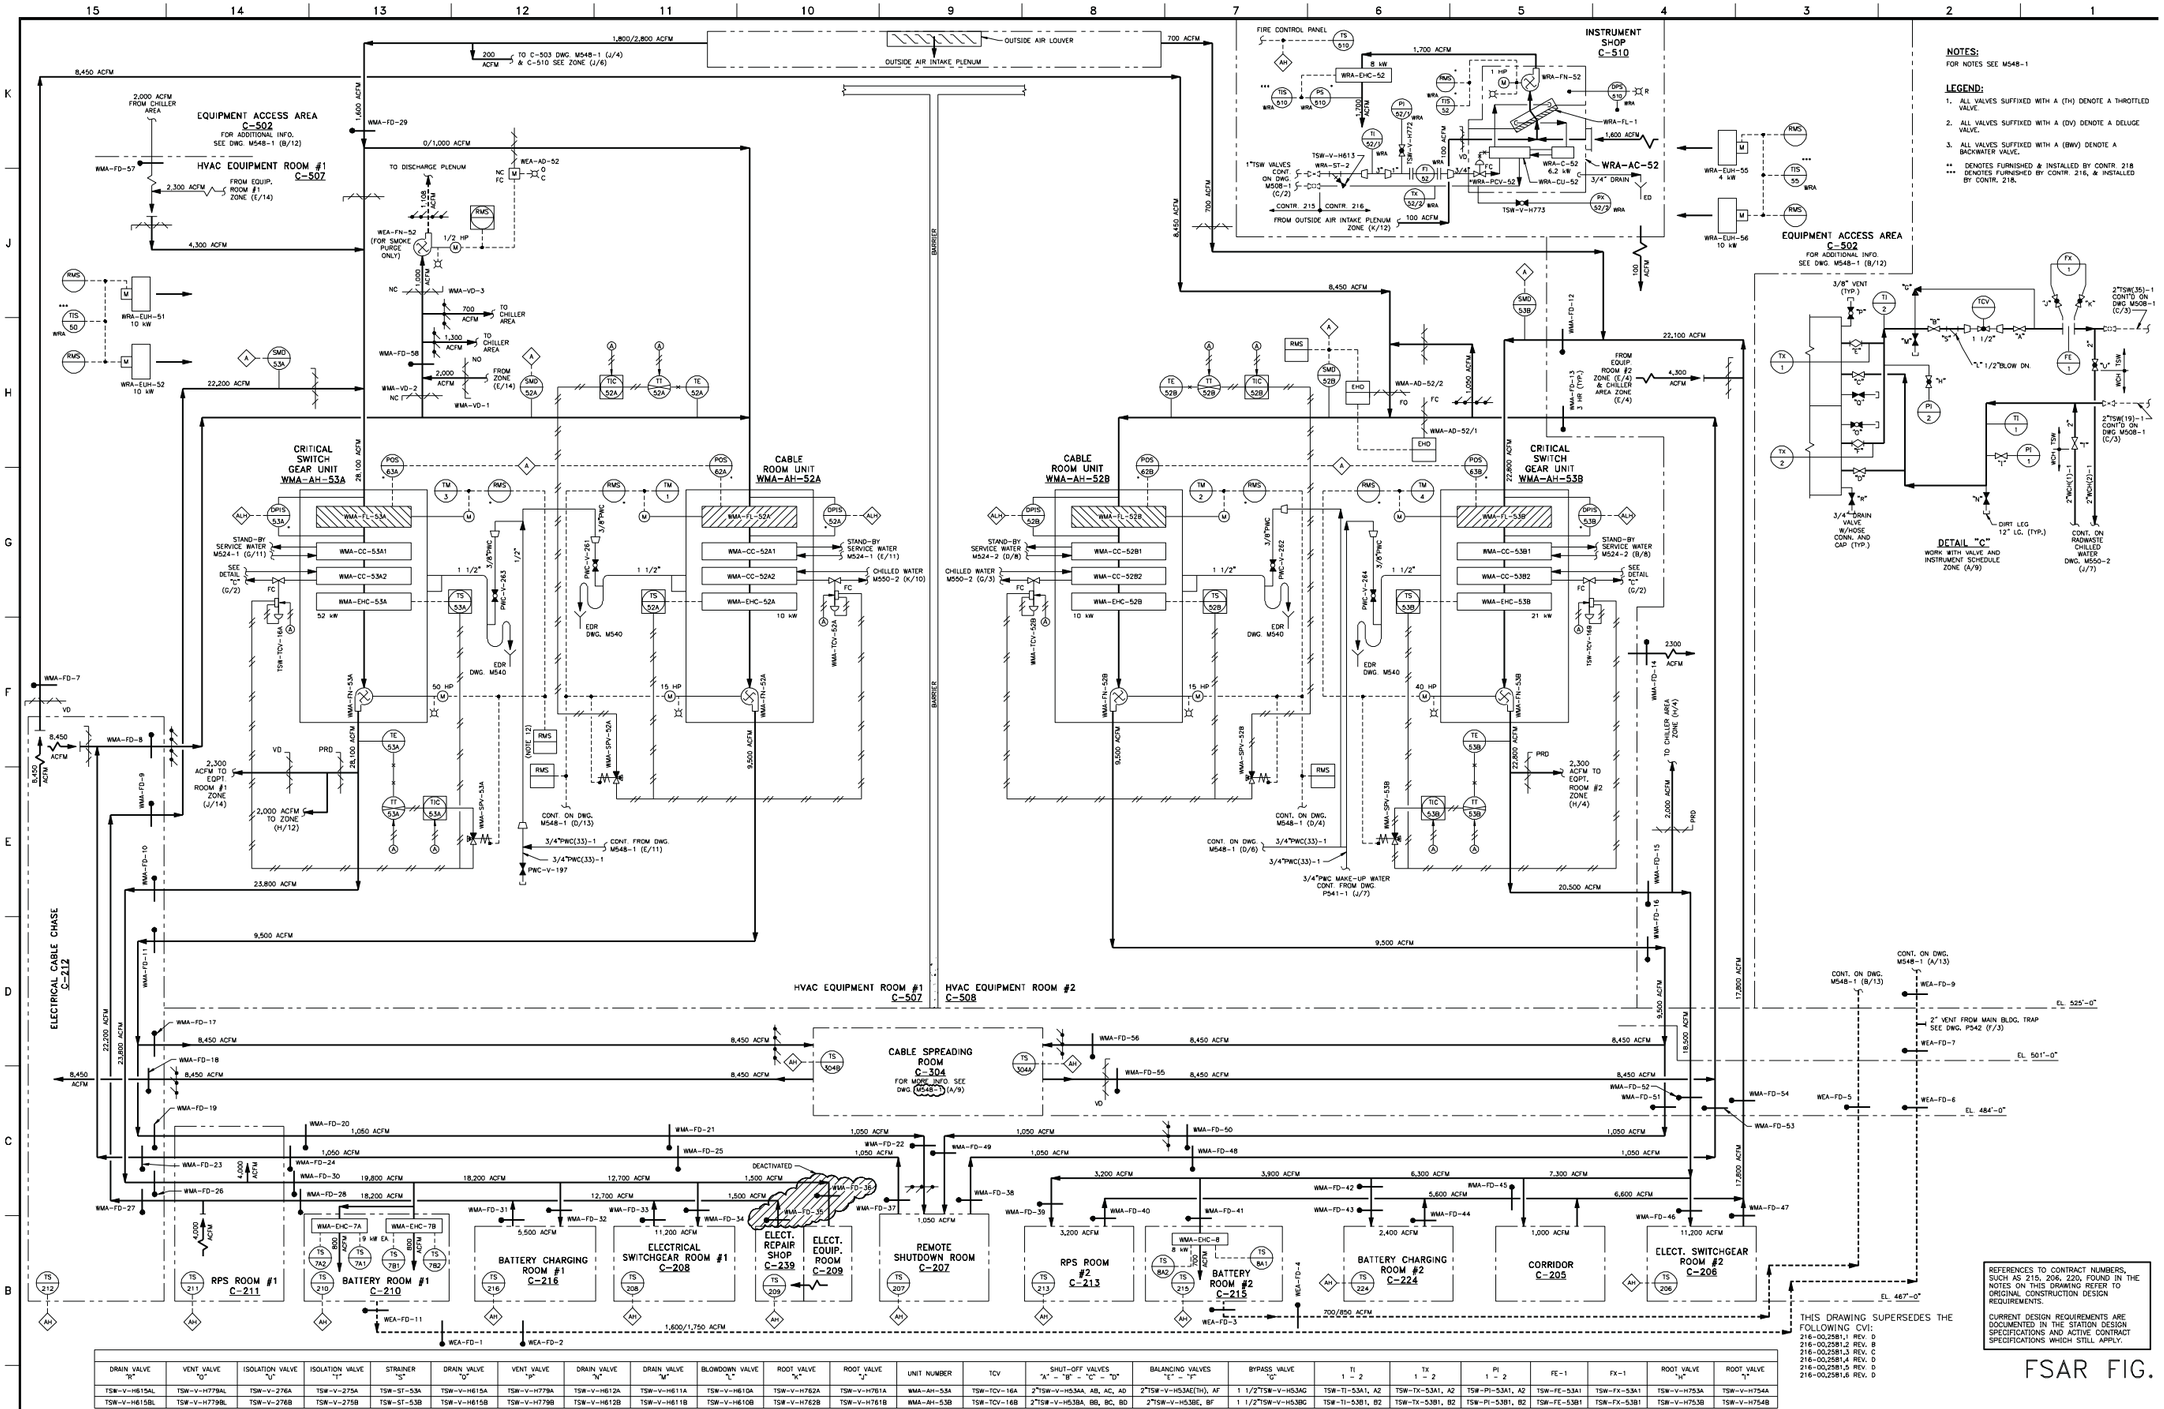
   SEISMIC CATEGORY I
   QUALITY CLASS II
10. TEMPERATURE CONTROL INSTRUMENTS AND CONTROL AIR SUPPLY FOR ELECTRIC HEATING COILS WMA-EHC-51A, 52A, 53A, 51B, 52B, AND 53B ARE SEISMIC CATEGORY II, QUALITY CLASS II. THE POWER SUPPLY TO THESE HEATERS ARE LOCKED "OFF" DURING PLANT OPERATION. THEY MAY BE TURNED ON WHEN THE PLANT IS SHUT DOWN IF DESIRED. SEE NOTE 4 ON DRAWING E503-11.
11. THE POWER SUPPLY FEEDERS FOR UNIT HEATERS WMA-EUH-51 THRU 56 ARE LOCKED "OFF" DURING TIMES OF THE YEAR WHEN CONTROL FAILURE COULD CAUSE EXCESSIVE AMBIENT TEMPERATURE TO CLASS 1E EQUIPMENT. SEE NOTE 3 ON DRAWING E503-5.
12. THIS EQUIPMENT IS NORMALLY CONTROLLED FROM THE MAIN CONTROL ROOM. IF THE MAIN CONTROL ROOM MUST BE VACATED, THIS CONTROL POINT MAY BE ISOLATED AND CONTROL TRANSFERRED TO THE ALTERNATE REMOTE SHUTDOWN PANEL C-CP-ARS.
13. PER EC 5397 PWC-V-499 HAS BEEN CLOSED. WRA-DPS-503, WRA-LS-51, WRA-HU-51 AND ALL PIPING DOWNSTREAM OF PWC-V-499 INCLUDING THE 3/4" DRAIN LINE HAS BEEN DEACTIVATED/DISABLED.
14. SAMPLE POINTS WOA-SP-91A, WOA-SP-91B, WOA-SP-91C, AND WOA-SP-91D HAVE BEEN DISABLED. SAMPLE TUBING HAS BEEN REMOVED OR CAPPED. WOA-SR-18A, WOA-SR-18B, WOA-SR-19A AND WOA-SR-19B HAVE BEEN REMOVED FROM THE PLANT PER EC 11373.

LEGEND:

1. ALL VALVES SUFFIXED WITH A (TH) DENOTE A THROTTLED VALVE.
2. ALL VALVES SUFFIXED WITH A (DV) DENOTE A DELUGE VALVE.
3. ALL VALVES SUFFIXED WITH A (BWV) DENOTE A BACKWATER VALVE.

** DENOTES FURNISHED & INSTALLED BY CONTR. 215.
*** DENOTES FURNISHED BY CONTR. 216, & INSTALLED BY CONTR. 215.

REFERENCES TO CONTRACT NUMBERS, SUCH AS 215, 206, 220, FOUND IN THE NOTES ON THIS DRAWING REFER TO ORIGINAL CONSTRUCTION DESIGN REQUIREMENTS.



CURRENT DESIGN REQUIREMENTS ARE DOCUMENTED IN THE STATION DESIGN SPECIFICATIONS AND ACTIVE CONTRACT SPECIFICATIONS WHICH STILL APPLY.

Radwaste Building

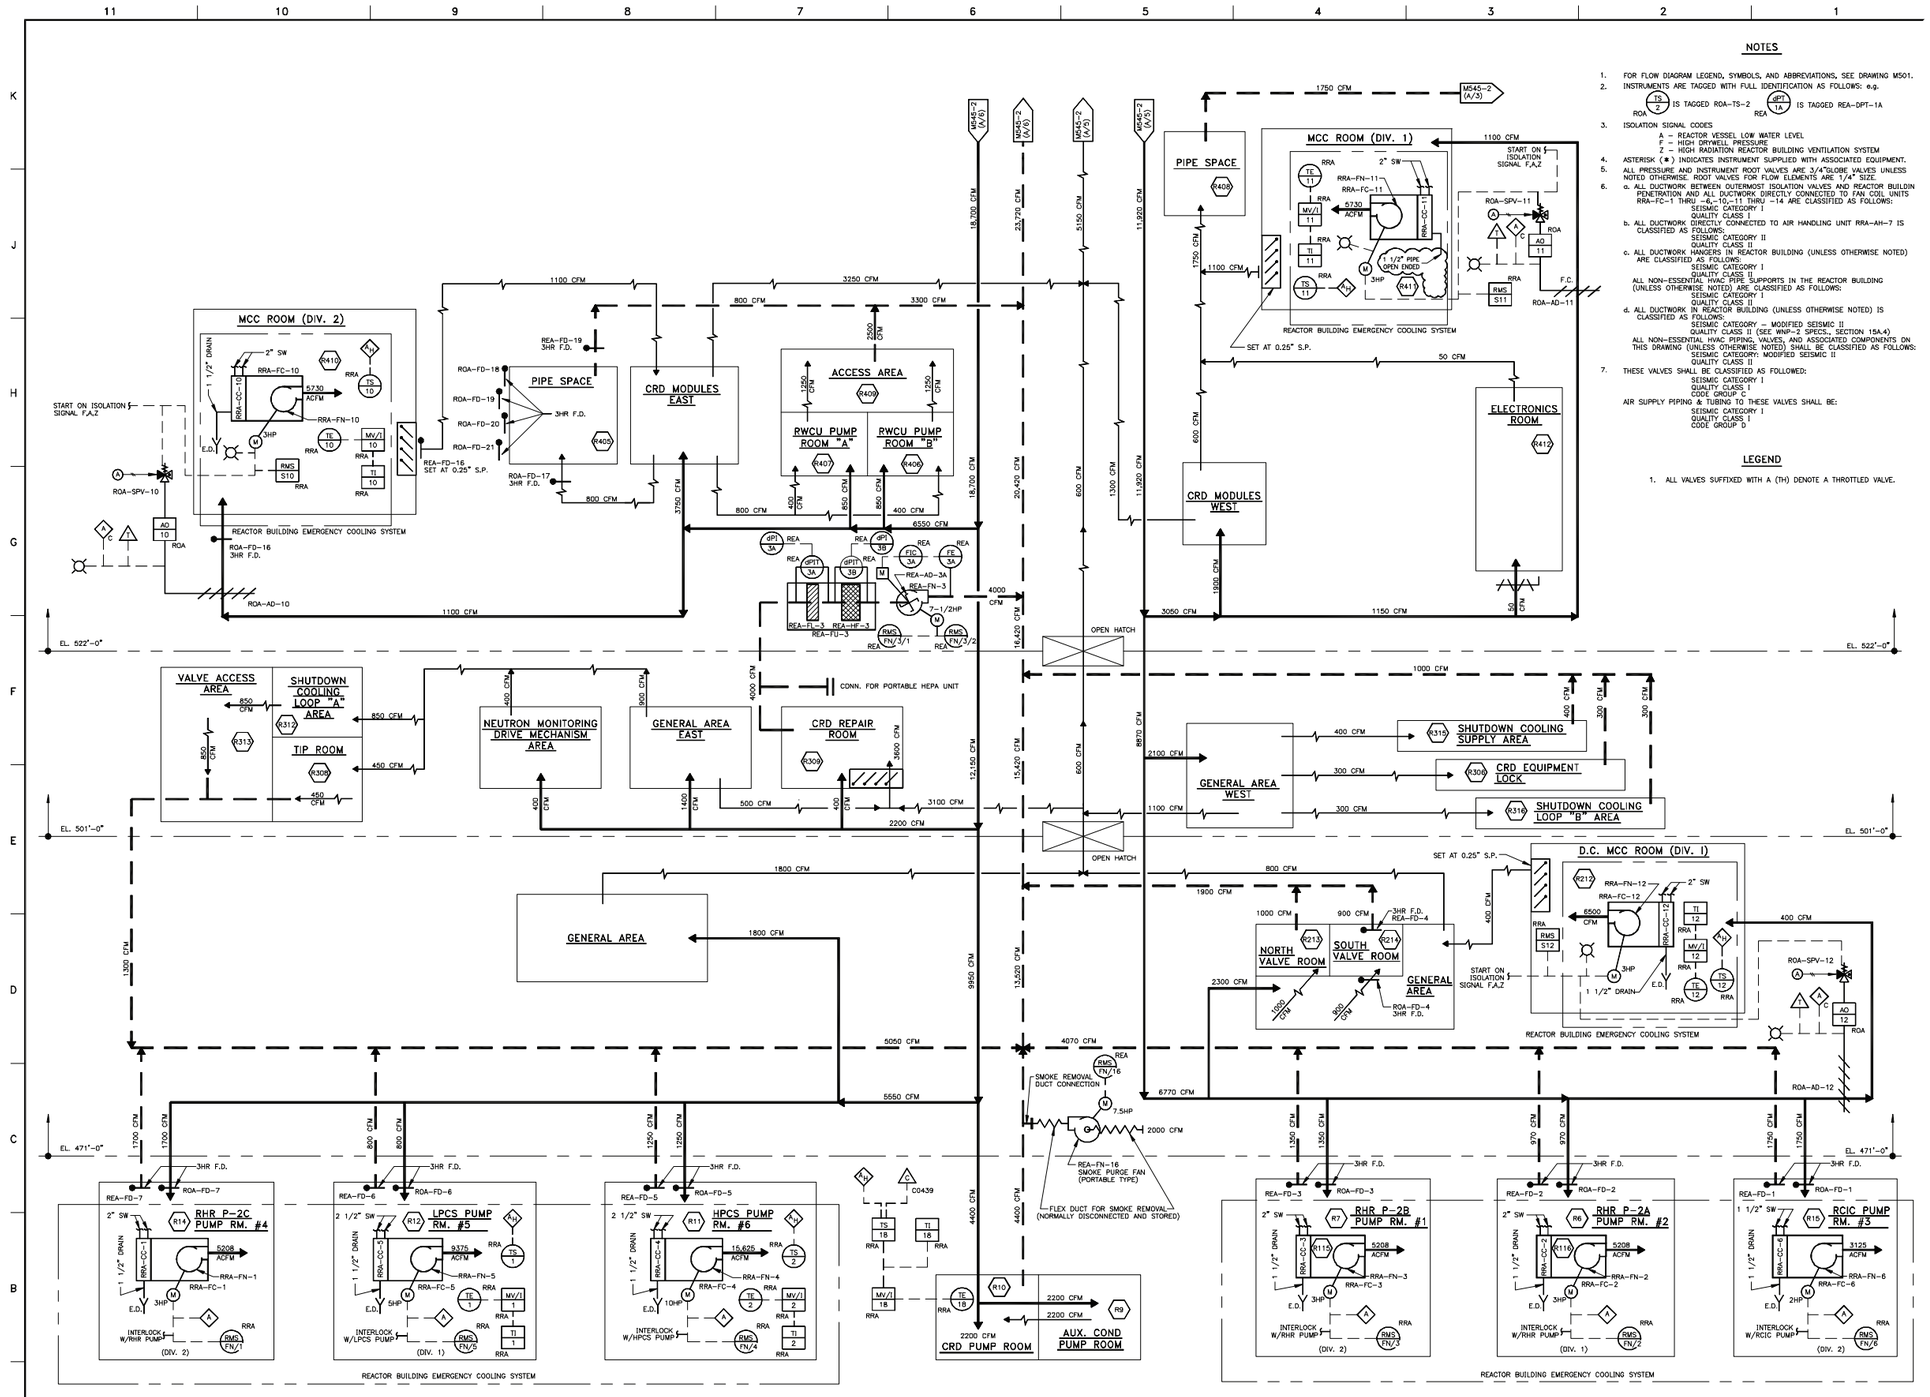
Draw. No. M548-2	Rev. 9	Figure 9.4-1.2

GENERAL NOTES

1. FOR FLOW DIAGRAM LEGEND, SYMBOLS AND ABBREVIATIONS SEE DWG M-501
2. ALL PIPING, INSTRUMENTATION, AND CONTROLS SHALL BE INSTALLED BY THE 215 CONTRACTOR
3. ALL INSTRUMENTATION FOR THE CHILLED WATER SYSTEM SHALL BE PREFIXED BY "CCH" AND ALL INSTRUMENTATION FOR THE STANDBY WATER SYSTEM SHALL BE PREFIXED BY "SW"
4. DELETED
5. ALL INSTRUMENT ROOT VALVES SHALL BE ¾" GLOBE VALVES UNLESS SPECIFICALLY NOTED OTHERWISE.
6. ALL PIPING, VALVES AND ASSOCIATED COMPONENTS IN THE SW, CCH AND CHILLER PACKAGE SYSTEM ON THIS DWG EXCEPT AS STATED IN NOTE 7 AND NOTE 13 SHALL BE CLASSIFIED AS FOLLOWS:
   QUALITY CLASS I
   SEISMIC CATEGORY I
   CODE GROUP C
7. ALL VENT AND DRAIN PIPING DOWNSTREAM OF THE ISOLATION VALVES AND RUPTURE DISCS SHALL BE CLASSIFIED AS FOLLOWS:
   SEISMIC CATEGORY II ⊕
   QUALITY CLASS II
   CODE GROUP D
   ⊕ PIPING SUPPORTS TO BE SEISMIC CATEGORY I
8. NORMAL VALVE LINEUP:
   WMA-CC-51A TO CHILLED WATER
   WMA-CC-51B TO CHILLED WATER
9. DELETED
10. DELETED
11. CHECK VALVE INTERNALS OF SW-V-223A AND SW-V-223B HAVE BEEN REMOVED.
12. FAILS WITH "THRU FLOW" OPEN AND "BYPASS" CLOSED.
13. ALL REFRIGERANT LINE NON ASME III/3 PIPING, TUBING, VALVES AND ASSOCIATED COMPONENTS SHALL BE CLASSIFIED AS FOLLOWS:
    QUALITY CLASS I
    SEISMIC CATEGORY I
    CODE GROUP D

LEGEND

1. ALL VALVES SUFFIXED WITH A "(V)" DENOTE A VENT VALVE.
2. ALL VALVES SUFFIXED WITH A "(D)" DENOTE A DRAIN VALVE.
3. ALL VALVES SUFFIXED WITH A (TH) DENOTE A THROTTLED VALVE
4. DELETED



ANNUNCIATION DETAIL

- A — HIGH REFRIGERANT PRESSURE; LOW REFRIGERANT PRESSURE; LOW OIL PRESSURE; HIGH MOTOR TEMPERATURE; HIGH OIL TEMPERATURE (COMPRESSOR DISCHARGE); MOTOR OVERLOAD
- A L — LOW CHILLED WATER FLOW THRU EVAPORATOR
- A L — LOW WATER LEVEL IN SURGE PIPE (16" CCH(4)-1-2; 16" CCW(14)-1-2)
- A — LOW CHILLED WATER TEMPERATURE

GENERAL NOTES

1. FOR FLOW DIAGRAM LEGEND, SYMBOLS AND ABBREVIATIONS SEE DWG. M501.
2. ALL INSTRUMENTATION AND CONTROLS ON THIS DRAWING SHALL BE IDENTIFIED BY PREFIX "WCH" UNLESS OTHERWISE NOTED.
   EXAMPLE: PI 55 IS WCH-PI-55
   PI 61 TSW IS TSW-PI-61
3. ALL ITEMS MARKED WITH AN ASTERISK (*) INDICATES SUPPLIED WITH ASSOCIATED EQUIPMENT.
4. ALL PIPING, PIPING SUPPORTS, VALVES AND ASSOCIATED COMPONENTS ON THIS DRAWING SHALL BE CLASSIFIED AS FOLLOWS:

   SEISMIC CATEGORY:

   PIPING SUPPORTS INSIDE CONTROL BLDG. – I
   PIPING SUPPORTS OUTSIDE CONTROL BLDG. – II
   PIPING, VALVES AND ASSOCIATED COMPONENTS – I

   QUALITY CLASS:

   PIPING SUPPORTS INSIDE CONTROL BLDG. – II
   PIPING SUPPORTS OUTSIDE CONTROL BLDG. – II
   PIPING, VALVES AND ASSOCIATED COMPONENTS – II
5. LINES SHOWN { —— R —— } ARE INTERCONNECTING REFRIGERANT LINES PROVIDED BY THE CHILLER MANUFACTURER.
6. ALL PRESSURE AND FLOW INSTRUMENT ROOT VALVES SHALL BE 3/4" GLOBE VALVES UNLESS OTHERWISE NOTED.

INDICATING LIGHTS (WCH-CR-51B)

MO LWF LOP LCWT LRT HRP MHT CBHT

MO —— MOTOR OVERLOAD
LWF —— LOW WATER FLOW
LOP —— LOW OIL PRESSURE
LCWT —— LOW CHILLED WATER TEMPERATURE
LRT —— LOW REFRIGERANT TEMPERATURE
HRP —— HIGH REFRIGERANT PRESSURE
MHT —— MOTOR HIGH TEMPERATURE
CBHT —— COMPRESSOR BEARING HIGH TEMPERATURE

SAFETY INDICATOR PANEL
(BY CHILLER MANUFACTURER)

WCH-CR-51B
MOTOR OVERLOAD
LOW WATER FLOW
LOW OIL PRESSURE
LOW REFRIGERANT TEMPERATURE
HIGH REFRIGERANT PRESSURE
MOTOR HIGH TEMPERATURE

Form No. 960690ai

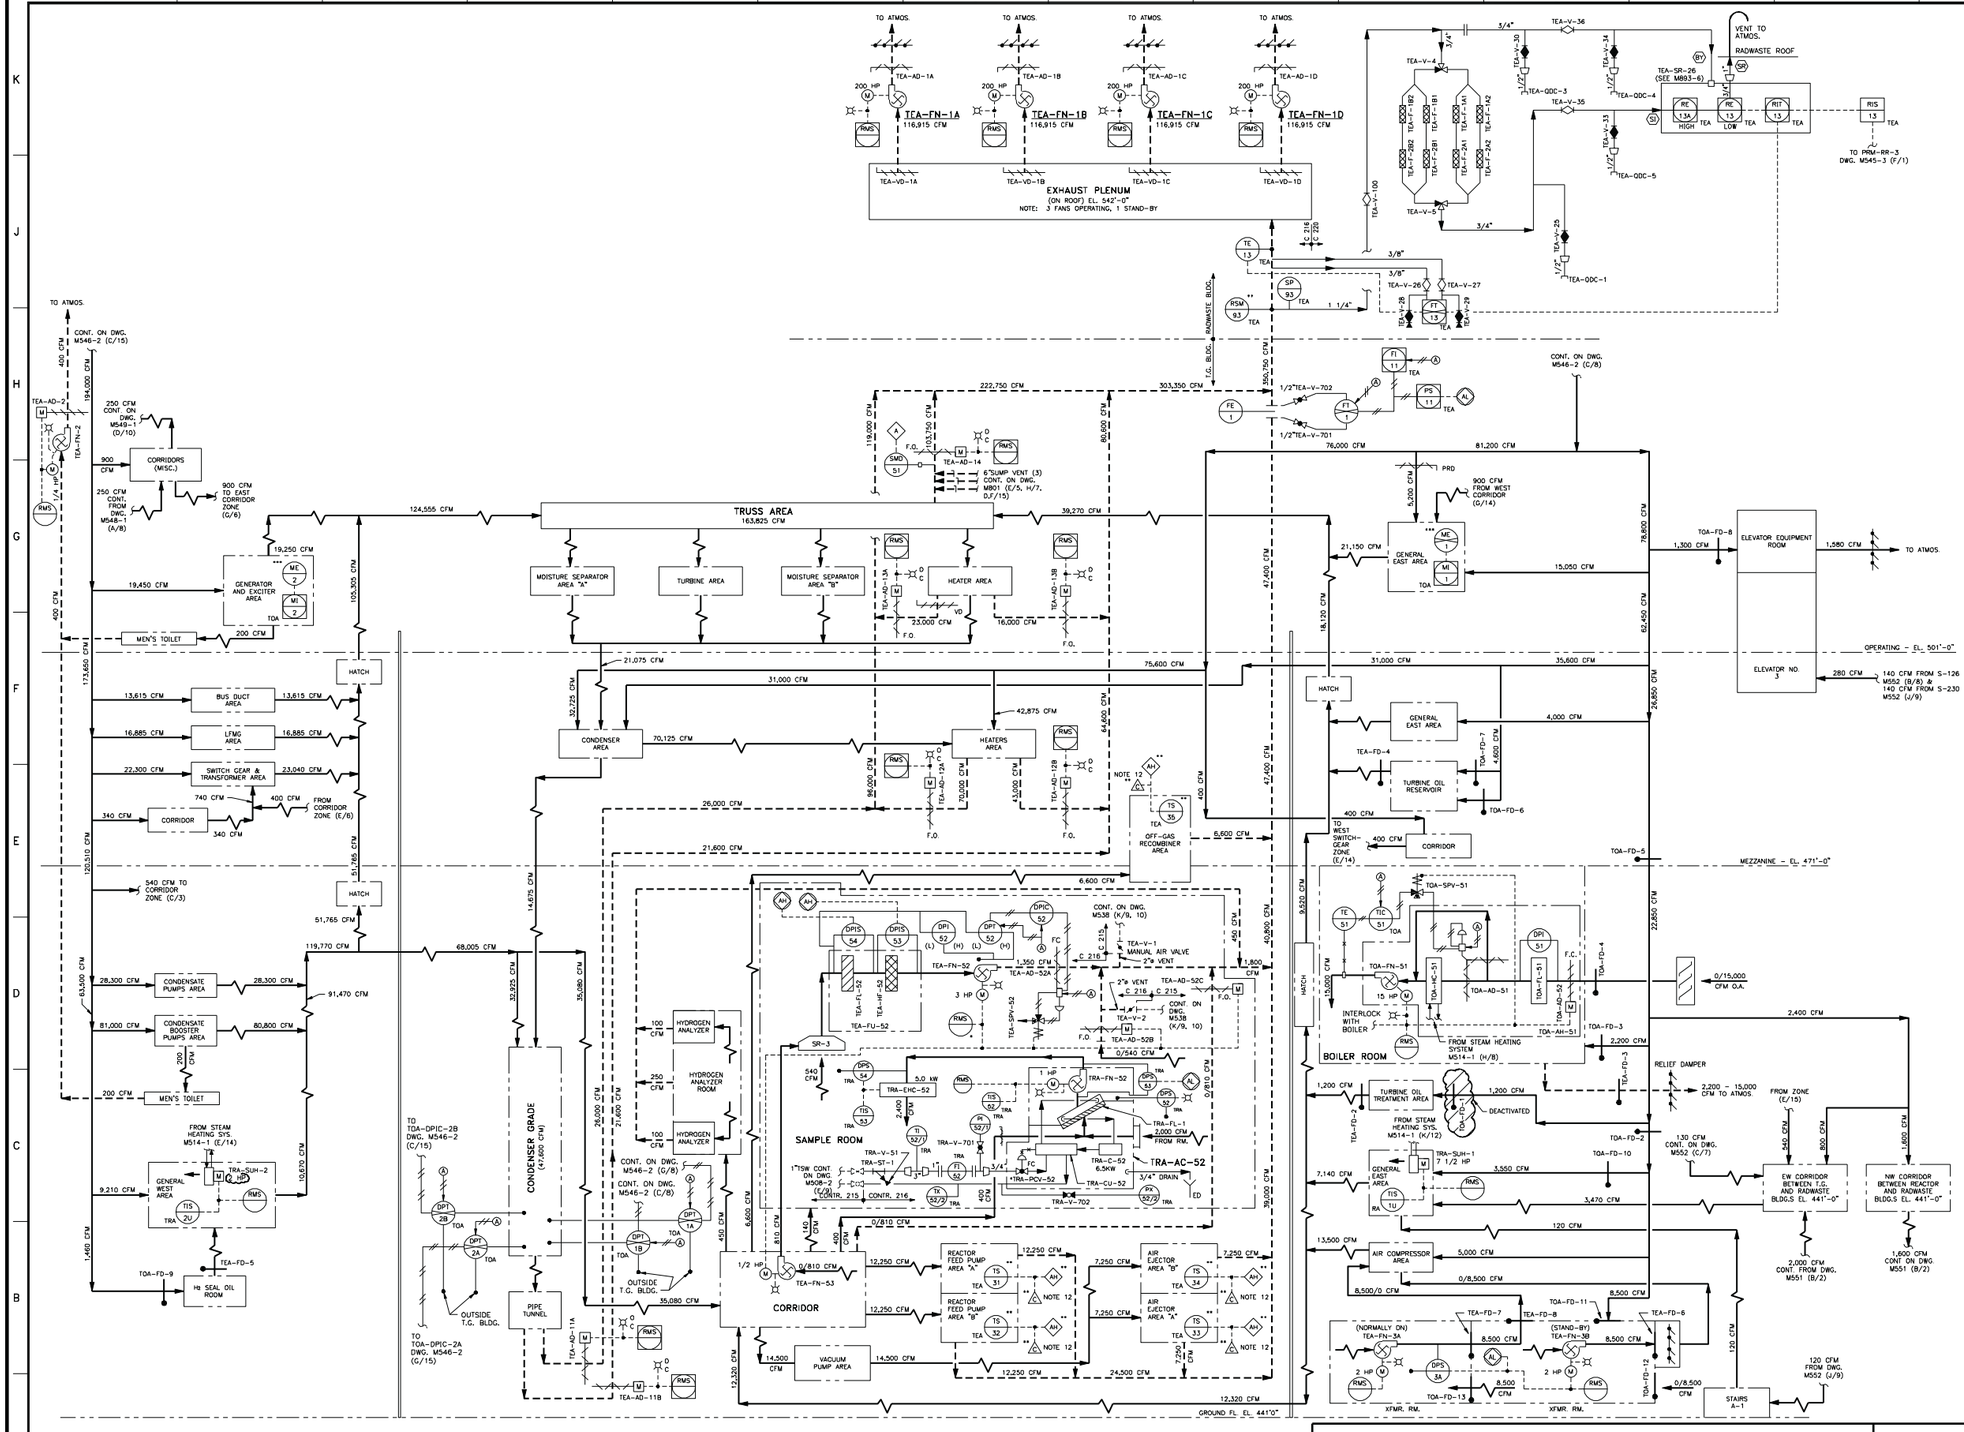
NOTES:

1. FOR FLOW DIAGRAM LEGEND, SYMBOLS, AND ABBREVIATIONS SEE DWG M501.
2. ALL PRESSURE AND FLOW INSTRUMENT ROOT VALVES SHALL BE 3/4" GLOBE VALVES UNLESS OTHERWISE NOTED.
3. ALL INSTRUMENTS ON THIS DRAWING TO BE PREFACED BY "WHI" UNLESS OTHERWISE NOTED.
   i.e. (FS/10) IS TAGGED WRE-FS-10.
4. ORIFICE PLATE FE-32 SHALL BE SQUARE-EDGED ON BOTH SIDES FOR FLOW IN BOTH DIRECTIONS.
5. ALL DUCTWORK, PIPING, VALVES, EQUIPMENT, AND ASSOCIATED COMPONENTS ON THIS DRAWING SHALL BE CLASSIFIED AS FOLLOWS:
   SEISMIC CATEGORY II
   QUALITY CLASS II
6. ALL TAGS FOR INSTRUMENT ROOT VALVES WILL BE FURNISHED AND INSTALLED BY OWNER.
7. * – INSTRUMENTS SUPPLIED WITH EQUIPMENT.
   ** – FURNISHED AND INSTALLED BY 218 CONTR.
   *** – FURNISHED BY 216 CONTR, INSTALLED BY 218 CONTR.
8. THE EQUIPMENT ASSOCIATED WITH THE OFF-GAS CHARCOAL REFRIGERATION VAULT IS DEACTIVATED AND SPARED IN PLACE SINCE IT IS NOT REQUIRED TO SUPPORT THE DESIGN FUNCTION OF THE OFF-GAS SYSTEM. (REF 93-0150-0A)
9. THE EQUIPMENT REFERENCING THIS NOTE HAS BEEN REMOVED FROM THIS DRAWING AND MOVED TO M535-2 ZONE: B/10-12.

LEGEND

1. ALL VALVES SUFFIXED WITH A (TH) DENOTE A TH-ROTTLED VALVE.

REFERENCES TO CONTRACT NUMBERS, SUCH AS 215, 206, 220, FOUND IN THE NOTES ON THIS DRAWING REFER TO ORIGINAL CONSTRUCTION DESIGN REQUIREMENTS.



CURRENT DESIGN REQUIREMENTS ARE DOCUMENTED IN THE STATION DESIGN SPECIFICATIONS AND ACTIVE CONTRACT SPECIFICATIONS WHICH STILL APPLY.

DESCRIPTION

Columbia Generating Station
Final Safety Analysis Report

HVAC Offgas Charcoal Adsorber Vault - Radwaste Building

Draw. No. M555	Rev. 41	Figure 9.4-5

NOTES:

1. FOR FLOW DIAGRAM LEGEND, SYMBOLS, NOTES AND ABBREVIATIONS SEE DWG. M501.
2. INSTRUMENTS SHALL BE TAGGED WITH FULL IDENTIFICATION AS FOLLOWS:
   a) INSTRUMENTS IN SUPPLY SYSTEM
   TC 13A IS TAGGED TOA-TE-13A
   b) INSTRUMENTS IN EXHAUST SYSTEM.
   DPT 1A IS TAGGED TEA-DPT-1A
3. * ASTERISK DENOTES INSTRUMENTS SUPPLIED WITH EQUIP. ** ASTERISKS DENOTE INSTR. SUPPLIED BY OTHERS *** ASTERISKS DENOTE INSTR. FURNISHED BY CONTR. 216, AND INSTALLED BY CONTR 218
4. ALL PRESSURE AND FLOW INSTRUMENT ROOT VALVES SHALL BE 3/4" GLOBE VALVES, UNLESS SPECIFICALLY NOTED OTHERWISE.
5. REFER TO HEATING STEAM FLOW DIAGRAM M514 FOR LINE AND VALVE DESIGNATIONS.
6. DELETED
7. DELETED
8. ALL DUCTWORK, EQUIPMENT, AND ACCESSORIES ON THIS DWG. ARE CLASSIFIED AS FOLLOWS, EXCEPT TOILET EXH:
   SEISMIC CATEGORY II
   QUALITY CLASS II
9. TOILET EXHAUST DUCTWORK, FAN, & ACCESSORIES ARE CLASSIFIED AS FOLLOWS:
   SEISMIC CATEGORY II
   QUALITY CLASS G
10. ALL INSTRUMENTATION SHALL BE FURNISHED AND INSTALLED BY HVAC CONTRACTOR (CONTR. 216), UNLESS OTHERWISE NOTED
11. ALL TAGS FOR INSTRUMENT ROOT VALVES WILL BE FURNISHED AND INSTALLED BY OWNER.
12. THESE COMPUTER INPUT POINTS ARE NOT USED.
13. NOTE TO BALANCING CONTRACTOR:
    a) THE TRANSFER AIR QUANTITIES THRU HATCHES AND OPEN AREAS ARE FOR ESTIMATING BALANCING REQUIREMENTS FOR A ZONE AND FOR ESTIMATING TOTAL EXHAUST QUANTITIES. THE TRANSFER AIR QUANTITIES NEED NOT BE BALANCED, HOWEVER CORRECT FLOW DIRECTION OF TRANSFER AIR SHALL BE ASSURED.
    b) CFM'S INDICATED ARE STANDARD CFM'S. THE EXHAUST CFM'S SHALL BE BALANCED TO ACTUAL CFM'S (ACFM = 1.1 x CFM).
14. INSTALL THESE FILTERS ACCORDING TO ABNORMAL CONDITION PROCEDURE ABN-ASH "ASH FALL."

LEGEND:

1. ALL VALVES SUFFIXED WITH A (TH) DENOTE A THROTTLED VALVE.

REFERENCES TO CONTRACT NUMBERS, SUCH AS 215, 306, 220, FOUND IN THE NOTES ON THIS DRAWING REFER TO ORIGINAL CONSTRUCTION DESIGN REQUIREMENTS.

CURRENT DESIGN REQUIREMENTS ARE DOCUMENTED IN THE STATION DESIGN SPECIFICATIONS AND ACTIVE CONTRACT SPECIFICATIONS WHICH STILL APPLY.

NOTES:

1. ALL PIPING AND VALVES AND ASSOCIATED COMPONENTS ON THIS DRAWING SHALL BE CLASSIFIED AS FOLLOWS:
   (BREAK POINTS INDICATED ON FLOW DIAGRAM)

   a. PIPING AND VALVES WITHIN PRIMARY CONTAINMENT AND UP TO THE OUTERMOST ISOLATION VALVES:

      SEISMIC CATEGORY I
      QUALITY CLASS I
      CODE GROUP B

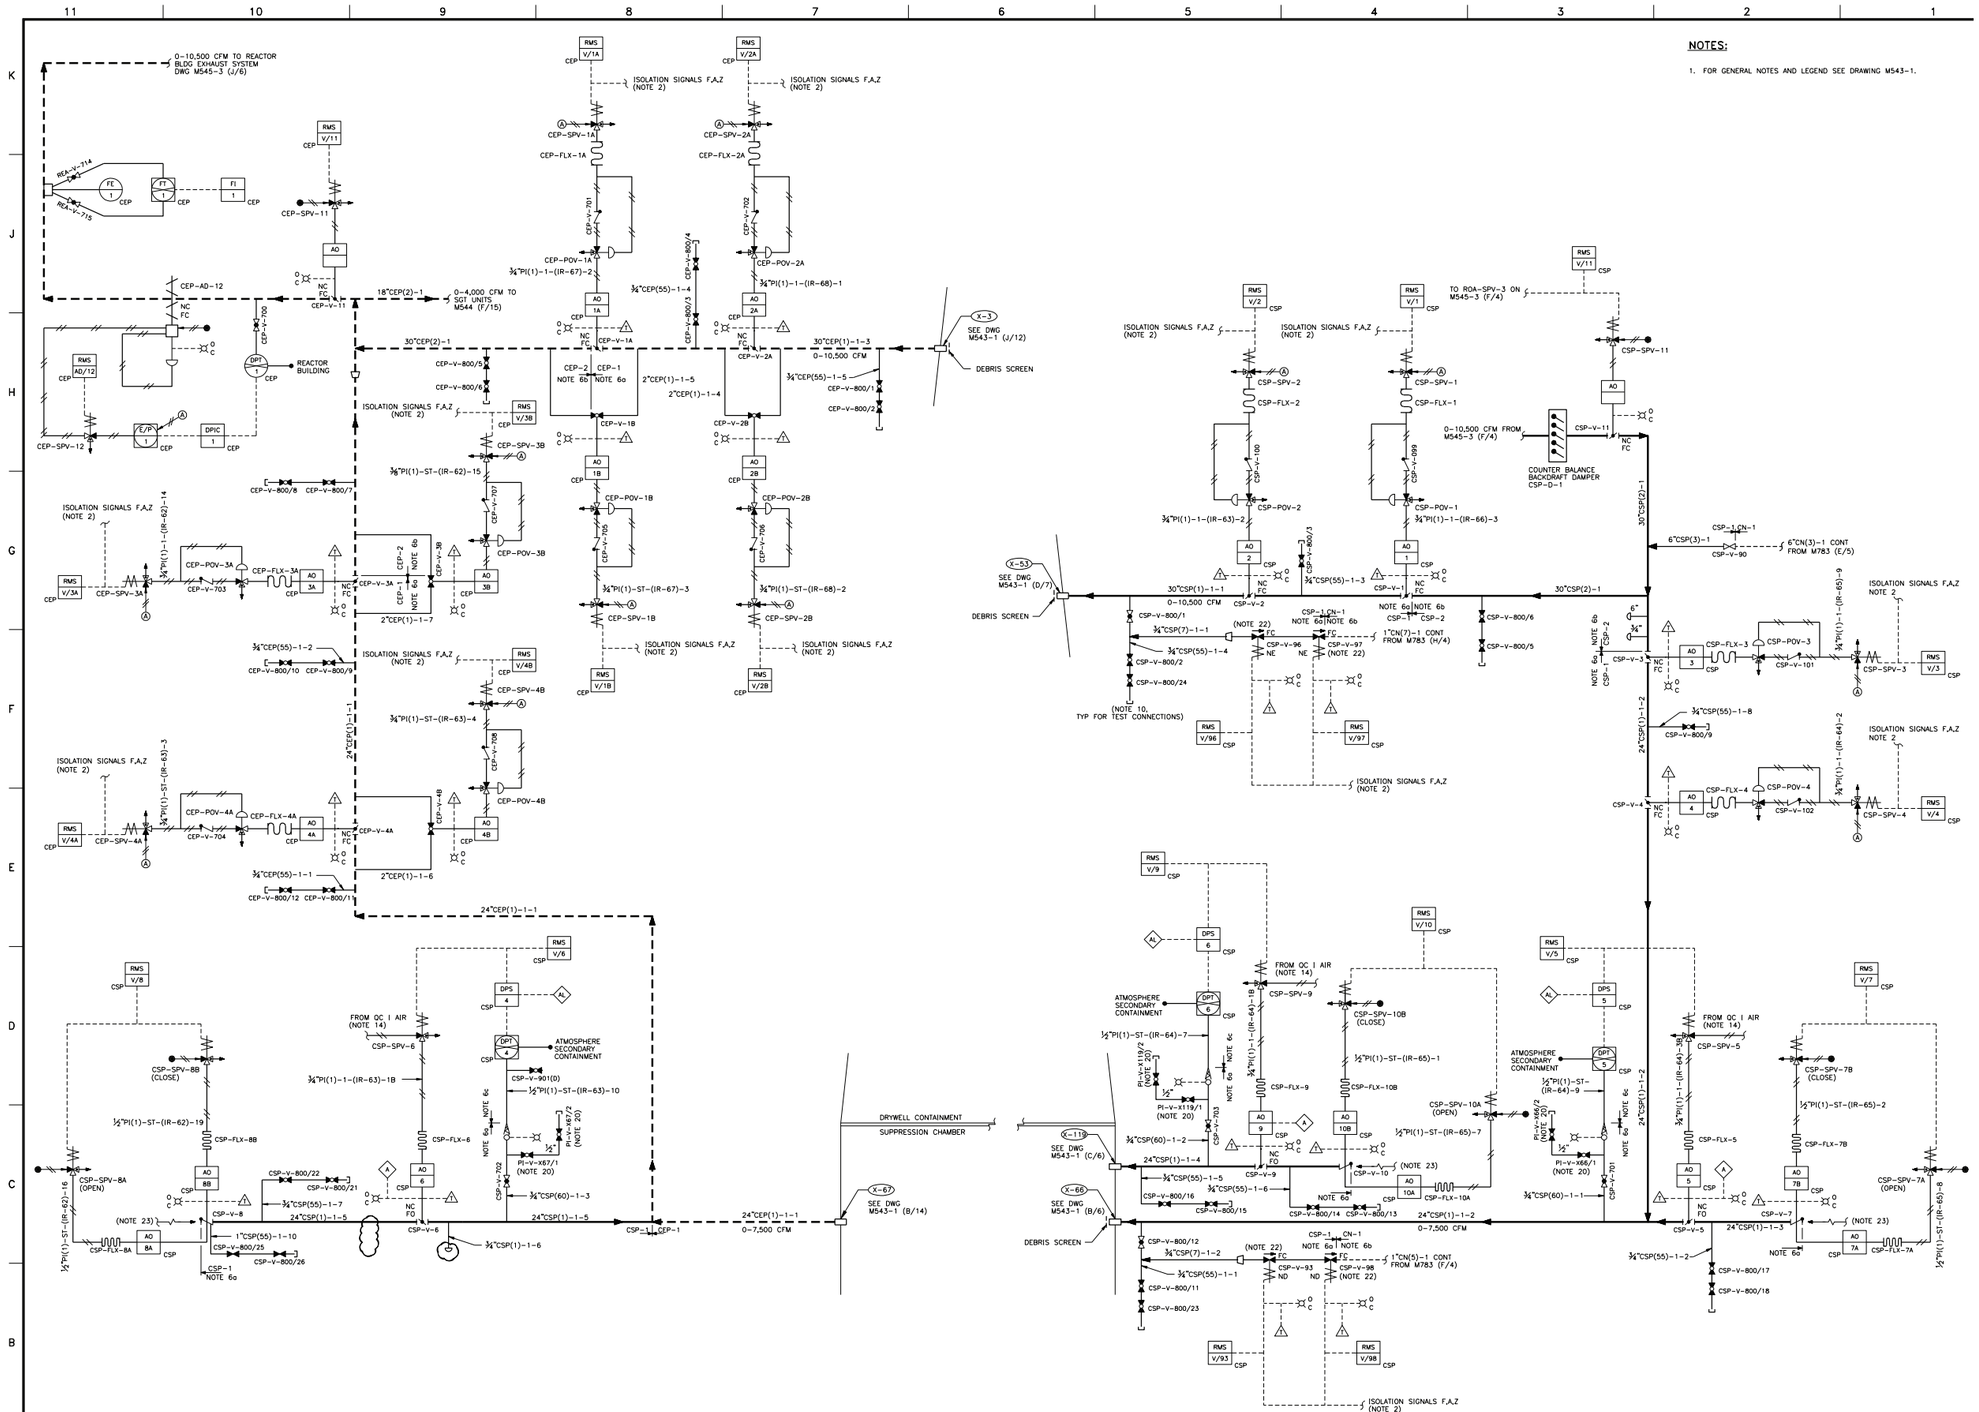
   b. PIPING AND VALVES BEYOND THE OUTERMOST ISOLATION VALVES (INSTRUMENT LINES):

      SEISMIC CATEGORY I
      QUALITY CLASS I
      CODE GROUP C

2. CMS EPN'S FOR CALIBRATION GAS:

TANK #	(1)REGULATOR#	(2)RELIEF VALVES#	TANK VALVE
CMS-TK-1301	CMS-PRV-1301	CMS-RV-1301	CMS-V-1351
CMS-TK-1302	CMS-PRV-1302	CMS-RV-1302	CMS-V-1352
CMS-TK-1303	CMS-PRV-1303	CMS-RV-1303	CMS-V-1353
CMS-TK-1304	CMS-PRV-1304	CMS-RV-1304	CMS-V-1354
CMS-TK-1305	CMS-PRV-1305	CMS-RV-1305	CMS-V-1355
CMS-TK-1401	CMS-PRV-1401	CMS-RV-1401	CMS-V-1451
CMS-TK-1402	CMS-PRV-1402	CMS-RV-1402	CMS-V-1452
CMS-TK-1403	CMS-PRV-1403	CMS-RV-1403	CMS-V-1453
CMS-TK-1404	CMS-PRV-1404	CMS-RV-1404	CMS-V-1454
CMS-TK-1405	CMS-PRV-1405	CMS-RV-1405	CMS-V-1455

3. ◯ REPRESENTS RACK CONNECTION BULKHEAD NUMBER.



REFERENCES TO CONTRACT NUMBERS, SUCH AS 215, 206, 220, FOUND IN THE NOTES ON THIS DRAWING REFER TO ORIGINAL CONSTRUCTION DESIGN REQUIREMENTS.

CURRENT DESIGN REQUIREMENTS ARE DOCUMENTED IN THE STATION DESIGN SPECIFICATIONS AND ACTIVE CONTRACT SPECIFICATIONS WHICH STILL APPLY.

Columbia Generating Station
Final Safety Analysis Report

Flow Diagram - Reactor Building Primary Containment Cooling and Purging System

Draw. No. M543-3	Rev. 6	Figure 9.4-8.3

NOTES:

1. FOR FLOW DIAGRAM LEGEND, SYMBOLS, AND ABBREVIATIONS SEE DWG. M501.
2. ALL PRESSURE AND FLOW INSTRUMENT ROOT VALVES SHALL BE 3/4" GLOBE VALVES UNLESS OTHERWISE NOTED.
3. ALL ITEMS MARKED WITH AN ASTERISK (*) ARE FURNISHED WITH ASSOCIATED EQUIPMENT. ALL INSTRUMENTS MARKED (***) ARE FURNISHED BY CONTRACT 216 AND INSTALLED BY CONTRACT 218.
4. ALL TRAPS SHALL BE FLOAT AND THERMOSTATIC TYPE, UNLESS OTHERWISE NOTED.
5. ALL TRAPS MARKED WITH A DOUBLE ASTERISK (**) SHALL BE INVERTED (G, F, & T). BUCKET TYPE (WITH THERMIC VENT BUCKET), AND WITH AN ARMSTRONG NUMBER AS NOTED, OR APPROVED EQUAL.
6. ALL PIPING, VALVES, AND ASSOCIATED COMPONENTS ON THIS DRAWING, UNLESS OTHERWISE NOTED, SHALL BE CLASSIFIED AS FOLLOWS:

   QUALITY CLASS II
   SEISMIC CATEGORY II
   CODE GROUP D

   ALL PIPING, VALVES, AND ASSOCIATED COMPONENTS IN THE REACTOR BUILDING SHALL BE CLASSIFIED AS FOLLOWS (SEE WNP-2 SPECS., SECTION 15A.4 &150):

   a) SEISMIC CATEGORY:
      PIPING SUPPORTS I
      PIPING, VALVES, & ASSOC. COMP. II

   b) QUALITY CLASS:
      PIPING SUPPORTS II
      PIPING, VALVES, & ASSOC. COMP. II

7. ALL TAGS FOR INSTRUMENT ROOT VALVES WILL BE FURNISHED AND INSTALLED BY OWNER.

LEGEND:

1. ALL VALVES SUFFIXED WITH A (TH) DENOTE A THROTTLED VALVE.

SYMBOLS:

——— DENOTES STEAM
– – – – – DENOTES CONDENSATE
FOR OTHER SYMBOLS SEE DWG. M501

REFERENCES TO CONTRACT NUMBERS, SUCH AS 215, 206, 220, FOUND IN THE NOTES ON THIS DRAWING REFER TO ORIGINAL CONSTRUCTION DESIGN REQUIREMENTS.

CURRENT DESIGN REQUIREMENTS ARE DOCUMENTED IN THE STATION DESIGN SPECIFICATIONS AND ACTIVE CONTRACT SPECIFICATIONS WHICH STILL APPLY.

Columbia Generating Station
Final Safety Analysis Report

Heating Steam System – All Buildings

Draw. No. M514-2 | Rev. 6 | Figure 9.4-9.2

Form No. 960690ai

9.5 OTHER AUXILIARY SYSTEMS

9.5.1 FIRE PROTECTION SYSTEM

Appendix F, Fire Protection Evaluation, contains information on the plant fire protection systems.

9.5.2 COMMUNICATIONS SYSTEMS

9.5.2.1 Design Basis

Columbia Generating Station is provided with the following communication systems:

a. Public telephone access,

b. Private branch exchange (PBX),

c. Sound-powered telephone system,

d. Public address and building-wide alarm system,

e. Radio communication systems, and

f. Telephone link to Bonneville Power Administration (BPA) Dittmer Control Center.

The public telephone network provides for connection of PBX phones to outside lines.

The PBX provides intraplant communications, communication to BPA, and access to the public address and radio paging systems.

The sound-powered telephone system provides a backup to the PBX and can be used as a supplementary communications circuit to aid in the testing and maintenance of plant process systems.

The public address system provides a way of contacting personnel in the various buildings of the plant and locations of the site that might be inaccessible using other means of communication. The building-wide alarm system alerts (via the public address system speakers) operating personnel to fire hazards and other trouble conditions for which plant management finds it necessary to alert plant personnel.

The radio communications system provides a communications link for security and emergency communications to local law enforcement agencies and emergency control centers. In

addition, the radio communications system is used for communications with personnel involved in maintenance and security in and around the plant complex by means of hand-held portable radio units, mobile radio units, and paging receivers. The telephone link to BPA provides a direct communication link to the BPA Dittmer Control Center.

Post-fire safe shutdown operator actions that require emergency communication with the control room or remote shutdown room rely on the PBX phone system. The post-fire safe shutdown communication system must remain operational during a loss of offsite power. Fire brigade activities use radio communication and may communicate with the control room or remote shutdown room using a PBX phone.

All equipment, components, raceways, and support systems located in the main control room are designed and anchored such that they will not cause loss of function of nearby safety-related equipment as a result of the safe shutdown earthquake. The same criteria is followed wherever such equipment is located close to safety-related equipment.

9.5.2.2 System Description

9.5.2.2.1 Public Telephone Access

This system consists of interconnections to the public telephone network as described in the following:

a. Individual direct lines with inward and outward dialing access to several plant locations:

   1. Plant Manager's office,
   2. Main control room,
   3. Security central alarm station (CAS),
   4. Remote shutdown room, and
   5. Security secondary alarm station (SAS).

b. Provisions for extension of individual lines with direct inward and outward dialing access to other plant locations:

   1. Shift Manager's office and
   2. Radwaste control room.

c. Trunks to the PBX provide inward and outward dialing access to various plant locations.

9.5.2.2.2 Private Branch Exchange

This system consists of an all electronic, stored program, computer controlled telephone switching system with integral redundant computers. Telephones are strategically located throughout the plant complex. The system receives power from an uninterruptible power supply (UPS) system for reliable operation, consisting of a battery E-B0-PBX and battery chargers E-C0-PBX/1 and E-C0-PBX/2, located in building 25 (PAAP).

The PBX provides complete intercommunication at all times between any two telephones. Connections are established by means of a dial on each telephone. Automatic dial tone, busy tone, and ringing current are provided.

Telephone communications boxes (CBs) are provided throughout the plant. The CBs in offices have a jack for plugging in a desk-type telephone. These CBs are extensions of the PBX exchange.

Most CBs in the operating and work areas have a PBX telephone jack and a sound-powered telephone jack. Instrument and control panels in the control room have PBX and sound-powered telephone jacks installed in the panels. Operating and work areas use portable telephones plugged into the jacks. A telephone number is assigned to one CB or jack of a compatible group and the others in the group are wired in parallel to it.

Head sets may be plugged into telephones in the operating and work areas when hands-free communication is required. Approved wireless communication devices, such as cordless handsets, may be used in the plant main control room and radwaste control room. To support outage activities approved wireless communication devices can be used in the drywell and approved reactor building elevations. Administrative control of wireless devices based on the location, operating frequency, field strength, minimum distance of an exclusion zone, visual postings, and end user training are established to preclude the effects of EMI.

Dedicated communication links provide access to BPA. The PBX provides the following special features:

a. Conference - up to eight telephones can be connected into a conference network to facilitate maintenance, testing, and management activities.

b. Paging - the Public Address System can be accessed from any PBX telephone extension.

c. Ringdown - the PBX can be programmed to provide ringdown (hotline) service for selected telephones. The service provides automatic ringing without dialing.

9.5.2.2.3 Sound-Powered Telephone System

The sound-powered telephone system consists of jack access in the communications boxes and panels and connecting wiring. The system is divided into eight circuits. Each circuit serves a different area of the plant. All wiring is routed to a terminal box located in the communications equipment room. The terminal box is equipped with jumpers for interconnecting the circuits. During normal operation the jumpers are connected to form a single bus so that all sound-powered jacks are connected in parallel. Each circuit can be isolated at the terminal box if shorts or grounds occur.

Portable sound-powered telephones are plugged into the jacks to complete a communications link.

9.5.2.2.4 Public Address and Building-Wide Alarm Systems

9.5.2.2.4.1 Public Address System. The public address system is designed to provide area-wide announcements throughout the plant by means of loudspeakers located in various areas. Audio power to the speakers is provided by electronics located in equipment racks in the communications equipment room, which is located in the radwaste and control building. Power to the electronics is provided from the UPS bus.

The speakers in each of the buildings or zones are connected in two separate circuit loops. This provides an alternative path for partial communications should one loop be damaged. Paging microphones are located in various areas and are used for "all zone" pages and have priority over telephone-accessed paging.

Most telephone instruments in the PBX can access the paging system by dialing the appropriate access number. Telephone pages can be directed to a specific building/zone or to all zones. The connection between the PBX and the paging system is provided through special paging adapters which interface the two systems.

Critical electronic equipment is redundant and is automatically switched on line as required. Failure of the amplifier systems is alarmed in the control room as well as locally at the public address racks.

9.5.2.2.4.2 Building/Zone-Audio Alarm System. The audio alarm system consists of a multitone generator with redundant backup which is located within the public address (PA) system racks. The audio generators are capable of producing five distinct audio tones which are amplified by the PA system. The redundant generator is automatically switched online should the primary unit fail and an alarm is activated. The units are fed from the UPS system along with the PA system. One tone is used to alert personnel, followed by specific announcements. The audio alarm system has priority over PBX paging and "microphone actuated paging," and will override either of these functions. The main control room is

capable of activating all tones that are used. The alert tone may be activated from either the Plant Manager's office or the remote shutdown room or the TSC.

9.5.2.2.5 Radio Communications System

The radio communications system for Columbia Generating Station is integrated into the Energy Northwest radio network, which provides communications for all Energy Northwest facilities in the Hanford area.

The system is comprised of the following:

a. P25 L2 Core
b. Fiber-Optic Distributed Antenna System
c. In-Plant Repeaters
d. Area Wide Repeaters
e. Base Radio Stations
f. Radio System Desk Sets
g. Radio Dispatch Consoles
h. Portable Handheld Radios, and
i. Mobile Radios installed in vehicles.

P25 L2 Core

The P25 L2 Core zone controller system is the core of the radio communications system and is run using the ASTRO 25 "L" Core platform. The system architecture is designed with inherent fault distribution to ensure that a single point failure will not cause a complete loss of radio communications. The fault distribution includes the ability to reroute IP voice and data packets among the various redundant router configurations. Faults within the network will provide notification on the fault management terminal.

Fiber-Optic Distributed Antenna Systems (FODAS)

The FODAS consist of the ION-M master unit, ION-M4 remote unit transceivers, antennas, and rediax cables used as antennas. The master unit transmits and receives radio frequency signals to/from the base radio stations while controlling the entire ION-M system, including provisioning of the backhaul connectivity. The remote units are connected to the master unit via fiber optic cable. Up to four antennas can be connected to a transceiver using a single fiber back to the master unit.

In-Plant Repeaters

In-plant repeaters are used to provide radio communications within the plant using a fiber optic distributed antenna system. In-plant repeaters provide in-plant radio communications for

Operations, Security, Emergency Preparedness, Fire Brigade, and Maintenance. The in-plant system consists of six repeaters. One repeater is designated as a "control channel" while the other five repeaters provide the audio communications. In a trunked system the control channel notifies the zone controller when a radio user initiates or ends a call using the push-to-to-talk button on the radio, console, or desk set. The zone controller then designates an audio repeater to start or end the call. The in-plant repeaters are located in the Diesel Generator Building and are separated from other communication systems. Six traffic channels support the in-plant radio communications.

Area Wide Repeaters

Area wide repeaters provide area wide radio communications for Operations, Security, and Emergency Preparedness talkgroups. Mobile radios have been programmed to operate using area wide talkgroups. Area wide repeaters are located in the Consolidated Community Communications Facility (CCCF) on Rattlesnake Mountain.

Base Radio Stations

Base radios are programmed with talkgroups to support the in-plant and area wide radio communications. Base radios are connected to radio system desk sets and allow the desk set to talk to any talkgroup programmed within the base radio.

Radio System Desk Sets

Desk sets enable managers, supervisors, and team leaders the ability to communicate with plant and field teams through the in-plant and area wide radio communication systems to provide directional instructions.

Radio Dispatch Consoles

Dispatch consoles have access to all RF resources available to the L2 Core Trunked Digital Radio System. Offsite agencies using conventional radio channels will only be available to the dispatch consoles. Dispatch consoles serve as the mutual aid for interoperability and have the ability to patch offsite agencies into talkgroups for communications with radio users.

All equipment other than mobile radios or handheld portable radios are powered by a UPS bus for reliable operation.

9.5.2.2.6 Telephone Link for Connection to the BPA Dittmer Control Center

This circuit consists of telephones located in the main control and remote shutdown rooms of the radwaste and control building, which are directly connected to the Columbia Generating Station/BPA communications equipment. These phones automatically ring to the Dittmer Control Center of BPA when they are used.

9.5.2.3 Inspection and Testing Requirements

All communication cable conductors are tested for continuity and insulation resistance before connection to the various communication apparatus. Fiber optic cables are tested using an Optical Time Domain Reflector (OTDR) to measure continuity. A functional test on all communications systems is made after installation.

The functional test on the total installed radio communications system included a complete test of all system functions such as operation from dispatch consoles, base radios, desk sets, and two-way communication between offsite and onsite stations. Tests were made using both the maintenance and security system frequencies. Tests were performed to ensure that no harmful interference results between this equipment, the repeater station on Rattlesnake Mountain, and control room equipment. During preoperational and postoperational surveillance testing, solid state electronics in some areas exhibited spurious response to radio transmission. These areas have been flagged by signs showing "Prohibited Area For Use of Radios" and are put under administrative control.

9.5.2.4 Capability During Postulated Accident and Anticipated Transients

Table 9.5-1 shows the strategic work areas and the type of communications available between these locations and the control room, remote shutdown room, and outside Columbia Generating Station.

9.5.2.4.1 Protective Measures

The plant communications system provides assurance that a reliable communications link is available from the strategic plant work stations to the control room. The following design factors contribute toward this goal:

a. The PBX is built with plug-in modular circuit boards so that defective boards can be quickly replaced,

b. The PBX has redundant processing units with automatic switching from a failed computer to the redundant computer,

c. The sound-powered telephone system backs up the PBX system in case of a major failure of the PBX,

d. Several telephones are connected directly to the public telephone network to operate independently of the PBX. These include telephones in the main control room, remote shutdown room, building 62, and the Plant General Manager's office, and

e. During a loss of offsite power, the PEC/PAAP diesel generator ensures the PBX system operation beyond the 8-hr capacity of the PBX communication system battery, E-B0-PBX.

9.5.2.4.2 Severing of Lines or Trunks

The failure of a single line or trunk cannot prevent communications from critical plant locations. Alternate facilities are available as follows:

a. Radios do not require offsite lines and can be used in lieu of telephones if telephone lines are not available,

b. Portable radios can be used if the antenna leads to fixed stations are inoperable, and

c. Tie lines connect the PBX to the BPA communications system. The lines provides telephone communications from Columbia Generating Station to telephones in BPA facilities. These communications are independent of the public telephone network.

9.5.2.4.3 High Noise

The communication system design addresses high noise area problems as follows:

a. Telephones may be installed in sound dampening booths with either or both noise-canceling handsets and amplified receivers, and

b. Public address system speakers have volume controls which are adjusted according to the ambient noise level.

9.5.2.4.4 Post-Fire Safe Shutdown

Fire induced failures of the PBX communication system are evaluated for the various fire areas as part of the post-fire safe shutdown analysis. See F.2.6.2 for more detail.

9.5.3 PLANT LIGHTING SYSTEM

9.5.3.1 Design Bases

a. Lighting intensities are designed to provide indoor and outdoor illumination consistent with the Illumination Engineering Society recommendations (July 1974), and to meet or exceed OSHA requirements,

b. Light sources are selected with consideration for environmental conditions and ease of maintenance,

c. Fluorescent or high-intensity discharge (HID) sources are not used inside primary containment. These contain mercury, a known contaminant in reactor coolant system,

d. The normal lighting supplied from either the main generator or offsite power is designed to provide adequate lighting for normal plant operation and associated plant access routes, and for control and maintenance of equipment, and

e. The emergency lighting supplied from onsite power is designed to provide adequate lighting for safe shutdown of the plant and for associated plant access routes during the full spectrum of accidents, transients and special events.

9.5.3.2 System Description

The plant lighting system consists of four systems: normal ac lighting, normal-emergency ac lighting, emergency dc lighting, and battery-pack emergency lighting. For the location of various fixed emergency lighting systems that support safe shutdown of the plant, see Table 9.5-2. See Figures F.6-18, F.6-19 and F.6-20 for locations of portable lantern use.

9.5.3.2.1 Normal Alternating Current (ac) Lighting Systems

This system consists of two systems (A and B) which are energized from the plant non-safety-related 480-V ac auxiliary system motor control centers directly from three-phase 480-V ac, or through 208/120-V ac dry type lighting transformers and local area lighting panels.

9.5.3.2.2 Normal-Emergency ac Lighting Systems

Normal-emergency ac lighting is provided for safe and orderly shutdown during the loss of normal ac power. This system is energized from the safety-related 480-V ac motor-control centers through isolation devices to non-Class 1E three-phase, four-wire 208/120-V ac dry type lighting transformers that feed lighting panels.

This lighting system consists of two systems (Divisions 1 and 2). Each system has ac lighting energized from critical buses that are connected both to and backed by their associated diesel generators (DG1 & 2).

This ac lighting comprises approximately 15% of the normal plant lighting load. The ac lighting fixtures in the main control room are designed and supported as Seismic Category I.

Some of the ac lighting system within the main control room can be manually transferred from its critical bus to an inverter supplied source if the associated battery charger is in service.

9.5.3.2.3 Emergency Direct Current (dc) Lighting Systems

Emergency dc lighting is provided in the main control room, the access route to the remote shutdown room, and in the remote shutdown room. The emergency dc lighting system is necessary for conducting shutdown operations during the coping period of a Station Blackout event.

This lighting consists of two systems (Divisions 1 and 2). Each system is energized from a 125-V dc plant emergency battery system. The remote shutdown room and access route lighting is continuously lit, and the control room dc lighting is energized on a loss of power to the normal-emergency lighting in the main control room. This dc lighting load consists of incandescent light sources.

9.5.3.2.4 Battery-Pack Emergency Lighting Systems

Battery-pack emergency lighting consists of 1.5-hr and Appendix R lighting units. The lamps automatically energize on loss of the respective normal and/or normal-emergency ac lighting. Emergency battery units in Seismic Category I areas of the radwaste building are Seismic Category I mounted and supported.

The 1.5-hr lighting consists of Emergency Battery Units (EBUs) and Emergency Reserve Ballast (ERB) units in areas without EBUs, installed for the safety of operating personnel to provide lighting for egress routes.

Appendix R 8-hr emergency battery packs and portable 8-hr lanterns are available for use to ensure operators can perform post-fire safe shutdown manual actions outside the control room, for a fire in specific plant areas, concurrent with a LOOP. At a minimum, 8-hr emergency battery pack lighting is installed at locations where operators perform long-term plant control and shutdown actions. The portable 8-hr lanterns are used for short-duration operator actions. There are four stations provided in various plant locations with five portable lanterns available at each location.

9.5.3.3 Safety Evaluation

Normal and normal-emergency lighting is located throughout the plant to provide necessary lighting during normal plant operation and during a power system failure. In the Reactor Building, during accident conditions, the normal lighting is tripped by an accident signal (FAZ) to reduce building heat load.

In areas that are serviced by HID lighting sources, 10% of the fixtures are provided with tungsten halogen standby lamps. These standby lamps will be immediately energized after an interruption of the power source and will provide partial illumination until the HID lamps restrike.

The normal and normal-emergency lighting provide no safety-related function and thus are non-safety related.

9.5.4 DIESEL GENERATOR FUEL OIL STORAGE AND TRANSFER SYSTEM

9.5.4.1 Design Bases

a. The onsite storage capacity of each subsystem provides for continuous operation of each diesel generator for at least 7 days while satisfying post-LOCA maximum load demands;

b. The design of the system conforms to Regulatory Guide 1.137. The equipment within the system conforms to the applicable codes and standards of ASME, ASTM, ANSI, DEMA, IEEE, API, and NFPA;

c. The system piping off of the engine skid is constructed to ASME Section III, Class 3 and Seismic Category I requirements except for the portions of the piping associated with the filter/polisher system. Except for the diesel oil storage tanks and portions of the filter/polisher system, all portions of the system, including the fuel oil day tanks, are protected from tornado missiles by enclosure in tornado-hardened, Seismic Category I structures. The diesel oil storage tanks and associated piping (except for exposed fill, vent, and filter/polisher piping as described in Section 3.5) are buried for tornado protection and to maximize containment of postulated oil spills. The system is not subject to flooding since the site is not subject to flooding. The piping on the engine is constructed using ANSI B31.1 as a guide and is Seismic Category I;

d. The diesel fuel storage system is augmented by the installation of a filter/polisher unit located in a separate filter/polisher building east of the storage tanks. This unit is non-safety-related. It is used to clean bulk fuel of contaminants and fuel degradation products formed due to long storage. It is also used to polish fuel oil delivered by fuel supply tankers, if necessary, prior to delivery to the storage tanks. The filter vessels are constructed to ASME Section VIII, Division I, and the piping components to ANSI B31.1 Power Piping Code.

e. The Quality Class II Auxiliary boiler storage tank is used as an additional storage tank for the emergency diesel generator fuel oil. This tank was cleaned before putting it into diesel fuel storage service and is maintained to the same cleanliness requirements as the other Class I fuel oil tanks. The diesel fuel oil stored in this tank is surveyed to the same requirements as the other diesel storage tank's fuel oil. This storage tank and its connective piping are not required to be Seismic Category I, since this additional qualified fuel oil is non-safety-related.

9.5.4.2 System Description

The fuel oil storage and transfer system consists of separate, independent diesel oil supply systems serving each of the two tandem diesel generators (DG 1 and DG 2) and the high-pressure core spray (HPCS) diesel engine generator (DG 3). Each of these systems consists of a fuel oil storage tank, a transfer pump, a day tank, interconnecting piping and valves, and associated instruments and controls. The system diagram is shown in Figure 9.5-1.

In each supply system, a transfer pump powered from a safety-related motor control center (MCC) takes suction from the diesel oil storage tank and discharges to an associated diesel generator fuel oil day tank to maintain the fuel oil level within the day tank. The transfer pump is sized to provide a flow several times the maximum engine consumption rate (of 110% load) and is automatically controlled by level switches activated by day tank fuel level. The fuel stored in each diesel generator 60,000-gal storage tank (50,000 gal for the HPCS diesel generator) plus the fuel maintained in each 3000-gal day tank is adequate for 7 days of operation.

Each transfer pump supplies a separate day tank for each diesel generator. There is a pipe interconnecting the diesel generator 1 and 2 transfer lines with normally locked closed valves. If a rupture occurs in the interconnecting cross line when in use, this line will be manually isolated and thereby the fuel oil supply will not be interrupted between any storage tank and its associated day tank.

The volume of the day tanks permits 8.5 hr of engine operation of the associated diesel generator without resupply to the day tank. This arrangement allows the transfer pump start signal to occur prior to the day tank low level alarm. In the event the transfer pump does not start, there remains at least 3.5 more hours of operation after low level alarms are actuated to take required corrective action. These operating times are for Division 1 and Division 2 with the diesel generators operating at 100% of the continuous rated load of 4400 kW. The maximum operating time for Division 3 (HPCS) will be substantially longer since the day tanks are the same size. The single HPCS engine carrying 2600 kW will use substantially less fuel than two engines carrying a load of 4400 kW.

At normal high oil level a switch will shut off the pump. If the fuel oil level goes above the normal high level, a high level switch is activated and sends an alarm signal. If the pump does not shut off, the day tank overflow line will return all pump flow to the storage tank of the same diesel generator.

The fuel oil storage system has provisions to fill the storage tanks, transfer fuel from one tank to another, and filter/polish the fuel in the tanks or fuel being delivered to the tanks. The fill header is designed to allow delivery of fuel directly to a storage tank or run through the filter/polisher unit prior to delivering it to the tank from the fuel tanker. The piping boundary between the ASME III fill lines and header and the Quality Class II filter/polisher are at ASME III, 3 normally closed butterfly valves.

The filter/polisher, when used to polish the fuel stored in the tanks, removes oil from the bottom of the tank through a suction sparger that extends along the length of the tank. This oil is filtered and polished removing water and particulates. Then the filter/polisher returns the oil to the tank through the fill line.

The filter/polisher can be used to transfer fuel from one tank to another with or without filtering and polishing. The filter/polisher is equipped with a recording flow meter so the operator knows the quantity of fuel that has passed through the filter/polisher.

The filter/polisher suction line from the storage tank flanged nozzle to the filter/polisher suction header isolation valves is ANSI B31.1 Quality Class 2, Seismic Category I. The sparger in the tank is ANSI B31.1, Quality Class 2, Seismic Category I, and the fill line returning oil to the tank is ANSI B31.1, Quality Class 2, Seismic Category II. The suction and fill line for the auxiliary boiler storage tank is ANSI B31.1, Quality Class 2, Seismic Category II.

Operation of the fuel storage tank transfer pump is controlled manually when fuel is being transferred through the interconnecting line from storage tank A to day tank B or from storage tank B to day tank A. High level annunciation of the day tank fuel level will provide a warning of overfilling the day tank.

The fuel oil supply from the day tanks to each diesel engine consists of two systems. Either system is capable of supplying fuel oil to the engine. For diesel generator 1 and 2 each system contains a fuel supply line strainer, fuel oil pump, duplex filter, pressure gauge, relief and check valves, and separate fuel return lines to the day tanks. The HPCS diesel generator fuel oil system is slightly different, see Section 8.3.1.1.7.2.6 for a description of the HPCS diesel generator fuel oil system.

One of the fuel supply pumps is mechanically driven by the engine and is normally used during engine operation. The other supply pump is driven by a 120-V dc motor and is used to fill the fuel oil system and fuel header prior to initial operation and after maintenance has been performed on system piping and components. The dc-motor-driven pump is running during engine operation in the event fuel supply through the engine-driven pump system fails.

The fuel pumps are located 2.3 ft higher than the suction pipes inside the day tank. The fuel pumps are designed to operate at this negative suction pressure. The fuel oil supply and return piping is not exposed to ignition sources such as open flames or hot surfaces. The transfer lines between the storage and day tanks are buried.

The fuel oil day tank is located in a separate ventilated room which is sized to contain the full contents of the tank should a leak develop. For discussion of fire protection see Section 9.5.1.

The tanks are filled through individual lines from a common fill header that has a strainer and locked fill connection. Each tank also has an individual vent with a flame arrestor.

The fill and vent lines terminate at 2.33 ft and 8.0 ft, respectively, above plant grade, which prevents direct seepage of any ground water into the storage tanks.

In the event of fill line damage due to a missile, the pump-out connection which is protected by a metal enclosure, located at ground level, may be used for the fuel oil filling operation.

Prior to filling the storage tanks, the day tank will be confirmed to be full. This will allow sufficient time for sediment to settle before oil from the storage tanks is transferred to the day tank.

Diesel fuel oil conforming with the requirements of the Technical Specifications is provided for operation of the diesel generators. This grade of diesel fuel complies with the engine manufacturer's requirements and is available from local distribution sources as discussed in Section 9.5.4.3.

Equipment design characteristics for the fuel oil supply system are shown in Table 9.5-3.

9.5.4.3 Safety Evaluation

The entire diesel oil supply system is located within the confines of a Seismic Category I building except for the buried storage tank and the fill, vent, and filter/polisher piping. Each system oil storage tank transfer pump, day tank, and diesel generator set is physically separated within separate concrete enclosures designed to protect against missiles, in compliance with Section 3.5, and to provide fire protection. No high- or moderate-energy piping is present in the diesel generator building which could present a potential hazard to the operational function of these systems. The oil storage tanks are buried for protection so that storage tank failure is completely contained within the soil at a level below any building penetration or access opening. Each storage and day tank is provided with a vent directly to the outside atmosphere. In addition, the enclosures are provided with exhaust ventilation to the outside atmosphere to ensure that diesel fuel vapors are maintained well below the combustible limit. The enclosures are automatically monitored by temperature detectors which initiate the preaction sprinkler system in the event of fire (Appendix F). All storage and day tank vents are equipped with flame arrestor devices.

Although a single failure may result in loss of fuel to one diesel generator, the other diesel generator can provide sufficient capacity for emergency conditions, including safe shutdown of the reactor (see Section 8.3) coincident with loss of offsite power.

The fuel level in each storage tank is maintained above the level at which the fuel in the storage tank plus the fuel in the corresponding day tank is adequate for 7 days of continuous operation at 4400 kW for diesel generators 1 and 2, and 2630 kW for diesel generator 3 (HPCS).

The minimum site storage of 7 days is considered adequate time for obtaining additional fuel oil, if required. The auxiliary boiler storage tank is available as an additional source for qualified diesel fuel oil. On an expedited basis fuel can also be available at the site from a remote source within 12 to 24 hr.

Materials for the fuel oil supply system are provided in Table 9.5-3.

For corrosion protection, the exterior surfaces of the buried piping and components are coated with coal tar enamel. Application of coatings are in strict accordance with AWWA Standard C203.

The buried components of the fuel oil system are all at a relatively uniform temperature and not subject to condensation phenomena. The periodic sampling of the diesel fuel storage tank bottom below the transfer pump will be performed to determine if any water has accumulated and if so corrective action will be taken.

A fuel oil filter and strainer is provided on each fuel line to each engine to eliminate passage of particles, 12 μ or larger in size to the engine injectors.

The overflow lines from the day tank to the storage tank run underground south of the diesel generator building. Diesel oil pipe lines extending under the diesel generator building do not receive full protection from the exterior rectifier-anode system because of the electrical shielding effect of the ground grid and foundation reinforcing and structural steel. Since the earth area under the diesel generator building is sheltered and hence relatively much drier than the earth exterior to this building, no additional cathodic protection system is provided or required.

9.5.4.4 Testing and Inspection Requirements

System components are inspected and cleaned prior to installation. Instruments are calibrated during testing and automatic controls are tested for actuation at the proper setpoints. Alarm functions are checked for operability and limits during plant preoperational testing. Automatic actuation of system components is tested periodically in accordance with the Technical Specifications and plant procedures. The system is operated and tested initially with regard to flow paths, flow capacity, and mechanical operability (see Chapter 14).

Operability of the diesel fuel oil system is ensured by

a. At least once per 10 years: Draining each fuel oil storage tank, removing the accumulated sediment, and cleaning the tank using a sodium hypochlorite or equivalent solution, and

b. At least once per 10 years: Performing a pressure test of those portions of the diesel fuel oil system designed to Section III, Subsection ND of the ASME Code in accordance with ASME Code Section XI, Article IWD-5000.

New and stored fuel oil is sampled and tested in accordance with the Technical Specifications.

9.5.4.5 Instrumentation Requirements

Each diesel oil storage tank is provided with local level indicators and high and low level switches which actuate alarm annunciators in the main control room. In addition, there are system fault annunciators in the main control room for each diesel oil storage tank that will alert the operator of a malfunction of the level instrumentation for a given storage tank. Each day tank is provided with two level switches and a float switch which perform the following functions:

a. Start and stop the transfer pump to maintain level in the day tank,
b. Actuate an alarm in the main control room on low level, and

c. Actuate an alarm in the main control room on high level.

The fuel oil filter/polisher is equipped with a flow totalizer to aid in maintaining minimum fuel quantity in each storage tank when transferring from tank to tank. The filter/polisher is equipped with instrumentation and a level switch in a sump to alarm in the main control room if a malfunction occurs or fuel oil leakage occurs in the filter/polisher building. The filter/polisher control panel contains a bargraph/digital level indicator for each diesel oil storage tank. Each bargraph drives a visual and audible annunciator that alerts the operator of a high level condition in that tank. An outside alarm is provided at the filter/polisher facility to alert the operator if any storage tank has a high level condition. A remote shutdown switch is provided in the control room for the operator to shut down the filter/polisher. An emergency shutdown switch is also located just outside of the door of the filter/polisher building.

Each transfer pump discharge line is provided with local pressure indicators. The system maintains the proper supply of diesel oil in each day tank by means of the level switches in the day tanks which signal the corresponding pump motor starters to automatically start and stop the transfer pumps.

Each diesel generator local control panel is provided with a control switch for control of its respective transfer pump.

Local indication of differential pressure is provided across the duplex filters of the fuel oil supply lines to the diesel engines of diesel generators 1 and 2.

9.5.5 DIESEL GENERATOR COOLING WATER SYSTEM

9.5.5.1 Design Bases

a. The diesel generator cooling water system is designed to provide full load cooling for the diesel generator engines while they are operating and to maintain each engine at an acceptable starting temperature under standby conditions;

b. The piping system associated with the diesel cooling water system was constructed to the guidelines of ANSI B31.1. Seismic classification of the system is Seismic Category I as discussed in Section 3.2.4. The diesel cooling water heat exchangers for diesel generators 1A and 1B are designed and built in accordance with ASME Section III, Class 3 and TEMA Standards, Class C; diesel generator 1C (HPCS) cooling water heat exchanger is designed and built in accordance with ASME Section VIII, TEMA Standards, Class C; and

c. The reliability of the diesel cooling water system is achieved by providing separate cooling water systems for each diesel generator. Thus, failure of a single component in one cooling water system would not effect the operation of

the other diesel generator. In addition the systems are housed separately in a Seismic Category I structure containing no high- or moderate-energy piping which could present a potential hazard to the operational function of these systems.

9.5.5.2 System Description

Each diesel generator is serviced by an independent cooling system. These systems are located in separate rooms associated with their respective diesel generator. Each engine cooling water system is a closed water circuit which recirculates treated water (see Section 9.2.3) for engine cooling (see Figures 9.5-1 and 9.5-3). The treated water is circulated through the water-jacketed components of the engine to remove heat from the engine parts. This jacket water heat is rejected through a shell and tube heat exchanger to the standby service water (SW) system (see Section 9.2.7). Location of the system is shown in Figure 9.5-2.

The forced circulation of cooling water through the engine, lube oil cooler, heat exchanger, and heat exchanger bypass circuit is maintained by two engine-driven pumps. The separate bypass piping flow paths are provided to bypass the heat exchanger at low engine outlet temperatures and to heat the jacket water system during standby. The heat exchanger bypass flow and temperature is automatically regulated by a three-way self-contained thermostatic valve. This valve is set to maintain the engine outlet water temperature at about 180°F. This thermostatic valve outlet opens to the heat exchanger when the engine jacket water temperature reaches 165°F and is full open to the heat exchanger at 180°F. A high temperature alarm annunciates at 200°F (195°F for HPCS diesel engine). A high temperature shutdown switch is provided to shut down the engine when coolant temperature reaches 208°F (205°F for HPCS diesel engine) during test conditions.

The heat exchangers are designed for 110% continuous rating of each diesel generator using 95°F service water to the heat exchanger. The maximum service water temperature is always well below 95°F. This provides a 10% margin in the size of the heat exchangers.

The only time the diesel generators are run at 110% of their continuous rating is during required surveillance testing. This is usually for 2 hr once a year, and always less than 10 hr/year, compared to the 2 hr/day as allowed by the engine manufacturer's rating.

The diesel generator heat exchangers are designed to perform as given in Table 9.5-4.

An expansion tank is mounted on the diesel engine skid, located above the cooling water circulating pump suction. The expansion tank is provided with a pressure cap that maintains pressure on the cooling water system (7 psi) and prevents loss of water due to evaporation.

The expansion tank is provided with a level sight glass which is mounted on the front with instructions that indicate minimum water level. An alarm is provided in the control room to

annunciate in case of low water level. Makeup water is normally supplied by the demineralized water system, but a Seismic Category I, Safety Class 3, makeup water line from the SW system is provided as an alternate supply to the expansion tank.

Diesel generator unit reliability, including the functions required of the circulating water pump and expansion tank were demonstrated prior to installation (qualification and shop performance tests). Periodic testing and maintenance ensure continued reliability.

During shutdown periods, an electric immersion heater is provided for standby heating. The engine can thus be kept in constant readiness for an immediate start. The heating unit is mounted at the bottom of the accessory rack to heat the engine cooling water which circulates by thermosyphon action to the lube oil cooler, engine, and turbocharger after coolers. A thermostat sensing water temperature controls the heating elements. The water temperature is controlled to maintain a lube oil temperature of approximately 120°F as described in Section 9.5.7. The auxiliary motor-driven oil pump circulates lube oil through the lube oil cooler to pick up heat during standby conditions and then returns the warmed oil to the engine sump (see Section 9.5.7). Low oil temperature alarm is provided to ensure that the immersion heater is operating properly (see Sections 9.5.7.2 and 8.3.1.1.7.2.3).

To ensure that all components and piping are initially filled with water, a demineralized water supply is temporarily connected to the 1.25-in. fill-drain connection located on the engine base at the cooling water pump end. Filling the cooling water system from the bottom up allows entrapped air to be vented to the expansion tank. (The HPCS engine has a permanent connection.)

The engine cooling water return pipe (between engine block and temperature regulating valve) is slightly higher than the top of the expansion tank. However, as may be seen from Figures 9.5-1 and 9.5-3, during system operation any entrapped air will be properly relieved to the expansion tank through the provided vent lines due to the differential pressures involved.

A 500-gal reservoir tank is provided in the cooling water system of each diesel engine associated with diesel generators 1 and 2 to permit operation of the engine for the time required to receive SW cooling. The HPCS diesel engine is designed to permit operation without cooling for a time equivalent to that required to bring the cooling equipment into service with energy from the HPCS diesel generator.

In accordance with the manufacturer's maintenance instructions, a corrosion inhibitor is added to the demineralized fill water to preclude corrosion and organic fouling in the diesel engine cooling water system. Since the entire system is enclosed in the diesel generator building and maintained in a warm condition with immersion heaters, antifreeze compounds are not needed.

Cooling system materials of construction include cast irons, carbon steel, rubber, and bronze. Corrosion inhibitors can be used effectively with these materials.

Demineralized water and a corrosion inhibitor are in conformance with the engine manufacturer's recommendations.

9.5.5.3 Safety Evaluation

The diesel generator cooling water system meets the single failure criterion in that if a failure in the system prevents the operation of its associated diesel generator, the remaining diesel generators will not be affected.

This redundancy is accomplished by segregating the power supplies to engineered safety features into three mutually exclusive divisions, each provided with a diesel generator and associated cooling water system. The cooling water systems associated with a particular diesel generator are cooled from an independent SW system.

In the event of the loss of offsite power, the SW pumps which supply cooling water to the heat exchangers begin operation within a safe margin of the point at which the diesel generators 1 or 2 would require the cooling capability of the heat exchangers. See Section 9.2.7 for evaluation of this system.

The high temperature shutdown switches are locked out of the safety circuit during the automatic (emergency) operational mode of the diesel generators to ensure the availability of the emergency power from each generator.

Evaluation of the diesel generator operation under light load conditions is presented in Sections 8.3.1.1.7.1.11 and 8.3.1.1.7.2.11.

9.5.5.4 Testing and Inspection Requirements

The system is operated and tested initially with regard to flow path, flow capacity, and mechanical operability (see Section 14.2).

To ensure continued integrity of the diesel generator cooling water system, scheduled testing of equipment is performed as part of the overall engine performance checks at regular intervals in accordance with the Technical Specifications. Periodic inspections are conducted in accordance with plant procedures prepared in conjunction with the manufacturer's recommendations.

Instrumentation is provided to monitor cooling water temperature and pressure, expansion tank level, and to alarm high water jacket temperature. These instruments receive periodic calibration and inspection to verify their accuracy.

The water in the cooling water system is periodically analyzed and treated, as necessary, to maintain the desired quality.

9.5.6 STARTING AIR SYSTEM

9.5.6.1 Design Bases

a. Each emergency diesel generator, including the HPCS diesel generator, is provided with separate, independent starting air systems;

b. Each starting air system on diesel generator 1 or 2 has sufficient air receivers to provide for five diesel generator starts. The starting air system on each diesel generator consists of two completely redundant systems including two banks of air receivers, separate piping and valves, and one pair of air motors per engine which are both actuated on a start signal. The starting system on HPCS diesel generator 3 consists of two separate systems from separate air receivers through separate piping and control valves to a pair of air motors on each side of the engine. The air receivers have sufficient air capacity for three starts; and

c. The starting air piping off the engine skid is designed, fabricated, inspected, and erected in accordance with ANSI B31.1. The piping on the engine skid is constructed using ANSI B31.1 as a guide. The system is designed to Seismic Category I requirements. The air receivers associated with diesel generators 1 or 2 are designed and constructed in accordance with the requirements of ASME Section VIII (1973 Edition). The HPCS diesel generator air receivers were designed and constructed in accordance with the 1971 Edition of the same code.

9.5.6.2 System Description

The starting air system is shown schematically in Figure 9.5-1. The starting air systems for diesel generators 1 and 2 consist of two electric-motor-driven air compressors, eight air receivers, and associated piping and controls.

Control switches for the electric-motor-driven operation of the air compressors on diesel generators 1 and 2 are on the local diesel engine control board. These control switches permit on-auto-off operation. A selector switch permits selection of either compressor function as the primary pressurization compressor.

Pressure switches in either air receiver bank automatically start the selected compressor when the receiver pressure decays to 241 psig. If the selected compressor fails to operate or cannot hold system pressure, a separate low pressure alarm switch is provided for each bank of air receivers and is set to alarm at 238 psig on a local panel and in the main control room. When the receiver pressure decays to a lower pressure, the back-up air compressor starts.

The HPCS starting air system has two separate air supply trains: one supplied by a diesel-driven compressor and the other by an electric-motor-driven compressor.

The compressor discharge piping is cross connected. Both air receivers charge if either compressor operates. A check valve on each receiver inlet isolates one train from the other.

The compressors are controlled automatically by pressure switches on their associated air receiver. The compressor's low pressure setpoint ensures that the compressor starts to maintain the air receiver pressure at a sufficient amount to start the engine the required number of times.

The HPCS diesel-driven compressor may shut down prior to clearing the low pressure alarm on the receiver in the electric-motor-driven compressor train.

The air receivers are equipped with safety/relief valves set at the receiver design pressure.

The major system components are located adjacent to the diesel generator skid.

For each diesel generator (1 and 2), two separate air-cooled compressors discharge through common piping to two banks of four 32 ft^3 air receivers which are connected in parallel. Each bank of air receivers has the capability of a minimum of five engine starts. Each bank is connected through separate piping to a pair of air start motors on each engine.

The flow path is from the air receiver manifold, through an isolation valve, a pressure reducing valve, through piping to the engine, then a strainer, an air relay valve, and a lubricator to each pair of air starter motors. The starting air system on each engine consists of four air start motors. These air start motors drive a flywheel ring gear which turns the engine. When a start signal is given, an air start solenoid valve in each redundant system admits air to engage a pair of the air start motor pinions on each engine to the flywheel ring gear. When the pinions are engaged, air is admitted through an air control valve to a pair of air start motors. The other pair of start motors on the engine are simultaneously engaged by the redundant start solenoid valves. Engine cranking time is approximately 2 sec.

The starting air system is designed to provide a reliable method for automatically starting each diesel generator unit. The system design is such as to preclude fouling of its components. Downstream of the air compressors, dryers are installed to ensure the dewpoint of the air will be below the minimum room temperature if the system is filled during the worst ambient air conditions. The air dryers are drained periodically to remove oil and moisture. A filter is provided downstream of the dryer to ensure no desiccant or debris can enter the system. In addition, "Y" type strainers are provided upstream of the starting air valves and motors. These strainers are cleaned periodically to ensure that they are kept free from contaminants.

The air starting system of the HPCS diesel generator is similar to that of diesel generators 1 and 2 described above except (a) the number of air receivers: two, of approximately 36 ft^3 each, (b) the number of engine starts: three from the air receivers with the compressors locked out, (c) the redundant starting air compressor is diesel driven and automatically operates without manual actions, and (d) there are two parallel systems that each simultaneously operate a pair of air motors on the diesel generator for a start. The parallel systems provide the ability to produce a start even if one system sustains a pressure boundary failure or a failure of one starting air solenoid valve to open.

See Section 8.3.1.1.7.2.5 for additional discussion of the HPCS diesel engine starting air system.

9.5.6.3 Safety Evaluation

Each diesel generator starting air system is capable of supplying a sufficient quantity of air from its associated air receivers to ensure a successful starting operation of the diesel generator independent of normal plant power sources.

The starting air systems for each diesel generator unit are physically and electrically separated to ensure that no single failure can cause malfunction of both divisions of standby ac power. The single failure criterion is satisfied and significantly enhanced by having redundant piping systems and mechanical equipment for diesel generators 1A and 1B and duplicate (but not functionally redundant) piping systems and mechanical components for the HPCS diesel generator. All three diesel generators also have redundant starting solenoid valves.

9.5.6.4 Testing and Inspection Requirements

Preoperational testing was performed as described in Section 14.2. To ensure continued integrity of the diesel generator starting air system, scheduled testing of equipment is performed as part of the overall engine performance checks at regular intervals in accordance with the Technical Specifications. Periodic inspections are conducted in accordance with plant procedures prepared in conjunction with the manufacturer's recommendations.

9.5.7 DIESEL GENERATOR LUBRICATION SYSTEM

9.5.7.1 Design Bases

a. The diesel generator lubrication system is designed to provide sufficient lubrication for proper operation of its associated diesel generator under all loading conditions. The system is required to circulate the lube oil to the diesel engine working surfaces and to remove excess heat generated by friction during operation. The system provides oil at the engine surfaces at approximately

120°F during the anticipated long periods of standby duty by use of an electric immersion heater in the cooling water system; and

b. The piping system was constructed to the guidelines of ANSI B31.1 and Seismic Category I requirements.

9.5.7.2 System Description

The lubrication system for each diesel generator is shown in Figure 9.5-1. The lubrication system for each diesel engine is mounted on its diesel generator skid (see Figure 9.5-4) and is a combination of three separate systems. These are the main lubricating oil systems, the piston cooling system, and the scavenging oil system. Each system has its own pump. The main lube oil pump and the piston cooling oil pump are in tandem housings and share a common drive shaft. All three pumps are positive displacement, helical gear type, mounted externally at the front of the engine, and are gear-driven from the engine.

The main lubricating pump supplies oil under pressure to the various moving parts of the engine. The piston cooling pump supplies oil for the cooling of the pistons and lubrication of the piston pin bearing surfaces. After circulation through the engine parts, the lubricating oil flows back to the engine oil sump. The scavenging oil pump takes suction from the engine oil sump and pumps this oil through a filter and lube oil cooler to the strainer sump which supplies the main and piston lubricating pumps. The lube oil cooler is a shell and tube, water-cooled type capable of adequately cooling the engine lube oil when operating at any load point within the engine generation load range. The diesel cooling water acts as the lube oil cooler heat sink.

The engine lubrication system including the lube oil cooler is furnished by the engine manufacturer, Electromotive Diesel, a division of General Motors. The diesel cooling water system, also furnished with the engine, removes the heat from the lube oil coolers. Heat from the diesel cooling water system is removed in the diesel generator cooling water heat exchangers. The characteristics of these heat exchangers are described in Section 9.5.5.

The lubrication system on each engine also has three small lube oil pumps to circulate oil through the engine main bearings and the turbocharger bearings to minimize wear when the engine starts.

The circulating lube oil pump continuously circulates lube oil through the main lube oil system filter, the lube oil cooler (where it is warmed to approximately 120°F) and then through the engine main bearings. This maintains the oil level in the engine just below the camshaft so the oil pressure will increase rapidly when the engine starts from a normal standby condition or on a hot restart.

An ac-driven soak back pump continuously circulates lube oil through the turbocharger bearings to minimize wear when the engine starts and to remove heat from the turbocharger following engine shutdown. A dc-driven soak back pump is arranged in parallel with the ac soak back pump and will automatically start on loss of pressure downstream of the ac and dc pumps.

Instrumentation is provided that alarms locally and activates a "DG Trouble Alarm" in the control room on loss of pressure downstream of any of the pumps.

Abnormal lube oil pressures, temperatures, low sump level, and loss of pressure on the lube oil circulating pump discharge are annunciated.

In the event of a high crankcase pressure, annunciator and computer alarms are provided to alert the operator. A manual shutdown will then be made for diesel generators 1 and 2. For diesel generator 3 (HPCS) an automatic shutdown will occur unless an auto initiation signal is present. The hand-hole or top deck covers, following a high crankcase pressure condition, will not be opened until the engine has been allowed to cool off. This will prevent ignition of oil vapors due to air admittance.

Suitable screens and/or filters in the engine lubrication oil fill pipes prevent entry of foreign material into the engine crankcase. Procedural control, operator training, and careful labeling of fill ports to identify the standard and grade of lubricant to be used ensures that the proper lubricant is used. Lubricant storage containers are similarly labeled to identify contents. Sampling and testing of the lubricating oil to verify conformance to ASTM Standard 0975-74, Grade 2-D, is performed periodically.

The manufacturers recommendations on measures to be taken to maintain the required quality of the lubricating oil provided in the engine instruction manual are followed.

The following sensors and alarms are provided as described below (diesel generator 3 values are in parentheses):

Sensor	Alarm Point	Purpose
Engine lube oil temperature low	115°F (100°F)	To warn of loss of warm-up immersion heater
Engine lube oil temperature high	240°F (230°F)	To warn of loss of cooling water system
Engine lube oil pressure low (alarm)	26 psig (25 psig)	To warn of low oil pressure prior to engine damage

Sensor	Alarm Point	Purpose
Engine lube oil pressure low (shut down)	21 psig (23 psig)	Shut down engine only during test mode to prevent damage
Shutdown engine lube oil pressure low (alarm)	7 psig (7 psig)	Warns of inadequate lube oil pressure in standby mode.

Operator actions to be taken to resolve alarm conditions are provided in appropriate plant procedures.

See Sections 8.3.1.1.7.1.4 and 8.3.1.1.7.2.4 for additional discussion of the diesel generator lubrication system.

9.5.7.3 Safety Evaluation

The diesel generator lubrication system is capable of providing sufficient lubrication under all loading conditions. Each engine oil sump is of adequate size to contain a supply of oil to support 7 days of continuous operation.

The provision for a physically separate lubrication system for each diesel engine satisfies the requirements of the single failure criterion for complete independence and redundance of the onsite power system by avoiding any commonality between diesel generator units. All system equipment is housed inside a Seismic Category I structure containing no high- or moderate-energy piping.

The lubrication system has a low level alarm in the sump to warn of low oil level. The engines are periodically visually inspected for oil leaks to guard against excessive oil leakage.

9.5.7.4 Testing and Inspection Requirements

Preoperational testing was performed as described in Section 14.2. To ensure continued integrity of the diesel generator lubrication system, scheduled testing of equipment and lubrication oil quality is performed as part of the overall engine performance checks at regular intervals in accordance with the Technical Specifications. Periodic inspections are conducted in accordance with plant procedures prepared in conjunction with the manufacturer's recommendations.

9.5.8 DIESEL GENERATOR COMBUSTION AIR INTAKE AND EXHAUST SYSTEM

9.5.8.1 Design Bases

a. The diesel generator combustion air intake and exhaust system is designed to supply clean combustion air to each diesel engine and to exhaust combustion gases in a manner that will not effect the operational function of the diesel engines;

b. Each diesel engine is provided with an independent combustion air intake train which filters and directs air from the exterior of the diesel generator building (south side) to the engine turbocharger, and an independent exhaust train which silences and directs engine exhaust gases to the exterior of the diesel generator building (north side). Since each diesel generator unit has its own independent and separate intake and exhaust train, the single failure criterion is satisfied;

c. The air intake trains are designed to eliminate contaminating substances, such as dust and larger foreign objects, by filtering the air supply through a screened air intake louver, a prefilter, and then through an oil bath air cleaner for the HPCS engine and a cartridge type air cleaner for the engines associated with diesel generators 1 and 2; and

d. The combustion air intake and exhaust system is protected from externally generated missiles (i.e., tornado missiles) by enclosure in a Seismic Category I structure. The piping for the diesel engine intake and exhaust systems is Seismic Category I and is in accordance with the requirements of ANSI B31.1. The exhaust silencers, however, are not ANSI B31.1 material but are ASTM A569 which is suitable for the service. The seismic and quality group classification of components in this system is provided in Section 3.2.

Nondestructive examination in accordance with ASME Section III, ND-5000 requirements, was performed on the welds in the combustion air intake and exhaust systems piping.

9.5.8.2 System Description

The combustion air intake and exhaust system is shown in Figure 9.5-1 and the location within the diesel generator building is shown in Figure 9.5-2.

The air intake trains associated with each diesel generator are housed in separate rooms and each is supplied air from the exterior of the diesel generator building (south side) through a screened air intake louver. Each engine air intake system consists of prefilters, an oil bath type air cleaner for the HPCS engine and cartridge type for the engines associated with diesel

generators 1 and 2, air turning box, the necessary piping, ductwork, and flexible connections to the inlet of the engine turbocharger and aftercooler. An in-line air intake silencer is also provided in the HPCS diesel engine air intake system.

Intake air is cooled in the aftercooler by the engine cooling water system to improve engine operational efficiency. The air intake capacity of each diesel engine associated with diesel generators 1 or 2, at 14.7 psi and ambient temperature, is 10,120 cfm. The air intake flow to the HPCS diesel engine at 14.7 psi and ambient temperature is 10,200 cfm.

The exhaust trains associated with each diesel generator are also housed in separate rooms. Each engine exhaust system consists of an exhaust manifold, turbocharger, exhaust silencer, and the necessary piping and ductwork. Exhaust piping from the diesel-driven air compressor in the HPCS starting air system is connected to the corresponding diesel exhaust line upstream of the exhaust silencer.

Exhaust gases are discharged through the turbocharger from the exhaust manifold and are expelled through ductwork and an exhaust silencer to the exterior of the diesel generator building (north side). The exhaust gas flow from each diesel engine associated with diesel generators 1 or 2 is 23,000 cfm at 770°F and from the HPCS diesel engine is 23,000 cfm at 735°F.

9.5.8.3 Safety Evaluation

The provision of a physically separated and independent intake and exhaust train for each diesel generator unit satisfies the requirements of the single failure criterion for complete independence between units.

Since each air intake and exhaust train is housed within a Seismic Category I building, they are protected from externally generated missiles. No high- or moderate-energy piping is present in the diesel generator building which could present a potential hazard to the operational function of these systems.

The air intake trains are designed so that an adequate supply of quality air is available to the diesel engines as required. To eliminate foreign objects which could restrict the supply of air to an engine, air is drawn into the system from the outside atmosphere through a screened intake louver and prefilter and then through combustion filters; oil bath cleaner for the HPCS engine and a cartridge type air cleaner for the engines associated with diesel generators 1 and 2. The postulated design worst-case dust storm is defined in Section 2.3. The postulated design basis ashfall event is defined as a 20 hour event concurrent with a 2 hour loss of offsite power. The dust storm concern is negligible by comparison with the design worst-case ashfall event due to the smaller amount of particulate accumulation associated with the dust storm. The results of an analysis of the oil bath and cartridge filters for the intake air system shows the adequacy of either of these combustion filters in handling a severe dust storm event without

affecting the diesel generators performance. The results of an analysis for the intake air systems shows the adequacy of the combustion filters and pre-filters in handling an ashfall event without affecting the safe shutdown credited Division 1 and 2 diesel generators. Evaluation of a postulated release from the containment inerting nitrogen tank determined that such a release could stall all three diesels for approximately 8 minutes. This postulated release, however would not result in any conditions that would lead to turbine trip or reactor scram. Because the postulated release from a non-mechanistic failure on the nitrogen tank does not result in a reactor scram or turbine trip, offsite power remains available during the postulated nitrogen tank release and reliance on the diesel generators is not required. This assumption is consistent with guidance in Standard Review Plan (SRP) Sections 3.6.1 and 3.6.2.

There is no appreciable effect on a diesel generator's ability to carry its required load as a result of barometric pressure drops which would effect the capacity of the combustion air intake train.

Recirculation of combustion products from the diesel exhaust to the air intake which could significantly effect the operation of the diesel engine is precluded by the degree of horizontal and vertical separation between the exhaust and air intake (see Figure 9.5-2).

9.5.8.4 Inspection and Testing Requirements

The combustion air intake and exhaust system was checked for system leaks and blockage following initial installation and testing of the diesel engines (see Section 14.2).

Periodic cartridge replacement/cleaning of air intake filter units is performed at regular intervals and when the filter differential pressure observed during engine operation indicates the filter is dirty. Periodic inspection of the adapter and screen assemblies in the exhaust manifold is performed as needed. Routine testing of the diesel engines in accordance with the Technical Specifications verifies the integrity of the air intake and exhaust systems. Periodic inspections are conducted in accordance with plant procedures prepared in conjunction with the manufacturer's recommendations.

9.5.9 PLANT DECONTAMINATION FACILITY

9.5.9.1 Design Bases

The plant decontamination facility is designed to provide a central location for equipment decontamination in a relatively safe and efficient environment. Safety of personnel has been carefully considered and built into all aspects of the operation. Local filtration and increased capability, per recommendations of the Handbook of the American Conference of Governmental Industrial Hygienists, have been incorporated into the existing radwaste building ventilation system to minimize airborne contamination. Each of the facility components has been strategically located to provide a safe, efficient, and relatively quiet process from entry to

disassembly, cleaning, reassembly, and exit. Controls and indication have been positioned in a central location to minimize setup time and thus reduce personnel exposure. The decontamination facility has been designed to Quality Class II and Seismic Category II requirements.

9.5.9.2 System Description

The decontamination facility is located in the radwaste building on the 467-ft el. adjacent to the contaminated tool room (see Figure 9.5-5). This facility consists of the equipment necessary to enable decontamination of a variety of plant components, tools, and other portable equipment.

To minimize airborne contamination and process fumes in the decontamination room, cleaning tanks are provided with individual exhaust hoods per recommendations of the Ventilation Handbook of Governmental Industrial Hygienists. The exhaust system for each hood is complete with its own high-efficiency particulate air (HEPA) filter unit and exhaust fan. The air from the exhaust fans is ducted to the radwaste building exhaust system (see Section 9.4.3.2 for system description).

Differential pressure switches are provided across the prefilters and the HEPA filters to annunciate in case of a dirty filter condition. The fan flow is controlled by the fan differential pressure controller which controls a modulating damper at the fan discharge. All the fans are located in the contaminated tool room to minimize noise levels in the decontamination room during operation.

An automatic sprinkler system has been installed for protection against the unlikely event of a fire. Curbs have been installed at all doors to the decontamination room, the equipment hatch, and the contaminated tool room to contain flooding caused by a major spill or activation of the sprinkler system. A decontamination sink and an emergency eyewash shower station have been installed to permit immediate treatment in case of a splashing accident.

9.5.9.3 Safety Evaluation

The plant decontamination facility has no safety function. Malfunction or failure of the decontamination facility will not impair normal or emergency plant operations.

9.5.9.4 Testing and Inspection Requirements

On installation and periodically thereafter, HEPA filters are given in-place DOP tests in accordance with ANSI N 510-1980, Testing of Nuclear Air Cleaning Systems.

Chapter 10

STEAM AND POWER CONVERSION SYSTEM

10.1 SUMMARY DESCRIPTION

The steam and power conversion system is designed to produce electrical energy through conversion of a portion of the thermal energy contained in the steam supplied from the reactor, to condense the main turbine exhaust steam, and to return condensate to the reactor as heated feedwater with a major portion of its gaseous dissolved and particulate impurities removed.

The power conversion system uses the Rankine steam cycle with a closed regenerative feedwater heating cycle. It has the capability to accept 105% of the reactor's rated steam flow. Steam leaves the reactor vessel at 1035 psia. Steam enters the turbine at 999 psia with a 0.30% moisture content. The turbine is a tandem-compound turbine generator having a six-flow exhaust end. Steam is exhausted into a triple pressure condenser designed for a 2.4-in. Hg average backpressure and is condensed with circulating water cooled by mechanical draft cooling towers. Six stages of regenerative feedwater heating are provided, four heated with extraction steam from the low pressure turbines and two from the high pressure turbine. The final design feedwater temperature at normal full load is 423°F.

The major components of the steam and power conversion system are the turbine generator, main condenser, condensate pumps, condensate booster pumps, mechanical vacuum pumps, steam jet air ejectors, turbine gland sealing system (which includes gland seal steam evaporators and condenser), turbine bypass system, condensate filter demineralizers, turbine driven reactor feed pumps, feedwater heaters, and condensate storage facilities. The turbine cycle heat balance for rated 102.4% power is given in Figure 10.1-1. This figure is representative of the overall power conversion system.

The saturated steam produced by the boiling water reactor is passed through the high pressure turbine where the steam is expanded and is then exhausted to two moisture separator/reheaters (two reheat stages) arranged in parallel. The moisture separators remove the moisture content of the steam and superheat the steam before it enters the low pressure turbines where the steam is expanded further.

Steam for the first-stage reheater is taken from the first extraction point of the high pressure turbine while steam for the second-stage reheater is taken from the main steam header. From the low pressure turbines, the steam is exhausted into the main condenser where it is condensed and deaerated. The condensate pumps take suction from the condenser hotwell and deliver the condensate through the gland seal steam condenser, steam-jet air ejector condenser, offgas condenser, and condensate demineralizers to the condensate booster pump suction. The condensate booster pumps then discharge through the low pressure feedwater heater trains to

the reactor feedwater pumps. The reactor feedwater pumps supply feedwater through the high pressure feedwater heaters to the reactor. Steam for heating the feedwater in the heating cycle is supplied from turbine extractions. The drains from the feedwater heaters, the reheaters, and the moisture separators are cascaded to the next lower pressure feedwater heater and finally discharged to the condenser.

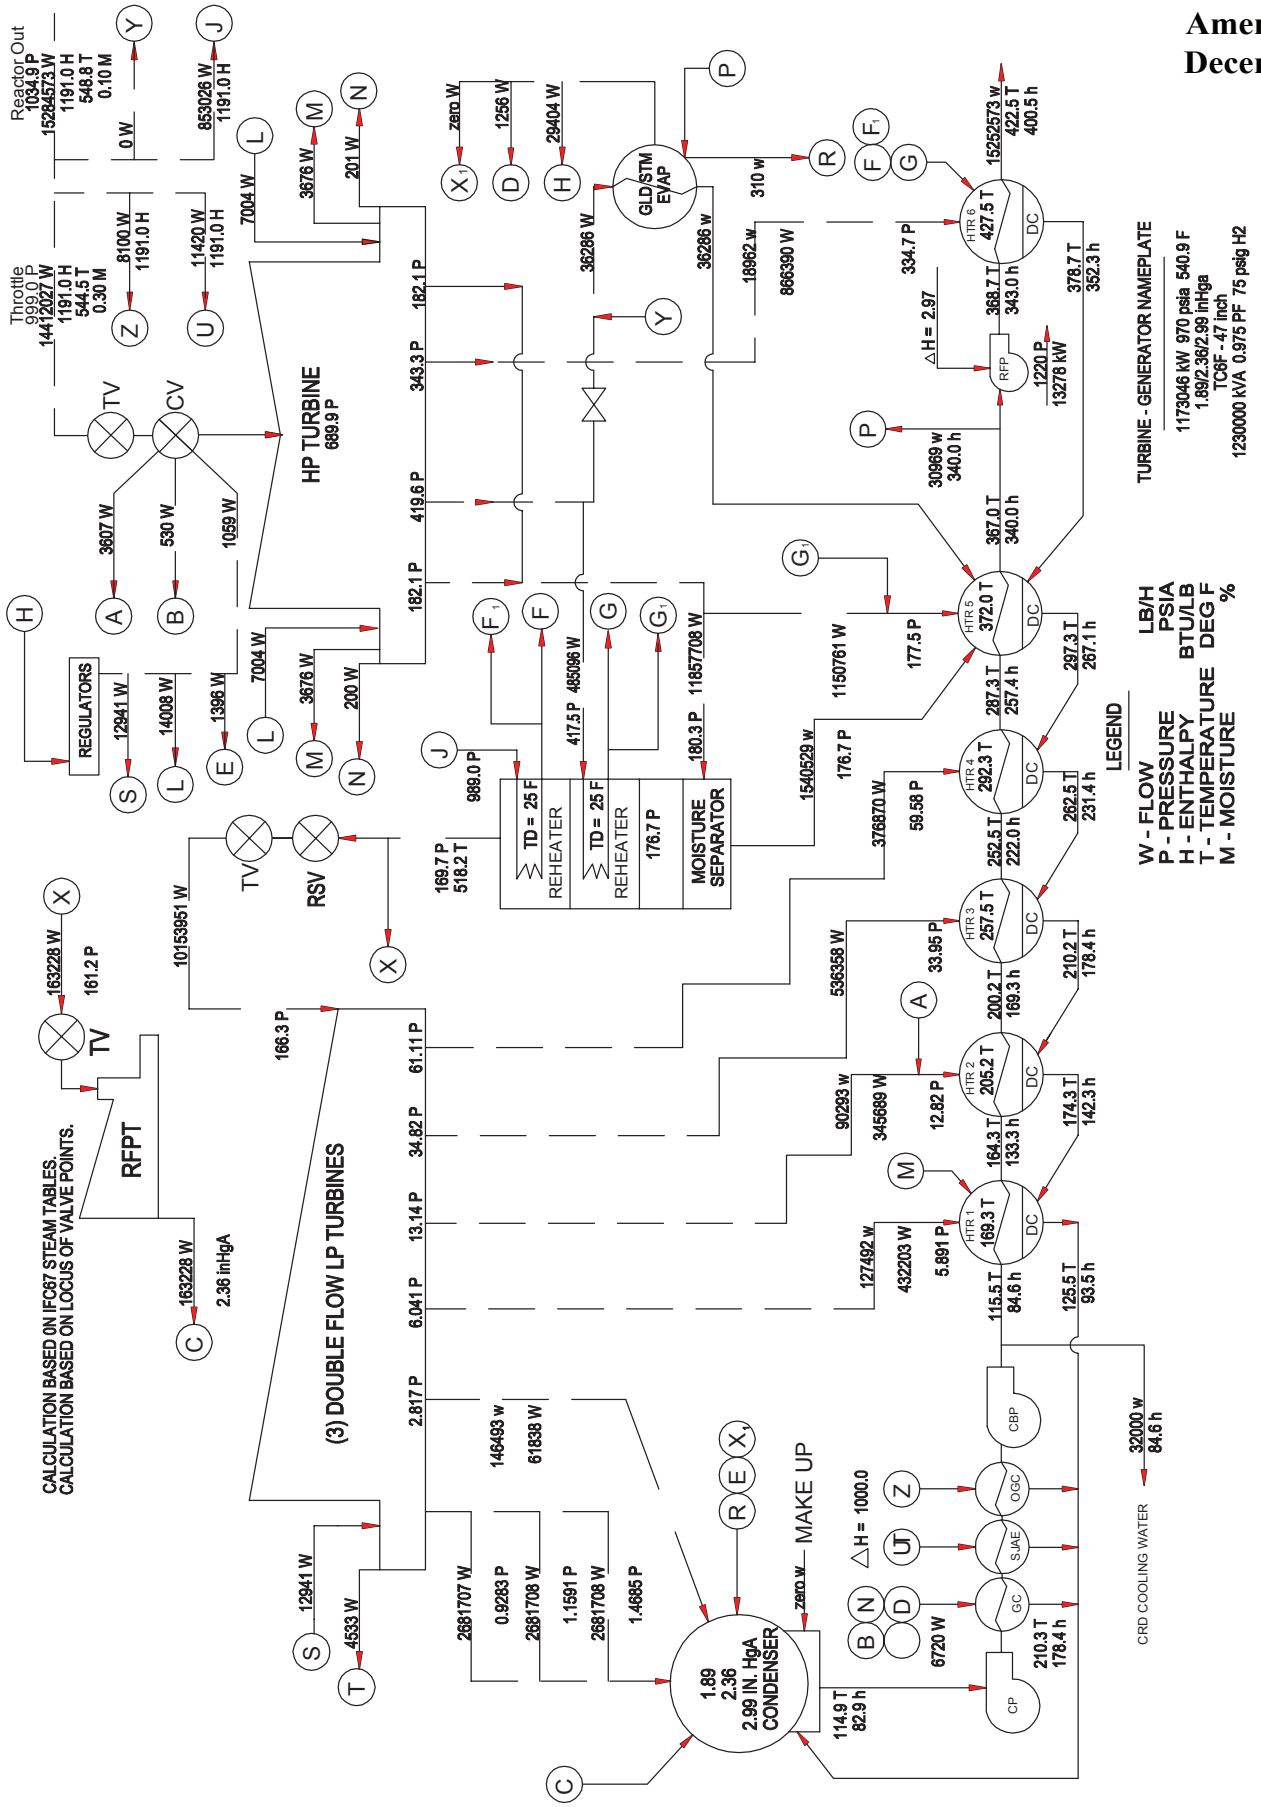
The ability of the plant to follow system loads depends on the adjustment of the reactor power level. The steam admission valves are controlled by the initial pressure regulator so that the turbine receives the proper amount of steam required for the load demand. The turbine speed governor, however, may override the initial pressure regulator to close the steam admission valves if an increase in system frequency or loss of generator load causes an increase in turbine speed. Reactor steam in excess of that which the admission valves will pass is bypassed directly to the main condenser through pressure controlled bypass valves. Load rejection in excess of bypass capacity causes the reactor safety/relief valves to open.

The main turbine, main condenser, and moisture separator/reheaters are located in a shielded area with controlled access to limit personnel exposure.

The portions of the power conversion system which constitute part of the reactor coolant pressure boundary are the main steam lines extending from the reactor pressure vessel to the outermost containment isolation valve.

Table 3.2-1 indicates the safety class, quality group classification, and seismic category of the power conversion system. Environmental design bases are discussed in Section 3.11.

Table 10.1-1 presents a summary of important design and performance characteristics of the steam and power conversion system.



The design of various steam and condensate instrumentation systems are based on the need to monitor and control normal power generation system functions such as level, flow, pressure, and temperature. The instrumentation provides information that enables the control room operator to start up, operate, and shut down these systems.

10.2 TURBINE GENERATOR

10.2.1 DESIGN BASIS

The turbine generator is designed to receive steam from the boiling water reactor, convert a portion of the thermal energy contained in the steam to electric energy, and provide extraction steam for feedwater heating.

The turbine generator, associated systems, and control characteristics, are integrated with the features of the reactor and associated systems to obtain an efficient and safe power generator unit. The turbine generator is designed to function only during normal plant conditions including startup, power generation, and shutdown. The turbine generator is not required for safe shutdown of the reactor nor to perform safety functions. The turbine generator equipment is in strict conformance with the latest edition in effect at the time of fabrication, of ANSI C.50.10, ANSI C.50.13, and the IEEE standards. The major portion of the manufacture was performed during 1975. The original LP turbine rotors were replaced with fully integral rotors during 1992. Safety class and seismic category are presented in Section 3.2.

The turbine generator design conditions are included in Table 10.1-1.

The turbine generator is intended for base load operation. Normal load swings are limited to the rate of change of power output of the nuclear steam supply system.

The turbine governor valves are capable of full stroke opening and closure within 7 sec for adequate pressure control performance. Normal governor valve closure is shown in Figure 10.2-1.

During events resulting in turbine throttle or governor valve fast closure, turbine inlet steam flow is not reduced faster than permitted by Figures 10.2-2 or 10.2-3.

10.2.2 SYSTEM DESCRIPTION

The main turbine is a tandem-compound unit, consisting of one double-flow high pressure turbine and three double-flow low pressure turbines (Figure 10.3-1), running at 1800 rpm with 47 in. last-stage blades. Exhaust steam from the high pressure turbine passes through two moisture separator/reheaters (two stage reheat) before entering the low pressure turbine inlets. The exhaust steam from the three low pressure turbines is condensed in the main condenser.

The generator is a three phase, 60 cycle, 25,000 V, 1800 rpm unit rated at 1,230,000 kVA at 0.975 power factor. The stator is water cooled and the rotor is hydrogen cooled. The hydrogen system is designed to minimize the hazard from fires or explosions as discussed in Appendix F.

The design of the system, Figures 10.2-4 and 10.2-5, and the specified operating procedures are such that explosive mixtures are not possible under normal operating conditions. The hydrogen gas supply system includes a storage trailer and storage cylinders used as backup if the trailer supply runs low. Pressure regulators are mounted on both the storage trailer and the bottle manifold for control of the hydrogen gas, and a circuit for supplying and controlling the carbon dioxide used in purging the generator during filling and degasing operations. To prevent hydrogen leakage by the generator shaft seals, a hydrogen seal oil system is provided. The hydrogen seal oil system, which includes pumps and controls, deaerates the oil before it is sent to the shaft seals.

The fundamental rule is that hydrogen and air should never be mixed. Carbon dioxide is used as an intermediate gas when changing either from air to hydrogen or from hydrogen to air. When changing from one gas to another, the generator is vented to the atmosphere. The valves, pressure gauges, regulators, and other equipment in the hydrogen gas supply system permit introducing hydrogen or prevent the flow of hydrogen into the generator and also provide means of controlling the gas pressure within the generator.

Steam is transported from the reactor by four main steam lines and flows through the turbine throttle valves and governor valves to the high pressure turbine. The steam lines are combined upstream of the throttle and governor valves. The turbine bypass valves are located upstream of the turbine throttle valves to permit steam bypass to the main condenser during transient conditions.

Two branch lines from the main steam heater supply steam to the two second-stage reheaters per moisture separator. The steam for the two first-stage reheaters per moisture separator is supplied by extraction lines from the high pressure turbine (see Figure 10.3-1). Moisture preseparator units remove moisture from the lower high-pressure turbine discharge exhaust steam as it exits the turbine. The moisture separator/reheaters remove the moisture from the high-pressure turbine exhaust steam and superheat the steam prior to admission to the low pressure turbines, thereby improving overall cycle efficiency. Extraction steam from the high pressure turbine is used in the first-stage reheater and for feedwater heating in heaters No. 5 and 6. Extraction steam from the low pressure turbines is used for the first, second, third, and fourth stage feedwater heaters. Moisture separator/reheater relief valves are provided to prevent overpressurizing the moisture separator/reheaters and the crossover lines in the event of crossover throttle or intercept valve closure; these relief valves discharge to the main condenser.

The turbine generator is equipped with a digital electrohydraulic (DEH) control system. See Section 7.7.1.5 for a detailed description of the turbine control system.

There are four methods of turbine overspeed control protection:

a. Digital Electro-Hydraulic (DEH) speed control,
b. Overspeed protection controller (OPC),
c. Digital control overspeed trip, and
d. Digital trip overspeed trip.

DEH Speed Control

The DEH speed control is designed to maintain turbine speed within 2-3 rpm of setpoint during startup; after the turbine generator has been synchronized to the grid, the grid frequency controls turbine speed. The DEH control system monitors turbine speed via three speed sensors. Upon detecting a separation from the grid and a resulting overspeed condition, the DEH speed control will rapidly close the governor valves via their servo-valves preventing an excessive overspeed condition from occurring.

Overspeed Protection Controller

The OPC primary function is to avoid excessive turbine overspeed such that a turbine trip is avoided. At 103% of rated speed, the OPC solenoids open, rapidly closing the governor and intercept valves to arrest the overspeed before it reaches the trip setting. When turbine speed falls below 101%, turbine speed control is returned to the DEH speed control mode.

Digital Control Overspeed Trip, Digital Trip Overspeed Trip and Quadvoter Hydraulic Trip Block

If the turbine accelerates further than 103% of rated speed, the digital control overspeed trip logic in the DEH control system will provide a trip signal that causes the quadvoter hydraulic trip block to de-energize and trip the turbine. Additionally, the digital trip overspeed trip has three redundant speed sensors and will initiate an independent trip of the quadvoter hydraulic trip block. Both the digital control overspeed trip and the digital trip overspeed trip use two out of three overspeed logic to initiate the trip signal prior to reaching 111% of rated speed. These signals cause the output module for the quadvoter to simultaneously de-energize, or trip, all of the quadvoter valves.

Redundant power supplies are auctioneered to assure loss of one power supply does not cause the quadvoter to trip. The quadvoter provides two channels, each with two solenoid valves in series, to depressurize the trip header and trip all the throttle, governor, intercept and reheat stop valves. The quadvoter design assures that a single failure of a quadvoter valve will neither cause the turbine to trip nor prevent the turbine from tripping if required. The DEH control system is designed to maintain the turbine speed below 120% of rated speed.

The quadvoter trip block assembly is a fail-safe design. Therefore a loss of all power or a loss of all signals to the quadvoter solenoids would cause a turbine trip as all of the quadvoter solenoid valves would de-energize. The turbine overspeed control equipment and electrical wiring may be destroyed by a postulated piping failure; however, this loss would result in a turbine trip based on the fail-safe design. A missile may destroy the electromagnetic speed pickups and associated electrical wiring, but the turbine will still trip on loss of all speed probe signals. Missile damage to the hydraulic lines for the trip block assembly would result in a loss of high pressure fluid thereby depressurizing the trip header and causing a turbine trip.

The operation of the DEH control system is continuously monitored during turbine generator operation. Detection of turbine speed variation is accomplished by the speed-control unit discussed in Section 7.7.1.5. The overspeed protection controller and two digital overspeed trips are tested during reactor startup from refueling outages. The turbine throttle, governor, interceptor, reheat stop valves and quadvoter solenoid valves are periodically tested during operation. Turbine throttle, governor, interceptor and reheat stop valves are periodically inspected. The manner and frequency of the inspection and testing will take into consideration the manufacturer's and others' recommendations and missile probability analysis (see Section 3.5.1.3) in conjunction with the plant generating requirements.

Instrumentation for the turbine generator is provided in the control room and is described in Section 7.7.1.5.

The turbine is equipped for normal operations with a shaft-driven lubricating oil pump and ac motor-driven lubricating oil pump for startup, shutdown, and turning gear, or for emergencies whenever oil pressure falls below set pressure. The turbine is also provided with a dc motor-driven lubricating oil pump with power supplied from storage batteries for emergency operation.

The turbine shaft is supplied with "clean" (essentially nonradioactive) sealing steam which prevents outleakage of steam from the high-pressure turbine and inleakage of air to the low pressure turbines. An evaporator generates essentially nonradioactive steam for turbine gland sealing (see Section 10.4.3).

Overpressure protection of the turbine exhaust hoods and the main condenser shell is provided by rupture diaphragms on the exhaust hoods.

The turbine incorporates protective devices including the exhaust hood relief diaphragms, exhaust hood temperature alarm, pilot dump valve for closing the extraction steam nonreturn valves, low vacuum alarm, thrust bearing wear alarm, and low bearing oil pressure alarm.

In addition, the following tabulation is a list of the turbine generator protective trips:

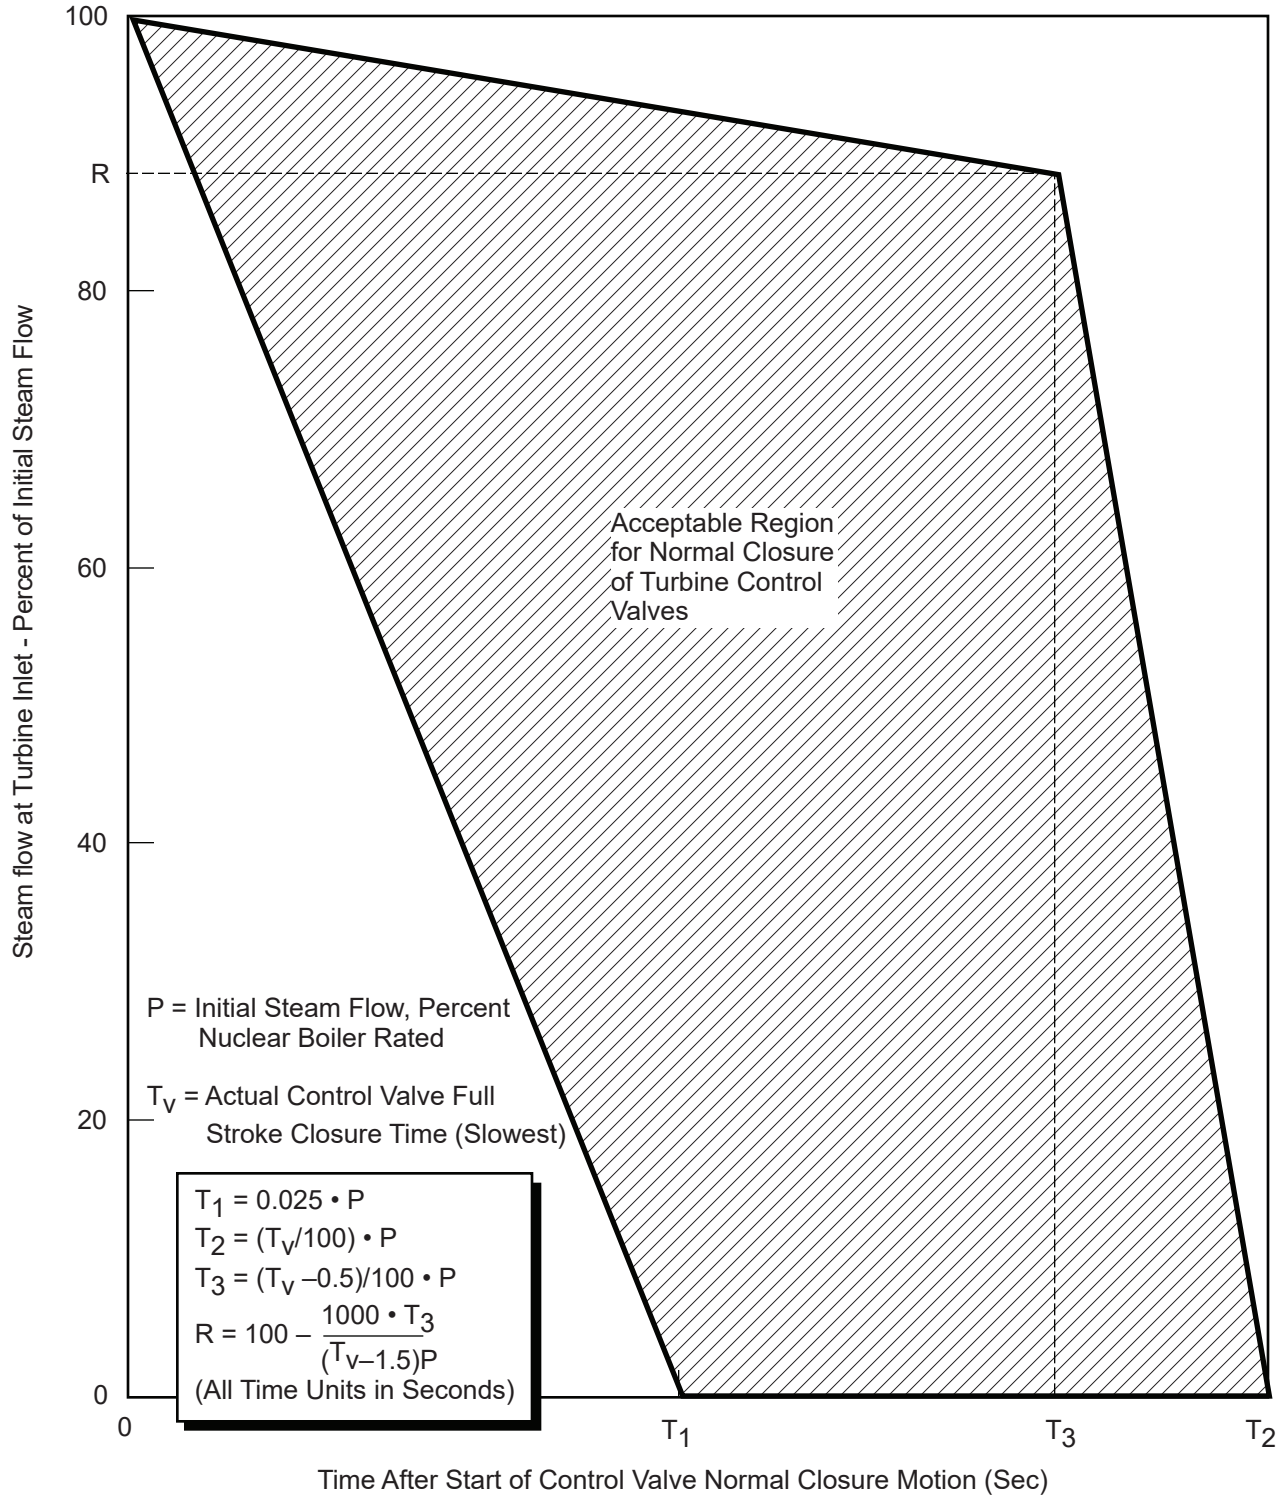
Mechanical Faults	Electrical Faults
Low vacuum	Generator power differential
Thrust bearing wear	Generator underfrequency
Low oil pressure	Generator differential current
Overspeed	Generator stator ground
Manual	Generator loss of excitation
Anti-motoring	Generator negative sequence
Low DEH pressure	Generator overcurrent during starting
Low EH (electrohydraulic) fluid level	Generator stator ground during starting
Reactor high water level	Generator overexcitation
RCIC-V-13 and 45 open	Generator/transformer overall differential
Moisture separator reheater shell side high level	Manual
Loss of DEH control power	Unit lockout
Both Throttle Valves on a steam chest closed	Unit overall lockout

The main steam throttle and governor valves are located in the steam chest assembly which is parallel to the axis of the high pressure turbine. The nominal closure time for a fully open throttle or governor valve is 0.15 sec. A failure of one governor valve causes the other valves to increase or decrease their opening to compensate for that valve. If one valve fails open at low load condition, the other valves close. If the closing of the other valves is not enough to compensate for that valve, the turbine load increases proportional to steam flow.

The reheat stop and intercept valves are in-line valves located in the crossover piping between the moisture separator/reheater and low pressure turbine. The closure time upon depressionization of the trip header for a fully open valve is 0.15 sec.

The valves described above are periodically tested as required by the Licensee Controlled Specifications (LCS) by using the DEH control system during power operation. Pressure variations caused by closing a governor valve cause the other governor valves to open. Therefore, testing must be done at a reduced power level to provide sufficient margin for pressure control. Details of the pressure control system are discussed in Section 7.7.1.5. In addition, one of each valve will have its internals periodically inspected as required by the LCS.

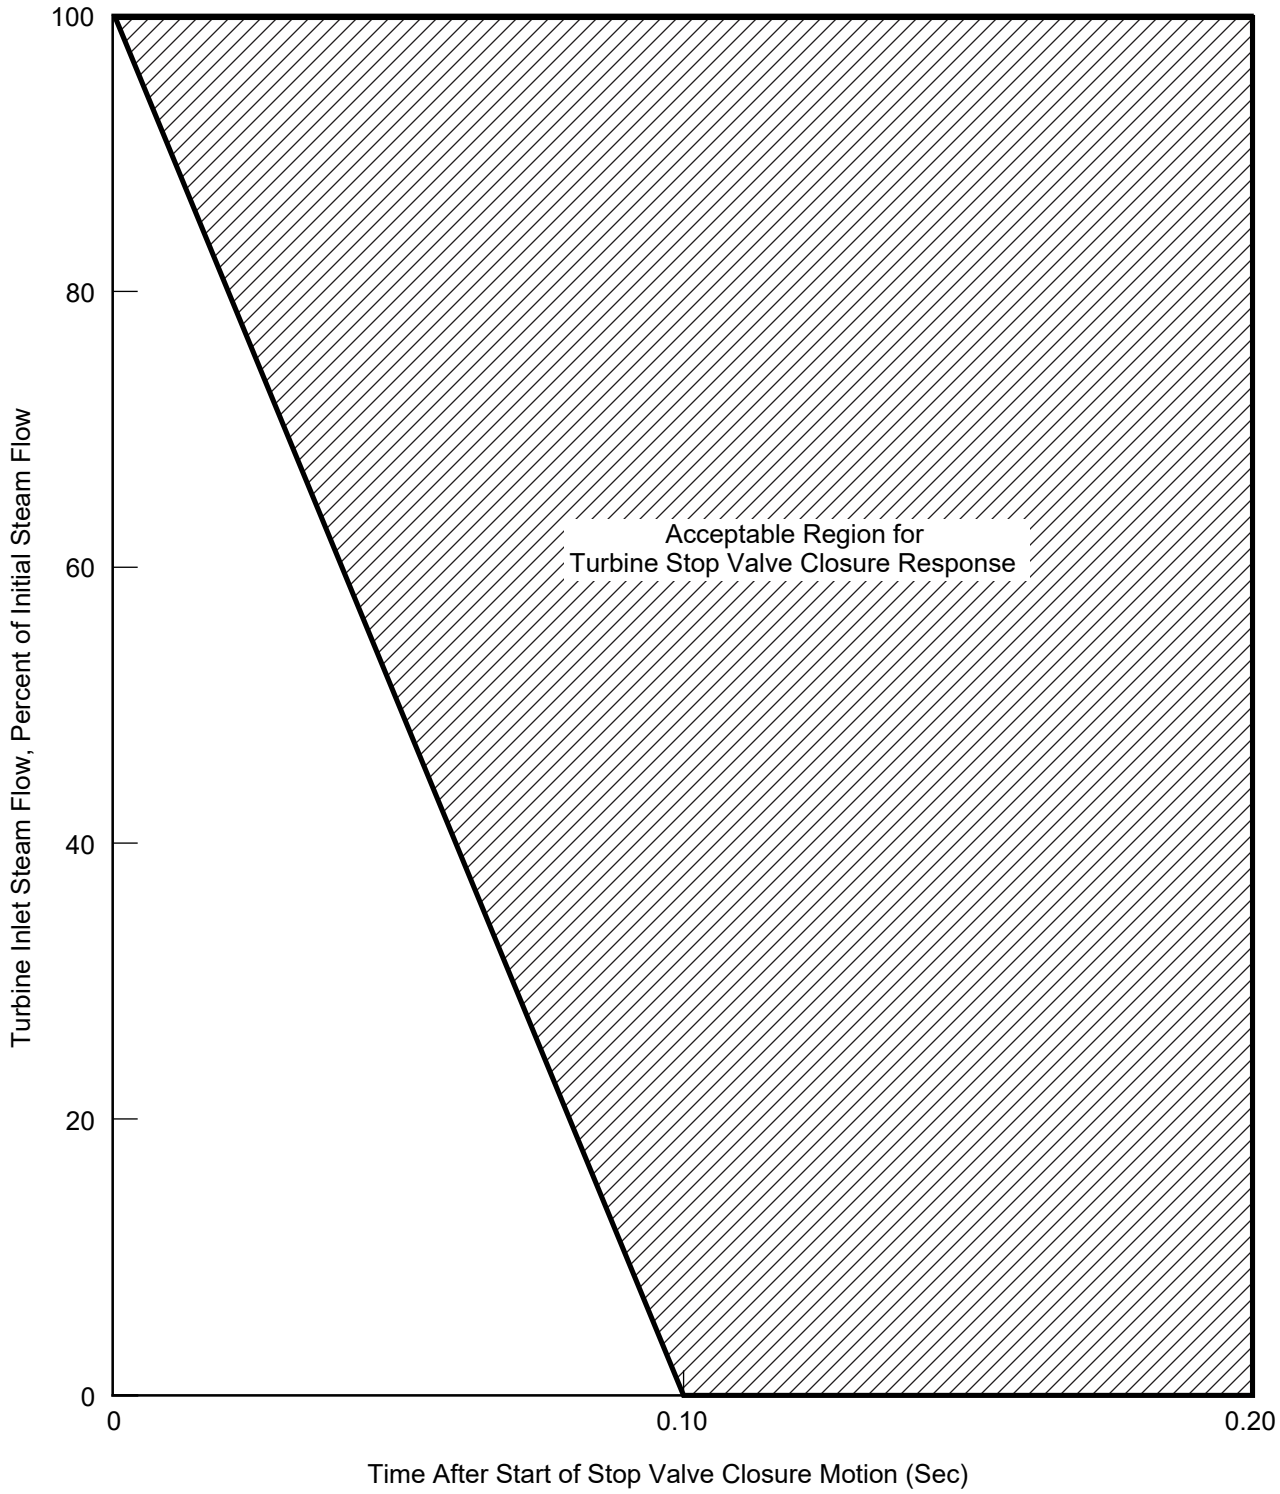
Each of the extraction steam lines has a reverse current valve and a gate valve, with the exception of the extraction lines to low pressure number 1 heaters. These valves are located near the condenser. On turbine trip the reverse current valves close immediately on reverse flow. Because of the fast closure and the short distance between these valves and the extraction points at the turbine, the amount of steam in these lines does not affect the turbine coastdown following a turbine trip.



10.2.3 TURBINE DISK INTEGRITY

Analysis of potential turbine missile hazards and drawings showing the orientation of the turbine with respect to important structures are presented in Section 3.5.1.3.

10.2.4 SAFETY EVALUATION



The steam entering the high pressure turbine may contain fission, coolant activation, and activated corrosion products. The anticipated concentration of nitrogen-16, which is the dominant radionuclide entering the high pressure turbine, is discussed in Section 12.2. Moisture separation and transit time between the high pressure and low pressure turbines reduces the concentration of radionuclides in the steam prior to entering the low pressure turbine. Most of the gaseous radioactivity is removed by the steam-jet air ejector and routed to the offgas system (see Section 11.3). The condensate in the condenser hotwell contains significantly less radioactive material than the inlet steam.

Access to the turbine area is controlled. Radiation levels associated with turbine components are described in Section 12.2 and shielding requirements are discussed in Section 12.3.

QUADVOTER MANIFOLD DETAIL
SEE M959 (ZONE E/4)

NOTES:

1. ALL INSTRUMENTATION ON THIS DRAWING TO BE IDENTIFIED BY PREFIX "DEH" UNLESS SPECIFICALLY NOTED OTHERWISE.
   (EXAMPLE.)
   X / Y — BS
2. ALL PIPING, VALVES, AND ASSOCIATED EQUIPMENT ON THIS DRAWING SHALL BE CLASSIFIED AS FOLLOWS:
   QUALITY CLASS II
   SEISMIC CATEGORY II
   CODE GROUP D
3. SEE DWG M501 FOR FLOW DIAGRAM LEGENDS, SYMBOLS AND ABBREVIATIONS.

Amendment 59
December 2007

NOTES:
1. FOR SYMBOL LIST SEE DW

SYMBOL LIST

PRESSURE SWITCHES

63/BL	-BEARING LIFT OIL-OPENS AT 850 PSIG DECR. PRESS.-LOCATED IN TERM. BOX "TB"
DEH-PS-5	-EH FLUID BACKUP PUMP START-CLOSES ON DECREASING PRESSURE 1800 PSIG
63/TG-1	-TURNING GEAR-OPENS AT INCREASE OF "ENGAGE AIR" PRESS. TO 20 PSIG
63/BOP	-BEARING OIL-CLOSES ON DECREASING PRESS AT 11-12 PSIG.-LOCATED IN TERM. BOX "L"
63/EOP	-BEARING OIL-CLOSES ON DECREASING PRESS. AT 10-11 PSIG.-LOCATED IN TERM. BOX "L"
63/XO	-EXHAUST HOOD SPRAY-OPENS ON PRESS. INCREASE AT 9 PSIG (EQUAL TO 15% LOAD)
DEH-PS-2	-EH FLUID RETURN-CLOSES ON INCREASING PRESS. AT 30 PSIG
DEH-DPIS-28A	-EH FLUID PUMP #1 FILTER DIFF. PRESS. SW. CLOSES ~50 PSID
DEH-DPIS-28B	-EH FLUID PUMP #2 FILTER DIFF. PRESS. SW. CLOSES ~50 PSID
SW-10	-DIFF. PRESS. SW. CLOSES ON LOW AIR SIDE SEAL OIL PUMP PRESSURE
SCW-DPS-15(SW-15)	-DIFF. PRESS. SW. OPERATES WHEN DIFF. PRESS. <60 PSI ON PUMP SCW-P-1
SCW-DPS-16(SW-16)	-DIFF. PRESS. SW. OPERATES WHEN DIFF. PRESS. <60 PSI ON PUMP SCW-P-2
63/EHS-1	-EXHAUST HOOD SPRAY-CLOSES ON DECREASING PRESSURE
63/EHS-2	-EXHAUST HOOD SPRAY-CLOSES ON DECREASING PRESSURE
63/EHS-3	-EXHAUST HOOD SPRAY-CLOSES ON DECREASING PRESSURE
DEH-PS-6	-EH FLUID PRESS. LOW-OPENS ON DECREASE PRESS. 1900 PSIG
DEH-PS-4	-EH FLUID PRESS HI-CLOSES ON INCREASE PRESS. 2420 PSIG
SW-9	-DIFF. PRESS. SW. CLOSES WHEN AIR SIDE SEAL OIL PUMP IS OFF
SW-12	-PRESS SW. CLOSES WHEN SEAL OIL TURBINE BACK-UP PRESS LO.
SW-13	-DIFF. PRESS. SW. CLOSES WHEN H2 SIDE SEAL OIL PUMP OFF
SW-14	-DIFF. PRESS. SW. CLOSES WHEN AIR SIDE SEAL OIL BACK-UP PUMP RUNNING
SW-17	-DIFF. PRESS. SW. CLOSES WHEN COOLING WATER FILTER CLOGGED
SW-18	-PRESS. SW. CLOSES WHEN MAKE-UP WATER FLOW IS ON
SW-23	-PRESS. SW. CLOSES WHEN STATOR COIL COOLING WATER TANK PRESS. IS HI
SW-24	-DIFF. PRESS. SW. CLOSES WHEN STATOR COIL COOLING WATER FLOW IS LO
SW-25	-DIFF. PRESS SW. CLOSES WHEN STATOR COIL COOLING WATER FLOW IS LO-LO
SW-30	-DIFF. PRESS. SW. CLOSES WHEN GEN. H2/H2O DIFF PRESS. LO
63/RPS	-RPS PRESS. SWS. OPENS ON DECREASE OF PRESS.

LIMIT SWITCHES (33)

(FOR DEVELOPMENT SEE E520-2A, EXCEPT AS NOTED)

33/TGD-1	-TURNING GEAR LEVER POSITION SWITCH WIRED TO TERMINAL BOX "x"
33/TGD-2	-TURNING GEAR LEVER POSITION SWITCH WIRED TO TERMINAL BOX "x"
33/TGE-1	-TURNING GEAR LEVER POSITION SWITCH WIRED TO TERMINAL BOX "x"
33/TGE-2	-TURNING GEAR LEVER POSITION SWITCH WIRED TO TERMINAL BOX "x"
33/TGT-1	-TURNING GEAR LEVER POSITION SWITCH WIRED TO TERMINAL BOX "x"
33/RO	-RELATCH OPERATOR-WIRED TO TERM. BOX "x"
33/VTL	-VACUUM TRIP LATCH-WIRED TO TERM. BOX "x"
33/DV	-DRAIN VALVE LIMIT SW.
33/RR	-REHEAT STOP V RIGHT LIMIT SW.
33/RL	-REHEAT STOP V LEFT LIMIT SW.
33/IR	-INTERCEPTOR V RIGHT LIMIT SW.
33/IL	-INTERCEPTOR V LEFT LIMIT SW.
33/RCV	-REHEAT CONTROL VALVE
33/EHS	-EXHAUST HOOD SPRAY
33/a & 33/b	-DISCONNECT SWITCH CONTACTS - 500kV
33/EHB-1	-SEE 33/COND-V-609A DWG. E519-5 -EXHAUST HOOD BY-PASS SPRAY VALVE LIMIT SW.
33/EHB-2	-SEE 33/COND-V-609B DWG. E519-5 -EXHAUST HOOD BY-PASS SPRAY VALVE LIMIT SW.
33/EHB-3	-SEE 33/COND-V-609C DWG. E519-5 -EXHAUST HOOD BY-PASS SPRAY VALVE LIMIT SW.
33/AR-V-3A	-(N) 33/VB1 -VACUUM BKR LIMIT SWITCH SEE DWG. E523 FOR SW. DEVELOPMENT
33/AR-V-3B	-(N) 33/VB2 -VACUUM BKR LIMIT SWITCH SEE DWG. E523 FOR SW. DEVELOPMENT
33/AR-V-3C	-(N) 33/VB3 -VACUUM BKR LIMIT SWITCH SEE DWG. E523 FOR SW. DEVELOPMENT
33/OS1	-ROTOR GLAND STEAM SPILL-OVER S.O. VALVE LIMIT SW. -SEE DWG. E523 FOR SW. DEVELOPMENT
33/OS2	-ROTOR GLAND STEAM SPILL-OVER B.P. VALVE LIMIT SW. -SEE DWG. E523 FOR SW. DEVELOPMENT
DEH-POS-TRIP/A,B,C,D	-TRIP SOLENOID POSITION

ELECTRICALLY OPERATED VALVES (20)

20-1/OPC	-SOL. V-OVERSPEED PROTECTION CONTROLLER WIRED TO TERM. BOX "B"
20-2/OPC	-SOL. V-OVERSPEED PROTECTION CONTROLLER WIRED TO TERM. BOX "B"
20/TGE	-SOL. V-TURNING GEAR ENGAGE -WIRED TO TERM. BOX "x"
20/TGV	-SOL. V-TURNING GEAR ENGAGE AIR VENT -WIRED TO TERM. BOX "x"
20/TGD	-SOL. V-TURNING GEAR DISENGAGE -WIRED TO TERM. BOX "x"
20/DVI	-SOL. VALVE ENERGIZED TO ADMIT AIR TO DRAIN VALVE OPERATOR
20/DVII	-SOL. VALVE ENERGIZED TO ADMIT AIR TO DRAIN VALVE OPERATOR
20/TGO	-TURNING GEAR LOW OIL
20/MPT	-SOL. V-ELECTRO HYDRAULIC PUMP NO'S 1 & 2 AUTO START TEST
20-EHS-1,2,3	-SOL. V TO OPEN EXHAUST HOOD SPRAY WHEN TURB. SPEED EXCEEDS 600RPM
20/RL	-SOL. V -REHEAT STOP V TEST, LEFT
20/RR	-SOL. V -REHEAT STOP V TEST, RIGHT
20/IL	-SOL. V -INTERCEPTOR V TEST, LEFT
20/IR	-SOL. V -INTERCEPTOR V TEST, RIGHT
20/BV1,2,3,4	-SOL. V -STEAM BY-PASS
20/RVB	-SOL. V -FOR TEST OF 63/RVB PRESS SWS.
20/RPS	-SOL. V -FOR TEST OF 63/RPS PRESS SWS.
DEH-SV-TRIP-A,B,C,D	-TRIP BLOCK

MISCELLANEOUS

63-1/ZA	-TURNING GEAR ZERO SPEED ALARM ACTUATING CONTACTS (APPROX. 10 SEC. TIME DELAY)-LOCATED IN TERM. BOX "A"
63-2/ZA	-TURNING GEAR ZERO SPEED ALARM ACTUATING CONTACTS (APPROX. 10 SEC. TIME DELAY)-LOCATED IN TERM. BOX "A"
52a & 52b	-500kV CIRCUIT BREAKER CONTACTS. (IN MICRO WAVE CAB.)
DEH-LS-7A,B,C	-LOW EH FLUID LEVEL LOCKOUT LEVEL SWITCH CLOSES ON LOW EH FLUID
TG-RLY-SPD ARM1/NC1	-TURNING GEAR ACTUATING CONTACT-CLOSED FROM ZERO TO 600RPM TURBINE SPEED-LOCATED IN TG-MON-SPD-BOARD "B" (RELAY NORMALLY DE-ENERGIZED)
TG-RLY-SPD ARM3/NC3	-CONTACT OPENS ON DECREASING TURBINE SPEED 600RPM-LOCATED IN TG-MON-SPD-BOARD "B" (RELAY NORMALLY ENERGIZED)
(N)	-LOAD REJECTION CONTACT IN DEH CONTROLLER CABINET
ARC	-AUX. RELAY CABINET
(GAP)	-ALARM CONTACTS LOCATED IN GEN. AUX. CONTROL PANEL
60/Cx	-GENERATOR P.T. FAILURE RELAY-LOCATED IN BOARD "F" IN CONTROL ROOM (DWG. E512-2)
✱	-FURNISHED AND INSTALLED BY (N) ON TURNING GEAR CONSOLET-WIRED TO TERM. BOX "x"
○	-FAN FAILURE ALARM RELAYS LOCATED IN FAN CONTROL PANEL
◇	-LOCATED IN GEN. AUX. CONTROL STATION "GACS."
⌀	-LOCATED IN RPS/REVAB1 TEST PANEL
(⌀)	-LOCATED IN RPS/REVAB2 TEST PANEL
⏚	-CLOSES WHEN E.H. CONTROL POWER SUPPLY FAILS-LOCATED IN DEH GOVERNOR CONTROLLER CABINET
41	-VOLT. REGULATOR SUPPLY BREAKER
PB/MPT	-PUSH BUTTON ELECTRO HYDRAULIC PUMP TEST
71/OL	-HIGH & LOW LUBE OIL LEVEL SW
M/EHB-1	-SEE M/COND-V-609A DWG. E519-5 -EXHAUST HOOD BY-PASS SPRAY VALVE
M/EHB-2	-SEE M/COND-V-609B DWG. E519-5 -EXHAUST HOOD BY-PASS SPRAY VALVE
M/EHB-3	-SEE M/COND-V-609C DWG. E519-5 -EXHAUST HOOD BY-PASS SPRAY VALVE
AFS	-AIR FLOW SWITCH-OPENS ON NO. 1SO. PHASE BUS DUCT AIR FLOW (DWG. E519-11)
SW-7	-THERMOSTAT CLOSES ON H2 HIGH TEMPERATURE
SW-8	-TURBINE END -CONTACT CLOSES ON DEFOAMING TANK LEVEL HI
SW-8A	-EXCITER END -CONTACT CLOSES ON DEFOAMING TANK LEVEL HI
SW-11	-CLOSES ON H2 SIDE SEAL OIL LEVEL LO
TG-P/B-CR/TT1	-EMERGENCY TRIP PUSHBUTTON-MOUNTED IN BD "B"
TG-P/B-CR/TT2	-EMERGENCY TRIP PUSHBUTTON-MOUNTED IN BD "B"
K-7A,B,C	-REACTOR HIGH WATER LEVEL TRIP
DEH-TS-3	-TEMPERATURE SWITCH EH FLUID TEMPERATURE HI
TG-P/B-TG/TT1,TT2	-TURB. TRIP PUSHBUTTON TG 501
TG-DET-TP/A,B,C,	- THRUST BEARING
MD-LS-ML-20A,B, 21A,B,23A,B	-MSR HIGH LEVEL A,B,C
RFW-LS-624A,B,C	-REACTOR HIGH WATER LEVEL
TG-SE-05/A,B,C	-SPEED PICKUP
TG-SE-SC/A,B,C	-SPEED PICKUP

RELAYS

86XU	-UNIT TRIP LOCKOUT RELAY (DWG. E512-2)
86XUOA	-UNIT TRIP OVERALL TRIP LOCKOUT RELAY (DWG. E512-2)
14/ZSX	-ZERO SPEED RELAY-LOCATED IN TERM BOX "x"
ACR/BOP	-EMERGENCY OIL PP-AUX. RELAY DEENERGIZED FAILURE. FOR BOP CIRCUIT POWER.
VHTX	-VOLTS/HERTZ AUX. RELAY
VHT	-VOLTS/HERTZ REGULATOR TRIP RELAY
49X-EOP	-EMERGENCY OIL PUMP OVERLOAD
49X-ASOBP	-AIR SIDE SEAL OIL BACK-UP PUMP OVERLOAD
59/81	-EXCESSIVE VOLTS/HERTZ RELAY
59/81T	-EXCESSIVE VOLTS/HERTZ TIMING RELAY
41TD	-REGULATOR SUPPLY BREAKER AUX. RELAY
41/aX1,2	-REGULATOR SUPPLY BREAKER AUX. RELAY
DCF	-DC FAILURE IN GENERATOR AUX. CONTROL PANEL
62/TGS	-TURN GEAR FAILURE T.D. ALARM RELAY 0-30 SEC.
QSV	-QUICK SOL. VALVE OPERATING RELAY
MX	-EMERG. OIL PUMP RUNNING
MX-X	-AUX. RELAY FOR EMERGENCY OIL PUMP RUNNING-ALARM
TG-X/ZSX	-AUX. RELAY FOR 14/ZSX/ZERO SPEED ALARM
86X1U	-UNIT PRIMARY LOCKOUT RELAY (DWG. E512-2)
86X1UOA	-UNIT SECONDARY LOCKOUT RELAY (DWG. E512-2)
30/64F	-FIELD GROUND DETECTION PWR. SUPPLY FAILURE RELAY
90C	-VOLTAGE REGULATOR ON RELAY
94RB	-VOLTAGE REGULATOR TRIP RELAY
K4	-VOLTAGE REGULATOR FORCING ALARM RELAY
V/HZ	-MAXIMUM VOLTZ/HERTZ RELAY
PC1, PC2	-VOLTAGE REGULATOR LOSS OF FIRING PULSE RELAY
41-A	-REGULATOR BKR. AUTO TRIP ALARM RELAY
94-A	-VOLTAGE REGULATOR TRIP ALARM RELAY
FFA	-REG. COOLING FAN FAILURE ALARM RELAY
FA	-FIELD FORCING ALARM RELAY
VH/A	-VOLTZ/HERTZ LIMIT EXCEEDED ALARM RELAY
FP/A	-REGULATOR BLOWN FUSE OR LOSS OF POWER ALARM RELAY
41TD/A	-REGULATOR BKR. CLOSED ALARM RELAY
PSF/A	-REGULATOR POWER SUPPLY FAILURE ALARM RELAY
R1	-D.C. POWER FAILURE RELAY FOR GEN. AUX. CONTROL PANEL
R3	-STATOR COIL WATER INLET CONDUCTIVITY HI RELAY
R4	-STATOR COIL WATER INLET CONDUCTIVITY HI-HI RELAY
R5	-DEMINERALIZER OUTLET CONDUCTIVITY HI RELAY
64K	-GENERATOR GROUND DETECTION ALARM RELAY
64E/X	-EXCITER GROUND DETECTION ALARM RELAY
63Y/AM1	-AUX. RELAY

TRANSMITTERS

TG-PT-1A/1B/1C	-BRG. OIL PRESS TRANSMITTERS
MS-PT-8A,B,C	-CONDENSER 1 PRESSURE TRANSMITTER
DEH-PT-63A,B,C	-EH HEADER PRESS TRANSMITTERS
DEH-PS-TRIP/A,B,C,D	-TRIP BLOCK PRESS
MS-DPT-63A,B,C	-TURB. 1st STAGE DIFF PRESS.

) SYSTEM ALARM RELAYS LOCATED IN ARC

EHL/1X - LEVEL HI
EHL/2X - LEVEL LO-LO
EHL/3X - LEVEL LO
EHPR/X - PRESSURE RETURN HI
EHPF/X - PRESSURE DIFF. ON FILTER
EHPH/X - PRESSURE HI
EHPL/X - PRESSURE LO
EHTH/X - TEMPERATURE HI

Turbine Generator Control Elementary Diagram

Draw. No. E520-5	Rev. 40	Figure 10.2-7.3

10.3 MAIN STEAM SUPPLY SYSTEM

10.3.1 DESIGN BASES

The main steam supply system is designed for the following conditions:

a. Deliver steam from the reactor to the turbine generator from warmup to 105% of rated load,

b. Provide steam for the second-stage reheaters and steam-jet air ejectors,

c. Bypass steam to the main condenser during startup and in the event steam requirements of the turbine generator are less than that produced by the reactor,

d. Provide steam to the gland seal steam evaporator during startup, low load operation, and shutdown,

e. Provide steam to drive reactor feedwater pumps during startup and low load operation, and

f. Provide steam to the offgas preheaters.

The design pressure and temperature of the main steam piping is 1250 psig and 575°F.

The main steam lines are designed to include accesses to permit inservice inspection and testing (refer to Sections 5.2.4 and 6.6).

Design codes are given in Table 3.2-1, item 2, Nuclear Boiler System, and item 43, Power Conversion System. The environmental design bases for the main steam supply system are contained in Section 3.11.

10.3.2 SYSTEM DESCRIPTION

The main steam supply system is shown in Figures 10.3-1 and piping drawings are shown in Figures 3.6-32, 3.6-33, 3.6-34, 3.6-35, 3.6-50, 3.6-51, 3.6-53, 3.6-58, 3.6-60, and 10.3-2. The main steam line piping consists of four 30-in. (26-in. in reactor building) lines extending from the reactor pressure vessel to the main steam header located upstream of the turbine stop and control valves. This header placement ensures a positive means of bypassing steam via the turbine bypass system during transient conditions and startup. Branch lines from the main steam line provide the steam requirements for the reactor feed pumps, second stage reheaters, gland seal steam evaporator, offgas preheaters, and steam jet air ejectors.

The MSIVs are a wye-pattern-type globe valve utilizing pneumatic air to open and spring load with pneumatic air assist to close. Energizing control valves provide pilot and actuator air to open the valve. Deenergizing the control valves removes pilot air which vents actuator opening air and directs air to assist the spring force in closing the valve.

Loss of compressed air failure mode results are

a. Loss of compressed air due to loss of nonseismic air lines* results in loss of pilot air and closure of the MSIV by both spring force and pneumatic air cylinder force.

b. Loss of compressed air due to loss of Seismic Category I air lines† results in loss of both pilot air and actuator air with the MSIVs closing by spring force only.

Under normal operation the air supply maintains the required air for holding the valve open and charging the air storage tank. The check valve at the air storage tank inlet ensures a pneumatic supply for assist in closing the valve. No safety-related makeup supply is required for closure of the MSIVs for safe plant shutdown.

The removal of electrical power or failure of both the solenoids on the control valve automatically initiates closure of the MSIVs. Safety-related components ensuring removal of power to the solenoids when required are the only electrical power requirement. Section 9.3.1 describes the compressed air systems.

Equalizing lines connecting steam lines outside of the containment are used to equalize pressure across the main steam line isolation valves prior to restart following a steam line isolation. Assuming all steam line isolation valves have closed, the outer containment isolation valves are opened first and the drain lines are used to warm up and pressurize the outside steam lines. Following warmup the inboard main steam line isolation valves are opened.

10.3.3 SAFETY EVALUATION

Table 3.2-1 lists the applicable seismic category, quality group classification, and safety class for the main steam supply system. The effects of main steam line breaks and other accident conditions outside the containment are evaluated in Chapter 15. Protection against dynamic effects associated with the postulated rupture of piping inside or outside of containment is discussed in Section 3.6.

---

* Nonseismic lines are those lines supplying air to the isolation valve upstream of the check valve and to the pilot side of the air pilot valves (Figure 9.3-1, detail B).

† Seismic Category I lines include an air storage tank, check valve, and lines from the check valve to the actuator pilot valve (Figure 9.3-1, detail B).

10.3.4 INSPECTION AND TESTING REQUIREMENTS

The main steam lines were hydrostatically tested prior to initial operation. Nondestructive testing is performed in accordance with the applicable code requirements.

Preoperational and inservice inspection of the main steam lines and the main steam line isolation valves are presented in Sections 5.2.4 and 6.6.

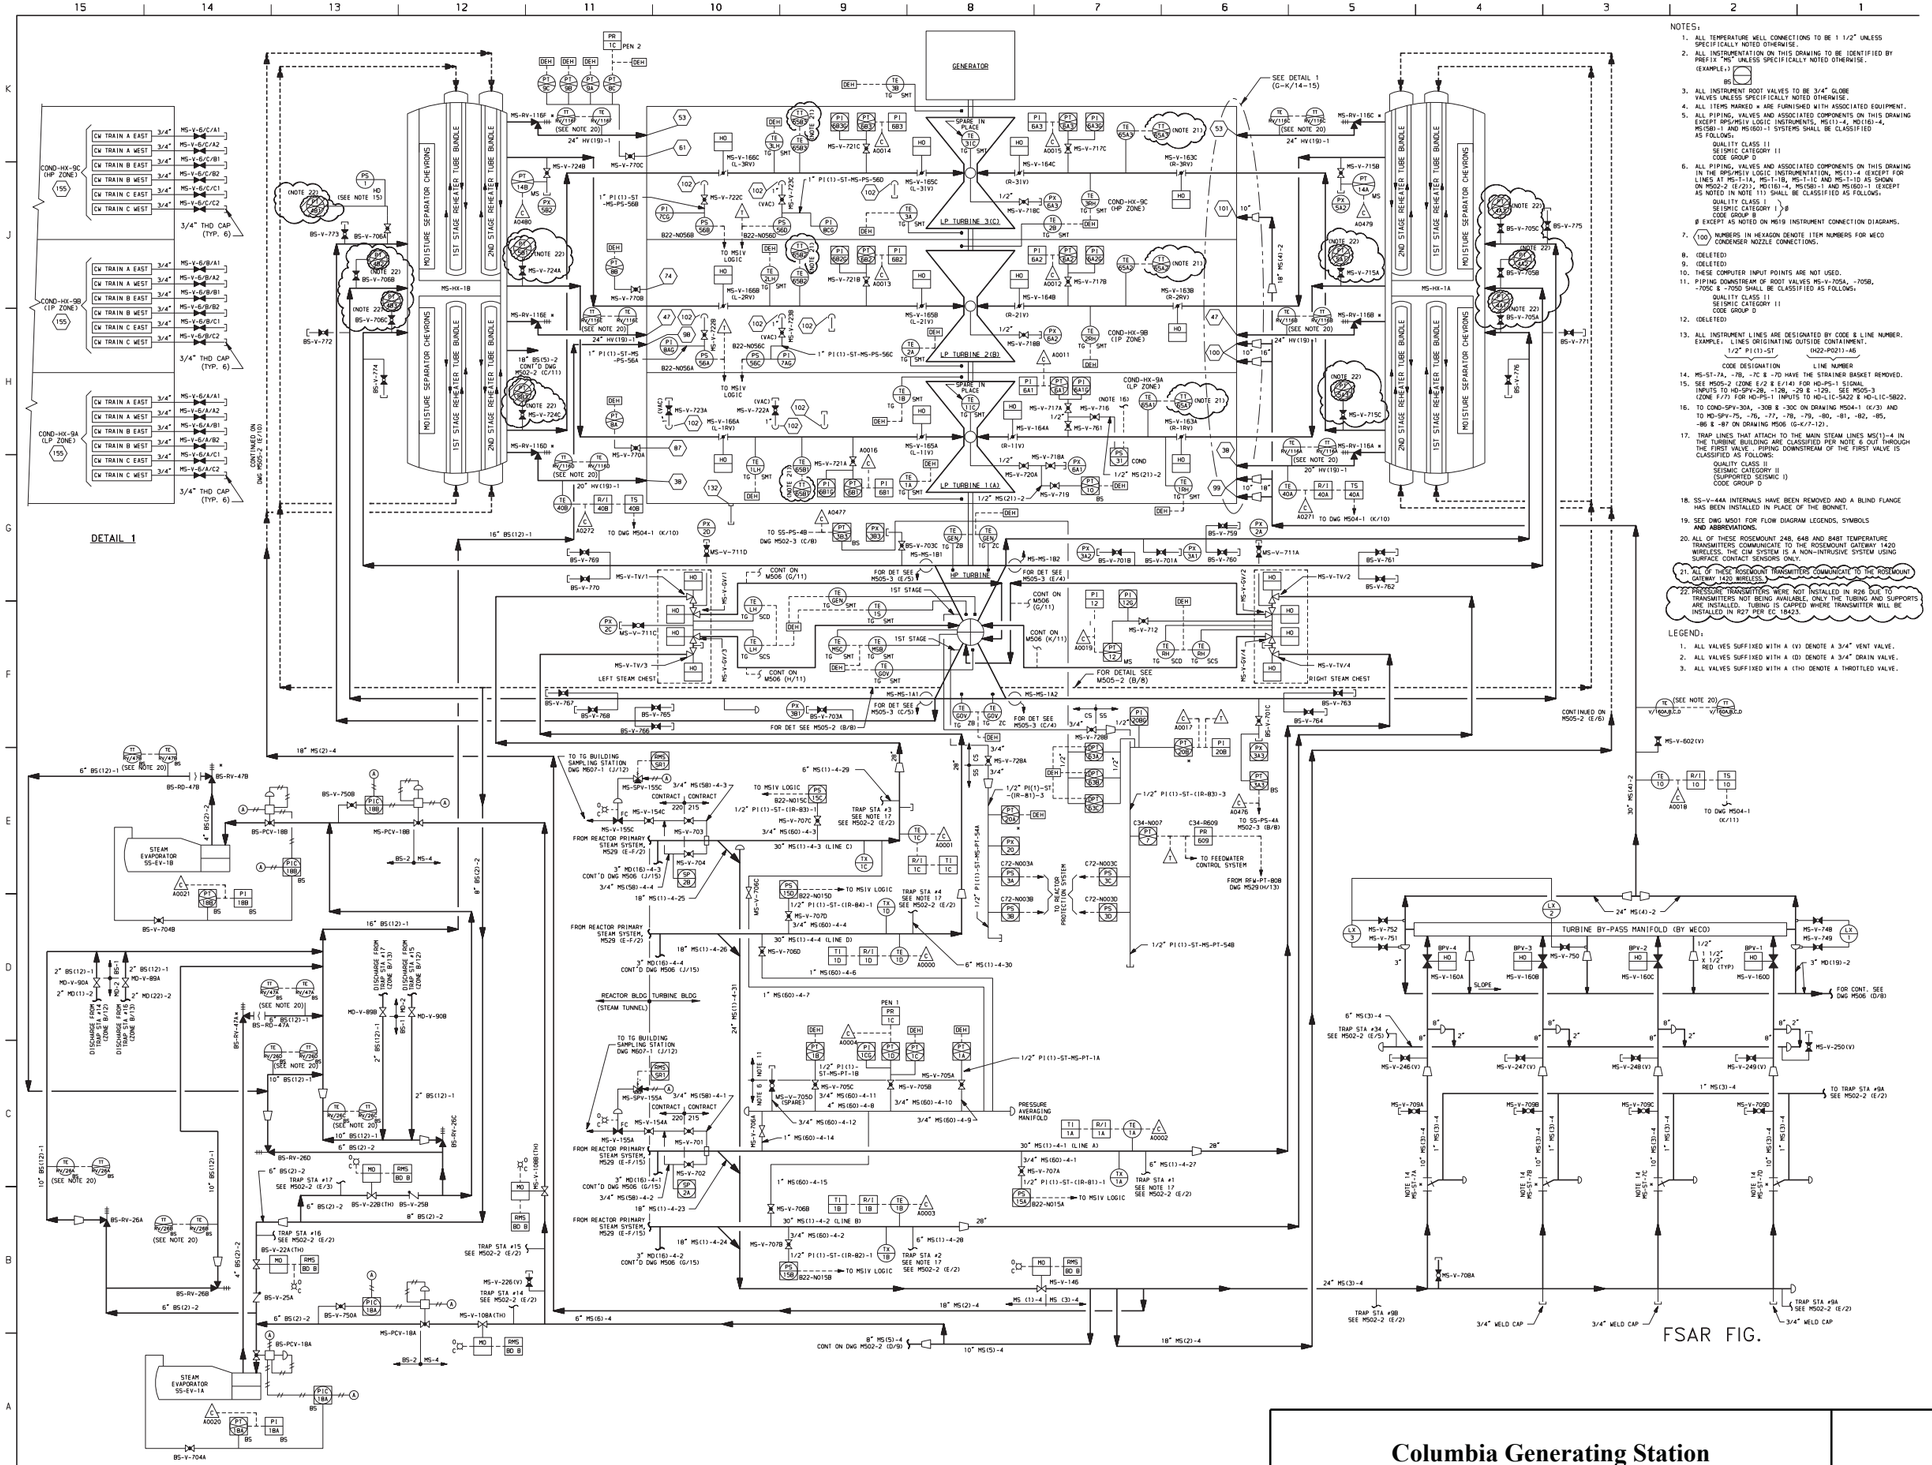
The use of four main steam lines permits inspection and testing of the turbine stop, control, reheat stop, and intercept valves and main steam line isolation valves during plant operation with a minimum of load reduction.

10.3.5 WATER CHEMISTRY

This section is not applicable to a BWR. See Section 10.4.6 for reactor coolant water chemistry considerations.

10.3.6 STEAM AND FEEDWATER SYSTEM MATERIALS

10.3.6.1 Fracture Toughness



Impact tests in accordance with the size limitations specified in ASME Code Section III, Class 1, are performed on all ASME Code Section III, Class 1, main steam and feedwater materials, as well as Class 2 main steam system materials for all pressure retaining ferritic steel parts. The tests are conducted at a temperature of 45°F or lower in accordance with NB or NC-2310 of the Summer 1972 or Winter 1973 Addendum of ASME Code Section III, as applicable.

10.3.6.2 Materials Selection and Fabrication

All materials used for portions of the main steam system described in this section are included in Appendix I to Section III of the ASME Boiler and Pressure Vessel (B&PV) Code. The requirements for welding the main steam piping from the reactor to the turbine generator are in accordance with ASME Section III, 1971 Edition through the Winter 1973 Addenda. The welding requirements for other steam and feedwater piping are in accordance with ANSI B31.1, October 1973 (see Section 3.2).

Cleaning of components in the main steam system is in accordance with ANSI N45.2.1 (October 1973) or ASTM A380-57 (October 1973) for stainless steel surfaces and Regulatory Guide 1.37.

Degree of conformance to the following Regulatory Guides is addressed in Section 1.8: 1.31, Control of Stainless Steel Welding; 1.36, Nonmetallic Thermal Insulation for Austenitic Stainless Steel; 1.44, Control of the Use of Sensitized Stainless Steel; 1.50, Control of Preheat Temperature for Welding of Low-Alloy Steel; and 1.71, Welder Qualification for Areas of Limited Accessibility.

Main Steam Supply System Piping

Draw. No. M529 | Rev. 110 | Figure 10.3-2

10.4 OTHER FEATURES OF STEAM AND POWER CONVERSION SYSTEM

10.4.1 MAIN CONDENSER

10.4.1.1 Design Bases

The purpose of the main condenser is to provide a heat sink for condensing the turbine exhaust steam, turbine bypass steam, reactor feed pump drive turbine exhaust steam, and to provide a receiver for miscellaneous drains. It also provides deaeration, noncondensable gas removal, and storage of condensate, which is returned to the condensate system after a period of radioactive decay.

The main condenser is designed for the following conditions (approximate values):

a.	Duty	7.7 x 10^9 Btu/hr
b.	Circulating water flow	555,600 gpm
c.	Circulating water inlet temperatures	78°F
d.	Circulating water outlet temperatures	106°F
e.	Total steam condensed	8,128,700 lb/hr
f.	Total condensate outflow	15,017,000 lb/hr
g.	Outlet temperature of condensate	105.0°F
h.	Condenser pressure (triple)	2.4 in Hg abs (average)
i.	Cleanliness factor	85%
j.	Number of passes	1
k.	Air inleakage flow rate limit	50 scfm
l.	Hotwell storage capacity	163,000 gal

The main condenser is designed to accept a maximum of 25% of the rated reactor steam flow from the turbine bypass system (described in Section 10.4.4) plus 75% of the rated reactor steam flow through the turbine. This steam flow is accommodated without increasing the condenser backpressure to the turbine trip setpoint or exceeding the allowable turbine exhaust temperature.

The main condenser is designed to deaerate the condensate and provide an oxygen content in the hotwell condensate between 30-100 ppb per liter over the entire load range.

Feedwater quality is maintained by the condensate filter demineralizer system described in Section 10.4.6.

The condenser hotwell is designed to contain the condensate that is required during 5 minutes of full power operation of the turbine. Baffling in the hotwell provides a minimum of 3 minutes condensate hold-up time which permits the decay of short-lived radioactive isotopes.

Condenser construction is designed in accordance with requirements of the Heat Exchange Institute, Standards for Steam Surface Condensers (October 1971). Construction of condenser module bundle replacement is designed in accordance with the Tenth Edition.

The piping associated with the condenser is designed, fabricated, inspected, and erected in accordance with ANSI B31.1 (October 1971). Seismic category, safety class, and design codes are discussed in Section 3.2.

10.4.1.2 System Description

Steam from the low-pressure turbine is exhausted directly downward into the condenser shells through exhaust openings in the bottom of the turbine casings and is condensed. The condenser serves as a heat sink for several other flows, such as exhaust steam from the reactor feedwater pump turbines, cascading feedwater heater drains, air ejector condenser drains, gland seal steam condenser drain, feedwater heater shell operating vents, turbine gland seals, and the offgas preheater drains.

Other flows to the condenser originate from the startup vents of the condensate pumps, the reactor feedwater pumps, condensate booster pumps, the condensate pumps, feedwater line startup flushing, reactor feedwater pump turbine drains, low-point drains, condensate makeup, reactor water cleanup (RWCU), and feedwater heater dumps or drains. All high temperature drains into the condenser shell have impingement baffles or spray pipes to prevent the steam and entrained water particles from impinging on the surface of the tubes. Stainless steel lagging is provided where required to protect other condenser components. The bypass valves are described in Section 10.4.4.2.

During transient conditions, the condenser is designed to receive turbine bypass steam and feedwater heater and drain tank high-level discharges. The condenser is also designed to receive relief valve discharges from moisture separators, feedwater heater shells, steam seal regulators, and various steam supply lines.

The condenser is cooled by the circulating water system described in Section 10.4.5. Air inleakage and noncondensable gases are removed by the main condenser evacuation system described in Section 10.4.2.

Before leaving the condenser, the condensate is deaerated to reduce the level of dissolved oxygen.

10.4.1.3 Safety Evaluation

During operation, radioactive steam, gases, and condensate are present in the shell of the main condenser. The inventory of radioactive contaminants during operation is discussed in Section 12.2.1.2.2.7. Shielding for and controlled access to the main condenser is provided in

Chapter 12. The means of controlling and detecting the leakage of this radioactive inventory in and out of the main condenser is discussed in Sections 11.3 and 11.5.2.2.

Hydrogen is generated by radiolysis in the reactor and injected by the Hydrogen Water Chemistry system.

Hydrogen generation buildup during operation is prevented by continuous evacuation of the main condenser by the air removal system (see Section 10.4.2) and the offgas system (see Section 11.3.2). The radiolytic decomposition rate at rated power is 102 scfm of hydrogen and 51 scfm of oxygen. Hydrogen is introduced into the condensate/feedwater system to mitigate intergranular stress corrosion cracking (IGSCC). The addition of hydrogen into a feedwater system results in reduced radiolysis. The net hydrogen in the steam during Hydrogen Water Chemistry (HWC) is less than during normal water chemistry (NWC) (without hydrogen injection). During plant shutdown, there are no hydrogen sources to the condenser. Hydrogen injection is shut down whenever the reactor is shut down. The inadvertent introduction of hydrogen to condensate/feedwater, from HWC, during extended shutdowns is prevented by isolation of the hydrogen supply, and purging the hydrogen injection system with nitrogen.

The main condenser is not required for safe shutdown of the reactor and does not perform safety functions. However, degradation of the condenser in the form of a leak, loss of circulating water, or air ejector malfunction could lead to a loss of condenser vacuum which removes the effective ability of the condenser as a heat sink. As a consequence, loss of vacuum provides a main steam isolation valve closure signal. See Section 7.3.1.1.2 for a further description. Due to the distance of the main condenser from safety-related equipment areas, there will be no damage to necessary safe shutdown equipment from flooding caused by failure of the condenser.

Exhaust hood overheating protection is provided by sprays located downstream of the last-stage blades of the turbine.

Loss of main condenser vacuum causes the turbine to trip. Should the turbine stop valves, control valves, or bypass valves fail to close on loss of condenser vacuum, rupture diaphragms on each turbine exhaust connection to the condenser protect the condenser and turbine exhaust hoods against overpressurization. In this event, steam would exhaust to the turbine building.

The main condenser is constructed with titanium tubes and the tubesheet is titanium clad carbon steel. Corrosion protection of the wetted carbon steel water boxes, inlet and outlet valves, and circulating water piping is being performed by a combination of a high quality coating, the use of stainless steels, and sacrifical anodes. The sacrifical anodes attach to the wall of the water boxes and will provide protection in case of any coating breaches or coating failure. All small bore nozzles on the circulating water side penetrating the water box 4 inches and less are of stainless steel. The water box coating will wrap into these connections to

prevent any carbon steel exposure. Isolation kits will electrically isolate any attached drain piping to help minimize any stray current corrosion.

10.4.1.4 Tests and Inspections

The condenser shell received a field hydrostatic test prior to initial operation. This test consisted of filling the condenser shell with water, and inspecting the entire tube sheet and shell welds and surfaces for visible leakage and/or excessive deflection.

The condenser module bundle replacement final test for tube or joint leakage was performed using a vacuum-bubble leak test.

During normal plant operation, the following parameters are routinely monitored:

a. Condenser vacuum,
b. Conductivity, and
c. Condensate temperature.

Any divergence from established limits for these parameters requires an investigation and testing as necessary to determine the extent of the divergence and correct the problem.

10.4.1.5 Instrumentation

The condenser shell is provided with local and remote hotwell level and pressure indication. The remote indication is by means of indicators and alarms in the main control room. The condensate level in the condenser hotwell is maintained within proper limits by automatic controls that provide for transfer of condensate to and from the condensate storage tanks as needed to satisfy the requirements of the steam system. Condensate temperature is measured in the outlet line of the condensate pumps.

Turbine exhaust hood temperature is monitored and controlled with water sprays to provide protection from exhaust hood overheating.

A main condenser low vacuum alarm is provided. Automatic turbine trip is activated on continued loss of main condenser vacuum followed by main steam isolation valve closure on further degradation of condenser vacuum. See Section 7.3.1.1.2 for a further description of main steam isolation.

Water box pressure and temperature measurements are provided.

Circulating water inleakage to the main condenser is monitored by conductivity elements located in the tube sheet troughs, in the condenser outlet line, and at the condensate pump discharge line (alarm in the main control room). Conductivity of the condensate demineralizer

influent is monitored and alarmed in the radwaste control room. A conductivity/chemical species sampling and measurement system is available for characterizing inleakage. Leakage is controlled (prevented) to the extent possible by maintaining chemistry control in the circulating water to provide optimization between scale formation and corrosion. Tube leakage can be corrected by isolating and draining the tube sections containing leaking tubes and then locating and plugging the leaking tube.

10.4.2 MAIN CONDENSER EVACUATION SYSTEM

10.4.2.1 Design Bases

The main condenser evacuation system removes gases from the turbine generator, the reactor feedwater pump turbines, and the main condenser during plant startup and maintains the condenser essentially free of noncondensable gases during operation. This system handles all noncondensable gases which may enter the main turbine and reactor feed pump turbines through their seals, the condensate piping, or which is generated by dissociation of water in the reactor. The main condenser evacuation system discharges to the offgas system through the steam jet air ejectors during normal operation (see Section 11.3).

The piping system associated with the main condenser evacuation system is designed, fabricated, and erected in accordance with ANSI B31.1 (October 1971). The air removal equipment is designed in accordance with the standards for Steam Surface Condensers, published by the Heat Exchange Institute (October 1971).

10.4.2.2 System Description

The main condenser evacuation system includes, for normal operation, two 100%-capacity steam jet air ejector units. Each unit consists of a twin-element first-stage steam jet air ejector and a single-element second-stage, steam jet air ejector which discharges to the offgas system. The capacity of each steam jet air ejector unit is 663 scfm at 70°F total equivalent of mixed gases and vapor at 1-in. Hg absolute. The main condenser design air inleakage flow rate is 50 scfm.

Two mechanical vacuum pumps are provided for hogging operation during startup (see Figure 10.4-1). During startup, both mechanical vacuum pumps can be used to rapidly remove air and noncondensable gases from the main condenser.

The discharge from the vacuum pumps is routed with the gland seal steam exhauster discharge to the reactor building elevated release duct. Because the reactor power is low, a minimal amount of activity is discharged to the environment. A radiation detector monitors the discharge and isolates the vacuum pumps when the radiation level exceeds established limits. The vacuum pumps operate until sufficient steam pressure is available to start the steam jet air ejector.

The source of steam to operate the steam jet air ejector is taken from the main steam header branch line, with steam pressure being regulated by the steam jet air ejector control valves. Air inleakage, noncondensable gases, as well as entrained water vapor, are removed from the main condenser by the first stage of the steam jet air ejector. The gas-vapor mixture is then discharged into the ejector condenser where the vapor is condensed. The resulting condensate is drained back to the main condenser via a loop seal. The ejector condenser is cooled by the condensate discharge from the condensate pumps. The noncondensing second stage of the steam jet air ejector removes the noncondensable gases and some entrained vapor from the ejector condenser and exhausts them to the offgas system (see Section 11.3). The offgas system processes the noncondensable gases and limits the release of radioactive gases to the environment.

10.4.2.3 Safety Evaluation

The main condenser evacuation system is not safety related. Consequently, the system is not designed to Seismic Category I requirements. Safety class and design codes are presented in Section 3.2.

The radionuclides in the effluent from the steam jet air ejector unit have been evaluated in Section 11.3.

The offgas from the main condenser contains hydrogen gas from dissociation of water in the reactor and from hydrogen injection. In the second-stage steam jet air ejector, sufficient steam is provided to dilute the hydrogen content to less than 4% by volume to keep the mixture below flammability limits.

10.4.2.4 Tests and Inspections

The mechanical vacuum pumps and the steam jet air ejectors were cleaned, inspected, and tested at the vendors' plant. System preoperational tests as described in Chapter 14 were successfully performed after installation. Main condenser evacuation system monitoring during normal operation along with routine maintenance and inspection ensures proper functioning and performance in accordance with its design bases. Instrumentation permits the operators to monitor system performance during operation.

10.4.2.5 Instrumentation

A radiation monitor is installed in the air removal piping discharge to the reactor building elevated release duct (a common exhaust line to the mechanical vacuum pumps and the gland seal steam condenser exhaust). A high-radiation signal from the monitor will trip both mechanical vacuum pump motors: The trip causes the suction and discharge valves to close and trips the mechanical vacuum pump seal water pumps. The vacuum pump is equipped with instrumentation to ensure proper operation (Figure 10.4-1).

A main steam line radiation monitor (MSLRM) high-radiation signal also trips both mechanical vacuum pump motors. The signal will also trip both gland seal steam condenser exhauster motors (see Section 11.5.2.1.1).

Low steam flow to the second-stage air ejector causes a signal to close the inlet gas valves to the first-stage air ejector. Steam pressure indicators for the first- and second-stage ejectors and a steam flow indicator for the second-stage ejector are provided in the main control room.

10.4.3 TURBINE GLAND SEALING SYSTEM

10.4.3.1 Design Bases

a. The turbine gland sealing system prevents air leakage into, or radioactive steam leakage out of, the main turbine and reactor feedwater pump turbines; and

b. The turbine gland sealing system is designed to provide nonradioactive (clean) sealing steam, at all loads, to the turbine shaft glands and valve stems (main stop, control reheat stop, intercept, and bypass valves). The condensate from the gland seal steam condenser is returned to the main condenser, and the noncondensable gases (inleaking air) are exhausted to the reactor building elevated release duct.

The turbine gland sealing system is in strict conformance with the latest edition in effect at the time of fabrication of the applicable ANSI, ASME, and IEEE standards. The major portion of manufacture was performed during 1975. The gland seal steam evaporators are designed, fabricated, inspected, tested, and stamped in accordance with Section VIII of the ASME Boiler and Pressure Vessel (B&PV) Code and the Standards of the Tubular Exchanger Manufacturers Association, Class R (May 1972). Seismic category, safety class, and design codes are provided in Section 3.2.

10.4.3.2 System Description

The turbine gland sealing system consists of two 100%-capacity gland seal steam evaporators, seal steam pressure regulators, seal steam header, gland seal steam condenser, exhauster blowers, and the associated piping, valves, and instrumentation (see Figures 10.3-1 and 10.4-2). Sealing steam for turbine shaft seal glands and valve stem seal glands (stop, control, reheat stop, intercept, and bypass valves) is supplied from the seal steam header at 200 psig. The source of sealing steam is from the gland seal steam evaporators or the auxiliary steam boiler. The sealing steam is produced in an evaporator which is heated by extraction steam taken from the high pressure turbine. The condensate fed to the evaporator is taken from the suction header of the reactor feedwater pumps in the feedwater system. During startup and low load operations, a branch line taken off the main steam header supplies the necessary heating steam for the evaporator.

Separate seal steam regulators are provided to regulate the pressure of sealing steam for the high pressure turbine, each low pressure turbine, each reactor feed pump turbine shaft seal, the bypass valve assembly, and the main stop and control valve assembly stems.

Since the low pressure (LP) turbine and reactor feedwater pump turbine exhaust pressures are at a vacuum, sufficient sealing steam is supplied to maintain positive pressure in the glands to prevent air inleakage along the shaft. The high pressure (HP) turbine exhaust pressure varies with load and is approximately 177 psia at its maximum. The system is designed to maintain the seal steam supply to the HP turbine glands at a pressure of 16 to 20 psi above HP turbine exhaust to prevent HP turbine exhaust steam leakage through the shaft gland seal.

The main stop, control, and bypass valve stems are provided with an intermediate zone to which sealing steam is supplied. This nonradioactive steam leaks in both directions, towards the HP stem leakoff and towards the LP stem leakoff. The HP stem leakoff contains radioactive steam and is directed to an LP feedwater heater. The LP steam leakoff is nonradioactive and is sent to the gland seal steam condenser. The reheat stop and intercept valve stems are supplied with sealing steam at a pressure greater than the crossover pressure so that any leakage that occurs is into the crossover pipes.

The reactor feedwater pump turbines at the high pressure end are provided with sealing steam at an intermediate point in the turbine gland seal. This nonradioactive steam leaks in both directions, towards the HP end leakoff and towards the LP end leakoff. The HP leakoff contains radioactive steam and is directed to the sixth stage of the turbine. The LP steam leakoff is nonradioactive and is sent to the gland seal steam condenser. Sealing steam for the reactor feed pump turbine LP stop valve, HP stop valve, and control valve is provided in a similar manner.

The outer leakoff of all glands is routed to the gland seal steam condenser which is maintained at a slight vacuum by the exhauster blower. During plant operation, the gland seal steam condenser and one motor-driven blower is in operation. The exhauster blower discharges gland air inleakage to the atmosphere via the reactor building elevated release duct. The gland seal steam condenser is cooled by the main condensate flow.

The steam evaporator is a shell-and-tube heat exchanger designed to provide a continuous supply of clean sealing steam to the seal steam header.

10.4.3.3 Safety Evaluation

The turbine gland sealing system is not safety related.

A supply of clean steam is always available from either of two 100%-capacity steam evaporators or the auxiliary steam boiler. Should the steam packing exhauster fail to function,

the sealing steam would continue to flow into the turbine and would be the only steam that could flow out of the glands and into the turbine building. Therefore, no reactor steam would be released to the environment.

A radiation monitor in the discharge of the blower alerts the operator to tube ruptures in the gland seal steam evaporator or other system malfunctions. Sealing system radioactive releases are discussed in Section 11.3.

Relief valves in the seal steam system prevent excessive steam pressure. The valves vent to the condenser and atmosphere.

10.4.3.4 Tests and Inspection

Prior to installation at the site, the gland seal steam evaporator and gland seal steam condensers were cleaned, inspected, and tested at the vendor's plant. Preoperational testing of this equipment included a hydrostatic test for visual inspection of welded joints to confirm leaktightness. The turbine gland sealing system is regularly inspected and monitored during operation to ensure proper functioning and performance in accordance with its design bases.

10.4.3.5 Instrumentation

The level in both the shell and tube sides of the steam evaporator are controlled by level-control valves: the condensate (shell) side by maintaining the water level surrounding the tubes and the steam side by maintaining the water level in the steam evaporator drain tank. The flow of heating steam is regulated by the steam pressure control valve.

Liquid level in the gland seal steam condenser is maintained by a trap connected to the main condenser. A local pressure indicator and high-level alarm switch are provided on the gland seal steam condenser. Temperature and pressure gauges and test points are provided to monitor operation and testing of the system. Instruments for monitoring system operation are provided in the main control room. Low and high level alarms are provided on the gland seal steam evaporator.

10.4.4 TURBINE BYPASS SYSTEM

10.4.4.1 Design Bases

a. The turbine bypass system controls reactor steam pressure by sending excess steam flow directly to the main condenser. This permits independent control of reactor pressure and power during reactor vessel heatup to rated pressure prior to and while the turbine is brought up to speed and synchronized under turbine speed-load control and when cooling down the reactor. Following main turbine generator trips and during power operation when the reactor steam generation

exceeds the transient turbine steam requirements, the turbine bypass controls reactor overpressure within its capacity and in accordance with the steam generation rate;

b. The turbine bypass system capacity is 25% of rated reactor steam flow. The bypass system can accommodate a 25% turbine load rejection without causing a significant change in reactor steam flow; and

c. The turbine bypass valves are capable of remote manual operation.

10.4.4.2 System Description

The turbine bypass system consists of four hydraulically operated control valves which are mounted on a valve manifold (see Figure 10.4-3). They are connected to the main steam line header upstream of the turbine main stop valves by four 10 in. lines. The four individual valves lower the pressure of the steam by reducing its flow velocity before it enters the condenser system.

Each valve outlet discharges into the manifold which is piped directly to pressure-reducing perforated pipes located in the condenser shell (see Figure 10.3-1).

The turbine DEH control system is designed to prevent spurious or unnecessary opening of the bypass valves, due to control signal noise or minor transients. The four valves in the manifold are operated automatically by the control system. The amount of steam flow allowed to pass through the turbine is limited by the DEH control system demand signal, which limits the amount that the governor valves can open. The DEH control system controls the governor valve position to maintain reactor pressure. When the governor valve opening position, required to maintain reactor pressure, exceeds the load demand limit, a signal is sent to the bypass valves to open to maintain reactor pressure. The bypass valves automatically trip closed whenever the vacuum in the main condenser is greater than approximately 23 in. Hg absolute. They have regulation capability and a fast-opening response approximately equivalent to the fast closure of the turbine stop and control valves.

The turbine bypass system piping and valves are designed to the class and seismic category presented in Table 3.2-1. The valve body is forged carbon steel while the internals are stainless steel. The environmental design bases for this system are contained in Section 3.11.

Each valve is sized for 8% of the total rated flow; however, all four valves are designed for 25% of the total flow. If the bypass system capacity is exceeded, the main steam relief valves open on high reactor pressure and excess steam is vented to the suppression pool.

10.4.4.3 Safety Evaluation

The effects of a malfunction of the turbine bypass system valves and the effects of such failures on other systems and components are evaluated in Section 15.2.2.

All safety-related components and the turbine speed control system are located remote from the turbine bypass piping and valves. The bypass system is located on the second floor of the turbine building (see Figure 1.2-3) and the speed control and safety-related components are located on the floor above, thus being separated by a concrete floor and wall making any adverse affects from a high-energy line failure in the turbine bypass system extremely unlikely. The turbine overspeed protection system is a fail-safe design, as described in Section 10.2.2.

The effects of a steam line break on the safety-related components in the turbine building are discussed in Section 3.6.1.

10.4.4.4 Tests and Inspections

The opening and closing of the turbine bypass system valves were checked during initial startup and shutdown for performance and timing. The bypass steam lines upstream of the bypass valves to MS-V-146 were hydrostatically tested to confirm leaktightness. Radiography and visual inspection of all pipe weld joints were performed on this piping. The branch connections and branch lines of this piping were examined in accordance with ANSI B31.1 rules.

Each turbine bypass valve can be tested independently and remotely during plant operation. The testing is conducted as required by the Technical Specifications.

10.4.4.5 Instrumentation

The controls and valves are designed so that the bypass valves shut on loss of control system electric power or hydraulic pressure. For testing the bypass valves during operation, the stroke time of the individual valves is increased during testing to limit the rate of bypass flow increase and decrease to approximately 1% per sec of reactor rated flow. Upon turbine trip or generator load rejection, the start of bypass steam flow is not delayed more than 0.1 sec after the start of the stop valve or the control valve fast closure motion. A minimum of 80% of the rated bypass capacity is established within 0.3 sec after the start of the stop valve or the control valve closure motion. For more detail refer to Section 7.7.1.5.

10.4.5 CIRCULATING WATER SYSTEM

10.4.5.1 Design Bases

The circulating water system is designed to provide cooling water for the condenser using the atmosphere as a heat sink via six circular mechanical-induced draft cooling towers designed to remove 7.962 x 10^9 Btu/hr from the circulating water. The design heat gain in the condenser is approximately 7.7 x 10^9 Btu/hr. In addition, the cooling towers have the capacity to cool the plant service water during normal operation and the standby service water during shutdown operation. The operation of the towers is not essential to the safety of the plant.

Makeup for tower evaporation, wind loss, and blowdown is obtained from the Columbia River by makeup pumps. Cooled blowdown from the cooling towers is discharged to the river.

Chemical treatment is provided for the circulating water system to preclude scale, biological growth, and consequent fouling of heat transfer surfaces.

The piping system associated with the circulating water system is designed, fabricated, inspected, and erected in accordance with ANSI B31.1 (October 1973) and AWWA C201. Major piping components are fabricated from carbon steel. Seismic category, safety classification and design codes are given in Section 3.2.

10.4.5.2 System Description

The circulating water system is shown schematically in Figure 10.4-4. The circulating water system is a closed cycle cooling system using six mechanical induced draft, cross-flow cooling towers. Three circulating water pumps, each having a total head of 95 ft at 186,000 gpm, are provided. These pumps, located in the circulating water pump house, take suction from a common intake plenum and discharge through a common 12-ft-diameter pipe to the three waterboxes of the single-pass triple-pressure zone condenser. The water from the condenser is returned to the cooling towers, cooled, and collected in the cooling tower basins which supply the circulating water pumps intake plenum.

In addition, as part of the cooling tower piping, a cooling tower bypass is provided for plant startup during the winter to prevent icing conditions at the towers. Inlet motor-operated valves are provided at each tower to isolate a tower for maintenance.

The towers are designed such that the buildup of ice will not restrict air flow through the louvers. Temperature range and low water temperature limits are maintained during reduced heat loads by shutting down individual towers (fans and flow) as required. In extreme cold weather, desired cold water temperatures can be achieved with all fan motors shut down but free to rotate with natural draft through the towers.

The six mechanical draft cooling towers are located such that there can be no physical interaction between them and plant structures important to safety in the unlikely event of a tower collapse.

The quantity of makeup water to the system is dependent upon cooling tower evaporation, drift losses, and system blowdown requirements. The system blowdown quantity is dependent on the concentration of dissolved solids allowed in the circulating water. The concentration of dissolved solids varies with operating status and the cycles of concentration which are controlled by operation of the blowdown valve. Makeup to the circulating water system is provided via the cooling tower makeup pumps located in a pump house adjacent to the Columbia River. The makeup pumps are designed to pump 12,500 gpm each with a TDH of 204 ft; the makeup flow can be directed into the circulating water bay or to one or both of the plant service water pump suctions by means of a weir box and sluice gate arrangement located in the circulating water inlet bay.

The evaporative-type cooling towers have the potential for creating visible plumes of water vapor under certain atmospheric conditions. The cooling tower system is designed to keep this environmental impact minimal. The cooling tower plumes rarely produce ground level fog or ice in the basin area where the plant is located and do not restrict traffic at the local airports. Since fogging occurs naturally in the area, the estimated incremental occurrences of fog attributable to cooling tower operations are small compared to the natural occurrences.

Cooling tower drift has been identified as a cause of arcing in switchyard equipment. Switchyard equipment is monitored and cleaned (as necessary) to preclude this phenomenon. Offsite environmental effects are monitored per Section 4.2.1 of the Environmental Protection Plan.

The radiological impact and the impact of thermal discharges on the environment are insignificant. The effect of cooling tower blowdown has no significant effect on the Columbia River temperature, and the environmental effect of chemical discharges is considered negligible. The system has no measurable effect on area groundwater.

The environmental considerations mentioned above are discussed in detail in Chapter 5 of the Environmental Report - Operating License Stage.

10.4.5.3 Safety Evaluation

The circulating water system is a non-safety-related system. Consequently, the circulating water system is not designed to Seismic Category I requirements. See Section 9.2.5 for a description of the ultimate heat sink which is designed to perform safety-related functions.

The condenser design ensures that the pressure on the tube side is always maintained higher than the pressure on the shell side, thus eliminating leakage into the circulating water system

should tube failure occur. Consequently, the design of the circulating water system precludes radioactive leakage into the system. Chemicals used to treat the CW system to preclude scale and biological growth and to control pH are evaluated in accordance with administrative controls to ensure compatibility with systems and components.

Two evaluations were performed to determine the effects of a postulated failure in the circulating water system inside the turbine building: a "realistic evaluation" and a bounding evaluation. For the "realistic evaluation," a moderate energy crack was postulated to occur in the circulating water system barriers (e.g., the rubber expansion joints) at the inlet to the main condenser. The inlet side was selected because it yields the severest results. For the bounding evaluation, a complete circumferential expansion joint break was assumed.

The entire condenser area is drained by means of sumps (see Figure 9.3-9), each equipped with duplex pumps. Sumps T-2 and T-3, servicing the inlet and outlet of the condenser, each have 50 gpm pumps. Each of these sumps is equipped with a level alarm and is therefore capable of detecting a circulating water system barrier failure. The level alarm will annunciate in the main control room upon reaching high level, providing a means of detecting the postulated failure within 5 minutes.

"Realistic" Break

The crack area for this postulated failure was assumed to be equal to one-half the pipe diameter times one-half the pipe wall thickness.

$$A = \frac{d}{2} x \frac{t}{2}$$ (see Section 3.6.2.1.4.2)

The flow exiting from such a crack would be an orifice flow. The head at expansion joint for normal three-pump operation at 186,000 gpm each was determined (from system energy gradients) to be 90 ft. The flow for these conditions was calculated to be

$$Q = 1737 \text{ gpm}$$

The system has different operating pressures for the various modes of pump operation. The piping was designed for an internal pressure of 60 psig, which is well above the design energy gradient.

The motor-operated inlet and outlet valves at the condenser are designed and manufactured to close in 60 sec to avoid excessive pressures caused by fast valve closure. Therefore, rapid valve closure is not a consideration. After closure of the inlet and outlet valves, however, the system will be operating with two-thirds of the condenser capacity. With three circulating water pumps in operation and two sections of the condenser in operation, the system flow as determined from the pump operating point diagram will be approximately 450,000 gpm.

Comparing the system energy gradients for this mode of operation to that when all three condenser units are in operation, the resultant difference in pressures will be

a. At the inlet side, an increase of approximately 4.3 ft of head (2 psi) occurs,
b. At the outlet side, a decrease of approximately 5.2 ft of head (2 psi) occurs.

Detection of the postulated failure will occur within 5 minutes, as described above, by the annunciation in the control room of the sump high level alarm. It is assumed that there will be a 15-minute time allowance for an operator in the control room to check the circulating water system barriers and close both the inlet and outlet valves of one unit of the condenser as may be required. This closure is accomplished by the activation of a remote manual switch in the control room, and therefore no control circuitry time delays nor coastdown times are involved. Flow will continue, however, after valve closure for about 106 minutes at a decreasing rate, until the remaining water from the condenser is completely discharged.

In the first 5 minutes after a crack, 8435 gal of water will spill into the inlet basin. The capacity of each basin and its capability to store excess flow were calculated to be as follows:

a. Inlet basin: 22,500 gal from el. 436 to el. 441,
b. Outlet basin: 27,500 gal from el. 436 to el. 441, and
c. Net volume under condenser: 180,500 gal from el. 433 to el. 441.

The time required to fill the inlet basin, after a postulated crack occurs, is computed to be 13.3 minutes. This includes the 50-gpm outflow from the sump pump. The circulating water leakage flow will continue for 6.7 minutes after filling the inlet basin, until reaching the total estimated shutoff time of 20 minutes. It can be assumed that 10% of this water will flow out over the floor at el. 441, and the remainder, about 10,170 gal, will flow into the condenser basin area. During this same time period, four sump pumps in the condenser basin area will have alternately pumped out 670 gal, leaving 9500 gal or 0.42 ft of water in the condenser basin. The rate of rise of water, therefore, is 0.021 ft/minute during the first 20 minutes after the postulated crack occurs. Note that on the high sump level, both pumps run simultaneously rather than alternately, thus doubling the calculated outflow capacity.

After the valves are closed, the water contained in the condenser unit water box will continue to discharge to the area. The quantity of water remaining is estimated to be 87,000 gal. The flow will vary with a diminishing head, the head going from about 25 ft to 0 ft. Using a 20-ft head and the same orifice flow criteria, the rate of flow will be approximately 819 gpm, discharging the remaining water in about 106 minutes. There will be an outflow from all the sump pumps of 150 gpm, with 10% of the flow from the crack again assumed to flow out over the floor. The water will accumulate in the condenser basin at about 590 gpm. After 106 minutes, the water level in this basin will rise an additional 2.77 ft, at 0.0261 ft/minute. The total height of water when the discharge has stopped is therefore 3.19 ft to el. 436.19.

This elevation is 5 ft below the floor level of the turbine building (el. 441), thus there will be no impacts on safety-related equipment from this event.

Boundary Evaluation

A complete circumferential expansion joint break in the circulating water system would result in the release of large amounts of water into the turbine generator building. The water would fill the net volume under the condenser, tripping the sump high level alarms that annunciate in the main control room. Remote-manual operation of the circulating water pumps and butterfly valves is provided in the main control room to mitigate the accident.

Disregarding operator action, however, the following evaluation is provided. Water would spill across the grade level floor of the turbine generator building at el. 441 ft, exiting through the railroad bay and access doors. Water could flow into the reactor building stairwells and elevator shafts from 441-ft el. down to the 422-ft 3-in. el., eventually filling the stairwells and elevator shafts with water. There is no safe shutdown equipment located in the stairwells or elevator shafts. The access doors to the emergency core cooling system (ECCS) and RCIC/CRD pump rooms at el. 422 ft 3 in. are designed to withstand a static head of approximately 44 ft (measured from centerline of door) of water. All penetrations into the reactor building below the 466 ft el. are designed to minimize flooding effects. Flooding will not affect any required safe shutdown equipment in the reactor building.

Water could also spill across the grade level floor into the radwaste/control building. The basement level of this building is 437 ft. It is thus possible to flood this level with 4 ft of water before the water would exit at grade level (441 ft) through access doors. No safety-related components will be affected by this flooding. The railroad bay and access doors of the turbine generator building are not watertight and are not designed to withstand any static head of water; therefore, no significant depth of water could accumulate in the turbine generator building. All safety-related equipment in the turbine generator building is located above the 471-ft el. and would not be affected.

In conclusion, a complete circumferential expansion joint break in the circulating water system inside the turbine generator building would have no effect on safety-related equipment in the turbine generator building and no effect on safe shutdown equipment in the reactor building.

Discharge operation of water accumulated under the condenser shall be performed in accordance with radioactivity checking requirements for sump discharges.

10.4.5.4 Tests and Inspections

All system components, except the condenser, are accessible during operation and may be inspected visually. The circulating water pumps were tested during preoperational testing.

The condenser was field hydrostatically tested in accordance with the Steam Surface Condenser Standards published by the Heat Exchange Institute.

All major components were inspected and cleaned prior to installation in the system, and preoperational tests were performed after system installation.

Sampling stations and test connections are provided to allow inservice testing during operation of the system.

10.4.5.5 Instrumentation

The circulating water pumps are individually equipped with shutoff valves that are interlocked with their respective pump motors to prevent startup unless the valve is closed and to prevent shutdown unless the valve is less than 15% open. Isolation valves are provided at the inlets of each condenser shell, which enable any water box to be isolated. The isolation valves are equipped with limit switches and are operated by manual switches located in the main control room. The system is monitored for temperature, pressure, level, and pH.

10.4.6 CONDENSATE FILTER DEMINERALIZER SYSTEM

10.4.6.1 Design Bases

The condensate filter demineralizer rated system capacity is 32,000 gpm, which is in excess of the 100% system capacity of 31,000 gpm.

As a design basis for this system, the effluent water quality is as follows:

NORMAL OPERATION FEEDWATER QUALITY TO THE REACTOR [a]

Parameter Frequency	*Limit*	*Sample*
Conductivity	*0.1 μmho/cm at 25°C* [b]	*Continuous*
pH	*6.5 to 7.5 at 25°C*	*As Required*
Total Metallic Impurity Filter Sample	*15 parts per billion (ppb)*	*Weekly; collected continuously*
Total Copper (Cu)	*2 ppb*	*Weekly*
Total Iron	*5 ppb*	*Weekly*

[a] *Measure after the last feedwater heater unless noted.*
[b] *Measured at demineralizer outlet.*

Nickel (Ni)	*2 ppb*	*Weekly*
Total Silica (SiO_2)	*5 ppb*	*As Required*
Chloride (Cl)	*10 ppb* [c]	*Daily*
Oxygen	*20 to 200 ppb*	*Continuous*

The design basis effluent water quality and sampling frequency was originally specified based on vendor fuel warranty and regulatory guidance. Since that time, enhanced analytical and testing techniques have determined that considerably lower concentrations of impurities can cause damage to system components. Through industry sponsored research, guidelines that are much more restrictive than the original design specifications have been developed and adopted. The implementation and documentation of these more restrictive specifications is controlled by chemistry administrative procedures.

This results in the system being designed to maintain feedwater quality such that the reactor water limits are not exceeded. This is achieved by the following:

a. Operation of the system to a less than 0.065 µS/cm conductivity end-point. After reaching this limit during normal operating conditions, the filter-demineralizer(s) are taken off line, backwashed, and precoated;

b. Establishing metallic impurity limits to preserved fuel performance by controlling the amount available for deposition on heat transfer and fluid transport surfaces. In addition, controlling corrosion product input minimizes the radiological impact from corrosion product activation, transport, and deposition;

c. Controlling undesirable anionic (chloride and sulfate) impurity input to maintain the reactor coolant concentrations below the levels where stress corrosion cracking is induced; and

d. Control of feedwater dissolved oxygen levels between 20 and 200 ppb falls in the minimal portion of the combined generalized and pitting corrosion curve for carbon steel piping. Piping is preserved and corrosion product activation, transport, and deposition are restricted.

This ensures that in conjunction with the RWCU system, reactor water quality will be maintained.

[c] *Or 25% of influent level, whichever is lower, to maintain reactor water quality of 200 ppb at rated operating pressure.*

The condensate filter-demineralizers are designed, fabricated, tested, and stamped in accordance with the ASME B&PV Code Section VIII, Division 1 (November 1971). Seismic category, safety class, and design codes are presented in Section 3.2.

10.4.6.2 System Description

The condensate filter demineralizer system consists of the necessary piping, valves, appurtenances, and instrumentation to control the condensate impurity concentration during plant operation (see Figure 10.4-5).

Six filter demineralizers are provided to polish 100% of the condensate flow: five or six are normally in operation at full power. The six filter demineralizers and associated piping, valves, and instrumentation are similar and piped in parallel.

Each filter demineralizer has an associated hold pump which is brought into service during low flow conditions to recirculate condensate through the filter demineralizer and hold the precoat material on the filter elements.

The individual effluent lines from the filter demineralizer vessels are provided with resin traps to prevent passage of ion exchange resins to the feedwater system.

The system design incorporates the following service systems which are common to all filter demineralizers:

a. Chemical mixing and supply system to circulate a chemical cleaning solution (e.g., inhibited citric acid) for the purpose of cleaning the filter demineralizer units and directing the waste to the chemical waste system (this system is not normally used);

b. A backwash system to remove the spent resin from the filter demineralizers and direct the radioactive waste to the backwash receiving tank (for further discussion of the backwash system discharge to the liquid waste management system, see Section 11.2); and

c. A precoat system wherein fresh precoat material is prepared and then circulated through the filter demineralizers to coat the filter elements.

The system control panels are located outside the equipment areas to permit remote operation of the condensate filter demineralizers without requiring the operator to enter high radiation areas.

The control panel has a graphic display. All major isolation valves, position indicators, and instrumentation are displayed at their respective locations.

10.4.6.3 Safety Evaluation

The condensate filter demineralizer system removes corrosion products, condenser inleakage impurities, and impurities present in the condensed steam.

Purified condensate and feedwater limits ensure sustained, safe plant operation by preserving the integrity of nuclear steam supply system components, vessel internals, fuel, and transport piping.

Due to improved water quality limits, any appreciable circulating water inleakage would result in water chemistry conditions outside acceptable limits and require action(s) to return the water quality to within applicable limits for continued plant operation.

Compliance with Regulatory Guide 1.56 is discussed in Section 1.8.

10.4.6.4 Tests and Inspections

The original condensate filter demineralizers, precoat and chemical mixing tanks, holding pumps, and system valves were hydrostatically tested prior to shipment by the manufacturer.

Field tests were performed after equipment installation to check satisfactory operation and functioning of control equipment, as well as to demonstrate guarantee performance. The guarantee performance test was governed by the ASTM Testing Method Procedures for High Purity Industrial Water.

10.4.6.5 Instrumentation

Instrumentation is provided for the condensate filter demineralizer system for proper operation, control, and protection against malfunction of the equipment.

The system design includes automatic flow balancing control for each filter demineralizer to maintain equal flow through each of the operating vessels by regulating the effluent discharge valve. The filter demineralizer flows are normally balanced manually and routinely monitored to maintain adequate flow balance. The cumulative flow through each filter demineralizer is recorded. Conductivity elements downstream of the flow control valves measure and record demineralizer performance. Differential pressure and conductivity alarms for each filter demineralizer annunciate when the pressure differential across a unit reaches a predetermined value or when the effluent conductivity indicates a significant reduction in ion exchange capacity. System influent and effluent conductivity are monitored and recorded. Alarms are provided for individual demineralizer differential pressures and outlet conductivities, and for the system inlet and outlet conductivities. These alarms annunciate at predetermined levels and

corrective action is initiated in accordance with plant procedures and licensee controlled specifications.

Conductivity instrumentation is calibrated in accordance with applicable ASTM Procedures.

An automatic bypass maintains the condensate system flow in the event the number of filter demineralizers in operation or the flow capacity of the units (due to clogging) is inadequate to handle the required flow.

The resin replacement equipment is designed for semiautomatic operation. A remote manual override is included as an alternate mode of operation.

Conductivity recorders, a grab sample rack with the necessary instrumentation and appurtenances to test influent and effluent condensate, differential pressure monitors, pressure indicators, and local alarms are provided for each unit in addition to the main graphic display control panel.

10.4.6.6 Demineralizer Resins

Compliance with Regulatory Guide 1.56 is discussed in Section 1.8.

Pressure precoat filter/demineralizer media on individual vessels is replaced on a cyclic basis when the pressure drop exceeds 25 psid or the effluent conductivity exceeds 0.065 µS/cm during normal operating conditions. The conductivity limitation does not apply when condenser vacuum is broken and during the period when condenser vacuum is being restored.

10.4.6.7 Water Chemistry Analyses

The filter-demineralizer condition during normal power operation is assessed by the effluent conductivity and ionic content. The influent conductivity is related to impurity concentration through the equivalent conductance of the constituents of the process fluid.

Chemical analysis methods used for determination of conductivity and ionic content are as follows:

Conductivity	Measured in accordance to ASTM-D-1125
Chloride	Determined by ion chromatography in accordance with the vendor's operating manual.

10.4.7 CONDENSATE AND FEEDWATER SYSTEMS

10.4.7.1 Design Bases

The condensate and feedwater system provides a reliable source of high purity feedwater during both normal operation and anticipated transient conditions. The system is designed with sufficient capacity to provide for 110% of the feedwater flow at rated load. This provides sufficient margin to provide flow under anticipated transient conditions. The feedwater heaters are designed to provide the required temperature of feedwater to the reactor. The final feedwater temperature is 423°F at rated load.

The condensate and feedwater system is designed and fabricated in accordance with ANSI B31.1, (October 1973) and ASME B&PV Code, Section VIII, Pressure Vessels (November 1971) and 2004 ASME B&PV Code, Section VIII, including 2005 Addenda for RFW-HX-6A and RFW-HX-6B. Seismic category and safety class are discussed in Section 3.2. The environmental design bases for this system are in Section 3.11.

10.4.7.2 System Description

The condensate and feedwater system shown in Figure 10.4-6 is a six-heater regenerative feedwater heating cycle. The extraction steam system supplying heating steam to each feedwater heater is shown in Figure 10.4-7. A discussion of the condensate supply system is presented in Section 9.2.6.

Feedwater heaters 1, 2, 3, and 4 are divided into three one-third capacity parallel trains; heaters number 5 and 6 are split into two one-half capacity parallel strings. The final feedwater temperature is approximately 423°F at design output. Tube material for RFW-HX-6A and RFW-HX-6B is type 316 stainless steel. For the rest of the heaters the tubes are type 304 stainless steel. The first-stage heaters are located in the condenser exhaust neck.

Figure 10.4-8 shows the heater drain system. All feedwater heater drains are cascaded back to the condenser (6-5-4-3-2-1 condenser). Reheater drains are carried to the number 6 heaters whereas the moisture separators drain to the number 5 heaters.

Condensate from the condenser hotwell is pumped by three motor-driven pumps of one-third capacity each. The condensate is pumped through the gland seal steam condenser, the steam jet air ejector condensers, the offgas condenser, the condensate demineralization system, and then to the suction of the condensate booster pumps. The condensate pumps are designed to pump approximately 11,000 gpm each with a TDH of 375 ft.

Three motor-driven condensate booster pumps are provided in the system. The capacity of the booster pumps matches that of the condensate pumps, one-third capacity for each pump at design rated feedwater flow. The booster pumps provide the required head to pump the

condensate through the five low pressure heaters and provide sufficient excess head to ensure sufficient net positive suction head (NPSH) at the reactor feedwater pumps suction.

The condensate booster pumps are designed to pump approximately 11,000 gpm each with a TDH of 925 ft. Using the condensate pumps, the condensate booster pumps and a series of heat exchangers, the system delivers 14,981,600 lb/hr of condensate at 467 psig and 366°F to the reactor feedwater pumps. Minimum flow through the gland seal steam condenser and steam jet air ejector condenser is controlled by using a recirculation control valve located in the condensate pump discharge lines to permit recirculation of condensate to the condenser.

Two one-half nominal capacity turbine-driven reactor feedwater pumps are provided. Each pump is capable of providing two-thirds of the rated feedwater flow during one pump operation. Minimum flow through the reactor feedwater pumps is controlled by using recirculation control valves located in the pump discharge lines to permit recirculation of feedwater to the condenser.

To minimize the corrosion product input to the reactor, a startup recirculation line is provided from the reactor feedwater supply lines, downstream of the high pressure feedwater heaters, to the main condenser.

The feedwater control system automatically controls the flow of feedwater into the reactor pressure vessel to maintain the water level in the vessel within predetermined levels during all modes of plant operation.

A hydrogen injection system is installed across the condensate booster pumps. The system uses discharge pressure to the pumps to feed dissolved hydrogen into the suction of the booster pumps.

A depleted zinc oxide (DZO) passive injection system (zinc) is installed across the feedwater pumps. The discharge pressure of the pumps can be used to inject a soluble zinc solution into the suction header of the feedwater pumps. Injection of zinc reduces the radioactive contamination on primary piping and components by reducing the levels of cobalt-60.

An iron injection system, installed on the suction line of the condensate booster pumps, can be used to inject an iron oxalate solution into the reactor feedwater. This iron injection system can be used to increase the reactor feedwater iron concentration to build a thin iron film on the inside of the piping to the vessel, vessel internals, and on the fuel.

Table 10.4-1 presents some of the major characteristics of equipment in this system.

10.4.7.3 Safety Evaluation

During operation, radioactive steam and condensate are present in the feedwater heating portion of the system which includes the extraction steam piping, feedwater heater shells, heater drain piping, and heater vent piping. Shielding and controlled access are discussed in Chapter 12. The condensate and feedwater system is designed to minimize leakage with welded construction used throughout the piping system. Feedwater heater shell-side relief valve discharges and operating vents are routed to the condenser.

The condensate and feedwater system is not required to effect or support the safe shutdown of the reactor or perform safety functions.

If it is necessary to remove a component such as a feedwater heater, pump, or control valve from service, continued operation of the system is possible by use of the multistream arrangement and the provisions for isolating and bypassing equipment and sections of the system.

The analysis of both the condensate and feedwater individual component failures is bounded by the feedwater component system failure analysis. These analyses are provided in Sections 15.1.1, 15.1.2, and 15.2.7. Included also in Section 15.6.6, are the isolation provisions that minimize release of radioactivity to the environment.

Criteria for feedwater isolation of the reactor coolant system is presented in Section 6.2.4.

10.4.7.4 Tests and Inspections

Each feedwater heater, heater drain tank, condensate pump, condensate booster pump, reactor feedwater pump, and system valves were shop hydrostatically tested at 1.5 times their design pressure. All pumps were shop performance tested. All tube joints of feedwater heaters were shop leak tested. Prior to initial operation portions of the completed ANSI B31.1 feedwater system welds were 100% X-rayed. The remainder of the completed condensate and feedwater system received a field hydrostatic test.

Pressure, temperature, conductivity, and flow instrumentation are provided to monitor system performance during operation. A separate, additional wireless monitoring system comprised of pressure, temperature and flow measuring equipment, is installed to monitor Feedwater Heaters 6A and 6B, as well as the Main Condensate Heaters 5A and 5B. The EMI/RFI characteristics were evaluated and found to be acceptable. Inservice inspection of applicable reactor feedwater piping is presented in Section 5.2.4.

10.4.7.5 Instrumentation

Feedwater flow-control instrumentation measures the feedwater flow rate from the condensate and feedwater system. This measurement is used by the feedwater control system that regulates the feedwater flow to the reactor to meet system demands. The feedwater control system is described in Section 7.7.1.4.

The isolation criteria for the feedwater system is loss of feedwater flow. Isolation valves are remotely operated from the main control room using signals which indicate loss of feedwater flow.

Instrumentation and controls regulate pump recirculation flow rate for the condensate pumps, condensate booster pumps, and reactor feed pumps. Measurements of pump suction and discharge pressures are provided for all pumps in the system. Sampling means are provided for monitoring the quality of the final feedwater (see Section 9.3.2). Temperature measurements are provided for each stage of feedwater heating and these include measurements at the inlet and outlet on both the steam and water sides of the heaters. Steam-pressure measurements are provided at each feedwater heater. Instrumentation and controls are provided for regulating the heater drain flow rate to maintain the proper condensate level in each feedwater heater shell and heater drain tank. High-level alarm and automatic dump-to-condenser on high level are provided.

Pressure, temperature, conductivity, and flow instrumentation are provided to monitor system performance. The operation of the hotwell makeup and high level dump valves is controlled by the hotwell level controller (Figure 10.4-6).

10.4.8 STEAM GENERATOR BLOWDOWN SYSTEMS

This section is not applicable to a BWR.

10.4.9 AUXILIARY FEEDWATER SYSTEM

This section is not applicable to a BWR.

10.4.10 HYDROGEN WATER CHEMISTRY SYSTEM

10.4.10.1 Design Bases

The Hydrogen Water Chemistry System (HWC) is designed to lower the electrochemical corrosion potential (ECP) of reactor coolant. Studies have shown that the lowering of ECP in the core below –230 mV_{SHE} will mitigate any existing intergranular stress corrosion cracking (IGSCC) and prevents future development of IGSCC in stainless steel components in the reactor coolant recirculation piping and lower reactor internals.

The HWC system injects hydrogen into the feedwater stream, increasing the concentration of dissolved hydrogen in reactor coolant. The presence of dissolved hydrogen suppresses the radiolytic generation of oxygen in the core and acts as a catalyst for the recombination of hydrogen and oxidants on the surface of piping and reactor internals. As a result, oxygen concentrations are reduced. The lower oxygen concentration reduces the ECP of the coolant.

The HWC system can inject up to 30 SCFM of hydrogen into the condensate/feedwater stream, resulting in a hydrogen concentration of up to 0.52 ppm in feedwater. Since the radiolytic generation of oxygen is suppressed, HWC also injects Service Air into the condenser Offgas stream to ensure that a stoichiometic ratio of hydrogen and oxygen are maintained for recombination.

10.4.10.2 System Description

The HWC system is shown schematically in Figures 10.4-9.1, 10.4-9.2, and 10.4-9.3. The system consists of a Hydrogen Storage and Supply Facility (HSSF), a hydrogen injection module, an air injection module, and a main control panel. The HSSF is located approximately 0.6 miles south-southeast of the Plant. A buried 2-inch pipe supplies hydrogen gas from the HSSF to the Turbine Generator Building (TGB) at approximately 200 psig. The hydrogen injection module, located on TGB 441′, regulates the gas flow to a sparger in a bypass line across the condensate booster pumps.

10.4.10.2.1 Hydrogen Storage and Supply Facility

The HSSF stores up to 14,000 gallons of liquid hydrogen at approximately 80 psig. The liquid H_2 is pumped, vaporized, and stored in six ASME storage tubes at approximately 2450 psig. The ASME tubes have a 40,000 SCF capacity, and serve as the primary source of gaseous H_2 for the HWC system. Gaseous hydrogen flows to a pressure control manifold that reduces the pressure to the 200 psig for supply to the TGB.

Two 100% capacity parallel pump trains, each with its own vaporizer, are provided for system reliability. One pump operates while the other acts as a backup. The ASME storage tubes are pressurized in a batch process, with pumping initiated when pressure in the tubes decays to approximately 650 psig.

The HSSF has a backup tube trailer that stores approximately 120,000 SCF of gaseous H_2. The HSSF has space for a second tube trailer that is used in the event of the functional loss of the liquid H_2 supply. Upon depletion of the inventory in the ASME tubes, the plant supply of hydrogen automatically switches to the tube trailer. As the inventory of the tube trailer is depleted, a replacement tube trailer is brought in. The depleted tube trailer is removed, replenished, and returned. In this way, the HSSF ensures a continuous, reliable supply of gaseous H_2 to the HWC system.

The HSSF also has a liquid nitrogen storage tank and vaporizer. Gaseous nitrogen is used for HSSF control functions and purging operations.

The operation of the hydrogen supply system at the HSSF is normally automatic, using programmable logic controllers (PLCs) located in a local pump control panel and hydrogen control panel.

The piping at the HSSF is designed to ASME B31.3, Chemical Plant and Petroleum Refinery Piping. The underground yard piping is designed to the requirements of ASME B31.1, Power Piping. All liquid and gas storage vessels are designed, fabricated, and stamped as ASME Boiler and Pressure Vessel Code, Section VIII, Division I, Unfired Pressure Vessels. The applicable fire protection codes are found in Appendix F Table F.3-1.

10.4.10.2.2 Hydrogen and Air Injection

The rate of hydrogen injection is regulated by a PLC in the HWC main control panel, located on the 471′ elevation of the TGB. Hydrogen injection is manually initiated above 5% reactor power, and is then automatically maintained at a rate proportional to reactor power when above 20% power. The injection rate is modulated based on reactor power.

HWC's suppression of radiolysis in the core results in an imbalance of hydrogen and oxygen in the condenser offgas stream. This imbalance is corrected by the injection of air into the Offgas system, upstream of the catalytic hydrogen recombiners. The Service Air system supplies the air for injection into offgas. The injection system is designed for a maximum flow rate of 93 SCFM.

The air injection rate is modulated based upon the rate of hydrogen injection. Since air leakage into the condenser contributes to the oxygen available for recombination, the required rate of air injection is reduced to account for the rate of air in-leakage.

The Mitigation Monitoring System (MMS) provides an indication of ECP in the reactor water. The MMS system contains an iron oxide element and a platinum element that may be used for measurement of the ECP of reactor water. ECP may also be monitored using an ECP LPRM probe in the core (see Section 7.6.1.4.2.2). The MMS and ECP LPRM provide an initial correlation of ECP to hydrogen injection to establish a baseline for operation of HWC.

10.4.10.3 Safety Evaluation

The HWC system does not fall within the definitions of any of the safety classifications identified in FSAR Section 3.2.3. However, the storage and handling of a combustible gas entails numerous safety issues that were addressed in the system's design.

The system was designed, procured, and installed to Quality Class II and Seismic Category II requirements. Exceptions are identified below.

- HWC cable terminations, electrical relays, and switches in the main control room panels are Quality Class I. Indicating lights in control room panels are Seismic Category 1M.
- HWC piping in the interfacing portion of the offgas system is Quality Class II+.
- The HSSF liquid hydrogen storage tank, its support foundation and soil were analyzed and installed to Quality Class I and Seismic Category I requirements.

All tanks and pipelines are provided with relief valves for overpressure protection. The liquid H_2 storage tank has redundant rupture discs for added protection.

The effects of the catastrophic failures of HSSF tanks at normal or elevated pressure were analyzed, and it was determined that the energy from such failures would not directly affect safety related or important to safety structures, systems, or components. Missiles generated from vessel failures at normal operating pressure would have insufficient energy to reach safety related or important to safety structures, systems, or components. Analysis has shown that missiles generated from an over pressurization event would have a total annual probability of impact less than 10^{-7} and therefore are not considered credible.

The hydrogen storage tanks at the HSSF are designed to stay in place for all natural phenomena (i.e., earthquakes, tornado winds, floods). No event will cause the tanks to be transported closer to the Plant. Local flooding from a Probable Maximum Precipitation (PMP) event would submerge the tanks (see Section 2.4.2.3), but not dislodge them. Similarly, the vent stack of the liquid H_2 storage tank is designed for flood conditions, with its outlet above PMP flood level. The vent stack design ensures that the tank will continue to off-gas vaporized hydrogen during the flood.

The HSSF is not designed to withstand tornado missiles. A tornado missile could cause the gross failure of a storage tank at the HSSF. However, as noted above, vessel failures have no effect on safety related or important to safety structures, systems, or components.

Similarly, an atmospheric release of all hydrogen stored at the HSSF will have no adverse impact on control room habitability. The HSSF has a maximum storage capacity of approximately 9800 pounds of liquid and gaseous hydrogen. The storage of this amount of hydrogen at the HSSF is not considered a hazard for control room habitability due to the distance from the plant air and remote air intakes to the HSSF.

Malfunctions at the HSSF will not have any adverse impact on Plant safety. The major potential effect of failures is the loss of supply of gaseous hydrogen for injection into condensate. The loss of hydrogen injection will cause a release of metallic radionuclides in reactor coolant, a transient N^{16} spike in the Main Steam lines and increase ECP in the reactor core. The Plant will continue to operate safely on loss of H_2 injection.

The buried supply line between the HSSF and the Plant is welded 2 in. schedule 80 pipe. Since the buried pipe passes under, and is routed next to a railroad track, the design was demonstrated to be in compliance with the American Railway Engineering Association (AREA) Manual for Railway Engineering.

In the area of the Plant, the buried H_2 supply line is encased in a guard pipe. The guard pipe provides mechanical protection, and a means to monitor the pipe for leakage. The vent of the buried line's guard pipe is directed to a hydrogen detector at the hydrogen supply valve station immediately outside the TGB. Hydrogen detectors are also located in the hydrogen injection module and at the Condensate system injection point. The HWC system is automatically shut down upon receipt of a high-high hydrogen signal from any of these detectors.

The hydrogen does not add to the combustible material in the TGB, since it is contained within welded pipe, and appropriate flow-limiting devices are included in the system. Excess flow valves are located in the supply line at both the HSSF and outside the TGB. The automatic closure of either excess flow valve would mitigate the effects of ruptures of the hydrogen supply line in or around the TGB.

The inadvertent introduction of hydrogen to condensate/feedwater during extended shutdowns is prevented by isolation of the hydrogen supply, and purging the hydrogen injection system with nitrogen.

The injection of hydrogen results in a transient increase in N^{16} activity in steam exiting the reactor, and an increase in the transport of metallic radionuclides to the recirculation system's piping and components. These effects are similar to those resulting from NobleChem injection (Section 5.2.3.2.2). The increased dose rates have no effect on equipment qualification.

The injection of hydrogen into feedwater reduces radiolysis in the reactor core, and results in a net reduction of hydrogen in Main Steam. The injection of hydrogen decreases secondary-side concentrations of dissolved oxygen. Secondary side chemistry is maintained in accordance with EPRI NP-5283-SR-A, "Guidelines for Permanent BWR Hydrogen Water Chemistry Installations". Dissolved oxygen is maintained in a range where Flow-Accelerated Corrosion (FAC) will not be exacerbated.

Hydrogen injection terminates automatically when feedwater flow drops below 25%. Hydrogen injection can also be terminated manually from the control room.

The injection of air into offgas increases the transport rate of radioactive species through the system with no adverse effect on system function. Offsite releases are maintained within the limits of 10 CFR 50 Appendix I and 10 CFR 20 Appendix B, Table II.

With the lowered net flow of hydrogen through offgas, the condenser's steam jet air ejectors provide sufficient dilution steam to maintain the hydrogen concentration below the maximum allowable concentration of 4% by volume (FSAR Section 10.4.2.3).

10.4.10.4 Tests and Inspections

The Hydrogen Water Chemistry system underwent a series of factory acceptance tests and site tests. The tests verified the operability of components, the logic of PLC programming, and the functionality of the integrated system. Site testing included the tuning of the HWC system to achieve the required ECP in the core, and benchmarking the Columbia Station's response to hydrogen and air injection.

10.4.10.5 Instrumentation

The Hydrogen Water Chemistry system is controlled by an integrated system of instrumentation and programmable logic controllers.

The HSSF is automatically operated by two PLCs, one located in the pump control panel and the other in the hydrogen control panel. The PLCs:

- Monitor pressures, temperatures and levels of the hydrogen and nitrogen systems,
- Control and monitor the hydrogen pumps and associated interlocks,
- Contain industrial safety interlocks for the HSSF facility, and
- Provide system status, process and alarm data to a remote annunciator panel.

The remote annunciator panel is located in the chemistry laboratory of the Radwaste Building, el 487′. The panel includes a human-machine interface PC that displays mimics, process information, and all HSSF alarms. The panel has one control interface with the HSSF, allowing the remote isolation of the HSSF from the Plant. The panel also receives HWC process information from a PLC in the HWC control panel, located on TGB el 441′.

The HWC control panel's PLC controls the injection of hydrogen and air into the condensate and offgas systems, respectively. The PLC control logic is based upon input flow signals from the hydrogen control module, oxygen control module, and feedwater system. In addition, the PLC receives signals from TGB hydrogen leakage detectors, offgas hydrogen analyzers, and a

summed alarm from the HSSF PLCs. Finally, the PLC receives an enable signal from a switch located on a panel in the main control room. The switch is a permissive for the operation of the hydrogen water chemistry system. The switch can also be used to shut the system down.

Hydrogen and air injection is manually initiated from the HWC Control Panel. Injection is automatically terminated by the PLC when the reactor is shut down. Injection can also be manually terminated at the HWC control panel.

Alarms from the HSSF and the HWC injection system are annunciated at the HWC control panel and in the main control room. HSSF process alarms display as a summed "HSSF Trouble Alarm" at the HWC control panel and as "HWC Trouble" in the main control room. The HWC control panel has annunciators for the display of specific, local process alarms. The HWC process alarms also actuate the summed "HWC Trouble" alarm in the main control room.

Any manual or automatic shutdown of HWC is annunciated as "HWC Shutdown" in the main control room. Automatic shutdown occurs if any of the following signals is received:

Reactor Scram
Offgas Isolation
High Hydrogen Flow
PLC Fault
High Hydrogen Pressure
Loss of Feedwater or H_2 Flow Signal
Low Process Air Pressure
Offgas Analyzers O.O.S.
High-High Area Hydrogen
Low Condensate flow at Injector
Offgas % Hydrogen High Shutdown
Purge
Local Shutdown Demand
Control Room Shutdown Demand

These signals simultaneously annunciate on the HWC control panel.

NOTES:

1. FOR LOCATION OF VENT STATIONS, STANDPIPES & PUMPED DRAIN STATIONS FOR THE TMU & CBD PIPE, SEE PLAN & PROFILE DWGS C536, C537, C538, C539 & C540.
2. FOR LOCATION OF PIPE SIZE CHANGE FOR THE TMU & CBD PIPE, SEE PLAN & PROFILE DWGS C536, C537 & C538.
3. ALL ITEMS MARKED * ARE FURNISHED WITH ASSOCIATED EQUIPMENT.
4. UNLESS OTHERWISE INDICATED ALL INSTRUMENT ROOT VALVES WILL BE 3/4" GLOBE VALVES.
5. ALL PIPING, VALVES AND COMPONENTS ON THIS DWG SHALL BE CLASSIFIED AS FOLLOWS:
   a. QUALITY CLASS II, EXCEPT FOR TMU PIPING EARTH WORK INSTALLATION ONLY WHICH SHALL BE QUALITY CLASS I, SEISMIC CATEGORY II, CODE GROUP D.
   b. TMU WEIR BOX SHALL BE CLASSIFIED QUALITY CLASS II, SEISMIC CLASS II, NON-COMMERCIAL QUALITY.
   c. TMU CONCRETE VAULTS SHALL BE CLASSIFIED QUALITY CLASS II, SEISMIC CLASS II, AWWA.
   d. BLOWDOWN LINE SAMPLE SYSTEM SHALL BE CLASSIFIED AS QC-IC AND INSTALLED TO SEISMIC CATEGORY II REQUIREMENTS.
   e. CW & TMU SUPPORTS ATTACHED TO STRUCTS ARE DESIGNED TO SEISMIC CATEGORY I REQUIREMENTS.
6. ⊗ INDICATES CHLORINATOR ASSEMBLY AVAILABLE FOR INTERFACE NOZZLE CONN. NO. AS SHOWN ON BALLACE & TIERNAN DWGS # 12305/2 & 12305/9 CHLORINATOR & ASSOCIATED PIPING ARE SPARED IN PLACE.
7. DELETED.
8. ULTRASONIC TYPE LEVEL TRANSMITTERS.
9. "ANNUBAR" FLOW ELEMENT (FE-7) SHALL BE LOCATED IN A PIT BUILT INTO THE TMU PUMP HOUSE FLOOR. FLOW TRANSMITTER (FT-7) SHALL BE WALL MOUNTED ABOVE THE 375'-0" FLOOR LEVEL.
10. PRESSURE INDICATORS PI-44G, 48G & 4CG ARE TO TEE INTO LINE UNDER AIR VALVE SUPPLIED WITH PUMP.
11. THESE COMPUTER INPUT POINTS ARE NOT USED.
12. HEAT TRACING IN TMU VALVE BOXES # 2 THRU #13 HAS BEEN SPARED IN PLACE.
13. DELETED.
14. TYGON TUBE SPOOL PIECE INSTALLED DURING OUTAGES FOR PH MONITORING PURPOSES.
15. COMPONENTS IDENTIFIED BY THIS NOTE ARE MOUNTED INSIDE THE COOLING TOWER 72" CONCRETE RISER.
16. BLANK FLANGE (CBD-BF-1) IS INSTALLED, VALVE CBD-V-3 IS LOCKED CLOSED AND CANNOT BE OPERATED.
17. DELETED.
18. ITEMS IN PHANTOM ARE INSTALLED AS NEEDED FOR TEMPORARY TSW SUPPLY AND CIRCULATING WATER DRAINING.
19. WIRELESS TRANSMISSION TO CW-RCVR-1, FROM CW-PT-7A,7B,7C, CW-PT-9A,9B,9C & CW-1T-5C thru 61, 902 TO 928 MHZ FHSS. .31 mW MAX RF POWER OUTPUT. ANTENNA GAIN IS 0.44 DBI. BASE RADIO SHALL HAVE AN EXCLUSION DISTANCE OF 1'-0" MIN. TO ELECTRICAL COMPONENTS

NOTES (CONT'D):

20. 36" NOZZLE WITH BLIND FLANGE AND INTERNAL PLUG.
21. 4" NOZZLE WITH BLIND FLANGE.
22. CW-FE-3 & CW-FE-4 ARE DEACTIVATED AND SPARED IN PLACE PER EC 10301.
23. A SECTION OF PIPING CONNECTING TO 36"TMU(4)-1 IS MISSING. THIS IS DOCUMENTED IN CR 24888.
24. SEE DWG M501 FOR FLOW DIAGRAM LEGENDS, SYMBOLS AND ABBREVIATIONS.
25. SAT-PDV-1 HAS A PVC COVER TO PROTECT IT FROM ICING UP IN WINTER. THIS COVER HAS BEEN EVALUATED AND ACCEPTED PER AR 290550.
26. CW-V-17A, 9 & C, CW-V-18A, 9 & C, AND CW-V-71A ARE AT INACTIVE STATUS. CW-V-18A, B & C ARE NOT ELECTRICALLY TERMINATED.

LEGEND

1. ALL VALVES SUFFIXED WITH A (V) DENOTE A 3/4" VENT VALVE.
2. ALL VALVES SUFFIXED WITH A (D) DENOTE A 3/4" DRAIN VALVE (EXCEPT AS NOTED).
3. ALL VALVES SUFFIXED WITH A (TH) DENOTE A THROTTLED VALVE.

NOTES:

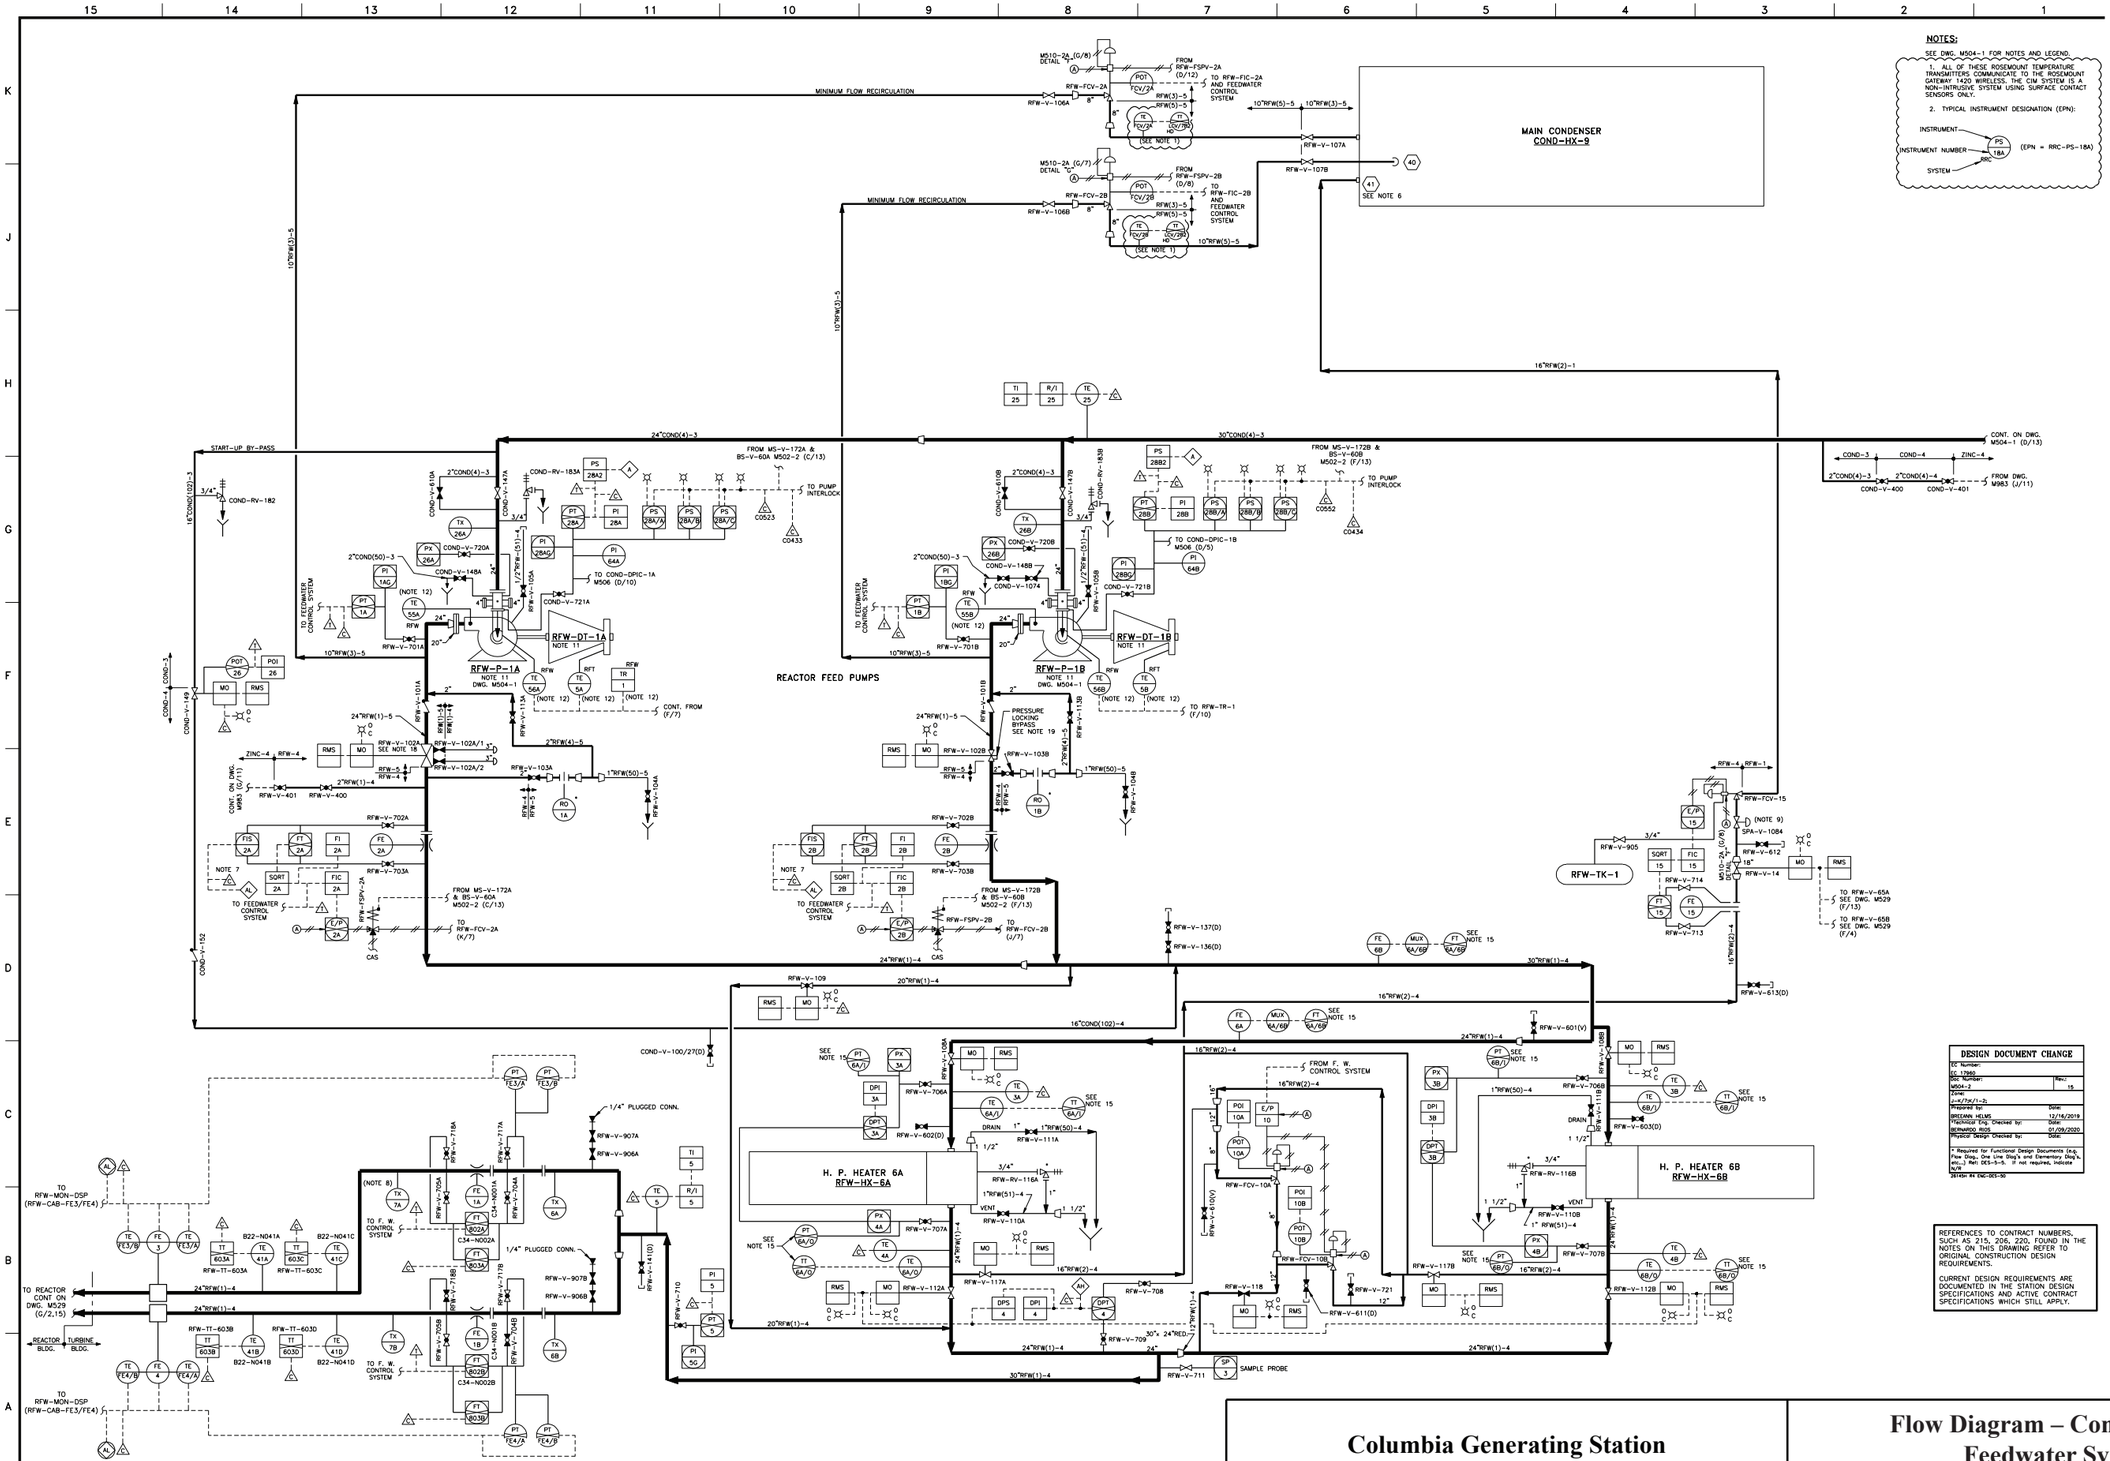
1. ALL TEMPERATURE WELL CONNECTIONS TO BE 1 1/2" UNLESS SPECIFICALLY NOTED OTHERWISE.
2. ALL INSTRUMENTATION ON THIS DWG. TO BE IDENTIFIED BY PREFIX "COND" UP TO THE SUCTION SIDE OF THE REACTOR FEED PUMPS & BY PREFIX "RFW" ON THE DISCHARGE SIDE OF THE REACTOR FEED PUMPS.
3. ALL INSTRUMENT ROOT VALVES NOT LABELED WILL BE 3/4" GLOBE VALVES UNLESS SPECIFICALLY NOTED OTHERWISE.
4. ALL ITEMS MARKED ▽ ARE FURNISHED WITH ASSOCIATED EQUIPMENT.
5. ALL PIPING, VALVES, AND ASSOCIATED COMPONENTS SHOWN ON THIS DRAWING SHALL BE CLASSIFIED AS FOLLOWS:
   QUALITY CLASS II
   SEISMIC CATEGORY II
   CODE GROUP D
6. ◯ INDICATES CONDENSER NOZZLE CONNECTION ITEM NUMBERS AS SHOWN ON WECO DWG. 731J185 SH. 1, 2, & 3 (CVI 08-00, 3, 1; 2; & 3).
7. THESE COMPUTER INPUT POINTS ARE NOT USED.
8. WHEN TX-7A IS TO BE USED, TE-N24A OR C SHALL BE UNSCREWED, AND TX-7A CAN BE INSERTED FOR ITS INPUT USE. AFTER USING TX-7A, REMOVE AND RE-INSERT THE "TE" WHICH WAS REMOVED.
9. VALVE SPA-V-1084, FORMERLY RFW-FCV-15, HAS HAD INTERNALS REMOVED AND WILL REMAIN INSTALLED IN A NON-FUNCTIONAL STATUS.
10. FOR CONDENSATE BOOSTER PUMP LUBE OIL SUMP LEVEL INDICATORS COND-LI-2A, 2B, & 2C SEE CVI 11A-99.7.
11. FOR GLAND SEAL & EJECTOR SYSTEM, SEE CVI 12-00.16. FOR UNIT OIL & CONTROL DIAGRAM, SEE M985-1 & M985-2.
12. FOR PUMP OR TURBINE THERMOCOUPLES AND THEIR INPUTS TO RFW-TR-1, SEE RECORDER DEVELOPMENT ON EWD-721-017. FOR ADDITIONAL THERMOCOUPLES CONNECTED TO RFW-TR-1, SEE M985-1 (B/2,6) & M985-2 (B/12,6).
13. VALVE COND-PCV-32A HAS CONTROLLER REMOVED AND IS LEFT IN THE OPEN POSITION.
14. COND-V-133A AND COND-V-139B HAVE THE DRAIN LINE TEMPORARILY CAPPED TO STOP VALVE LEAK BY.
15. WIRELESS TRANSMISSION TO RFW-RCVR -6A/6B/5A/5B, 902 TO 928 MHz FHSS, 31 MW MAX. RF POWER OUTPUT, ANTENNA GAIN IS 0.44 DBI, BASE RADIO SHALL HAVE AN EXCLUSION DISTANCE OF 1'-0" MIN. TO ELECTRICAL COMPONENTS.
16. WIRELESS TRANSMISSION TO COND-RCVR -3, FROM COND-TT-3 & COND-TT-42, 902 TO 928 MHz FHSS, 31 mW MAX. RF POWER OUTPUT, ANTENNA GAIN IS 0.44 DBI, BASE RADIO SHALL HAVE AN EXCLUSION DISTANCE OF 1'-0" MIN. TO ELECTRICAL COMPONENTS.
17. SEE DWG M501 FOR FLOW DIAGRAM LEGENDS, SYMBOLS AND ABBREVIATIONS.
18. RFW-V-102A PRESSURE LOCKING RELIEF HOLE ON DOWN-STREAM SIDE OF WEDGE ALLOWS ISOLATION ON UP-STREAM SIDE ONLY.
19. RFW-V-1028 PRESSURE LOCKING BYPASS ALLOWS ISOLATION ON UP-STREAM SIDE ONLY.

LEGEND:

1. ALL VALVES SUFFIXED WITH A (V) DENOTE A 3/4" VENT VALVE.
2. ALL VALVES SUFFIXED WITH A (D) DENOTE A 3/4" DRAIN VALVE (EXCEPT WHERE NOTED).
3. ALL VALVES SUFFIXED WITH A (TH) DENOTE A THROTTLED VALVE.

REFERENCES TO CONTRACT NUMBERS, SUCH AS 215, 206, 220, FOUND IN THE NOTES ON THIS DRAWING REFER TO ORIGINAL CONSTRUCTION DESIGN REQUIREMENTS.



CURRENT DESIGN REQUIREMENTS ARE DOCUMENTED IN THE STATION DESIGN SPECIFICATIONS AND ACTIVE CONTRACT SPECIFICATIONS WHICH STILL APPLY.

NOTES:
1. ALL PIPING, VALVES AND ASSOCIATED COMPONENTS IN THE HYDROGEN WATER CHEMISTRY SYSTEM (HWC) AND THE HYDROGEN SUPPLY STORAGE FACILITY (HSSF) ON THIS DRAWING ARE
   -QUALITY CLASS: II
   -SEISMIC CATEGORY: II
   -CODE GROUP: D
2. ALL VALVES AND INSTRUMENTS HSSF UNLESS OTHERWISE NOTED.
3. ALL EQUIPMENT AND INTERCONNECTING PIPING WITHIN THIS BOX SUPPLIED AND DESIGNED BY CHART MANUFACTURING. SEE CVI # 1002-00,103 AND CVI # 1002-00,110 FOR BILL OF MATERIALS AND SPECIFICATIONS FOR THESE COMPONENTS AND PIPING.
4. ALL PIPING NOT INCLUDED IN NOTE 3, INSTALLED BY INSTALLATION CONTRACTOR. FOR PIPE DESIGN SPECIFICATION SEE CVI # 1002-00,7.
5. SEE DWG M501 FOR FLOW DIAGRAM LEGENDS, SYMBOLS AND ABBREVIATIONS
