Section 1 Introduction and Purpose

1.1 INTRODUCTION

Duke Energy Carolinas, LLC (DEC), referred to herein as “Duke Energy,” a wholly-owned subsidiary of Duke Energy Corporation, is submitting this application for an Early Site Permit (ESP) to the United States Nuclear Regulatory Commission (NRC) in accordance with the requirements of Title 10 of the Code of Federal Regulations (CFR), Part 52 (10 CFR 52) Subpart A, “Early Site Permits.” Duke Energy is the applicant for this ESP. Duke Energy Progress, LLC (DEP) an indirect subsidiary of Duke Energy Corporation, and DEC (together referred to as “the Companies”) combined make up the Carolinas service territory within the region of interest. Duke Energy requests that the NRC issue an ESP for the proposed site described in this application for 20 years from the date of issuance.

The Belews Creek, NC site (Project site) is located primarily in Sauratown Township, in the southeastern corner of Stokes County, North Carolina (NC), with a small portion in Belews Creek Township, Forsyth County, NC. The site is referred to as the Belews Creek, NC site or Project site throughout this application. A description of the Project site may be found in Part 2 of the application, Site Safety Analysis Report (SSAR), Section 1.2.

The Project site is owned by Duke Energy and is bounded on the north, east, and west by Belews Lake, a reservoir also owned by Duke Energy. Belews Lake was constructed in the early 1970s by Duke Energy as a cooling reservoir for the adjacent Belews Creek Steam Station, which is a two-unit, 2220-megawatts electric (MWe) fossil fuel plant. The Project site comprises approximately 1187 acres.

At this juncture, Duke Energy has not selected a reactor technology to be built at the Project site. Accordingly, this Early Site Permit Application (ESPA) was developed using the plant parameter envelope (PPE) approach. Technical information from various reactor vendors was used to establish bounding parameters that envelop the facility characteristics needed to evaluate the site's suitability for the future construction and operation of one or more of the reactor technologies. The PPE approach provides the NRC with the necessary information to assess the suitability of the Project site for the reactor technologies selected, while providing Duke Energy additional time to evaluate the technologies and select the technology best suited for the site and Duke Energy’s customers and increasing demand before proceeding with construction. The information in this application supports the issuance of an ESP.

The potential reactor deployment schedule for this ESPA is based on the 2023 Carolinas Resource Plan (CRP), which was submitted to the North Carolina Utilities Commission (NCUC) and Public Service Commission of South Carolina (PSCSC) in August 2023 and supplemented in January 2024. Most recently, the 2025 Carolinas Resource Plan was submitted to the NCUC and PSCSC in October and November 2025, respectively. The 2025 CRP projects the commercial on-line date for the initial 600 MWe of new nuclear generation in 2037. The early deployment date included in the 2023 CRP was used as the basis for the analysis supporting the ESPA. The delay in the on-line date described in the 2025 CRP has been evaluated and concluded that there is no material impact to the conclusions as the results of the analysis do not have a strong dependency on timing.

This ESPA has been divided into parts as follows:

Part 1 – Administrative Information

Part 2 – Site Safety Analysis Report (SSAR)

Part 3 – Environmental Report (ER)

Part 5 – Emergency Plan

Part 7 – Exemptions, Departures, and Variances

Part 8 – License Conditions; Inspections, Tests, Analyses and Acceptance Criteria

Part 9 – Withheld Information

Part 10 – Quality Assurance Program Description

Part 11 – Supplemental Information

1.2 PURPOSE OF AN EARLY SITE PERMIT APPLICATION

U.S. Nuclear Regulatory Commission (NRC) regulations allow an applicant to obtain site approval for a nuclear power plant before deciding to proceed with construction. According to 10 CFR 52.13, an ESP applies when "any person who may apply for a construction permit under 10 CFR Part 50, or for a combined license under 10 CFR Part 52, seeks an ESP from the Commission separately from an application for a construction permit or a combined license."

Prior to the introduction of the ESP application process, applicants had to commit significant resources well before resolving key environmental, site safety, and emergency planning issues. The ESP process allows these critical issues to be addressed early, before making substantial capital investments in nuclear power plant construction.

Environmental issues, site safety issues, and specific aspects of emergency preparedness are addressed as part of the ESP process. In those cases where the ESP applicant has not selected a particular reactor technology, the applicant may use the PPE approach as a surrogate for facility information to support required safety and environmental reviews. Under the PPE approach, the resulting ESP is applicable for a range of reactor designs.

To grant an ESP to Duke Energy for the Project site, the NRC must be assured, among other things, that a nuclear reactor (or reactors) with characteristics within the site parameters can be constructed and operated safely, without undue risk to the health and safety of the public. The specific issuance criteria are set forth in 10 CFR 52.24. This ESPA was prepared in accordance with 10 CFR Part 52, Subpart A.

Site safety issues, environmental issues, and major features of emergency preparedness are addressed as part of the ESP process. ESP licensing issues are resolved with a degree of finality during the ESP review process, subject to the exceptions specified in 10 CFR 52.39.

1.3 CONTACT INFORMATION

Any notices, questions, or correspondence in connection with this filing should be directed to:

Chris Nolan
Vice President New Nuclear Generation Strategy & Regulatory Engagement

Section 2 Early Site Permit Application Format and Content

2.1 FORMAT AND CONTENT

Where applicable to the technologies being considered, this application contains the information required by 10 CFR 52.17, “Contents of applications; technical information,” for an ESP, and is submitted in accordance with NRC guidance on electronic submittals. Each part of the application is intended to stand alone to the extent practical. Information presented within one part may be referenced elsewhere within the same part to minimize duplication. However, if the same information is used in more than one part, that information may be replicated so that each part may be used without reliance on another part. Key references used in the development of the application are listed within the application documents. However, the inclusion of references in these lists does not imply full adherence to all criteria or guidance stated in each individual reference. The various reports and plans required for the ESPA were developed in accordance with applicable regulatory requirements and with consideration of available NRC guidance. A general description of the contents of this application is provided below.

Part 1 - Administrative Information

The Administrative Information section contains an overview of the ESPA, a general description of the format and content of the application, and general information required by 10 CFR 50.33(a) through (d) and (j).

Part 2 - Site Safety Analysis Report

The SSAR covers the site description, safety assessment, quality assurance (QA), and key design parameters for the Project site. It also evaluates site suitability, population profiles, and features that may influence the chosen design. The SSAR complies with the applicable portions of 10 CFR 52.17(a)(1). The SSAR provides a description and safety assessment of the proposed site, including any aspects of the plant that could affect the site and contribute to radiological consequences. The suitability of the site in relation to 10 CFR Part 100 is also described in the SSAR.

As noted earlier, a specific reactor design has not been selected for construction at the Project site. To provide sufficient design information for the NRC to assess the proposed site, a surrogate design has been included in the application. The surrogate plant consists of a set of bounding parameters, the PPE. The combination of PPE values and site characteristics forms the basis for the NRC's issuance of an ESP. Further details of the PPE approach are provided in Section 2.0 of the SSAR.

The SSAR also addresses the facility’s ability to withstand natural and man-made hazards that could affect the site. The emergency preparedness information includes an assessment of potential impediments to implementing an emergency plan (EP) at the Project site, as required by 10 CFR 52.17(b)(1). The QA program under which ESP-related activities are conducted is also provided.

Where practical, the SSAR section numbers align with those identified in NUREG-0800, *Standard Review Plan for the Review of Safety Analysis Reports for Nuclear Power Plants: LWR [Light Water Reactor] Edition*. Consistent with that guidance, there are some intentional gaps in the numbering sequence. This approach is intended to facilitate subsequent integration

of the information from this ESPA into a construction permit application or a combined license application, in which the complete numbering sequence is used.

The regulatory basis for the SSAR includes:

- NRC Regulations – 10 CFR Part 20, 10 CFR Part 50, 10 CFR Part 52, and 10 CFR Part 100.
- NRC Regulatory Guide (RG) 1.70, *Standard Format and Content of Safety Analysis Reports for Nuclear Power Plants*.
- NUREG-0800, *Standard Review Plan for the Review of Safety Analysis Reports for Nuclear Power Plants, LWR Edition.*
- NRC RG 1.206, *Applications for Nuclear Power Plants*.
- Review Standard RS-002, *Processing Applications for Early Site Permits*.
- NRC RG 4.27, *Use of Plant Parameter Envelope in Early Site Permit Applications for Nuclear Power Plants* (NEI 10-01, *Industry Guideline for Developing a Plant Parameter Envelope in Support of an Early Site Permit)*.

The following provides a brief description of the individual chapters of the SSAR:

Chapter 1, *Introduction and General Description*, includes an overview of the Project site.

Chapter 2, *Site Characteristics*, addresses geography and demography; nearby industrial, transportation and military facilities; meteorology; hydrologic engineering; geology, seismology, and geotechnical engineering; and the PPE.

Chapter 3, *Design of Structures, Systems, Components, and Equipment*, contains a summary of the aircraft hazards analysis performed in Chapter 2.

Chapter 11, *Radioactive Waste Management*, provides information on liquid and gaseous radioactive releases.

Chapter 12, *Radiation Protection*, addresses doses to construction workers and the public from on-site sources of direct radiation; however, this chapter will not be included in the SSAR. This information is provided in ER Section 4.9 and SSAR Section 11.3.3, respectively.

Chapter 13, *Conduct of Operations*, provides an overview of emergency planning for the site and surrounding area in case of plant accidents and of the physical security provided for the site and plant sensitive areas.

Chapter 15, *Accident Analysis*, provides a discussion of radiological consequences of bounding plant accidents and conformance with applicable 10 CFR Part 100, Reactor Site Criteria, for the reactor technologies being considered.

Chapter 17*, Quality Assurance Program Description*, provides a description of the QA program under which the ESPA was prepared.

Part 3 – Environmental Report

This part presents information concerning site environmental issues, as required by 10 CFR 51.45 and 51.50. This part also satisfies the application content requirement of 10 CFR 52.17(a)(2). The ER focuses on the environmental impacts to the Project site from the construction and operation of multiple advanced reactors having characteristics that fall within the PPE. The ER discusses the existing environment surrounding the Project site and in the vicinity of the site, postulates environmental impacts of construction and operation, and considers appropriate mitigation measures where indicated; reviews the impacts of design basis and severe accidents; and presents the evaluation of alternative sites. This ER assesses impacts based on representative conditions developed from the facility designs included in the PPE; however, it does not postulate specific costs and benefits associated with construction or operation of any specific design option.

For evaluation purposes, the following categories of information regarding interfaces of the proposed site and facilities are reviewed:

- Comparison of the functional operational needs of the facility as they relate to the site's natural and environmental resources.
- Impact of the facility on the site's natural and environmental resources.

The regulatory bases for the ER include the following:

- National Environmental Policy Act
- NRC Regulations: 10 CFR Part 51 and 10 CFR Part 52
- NRC RGs:
  - RG 4.2, *Preparation of Environmental Reports for Nuclear Power Stations*
  - RG 4.7, *General Site Suitability Criteria for Nuclear Power Stations*
- NUREG-1555, Initial, *Standard Review Plans for Environmental Reviews for Nuclear Power Plants*
- RS-002, *Processing Applications for Early Site Permits*
- Applicable federal, regional, state, and local environmental statutes

The following provides a brief description of the individual chapters of the ER:

- Chapter 1, *Introduction, d*iscusses the purpose and need for requesting an ESP.
- Chapter 2, *The Proposed Site and the Affected Environment*, examines current site use, the surrounding physical environment, and existing socioeconomic, demographic, historic, and community characteristics.

- Chapter 3, *Site Layout and Project Description*, describes the characteristics and parameters of the technologies considered that could impact the site, as well as the related construction activities.

- Chapter 4, *Environmental Impacts from Construction of the Proposed Project*, evaluates potential environmental impacts of constructing new nuclear plants at the Project site.

- Chapter 5, *Environmental Impacts from Operation of the Proposed Plant*, assesses potential environmental impacts of plant operation.

- Chapter 6, *Fuel Cycle, Transportation, and Decommissioning Impacts*, addresses the environmental impacts from the uranium fuel cycle and solid waste management, the transportation of radioactive material, and the decommissioning of the proposed nuclear plants at the Project site.

- Chapter 7, *Cumulative Impacts*, assesses any past, present, and reasonably foreseeable future actions in the geographic area of interest surrounding the site that would affect the same resources that would be affected by building and operation of the proposed project.

- Chapter 8, *Need for Power*, as specified in RG 1.206, *Applications for Nuclear Power Plants*, and directed by 10 CFR 51.50(b)(2), this chapter is not required nor included as part of the ER for this ESPA.

- Chapter 9, *Environmental Impacts of Alternatives*, reviews potential alternatives to constructing and operating new nuclear plants at the Project site.

- Chapter 10, *Conclusions*, summarizes the conclusions reached in the assessments of the environmental impacts of the proposed project as they support the suitability of the proposed site.

Part 4 – Technical Specifications

As specified in RG 1.206, *Applications for Nuclear Power Plants*, the submission of Technical Specifications is not required at the ESP phase.

Part 5 – Emergency Plan

The emergency planning information includes major features of the EP, as allowed by 10 CFR 52.17(b)(2)(i) using guidance provided in NUREG-0654/FEMA-REP-1, *Criteria for Preparation and Evaluation of Radiological Emergency Response Plans and Preparedness in Support of Nuclear Power Plants*.

The regulatory bases for the emergency planning information include consideration of the following:

- NRC Regulations – 10 CFR Part 50, 10 CFR Part 52, and 10 CFR 50.160

- Federal Emergency Management Agency (FEMA) Regulations - 44 CFR Part 350

- NRC/FEMA Memorandum of Understanding (58 Federal Register 47996)

- U.S. Environmental Protection Agency (USEPA), EPA-400/R-17/001, *PAG Manual: Protective Action Guides and Planning Guidance for Radiological Incidents*
- NRC RG 1.101, *Emergency Response Planning and Preparedness for Nuclear Power Reactors*
- NRC RG 1.242, *Performance-Based Emergency Preparedness for Small Modular Reactors, Non-Light-Water Reactors, and Non-Power Production or Utilization Facilities*

The following briefly describes the contents of Part 5:

Part 5 outlines EP details, focusing on an Exposure Pathway Emergency Planning Zone specific to the reactor technologies under consideration. The EP establishes the concepts, evaluation and assessment criteria, and protective actions that are necessary to limit and mitigate the consequences of potential or actual radiological emergencies.

Part 6 – Security Plans

As specified in RG 1.206, the submission of Security Plans is not required at the ESP phase. As noted in ESPA Part 2 (SSAR Section 13.6), the characteristics of the Project site are such that adequate security plans and measures can be developed. Additional details regarding physical security will be provided during the construction permit or license application phase.

Part 7 – Exemptions, Departures, and Variances

The ESPA submitted herein has been reviewed, and it has been determined that no exemptions from the applicable requirements of 10 CFR are necessary for consideration by the NRC under the provisions of 10 CFR 52.7 and the exemption criteria set forth in 10 CFR 50.12. Variances under 10 CFR 52.93 and departures under 10 CFR 52.63 are not applicable to this ESPA. No NRC approval is required in this regard.

Part 8 – License Conditions; Inspections, Tests, Analyses and Acceptance Criteria

As specified in 10 CFR 52.17(b)(3), major features of an emergency plan may include proposed inspections, tests, analyses, and acceptance criteria (ITAAC). Part 5 of the ESPA (Emergency Plan) includes the major features of the proposed Emergency Plan for the Project site; however, it does not include any proposed ITAAC associated with those major features.

No License Conditions or Inspections, Tests, Analyses, and Acceptance Criteria are required for this ESPA.

Part 9 – Withheld Information

Part 9 contains the information redacted from other parts of the application due to the sensitive or proprietary nature of the information.

Part 10 – Quality Assurance Program Description

The Quality Assurance (QA) Program for safety-related activities is described in the Duke Energy Topical Report, *Quality Assurance Program Description Operating Fleet* (DUKE-QAPD-001, referred to as QAPD). The QAPD and associated procedures establish controls for

activities that could affect the quality of safety-related structures, systems, and components (SSCs) for the proposed advanced reactors at the Project site.

Part 11 – Supplemental Information

The ESP application submitted herein has been reviewed, and it has been determined that no supplemental information is currently needed to support the application.

2.2 LABELING CONVENTIONS

Each page of this application, except for title sheets, includes a header and footer indicating its corresponding section and current revision. Additional content identification is detailed in the following sections.

2.2.1 PAGINATION

Content pages are numbered to indicate their chapter and section, and page within a section. For example, page 3.5-1 is the first page in Chapter 3, Section 3.5. Tables, in a given chapter, are located at the end of the associated section and the figures, in a given chapter, are located at the end of the chapter. Both tables and figures are numbered by section and sheet number as appropriate. In addition, each chapter contains a Table of Contents, List of Tables, List of Figures, and a Glossary. The Table of Contents, List of Tables, List of Figures, and Glossary are sequentially numbered i, ii, etc., with the chapter number indicated. Page numbers are located in the page footer.

2.2.2 SECTION NUMBERING

Each part of the ESPA has multiple chapters, sections, and subsections. The term “Chapter” is applied to X-level material. The term “Section” is applied to X.Y-level content and further subsections, as necessary. Chapter numbering and titles for the SSAR are consistent, to the extent practicable, with NUREG-0800, and for the ER, consistent, to the extent practicable, with RG 4.2.

2.2.3 REFERENCES

Reference lists appear at the end of each chapter. For example, the references list for Part 3, Chapter 2 appears at the end of Chapter 2. In general, NRC regulations or guidance documents (i.e., CFRs, NUREGs, Regulatory Guides, etc.) are not included in the reference lists.

2.2.4 TABLES, FIGURES AND APPENDICES

Tables are generally located at the end of the associated X.Y section, and figures are located at the end of each chapter. Multi-page tables have “Sheet X of Y” in parentheses below table’s name on each page. Each figure has a title block to indicate the figure’s name, number and corresponding section. Multi-page figures have “Sheet X of Y” in parentheses after the figure number on each page. Tables and figures are numbered with their two-digit section number and a sequential number. For example, Figure 1.2-3 is the third figure for Section 1.2. If an appendix is required, it is included at the end of the associated chapter.

2.2.5 DOCUMENT REVISION LEVEL

The current revision level of the document is denoted in the footer on each page.

2.3 UNIT CONVENTION

In the ESPA, units used are those found in the source documents from which parameter information is drawn. In some cases, unit conversions are provided to facilitate comparison with other parameters. In general, English units are followed by metric units in parentheses, unless the source is in metric units, in which case an English unit equivalent is provided in parentheses.

Section 3 General Corporate Information

3.1 NAME OF APPLICANT AND OWNER

DEC, referred to herein as “Duke Energy,” a wholly-owned subsidiary of Duke Energy Corporation.

3.2 ADDRESS OF APPLICANT

Duke Energy Carolinas, LLC
525 S. Tryon St.
Charlotte, NC 28202

3.3 DESCRIPTION OF BUSINESS OF APPLICANT

DEC is the applicant for an ESP at the Project site. Headquartered in Charlotte, NC, Duke Energy is a regulated public utility focused on generating, transmitting, distributing, and selling electricity in parts of NC and South Carolina (SC). In filing this ESP application, the applicant is not acting as an agent or representative of any other entity.

Duke Energy Corporation is a Fortune 150 company and one of largest energy holding companies in America. The company’s electric utilities serve 8.6 million customers in several states including NC, SC, Florida, Indiana, Ohio, and Kentucky. The company’s electric utilities collectively own approximately 55,100 MWe of energy capacity. DEC and DEP operate eleven nuclear units at six sites in NC and SC with a generating capacity of 10,819 MWe. Duke Energy is executing an ambitious clean energy transition plan to achieve a goal of net-zero carbon emissions from electrical generation by 2050. The company is investing in major electric grid upgrades and cleaner generation, including expanded energy storage, renewables, natural gas, and nuclear generation.

DEC (the Applicant) is not owned, controlled, or dominated by an alien, a foreign corporation, or foreign government. The application does not contain Restricted Data or classified National Security Information.

3.4 DESCRIPTION OF ORGANIZATION AND MANAGEMENT OF APPLICANT

Duke Energy Corporation is currently governed by a 15-member Board of Directors (Board), with the Chair selected from among the members. The Board’s corporate governance framework is designed to enhance shareholder value and ensure timely responses to issues affecting the corporation’s compliance with Securities and Exchange Commission regulations. The Chief Executive Officer (CEO) is elected by the Board and is responsible for managing the Corporation’s affairs. The CEO performs all legally required duties and any additional responsibilities assigned by the Board. The CEO reports directly to the Board, while the Company’s Officers report to the CEO. All Directors, the CEO, and Officers are United States citizens.

The business address for all Board members is:

Duke Energy Corporation
DEP-101
PO BOX 1414
Charlotte, NC 28201

As of the date of this application, the names of the Board members are as follows:

Harry K. Sideris, President and Chief Executive Officer, Duke Energy Corporation
Derrick Burks
Annette K. Clayton
Theodore F. Craver, Jr., Independent Chair
Robert M. Davis
Caroline Dorsa
W. Roy Dunbar
Nicholas C. Fanandakis
Jeffrey B. Guldner
John T. Herron
Idalene F. Kesner
E. Marie McKee
Michael J. Pacilio
Thoms E. Skains
William E. Webster, Jr.

The business address for all Officers is:

Duke Energy Corporation
525 S. Tryon Street
Charlotte, NC 28202

As of the date of this application, the names (and titles) of the Directors and Principal Officers of the Applicant are as follows:

Capps, Steven D.	Senior Vice President, New Nuclear Development and Operations Support
Flippin, Nicole L.	Senior Vice President, Nuclear Operations
Ghartey-Tagoe, Kodwo	Executive Vice President, Chief Legal Officer and Secretary
Gibby, Shawn K.	Vice President, Nuclear Engineering
Glenn, R. Alexander	Executive Vice President
Haff, Thomas P.	Senior Vice President, Nuclear Operations
Henderson, Kelvin	Senior Vice President and Chief Nuclear Officer
Nader, Rounette K.	Vice President, New Nuclear Generation and License Renewal
Sideris, Harry K.	Chief Executive Officer

Chapter 1 Introduction and General Description

1.1 INTRODUCTION

Duke Energy Carolinas, LLC (DEC), referred to herein as “Duke Energy,” a wholly-owned subsidiary of Duke Energy Corporation, hereby submits this application for an Early Site Permit (ESP) to the United States Nuclear Regulatory Commission (NRC) in accordance with the requirements of Title 10 of the Code of Federal Regulations (CFR), Part 52, (10 CFR 52) Subpart A, Early Site Permits. Duke Energy is the Applicant for this ESP. Duke Energy Progress, LLC (DEP) an indirect subsidiary of Duke Energy Corporation, and DEC (together referred to as “the Companies”) combined make up the Carolinas service territory within the region of interest. Duke Energy requests that the NRC issue an ESP for the proposed site described in this application for a period of 20 years from the date of issuance. The information in this application has been developed to support the issuance of that permit.

The Belews Creek, North Carolina (NC), site (Project site) is located primarily in Sauratown Township, in the southeastern corner of Stokes County, NC, with a small portion in Belews Creek Township, Forsyth County, NC. All proposed nuclear units will be in Stokes County. The Project site, located adjacent to Belews Lake, is approximately 14 miles (mi.) (23 kilometers [km]) northeast of Winston-Salem, NC, and approximately 19 mi. (31 km) northwest of Greensboro, NC.

The Project site is owned by Duke Energy and is bounded on the north, east, and west by Belews Lake, also owned by Duke Energy. Belews Lake was constructed in the early 1970s by Duke Energy as a cooling reservoir for the adjacent Belews Creek Steam Station, which is a two-unit, 2220-megawatt (MW) fossil fuel plant.

The Project site is comprised of a total area of approximately 1187 acres (ac.) (480 hectares [ha]). A specific reactor design has not been selected by Duke Energy to be constructed at the Project site. However, to facilitate the NRC's determination regarding suitability of the site for new nuclear units, Duke Energy has provided a set of bounding plant parameters, referred to as the plant parameter envelope (PPE). Technical information from various reactor designs was used to develop a set of bounding parameters that envelope the proposed facility characterization. This approach provides the NRC with information to assess the suitability of the Project site and allows Duke Energy to choose the best technology when a decision is made to proceed with construction. An overview of the reactor designs used to develop the PPE is provided in Section 1.11, and Section 2.0 identifies the PPE and site characteristic values, which may be used as a basis for the NRC’s determinations.

The Site Safety Analysis Report (SSAR) contains information describing the site characteristics, acceptability of the site for constructing and operating the proposed reactors, emergency preparedness, and quality assurance. Each chapter includes relevant regulatory considerations as necessary. The following paragraphs briefly describe the contents of the SSAR:

Chapter 1, Introduction and General Description, includes a general site description, an overview of reactor technologies considered in the development of the PPE, and a summary of SSAR compliance with regulations and regulatory guidance.

Chapter 2, Site Characteristics, includes a description of the PPE approach, the geography, demography, meteorology, hydrology, geology, and seismic characteristics of the site, and description of nearby industrial installations, military facilities, and transportation facilities.

Chapter 3, Design of Structures, Systems, Components, and Equipment, contains information on aircraft hazards in the vicinity of the Project site and references information on aircraft hazards provided in Section 2.2.

Chapter 11, Radioactive Waste Management, includes information concerning liquid and gaseous radioactive releases and associated doses during normal operations.

Chapter 13, Conduct of Operations, includes an overview of emergency planning and physical security for the site and plant sensitive areas.

Chapter 15, Accident Analysis, provides the radiological assessment required by 10 CFR 52.17(a)(1)(ix) to demonstrate compliance with the radiological dose criteria in 10 CFR Part 100. The assessment is based on information provided in the PPE.

Chapter 17, Quality Assurance Program Description, includes a description of the Quality Assurance Program under which the ESP application (ESPA) was prepared, as applied to activities related to the design, construction, and testing of the potential future facility.

The SSAR conforms with the applicable guidance contained in NUREG-0800, *Standard Review Plan for the Review of Safety Analysis Reports for Nuclear Power Plants: LWR [Light Water Reactor] Edition* (SRP), except where explicitly indicated otherwise. Where possible, the SSAR section numbers correspond to the section numbers identified in NUREG-0800. Consistent with that guidance, there are some gaps in the numbering sequence. This is intentional; this approach is intended to facilitate subsequent integration of the information in this application with reactor design information in the construction permit or license application, in which the complete numbering sequence is used.

1.2 GENERAL SITE DESCRIPTION

1.2.1 SITE LOCATION

As discussed in Section 1.1, the Project site is primarily located in Sauratown Township, in the southeastern corner of Stokes County, NC, with a small portion in Belews Creek Township, Forsyth County, NC. All proposed nuclear units will be in Stokes County.

The Project site, adjacent to Belews Lake, is approximately 14 mi. (23 km) northeast of Winston-Salem, NC, and approximately 19 mi. (31 km) northwest of Greensboro, NC. The Project site comprises approximately 1187 ac. (480 ha) Figures 1.2-1 and 1.2-2 show the Project site location and the surrounding 6-mi.(10 km) and 50-mi. (80 km) region, respectively. A more detailed description of the Project site location is provided in Section 2.1.

1.2.2 SITE DEVELOPMENT

The Project site is owned by Duke Energy and is bounded on the north, east, and west by Belews Lake. Belews Lake was constructed in the early 1970s by Duke Energy as a cooling reservoir for the adjacent Belews Creek Steam Station, which is a two-unit, 2220-MW fossil fuel plant.

Duke Energy is seeking this ESP for optionality to construct up to three nuclear power Plant Complexes on the Project site (designated as the North, Middle, and South Plant Complexes) as shown in Figure 1.2-3. Each Plant Complex would be designed to house one or more advanced reactors, with the total number of reactors dependent on the specific technology selected. For the purposes of this application, advanced reactors include light-water small modular reactors (SMRs) and non-light water reactors (non-LWRs). Each reactor will have a thermal output of up to 1000 megawatts thermal (MWt). The Project site is planned to accommodate up to three nuclear power Plant Complexes, with a bounding gross electrical output of 2250 megawatts electric (MWe) and a maximum thermal output of 6250 MWt. The specific number of reactor units will depend on the technology selected. The specific reactor technology has not been selected; consequently, this ESPA was developed using the PPE approach. The PPE defines a set of bounding values that provide the bases for future site development at the Project site. Section 2.0 provides the PPE information selected for the Project site and further details concerning development of the PPE including information on the reactor technologies that were evaluated.

The Project site general arrangement is shown on Figure 1.2-3 including the site boundary, power blocks, cooling tower areas, and laydown areas. Because a technology or set of technologies has not yet been selected, Figure 1.2-3 provides a composite arrangement showing the power block areas, existing infrastructure in the area, and other site utilization characteristics.

1.3 COMPARISON WITH OTHER FACILITIES

This section is not applicable to an ESPA using the PPE approach.

1.4 IDENTIFICATION OF AGENTS AND CONTRACTORS

1.4.1 APPLICANT/PROGRAM MANAGER

Duke Energy is the Applicant for an ESP at the Project site. Duke Energy Corporation is a Fortune 150 company headquartered in Charlotte, NC. Duke Energy Corporation is one of the largest energy holding companies in America. The company's electric utilities serve 8.4 million customers in several states including NC, South Carolina (SC), Florida, Indiana, Ohio, and Kentucky. The company's electric utilities collectively own approximately 55,100 MW of energy capacity. The Companies operate 11 nuclear units at six sites in NC and SC with a generating capacity of approximately 10,819 MW. Duke Energy is executing an ambitious clean energy transition plan to achieve a goal of net-zero carbon emissions from electrical generation by 2050. The company is investing in major electric grid upgrades and cleaner generation, including expanded energy storage, renewables, natural gas, and nuclear generation.

1.4.2 PRINCIPAL CONTRACTORS AND PARTICIPANTS

1.4.2.1 Sargent & Lundy

Sargent & Lundy is a full-service architect-engineering firm with considerable nuclear plant expertise. The firm has demonstrated capabilities in the design and licensing of nuclear plants. Sargent & Lundy has engineered, designed, planned, evaluated, and managed large, complex nuclear projects. Sargent & Lundy is Duke Energy's primary contractor for the development of the Belews Creek, NC ESPA project, providing engineering, licensing, management, and consulting services. Responsibilities included the oversight and development of the SSAR, Environmental Report (ER), and Emergency Plan.

1.4.2.2 WSP USA (WSP)

WSP is a global leader in the energy market, providing a full range of services for the nuclear industry including technical and engineering assessments for new nuclear projects. Their services have included siting, licensing, commissioning, civil engineering, seismic design, and construction materials testing. For the Belews Creek, NC ESPA project, WSP is subcontracted to Sargent & Lundy. For the development of this ESPA, WSP provided expertise in the areas of hydrology, geology, seismology, and geotechnical engineering, including subsurface investigations. WSP was also responsible for preparation of significant portions of the ER.

1.4.2.3 Other Contractors and Participants

Sargent & Lundy and WSP established contractual relationships with specialized consulting firms to assist in the development of the Project site ESPA. These are briefly described in the following subsections.

1.4.2.3.1 GEOVision Geophysical Services

GEOVision Geophysical Services performed borehole geophysical testing.

1.4.2.3.2 University of Texas at Austin

The University of Texas at Austin assisted in performing seismic spectral analysis.

1.4.2.3.3 Coppersmith Consulting, Inc.

Coppersmith Consulting, Inc., provided expertise in probabilistic seismic hazard analysis, probabilistic fault displacement hazard analysis, seismic source characterization, and data collection methods.

1.4.2.3.4 Emergency Management Consulting, LLC

Emergency Management Consulting, LLC, provided expertise in emergency preparedness and developed the Emergency Plan provided in Part 5 of the ESPA.

1.5 REQUIREMENTS FOR ADDITIONAL TECHNICAL INFORMATION

No technical development programs remain to be performed to support this application.

1.6 MATERIAL REFERENCED

No material has been incorporated by reference in this application.

1.7 DRAWINGS AND OTHER DETAILED INFORMATION

No drawings or detailed information have been submitted separately as part of this application.

1.8 INTERFACES WITH STANDARD DESIGN

This section is not applicable to an ESPA using the PPE approach and is to be addressed, if applicable, in the construction permit or license application stage.

1.9 CONFORMANCE WITH REGULATORY CRITERIA

This section evaluates the conformance of the SSAR with relevant NRC guidance contained in NRC Regulatory Guides (RGs) and NUREG-0800.

The applicable NRC RGs were identified through a review of the applicable SRP sections. Table 1.9-1 lists the applicable RGs by number and title, along with the associated SSAR section numbers and conformance statements. Exceptions to conformance with a RG are noted with an explanation. RGs included are those identified in the applicable SRP sections.

Table 1.9-2 provides a listing of the SRP sections applicable to an ESPA, including conformance statements. An exception to conformance is noted when the SSAR does not meet regulatory guidance as stated, but the intent or objective is met using an acceptable alternative. Exceptions to conformance with the SRP are noted with an explanation.

Exemptions to NRC regulations required to support this ESPA are identified and described in ESPA Part 7.

1.10 IMPACT OF CONSTRUCTION OF NEW NUCLEAR POWER PLANT UNITS ON OPERATING UNITS AT MULTI-UNIT SITES

This section is not applicable to this ESPA and is to be addressed during the construction permit or license application phase.

1.11 OVERVIEW OF REACTOR TYPES

Duke Energy is seeking this ESP for optionality to construct up to three nuclear power Plant Complexes on the Project site (designated as the North, Middle, and South Plant Complexes). Each Plant Complex would be designed to house one or more advanced reactors, with the total number of reactors dependent on the specific technology selected. For the purposes of this application, advanced reactors include light-water SMRs and non-LWRs. Since the specific reactor technology has not been selected, this ESPA was developed using the PPE approach. The PPE is based on a project site designed to accommodate up to three nuclear power Plant Complexes, with a bounding gross electrical output of 2250 MWe and a maximum thermal output of 6250 MWt, along with other site-specific considerations. Each reactor will have a thermal output of up to 1000 MWt. Refer to Section 1.11.3 for additional discussion concerning the application of this power level limit to the Holtec SMR-300 technology.

To support this approach, six advanced reactor designs were used to create a “surrogate plant.” As defined in NEI 10-01*, Industry Guideline for Developing a Plant Parameter Envelope in Support of an Early Site Permit* (Reference 1.11-1), the surrogate plant provides the basis for developing the site-related design parameter values listed in Table 2.0-2 of Chapter 2. A basis summary for each plant parameter is provided in the SSAR section referenced in Table 2.0-2.

The PPE defines a set of bounding values that provide the bases for future site development at the Project site. In development of the PPE, the following reactor technologies were evaluated:

- GVH BWRX-300
- NuScale VOYGR
- Holtec SMR-300
- WEC AP300
- TerraPower Natrium
- X-energy Xe-100

All six designs are advanced reactors, with four SMRs (i.e., BWRX-300, VOYGR, SMR-300, and AP300) and two non-LWRs (i.e., Natrium and Xe-100) incorporating enhanced safety features aimed at improving overall reactor safety compared to current operating reactors.

1.11.1 GVH BWRX-300

The GVH BWRX-300 is an advanced boiling-water reactor (BWR) that includes passive safety features. The BWRX-300 is an evolutionary design based on an NRC-licensed technology (Economic Simplified BWR). Each reactor generates 870 MWt, with an estimated electrical output of 315 MWe. The reactor design uses standard LWR fuel. Each BWRX-300 is enclosed by a containment structure. Up to six reactors would be placed on the Project site with a total thermal power output estimate of 5220 MWt.

1.11.2 NUSCALE VOYGR

The NuScale VOYGR is an advanced integral pressurized-water reactor (PWR) that includes passive safety features. Each reactor generates 250 MWt, with an estimated electrical power output of 77 MWe. The NuScale VOYGR uses standard LWR fuel with a shorter fuel assembly length. The reactor sits within a containment vessel, and up to 12 reactors can be housed in one below-grade shared pool.

One plant (12 total reactors) would be placed on the Project site with a total thermal power output estimate of 3000 MWt.

1.11.3 HOLTEC SMR-300

The Holtec SMR-300 is an advanced PWR that includes passive safety features. Each reactor generates approximately 1050 MWt, with an estimated electrical power output of approximately 320 MWe. Up to six SMR-300 reactors would be placed on the Project site with a total thermal power output of less than 6000 MWt. The Holtec SMR-300 uses standard LWR fuel. The reactor, steam generator, and spent fuel pool are located inside the containment structure, with the reactor situated below grade.

Duke Energy is only considering reactor technologies that meet the NRC definition of a SMR under 10 CFR 50.2, which limits the maximum thermal output of an SMR module to 1000 MWt. Duke Energy understands that with a maximum thermal output of 1050 MWt, the SMR-300 thermal power rating exceeds the 10 CFR 50.2 1000 MWt SMR power limit, and thus poses an obstacle for implementing a performance-based emergency plan in accordance with 10 CFR 50.160. Duke Energy is aware that Holtec is considering various options for resolution of the issue (Reference 1.11-2). Should Duke Energy select the Holtec SMR-300 technology, any additional information or measures needed to resolve the issue are to be addressed in the construction permit or license application.

1.11.4 WEC AP300

The WEC AP300 is an advanced PWR that includes passive safety features. Each reactor generates 990 MWt, with an estimated electrical power output of 330 MWe. The WEC AP300 uses standard LWR fuel. The reactor and steam generator are located inside the containment structure. Up to six AP300 reactors would be placed on the Project site with a total thermal power output estimate of 5940 MWt.

1.11.5 TERRAPOWER NATRIUM

The TerraPower Natrium reactor is a metal fueled, pool-type sodium fast reactor that contains a molten salt energy storage system, enabling the plant to vary its supply of energy to the grid. Each reactor generates 840 MWt with an estimated electrical power output of 345 MWe, while maintaining constant reactor power. The Natrium reactor uses high-assay low-enriched uranium (HALEU) metallic fuel. The reactor operates near atmospheric pressure, circulating sodium through its core with pumps. Up to two Natrium reactors would be placed on the Project site with a total thermal power output estimate of 1680 MWt.

1.11.6 X-ENERGY XE-100

The X-energy Xe-100 is an advanced high-temperature gas-cooled reactor (HTGR) that

includes passive safety features. Each reactor generates 200 MWt, with an estimated electrical power output of 80 MWe. The X-energy Xe-100 uses HALEU TRi-structural ISOtropic (TRISO) particle fuel. The reactor and steam generator are located inside the containment structure. The standard design is for a four-reactor plant. Up to 14 Xe-100 reactors would be placed on the Project site with a total thermal power output estimate of 2800 MWt.

GLOSSARY

Term	Definition
2D	two-dimensional
40Ar/39Ar	argon-argon dating
°C	degrees Celsius
°F	degrees Fahrenheit
ac.	acre
ACES	Automated Coastal Engineering System
ac-ft	acre-foot
ACH	air changes per hour
AECL	Atomic Energy of Canda Limited
AFDD	accumulated freezing degree days
AFE	annual frequency of exceedance
AGL	above ground level
AHEX	Atlantic Highly Extended Crust
AHPS	Advanced Hydrologic Prediction Service
AL	approach and landing
ALOHA	Areal Locations of Hazardous Atmospheres

Term	Definition
AMSL	above mean sea level
ANS	American Nuclear Society
ANSI	American National Standards Institute
ANSS	Advanced National Seismic System Comprehensive Earthquake Catalog
APT	aquifer pumping test
ArcMap	ArcMap 10.8.2
ASCE	American Society of Civil Engineers
ASHRAE	American Society of Heating, Refrigerating, and Air-Conditioning Engineers
ASTM	American Society of Testing and Materials
ATV	acoustic televiewer
BCSS	Belews Creek Steam Station
bgs	below ground surface
BLEVE	Boiling Liquid Expanding Vapor Explosion
BNL	Brookhaven National Laboratory
bpf	blows per foot
Bq	Becquerels (decays per second)

Term	Definition
BTOC	below top of casing
BTU	British Thermal Unit
c	cohesion
c'	effective cohesion
CAA	Clean Air Act
cal	calories
cal/s	calories per second
CAMP	Central Atlantic magmatic province
CAP	corrective action plan
CBR	center, body, and range
CEM	Coastal Engineering Manual
CENA	Central and Eastern North America
CEUS	Central and Eastern United States
CFR	Code of Federal Regulations
cfs	cubic feet per second
Ci	Curie

Term	Definition
cm	centimeter
cm/yr	centimeters per year
CO	carbon monoxide
Co.	Company
CO_2	carbon dioxide
CO_2-eq	carbon dioxide equivalent
COV	coefficient of variation
COVID-19	coronavirus disease 2019
CP	Coastal Plain
CR	core recovery
CRREL	Cold Region Research and Engineering Laboratory
CSM	conceptual site model
CU	consolidated-undrained
CVSZ	Central Virginia Seismic Zone
CZbg	biotite gneiss and schist
CZfg	felsic mica gneiss

Term	Definition
D/Q	deposition factor
DBR	deep bedrock
DBT	dry bulb temperature
Delta-T	vertical temperature gradient
DEM	Digital Elevation Model
D_{min}	minimum damping
DOE	U.S. Department of Energy
DPT	dewpoint temperature
DPR	deepest bedrock
DRS	design response spectrum
DYFI	(USGS) Did you feel it?
E[M]	expected moment magnitude
EAB	exclusion area boundary
ECC-AM	Extended Continental Crust-Atlantic Margin
ECC-GC	Extended Continental Crust-Gulf Coast
ECL	effluent concentration limit

Term	Definition
EF Scale	Enhanced Fujita Scale
EL	elevation
ENE	east-northeast
EPRI	Electric Power Research Institute
ER	electrical resistivity
ERM	Eastern Rift Margin
ERM-N	Eastern Rift Margin-North
ERM-S	Eastern Rift Margin-South
ESC	Environmental Systems Corporation
ESE	east-southeast
ESP	Early Site Permit
ESPA	Early Site Permit Application
ESRI	Environmental Systems Research Institute
ETSZ	Eastern Tennessee Seismic Zone
FAA	Federal Aviation Administration
FDD	freezing degree days

Term	Definition
FEMA	U.S. Federal Emergency Management Agency
FERC	U.S. Federal Energy Regulatory Commission
FGD	flue gas desulfurization
FIRS	foundation input response spectrum
Fr-Fr	Free-Free
FS	factor of safety
ft.	feet
ft/day	feet per day
ft/ft	feet per foot
ft/s	feet per second
ft^2	square feet
ft^2/day	square feet per day
ft^2/lb	square feet per pound
ft^3	cubic feet
g	standard acceleration due to earth’s gravity
Ga	giga-annum (billion years)

Term	Definition
gal.	gallon
GCR	Gulf Coast Region
GHEX	Gulf Coast Highly Extended
GHG	greenhouse gases
GIS	geographic information system
G_{max}	maximum shear modulus
GMC	ground motion characterization
GMH	Great Meteor Hotspot
GMM	ground motion model
GMPE	ground motion prediction equation
GMRS	ground motion response spectrum
gpm	gallons per minute
GPS	Global Positioning System
Gt	gigaton
GVH	GE Vernova Hitachi Nuclear Energy
GWT	groundwater level

Term	Definition
H	horizontal
ha	hectare
ha-m	hectare-meter
HEC-RAS	Hydrologic Engineering Center River Analysis System
HHA	hierarchical hazard assessment
HMR	National Weather Service Hydrometeorological Reports
Holtec	Holtec International
hr.	hour
HW	hanging wall
IBEB	Illinois Basin Extended Basement
IEEE	Institute of Electrical and Electronic Engineers
I_h	horizontal hydraulic gradient
in.	inch
in/yr	inches per year
Inc.	incorporated
ISG	Interim Staff Guidance

Term	Definition
i_v	vertical hydraulic gradient
Jd	diabase dike
JFD	joint frequency distribution
K	hydraulic conductivity
K_d	solid/liquid partition coefficient
K_0	site attenuation parameter
kg	kilogram
KGS	Kansas Geological Survey
KGSO	National Weather Service Station at Piedmont Triad International Airport, Greensboro, NC
KINT	National Weather Service Station at Smith Reynolds Airport, Winston-Salem, NC
km	kilometer
km^2	square kilometer
kPa	kilopascal
kph	kilometer per hour
KRDU	National Weather Service Station at Raleigh/Durham International Airport, Raleigh, NC

Term	Definition
ksf	kips per square foot
kts	knots
kW	kilowatt
kyr	thousand year duration
L	horizontal projection of the flow path length
lb.	pound
LCD	local climatological data
LiDAR	Light Detection and Ranging
LIP	local intense precipitation
LMDCT	linear mechanical draft cooling towers
lpm	liters per minute
LPZ	low population zone
LTP	load transfer platform
LWR	light-water reactor
LWSP	local water supply plans
m	meter

Term	Definition
m/s	meters per second
m^2/kg	meters squared per kilogram
m^3	cubic meter
m^3/s	cubic meters per second
Ma	mega-annum (million years)
mb	millibar
MEL	Maximally Exposed Location
MESE	Mesozoic and younger extended crust
MESE-N	Mesozoic and younger extended crust-narrow
MESE-W	Mesozoic and younger extended crust-wide
MET tower	Belews Creek, NC site meteorological tower
mGal	milligal
mi.	mile
mi^2	square mile
MidC	Midcontinent-Craton
ml	milliliter

Term	Definition
ML	non-plastic silts
mld	million liters per day
mm	millimeter
mm/yr	millimeter per year
Mmax	maximum magnitude
MMI	Modified Mercalli Intensity
mo	month
MPa	megapascal
mph	miles per hour
mps	meter per second
MQ	Marquesas
MRI	mean return interval
MW	megawatt
MWe	megawatts electric
MWh	megawatt-hour
MWIS	makeup water intake structure

Term	Definition
MWSEL	Maximum Water Surface Elevations
my	million years
n	effective porosity
N	resistance
N*	NUREG-2115 methodology that adjusts earthquake counts to account for the uncertainty in the magnitude estimate
NAAQS	National Ambient Air Quality Standards
NAD 1983	North American Datum of 1983
NAP	Northern Appalachian
NAVD 88	North American Vertical Datum of 1988
NC	North Carolina
NCA	National Climate Assessment
NCCSR	North Carolina Climate Science Report
NCDC	National Climatological Data Center
NCDEQ	North Carolina Department of Environmental Quality
NCDWR	North Carolina Division of Water Resources
NCEI	National Centers for Environmental Information

Term	Definition
NCGS	North Carolina Geological Survey
NCOSBM	North Carolina Office of State Budget and Management
NEDB	National Earthquake Database of Canada
NEI	Nuclear Energy Institute
NGA	Next Generation Attenuation
NGVD 29	National Geodetic Vertical Datum of 1929
NID	National Inventory of Dams
NIST	National Institute of Standards and Technology
NLCD	National Land Cover Database
NM	Nautical Mile
NMESE	non-extended crust or crust where the most recent extension occurred before the Mesozoic
NMESE-N	non-extended crust or crust where the most recent extension occurred before the Mesozoic-Narrow
NMESE-W	non-extended crust or crust where the most recent extension occurred before the Mesozoic-Wide
NMFS	New Madrid Fault System
NNE	north-northeast

Term	Definition
NNW	north-northwest
NO_2	nitrogen dioxide
NOAA	U.S. National Oceanic and Atmospheric Administration
non-LWR	non-light-water reactor
NPDES	National Pollutant Discharge Elimination System
NPS	U.S. National Park Service
NRC	U.S. Nuclear Regulatory Commission
NS	Norfolk Southern
NSHM	National Seismic Hazard Map
nT	nanotesla
NUREG	NRC Technical Report designation
NUREG/CR	NRC Contractor Technical Report
NuScale	NuScale Power, LLC
NWI	National Wetland Inventory
NWS	National Weather Service
OB	overburden

Term	Definition
OSHA	U.S. Occupational Safety and Health Administration
PBIRS	performance-based interface response spectrum
pcf	pounds per cubic foot
PEZ-N	Paleozoic Extended Zone-Narrow
PEZ-W	Paleozoic Extended Zone-Wide
PGA	peak ground acceleration
pH	potential of hydrogen
PI	Plasticity Index
PIR	Potential Impact Radius
$PM_{2.5}$	particulate matter with a diameter of 2.5 microns or less
PM_{10}	particulate matter with a diameter of less than 10 microns
PMF	probable maximum flood
PMP	probable maximum precipitation
PMWP	probable maximum winter precipitation
PPBA	potential power block area
PPE	plant parameter envelope

Term	Definition
PPg	porphyritic granite
ppm	parts per million
PPRP	participatory peer review panel
Project site	Belews Creek, NC site
psf	pounds per square foot
PSHA	Probabilistic Seismic Hazard Analysis
psi	pound per square inch
psig	pounds per square inch gauge
PWR	partially weathered rock
PWS	public water supply
RCP	Representative Concentration Pathway
RCTS	Resonant Column Torsional Shear
Rd	road
RG	Regulatory Guide
RH	relative humidity
RLME	repeated large-magnitude earthquake

Term	Definition
RQD	rock quality designation
RR	Reelfoot Rift
RR-RCG	Reelfoot Rift with Rough Creek Graben
Rrup	distance to earthquake rupture
RSL	relative sea level rise
RTD	resistance temperature and detector
S	storage coefficient
s/m^3	seconds per cubic meter
SACTI2	Seasonal/Annual Cooling Tower Impact Prediction Code 2
SASW	Spectral Analysis of Surface Waves
SBR	shallow bedrock
SCRAM	Support Center for Regulatory Atmospheric Modeling
sec.	second
SLR	St. Lawrence Rift
SM	silty sands
SMR	small modular reactor

Term	Definition
SO_2	sulfur dioxide
SPT	Standard Penetration Test
sq.	square
sq. mi.	square mile
SRA	Site Response Analysis
SRP	Standard Review Plan
SSAR	Site Safety Analysis Report
SSC	seismic source characterization
SSCs	structures, systems, and components
SSE	south-southeast
SSHAC	Senior Seismic Hazard Analysis Committee
SSW	south-southwest
STUDY-R	Study Region
T	transmissivity
T_a	air temperature
TDIs	technically defensible interpretations

Term	Definition
TerraPower	TerraPower, LLC
t_i	ice thickness
TI Team	Technical Integration Team
TNT	Trinitrotoluene
TOC	top of casing
TOK	Texas-Oklahoma-Arkansas region
tsf	tons per square foot
U.S.	United States
UCS	unconfined compressive strength
UHRS	uniform hazard response spectrum
UHS	ultimate heat sink
USACE	U.S. Army Corps of Engineers
USCB	U.S. Census Bureau
USCS	Unified Soil Classification System
USDA	U.S. Department of Agriculture
USDOC	U.S. Department of Commerce

Term	Definition
USEPA	U.S. Environmental Protection Agency
USGS	U.S. Geological Survey
UTM	Universal Transverse Mercator
UU	unconsolidated-undrained
V	vertical
V/H	vertical-to-horizontal
VA	Virginia
VDWR	Virginia Department of Wildlife Resources
V_p	compression wave velocity
V_S	shear wave velocity
WBT	Wet Bulb Temperature
WEC	Westinghouse Electric Company, LLC
WNW	west-northwest
WOTUS	Waters of the U.S.
WSEL	water surface elevation
WSW	west-southwest

Term	Definition
X-energy	X-energy, LLC
yr.	year
Δh	difference in hydraulic head
ΔT	temperature difference
µg	micrograms
χ/Q	atmospheric dispersion factor
φ	total stress friction angle
φ'	effective total stress friction angle

Chapter 2 Site Characteristics

Chapter 2 describes the key characteristics of the Belews Creek, North Carolina (NC) site (Project site), including the plant parameter envelope (PPE), and the geographical, demographical, geological, seismological, hydrological, and meteorological characteristics of the site and vicinity. Additionally, the chapter includes an assessment of nearby industrial, transportation, and military facilities to assess the potential for accidents that could compromise safe operations. Chapter 2 provides sufficient detail about the Project site location, attributes, and related design parameters to support a safety assessment. Chapter 2 is organized into the following sections:

Section 2.0: Plant Parameter Envelope

Section 2.1: Geography and Demography

Section 2.2: Nearby Industrial, Transportation, and Military Facilities

Section 2.3: Meteorology

Section 2.4: Hydrologic Engineering

Section 2.5: Geology, Seismology, and Geotechnical Engineering

2.0 PLANT PARAMETER ENVELOPE

Duke Energy is pursuing an Early Site Permit (ESP), utilizing a PPE for site evaluation approval, to support potential construction of multiple advanced reactors at the Project site. Advanced reactors include light water small modular reactors (SMRs) and non-light-water-reactors (non-LWRs). Each reactor will have a thermal output of up to 1000 megawatts thermal (MWt). These advanced reactors are planned across three areas at the site, referred to as the North Plant Complex, Middle Plant Complex, and the South Plant Complex (collectively referred to as Plant Complexes). The final number and type of advanced reactors will depend on the technology selected.

Because a technology has not yet been selected, a PPE has been developed. The PPE was prepared using the guidelines in Nuclear Energy Institute (NEI) 10-01, *Industry Guideline for Developing a Plant Parameter Envelope in support of an Early Site Permit* (Reference 2.0-1). The PPE uses information supplied by reactor vendors for the technologies under consideration to establish a surrogate plant.

The final technology selected for the Project site will be identified during the construction permit or license application phase, at which time it will be confirmed that the selected design is bounded by the PPE. Any parameters that are determined to be non-bounding will require a variance during the construction permit or license application phase, in accordance with Title 10 of the Code of Federal Regulations (CFR) Part 52, Section 52.39(d) (10 CFR 52.39(d)). This approach ensures site suitability for multiple reactor technologies without committing to a specific technology. A summary of the reactor designs considered in developing the PPE is

provided in Section 1.11, Overview of Reactor Types.

Tables 2.0-1 and 2.0-2 present the principal site characteristics and site-related design parameters for the Project site. This information is presented consistent with the guidance in the U.S. Nuclear Regulatory Commission (NRC) technical guidance document NUREG-0800, *Standard Review Plan (SRP) for the Review of Safety Analysis Reports for Nuclear Power Plants: LWR Edition,* Tables 2.0-3 through 2.0-6 are part of the PPE and provide isotopic source term information used to assess dose consequences from both routine releases and postulated accident scenarios.

Tables 2.0-4 and 2.0-6 provide the bounding annual normal release of gaseous and liquid radionuclide activity, respectively. The bounding release values in these tables were determined in the following manner:

- Two technologies were primarily used to identify the overall bounding values based largely on the conservative total activity for each radionuclide.
- A third technology was used when the two initial technologies' values were "zero."
- The fourth technology was used to replace extraordinarily low exponent values from the third technology.
- Where "negligible" was provided for radionuclide activity by one of the first two technologies, a value of 1.00E-05 curies per year (Ci/year) per reactor was used.
- The radionuclide activity considers the number of reactors of the specific technology proposed to be built at the Project site.

The site characteristics and design parameters presented below, and throughout the Site Safety Analysis Report (SSAR), establish the findings required by 10 CFR Part 52 and 10 CFR Part 100 regarding the suitability of the Project site.

Table 2.0-1
Site Characteristics
(Sheet 1 of 7)

Characteristic Parameter	Site-Specific Value/ Characteristic	Description	SSAR Section
Geography and Demography			
Exclusion Area Boundary (EAB)	Figure 2.1-5 shows the proposed EAB.	The area surrounding the reactors, in which the reactor licensee has the authority to determine all activities, including exclusion or removal of personnel and property from the area.	2.1.3.3
Low Population Zone (LPZ)	Figure 2.1-5 shows the LPZ. For the reactor technologies under consideration, the LPZ and EAB are equivalent. There are no residents within the LPZ.	The area immediately surrounding the exclusion area such that there is a reasonable assurance that appropriate protective measures could be taken in the event of a serious accident.	2.1.3.3
Population Center Distance	7.7 mi. (12.4 km)	The distance from the Project site boundary to the nearest boundary of a densely populated center containing more than about 25,000 residents.	2.1.3.4

Table 2.0-1
Site Characteristics
(Sheet 2 of 7)

Characteristic Parameter	Site-Specific Value/ Characteristic	Description	SSAR Section
Meteorology and Hydrology			
Winter Precipitation		The highest ground-level weight among the: 1. 100-year return snowpack, 2. historical maximum snowpack, 3. 100-year return 2-day snowfall event, and 4. historical maximum 2-day snowfall event.	2.3.1.2.2.3
Normal Winter Precipitation Event	24.4 psf (119 kg/m^2)		
Extreme Frozen Winter Precipitation Event	15.8 psf (77.2 kg/m^2)	The highest ground-level weight between the: 1. 100-year return 2-day snowfall event, and 2. historical maximum 2-day snowfall event.	2.3.1.2.2.4
Extreme Liquid Winter Precipitation Event (48-hour Probable Maximum Winter Precipitation [PMWP])	23 in. (0.58 m)	The extreme liquid winter precipitation event is defined as the greatest depth of precipitation for a 48-hr period that is physically possible over a 25.9 square kilometer (10 square mile) area.	2.3.1.2.2.5
Maximum Rainfall Rate	18.8 in/hr (0.478 m/h) 6.2 in/5-min (0.158 m/5-min)	PMP for 1-hour and for 5-minute durations at the Project site.	2.4.2.3.1
Maximum Flood	747.86 ft. (227.95 m)	Maximum flood level from combined effects PMP and wind waves.	2.4.2.2

Table 2.0-1
Site Characteristics
(Sheet 3 of 7)

Characteristic Parameter	Site-Specific Value/ Characteristic	Description	SSAR Section
Maximum Groundwater	810 ft. (247 m)	Maximum groundwater level under foundation structures in power block area.	2.4.12.2.6
Travel Time for Groundwater Flow	Maximum – 28 years Minimum – 35 days	Groundwater travel time from power block area to potential receptor.	2.4.12.6
Travel Time for Radionuclide Transport in the Groundwater	Maximum – greater than 1000 years Minimum – 35 days	Radionuclide transport time in groundwater.	2.4.13.1
100-Year Return Period 3-Second Gust Wind Speed	93 mph (42 m/s)	100-Year Return Period 3-Second Gust Wind Speed.	2.3.1.2.1.2
Historical Maximum Wind Speeds	69 mph (111 km/h) 115 mph (185 km/h)	Maximum recorded win speed (non-thunderstorm). Maximum recorded wind speed (thunderstorm).	2.3.1.2.1.2
Design-Basis Hurricane Windspeed	160 mph (258 km/h)	The 3-second gust wind velocity at 33 ft (10 m) above ground level (AGL) in the site area, corresponding to a hurricane wind event with a 10^{-7} annual exceedance probability. The site-specific value is determined from the windspeed contour maps presented in Regulatory Guide (RG) 1.221.	2.3.1.2.1.5
Design Basis Tornado			2.3.1.2.1.4
Maximum Pressure Drop	1.2 psi (83 mb)	Decrease in ambient pressure from normal atmospheric pressure due to passage of a tornado.	

Table 2.0-1
Site Characteristics
(Sheet 4 of 7)

Characteristic Parameter	Site-Specific Value/ Characteristic	Description	SSAR Section
Maximum Rotational Speed	184 mph (82 m/s)	Rotation component of maximum wind speed due to passage of a tornado.	2.3.1.2.1.4
Maximum Translational Speed	46 mph (21 m/s)	Translation component of maximum wind speed due to the movement of a tornado across the ground.	2.3.1.2.1.4
Maximum Wind Speed	230 mph (103 m/s)	Sum of the maximum rotational and translational wind speed components due to passage of a tornado.	2.3.1.2.1.4
Radius of Maximum Rotational Speed	150 ft. (45.7 m)	Distance from the center of the tornado at which the maximum rotational wind speed occurs.	2.3.1.2.1.4
Maximum Rate of Pressure Drop	0.5 psi/s (37 mb/s)	Maximum rate of pressure drop at site due to passage of a tornado.	2.3.1.2.1.4
Site Characteristics Ambient Air Temperature Dry Bulb Temperature (DBT)		DBT parameters used in establishing design capacity and performance requirements for heat removal systems.	2.3.1.2.1.4
0.4% Annual Exceedance (Mean Coincident WBT)	92.4˚F (33.6˚C) 74.0˚F (23.3˚C)		
1% Annual Exceedance (Mean Coincident WBT)	90.3˚F (32.4˚C) 73.5˚F (23.1˚C)		
2% Annual Exceedance (Mean Coincident WBT)	88.2˚F (31.2˚C) 72.9˚F (22.7˚C)		
Mean	58.3˚F (14.6˚C)		
Minimum Mean	11.4˚F (-11.4˚C)		

Table 2.0-1
Site Characteristics
(Sheet 5 of 7)

Characteristic Parameter	Site-Specific Value/ Characteristic	Description	SSAR Section
Wet Bulb Temperature (WBT)		WBT parameters used in establishing design capacity and performance requirements for heat removal systems.	2.3.2.3
0.4% Annual Exceedance	77.0˚F (25.0˚C)		
1% Annual Exceedance	75.8˚F (24.3˚C)		
Mean	50.1˚F (10.1˚C)		
Minimum Mean	9.3˚F (-12.6˚C)		
Atmospheric Dispersion (χ/Q) (Accident)		Atmospheric dispersion coefficients used in safety analyses to estimate dose consequences of accident airborne releases. For the technologies under consideration, the EAB and LPZ boundaries are equivalent.	2.3.4
0-2 hr. @ EAB	1.78E-03 s/m^3		
0-8 hr. @ LPZ	1.33E-03 s/m^3		
8-24 hr. @ LPZ	1.15E-03 s/m^3		
1-4 day @ LPZ	8.42E-04 s/m^3		
4-30 day @ LPZ	5.37E-04 s/m^3		
Atmospheric Dispersion (χ/Q) (Annual Average)	Refer to Table 2.3-57 Table 2.3-58 Table 2.3-59 Table 2.3-60	Atmospheric dispersion coefficient used in the safety analysis for the dose consequences of normal airborne releases.	2.3.5
Gaseous Releases			
Dose Consequences			
Normal	10 CFR 20.1301(e) 10 CFR Part 20, App. B 10 CFR Part 50, App. I 40 CFR Part 190	Estimated radiological dose consequences due to gaseous releases from normal operation of the plant.	11.3.3
Post-Accident	10 CFR 52.17(a)(1)(ix)	Estimated radiological dose consequences due to gaseous releases from postulated accidents.	15.3
Minimum Distance from Release Point to EAB	725 ft. (221 m)	Minimum lateral distance from release point to EAB.	2.3.4

Table 2.0-1
Site Characteristics
(Sheet 6 of 7)

Characteristic Parameter	Site-Specific Value/ Characteristic	Description	SSAR Section
Liquid Releases			
Dose Consequences			
Normal	10 CFR 20.1301(e) 10 CFR Part 20, App. B 10 CFR Part 50, App. I 40 CFR Part 190	Estimated radiological dose consequences due to liquid releases from normal operation of the plant.	11.2.3
Post-Accident	10 CFR 20, Appendix B, Table 2, Column 2	Estimated radiological dose consequences due to liquid releases from postulated accidents.	2.4.13
Geology, Seismology, and Geotechnical Engineering			
Ground Motion Response Spectra	Refer to Table 2.5-42 Table 2.5-49	The design response spectra used to establish a plant's seismic design.	2.5.2.6
Capable Tectonic Structures or Sources	None	The assumption made in a plant design about the presence of capable faults or earthquake sources in the vicinity of the plant site.	2.5.3
Soil Properties			
Liquefaction	None	Liquefaction potential at the site.	2.5.4
Minimum Static Bearing Capacity	14.0 kips per square foot (ksf) (670 kPa) (safety-related structures) 8.9 ksf (426 kPa) (other structures)	Allowable load-bearing capacity of layer supporting plant structures.	2.5.4
Minimum Dynamic Bearing Capacity	35 ksf (1676 kPa)	Capacity of the foundation soil/rock to resist loads imposed by the structures in the event of an earthquake.	2.5.4

Table 2.0-1
Site Characteristics
(Sheet 7 of 7)

Characteristic Parameter	Site-Specific Value/ Characteristic	Description	SSAR Section
Minimum Shear Wave Velocity	1000 ft/s (305 m/s)	The assumed limiting propagation velocity of shear waves through the foundation materials used in the plant design.	2.5.4
Minimum Soil Angle of Internal Friction	35 degrees	Design assumption for the minimum value of the internal friction angle of foundation soils, fill soils, or excavation slopes that would provide a safe design of plant through soil structure interaction analyses including sliding along the base.	2.5.4
Maximum Settlement	4 in. (10.2 cm)	The greatest vertical displacement of a structure's foundation anticipated to occur under the combined effects of static, dynamic, and operational loading conditions.	2.5.4.10
Slope Failure Potential (Y/N)	N	The potential for critical slope failure under static, hydraulic, and dynamic conditions.	2.5.5
Lateral Soil Variability (Y/N)	Y	Site investigations have been conducted to characterize the spatial (lateral) variability of soil and rock properties across the site.	2.5.4.2

Table 2.0-2
Site-Related Design Parameters
(Sheet 1 of 4)

Characteristic Parameter	Site-Specific Value	Description	SSAR Section
Structure Height	176 ft. (53.6 m)	The height from finished grade to the top of the tallest power block structure, excluding stacks and cooling towers.	3.5.1.6
Structure Foundation Embedment	125 ft. (38.1 m)	The depth from finished grade to the bottom of the basemat for the most deeply embedded power block structure.	2.4.12.2 2.4.12.5.1 2.4.12.5.3
Minimum Site Grade	810 ft. (247 m) NAVD 88	Minimum finished ground elevation in the power block area.	2.4.4
Plant Megawatts Thermal (MWt)	6250 MWt	The combined maximum thermal power generated by the Project site.	1.11
Control room air changes per hour (ACH)	2.64/hr.	The control room air exchange rate (volume changes per hour) for evaluating toxic chemical releases from nearby facilities.	2.2.2.2
Condenser Design Duty	1.32E10 BTU/hr (3869 MW)	Design value for the waste heat rejected to the circulating water system across the condensers (site total).	-

Table 2.0-2
Site-Related Design Parameters
(Sheet 2 of 4)

Characteristic Parameter	Site-Specific Value	Description	SSAR Section
Cooling Water Flow Rate	1.4E06 gpm (88.33 m³/s)	Design value for the maximum flow rate of the circulating water system through the condenser tubes (site total).	-
Maximum Inlet Temperature to Condenser	100˚F (37.8˚C)	Design assumption for the maximum acceptable circulating water temperature at the inlet to the condenser or cooling water system heat exchangers.	-
Evaporation Rate for the Facility During Normal Operation	26,256 gpm (1.66 m³/s) – normal 32,580 gpm (2.06 m³/s) – maximum	The expected (and maximum) rate at which water is lost by evaporation from the cooling water systems (site total).	-
Gaseous Releases			
Source Term (Accident)	Refer to Table 2.0-3	Bounding design basis accident atmospheric release by post-accident interval.	15.2
Source Term (Routine)	Refer to Table 2.0-4	Annual activity, by radionuclide, contained in routine plant airborne effluent streams.	11.3.3.1

Table 2.0-2
Site-Related Design Parameters
(Sheet 3 of 4)

Characteristic Parameter	Site-Specific Value	Description	SSAR Section
Release Point Elevation			
Accident	Ground Level	The elevation above finished grade of the release point for releases due to an accident.	2.3.4.2
Normal	Ground Level	The elevation above finished grade of the release point for normal effluent releases.	2.3.5.2
Liquid Releases			
Source Term (Accident)	Refer to Table 2.0-5	The assumed activity, by radionuclide, contained in accidental liquid radwaste release from postulated tank failure.	2.4.13
Source Term (Routine)	Refer to Table 2.0-6	The annual activity, by radionuclide, contained in routine plant liquid effluent streams.	11.2.3

Table 2.0-2
Site-Related Design Parameters
(Sheet 4 of 4)

Characteristic Parameter	Site-Specific Value	Description	SSAR Section
Release Point Characteristics		Liquid release point characteristics (for routine and accident releases).	
Accident	A liquid accident release is assumed to occur at ground level. Section 2.4.13 describes the release point and underlying assumptions for an accidental liquid release.		2.4.13
Routine	Routine liquid releases are controlled, monitored, and processed to ensure compliance with regulatory limits and applicable standards. Section 11.2.3 describes the release points and assumptions associated with routine liquid discharges.		11.2.3

2.1 GEOGRAPHY AND DEMOGRAPHY

This section of the SSAR identifies the Project site location and describes the distribution of infrastructure, natural features, and population in the vicinity of the Project site. This section also identifies the proposed exclusion area boundary (EAB) for each Plant Complex planned for the Project site and establishes Duke Energy's authority to determine the activities within these areas. The discussion addresses the guidance in NUREG-0800.

2.1.1 SITE LOCATION AND DESCRIPTION

2.1.1.1 Specification of Site Location

As illustrated in Figure 2.1-1, the proposed Project site is located primarily in Sauratown Township, in the Southeastern corner of Stokes County, NC, with a small portion in Belews Creek Township, Forsyth County, NC. As discussed in Section 1.2.2, Duke Energy Carolinas, LLC (Duke Energy), a wholly-owned subsidiary of Duke Energy Corporation, proposes to construct and operate multiple advanced reactors on one to three Plant Complexes planned for the Project site. All proposed nuclear units (all three Plant Complexes) are to reside in Stokes County. The Project site, adjacent to Belews Lake, is approximately 14 miles (mi.) (23 kilometers [km]) northeast of Winston-Salem, NC, and approximately 19 mi. (31 km) northwest of Greensboro, NC. Political subdivisions and prominent natural and man-made features, including rivers, lakes, industrial, and transportation facilities in the vicinity of the site and surrounding area are illustrated in Figures 2.1-1 through 2.1-4. Figure 2.1-5 depicts the general layout of the Project site. The total site area is approximately 1187 acres (ac.) (480 hectares [ha]).

The Project site center point coordinates are:

Universal Transverse Mercator (UTM) Coordinates

UTM Zone	17N
Northing	4,014,636.73 meters (m)
Easting	584,805.45 m

Latitude/Longitude [Deg/Min/Sec]

Latitude	36° 16' 22.62" N
Longitude	80° 03' 20.88" W

The Project site is owned by Duke Energy and is bounded on the north, east, and west by Belews Lake, also owned by Duke Energy. Belews Lake was constructed in the early 1970s by Duke Energy as a cooling reservoir for the Belews Creek Steam Station (BCSS), a two-unit, 2220-megawatt (MW) fossil fuel plant located adjacent to the Project site that has been in operation since 1974. The BCSS cooling system is classified as closed-cycle and utilizes once-through cooling, with water supplied by and discharged back into Belews Lake during plant

operation. In 2020 and 2021, natural gas was added to the station to allow up to 50 percent natural gas co-firing on both units. An existing pumping station can transfer makeup water from the nearby Dan River into Belews Lake to maintain the reservoir level.

The BCSS is the only industrial facility within the immediate vicinity of the Project site. There are no significant commercial or recreational structures or features within the immediate vicinity of the Project site, with the exception of Belews Lake.

2.1.1.2 Site Area Description and Site Map

Figure 2.1-5 shows the general layout of the Project site. As discussed above, the Project site is separated into three Plant Complexes. The three Plant Complexes are designated as the North, Middle, and South Plant Complexes. The power block areas shown in the figure represent composite footprints based on the technologies and number of units being considered for each Plant Complex. The figure also shows the potential locations of the Project site switchyard, cooling towers, cooling tower makeup intake, and the planned discharge location of other station liquid effluents. The temporary laydown areas depicted may be repurposed following construction for site support buildings, material storage, parking areas, or be restored. The proposed EAB developed for each Plant Complex planned for the Project site are also shown on Figure 2.1-5. The distance from each plant feature to its respective EAB can be estimated using the graphic scale provided on the figure.

Figures 2.1-1 through 2.1-4 show the proximity of the site to highways, railroads, and waterways in the vicinity of the Project site. Figures 2.1-2 and 2.1-3 show the location of the Project site with respect to the surrounding municipalities within a 6-mi. (10-km) and 50-mi. (80-km) radius, respectively. Access to the project site is available by road using the Duke Power Steam Plant Road (Rd), via Pine Hall Rd, or using Craig Rd, via State Highway 65.

As discussed further in Section 2.2.2.6 and shown in Figure 2.1-2, there is a Norfolk Southern (NS) rail line that runs within approximately 1.5 mi. (2.4 km) of the site, with a spur that serves the BCSS and the proposed Project site. Figure 2.1-4 identifies the principal transportation means including major airports, highways, and railways in the Project site region. The area is served by the Smith Reynolds Airport (Winston-Salem, NC) and the Piedmont Triad International Airport (Greensboro, NC).

The Project site has nearby access to 230 kV transmission lines. Three double-circuit 230 kV transmission lines cross the Project site. Duke Energy Corporation owns and operates the lines.

2.1.2 EXCLUSION AREA AUTHORITY AND CONTROL

2.1.2.1 Authority

As discussed in Section 2.1.1.1 and shown in Figure 2.1-5, the Project site is approximately 1187 ac. (480 ha) and situated on a peninsula that extends into Belews Lake. As shown in Figure 2.1-6, Duke Energy, the applicant for the ESP, owns the Project site, Belews Lake, and all the land within and immediately adjacent to Belews Lake. That ownership also includes the

mineral rights to those properties. Figure 2.1-5 shows the proposed EAB for each Plant Complex proposed for the Project site. The proposed EABs reside, in their entirety, within the property owned and controlled by Duke Energy. Duke Energy grants shoreline access leases to property owners adjacent to Belews Lake to enable their access to the lake.

As shown in Figures 2.1-2 and 2.1-5, there are no public transportation routes traversing the Project site or exclusion areas.

There are no mineral resources, including oil and natural gas being exploited within or adjacent to the site.

Duke Energy holds existing easements for transmission lines and a natural gas pipeline that traverse the Project site. These easements are illustrated in Figure 2.1-1 of the Environmental Report. The transmission lines are owned and operated by Duke Energy, and the gas line is owned and operated by the Piedmont Natural Gas Company, a Duke Energy business unit. Accordingly, while these easements pass through the North Plant Complex EAB, they do not impact Duke Energy's authority to control access to the Project site and determine activities within any of the three Plant Complex exclusion areas.

2.1.2.2 Control of Activities Unrelated to Plant Operation

As shown in Figure 2.1-5, there are no residences or commercial activities within the proposed EABs. As owner of the land within the EABs, Duke Energy determines all activities within the exclusion areas and has the authority to exclude and remove personnel and property from the area and prohibit recreational activities within the areas. As discussed above, there are no public highways or active railroads that traverse the exclusion areas.

The owner-controlled area for the Project site will be determined during the development of the physical security plan in support of the construction permit or license application. The owner-controlled area will include physical barriers as needed to satisfy the physical protection program design requirements of 10 CFR 73.55(b). The owner-controlled area is to be clearly posted with "no trespassing" signs along its border over land. Where the EABs extend over Belews Lake, Duke Energy plans to install buoys or other suitable barriers to demarcate the EABs in this area and provide notification to recreational users of the lake that crossing the boundary is prohibited. All road access points to the Project site will be controlled. Once inside the owner-controlled area, access to the nuclear plant will be controlled with security checkpoints and barriers. The site's physical security plan contains information on actions to be taken by security force personnel in the event of unauthorized persons crossing an EAB by land or water. The permanent population distribution within the EAB is zero.

An existing historic cemetery located on the Project site within the Middle Plant Complex will require relocation to a suitable off-site location.

2.1.2.3 Arrangements for Traffic Control

Arrangements for control of traffic in the event of an emergency are not required in that no

publicly used transportation routes cross the EABs.

2.1.2.4 Abandonment or Relocation of Roads

There are no public roads within the exclusion area (see Figure 2.1-5).

2.1.3 POPULATION DISTRIBUTION

This section provides a description of the current and projected population distribution in and around the Project site. The current population distribution surrounding the Project site was estimated based on the year 2020 United States (U.S.) Census Bureau (USCB) decennial census data (Reference 2.1-4). Population projections were developed for 2024, 2030 (the estimated construction start date), 2034 (the estimated year of plant approval), 2039 (five years following plant approval), 2049, 2059, 2069, and 2079 by calculating annualized growth rates using county population projection estimates employing data from the North Carolina Office of State Budget and Management (NCOSBM) and the University of Virginia Weldon Cooper Center for Public Service as the base (References 2.1-2, 2.1-3).

As shown in Figure 2.1-7 and Figure 2.1-8, the population distribution is described for an area extending from a one (1) mile (mi.) site bounding limit – defined by a circle centered on the preliminary Project site center point with a radius of 5280 feet (ft.) (1609.34 meters [m]) or 1.0 mi. (1.2 km) – to a concentric circle with a 50-mi. (80.5-km) radius from the Project site bounding limit. The population is estimated in 15 concentric distance bands at incremental distances from the site bounding limit and in 16 wedge-shaped directional sectors, with each sector measuring 22.5 degrees. Table 2.1-1 and Table 2.1-2 summarize the distance bands and directional sectors utilized in estimating the population distribution. Figure 2.1-7 and Figure 2.1-8 present the distance bands and directional sectors surrounding the Project site.

2.1.3.1 Resident Population

The population distribution within 50 mi. (80 km) of the Project site was computed by overlaying the 2020 USCB block group data on the grid of segments shown in Figure 2.1-7 and Figure 2.1-8 and summing the population of the block group(s) within, or partially intersecting, each segment. The ArcGIS Pro geoprocessing tool “tabulate intersection” was used to calculate overlapping areas (Reference 2.1-1). To prepare for the tabulate intersection function, individual distance and direction segment and block group areas were first calculated in ArcGIS Pro. The tabulate intersection tool was used to calculate the overlapping area of each block group-segment intersection. This value was used to calculate the proportion of the USCB 2020 Census block group population within the individual segment, assuming block group populations are spread uniformly across the block group area. The block group populations in the segment were grouped and summed to calculate a total segment population. Calculations of the proportional value and the segment population calculations were performed in Microsoft Excel.

Population projections were produced for the 26 counties and two independent cities within NC and Virgina (VA) identified as wholly or partially intersecting the 50-mi. (80.5-km) radius surrounding the Project site bounding limit. Projected annual growth rates for the identified

counties and independent cities were calculated using county population estimates from the USCB 2020 Census as the base year and the projected population growth rates from the NCOSBM and the University of Virginia Weldon Cooper Center for Public Service datasets. The projected annual growth rates were then applied to the 2020 segment populations to project forward through the construction and operational licensing period of the Project site.

2.1.3.1.1 Resident Population within 20 Miles

Figure 2.1-7 shows the general locations of the municipalities and other features within 20 mi. (32.2 km) of the Project site. According to the 2020 Census, the City of Greensboro, with a population of 299,035, is the largest municipality within 20 mi. (32.2 km) of the site (Reference 2.1-4). The closest municipality to the site is Stokesdale, a community with a 2020 Census population of 5924, located approximately 1.6 mi. (2.6 km) southeast of the Project site (Reference 2.1-4).

In 2020, the residential population within 5 mi. (8.0 km), from 5 – 10 mi. (8 – 16.1 km), and from 10 – 20 mi. (16.1 – 32.2 km) of the Project site was 16,951, 74,442, and 675,829, respectively (Table 2.1-3). Figure 2.1-9 illustrates the 2020 population within 20 mi. (32.2 km). Population projections for the years 2024 through 2079 are summarized in Table 2.1-3. Distance and directional segment population estimates for 2020, 2024, 2030, 2034, 2039, and 2079 are included in Figures 2.1-9 through Figure 2.1-14.

2.1.3.1.2 Resident Population Between 20 and 50 Miles

As detailed in Section 2.1.3.1, the 50-mi. (80.5-km) radius around the Project site includes all or parts of 26 counties and two independent cities in NC and VA (Figure 2.1-8). Estimates of the 2020 resident population and projected populations for 2024, 2030, 2034, 2039, and 2079 for the area between 20 (32.2 km) and 50 mi. (80.5 km) from the Project site are shown in Figure 2.1-15 through Figure 2.1-20. The total area resident population and projections between zero and 50 mi. (80.5 km) are summarized in Table 2.1-4.

2.1.3.2 Transient Population

2.1.3.2.1 Transient Population within 20 Miles

While the Project site is in a relatively rural area, the 20 mi. (32.2 km) region surrounding the site contains a significant transient population associated with the Piedmont metropolitan area. The cities of Greensboro, High Point, and Winston-Salem anchor the Piedmont metropolitan area (Piedmont Triad). Data on significant transient population sources within 20 mi. (32.2 km) of the Project site were collected from a variety of public sources to estimate current and projected populations associated with major employers, schools, medical facilities, lodging facilities, and recreational areas and venues. The area's transient population also includes several regional airports and detention facilities.

Outdoor recreation is an important recreational pastime in the Piedmont Triad metropolitan area and a large draw for transient population into the region. The 20 mi. (32.2 km) area contains

multiple state and county parks, as well as community centers and historic places, athletic complexes, and other outdoor activities associated with the region's various lakes and rivers. Projects in development like Forsyth County's Belews Lake Park, Piedmont Land Conservancy's Shoebuckle Tract (recently acquired by the NC Forest Service and will be known by the Dan River Educational State Forest), and VA's Mayo State Park indicate that recreational land use, already widespread, is of increasing importance in the region.

The urban areas of Winston-Salem and Greensboro provide many opportunities for employment at large facilities. While many employees of these facilities are likely to be area residents, others are likely to commute from outside the region. Major regional medical facilities and multiple residential colleges and universities are also found in Winston-Salem and Greensboro.

Transient visitor data was gathered through publicly available information such as government and corporate websites, federal databases, tourism sites, and aggregators of service provider records for the region. Raw transient population estimates were weighted according to the length of time each population group was expected to be in the 20 mi. (32.2 km) area. Weighted transient population estimates were rounded to the nearest whole number to avoid estimating a fraction of a person. The transient population estimates were assumed to be reflective of 2020. Projected transient populations were computed with the same methodology used to develop the resident population projections.

Table 2.1-5 summarizes the unweighted and weighted transient population estimates by facility type within 20 mi. (32.2 km) of the site.

2.1.3.2.2 Transient Population Between 20 and 50 Miles

Airports, residential schools, detention facilities, hospitals, major recreation areas, and large events and venues are located between 20 and 50 mi. (32.2 to 80.5 km) from the Project site. Within the 20 to 50 mi. (32.2 to 80.5 km) area, there are 41 significant events and attractions identified that may contribute to over 700,000 daily visitors to the larger region. Notably, the Piedmont Triad metropolitan area hosts the Carolina Classic Fair, which averages 325,000 visitors each year (Reference 2.1-5). Significant sources of transient population in this area were noted but not added to segment populations in the 20 to 50 mi. (32.2 to 80.5 km) area. Table 2.1-6 details known transient facilities and attractions with their capacity and attendance estimates between the 20 and 50 mi. (32.2 and 80.5 km) area.

2.1.3.2.3 Total Resident and Transient Population

The estimated 2020 resident and weighted transient population values were combined and then projected to obtain an estimate of the total population surrounding the Project site. All estimates were rounded to the nearest whole number to avoid estimating a fraction of a person. Table 2.1-7 displays the combined resident and weighted transient population within 20 mi. (32.2 km) of the Project site for 2020 through 2079. Figure 2.1-9 through Figure 2.1-14 show the combined resident and weighted transient populations within 20 mi. (32.2 km) of the Project site for 2020, 2024, 2030, 2034, 2039, and 2079.

2.1.3.3 Exclusion Area and Low Population Zone

As discussed in Section 2.1.1.2, an EAB has been developed for each Plant Complex proposed for the Project site. An EAB has been developed based on the technologies being considered for each Plant Complex, and the associated number of units for each technology being considered for each Plant Complex. For the Project site, the EAB for each Plant Complex also represent the Low Population Zones (LPZs) established for each Plant Complex. Figure 2.1-5 shows the Plant Complexes, planned site features, and the EAB for each Plant Complex. As shown in Figure 2.1-5, there are no resident or transient populations existing within the EABs and LPZs. Desktop reconnaissance of aerial imagery confirmed that no housing structures are located within the EAB and LPZ. No facilities or other attractions, including schools, parks, hospitals, or prisons, were identified in the EAB and LPZ that would attract additional transient populations. The nearest transient facilities to the Project site within one (1) mi. (1.6 km) of the bounding limit include the Bella Collina Mansion (0.2 mi. [0.3 km] southeast), Humphrey's Ridge Family Marina (0.7 mi. [1.1 km] east-northeast), the NC Wildlife Resources Commission Pine Hall Public Boat Ramp (0.9 mi. [1.4 km] north), and the future Forsyth County Belews Lake Park (0.4 mi. [0.6 km] south).

2.1.3.4 Population Center

The nearest population center to the Project site with more than 25,000 residents is the Town of Kernersville, NC, with a 2020 population of 26,449 (Reference 2.1-4). The closest boundary of Kernersville is approximately 7.7 mi. (12.4 km) from the Project site bounding limit, exceeding the minimum distance specified by 10 CFR 100.11(a)(3).

Population projections from 2024 to 2079 using the same methods described in Section 2.1.3.1 were also calculated for all municipalities within 50 mi. (80.5 km) of the Project site. Table 2.1-8 presents the projected municipality populations.

2.1.3.5 Population Density

The NRC Regulatory Position C.4 in Regulatory Guide (RG) 4.7, Rev. 4, *General Site Suitability Criteria for Nuclear Power Stations*, and NUREG-0800 (Section 2.1.3,"Population Distribution") provide guidance on suitable population densities, including weighted transient population, for the area surrounding a nuclear power plant site. Given a construction start date of 2030 for the first unit, the first full year of commercial operations in 2034, and an operational period of 40 years, operations could extend until 2079. Figure 2.1-21 is a plot of estimated population density against radial distance from the plant. Population curves were plotted to illustrate the Project site vicinity population density in comparison to the regulatory guidance for population density. The population curves show the estimated cumulative 2024 population within 20 mi. (32.2 km) of the site and estimated cumulative populations for 2030, 2034, 2039, and 2079. On the same figure, for the same radial distances, regulatory guidance population curves are plotted for hypothetical densities of 500 persons per square mile (sq. mi.) and 1000 persons per sq. mi. This information is also presented in Table 2.1-9. Based on these projections, population densities, averaged over any radial distance out to 10 mi. (16.1 km) for 2024, 2030, 2034, and

2039, are expected to be less than 500 persons per sq. mi. over the lifetime of the new units. However, population densities averaged to 20 mi. (32.2 km) are expected to be greater than 500 persons per sq. mi. through 2039. As noted in Figure 2.1-21, the population projections are not significantly above 500 persons per sq. mi. and are considered acceptable given they are not well in excess of this value. Population densities averaged over any radial distance at the end of the Project site licensing period (2079) are expected to be less than 1000 persons per sq. mi. Therefore, the projected population distribution meets the intent of the regulatory guidance and is considered acceptable for site suitability.

As provided in Sections 2.1.2, 2.1.3, and 13.3, and as further supported by the analyses in Chapter 15, sufficient details have been provided regarding the site location, site area, surrounding population distribution, and emergency planning considerations to allow the staff to evaluate that the relevant requirements of 10 CFR 52.17(a)(1) and 10 CFR Part 100 have been met.

Table 2.1-1
Distance Bands

Distance from Project Site Center Point	Distance from Site Bounding Limit (Distance Band)		
	mi.	km	ft.
1.0 to 1.3 mi.	0 to 0.3	0.0 to 0.5	0 to 1584
1.3 to 2.0 mi.	0.3 to 1	0.5 to 1.6	1584 to 5280
2.0 to 3.0 mi.	1 to 2	1.6 to 3.2	5280 to 10,560
3.0 to 4.0 mi.	2 to 3	3.2 to 4.8	10,560 to 15,840
4.0 to 5.0 mi.	3 to 4	4.8 to 6.4	15,840 to 21,120
5.0 to 6.0 mi.	4 to 5	6.4 to 8.0	21,120 to 26,400
6.0 to 7.0 mi.	5 to 6	8.0 to 9.7	26,400 to 31,680
7.0 to 8.0 mi.	6 to 7	9.7 to 11.3	31,680 to 36,960
8.0 to 9.0 mi.	7 to 8	11.3 to 12.9	36,960 to 42,240
9.0 to 10.0 mi.	8 to 9	12.9 to 14.5	42,240 to 47,520
10.0 to 11.0 mi.	9 to 10	14.5 to 16.1	47,520 to 52,800
11.0 to 21.0 mi.	10 to 20	16.1 to 32.2	52,800 to 105,600
21.0 to 31.0 mi.	20 to 30	32.2 to 48.3	105,600 to 158,400
31.0 to 41.0 mi.	30 to 40	48.3 to 64.4	158,400 to 211,200
41.0 to 51.0 mi.	40 to 50	64.4 to 80.5	211,200 to 264,000

Key: feet = ft; mi. = mile

Notes:
(a) Per the USCB, population centers are categorized as cities, towns, villages, or Census Designated Places (CDP).
(b) USCB 2020 Census Population Estimate, Redistricting Data Table P1.
(c) Nine North Carolina municipalities were discovered to cross county boundaries. Population growth rates were assigned based on the proportion of each municipality in its intersecting county.

Population centers identified by performing an intersection between North Carolina and Virginia municipalities and the project's 50 mi. radius in ArcGIS.
Projected populations were calculated using annual county population growth rates for 2020-2070 and applied to each intersecting population center. Highlighted rows (bold text) indicate population centers that are either greater than 25,000 people or will grow to greater than 25,000 during the lifetime of the proposed project.
Projected population center population calculation results abbreviated to key analysis years for presentation purposes.

2.2 NEARBY INDUSTRIAL, TRANSPORTATION, AND MILITARY FACILITIES

This section establishes whether the effects of potential accidents in the site vicinity from present and projected industrial, transportation, and military installations and operations should be used as design-basis events for plant design parameters related to the selected accidents. Facilities and activities within the 5-mi. (8-km) vicinity of the Project site are considered to meet the guidance in NUREG-0800. Facilities and activities at greater distances are included as appropriate based on their potential for affecting plant safety-related features.

2.2.1 LOCATIONS AND ROUTES

The proposed Project site is located in the southeastern corner of Stokes County, NC, just north of Belews Creek Township, NC, extending slightly into the northeastern corner of Forsyth County, NC, and adjacent to Belews Lake. The Project site is approximately 14 mi. (23 km) northeast of Winston-Salem, NC and approximately 19 mi. (31 km) northwest of Greensboro, NC. Potential hazardous facilities and routes within the 5 mi. (8 km) vicinity of the Project site, and airports within 20 mi. (32 km) of the site were identified along with facilities at a greater distance in accordance with the following:

RG 1.70, Rev. 3, *Standard Format and Content of Safety Analysis Reports for Nuclear Power Plants (LWR Edition)*

RG 1.78, Rev. 2, *Evaluating the Habitability of a Nuclear Power Plant Control Room During a Postulated Hazardous Chemical Release*

RG 1.91, Rev. 3, *Evaluations of Explosions Postulated To Occur at Nearby Facilities and on Transportation Routes Near Nuclear Power Plants*

RG 1.206, Rev. 1, *Applications for Nuclear Power Plants*

RG 4.7, Rev. 4, *General Site Suitability Criteria for Nuclear Power Stations*

Relevant sections of 10 CFR Parts 50, 52, and 100

Major facilities and transportation routes identified are listed below along with the figure that shows their location relative to the Project site. Major facilities are those that store chemicals as identified on a Tier II report submitted under Sections 311 and 312 of the U.S. Environmental Protection Agency (USEPA) Emergency Planning and Community Right-to-Know Act that pose a hazard to the nuclear facility.

- Industrial facilities (Figure 2.2-1)

There are no military bases, oil wells, gas wells, underground gas storage facilities, or navigable waterways identified in the vicinity of the Project site

2.2.2 DESCRIPTIONS

Industrial, transportation, and military facilities located in the vicinity of the Project site are identified in Section 2.2.1 and are described in the subsequent sections.

2.2.2.1 Descriptions of Facilities

The following sections provide short descriptions of the industrial, transportation, and military facilities located within 5 mi. (8 km) of the Project site, based on available information. The facilities of interest are summarized in Table 2.2-1. The location of facilities within 5 mi. (8 km) of the Project site are shown on Figure 2.2-1. For the purpose of identifying nearby hazards, the Project site is represented as a 1 mi. (1.6 km) radius circle around the site center. This 1 mi. (1.6 km) radius circle defines the site bounding limit. A second 6-mi. (10-km) radius circle is drawn to identify any facilities that come within 5 mi. (8 km) of the 1-mi. (1.6-km) radius circle. Distances from the Project site are measured from the site bounding limit 1 mi. (1.6 km) circle for most hazards. Some hazards that are close to the Project site, or within the site bounding limit, required more refined distance measurements. There are three Plant Complexes within the Project site and each Plant Complex has a power block within it. Refined distances for nearby hazards are measured from the nearest Plant Complex power block. The Plant Complex power blocks are shown in Figure 1.2-3.

Facilities further than 5 mi. (8 km) from the Project site bounding limit do not present a credible hazard. For example, the Pine Needle liquified natural gas (LNG) facility located 5.5 mi. (8.9 km) southeast of the Project site was evaluated and determined not to present a credible hazard. The only significant facility outside of 5 mi. (8 km) is Vulcan Materials Co. since potentially hazardous materials are shipped to Vulcan Materials Co. via roadways within 5 mi. (8 km) of the Project site.

2.2.2.2 Descriptions of Products and Materials

Detailed information regarding hazardous and explosive chemicals in the vicinity of the Project site due to facilities or transportation routes (described in the sections below) is provided in Tables 2.2-2 through 2.2-5. Information provided includes toxicity and explosion limits, quantity, and shipment frequency (if available).

The tables only include chemicals which could pose a toxic or explosive hazard to the Project site. If a chemical presents neither a toxic nor explosive hazard, it is not presented in the tables.

Toxicity screenings were performed based on the guidance in RG 1.78, while explosivity screenings were performed based on a chemical's vapor pressure relative to its lower explosive limit (if applicable). RG 1.78 screenings for potential toxic hazards are based on chemical toxicity, quantity, vapor pressure, and number of shipments per year (for transported chemicals). Because a reactor technology has not been selected, the screening described in RG 1.78, Appendix A, based on distance from the Project site, chemical toxicity, weather, and control room parameters was performed using a bounding set of control room parameters from a survey of potential technologies. The bounding set of control room parameters yields 2.64 air changes per hour (ACH) for the control room envelope. If the selected technology has a safety-related control room, it will be confirmed that the control room envelope air change rate is less than or equal to 2.64 ACH or the habitability analysis will be updated accordingly.

2.2.2.2.1 Belews Creek Steam Station

BCSS is north of the Project site center and within the 1 mi. (1.6 km) bounding limit, as identified on Figure 2.2-1. The BCSS is a two-unit coal and natural gas-fired power plant. [[

]]^{SRI} There is a rail spur line that is used to transport coal and [[ ]]^{SRI} to the steam station as shown in Figure 2.2-2. Other toxic and explosive chemicals stored at the BCSS are included in Table 2.2-2. Toxic and explosive chemicals transported via truck and rail are included in Tables 2.2-4 and 2.2-5.

2.2.2.2.2 Wieland Copper

Wieland Copper is a copper supplier located 3.7 mi. (6 km) north of the Project site. Toxic and explosive chemicals stored at Wieland Copper are included in Table 2.2-2. Toxic and explosive chemicals transported via truck and rail are included in Tables 2.2-4 and 2.2-5.

2.2.2.2.3 Endura Products

Endura Products is a supplier of residential exterior door components located 4.9 mi. (7.9 km) east-southeast of the Project site. Toxic and explosive chemicals stored at Endura Products are included in Table 2.2-2. Toxic and explosive chemicals transported via truck and rail are included in Tables 2.2-4 and 2.2-5.

2.2.2.2.4 Hall Oil and Propane

Hall Oil and Propane is a propane supplier located 4.0 mi. (6.4 km) northwest of the Project site. Toxic and explosive chemicals stored at Hall Oil and Propane are included in Table 2.2-2. Toxic and explosive chemicals transported via truck and rail are included in Tables 2.2-4 and 2.2-5.

2.2.2.2.5 Parkdale Mills

Parkdale Mills is a small textile manufacturer located 3.6 mi. (5.8 km) northwest of the Project site. Toxic and explosive chemicals stored at Parkdale Mills are included in Table 2.2-2. Toxic and explosive chemicals transported via truck and rail are included in Tables 2.2-4 and 2.2-5.

2.2.2.2.6 Vulcan Materials Company

Vulcan Materials Co. is located 5.8 mi. (9.3 km) east-southeast from the Project site. Vulcan Materials Co. is a supplier and manufacturer of construction materials including gravel, sand, and crushed stone. This facility utilizes explosives for blasting operations at the quarry that are shipped via US-158 as indicated in Table 2.2-4.

2.2.2.2.7 Oliver Diesel and Auto Repair, Mobil, and Pure

There are gas stations and auto repair shops located within 5 mi. (8 km) of the Project site, specifically Oliver Diesel and Auto Repair, Mobil, and Pure. The potentially toxic and explosive chemicals stored at these facilities are listed in Table 2.2-2.

2.2.2.3 Description of Pipelines and Mining Operations

There is one pipeline within 5 mi. (8 km) of the Project site. The pipeline is operated by Piedmont Natural Gas Co., a Duke Energy business unit, and transports odorized natural gas to the BCSS. The distance of the pipeline from the Project site as well as the available data for design pressure, pipe size, and capacity, is presented in Table 2.2-3.

There are no mining operations identified within 5 mi. (8 km) of the Project site.

2.2.2.4 Description of Waterways

Waterways in the vicinity of the Project site include Belews Lake, Belews Creek, and the Dan River. There is no commercial freight traffic or navigable waterways where hazardous commodities would be shipped within 5 mi. (8 km) of the Project site.

2.2.2.5 Description of Highways

The survey of chemical hazards transported by truck considers those chemicals known to be stored or shipped in the vicinity of the Project site based on the stationary facility survey presented in Section 2.2.2.2.

There are three major roadways within 5 mi. (8 km) of the Project site: NC-65, US-311, and US-158 as shown in Figure 2.2-2. At their closest points, NC-65, US-311, and US-158 are approximately 1.1 mi. (1.8 km), 3.2 mi. (5.2 km), and 2.2 mi. (3.5 km) from a 1 mi. (1.6 km) radius circle surrounding the Project site center, respectively. A radius larger than 5 mi. (8 km) was considered when identifying chemical hazards stored near the site as these chemicals may be transported within 5 mi. (8 km) of the site along the nearby roadways. The survey identified several facilities farther than 5 mi. (8 km) from the site but located close to one or more of these roadways. Additionally, one of these facilities, Vulcan Materials Co., identified Orica, an explosives supplier that is not close to the site, which sometimes ships chemicals for blasting to Vulcan Materials Co. on a route that includes US-158.

Table 2.2-4 presents the identified toxic and explosive hazardous chemicals transported along the major roadways. Unless specific maximum transported quantities were provided by facilities

along the roadways, trucks are considered to contain 50,000 pounds (lb.) (22,700 kilograms [kg]) of chemical consistent with RG 1.91.

2.2.2.6 Description of Railroads

There is one NS rail line within 5 mi. (8 km) of the Project site. The NS line is northwest of the site coming within 1.5 mi. (2.4 km) of the Project site at its closest point. Additionally, there is a spur off this line leading to the BCSS which is less than 1 mi. (1.6 km) from the Project site center point. The railroad spur is approximately 0.4 mi. (0.6 km) from the nearest Plant Complex power block. Railways are shown in Figure 2.2-2.

The list of chemicals transported provided by the railroad operators was screened and reduced to the list of potentially hazardous chemicals presented in Table 2.2-5. Chemicals shipped fewer than 30 times per year (the RG 1.78 definition of frequent for rail traffic) are not identified as potential toxic hazards; however, these chemicals are evaluated as potential explosive hazards.

2.2.2.7 Description of Airports, Aircraft, and Airway Hazards

NUREG-0800 establishes that the risks as the result of aircraft hazards should be sufficiently low, in that it requires that aircraft accidents that could lead to radiological consequences in excess of the exposure guidelines of 10 CFR 50.34(a)(1) with a probability of occurrence greater than an order of magnitude of 10^{-7} per year should be considered in the design of the plant.

However, Section 3.5.1.6 of NUREG-0800 provides that 10 CFR 100.20, 10 CFR 100.21, and 10 CFR 52.17 requirements are met if the probability of aircraft accidents resulting in radiological consequences greater than the 10 CFR Part 100 exposure guidelines is less than an order of magnitude of 10^{-7} per year. Additionally, these guidelines provide that the probability is considered to be less than an order of magnitude of 10^{-7} per year by inspection if the distances from the plant meet all of the criteria listed below:

1. The plant-to-airport distance, D, is between 5 and 10 statute mi. (8 and 16 km), and the projected annual number of operations is less than 500 D^2, or the plant-to-airport distance, D, is greater than 10 statute mi. (16 km), and the projected annual number of operations is less than 1000 D^2.

2. The plant is at least 5 statute mi. (8 km) from the nearest edge of military training routes, including low-level training routes, except for those associated with usage greater than 1000 flights per year, or where activities (such as practice bombing) may create an unusual stress situation.

3. The plant is at least 2 statute mi. (3.2 km) beyond the nearest edge of a federal airway, holding pattern, or approach pattern.

Therefore, utilizing the proximity criteria presented above, a screening analysis was first performed to establish whether the probability of aircraft accidents for the Project site is considered to be less than an order of magnitude of 10^{-7} per year by inspection. The screening

and analysis of airport and airway hazards uses distances measured from the hazard to the Project site boundary as defined in Figure 2.1-1.

2.2.2.7.1 Airports

There are two airfields within 5 statute mi. (8 km) of the Project site boundary: Meadow Brook Field (N63) and DS Butler Farm and Airfield (N83).

Meadow Brook Field is located 4.7 statute mi. (7.6 km) west-northwest of the Project site boundary. The most recent Meadow Brook Field FAA filing listed 12,050 total annual operations. Due to its proximity to the site, the airport owner was contacted. The owner confirmed that the current operations are accurate; however, the airport is installing two new airplane hangars and is hoping to expand to approximately 30,000 total operations annually.

DS Butler Farm and Airfield is located 5 statute mi. (8 km) south-southeast of the Project site boundary. The most recent DS Butler FAA filing listed 2100 total annual operations. Due to its proximity to the site, the airport owner was contacted. The owner confirmed that the reported annual operations are accurate and are not expected to grow.

There are four airports between 5 statute mi. (8 km) and 10 statute mi. (16 km) of the Project site boundary: Dusenbury Field (13NR), Lindsay (0NC7), Lewis Airstrip (7NC7), and Meylor Field (9NC9). There are eight airports between 10 statute mi. (16 km) and 20 statute mi. (32 km) of the site: Robertson Field (NC63), Smith Reynolds (INT), Piedmont Triad International (GSO), Mountain View Aerodrome (NC37), Air Harbor (W88), Warf (NR33), Rockingham County NC Shiloh (SIF), and Moorefield's Airstrip (VA27).

Although Piedmont Triad International (GSO) currently satisfies the screening criteria for allowable airport operations in NUREG-0800, Section 3.5.1.6, it is projected that this limit will be exceeded during the life of the plant. Because of this, all runways, approach patterns, and holding patterns for Piedmont Triad International (GSO) were evaluated to ensure the risks associated with operations into and out of GSO are properly quantified. One approach pattern, approach and landing (AL) 178 to Runway 14, lies within 2 statute mi. (3.2 km) of the Project site boundary. Because of this, Piedmont Triad International was contacted to better understand operations on this approach pattern. Per airport staff, there were 72,000 total operations at Piedmont Triad International (GSO) from March of 2023 to March of 2024. This value is slightly higher than what was reported on the most recent FAA filing.

Runway 14 is oriented 140 degrees from North and is the shortest runway at Piedmont Triad International (GSO) with a length of 6380 ft. In the timeframe from March 2023 to March 2024 there were only 220 landing operations on Runway 14. This value was doubled (i.e., 440 operations) to accurately quantify the total number of operations (takeoffs and landings) on Runway 14. Additionally, the total number of operations was scaled proportional to the total 2050 projected operations to conservatively maximize the associated probabilistic risk resulting in 834 total operations. All operations on this runway are assumed to utilize the portion of approach pattern AL-178 that comes within 2 statute mi. (3.2 km) of the Project site boundary.

In addition to the approach and holding patterns for Piedmont Triad International (GSO), the approach and holding patterns for Meadow Brook Field (N63) and Smith Reynolds (INT) were also evaluated. Other airports within 10 statute mi. (16 km) do not have holding or approach patterns. None of these holding or approach patterns come within 2 statute mi. (3.2 km) of the Project site boundary. Therefore, no further analysis is required for approach and holding patterns associated with Meadow Brook Field (N63) and Smith Reynolds (INT).

The airports discussed above are identified in Table 2.2-6 and shown in Figure 2.2-4. The table also includes information for Charlotte/Douglas International (CLT), the largest airport in NC. The table includes the distance from the Project site boundary, current annual operations categorized by type, projected future operations (where available), and the screening value for number of allowable operations below which further analysis is not required.

Based on the number of operations and proximity to the Project site boundary, the only airports requiring quantitative aircraft hazard evaluation are Meadow Brook Field (N63), DS Butler Farm and Airfield (N83), and Piedmont Triad International (GSO) Runway 14. NUREG-0800, Section 3.5.1.6, provides methodology for the evaluation of crash frequency for airport and non-airport operations; however, some specific information required to implement the methodology is not available (e.g., flight count on airway routes, methodology for computation of effective area of the plant, etc.). Therefore, an alternate methodology outlined in U.S. Department of Energy (DOE) Standard DOE-STD-3014-2006, herein referred to as the DOE standard, is used (Reference 2.2-13). Prior NRC acceptance of the DOE standard methodology is documented in the safety evaluation for Chapter 3 of the PSEG early site permit application (ESPA) (Reference 2.2-15).

The airport operation crash impact frequency evaluation is determined using the following four-factor formula:

$$F_j = N_j \cdot P_j \cdot f_j(x,y) \cdot A_j \qquad \text{(Equation 2.2-1)}$$

Where:

F_j = site crash frequency per year for aircraft class j

j = each aircraft class suggested in the DOE standard

N_j = expected number of flights per year for aircraft class j

P_j = aircraft takeoff and landing crash rates for aircraft class j

$f_j(x,y)$ = probability, given a crash, that the crash occurs in a 1 sq. mi. (2.6 sq. km) area surrounding the plant

A_j = effective plant area in sq. mi.

Table B-1 of the DOE standard provides P_j values for airport takeoffs and landings, while Tables B-4 and B-5 of the DOE standard provide $f_j(x,y)$ values for airport takeoffs and landings for

general aviation aircraft (Reference 2.2-13). Only the general aviation aircraft class data is needed since the airports requiring detailed evaluation only use general aviation aircraft.

The effective plant area depends on the length, width, and height of the new plant, as well as the aircraft's wingspan, skid distance, and impact angle as explained in Section B.4 of the DOE standard and below (Reference 2.2-13).

$$Aj = Afj + Asj \quad \text{(Equation 2.2-2)}$$

$$Af_j = H \cot(\Phi)_j (WS_j + R) + (2 L W WS) / R + L W \quad \text{(Equation 2.2-3)}$$

$$As_j = S_j (WS_j + R) \quad \text{(Equation 2.2-4)}$$

$$R = (L^2 + W^2)^{0.5} \quad \text{(Equation 2.2-5)}$$

Where:

A_j = effective plant area for aircraft class j.

Af_j = effective fly-in area for aircraft class j.

As_j = effective skid area for aircraft class j.

WS_j = aircraft wingspan for aircraft class j (Page B-28 of DOE standard).

R = length of the diagonal of the plant, reactor technology specific.

H = plant height, reactor technology specific.

$\cot(\Phi)_j$ = mean of the cotangent of the aircraft impact angle for aircraft class j (Page B-29 of DOE standard).

L = length of plant, reactor technology specific.

W = width of plant, reactor technology specific.

S_j = aircraft skid distance for aircraft class j (Page B-29 of DOE standard).

Meadow Brook Field uses only general aviation aircraft. The total crash frequency for general aviation aircraft is 4.33×10^{-6} crashes per year for takeoffs and landings at Meadow Brook Field.

DS Butler Farm and Airfield uses only general aviation aircraft. The total crash frequency for general aviation aircraft is 4.26×10^{-7} crashes per year for takeoffs and landings at DS Butler Farm and Airfield.

Approaches to Runway 14 of Piedmont Triad International may come within 2 mi. (3.2 km) of the Project site boundary and have a crash frequency of 4.51×10^{-8} crashes per year.

There is a single heliport located within 20 statute mi. (32 km) of the Project site boundary. NC Baptist Hospital heliport is located 16 statute mi. (26 km) from the Project site boundary and has

significantly less than the 256,000 operations per year screening limit.

2.2.2.7.2 Airways

Federal airways within 10 statute mi. (16 km) of the Project site boundary are identified and are shown in Figure 2.2-5. There are five airways within 10 statute mi. of the Project site boundary. The center of airway V-20/T-224 is located approximately 1.9 statute mi. (3.1 km) from the site boundary, the center of airway V-45 is located approximately 3.1 statute mi. (5 km) from the site boundary, the center of airway V-103 is located approximately 3.5 statute mi. (5.6 km) from the site boundary, the center of airway V-143 is located approximately 11 statute mi. (18 km) from the site boundary, and the center of airway IR-719 is located 13 statute mi. (21 km) from the site boundary. Commercial airways are generally 8 nautical miles (NM) (15 km) wide and military airway IR-719 is 10 NM (19 km) wide. Based on the proximities of airways V-20/T-224, V-45, and V-103 to the Project site, quantitative aircraft hazard evaluation for the airways is required.

The non-airport operations crash frequency evaluation is performed using the same four-factor formula presented in Equation 2.2-1 for airport operations. For the non-airport operations, Tables B-14 and B-15 of DOE Standard DOE-STD-3014-2006 (Reference 2.2-13) provide values for the product of N_j, P_j, and $f_j(x,y)$ applicable for specific DOE sites and for a general location in the continental U.S. Since none of the DOE sites are in the vicinity of the Project site, the values for a general U.S. location are used. The effective plant area is the same as that calculated for airport operations.

The total frequency of a crash for non-airport operations for air carrier, air taxi, large and small military, and general aviation aircraft is 3.23×10^{-6} crashes per year for airways.

2.2.2.7.3 Total Aircraft Risk

Combining the crash frequency due to the airports and airways results in a total crash frequency of 8.04×10^{-6} per year. The majority of the risk is from general aviation aircraft, which have a crash frequency of approximately 7.85×10^{-6} per year. Treating all traffic on Runway 14 of Piedmont Triad International as Air Carrier, the total crash frequency for Air Carrier is 6.03×10^{-8} per year, Air Taxi is 3.31×10^{-8} per year, Large Military is 7.02×10^{-9} per year, and Small Military is 8.67×10^{-8} per year. This breakdown by aircraft type is provided in Table 2.2-8. Since the total crash frequency exceeds the 10^{-7} per year screening criterion in NUREG-0800, Section 3.5.1.6, additional evaluation is required as discussed in SSAR Section 3.5.1.6.

2.2.2.8 Projections of Industrial Growth

Research was conducted to identify planned industrial facilities that, when completed, could become a potential hazard to the Project site. Economic development representatives in each of the four counties surrounding the site, Stokes, Forsyth, Rockingham, and Guilford, were contacted to collect information. There are several ongoing and upcoming industrial projects in the surrounding counties, but none within the immediate vicinity of the Project site. Since Stokes County, where the site is located, is primarily rural and lacks developed infrastructure and nearby interstate access, many these projects are likely to be located in other counties far

enough away so as to not present a hazard to the site. Additionally, many of these projects would not require a large chemical inventory. A summary of some of the larger projects in the surrounding counties in central NC, which include the cities of Greensboro, Winston-Salem, High Point, and Kernersville, is given in Table 2.2-7.

The locations of the future facilities listed in Table 2.2-7 are all farther than 5 mi. (8 km) from the Project site and none are located along the major roadways which come within 5 mi. (8 km) of the Project site. Therefore, it is unlikely that these facilities, once built, would be required to ship chemicals near the Project site, and these projects do not affect the hazard evaluation.

2.2.3 EVALUATION OF POTENTIAL ACCIDENTS

An evaluation of the information provided in Sections 2.2.1 and 2.2.2 was performed to determine potential accidents to be considered as design-basis events, and the potential effects of these accidents on the nuclear plant in terms of design parameters (e.g., overpressure, missile energies) or physical phenomena (e.g., concentration of flammable or toxic clouds outside building structures). The potential effects of these accidents on the nuclear plant were evaluated using guidance in RG 1.78, RG 1.91, RG 4.7, and RG 1.206.

2.2.3.1 Determination of Potential Accidents

NUREG-0800 states that design-basis events in the vicinity of the nuclear plant are defined as those accidents for which the expected rate of occurrence of potential exposures resulting in radiological dose in excess of the 10 CFR 50.34(a)(1) as it relates to the requirements of 10 CFR Part 100 is estimated to exceed an order of magnitude of 10^{-7} per year. The following accident categories are considered in selecting design-basis events: explosions, flammable vapor clouds (delayed ignition), toxic chemicals, aircraft crashes, fires, collisions with the intake structure, and liquid spills.

There are two types of analyses described in this section: deterministic and probabilistic.

Deterministic analyses use a single set of worst-case, or near worst-case, conditions to show that a defined hazardous condition will not exist due to a failure external to the plant. Worst-case conditions typically include: an immediate full rupture of a tank or transportation source, worst-case weather conditions, and the closest possible location to the Project site.

RG 1.78 suggests that the weather conditions used should be the worst-case ones that are exceeded less than 5 percent of the time. In other words, a successful analysis shows that the acceptance criteria are met for more than 95 percent of weather conditions. Wind frequency data was developed at the Project site over the time period of February 7, 2024, through February 6, 2025. This data was tabulated into a joint frequency distribution (JFD) of Pasquill stability class, wind speed, and wind direction for use in gas dispersion analyses. For deterministic cases, the worst Pasquill stability class that occurs at least 5% of the time is Class F, as shown in Table 2.3-37 through 2.3-40. The minimum wind speed used in the deterministic analysis is 1.1 mph (0.5 m/s). In some deterministic cases, higher or lower wind speeds may be conservative. As a result, some deterministic analyses model several cases to show that

acceptance criteria are met for more than 95 percent of stability class and wind speed combinations.

As there is not a joint table including ambient temperature and stability class, a high analysis ambient temperature of 91 degrees Fahrenheit (°F) (33 degrees Celsius [°C]) is used. This temperature is higher than the 1 percent high cooling dry-bulb temperature at Piedmont Triad International Airport (Reference 2.2-1).

A probabilistic analysis determines the frequency of hazardous conditions using the results of many deterministic analyses. NUREG-0800 indicates that chemical sources are acceptable if the expected rate of occurrence of potential exposures resulting in radiological dose is on the order of magnitude of 10^{-7} per year. NUREG-0800 goes on to say that "an expected rate of occurrence of potential exposures resulting [in] radiological dose [on the] order of magnitude of 10^{-6} per year is acceptable if, when combined with reasonable qualitative arguments, the realistic probability can be shown to be lower." RG 1.91 states that if "estimates of explosion rate, frequency of shipment, and exposure distance are made on a realistic or best-estimate basis, an exposure rate less than $1x10^{-7}$ per year is sufficiently low. If conservative estimates are used, an exposure rate less than $1x10^{-6}$ per year is sufficiently low." For the analyses herein, the probabilistic requirement is that the frequency of hazardous conditions must be less than 10^{-6} events per year.

The general method for all probabilistic assessments comes from RG 1.91.

$$R = n \cdot f \cdot s = n1 \cdot n2 \cdot f \cdot s \qquad \text{(Equation 2.2-6)}$$

Where:

R = the exposure rate in hazardous conditions per year.

n = the rate of hazardous conditions per mi.

f = the frequency of the shipment per year.

s = the exposure distance in mi. per shipment. For fixed sources, n represents hazardous conditions per year.

For transportation hazards, the parameter n is broken up into n1, accidents per mi. for the transportation mode, and n2, hazardous conditions per accident. The values for n1, n2, f, and s are dependent on the weather conditions, chemical, storage or transportation conditions, method of transportation, transportation route or location of fixed sources, and the accident category being evaluated.

Probabilistic analyses also use the Project site joint wind speed, wind direction, and Pasquill stability class table. Similarly, the high analysis ambient temperature of 91 °F (33 °C) is used.

2.2.3.1.1 Explosions

Accidents involving detonations of explosives, munitions, chemicals, liquid fuels, and gaseous

fuels are considered for facilities and transportation routes in the vicinity of the Project site, where such materials are processed, stored, used, or transported in a sufficient quantity. Blast pressures from explosions from nearby sources were evaluated to determine if the explosion would have an adverse effect on plant operation or would prevent safe shutdown of the plant. As shown below, the explosions evaluated meet the acceptance criteria and are not design-basis hazards to the Project site.

The allowable and actual distances of hazardous chemicals transported or stored are evaluated in accordance with RG 1.91, which cites 1 pound per square inch (psi) (6.9 kilopascal [kPa]) as a conservative value of peak positive incident overpressure below which no significant damage would be expected. RG 1.91 provides the relationship between explosive energy and safe distance as:

$$R = k \cdot W^{(1/3)} \qquad \text{(Equation 2.2-7)}$$

Where:

R = the distance in ft. from the explosion.

W = the equivalent weight of trinitrotoluene (TNT) in lb.

k = the scaled distance for a given overpressure. For a 1 psi (6.9 kPa) overpressure, k is 45 $ft/lb^{1/3}$ (18 $m/kg^{1/3}$).

The method to determine the equivalent weight of TNT is dependent on the storage conditions of the chemical hazard. For gaseous and liquid chemicals, the equivalent weight of TNT is calculated by scaling the explosive chemical mass by the ratio between the heat of combustion of the explosive chemical with the heat of combustion of TNT, as shown in Equation 2.2-8.

$$W = \alpha \cdot \Delta H_c \cdot m / \Delta H_{TNT} \qquad \text{(Equation 2.2-8)}$$

Where:

α = the yield of the explosion.

ΔHc = the heat of combustion of the chemical.

m = the explosive mass of the chemical.

ΔH_{TNT} = the heat of combustion of TNT, 1900 British Thermal Unit (BTU)/lb (4500 KJ/kg) per RG 1.91.

For solid chemicals, RG 1.91 states that a minimum yield of 1 should be used (i.e., the mass of explosive material is used as the mass of TNT in Equation 2.2-7).

Additionally, boiling liquid expanding vapor explosions (BLEVE) are considered for chemicals that are gases at standard conditions but are stored as a liquid (e.g., ammonia). Overpressure due to a BLEVE is caused by the rapid expansion of a chemical from its storage conditions. The BLEVE expansion occurs isentropically and the energy release is calculated using the change

in internal energy before and after expansion.

$$x = (s_{stor} - s_f) / (s_v - s_f) \quad \text{(Equation 2.2-9)}$$

$$\Delta u = u_{stor} - (u_v \cdot x + u_f (1 - x)) \quad \text{(Equation 2.2-10)}$$

Where:

x = the fraction of the gas that flashes to vapor.

s = entropy, u is internal energy, the subscript ‘stor’ refers to the liquid storage conditions, the subscript v refers to the post-expansion vapor conditions, and the subscript f refers to the post-expansion liquid conditions. The change in internal energy is substituted into Equation 2.2-8 to determine the equivalent weight of TNT for the BLEVE as shown in Equation 2.2-11.

$$W = \Delta u \, m / \Delta H_{TNT} \quad \text{(Equation 2.2-11)}$$

Stationary explosions of [[ ]]SRI are modeled as both fully confined explosions and as semi-confined explosions. The [[ ]]SRI at the BCSS are housed in a partially open enclosure that has a greater volume than the individual storage tanks. Conservatively, the enclosure is treated as a fully confined explosion with the entire free volume filled with [[ ]]SRI at the upper explosive limit of 25 percent and an explosive yield of 100 percent. Since the explosive mass in this scenario is only a fraction of the total mass in the [[ ]]SRI, a BLEVE scenario is also evaluated. The [[ ]]SRI railcar is analyzed as a fully confined explosion with the railcar filled with gas at ambient pressure and an explosive yield of 100 percent. Finally, a conservative semi-confined explosion is analyzed that assumes the entire inventory of one railcar is released, vaporized, and ignited. The explosive yield for such semi-confined explosions is chemical dependent and set to 5 percent, 10 percent, or 15 percent per RG 1.91 and Factory Mutual Global guidelines (Reference 2.2-2). For [[ ]]SRI, a yield of 15 percent was used.

[[

]]SRI For these remaining hazards, the full inventory of the chemical is assumed released, vaporized, and ignited with an explosive yield of 100 percent.

The materials stored at nearby facilities (Table 2.2-2) and potentially transported along roadways (Table 2.2-4), railways (Table 2.2-5) and pipelines (Table 2.2-3) are evaluated to determine whether they have the potential to explode. The effects of these explosion events from external sources are described in the following sections relative to the release source.

2.2.3.1.1.1 Explosions at Nearby Facilities

The facilities listed in Table 2.2-1 were identified as facilities of concern with regard to storage of materials with the potential for explosion within the vicinity of the Project site. Each material stored at the identified offsite facilities was evaluated with respect to explosion potential. The potentially explosive materials are those with a lower explosive limit listed in Table 2.2-2. Each material was then assessed based on the identified physical properties of the material using the applicable methods from Section 2.2.3.1.1.

[[

]]SRI The tanks and supporting piping are housed beneath a roofed structure with open walls allowing ventilation to the environment. The area around the structure is unconfined. To support the stationary explosion evaluation for the [[

]]SRI At atmospheric conditions, [[ ]]SRI could be contained in this confined volume if a spill were to occur. Assuming 100 percent yield, a detonation of [[ ]]SRI gives a 1 psi (6.9 kPa) standoff distance of 333 ft (102 m), which is less than the distance to the Project site of 2100 ft. (640 m). Since the stationary explosion of [[ ]]SRI considered only the mass of confined vapor in the enclosure, a BLEVE scenario is also considered. The BLEVE assumed the catastrophic failure of one of the [[

]]SRI Approximately 20 percent of the [[ ]]SRI mass flashes to vapor which equates to an equivalent TNT mass of 78,900 lb. (35,800 kg). The BLEVE gives a 1 psi (6.9 kPa) standoff distance of 786 ft (240 m), which is less than the distance to the Project site of 2100 ft. (640 m).

The second hazard analyzed for the BCSS is 5 million lb. (2.3 million kg) of bituminous coal and bituminous coal dust. It is unlikely that this large outdoor pile of coal poses an explosion risk; however, it was conservatively assumed that 5 percent of the entire pile becomes aerosolized dust and explodes as TNT. Using this approach, the 1 psi (6.9 kPa) standoff distance is 2840 ft (866 m), which is less than the distance to the Project site of 3170 ft. (966 m).

Three explosive chemicals were analyzed for the Wieland Copper facility: gasoline, hydrogen, and odorized propane. For simplicity, each of these chemicals was analyzed by assuming the entire stored mass is released, vaporized, and detonated with a yield of 100 percent. Using this approach, the 1 psi (6.9 kPa) standoff distance for 13,200 lb. (6000 kg) of gasoline is 2280 ft. (695 m), the 1 psi (6.9 kPa) standoff distance for 2450 lb. (1110 kg) of hydrogen is 1800 ft. (549 m), and the 1 psi (6.9 kPa) standoff distance for 102,000 lb. (46,300 kg) of propane is 4590 ft. (1400 m). The standoff distance for each of these cases is substantially less than the distance to the Project site of 21,100 ft. (6430 m).

Two potentially explosive materials were identified for Endura Products: wood dust and Sherwin-Williams primer. Like the previously discussed coal dust, the wood dust was analyzed

assuming 5 percent of the mass becomes aerosolized dust and explodes as 2180 lb. (989 kg) TNT. This approach gives a 1 psi standoff distance of 583 ft. (178 m), which is significantly less than the distance to the Project site of 30,100 ft. (9170 m). The 3460 lb. (1570 kg) of Sherwin-Williams primer was not analyzed as it is bounded by nearer hazards with greater mass and heat of combustion.

Two explosive chemicals were analyzed for Hall Oil and Propane: gasoline and odorized propane. For simplicity, each of these chemicals was analyzed by assuming the entire stored mass is released, vaporized, and detonated with a yield of 100 percent. Using this approach, the 1 psi (6.9 kPa) standoff distance for 60,000 lb. (27,200 kg) of gasoline is 3780 ft. (1150 m) and the 1 psi (6.9 kPa) standoff distance for 150,000 lb. (68,100 kg) of propane is 5220 ft. (1590 m). The standoff distance for each of these cases is substantially less than the distance to the Project site of 25,900 ft. (7890 m).

One explosive chemical was analyzed for Parkdale Mills: odorized propane. For simplicity, the hazard was analyzed by assuming the entire stored mass is released, vaporized, and detonated with a yield of 100 percent. Using this approach, the 1 psi (6.9 kPa) standoff distance for 4850 lb. (2200 kg) of propane is 1660 ft. (506 m). The standoff distance is substantially less than the distance to the Project site of 22,700 ft. (6920 m).

One explosive chemical was analyzed for Oliver Diesel and Auto Repair: brake cleaner. The brake cleaner is primarily composed of acetone and was treated as acetone when performing the analysis. For simplicity, the hazard was analyzed by assuming the entire stored mass is released, vaporized, and detonated with a yield of 100 percent. Using this approach, the 1 psi (6.9 kPa) standoff distance for 404 lb. (183 kg) of acetone is 637 ft. (194 m). The standoff distance is substantially less than the distance to the Project site of 23,800 ft. (7250 m).

The Mobil and Pure gas stations each have underground gasoline storage tanks. These are minimal risk since overpressure from an explosion in the tank would be mitigated by the ground and a spill from the tanks would be released into the ground rather than into the air. For simplicity, each of these chemicals was analyzed by assuming the entire stored mass is released, vaporized, and detonated with a yield of 100 percent. Using this approach, the 1 psi (6.9 kPa) standoff distance for 12,000 gallons (gal.) (45.4 m^3) of gasoline at Mobil is 4070 ft. (1240 m). The 1 psi (6.9 kPa) standoff distance for the 4000 gal. (15.1 m^3) of gasoline at Pure is 2820 ft. (859 m). The standoff distances for each of these cases is substantially less than the actual distance from the Project site to Mobil of 23,800 ft. (7250 m) and Pure of 10,600 ft. (3230 m).

Therefore, damaging overpressures from an explosion of stored materials at each of the identified facilities would not adversely affect the operation or shutdown of units located within the Project site.

2.2.3.1.1.2 Explosions from Roadways and Railways

The materials listed in Tables 2.2-4 and 2.2-5 were identified as materials of concern with the potential for explosion on roadways and railways within the vicinity of the Project site. Each

material identified was evaluated with respect to explosion potential. The potentially explosive materials are those with a lower explosive limit listed in Tables 2.2-4 and 2.2-5. Each material was then assessed based on the identified physical properties of the material using the applicable methods from Section 2.2.3.1.1.

To simplify the evaluation, the mass of TNT that would yield a 1 psi (6.9 kPa) overpressure was determined at the shortest distance between the analyzed route and the Project site. This is defined as the allowable mass of TNT (W_{TNT} Allowable). As described in Section 2.2.2.5, the nearest major roadway is 1.1 mi. (1.8 km) from the site. The NS rail line is 1.5 mi. (2.4 km) from the Project site at its closest point per Section 2.2.2.6; however, the nearest approach of the NS rail line is 2.1 mi. (3.4 km) from the nearest of the three Plant Complex power block boundaries within the Project site. The NS rail spur off this line leading to the BCSS is 0.44 mi. (0.7 km) from the nearest of the three Plant Complex power block boundaries within the Project site. Utilizing these distances, the allowable mass of TNT for each transportation source is determined from Equation 2.2-7.

Route	Distance	W_{TNT} Allowable
Roadway	1.1 mi. (5810 ft.)	2,150,000 lb.
Railway	2.1 mi. (11,100 ft.)	14,900,000 lb.
Rail Spur	0.44 mi. (2320 ft.)	138,000 lb.

To determine acceptability of the roadway and railway hazards, the equivalent TNT was determined using Equation 2.2-8 for each postulated hazard scenario. The hazard is acceptable if the equivalent TNT is less than the allowable TNT for the applicable route.

For the roadways, the equivalent TNT was determined for each of the explosive chemicals described in Table 2.2-4. These include [[ ]]^{SRI}, gasoline, heptane, hydrogen, propane, and solid explosives. The equivalent TNT for all these postulated hazards is significantly below the allowable TNT mass of 2,150,000 lb. (975,000 kg).

For the railway, the equivalent TNT was determined for each of the explosive chemicals described in Table 2.2-5. These include acetic acid, acrylonitrile, butane, ethanol, gasoline, isopropyl alcohol, petroleum distillates, petroleum gases, propane, and xylenes. The equivalent TNT for all these postulated hazards is significantly below the allowable TNT mass of 14,900,000 lb. (6,760,000 kg).

For the rail spur, [[ ]]^{SRI} and coal dust are the only applicable explosive hazards. The [[ ]]^{SRI} railcar on the spur is analyzed two ways: as a fully confined explosion with the railcar filled with gas at ambient pressure and an explosive yield of 100 percent, and as a semi-confined explosion that assumes the entire inventory of one railcar is released, vaporized, and ignited with an explosive yield of 15 percent. The calculated equivalent TNT for the coal dust and both [[ ]]^{SRI} explosion cases is below the allowable of 138,000 lb. (62,600 kg). A BLEVE scenario was not analyzed for the [[ ]]^{SRI} railcar since the full railcar mass was used in the semi-confined explosion case and 15 percent of the heat of combustion is larger than the energy of expansion for [[ ]]^{SRI}

2.2.3.1.1.3 Explosions from Pipelines

There is one natural gas pipeline within the vicinity of the Project site as described in Table 2.2-3. A natural gas pipeline explosion occurring in the vicinity of the release point would be unconfined. A damaging detonation from an unconfined natural gas release is not credible according to the NRC safety evaluation report for a Hartsville, Tennessee, nuclear power plant (Reference 2.2-14). As such, the natural gas pipeline is not analyzed as a stationary explosion hazard. The natural gas pipeline is analyzed in subsequent sections as a source of flammable vapor clouds and jet fires.

The effects of pipeline missiles were considered consistent with methods discussed in the Indian Point pipeline hazards report (Reference 2.2-6) and the Dresden pipeline hazards report (Reference 2.2-7). The Indian Point report concluded that pipeline missiles are not a concern beyond 600 ft. (183 m) from the rupture location. The Dresden report noted that in most cases the travel distance of pipeline missiles is less than 50 percent of the potential impact radius (PIR) defined in 49 CFR 192.903. The PIR for the Piedmont pipeline is 524 ft. (160 m). Since the Piedmont pipeline is at least 790 ft. (241 m) from the nearest safety-related structures, pipeline missiles are not a concern.

2.2.3.1.1.4 Flammable Vapor Clouds

A flammable vapor cloud occurs when a flammable chemical source is released, and the vapor travels with the wind toward the site. The Plant Complex power block structures may provide confinement and ignition sources which could support a detonation that damages safety-related equipment. The acceptance criterion, therefore, is that the concentration of a chemical vapor cloud must be less than the lower explosive limit at Plant Complex power block structures where confinement and ignition sources exist.

A flammable vapor cloud analysis requires calculation of the mass release rate and downwind dispersion. The mass release rate for tanks (including fixed sources and sources transported by rail and road) uses methods from NUREG-0570 which have different release rate equations for chemicals that are gases at standard conditions but are stored as a pressurized liquid, or chemicals that are liquid at standard conditions. Chemicals stored as gases are considered released in a single puff. Chemicals that are gases at standard conditions but are stored as compressed liquids (e.g., propane), flash to vapor upon release. The remainder of the stored chemical that does not flash then boils from a pool on the ground. Lastly, chemicals that are liquids at standard conditions evaporate from pools on the ground. All analyses use the high ambient temperature of 91 °F (33 °C) to maximize the release rates.

For pipelines, the release rate is calculated using the Areal Locations of Hazardous Atmospheres (ALOHA) software (Reference 2.2-5), developed by the National Oceanic and Atmospheric Administration (NOAA) and the USEPA.

Pipeline break air-fuel mixing and dilution due to the rapid release of pressurized gases, using the methods from Lee (Reference 2.2-4), is only credited in the probabilistic evaluations of pipelines (further discussion in the pipeline section). Not crediting the energetic mixing in the

analysis of other compressed gases (hydrogen and propane) is a significant conservatism in the analysis.

Downwind dispersion is modeled using the methods from NUREG-0570, *Toxic Vapor Concentrations in the Control Room Following a Postulated Accidental Release* and RG 1.145.

The analyses presented for flammable vapor clouds credit meander using the meander coefficients as defined in RG 1.145.

$$\frac{\chi}{Q} = \frac{1}{U \cdot \pi \cdot \Sigma_y \cdot \sigma_z} \qquad \text{(Equation 2.2-12)}$$

$$\Sigma_y = \begin{matrix} M \cdot \sigma_y \; if \; distance \leq 800\; m\; (2620\; ft) \\ or \\ (M-1)\sigma_{y,800m} + \sigma_y \; if \; distance > 800\; m\; (2620\; ft) \end{matrix}$$

Where:

χ = the chemical concentration in kg/m^3.

Q = the release rate in kg/s.

U = the wind speed in m/s.

σ_z = the vertical dispersion coefficient in m.

σ_y = the horizontal dispersion coefficient in m.

M = the meander coefficient from RG 1.145 which is based on wind speed and stability class. It is important to note that M is 1 for all wind speeds above 6 m/s (13 mph). As a result, worst-case analytical conditions often occur when the wind speed is 6 m/s (13 mph), however, the full range of wind speeds is evaluated.

Buoyancy driven plume rise is not credited in the analysis, which is a significant conservatism for large natural gas pipeline releases where the buoyant plume may rise above areas of confinement that could support a detonation.

Building wake is also not credited in any analysis. This is conservative for cases where the vapor cloud encounters structures prior to reaching one of the Plant Complex power blocks within the Project site.

2.2.3.1.1.4.1 Vapor Cloud Explosions from Nearby Facilities

The facilities within 5 mi. (8 km) of the Project site with chemicals that could form flammable vapor clouds are the BCSS, Wieland Copper, Hall Oil and Propane, Parkdale Mills, Oliver Diesel and Auto Repair, Mobil, and Pure. Table 2.2-9 shows the chemicals evaluated at these facilities. These facilities are described in Section 2.2.2.

The flammable vapor cloud analysis found that all the chemicals at stationary facilities are

acceptable. No chemical releases from nearby facilities result in flammable vapor clouds at the Project site using deterministic analyses with more than 95 percent of stability class and wind speed combinations.

2.2.3.1.1.4.2 Flammable Vapor Clouds from Roadways and Railways

All chemicals that are used in the vicinity of the Project site are considered to be transported on local roadways. The lower mass between 50,000 lb. (22,700 kg), based on RG 1.91, and the maximum used at any facility within 5 mi. (8 km) is used for each trucked chemical (aside from hydrogen, where the maximum mass that can fit on a truck is evaluated). The nearest roadway that would likely be used to transport chemicals in the vicinity of the Project site is highway NC-65. Chemicals analyzed on NC-65 are shown in Table 2.2-10.

The flammable vapor cloud analysis found that all the trucked chemicals are acceptable. The analysis shows that the lower explosive limit is not exceeded for stability class and wind speed combinations that occur more than 95 percent of the time.

The chemicals shipped on the NS rail line and NS rail spur that can produce a flammable vapor cloud are also identified on Table 2.2-10.

The flammable vapor cloud analysis found that all the chemicals on the NS rail line and NS rail spur are acceptable. The analysis shows that the lower explosive limit is not exceeded for stability class and wind speed combinations that occur more than 95 percent of the time.

2.2.3.1.1.4.3 Flammable Vapor Clouds from Pipelines

There is a single pipeline in the vicinity of the Project site as described in Section 2.2.2.3. To evaluate the delayed ignition vapor cloud explosion hazard for the pipeline, nine pipeline releases are evaluated. These are presented in Table 2.2-11.

The first six scenarios are full double-ended pipe ruptures of the 23-inch (in.) (58-centimeter [cm]) inner diameter pipeline. The six different scenarios are to address each of the Plant Complex power block locations. For each of the Plant Complex power block locations, the analysis is performed both with and without credit for dilution of the turbulent jet due to energetic mixing with air at the release point (Reference 2.2-4). This jet-dilution mixing is significant in that it reduces the concentration of methane at the release point prior to atmospheric dispersion to the Plant Complex power block. For all the full break cases, the release rate is determined using two ALOHA runs. Since the analyzed pipeline is a lateral that terminates at the BCSS, only one side of the break is fed by a constant pressure source, while the other side is a capped, depressurizing, pipe volume. One ALOHA model represents the pressurized side of the pipe, which is held at a constant 800 pounds per square inch gauge (psig) (5520 kPa) pressure. The second ALOHA model represents the capped, depressurizing pipe, side of the break. A pipe length of 5 mi. (8 km) is used in each model. This is reasonable since the total pipe length is approximately 10 mi. (16 km) and the Project site is near the capped end of the pipeline (see Figure 2.2-3). Using a longer length on the capped side of the break is conservative since it maximizes the blowdown volume and using a shorter length on the pressurized side of the

break is conservative since it minimizes friction losses between the fixed pressure and the break. The calculated break flow rates from these two ALOHA runs are summed to create a total transient break flow which is shown in Table 2.2-12.

The final three scenarios are leak scenarios from a 1-in. (2.5-cm) diameter hole in the pipe (Reference 2.2-12). ALOHA again is used to calculate the break flow assuming a fixed upstream pressure of 800 psig (5520 kPa). A constant break flow rate of 611 pounds per minute (lb/min) (4.62 kilogram per second [kg/s]) was calculated for these leak scenarios.

All pipeline scenarios are evaluated using Monte Carlo methods. The Monte Carlo analysis uses break location along the pipeline, wind speed, wind direction, and atmospheric stability class as randomly sampled variables. For each of the scenarios, 10,000 deterministic cases were analyzed with randomly sampled inputs. The analysis determined that none of the small leak scenarios resulted in an explosive concentration at the Plant Complex power blocks. The analysis also determined that when jet-dilution was credited, none of the full pipe break scenarios resulted in an explosive concentration at the Plant Complex power blocks. When jet-dilution is not credited, 235 of 10,000 cases resulted in an explosive concentration at the worst-case Plant Complex power block. This gives a conditional probability of an explosive cloud reaching a given Plant Complex power block of 0.026 for each release that is not ignited at the break location with 95 percent confidence.

The pipe rupture frequency used in the analysis is based on that cited in reports related to natural gas pipeline hazards near the Indian Point Nuclear Station (Reference 2.2-6) and the Dresden Nuclear Station (Reference 2.2-7). These reports cite a full pipe rupture frequency for pipelines greater than 20-in. (51-cm) diameter with a maximum operating pressure greater than 300 pound per square inch absolute (2070 kPa) of 2.4×10^{-5} ruptures/mi-yr (1.5×10^{-5} ruptures/km-yr). A failure frequency for small leaks was not required since the leak scenarios did not result in any explosive concentrations at a Plant Complex power block. Some additional conditional probabilities are used in the probabilistic analysis of the pipeline. First, although a majority of large pipe breaks are expected to remove soil covering the break resulting in an unobstructed turbulent jet, jet-dilution is credited for only 50 percent of the full pipe ruptures. Application of jet-dilution to only 50 percent of pipe ruptures accounts for less than full ruptures, which may not result in an unobstructed turbulent jet. Direct ignition at the release point is expected to occur 9 percent of the time (Reference 2.2-10) and the remaining 91 percent become unignited clouds that may drift to a Plant Complex power block. Further, the probability of a flammable cloud resulting in a detonation if above the lower flammable limit at the Plant Complex power block is 0.4 (Reference 2.2-10).

The length of pipeline within 5 mi. (8 km) of the nearest Plant Complex power block is 6.57 mi. (10.6 km). Using the above probabilities and pipeline length, the frequency of hazardous explosions is calculated to be 7.46×10^{-7} hazardous explosions per yr.

The pipeline hazard analysis is applicable to all reactor technologies with determined bounding building dimensions less than or equal to that for the analyzed plant (i.e., with a confined area footprint less than or equal to 1000 ft. [305 m] by 1000 ft. [305 m]). The bounding building

dimensions associated with the selected reactor technology will be confirmed at the time of the construction permit or license application.

2.2.3.1.1.5 Cumulative Explosion Hazard Frequency

The acceptance criterion is that the frequency of hazardous explosions must be less than 10^{-6} hazardous explosions per year. The analyses are described in Section 2.2.3.1.1 and summarized here.

For most explosive hazard sources, the risk is dispositioned deterministically, and probabilistic assessments are not used.

The analysis only uses probabilistic risk models for pipeline delayed ignition vapor cloud explosions (7.46×10^{-7} per year). The total risk to the Plant Complex power blocks within the Project site is, therefore, 7.46×10^{-7} hazardous explosions per year. This value includes significant conservatisms:

- All analyses use the site high analysis temperature of 91°F (33 °C). High temperatures are conservative for estimating flashing fractions and boiloff rates for compressed gases. High temperatures concurrent with the worst-case wind speed and stability class are not expected because more stable classes occur at night with low wind speeds.
- Gas buoyancy is not credited for the natural gas pipeline releases. For the large release rates modeled for full pipe breaks, significant plume rise is expected. Plume rise enhances the gas dispersion and may eliminate the possibility of a confined explosion in many cases.
- The pipeline is not considered to have any protection or isolation that would limit the release rate. Releases are modeled as continuing past the time when the peak concentration would reach the Plant Complex power blocks within the Project site.
- The calculated conditional probabilities of an explosive cloud given a release are 95 percent confidence estimates rather than point estimates.

Therefore, flammable vapor clouds meet the acceptance criterion and are not a design-basis hazard to the Plant Complex power blocks within the Project site.

2.2.3.1.2 Toxic Chemicals

Accidents involving the release of toxic or asphyxiating chemicals from nearby facilities and nearby transportation sources were considered. Toxic chemicals known to be present within the vicinity of the Project site, or to be frequently transported in the vicinity, were evaluated. The materials stored at nearby facilities (Table 2.2-2) and transported by pipeline (Table 2.2-3), along highways (Table 2.2-4) and by railway (Table 2.2-5) were evaluated to ascertain which chemicals should be analyzed with respect to their potential to form a toxic or asphyxiating vapor cloud following an accidental release.

Each identified chemical was evaluated based upon the chemical properties, quantities, and distance in relation to the Plant Complex power block, with consideration of plant control room envelope air exchange rate. As described in Section 2.2.2.2, a bounding air exchange rate of 2.64 ACH is used in the analysis. Additionally, the analysis conservatively uses the shortest distance between each hazard and a Plant Complex power block for the location of the control room air intake.

Chemicals were first evaluated using the screening process from RG 1.78, which determines an allowable weight of hazardous chemical at a given distance based on the toxicity, the distance to the control room air intakes, Pasquill stability class, and the control room air exchange rate. Chemical hazards failing this screening are retained for detailed dispersion analysis.

The atmospheric dispersion model was used to predict the chemical concentrations within a toxic or asphyxiating vapor cloud as it disperses downwind for all facilities and sources. The control room habitability analyses performed follows methodology for toxic chemical release and atmospheric dispersion as described in:

- RG 1.78, Rev. 2, *Evaluating the Habitability of a Nuclear Power Plant Control Room During a Postulated Hazardous Chemical Release*
- RG 1.145, Rev. 1, *Atmospheric Dispersion Models for Potential Accident Consequence Assessments at Nuclear Power Plants*
- NUREG-0570, *Toxic Vapor Concentrations in the Control Room Following a Postulated Accidental Release*, June 1979

The toxic limit used for odorized natural gas is 5000 parts per million (ppm), which is 10 percent of the lower explosive limit for methane. The toxicity limits for other analyzed chemicals are as listed in Tables 2.2-2, 2.2-4, and 2.2-5. As described in RG 1.78, trained operators are expected to don an available self-contained breathing apparatus within two minutes of detection of a toxic gas and nasal detection of toxic gases is credible. Failed scenarios are therefore those that exceed the toxic limit less than two minutes from the time the chemical is detected.

Deterministic analyses for each postulated toxicity event were evaluated under a spectrum of meteorological conditions. The spectrum of meteorological parameters was selected based on the Pasquill stability class and wind speed combinations for the Project site that occur greater than 95 percent of the time. For hazards that require a probabilistic analysis, meteorological conditions are randomly sampled from the site-specific joint frequency weather distribution.

2.2.3.1.2.1 Toxic Chemicals from Nearby Facilities

The facilities within 5 mi. (8 km) of the Project site with chemicals that could form toxic vapor clouds are the BCSS, Wieland Copper, Hall Oil and Propane, Parkdale Mills, Oliver Diesel and Auto Repair, Mobil, and Pure. These facilities are described in Section 2.2.2.

All chemicals at nearby facilities passed the RG 1.78 screening except for [[
]][SRI] and hydrochloric acid at the BCSS. Detailed dispersion analysis is required for

these two hazards.

The analysis of a release of 35,000 lb. (15,900 kg) of hydrochloric acid at the BCSS is acceptable because although the toxicity limit is exceeded, there will be greater than two minutes between the time of nasal detection and the time the toxic limit is exceeded.

The [[ ]]SRI at the BCSS was analyzed for both a catastrophic tank failure and a sustained leak through a 1-in. (2.5-cm) diameter opening. A constant break flow rate of 27.2 lb/s (12.3 kg/s) was calculated using ALOHA. The analysis of a release of 27.2 lb/s (12.3 kg/s) of [[ ]]SRI at the BCSS is acceptable because although the toxicity limit is exceeded, there will be greater than two minutes between the time of nasal detection and the time the toxic limit is exceeded.

The catastrophic rupture of an [[ ]]SRI tank at the BCSS is analyzed using probabilistic methods. The Monte Carlo analysis conservatively considers a catastrophic failure of one of the [[ ]]SRI
Only the wind speed, wind direction, and stability class are variables in the Monte Carlo model. The analysis was performed for each Plant Complex. The North Plant Complex, which is nearest the BCSS, was found to have the worst results of the Plant Complexes. The analysis shows 7540 out of 100,000 cases resulted in an uninhabitable control room at the North Plant Complex power block. The failure probability is 7.68×10^{-2} hazardous conditions per release with 95 percent confidence. Using methods presented in Equation 2.2-6, the rate of toxic vapor clouds of [[ ]]SRI reaching a Plant Complex power block is calculated. From quantitative risk assessment studies by the Dutch government (Reference 2.2-9), the rate of failure of single walled tanks is 5×10^{-6} per year. Using these inputs, the total risk of a hazardous condition at the North Plant Complex power block due to an [[ ]]SRI traveling vapor cloud is 2.3×10^{-6} per year. This is added to the total frequency for [[ ]]SRI toxicity for the North Plant Complex power block in Section 2.2.3.1.2.4.

Since the results for the North Plant Complex exceed 10^{-6} toxic control rooms/yr, the Middle Plant Complex is also analyzed. The Middle Plant Complex is nearer to the BCSS than the South Plant Complex and was found to have worse results than the South Plant Complex. The analysis shows 1960 out of 100,000 cases resulted in an uninhabitable control room at the Middle Plant Complex power block. The failure probability is 2.03×10^{-2} hazardous conditions per release with 95 percent confidence. Using methods presented in Equation 2.2-6, the rate of toxic vapor clouds of [[ ]]SRI reaching the Middle Plant Complex power block is calculated. Using the single wall tank failure rate, the total risk of a hazardous condition at the Middle Plant Complex power block due to an [[ ]]SRI traveling vapor cloud is 6.1×10^{-7} per year. This is added to the total frequency for [[ ]]SRI toxicity for the Middle Plant Complex power block in Section 2.2.3.1.2.4.

2.2.3.1.2.2 Toxic Chemicals from Roadways and Railways

All chemicals that are used in the vicinity of the Project site are considered to be transported on local roadways and railways as applicable. Those chemicals with toxic limits identified in Tables

2.2-4 and 2.2-5 are considered toxic hazards and are first evaluated using the RG 1.78 screening.

All identified hazards pass the RG 1.78 screening except: [[ ]]SRI railcar and truck deliveries at the BCSS, hydrogen and propane trucks on NC-65, and LPG and hydrochloric acid railcars on the NS railway.

The analysis of a release of 50,000 lb. (22,700 kg) of propane from a truck on NC-65 and 145,000 lb. (66,000 kg) of LPG from a railcar on the NS railway are acceptable. Using a variety of atmospheric conditions that cover more than 95 percent of stability class and wind speed combinations, the toxic limit is never reached in the control room. The remaining roadway and railway hazards are evaluated probabilistically.

Truck deliveries of [[ ]]SRI to the BCSS are analyzed using probabilistic methods. The Monte Carlo analysis considers a catastrophic failure of a truck of [[ ]]SRI Only the location on the roadway, wind speed, wind direction, and stability class are variables in the Monte Carlo model. The analysis shows a maximum of 176 out of 100,000 cases resulted in an uninhabitable control room at a Plant Complex power block. The failure probability is 1.98×10^{-3} hazardous conditions per release with 95 percent confidence. NUREG/CR-6624 summarizes accident rates and conditional spill probabilities from several sources. The most conservative data cited within NUREG/CR-6624 when considering both accident rate and spill probability is from the U.S. Atomic Energy WASH-1238, Commission *Environmental Survey of Transportation of Radioactive Materials To and From Nuclear Power Plants* and is used in this analysis. The truck accident rate is 1.69×10^{-6} accidents per mile with a conditional spill probability of 0.18. This results in a hazardous spill rate for trucks of 3.04×10^{-7} ($1.69 \times 10^{-6} * 0.18$) accidents with spills per mile. Using methods presented in Equation 2.2-6, the allowable number of trips per year that would yield a total probability of 1×10^{-6} per year is 401 deliveries based on the exposure distance of 4.14 mi. (6.67 km) per delivery. The calculated allowable deliveries are greater than the current number of 14 deliveries per year. The risk from the current 14 deliveries per year is added to the total frequency for [[ ]]SRI toxicity in Section 2.2.3.1.2.4.

Truck shipments of hydrogen on NC-65 are analyzed using probabilistic methods. The Monte Carlo analysis considers a catastrophic failure of a truck of hydrogen, which releases 10,000 lb. (4540 kg) of hydrogen. Only the location along the roadway, wind speed, wind direction, and stability class are variables in the Monte Carlo model. The analysis shows a maximum of 25 out of 100,000 cases resulted in an uninhabitable control room at a Plant Complex power block. The failure probability is 3.32×10^{-4} hazardous conditions per release with 95 percent confidence. Using the hazardous spill rate for trucks of 3.04×10^{-7} accidents with spills per mi. and methods presented in Equation 2.2-6, the allowable number of trips per year that would yield a total probability of 1×10^{-6} per year is 819 deliveries based on the exposure distance of 12.0 mi. (19.3 km) per delivery. The calculated allowable shipments is greater than the current number of 183 shipments per year.

Deliveries of [[ ]]SRI on the NS rail spur to the BCSS are analyzed using

probabilistic methods. The Monte Carlo analysis considers a catastrophic failure of a railcar of [[ ]]SRI Only the location on the rail spur, wind speed, wind direction, and stability class are variables in the Monte Carlo model. The analysis shows 1340 out of 100,000 cases resulted in an uninhabitable control room at a Plant Complex power block. The failure probability is 1.4×10^{-2} hazardous conditions per release with 95 percent confidence. Rail spurs, also known as industrial/private sidings, have a different, higher accident rate than main lines due to the nature of sorting, unloading, and loading. Accident frequencies differ between the shunting yard part of the siding and the railway part of the siding (Reference 2.2-9). As a distinction in the Belews Creek spur could not be made, the accident frequency is conservatively taken as the higher of the two values. The accident frequency for the spur is treated as 1.77×10^{-6} accidents per railcar mi. (1.1×10^{-6} accidents per railcar km). Furthermore, the outflow probability for pressurized tank cars in a collision scenario is 0.01 (Reference 2.2-9). This results in a hazardous spill rate for railcars on the spur of 1.77×10^{-8} ($1.77 \times 10^{-6} * 0.01$) accidents with spills per mi. Using methods presented in Equation 2.2-6, the allowable number of trips per year that would yield a total probability of 1×10^{-6} per year is 840 deliveries based on the exposure distance of 4.79 mi. (7.71 km) per delivery. The calculated allowable deliveries are greater than the current number of 56 deliveries per year. The risk from the current 56 deliveries per year is added to the total frequency for [[ ]]SRI in Section 2.2.3.1.2.4.

Deliveries of hydrochloric acid on the NS railway are analyzed using probabilistic methods. The Monte Carlo analysis considers a catastrophic failure of a railcar of hydrochloric acid, which releases 235,000 lb. (107,000 kg) of hydrochloric acid. Only the location along the railway, wind speed, wind direction, and stability class are variables in the Monte Carlo model. The analysis shows 1260 out of 100,000 cases resulted in an uninhabitable control room at a Plant Complex power block. The failure probability is 1.32×10^{-2} hazardous conditions per release with 95 percent confidence. NUREG/CR-6624 summarizes train accident rates and spill probabilities from several sources using old data. Since the collection of this data, safety features and automation have improved in railroad transportation, making it safer over time. For this reason, a more current railroad accident rate was developed based on data from the Federal Railroad Administration (Reference 2.2-3) and U.S. Department of Transportation (Reference 2.2-8). Using the available data, the rate of railroad accidents with a hazmat release on main line track is 4.2×10^{-9} hazmat car releases per freight car mi. Based on methods presented in Equation 2.2-6, the allowable number of shipments per year that would yield a total probability of 1×10^{-6} per year is 2070 deliveries based on the exposure distance of 8.72 mi. (14.0 km) per delivery. The calculated allowable shipments are greater than the current number of 34 shipments per year.

2.2.3.1.2.3 Toxic Chemicals from Pipelines

There is a single pipeline in the vicinity of the Project site as described in Section 2.2.2.3. To evaluate the toxic vapor cloud hazard for the pipeline, both a full double-ended pipeline release and leak from a 1-in. (2.5-cm) diameter hole are evaluated for each Plant Complex.

For the analysis of the leak scenarios from a 1-in. (2.5-cm) diameter hole in the pipe (Reference

2.2-12), ALOHA was used to calculate the break flow assuming a fixed upstream pressure of 800 psig (5520 kPa). A constant break flow rate of 10.2 lb/s (4.63 kg/s) was calculated for these leak scenarios. Using a variety of atmospheric conditions that cover more than 95 percent of stability class and wind speed combinations, deterministic analyses show that operators have at least two minutes to don a self-contained breathing apparatus prior to reaching a toxic concentration in the control room for the 1-in. (2.5 cm) leak scenario.

The pipeline is also analyzed for a full double-ended rupture of the 23-in. (58-cm) inner diameter pipeline. The calculated release rate is consistent with that described in Section 2.2.3.1.1.4.3 and shown in Table 2.2-12. Conservatively, jet dilution mixing is not credited in the toxic vapor cloud analysis. The full rupture scenario is evaluated using Monte Carlo methods. The Monte Carlo analysis uses break location along the pipeline, wind speed, wind direction, and atmospheric stability class as randomly sampled variables. For each of the scenarios, 100,000 deterministic cases were analyzed with randomly sampled inputs. The analysis determined that 942 of 100,000 cases resulted in a toxic control room at the worst-case Plant Complex power block. This gives a conditional probability of an unacceptable control room environment of 9.92 x 10^{-3} for each release with 95 percent confidence. The pipe rupture frequency used in the analysis is 2.4 x 10^{-5} ruptures/mi.-yr (1.5 x 10^{-5} ruptures/km-yr) consistent with that described in Section 2.2.3.1.1.4.3. Pipe ruptures are ignited at the point of release 9% of the time resulting in a jet fire rather than a toxic gas plume (Reference 2.2-9). The length of pipeline within 5 mi. (8 km) of the nearest Plant Complex power block is 6.57 mi. (10.6 km). Using the above probabilities and pipeline length, the frequency of hazardous control room is calculated to be 1.42 x 10^{-6} hazards per year for the North Plant Complex power block.

Since the results for the North Plant Complex exceed 10^{-6} toxic control rooms/yr, the Middle Plant Complex is also analyzed. The Middle Plant Complex is nearer to the pipeline than the South Plant Complex and was found to have worse results than the South Plant Complex. The analysis shows 133 out of 100,000 cases resulted in an uninhabitable control room at the Middle Plant Complex power block. The failure probability is 1.52 x 10^{-3} hazardous conditions per release with 95 percent confidence. The length of pipeline within 5 mi. (8 km) of the Middle Plant Complex power block is 6.12 mi. (9.85 km). Using the failure data presented above for the North Plant Complex, the total risk of a hazardous condition at the Middle Plant Complex power block due to pipeline rupture traveling vapor cloud is 2.03 x 10^{-7} per year.

2.2.3.1.2.4 Cumulative Toxic Hazard Frequency

The acceptance criterion is that the frequency of a hazardous control room for each chemical hazard must be less than 10^{-6} hazardous environments per year. The analyses are described in Section 2.2.3.1.2 and summarized here.

For most toxic hazard sources, the risk is dispositioned deterministically and probabilistic assessments are not used.

The analysis uses probabilistic risk models for multiple different [[ ]]^{SRI} sources including storage, truck deliveries, and railcar deliveries to the BCSS. The total risk due to [[ ]]^{SRI}

is determined using the current estimated number of annual deliveries by truck (14/yr.) and railcar (56/yr.). The risk from stationary [[ ]]^{SRI} storage, truck deliveries, and railcar deliveries are summed to determine the total risk at both the North and Middle Plant Complexes as shown in Table 2.2-13. The total risk to the North Plant Complex power block control room from all [[ ]]^{SRI} sources exceeds 1.0×10^{-6} hazardous control rooms per year. The total risk to the Middle Plant Complex power block control room, which also bounds that of the South Plant Complex, from all [[ ]]^{SRI} sources is 7.11×10^{-7} hazardous control rooms per year.

The total risk to the North Plant Complex power block control room from natural gas also exceeds 1.0×10^{-6} hazardous control rooms per year. The total risk to the Middle Plant Complex power block control room, which also bounds that of the South Plant Complex, from all natural gas sources is 2.03×10^{-7} hazardous control rooms per year.

All other chemicals analyzed probabilistically have a total hazard frequency less than 1.0×10^{-6} hazardous control rooms per year.

This analysis of toxic gas clouds includes the following significant conservatisms:

- All analyses use the site high analysis temperature of 91°F (33 °C). For the [[ ]]^{SRI} analyses, this maximizes the mass of the initial puff release and maximizes the evaporation rate. High temperatures concurrent with the worst-case wind speed and stability class are not expected because more stable classes occur at night with low wind speeds.

- Gas buoyancy is not credited for the natural gas pipeline releases. For the large release rates modeled for full pipe breaks, significant plume rise is expected. Plume rise enhances the gas dispersion and may eliminate the possibility of a confined explosion in many cases.

- Jet dilution of pipeline releases is not credited for the toxic gas analysis.

- None of the pipelines are considered to have any protection or isolation. Releases are modeled as continuing indefinitely.

- The calculated conditional probabilities of a toxic control room given a release are 95 percent confidence estimates rather than point estimates.

[[

]]^{SRI} Analysis may be refined or mitigating features employed once a final reactor technology is selected. Additional information will be provided in the construction permit or license application to demonstrate acceptability for the North Plant Complex.

All toxic chemical clouds meet the acceptance criterion and are not a design-basis hazard for the Middle and South Plant Complex power blocks.

The analysis credits nasal detection and donning of a self-contained breathing apparatus for

the following chemicals: [[ ]]SRI, hydrochloric acid, and natural gas (odorized). If the selected reactor technology has a safety-related control room, operators will be required to be trained in nasal detection and use of a self-contained breathing apparatus.

2.2.3.1.3 Fires

Natural fires (e.g., vegetation) and chemical fires are evaluated for the Project site. In all cases, analysis is used to determine a heat load and fire duration. The results are then compared to heat load and duration limits for structural concrete from NUREG/CR-3330. From NUREG/CR-3330, concrete walls can withstand 15 Kilowatts (kW)/m^2 (79 BTU/min-ft^2) for 11.6 hr., 25 kW/m^2 (132 BTU/min-ft^2) for 8.1 hr., and 50 kW/m^2 (264 BTU/min-ft^2) for 4.95 hr.

Natural fires are dispositioned using a conservative estimation of the available fuel heat load. The land surrounding the Project site contains hardwood and evergreen trees. A simple evaluation of the surrounding land using heat loads derived from United States Forestry Service fire modeling guidelines (Reference 2.2-11) found that a worst-case fire would result in at most 22.6 kW/m^2 (119 BTU/min-ft^2) of incident heat flux for 4.5 hr, when wooded areas are at least 100 ft. (30 m) from safety-related buildings. This is well below the NUREG/CR-3330 acceptance criteria. It will be confirmed that wooded areas are at least 100 ft. (30 m) from safety-related buildings in the construction permit or license application.

Three types of off-site chemical fires are considered: jet fires from the pipeline in the vicinity of the site, pool fires following spills of tanks or railcars of liquid flammable chemicals, and BLEVEs of chemicals that are gases at standard conditions but are stored as pressurized liquids. A bounding hazard was selected for each hazard type based on the mass of chemical, the heat of combustion, and the distance of the hazard from the Plant Complex power blocks. The analyzed hazards are a BLEVE of a [[ ]]SRI, a 235,000 lb. (107,000 kg) heptane pool fire on the NS rail line, and a methane jet fire of the 23-in. (58-cm) inner diameter Piedmont Natural Gas Co. pipeline. All three hazards were evaluated using ALOHA (Reference 2.2-5). All three hazards were evaluated at a distance of 870 ft. (265 m), which is the closest approach of any chemical hazard to a Plant Complex power block.

The bounding BLEVE fireball for release of [[ ]]SRI has a heat load of 25.6 kW/m^2 (135 BTU/min-ft^2) at a distance of 870 ft. (265 m) and burns for 18 sec. From NUREG/CR-3330, a concrete wall can withstand a 50 kW/m^2 (264 BTU/min-ft^2) heat load for 4.95 hr.

A pool fire of heptane was analyzed as the bounding liquid chemical at ambient conditions. The worst-case pool fire of 235,000 lb. (107,000 kg) of heptane has a heat load of 36.3 kW/m^2 (192 BTU/min-ft^2) at a distance of 870 ft. (265 m) and burns for 35 seconds. Note that the conditions of the bounding pool fire, such as pool diameter, were selected to maximize the heat flux. From NUREG/CR-3330, a concrete wall can withstand a 50 kW/m^2 (264 BTU/min-ft^2) heat load for 4.95 hr.

The jet fire for the 23-in. (58-cm) inner diameter natural gas pipeline was modeled such that the break release rate bounds that of the maximum flow documented in Table 2.2-12. The methane

jet fire has a maximum heat load of 3.86 kW/m^2 (20.4 BTU/min-ft^2). From NUREG/CR-3330, a concrete wall can withstand a 15 kW/m^2 (79 BTU/min-ft^2) heat load for 11.6 hr.

The evaluated fires do not pose a risk of thermal damage to structures at the Plant Complex power blocks within the Project site.

2.2.3.1.4 Collisions with Intake Structure and Liquid Spills

The cooling and makeup water intake for the Project site is provided from Belews Lake and the Dan River, which are not waterways used for commercial shipping (see Section 2.2.2.4). Therefore, an evaluation that considers the probability and potential effects of collision or hazardous liquid spills affecting the plant intake structure is not warranted.

2.2.3.2 Effects of Design-Basis Accidents

Evaluations were performed of potential hazards near the Plant Complex power blocks within the Project site. These evaluations concluded that potential accidents involving off-site explosions, flammable vapor clouds, and fires do not pose a threat to the Plant Complex power blocks within the Project site. [[

]]^{SRI} Toxic vapor clouds are not a design-basis hazard for the Middle Plant Complex and South Plant Complex power blocks. The effects of chemical releases from on-site chemical storage will be evaluated in the construction permit or license application because the required chemicals and location of safety-related structures must be considered to determine there is no adverse effect from these hazards.

2.3 METEOROLOGY

This section addresses the local and regional climatology and meteorology, as well as air quality, in the vicinity of the Project site. The information evaluates meteorological impacts that could affect the safe design and siting of the plant. Section 2.3.1 describes characteristics of the regional climate. Section 2.3.2 describes local meteorology, including measurements from an on-site meteorological tower. Section 2.3.3 describes the on-site multi-level meteorological tower (MET tower) and the meteorological data collection program. Section 2.3.4 provides short-term atmospheric diffusion estimates. Section 2.3.5 provides long-term atmospheric diffusion estimates.

2.3.1 REGIONAL CLIMATOLOGY

Information about regional climatology conditions was obtained from the National Climatological Data Center (NCDC) Storm Events Database and Local Climatological Data (LCD) for the cities of Winston-Salem and Greensboro. The Project site is located within the NCDC's NC Northern Piedmont Climate Division, or Climate Division 3. The nearest National Weather Service (NWS) Station is the Piedmont Triad International Airport (KGSO), which is approximately 14 mi. [22 km] to the southeast of the Project site. Meteorological Data from the Smith Reynolds Airport NWS Station at Winston-Salem, NC (KINT), and the NWS Station at Raleigh/Durham International Airport (KRDU) were also utilized. KGSO is located in Guilford County and is a reliable station for collecting meteorological data. (References 2.3-26; 2.3-27; 2.3-39).

More specific information for the Project site was obtained from the MET tower collection period from February 7, 2024, through February 6, 2025.

2.3.1.1 General Climate

The Project site is located in north-central NC in the southeast portion of Stokes County and is bordered by Rockingham County to the east, Guilford County to the southeast, and Forsyth County to the south. The state of NC spans approximately 500 mi. (802 km) east to west and 186 mi. (301 km) north to south. The Project site is in the northern Piedmont region which is east of the Blue Ridge Mountain Range. The mountain range barriers affect temperature, precipitation, and wind. The Project site is in a humid subtropical climate zone. Figure 2.3-1 shows an aerial view of the Project site with a 50 mi. (80.5 km) radius around the site.

KGSO is in the west-central part of Guilford County, in the northern Piedmont section of NC. The location is approximately centrally located between the mountains to the west and the coastline to the east and south, which provides a temperate climate. The mountains block cold air masses moving eastward; therefore, few days in the winter are below 20 °F (-6.7 °C). KINT, located in Winston-Salem, NC, is within 50 mi. (80.5 km) of the Project site, and experiences warm and muggy summers and very cold winters with variable snowfall.

The average minimum extreme annual temperature at KGSO is 11.4 ˚F (-11.4 ˚C) and at KINT the average minimum extreme annual temperature is 12.4 ˚F (-10.9 ˚C) (see Table 2.3-1). Tropical air brings warm temperatures and high humidity to the area during the summer months.

During the summer, the average maximum annual temperatures at KGSO and KINT are 95.7 ˚F (35.4 ˚C) and 95.5 ˚F (35.3 ˚C), respectively.

Table 2.3-14 summarizes average, daily minimum, and daily maximum temperatures (dry bulb and wet bulb) recorded at the Project site during the collection period from 2024–2025. The highest daily maximum temperatures for the collection period occurred during the months of June and July. The lowest daily minimum temperatures occurred in December and January. The average dry bulb monthly temperatures range from the mid-30s (°F) (around 0 ˚C) in the winter to the upper 70s (°F) (around 25 ˚C). The extreme daily maximum recorded at the Project site was 97.3°F (July 2024), while the extreme daily minimum was 15.8 °F (January 2025).

Rainfall is fairly consistent throughout the year but varies significantly from year to year. July and August have the highest rainfall amounts, while October and November have the least. Summer rainfall is usually from thunderstorm activity that can also bring strong winds and hail.

Tornadoes, hurricanes, tropical storms, and depressions are infrequent in the area of the Project site (References 2.3-23; 2.3-26; 2.3-27; 2.3-40). See Sections 2.3.1.2.1.4 and 2.3.1.2.1.5 for additional information on the infrequency of these events.

2.3.1.2 Regional Meteorological Conditions for Design and Operating Basis

The regional meteorological conditions that are relevant to the design and operating basis for the Project site are discussed herein.

2.3.1.2.1 Severe Weather

Severe weather may require consideration in the design of safety-related structures, systems, and components (SSCs). Information about severe weather phenomena was obtained from the NCDC Storm Events Database that covers a 73-year period between 1950 through 2023. Additionally, LCD for the counties of Forsyth and Guilford were obtained.

Overall, severe storms are relatively infrequent in NC. The Project site is far enough inland that it is typically not affected by the brunt of intense tropical cyclones and hurricanes.

2.3.1.2.1.1 Thunderstorms, Hail, and Lightning

Thunderstorms and lightning mainly occur in the spring and summer months. Thunderstorms are occasionally accompanied by strong winds, heavy rain, and hail. Damaging thunderstorms are infrequent in the area of the Project site, according to the 75-year period reported on the KGSO and KRDU 2022 LCDs (References 2.3-26; 2.3-27). From 2002 to 2023 (8035 days), 174 severe thunderstorm warnings over 154 days were issued for the site center point of the facility. The percentage of days with a severe thunderstorm warning being issued for the site center is 1.92 percent during this period.

Hail has a diameter of five millimeters (mm) or greater and is always produced by convective clouds (Reference 2.3-5). Hail usually occurs coincident with thunderstorms in Forsyth County, Guilford County, Rockingham County, and Stokes County. A total of 553 hail events are

recorded in the National Centers for Environmental Information (NCEI) Storm Events Database from 1950 to 2023 in these counties. The largest size of hailstones reported were 2.25 in. (5.72 cm) in Stokes County, June 2002; 2.75 in. (6.99 cm) in Guilford County, April 1983; Rockingham County, June 1998; and Forsyth County, March 2005 (Reference 2.3-23).

In Forsyth County and Guilford County, severe hail (3/4 inch [in.] diameter or larger) has been reported 161 times during 1950 through 2023 (Reference 2.3-23). This corresponds to between 2 and 3 severe hail events per year.

2.3.1.2.1.2 Extreme Winds

The maximum strong wind recorded in Forsyth County, Guilford County, Rockingham County, or Stokes County was 50 knots (kts) (57.5 mph 92.6 kilometers per hour [kph]) which occurred in Stokes County, April 2003 (Reference 2.3-23). The maximum high wind recorded in those counties was 60 kts (69 mph [111 kph]), which occurred in February 2003 and March 2004 in Rockingham County and Stokes County (Reference 2.3-23). The thunderstorm wind maximum was 100 kts (115 mph [185 kph]) in Forsyth County in July 1962 (Reference 2.3-23). The database was queried from 1950 to 2023 for Forsyth County, Guilford County, Rockingham County, and Stokes County. The 100-year mean return interval (MRI) 3-second wind gust is 93 mph (42 meters per second [m/s]) (Reference 2.3-11).

The wind patterns are influenced by the local topography, which will affect the severe weather regionally. In the Piedmont region rainfall is modified by the mountain barrier, but to a lesser extent than in areas closer to the Appalachian Range. Shallow cold air masses from the W tend to be stopped or turned aside by the mountains, while deeper masses are lifted over the range, losing moisture, and warming during the passage. Summer precipitation is largely from thunderstorms, which signal an unstable atmosphere, mostly local in character. Damaging storms are infrequent in the Northern Piedmont area. The highest winds to occur have been associated with thunderstorms and are brief in duration.

2.3.1.2.1.3 Precipitation Extremes

Precipitation events were obtained from the NCEI Storm Events Database for Guilford County and Stokes County. Records indicate heavy rain is mostly associated with thunderstorms and tropical weather (hurricanes and tropical storms). The Storm Events Database defines heavy rain as an unusually large amount of rain which does not cause a Flash Flood or Flood event but causes damage. There are a total of three heavy rain (rain at a rate of accumulation exceeding the geographically dependent value [Reference 2.3-6]) events recorded in the NCEI Storm Events Database for Guilford County and Stokes County. The first was the rain event of February 3 – 4, 1998 when Goldsboro recorded 2.25 in. (5.72 cm), then on May 18, 2018, the NWS Cooperative Observer Program observer at King recorded 2.70 in. (6.86 cm) over a 24-hr. period which was the highest daily May rainfall at that station. More recently on February 6 – 7, 2020 the station at Danbury set a February two-day record with 4.89 in. (12.42 cm).

Floods are defined as the overflowing of the normal stream or body of water, or the accumulation of water over areas not normally submerged (Reference 2.3-7), whereas flash

floods are rapidly rising water levels in waterways, usually as a result of intense rainfall (Reference 2.3-8). The NCEI Storm Events Database recorded a total of 55 flood events and 254 flash flood events for the time period from 1950 to 2023 in Forsyth County, Guilford County, Rockingham County, and Stokes County for a total of 309 flooding events (Reference 2.3-23). This is an average of less than five flood events per year.

2.3.1.2.1.4 Tornadoes

Tornado intensity is classified according to the Enhanced Fujita Tornado Intensity Scale (EF Scale). This scale correlates wind speeds from a tornado event to the magnitude of observed damage according to 28 indicators. The EF Scale ranks tornadoes in categories EF-1 to EF-5. This updated scale uses more specific structural damage indicators than the original previously used tornado intensity classification scale, the Fujita Scale, which was established in 1971 (Reference 2.3-33).

Tornadoes infrequently occur around the Project site, with only 52 recorded in Guilford, Stokes, Rockingham, and Forsyth counties over 39 days from 1950 to 2023 (27,028 days). The percentage of days with a tornado occurring during this period is 0.14 percent. The strongest tornadoes recorded in the area (F3/EF-3) occurred during the months of March and May on the following dates and in these counties (Reference 2.3-23):

- May 1985 Forsyth County
- May 1989 Forsyth County
- March 1998 Rockingham County
- May 1998 Forsyth County
- May 2008 Forsyth County
- March 2010 Guilford County

Tornado Strike Probability

The probability of a tornado occurring at the Project site is low based on records from the NCDC Strom Events Database. Based on the tornado strike probability presented in NUREG/CR-4461, the number of tornado events from 1950 through August 2003 within a 2-degree box surrounding the Project site is 221, based on the latitude and longitude of the Project site (Figure 5-7 of Reference 2.3-37). This gives an annual average (221 tornadoes/53 years) of approximately 4 tornado events striking somewhere within the 2-degree box.

Based on the principle of geometric probability (Reference 2.3-41), the probability of a tornado striking any point in a 1-degree latitude by 1-degree longitude square may be calculated as follows:

$$P = \frac{zt}{A}$$ (Equation 2.3.1-1)

Where:

P = mean probability of a tornado striking a point in any year in a 1-degree square.

z = mean path area of a tornado (miles squared) = 0.314 mi. squared based on weight average from Table 2-14 of NUREG/CR-4461.

t = mean number of tornadoes per year from Figure 2-1 of NUREG/CR-4461.

= 38 tornadoes / 53.67 years = 0.71 tornadoes per year.

A = area (in miles squared) = approximately 3857 miles squared for the 1-degree square containing the Project site.

Therefore, the annual tornado probability for the 1-degree square containing the Project site (P, from Equation 2.3.1-1) = (0.314 x 0.71) / 3857 = 5.78×10^{-5} per year.

The inverse of tornado probability gives the mean recurrence interval (R) for a tornado striking a point within the 1-degree square.

$$R = \frac{1}{P}$$ (Equation 2.3.1-2)

Recurrence interval (R, from Equation 2.3.1-2) = 17,260 years

Design Basis Tornado Parameters

Site characteristic tornado parameters are based on guidance provided NRC RG 1.76, *Design Basis Tornado and Tornado Missiles for Nuclear Power Plants*. Based on RG 1.76, the Project site is in Region I. The characteristics applicable to SSCs important to safety at the Project site include the tornado maximum wind speed, translational speed, maximum rotational speed, radius of maximum rotational speed, pressure drop, and rate of pressure drop (from Table 1 of RG 1.76). The values of these parameters for the Project site are given in Table 2.3-2. Additionally in accordance with 10 CFR 50.34, SSCs that are important to safety are required to be designed to withstand natural weather phenomena without their safety function capability being compromised. Table 2.3-3 summarizes the design basis tornado missile spectrum and maximum horizontal speeds (from Table 2 of RG 1.76).

2.3.1.2.1.5 Hurricanes

Hurricanes, also known as tropical cyclones, have 1-minute average surface (10 m [32.8 ft]) winds exceeding 33 m/s (65 kts). Hurricanes originate from tropical depressions (winds up to 17 m/s [34 kts]), which can develop into tropical storms (winds 18 – 32 m/s [35 – 64 kts]) prior to being classified as a hurricane (Reference 2.3-2).

Twenty-two historical hurricane tracks are reported within 50 mi. of the site center point, by the

NOAA Historical Hurricane Tracks website. Of these, only an unnamed 1993 storm-maintained hurricane strength (Category 1) in the area, which is also confirmed by the NC State Climate Office (Reference 2.3-39). Additionally, four tropical storms were recorded from 1959 to 2023. Hurricanes and tropical storms can produce heavy rainfall, severe thunderstorms, hail, high winds, and flooding in the area. From 1859 to 2023, NOAA Atlantic Storm Totals climatology recorded 2950 total storms (hurricanes, tropical storms, and major hurricanes). The percentage of any Atlantic tropical system tracking within 50 mi. (80.5 km) of the site center point is 0.88 percent during this period.

Other storms impacted the area, but the centers of those storms did not pass through a 50 mi. radius of the site center point. The strongest hurricane which was within a 200 mi. (322 km) radius and had rains impacting Forsyth County and Guilford County was Hurricane Fran (September 5, 1996), a Category 3 hurricane (References 2.3-28; 2.3-23). Hurricane Floyd made landfall on NC's eastern coast and the hurricane-related rainfall (September 15, 1999) extended inland as far as Forsyth County and Guilford County (References 2.3-29; 2.3-23).

Design Basis Hurricane Wind Speed Parameter

The Project site design basis hurricane wind speed parameter is based on guidance provided in NRC RG 1.221, *Design-Basis Hurricane and Hurricane Missiles for Nuclear Power Plants*. Based on RG 1.221, Figure 2, the Project site is located within wind speed contour band corresponding to 160 mph (258 km/h). This wind speed represents a 3-second gust wind velocity at 33 ft. (10 m) AGL in the site area, corresponding to a hurricane wind event with a 10^{-7} annual exceedance probability.

2.3.1.2.2 Winter Storm Events

Snow, sleet, glaze, and ice accumulation are rare during the winter months and short-lived when experienced. Snowfall amounts vary greatly, with some winters experiencing only trace snowfall amounts. Glazing is more common in the Piedmont area of NC (where the Project site is located) than the rest of the state but is usually not damaging.

Normal annual snowfall for the Project site is between 5.2 in. (13.2 cm) and 7.1 in. (18.0 cm). Maximum monthly snowfall ranges from 25.8 in. (65.5 cm) at KRDU, 22.9 in. (58.2 cm) at KGSO, and 21.3 in (54.1 cm) at KINT. The mountains to the W affect the winter temperatures and weather. This area experiences winter rain or snowfall amounts that are variable from year to year and rarely persist for more than a few days (References 2.3-26; 2.3-27).

2.3.1.2.2.1 Ice Storms

According to Tattelman and Gringorten's, "Estimated Ice and Wind Loads at the Earth's Surface for the Contiguous United States," ice thickness (t_i) greater than or equal to 2.5 cm (0.98 in.) occurred only two times in the state of NC during 50 years (Reference 2.3-40). From the Bennett 1959 study referenced in Tattelman and Gringorten's report, a total of 9 to 17 glaze storms, without regard to thickness. were observed. NC is in Region V in their report, five ice storms in 50 years with accumulation greater than or equal to 2.5 cm (0.98 in.) (Reference 2.3-

40).

Since Tattelman and Gringorten's 1973 publication, there have been multiple ice storms in the region. On December 4 – 5, 2002 a high-pressure system over the northeast U.S. created a system in the western Piedmont where snow fell for up to 8 hours in Greensboro before transitioning to sleet and freezing rain. The freezing rain lasted for more than 12 hours with up to an inch of ice accumulation in parts of the Piedmont. Back-to-back ice storms occurred in 2020. The February 12 – 13 storm had a quarter-inch of ice accumulation in the Greensboro area then the February 18 – 19 storm with areas along I-40 and US 421 between Burlington and Boone generally received around a quarter-inch of glaze.

2.3.1.2.2.2 Ground-Level Weights of Extreme Snowpacks and Snowfall Events

The snowpack, as defined in this section, is the depth of a layer of ice and snow on the ground surface measured routinely at manned weather observing stations. Maps of the weight of the 50-year mean recurrence interval snowpack are available in ASCE 7/16. The weight of the 50-year snowpack from Figure 7.2.1 in ASCE 7/16 is 20 pounds per square foot (psf) at the Project site (Reference 2.3-10). Using an adjustment factor of 1.22 presented in Section C7.3.3 of ASCE 7/16, the weight of the 100-year snowpack is 24.4 psf (24.4 psf = 20 psf x 1.22).

Note that ASCE changed its methodology for compiling snowpack information to design structures in its more recent ASCE 7/22. ASCE 7/22 compiled snowpack information to target a uniform structure reliability instead describing a uniform meteorological hazard (e.g., a 50-year return-interval snowpack) (Reference 2.3-11). ASCE 7/22 does not provide guidance on estimating 100-year snowpacks from snowpack information provided therein. Therefore, for purposes of estimating the weight of a 100-year snowpack in this report, guidance from ASCE 7/16 is used.

The maximum reported snow depth at KGSO is 15.0 in. (38.1 cm) which occurred in January 1966. The maximum reported snow depth at KRDU is 20.0 in. (50.8 cm) which occurred in January 2000 (References 2.3-26; 2.3-27).

The NRC's Interim Staff Guidance (ISG) on Assessment of Normal and Extreme Winter Precipitation Loads on the Roofs of Seismic Category I Structures (NRC ISG DC/COL-ISG-07) (Reference 2.3-35), provides an algorithm (below) for converting historical maximum snowpack depth to a ground snow load:

$$L = 0.279D^{1.36} \quad \text{(Equation 2.3.1-3)}$$

Where:

D = the snowpack depth in inches.

L = the resulting snow loads in pounds per square foot (psf).

Using the higher of the two maximum observed snow depths at KGSO and KRDU (20.0 in. [50.8 cm] at KRDU) in Equation 2.3.1-3, the weight of the historical snowpack is 16.4 psf (16.4 psf = $0.279 \times 20.0^{1.36}$).

For purposes of applying guidance in NRC ISG DC/COL-ISG-07, two-day snowfalls are used to ensure that storms that persist for more than a one-day recording period are accurately captured. From the U.S. Department of Commerce (USDOC), 1998 the maximum two-day snowfall event at KRDU is 11.1 in. (28.2 cm) (Reference 2.3-44). In the four-county area around the Project site, (Stokes, Rockingham, Guilford, and Forsyth counties) the highest two-day, snowfall is 14.0 in. (35.6 cm) at Reidsville in Rockingham County, NC.

Other information regarding historical maximum snowfall events is available from KGSO and KRDU. The maximum observed 24-hour snowfall at KGSO is 14.3 in. (36.3 cm) in December 1930 (Reference 2.3-26). Digital records from KGSO are not available for December 1930 to determine a corresponding two-day snowfall. However, a cooperative weather observer in Greensboro, NC recorded a one-day snowfall of 14.0 in. (35.6 cm) on December 17, 1930 (Reference 2.3-24). This suggests that a maximum two-day snowfall at KGSO of 14.3 in. (36.3 cm) is reasonable. The maximum two-day snowfall at KRDU is 20.3 in. (51.6 cm) in January 24 – 25, 2000 (References 2.3-26; 2.3-25).

NRC ISG DC/COL-ISG-07 (Reference 2.3-35) provides an algorithm that converts a snowfall event to a ground snow load. The algorithm relates the snowfall depth in inches (S) to the resulting ground snow load (L) in psf:

$$L = (0.15)(S)(5.2) \qquad \text{(Equation 2.3.1-4)}$$

In Equation 2.3.1-4, the constant (0.15) represents the ratio of the volume of melt water derived from a snow sample and the constant (5.2) is the weight of 1 in. of water in psf. Using this algorithm with the highest observed two-day snowfall (20.3 in. [51.6 cm] at KRDU), the weight of the historical maximum two-day snowfall event is 15.8 psf (15.8 psf = 0.15 x 20.3 in. x 5.2).

The 100-year return period snowfall event is available from the U.S. Snow Climatology data (Reference 2.3-44). For purposes of applying guidance in NRC ISG DC/COL-ISG-07, two-day, 100-year snowfalls are used to ensure that storms that persist for more than a one-day recording period are accurately captured.

From USDOC (Reference 2.3-44), the maximum two-day, 100-year snowfall event at KRDU is 13.7 in. (34.8 cm). In the four-county area around the Project site, (Stokes, Rockingham, Guilford and Forsyth counties) the highest two-day, 100-year snowfall is 19.9 in. (50.5 cm) at Danbury 1 northwest (a cooperative observing station located approximately one mile [1.6 km] northwest of Danbury in Stokes County, NC). Thus, from available data the maximum two-day, 100-year snowfall event is 19.9 in. (50.5 cm). The weight of the highest two-day, 100-year snowfall event estimated from Equation 2.3.1-4 is 15.5 psf (15.5 psf = 0.15 x 5.2 x 19.9 in.).

The estimated weights of the 100-year snowpack, historical maximum snowpack, historical maximum two-day snowfall event, and the maximum 100-year return two-day snowfall event for

the Project site are summarized in Table 2.3-5.

2.3.1.2.2.3 Normal Winter Precipitation Event

The NRC ISG DC/COL-ISG-07 defines the Normal Winter Precipitation Event as the highest ground-level weight (in psf) among (1) the 100-year return period snowpack; (2) the historical maximum snowpack, (3) the 100-year return two-day snowfall event, or (4) the historical maximum two-day snowfall event. Thus, from the results above the Normal Winter Precipitation Event for the Project site is 24.4 psf.

2.3.1.2.2.4 Extreme Frozen Precipitation Event

The NRC ISG DC/COL-ISG-07 defines the Extreme Frozen Precipitation Event as the higher ground-level weight (in psf) between (1) the 100-year return (two-day) snowfall event and (2) the historical maximum (two-day) snowfall event (Reference 2.3-35). Thus, from the results above the Extreme Frozen Precipitation Event for the Project site is 15.8 psf.

2.3.1.2.2.5 Extreme Liquid Winter Precipitation Event

The Extreme Liquid Winter Precipitation Event is defined as the theoretically greatest depth of precipitation (in inches of water) for a 48-hour period that is physically possible over a 25.9-sq. km. (10 sq. mi.) area. Per NRC ISG DC/COL-ISG-07, the extreme liquid winter precipitation event is determined in accordance with the respective Hydrometeorological Reports (HMR) published by NOAA's Hydrometeorological Design Studies Center (Reference 2.3-45).

From USDOC (Reference 2.3-45), the 24-hour Probable Maximum Winter Precipitation (PMWP) (December – February) for a 10 sq. mi. area around the Project site is approximately 20 in. (50.8 cm). The corresponding 72-hour PMWP for a 10 sq. mi. area around the Project site is 26 in. (66.0 cm). Assuming a linear relationship between these values produces a 48-hour PMWP of approximately 23 in. (58.4 cm). Due to the warm climate of the Project site, most of the 48-hr. PMWP remains in liquid form and does not contribute to roof loading.

2.3.1.2.3 Atmospheric Stagnation

Air pollution episodes are typically the result of persistent surface high pressure systems that cause light and variable surface winds and stagnant meteorological conditions. The Bermuda High is a large area of semi-permanent high pressure, usually situated off the United States' southeastern Atlantic coast. Depending upon the position and strength of this weather system, the Bermuda High can lead to stagnant meteorological conditions in the region. The Bermuda High is strongest in July (Reference 2.3-53). This high-pressure system has a clockwise circulation, which puts the eastern United States in the position to receive south to southeast winds. These winds pump in heat and humid air from the Atlantic Ocean and Gulf of America over the Carolinas. It can often lead to many days or even weeks of hot and sticky weather, especially across the southeastern United States. Therefore, the Bermuda High is a unique controlling factor for air stagnation and stable atmospheric conditions over the eastern United States, besides the seasonal cycle of minimum wind in summer and maximum wind in winter.

Another unique feature of air stagnation in the eastern United States is its early onset in May, compared to the onset in June in the western and central United States. This results in a prolonged air stagnation season in the eastern United States.

Estimates

Estimates of the stagnation frequency are provided in Wang and Angell (Reference 2.3-53); Figures 1 and 2. Those estimates indicate that, on average, the Project site experiences approximately two to four cases of air stagnation per year. When stagnation occurs, stagnation lasts approximately five days.

2.3.1.3 Design Basis Dry- and Wet-Bulb Temperatures

This section provides ambient temperature and humidity statistics for use in establishing heat loads for the design of normal plant heat sink systems, post-accident containment heat removal systems, and plant heating, ventilating, and air conditions systems.

The mean dry bulb temperature (DBT) at KGSO is 58.3 °F (14.6 °C) with a mean maximum of 77.8 °F (25.4 °C) and mean minimum of 39.0 °F (3.9 °C). The mean wet bulb temperature (WBT) at KGSO is 50.1 °F (10.1 °C) with a mean maximum of 69.0 °F (20.6 °C) and mean minimum of 30.9 °F (-0.6 °C) (References 2.3-26; 2.3-27).

Design basis DBTs and WBTs were estimated for the Project site, using data from KGSO, KRDU, and KINT (Table 2.3-4 for items 1-17 and Table 2.3-1 for items 18 and 19). These include the following temperatures:

1. Normal DBT
2. Mean DBT
3. Mean WBT
4. Maximum Normal DBT
5. Maximum Mean DBT
6. Maximum Mean WBT
7. Minimum Normal DBT
8. Minimum Mean DBT
9. Minimum Mean WBT
10. DBT with Annual Exceedance Probability of 0.4 percent
11. Mean Coincident WBT with Annual Exceedance Probability of 0.4 percent
12. DBT with Annual Exceedance Probability of 1.0 percent

13. Mean Coincident WBT with Annual Exceedance Probability of 1.0 percent
14. DBT with Annual Exceedance Probability of 2.0 percent
15. Mean Coincident WBT with Annual Exceedance Probability of 2.0 percent
16. WBT (Non-Coincident) with Annual Exceedance Probability of 0.4 percent
17. WBT (Non-Coincident) with Annual Exceedance Probability of 1.0 percent
18. 100-year extreme maximum and minimum DBT
19. 100-year extreme maximum and minimum non-coincident WBT

The 100-year return interval extreme maximum and minimum DBT and WBT ([18] and [19] in the above list) are estimated using a technique described in American Society of Heating, Refrigerating, and Air-Conditioning Engineers (ASHRAE) (Reference 2.3-12). This technique calculates the n-year return interval extreme maximum or minimum temperature using the average and standard deviation of a series of annual maximum and minimum temperatures with the following equation:

$$T_n = M + IF_s \qquad \text{(Equation 2.3.1-5)}$$

Where:

T_n = n-year return period value of the extreme temperature computed (years).

M = mean annual extreme temperature.

I = +1 if the maximum temperature is being computed, -1 if the minimum temperature is being computed.

S = standard deviation of the annual extreme temperature.

N = return period in years (e.g., n = 100 for a 100-year return interval).

$$F = -\sqrt{6}/\pi \{0.5772+\ln\{\ln[(n/(n-1)]\} \qquad \text{(Equation 2.3.1-6)}$$

Where:

F = a function that converts the standard deviation of annual extreme temperature parameters to a new variable that is linearly related to the n year return interval extreme temperature (T_n).

ASHRAE (Reference 2.3-12), provides the mean annual extreme maximum and mean annual extreme minimum temperature (M) and the corresponding standard deviation(s) used in Equation 2.3.1-5. The 100-year return minimum and maximum annual extreme DBT and non-coincident WBT are computed using Equations Equation 2.3.1-5 and Equation 2.3.1-6 for KGSO, KINT, and KRDU and are listed in Table 2.3-1.

Winter Storm Elliott presented a cold event in December 2022 with a minimum temperature of 5 ˚F (-15.0 °C) recorded at KGSO. An arctic cold front swept across the foothills and the Piedmont area of western NC during the morning of December 23, 2022, and introduced the coldest air mass in more than five years. Temperatures in the single digits and lower teens combined with 10 to 20 mph (16.1 – 32.2 kph) winds to produce wind chill values in the 0˚ to -15 ˚F (-18 to -26 ˚C) range from the evening of the December 23, 2022, through December 24, 2022. While winds abated through December 25, 2022, unseasonably cold weather persisted for the better part of four days. There were numerous reports of frozen and burst pipes along with mostly minor damage to infrastructure throughout the area. Using the 5 ˚F (-15.0 °C) minimum temperature in the ASHRAE calculation for return intervals, a return interval of nine years is computed.

2.3.1.4 Meteorological Data for Evaluating Ultimate Heat Sink

None of the advanced reactor designs being evaluated rely on an external water source as its ultimate heat sink (UHS). Therefore, meteorological parameters (dry and wet bulb temperature, ambient temperature, humidity, and degree-days below freezing) that characterize evaporation and drift loss of water, minimum water cooling, and the potential for water freezing in a UHS water storage facility are not applicable to the Project site.

2.3.1.5 Climate Changes

Historical long-term meteorological data are considered in the project's impact on the surroundings of the Project site. Though the impact of global climate change is uncertain, projected trends are discussed in this section. Consistent with NRC ISG NRC COL/ESP-ISG-026 (Reference 2.3-36), the normal project lifetime, decommissioning period, and resources that may be impacted by climate change are considered. The first unit at the Project site is estimated to be online in 2034 as the earliest possible commercial operation date, with a planned 12-month stagger between units for units 2 – 6 to come online. The initial operating license for each unit is for 40 years and license renewals could extend the operating period an additional 40 years. Thus with the initial license and renewals, the units could operate up to 80 years, with potential in the future to extend the operating life up to a total of 100 years.

The North Carolina Climate Science Report (NCCSR) (Reference 2.3-20) assesses historical climate trends and potential future climate change in NC under increased greenhouse gases (GHG) concentrations and provides projected changes for the climate of NC for two hypothetical climate futures: a higher scenario (Representative Concentration Pathway 8.5, or RCP8.5), in which GHG emissions continue to increase through the end of the century, and a lower scenario (RCP4.5), in which emissions increase at a slower rate, peak around the middle of the century, and then begin to decrease.

Sea level along the northeastern coast of NC has risen about twice as fast as along the southern half of the coast, averaging 1.8 in. (4.6 cm) per decade since 1978 at Duck, NC, and 0.9 in. (2.3 in.) per decade since 1935 at Wilmington, NC (Reference 2.3-20). A more recent study considered the effect of relative sea level rise (RSL) on historical water levels observed

along the NC coast and found that under the higher scenario (RCP8.5) after 2050, water levels that currently have a 10 percent probability of occurring each year would have nearly a 100 percent probability of occurring each year in Wilmington. Furthermore, water levels that currently have a 1 percent probability of occurring each year would have nearly a 60 percent probability of occurring each year from 2050 to 2100. Threats associated with these conditions would not have a direct effect on the Project site, due to its inland location.

The NCCSR projects that it is very likely that NC temperatures and extreme precipitation frequency and intensity will increase, and it is likely that the frequency and severity of inland flooding will increase (Reference 2.3-20).

The National Climate Assessment (NCA) Report provides detailed information related to the potential effects of climate change on the U.S. by region (Reference 2.3-52). The Project site is in the southeast region of the U.S. as defined by the report. In general, the NCA report states that the southeast region is vulnerable to sea level rise and coastal flooding, extreme heat events, hurricanes, and tropical cyclones, and increasing wildfire risk (Reference 2.3-52).

The NCA report found that heatwaves in the southeast region are happening more frequently and are occurring during a longer heat season, with some cities also showing increasing trends in heatwave duration and intensity.

The number of extreme warm days (above 95 °F [35 °C]) is expected to continue increasing with every increment of global warming. Further, there have been an increasing number of days that exceed 95 °F (35 °C) and nights that exceed 75 °F (24 °C) and a decrease in the number of “extremely cold” days since 1900. (Reference 2.3-52).

Temperatures have steadily increased across the southeast since the 1970s. Climate models agree that annual temperatures will continue to increase in the future, with an average annual increase of 3 – 5 °F (approximately 1.7 – 2.8 °C) by 2041 – 2070. Simulated temperature increases for winter and spring are between 2.5 – 5 °F (1.4 – 2.8 °C). For summer the simulated temperature increases from 3.5 – 6 °F (1.9 – 3.3 °C), and during the fall the increase is between 3 – 5 °F (1.7 – 2.8 °C) (Reference 2.3-43). These are probabilistic predictions; however, if these numbers are simply interpolated for the next 50 years, results indicate an approximate total increase of 2 °F (1.1 °C) to 4 °F (2.2 °C) during the operating lifetime of the Project site. The report also finds that days with maximum temperatures exceeding 95 °F (35 °C) are predicted to increase, with more than 35 additional days occurring in central Florida and 20 – 30 additional days across the rest of the region, and there is likely to be a decrease in days with freezing temperatures (Reference 2.3-52).

The NCA report states that the southeast region is more prone to extreme drought due to higher rates of evapotranspiration than other parts of the eastern United States. Longer-term droughts in the region appear to be increasing in severity but do not appear to be occurring more frequently (Reference 2.3-52).

The NCA report states that the southeast region has received increasing precipitation in the fall, but over the past few decades there has been a decreasing trend in rainfall in summer. Most

climate models forecast that the decrease in summer rainfall will continue with mean annual precipitation expected to decrease across the western portion of the southeast region. Extreme rainfall events have occurred more frequently across the southeast region in the past 20 years. Average annual precipitation from 2002 to 2021 was 5 percent to 15 percent higher relative to the 1901 – 1960 average in the central and eastern U.S. (Reference 2.3-52).

The NCA has investigated severe weather events including hurricanes, tropical storms, and tornadoes. The NCA report states that warmer temperature projections would result in a decrease in tropical storms globally, however, there has been a slight increase in the frequency of tropical storms in the Atlantic, and the number of major hurricanes (category 3 – 5) has increased over the past few decades (Reference 2.3-43). The Project site is located inland and not likely to experience the most severe impacts of hurricanes. However, extreme rain events are a risk with or without tropical systems. The study reports that the number of major tornadoes has increased in the past 50 years, however, there is "no statistically significant trend." The study indicates that the increase in the number of tornadoes reported may be attributable to expanded and better reporting of tornadoes (Reference 2.3-52).

Based on the NCA report, the greatest potential effects of climate change are increased temperatures and reduced water availability due to evapotranspiration and droughts for the Project site, and its surroundings. At the same time, stormwater from extreme precipitation events may increase. As the models used to develop these projections are based on future estimates of population growth, land use, energy consumption, emissions patterns, etc., there is a level of uncertainty associated with the events and meteorological conditions predicted. The Project site is required to continuously monitor meteorological and environmental conditions throughout the life cycle of the project to ensure it remains within its allowable licensed limits of operation. Details related to meteorological monitoring and water monitoring are covered in Duke Energy's Environmental Report Sections 2.7 and 4.2.4, respectively.

2.3.1.6 Regional Air Quality Conditions

The Project site is located within the Northern Piedmont Intrastate Air Quality Control Region. The Clean Air Act (CAA) was enacted in 1970 to protect public health and welfare and authorizes the USEPA to set National Ambient Air Quality Standards (NAAQS) for six common pollutants, called criteria pollutants. There are also provisions to regulate hazardous air pollutants, which are pollutants that are harmful to human health and/or the environment, as well as GHG, primarily carbon dioxide (CO_2) (42 U.S. Code 7401 et seq).

The CAA requires the USEPA to set NAAQS for pollutants considered to be harmful to public health and the environment. Primary NAAQS provide public health protection including protecting the health of sensitive populations (asthmatics, children, elderly, etc.). Secondary NAAQS provide public welfare protection against decreased visibility and damage to animals, crops, vegetation, and buildings (Reference 2.3-48).

On February 7, 2024, the USEPA issued its final rule reconsidering the particulate matter NAAQS (40 CFR Parts 50, 53, and 58). USEPA is revising the level of the primary (health-

based) annual standard for fine particles (particulate matter with a diameter of 2.5 micrometers or smaller, $PM_{2.5}$) from the current level of 12 micrograms (µg) per m^3 to 9 µg per m^3. The NAAQS are presented in Table 2.3-6. NC reached full attainment with all NAAQS across the entire state in 2015. The most recent pollutant to be redesignated was ozone. On July 28, 2015, the USEPA redesignated to attainment the NC portion of the Charlotte-Rock Hill, NC-SC, nonattainment area for the 2008, 8-hour ozone NAAQS, effective August 27, 2015.

2.3.1.6.1 Class I Areas

The CAA defines Class I areas as national parks greater than 6000 ac. (2428 ha), wilderness areas greater than 5000 ac., national memorial parks greater than 5000 ac. (2023 ha), and international parks that were in existence as of August 1977. These areas are potentially sensitive to visibility impairment. The USEPA states that a Class I visibility impact analysis is necessary for a major source within 100 km (62 mi.) of a Class I area (Reference 2.3-46).

The USEPA promulgated the Regional Haze Rule to Improve visibility in Class I areas in 1999 with the ultimate goal of restoring natural background visibility by 2064 (Reference 2.3-16). This rule was amended in 2005 to require certain industrial facilities to install emission controls to reduce emissions of air pollutants that reduce visibility (References 2.3-17; 2.3-49). These pollutants include particulate matter with $PM_{2.5}$ and compounds that contribute to $PM_{2.5}$ formation, such as nitrogen oxides, sulfur dioxide (SO_2), certain volatile organic compounds, and ammonia.

The closest Class I areas to the Project site area are Linville Gorge Wilderness Area, located in NC just over 100 mi. (roughly 168 km) to the southwest, Shenandoah National Park, located in VA approximately 143 mi. (230.5 km) to the north-northeast (NNE), and the Great Smoky Mountains National Park, located in NC and Tennessee approximately 174 mi. (280.3 km) to the southwest. There are no Class I areas within 100 km (62 mi.) of the Project site, therefore, no Class I areas are affected (Reference 2.3-49). The nearest state park is Mayo River State Park located approximately 10 mi. (16.1 km) to the northeast of the Project site.

2.3.1.6.2 Greenhouse Gas Emissions

Global net anthropogenic GHG emissions have been estimated to be 59 ± 6.6 gigaton CO_2-equivalent ($GtCO_2$-eq) in 2019, about 12 percent (6.5 $GtCO_2$-eq) higher than in 2010 and 54 percent (21 $GtCO_2$-eq) higher than in 1990, with the largest share and growth in gross GHG emissions occurring in CO_2 from fossil fuels combustion and industrial processes (Reference 2.3-19). At the national level, net GHG emissions in the U.S. in 2022 totaled 6343.2 million metric tons CO_2-eq after accounting for sequestration from the land sector (Reference 2.3-50). The increase in total GHG emissions was driven largely by an increase in CO_2 emissions from fossil fuel combustion.

In 2022, CO_2 emissions from fossil fuel combustion increased by 1 percent relative to the previous year. This increase in fossil fuel consumption emissions was from increased energy use, due in part to the continued rebound in economic activity after the height of the coronavirus disease 2019 (COVID-19) pandemic. GHG emissions in 2022 (after accounting for

sequestration from the land sector) were 17 percent below 2005 levels (Reference 2.3-50). At the state level, GHG emissions in NC are 115.6 million metric tons total CO_2 (Reference 2.3-15).

The impact of estimated GHG emissions resulting from the Project site on air quality is compared to state and national GHG emissions. The lifetime GHG emissions footprint from a generic 1000-megawatt electric (MWe) reactor is estimated to be 10.5 million metric ton (MT) CO_2eq. (Table A-3, Nuclear Power Plant Lifetime GHG Footprint, Reference 2.3-36). Using the emissions from the generic 1000 MWe reactor provides a conservative estimate. Lifetime GHG emissions from a new power plant are an estimated 9.1 percent of annual 2022 GHG emission in the state of NC (10.5 million to 115.6 million MTs) and 0.17 percent of the annual 2022 carbon equivalent emissions in the United States (10.5 million to 6343.5 million MTs).

2.3.1.6.3 Project Air Quality

Generation of electricity from the advanced reactors at the Project site would not be a source of criteria pollutants or other air toxic pollutants. However, supporting equipment such as cooling towers, auxiliary boilers, fire pump engines, and emergency or standby diesel generators would emit criteria pollutants. These supporting sources are not expected to be a significant source of criteria pollutant emissions or to significantly impact ambient air quality. If the Belews Creek facility were to emit criteria pollutants above significance thresholds, it would need to apply for a Prevention of Significant Deterioration permit prior to construction. The application for this permit would require a demonstration of compliance with applicable regulations and a demonstration that ambient air quality standards will not be threatened or exceeded as a result of the operation of this facility.

There may be some minor impacts on local air quality during construction. Construction impacts are mitigated using construction best management practices according to Duke Energy procedures and state air permits.

2.3.2 LOCAL METEOROLOGY

This section provides information concerning the local (e.g., on-site) meteorological parameters, the assessment of the potential influence of the proposed plant and its facilities on local meteorological conditions, and a topographical description of the site and its environment.

Short-term site-specific meteorological data, collected from MET tower during February 7, 2024 – February 6, 2025, are the primary basis for this dispersion meteorology analysis. In addition to on-site measurements, data representative of the site or indicative of site conditions were also obtained from LCDs recorded at the KGSO which is approximately 14 mi. (22.5 km) to the southeast of the Project site, KINT, and KRDU (References 2.3-26; 2.3-27; 2.3-39).

Meteorological measurements at the Project site were made using one on-site tower, as listed in Table 2.3-7, and further described in Section 2.3.3.1. Data from the on-site tower and regional towers were used to evaluate the impact of topography. The principal impact is on wind directions.

Topography around the site strongly influences the local climate. The Project site is located at an elevation of approximately 810 ft. (247 m) above mean sea level (AMSL) on a peninsula surrounded on three sides (west, north, and east sides) by Belews Lake. Most of the terrain in the vicinity of the Project site (Figure 2.3-1), is characterized by Belews Lake and the foothills of the Blue Ridge mountains to the northwest. Belews Lake was formed in the early 1970s from Belews Creek, a small tributary of the Dan River, under the authorization of the NC Department of Water and Air Resources specifically to provide cooling water to the BCSS. The location is at the southwest edge of the Dan River Basin. The Dan River runs parallel to the northwest boundaries of Belews Lake. The Dan River rises from springs on Belcher Mountain on the Blue Ridge Plateau in Patrick County, VA then flows 214 mi. (344 km) across the state border into Stokes County, NC. The lake sits in the North Central Piedmont of NC, and the land gradually rises to the Blue Ridge Mountains in the west and northwest. Outcroppings southeast of the Blue Ridge rise into peaks occasionally exceeding 2500 ft. (762 m). The Blue Ridge forms a northeast to southwest barrier about 50 mi. (80 km) from the Project site.

The Sauratown Mountains are located within Stokes and Surry counties and lie west-northwest (WNW) of the Project site. The range is home to two state parks located within a 25 mi. (40 km) radius of the Project site. Pilot Mountain State Park, which includes Pilot Mountain, peak elevation 2241 ft. (683 m), is approximately 24 mi. (39 km) west, and Hanging Rock State Park, peak elevation 2159 ft. (658 m), is approximately 14 mi. (23 km) northwest of the Project site.

Terrain in the vicinity of the Project site is characterized as alternating ridges and valleys oriented along a northeast to southwest axis. Nearby ridges reach an elevation of 1100 ft. (335 m) AMSL (approximately 300 ft. [91 m] above plant grade). The structures in all three areas (North, Middle, South) are located at a distance from the MET tower that would meet the offset requirement in RG 1.23, Rev.1, *Meteorological Monitoring Programs for Nuclear Power Plants,* that states the sensors should be located over level, open terrain at a distance of at least 10 times the height (10L) of any nearby obstruction. The MET tower is approximately 1218 ft. (371 m) ENE of the closest turbine and reactor building (the North Area). Since the turbine and reactor building is 120 ft. (37 m) tall, the tower would meet the 10:1 offset distance requirement for the North Area to minimize adverse effects of turbulence and building wake effects. This assumes that the maximum obstruction height is the turbine and reactor building, which is roughly 120 ft. above grade. The MET tower is approximately 1065 ft. (371 m) northeast of the closest cooling tower area (maximum height of 75 ft.) and meets the 10:1 offset distance requirement. In the area near the MET tower, trees with a vertical penetration within the 10L slope, or within 10 vertical ft. to the 10L surface have been cleared and removed.

A topographic map outlining a 5 mi. boundary from the Project site center point is shown in Figure 2.3-2. Figures 2.3-3 (Sheets 1 through 8) provide elevation profiles of the maximum elevation at the 16 compass directions radiating out from the Project site to 50 mi. (80.5 km). Figure 2.3-4 provides a topographic map of the elevation profile radials.

2.3.2.1 Normal and Extreme Values of Meteorological Parameters

Long-term temperature and precipitation records were examined to determine if data collected

at the Project site are consistent with regional conditions, both spatially and over time.

Meteorological data collected at nearby KGSO are presented and evaluated in the following sections in more detail. Table 2.3-8 summarizes annual meteorological parameters from KGSO, including normal temperature and relative humidity (RH), mean wind speed, prevailing wind direction, and normal precipitation for the time period of 1991 – 2020.

Comparisons of common measurements for the different data periods have been made to determine if site meteorological conditions are changing significantly over time. Common variables (except wind direction) can be compared directly, but wind direction is too dependent on topography for direct comparison particularly with off-site data. Comparing data from nearby off-site locations helps to determine if the Project site is consistent with regional conditions.

Comparison of the KGSO, KRDU, and KINT regional airport data to the Project site data summarized in Table 2.3-9, shows that there is generally good agreement between the Project site and off-site regional locations over different data periods. The differences fall within the normally expected variations. Therefore, it is concluded that meteorological characteristics for the Project site have not changed significantly over time. Additionally, data from the Project site appear to be consistent with overall meteorological conditions in the vicinity. This is characteristic of the controlling synoptic influences throughout the region.

2.3.2.1.1 Winds

From February 2024 to February 2025, 10 m wind data were collected by the MET tower at the Project site. The meteorological tower at the Project site meets the criteria for obtaining data representative of the atmospheric conditions on-site.

The following discussion considers the 10 m wind data from KGSO and the on-site MET tower as representative of potential ground-level releases for air dispersion modeling purposes. Local conditions are important in evaluating ground-level releases because maximum air concentrations from contaminants released into the atmosphere generally occur close to the release point.

2.3.2.1.1.1 Average Wind Direction and Wind Speed Conditions

JFDs of wind direction (unit vector approximation of scalar values), average (scalar) wind speed, and stability class from instruments at 10 m at the Project site are presented in Section 2.3.4. Wind roses for KGSO based on ten years of data (2013–2023), are presented in Figures 2.3-5 through 2.3-17. The Project site data are presented as wind roses at 10 m in Figures 2.3-18 through 2.3-30 and at 60 m in Figures 2.3-31 through 2.3-43.

Mean wind speeds recorded at KGSO for the 39-year period 1983 – 2022 (Table 2.3-10) were generally moderate with an average annual mean speed of 7.1 mph and prevailing wind direction from the SW. Wind gusts were recorded over a 27-year period, 1996 – 2022, with the maximum 2-minute wind speed recorded in May 2000 at 62 mph (100 kph). The maximum 3-second gust recorded was 82 mph (132 kph) on May 25, 2000, when Guilford and Alamance

counties were impacted by a severe storm with reports of property damage and tornado sightings (References 2.3-54; 2.3-55).

Wind speeds at the Project site during 2024–2025 were generally light with an average 10 m speed of 4.3 mph and prevailing wind direction from the WSW. The daily maximum 10 m (scalar) wind speed was 19.2 mph (Table 2.3-11).

The Project site and KGSO data indicate winds consistent with the southwest to northeast orientation of the terrain in the region (Figure 2.3-1). The geographic orientation of the local and regional terrain in the vicinity and region around the Project site aligns with the prevailing on-site and offsite winds from the southwest. The local wind patterns are influenced by the local terrain, with up-valley (southwest-WSW)/down-valley (northeast-ENE) flow patterns common on-site and stable conditions, with light to moderate winds frequently observed, especially during the summer and fall seasons.

2.3.2.1.1.2 Wind Direction Persistence

Generally, the longer the winds blow in the same direction, the lower the dilution potential because effluent is not dispersing significantly downwind. Wind direction persistence is an indicator of the duration of atmospheric transport from each direction. For the Project site (Table 2.3-12), the maximum persistence at 10 m is 27 hours from the SW.

The wind data for KGSO and the Project site show a consistent pattern of wind directions with predominant winds from the SW. There is moderate seasonal variation (Figures 2.3-44 through 2.3-51). Due to the combination of uniformly light to moderate wind speeds and surrounding terrain, there could often be minimal transport, with a potential for recirculation of gaseous effluent near the site.

2.3.2.1.2 Air Temperature

Table 2.3-13 summarizes normal maximum and minimum temperatures recorded at KGSO for the time period of 1991 – 2020. Maximum temperatures recorded for the 30-year period 1991 – 2020 usually occur between the months of June and September. Minimum temperatures for the 30-year period 1991 – 2020 usually occur from November through March. Mean monthly temperatures range from the lower 30s (°F) (around 0 ˚C) in the winter to the upper 80s (°F) (around 30 ˚C) in the summer.

The extreme maximum temperature recorded at KGSO for the 94-year period 1928 – 2020 was 103 °F (39.4 °C) in August 1988 and the extreme minimum temperature for the 94-year period was -8 °F (-22.2 °C) recorded in January 1985 (Reference 2.3-26).

Table 2.3-14 summarizes average, daily minimum, and daily maximum DBT and WBT recorded at the Project site during the collection period from 2024–2025. The highest daily maximum temperatures for the collection period occurred during the months of June and July. The lowest daily minimum temperatures occurred in December and January. The average monthly DBTs range from the mid-30s (°F) (around 0 ˚C) in January to the upper 70s (°F) (around 25 ˚C) in

July. The daily maxima recorded at the Project site was 97.3°F (36.3 °C) (July 2024), while the daily minimum was 15.8 °F (-9 °C) (January 2025).

2.3.2.1.3 Atmospheric Moisture

Long-term RH and WBTs for KGSO are presented in Table 2.3-15. The normal annual RH is 69 percent at KGSO and ranges from 61 percent in April to 77 percent in September. Normal mean annual WBT average is 50.1 °F (10.1 °C) at KGSO (Reference 2.3-26). Maximum monthly mean WBTs are 69.0 °F (20.6 °C) during July. Minimum monthly mean WBTs are recorded in January; 30.9 °F (-0.6 °C) (Reference 2.3-26).

Average humidity data for the Project site is summarized in Table 2.3-16. The average annual RH is 68 percent at the Project site and ranges from 53. percent in January to 80 percent in September. The average annual WBT is 54.7°F (12.6 °C). The highest daily maximum WBT is 71.8 °F (22.1 °C) during July. The lowest daily minimum WBT was recorded in January; 30.5 °F (-0.8 °C). The Project site data aligns with the long-term KGSO data.

2.3.2.1.4 Precipitation

2.3.2.1.4.1 Rain

Precipitation data from KGSO are presented in Table 2.3-17. Precipitation falls an average of about 116 days per year, and the normal annual precipitation is nearly 44 in. (112 centimeters [cm]). The maximum monthly rainfall in the 94-year period 1928 – 2022 was 13.26 in. in September 1947. The minimum monthly amounts in the 94-year period were trace amounts in September 1985 and June 1990. The maximum precipitation in 24 hours was 7.49 in. (19.02 cm) in September 1947. Except for late winter, which is slightly drier, precipitation is fairly uniformly distributed throughout the year. August and September are normally the wettest months of the year, and February is normally the driest.

Approximately 43 thunderstorms occur in a typical year (Table 2.3-17). Thunderstorm activity is greatest during the late spring and summer months, and the maximum frequency of thunderstorm days is normally in July.

The Belews Creek, NC precipitation data for the 2024-2025 data collection period (Table 2.3-18) indicate drier than normal precipitation. The annual precipitation was 38.07 in. (96.70 cm). The maximum monthly precipitation was recorded in September with 7.08 in. (17.98 cm). The maximum precipitation in 1 hour was 1.28 in. (3.25 cm) and the maximum precipitation in 24 hours was 4.23 in. (10.74 cm).

Maximum possible precipitation, estimated by statistical analysis of regional precipitation data, is given in Table 2.3-26 for return periods of one to 100 years and for rainfall durations from five minutes to ten days. Probable maximum precipitation (PMP), sometimes called maximum possible precipitation, for a given area and duration is the depth which can be reached but not exceeded under known meteorological conditions (Reference 2.3-42). This data was taken from the NOAA Atlas 14, Volume 2, Version 3 (Reference 2.3-21) and the NOAA Atlas 14 Point

Precipitation Frequency Estimates (Reference 2.3-22) for the area nearest the Project site. For the Project site, using a 100-year return period, the PMP for 6, 12, 24, and 48 hours is 5.1, 6.4, 7.8, and 8.8 in., respectively.

2.3.2.1.4.2 Precipitation Wind Roses

Table 2.3-19 shows composite precipitation data for the 2024-2025 collection period based on the Project site hourly precipitation and wind directions. The precipitation value used in the analysis is based on the amount that accumulated over the hour. Precipitation is most associated with wind direction from the W. There is a secondary maximum with wind direction from the WNW. The Project site composite precipitation and wind direction data are presented as precipitation wind roses at 10 m in Figures 2.3-52 through 2.3-68.

2.3.2.1.4.3 Snow

Appreciable snowfall is relatively infrequent in the area. Snowfall data are summarized in Table 2.3-20 for KGSO. Normal annual snowfall is about 7 in. (18 cm). Generally, significant snowfalls are limited to December through March. The 24 hour maximum snowfall was 14.3 in. (36.3 cm) in December 1930. Recorded maximum monthly snowfall was 22.9 in. (58.2 cm) in January 1966.

2.3.2.1.5 Fog

Fog is defined as water droplets suspended in the atmosphere in the vicinity of earth's surface that affect visibility. Fog reduces visibility below 1 km (0.62 mi.) (Reference 2.3-9). The number of days with heavy fog (visibility equal to or less than one-quarter mile) at the Project site, was determined based on data from the KGSO LCD and KRDU LCD (References 2.3-26; 2.3-27). Fog data for KGSO and KRDU is presented in Table 2.3-21. These data indicate that heavy fog occurs about 27 days per year, with the winter normally the foggiest season.

2.3.2.1.6 Atmospheric Stability

Atmospheric stability is based on the temperature difference (ΔT) between the 60 m and 10 m measurement levels. The Pasquill atmospheric stability classes (A – G) are described in Table 2.3-22 and the frequency occurrence of each class is presented in Table 2.3-23. While neutral lapse conditions (class D) occur most frequently (31.2 percent), stable lapse conditions (i.e., inversions) typically occur over 36.4 percent of the time. The most unstable class (class A) occurs 21.3 percent of the time, while the most stable class (class G) occurs 2.2 percent of the time.

Inversion Persistence

Tables 2.3-24 and 2.3-25 present a summary of on-site persistence data, with a breakdown by stability class, for the Project site for the 2024-2025 collection period. Inversion persistence is defined as two or more consecutive hours of a single stable class, or combination of stable classes (Stability Classes E through G). The longest contiguous period of inversion conditions (Stability Class E) was 19 hours.

Mixing Heights

Mixing heights for Greensboro, NC, were obtained from the USEPA Support Center for Regulatory Atmospheric Modeling (SCRAM). The USEPA data are more current than the traditional Holzworth reference that is often used. Mixing heights vary during the day, with the lowest average mixing heights (approximately 379 m [1243 ft]) generally recorded during the morning hours in the autumn and the highest readings (approximately 1609 m [5278 ft.]) recorded during the afternoon in the summer for the 7-year period of record (1984-1987 and 1989-1991) used by the USEPA in the SCRAM dataset (Reference 2.3-51). Approximate seasonal and annual estimates of mixing heights for the Project site are presented in Table 2.3-27.

2.3.2.2 Potential Influence of the Plant and Its Facilities on Local Meteorology

Larger structures on-site would influence wind conditions (wind speed, direction, and turbulence), although these effects are not expected to be significant beyond ten building/structure heights from the building or structure in question, per RG 1.23.

The only nearby feature which may have any noticeable effects on the local meteorology is the new on-site Ash Basin Landfill. The Ash Basin Landfill is planned to:

- Be located partially within the former footprint of the ash impoundment, called the Basin, at the BCSS, adjacent to Pine Hall Rd.
- Be approximately 90 ac.
- Be designed to contain approximately 14.1 million cubic yards of coal ash.
- Stand 168 ft. tall (from primary liner to top of final closure cap), rising approximately 125 ft. above Pine Hall Rd.

The new landfill is approximately 2 mi. (3.2 km) northwest of the Project site. While there could be some localized blockage and diversion of winds around the new landfill, the distance of the new landfill from the project is too far away to produce downstream effects at the Project site. Impacts on the proposed nuclear facility are expected to be minimal.

Project-related structures that may have noticeable effects on the local meteorology is the new cooling tower. The nearest cooling tower is in the North Area and is 1061 ft. (324 m) to the MET tower. If linear mechanical draft cooling towers (LMDCTs) are used, they are expected to produce elevated plumes that somewhat alter overall local frequencies of overhead clouds. LMDCTs are also expected to produce small increases of ground level fog, rime icing, and drift deposition as potential impacts. Ground fog events are defined to occur when a modeled plume contacts the ground and/or the plume is below the height of the cooling towers. No hours of fogging are predicted.

2.3.2.2.1 Cooling Tower Impact Modeling

The NRC has identified several plume-related codes as acceptable methodologies for modeling cooling tower impacts to the environment. A model in Carhart et al., 1992 is endorsed in NUREG-1555, Initial, *Standard Review Plans for Environmental Reviews for Power Plants*, Section 5.3.3.1. In NUREG-1555, the NRC accepts the conclusion of Carhart et al., 1992 that their model predicts plume rise within a factor of two approximately 75 percent of the time and visible plume length within a factor of 2.5 approximately 70 percent of the time. Their model is embedded into the Electric Power Research Institute's (EPRI) Seasonal/Annual Cooling Tower Impact Prediction Code (SACTI) in 1991 and later modified in 2015 in accordance with Carhart et al., 1992 and Policastro et al., 1994.

Evaluations of cooling tower impacts were performed assuming that LMDCT will be utilized. Salt deposition rates, as a function of distance and direction from the cooling towers, were calculated for a representative model of the LMDCT using the SACTI code. The current version of the SACTI plume modeling code, hereinafter referred to as SACTI2, was used to develop the model for the evaluation of potential plumes from LMDCTs on the Project site.

Significant levels of Chloride run-off can contribute to water quality degradation which can affect aquatic life. However, since the predicted salt deposition rates are relatively low and precipitation is relatively high and frequent at the Project site, deposited salts will be diluted quickly and therefore do not greatly impact Belews Lake and the surrounding area (SACTI2 does not predict the dilutive effects of precipitation on deposited solids). The highest modeled seasonal salt deposition rate (summer — 63.51 kg/km^2/mo) is located 300 m (984 ft.) ENE of the site center point. The maximum modeled seasonal salt deposition rate is in the very light range per guidance from the Institute of Electrical and Electronic Engineers (IEEE). The maximum modeled seasonal salt deposition rate is well below the 1000 – 2000 kg/km^2/mo range that could cause leaf damage in many species as noted in NUREG-1555. The maximum modeled annual deposition rate (41.57 kg/km^2/mo) is also located 300 m (984 ft.) ENE of the site center point within Duke property. This deposition rate is also well below the range that could cause leaf damage. Overall, salt drift deposition is not expected to be a significant concern. Results for these parameters are shown in Figures 2.3-69 and 2.3-70 and summarized in Table 2.3-28.

Water deposition, plume shadowing, plume length frequency, and plume height frequency were also determined for the LMDCTs and summarized in Tables 2.3-29 through 2.3-32. Table 2.3-29 shows the maximum modeled plume water deposition rate of 50,100 kg/km^2/mo occurred in summer. The maximum modeled cooling tower plume shadowing occurred in winter with a frequency of 137.0 hours in a northeast direction from the site center point (Table 2.3-30). The table shows that impacts are highest in winter and lowest in summer and fall. Table 2.3-31 shows the percentage of the time that plumes exceed a specified length. Modeled plumes are longest in the winter and shortest in the summer. Table 2.3-32 shows the percentage of time that plumes exceed a specified height. Modeled plume heights are typically 30 m (98.4 ft.) or less, as modeled seasonal plume heights exceed 50 m (164 ft.) and above less than 13 percent in winter (maximum seasonal value) and 6 percent annually.

2.3.2.3 Local Meteorological Conditions for Design and Operating Bases

The local meteorological conditions for the design and operational basis are provided in Section 2.3.1. The Design Basis Temperatures for KGSO, KRDU, and KINT are summarized in Table 2.

2.3.3 ON-SITE METEOROLOGICAL MEASUREMENTS PROGRAM

The following section provides information concerning the on-site meteorological monitoring program and the resulting data. The primary source of meteorological data during early site permitting through construction is a MET tower.

2.3.3.1 Meteorological Measurements History

Duke Energy installed a 60 m (196.9 ft.) on-site tower in late January 2024. The MET tower measures wind speed/direction, temperature, and RH with dewpoint temperature at 10 m AGL and wind speed/direction at 60 m AGL. The 60 – 10 m vertical DBT difference (Delta-T) is also measured. Precipitation is measured at ground level.

On-site meteorological monitoring data collection began in February 2024. The first full year of data was collected from February 7, 2024, through February 6, 2025. The joint data availability of 10 m (32.8 ft.) and 60 m (196.9 ft.) wind speed/direction, Delta-T between 10 m and 60 m, dewpoint, and RH during this period is 92.98 percent. This joint data availability exceeds the annual 90 percent data availability requirements in RG 1.23 and Reference 2.3-47.

2.3.3.2 Primary Meteorological Facility

The primary meteorological facility is a 197-ft. tall, open-lattice tower at the Project site equipped with various monitoring instruments and sensors (referred to as the “MET tower”). This Meteorological Monitoring system is designed to meet or exceed RG 1.23 requirements. Meteorological parameters measured or calculated at the on-site MET tower are listed below.

- Wind speed and direction – measured on an open-lattice tower at approximately 10 m (33 ft.) and 60 m (197 ft.) AGL.
- Sigma-theta, the standard deviation of wind direction. Calculated for both the 10 m (33 ft.) and 60 m (197 ft.) level wind direction.
- Ambient temperature – monitored at approximately 10 m (33 ft.) AGL. Temperature is also measured on the MET tower at the 60 m (197 ft.) level to determine the vertical temperature gradient and stability class.
- Vertical temperature gradient, Delta-T is used to determine the Pasquill atmospheric stability class for air dispersion modeling.
- Precipitation – measured near ground level near the base of the MET tower.
- Atmospheric moisture based on dewpoint temperature (DPT) and RH measured at 10 m (33 ft.) AGL.

Table 2.3-33 provides the specifications of the meteorological instruments installed on the MET tower comply with the guidance contained in RG 1.23. As discussed in Section 2.3.2, the sensors have been installed in open terrain at a distance of at least 10 times the height of any nearby obstruction.

Per RG 1.23, the tower is sited to provide representative measurements of the atmospheric conditions into which material may be released and transported. The MET tower is located at latitude 36˚ 17' 10.067" north and longitude 80˚ 2' 39.038" west and stands 197 ft. (60 m) AGL. The grade elevation of the tower is 810 ft. (247 m) and located at the approximate grade level of the plant. The location of the on-site tower is shown in Figure 2.3-1.

2.3.3.2.1 Instrument Description

Meteorological sensors meet or exceed specifications in RG 1.23 and are detailed in Table 2.3-33 and summarized below:

Sensor	Height (m)	Description
Wind Direction and Wind Speed	10 and 60	Balanced vane wind sensor with a 4-blade propeller
Temperature	10 and 60	Platinum wire resistance temperature and detector (RTD) sensor with aspirated radiation shield
RH with Dewpoint	10	RM Young humidity sensor that also calculates the dewpoint temperature
Rainfall	1	Tipping bucket rain gauge

2.3.3.2.2 Data Acquisition System

The data acquisition system consists of meteorological sensors, a data controller and various interface devices. These devices allow offsite access to the datalogger for downloading the meteorological data to a computer for validation and archiving.

2.3.3.2.3 System Accuracies

The meteorological data collection system is designed to meet or exceed specifications for accuracy and resolution in Table 2 of RG 1.23. The accuracies of the various sensors are provided in Table 2.3-33.

The joint annual data recovery for the 60 m wind speed/wind direction/Delta-T for the period February 7, 2024 – February 6, 2025, is 94.48 percent. The joint annual data recovery for the 10 m wind speed/wind direction/Delta-T for the period February 7, 2024 – February 6, 2025, is 96.07 percent. These data recovery rates exceed (better than) the requirement for annual 90 percent joint data availability in RG 1.23. Therefore, meteorological data meet or exceed data completion requirements RG 1.23.

2.3.3.2.4 Data Recording and Display

Data recording is controlled by an Environmental Systems Corporation (ESC) 8864 data logger that receives the output of each meteorological sensor in a specified time interval. Meteorological sensor outputs are measured every five seconds (720 measurements per hour), with exception of rainfall which is measured continuously as it occurs. Software within the data logger processes incoming data from the sensors to average one minute data into 1-hour averages, with the exception of precipitation (which is total amount per hour). Windspeed is scalar averaged, and the wind direction is a unit vector which approximates a scalar average.

Average wind direction, wind speed and Delta-T are used for meteorological air dispersion modeling applications. Tables 2.3-34 through 2.3-49 provide JFD tables of wind speed and wind direction by Atmospheric Stability Class.

Data is accessed by dialing into the BCNS datalogger which has a wireless modem and antenna for remote access. Data is validated and stored in a database by Duke Energy for reporting and archiving.

2.3.3.2.5 Equipment Servicing, Maintenance and Calibration

Personnel from the Duke Energy Environmental Services division and/or contractors maintain the meteorological data collection system (sensors, electronics, data logger, etc.). Maintenance includes field checks, calibration and/or replacement of components as necessary. Personnel follow procedures to maintain meteorological equipment and validate recorded data.

In accordance with RG 1.23, meteorological instrument calibration and maintenance procedures support meeting a data recovery rate of at least 90 percent on an annual basis for each meteorological variable and annual JFDs of wind speed, wind direction, and stability class. Meteorological data are available in real-time for analysis. Time average accuracies for digital systems meet the criteria listed in Table 2 of RG 1.23.

Calibration of instruments and maintenance of the MET tower is performed or overseen by Duke Energy. The MET tower instrumentation maintenance and service scheduling intended to support compliance with RG 1.23 are summarized below.

- Instrument maintenance and servicing schedules. Semi-annual calibrations, daily data review.
- Data reduction and compilation. The ESC 8864 data logger meets the digital sampling and display rate requirements.
- Guy wires are inspected annually, and the guy wire anchors are inspected once every three years.

2.3.3.3 Operational Meteorological Program

The meteorological monitoring program is designed to collect data that meets the 90 percent

joint data recoverability requirement for wind speed, wind direction and stability class in RG 1.23. The restoration of the data collection capability of the meteorological facility in the event of equipment failure or malfunction is accomplished by replacement or repair of affected equipment. An inventory of spare parts and equipment is maintained off-site at Duke Energy's Environmental Center to minimize periods of outages. Equipment malfunctions or outages are detected by data validation staff, environmental personnel, or contractors during routine or special checks. When an outage of one or more of the critical data items occurs, the appropriate environmental staff or contractor is notified to correct equipment problems and restore the meteorological monitoring system.

2.3.4 SHORT-TERM (ACCIDENT) DIFFUSION ESTIMATES

2.3.4.1 Purpose and Background

This section presents the methodology and results used to evaluate short-term atmospheric dispersion conditions applicable to a design-basis accident for the Project site. The evaluation supports demonstration of compliance with 10 CFR 100.21 and has been performed consistent with the guidance contained in NRC RG 1.145, and NUREG-0800, Section 2.3.4. Atmospheric dispersion consists of two components: (1) atmospheric transport, or the movement of gaseous effluents through the atmosphere; and (2) atmospheric diffusion, or the spread of gaseous effluents through the atmosphere. Atmospheric dispersion conditions are represented by relative air concentration (χ/Q) values at specified receptor distances, primarily at the Exclusion Area Boundary (EAB) and the outer boundary of the LPZ. The evaluations support the siting requirements by demonstrating that appropriate protective measures can be taken in response to a postulated accidental release.

2.3.4.2 Calculation Methodology and Assumptions

Atmospheric dispersion calculations were performed using the PAVAN computer program (NUREG/CR-2858), consistent with RG 1.145. PAVAN is designed to calculate relative air concentration (χ/Q) values using JFDs of wind direction, wind speed, and atmospheric stability class over a defined two-year meteorological data period.

Meteorological data are collected and processed in accordance with RG 1.23. Wind direction and speed data are measured at 10 m and 60 m AGL, and temperature data are collected at the 60 m and 10 m levels for determining atmospheric stability. JFDs are compiled into 16 compass sectors with wind speed and stability classifications. In accordance with RG 1.23, at least two consecutive years of site-specific meteorological data are recommended to ensure the data are representative of the site area meteorological conditions.

JFDs for each stability class, consistent with NUREG/CR-2858 and RG 1.23, are included as Tables 2.3-34 through 2.3-41, and 2.3-42 through 2.3-49, respectively, both using wind direction and wind speed data from 10 m AGL. Currently, only one year of site-specific data is available. When two years of site-specific meteorological data are available, Duke Energy will update the JFDs for the site and revise the short-term atmospheric dispersion calculation as indicated.

Dispersion factors are calculated for various time intervals post-accident, typically including 0–2 hours for the EAB and 0–8 hours and 4–30 days for the LPZ. The analysis uses a ground-level release assumption for conservatism, as defined by RG 1.145 and excludes credit for building wake effects.

For each receptor (EAB and LPZ), χ/Q values are calculated using both directionally dependent (maximum sector) and directionally independent (overall site) methods. The bounding χ/Q is the greater of the two values, consistent with RG 1.145 guidance. In the directionally dependent approach, χ/Q values are determined for each sector, and the 0.5 percent exceedance value is used. For the directionally independent approach, a site-wide cumulative distribution is compiled, and the 5 percent exceedance value is used.

Building wake effects are excluded (building height and cross-sectional area set to zero) for conservatism. Ground-level release is modeled since it results in the highest downwind concentrations. Plume meander is considered for neutral or stable conditions and wind speeds below 6 m/s. For higher wind speeds or unstable conditions, NUREG/CR-2858 states that the PAVAN computer program does not consider plume meander. For higher wind speeds or unstable conditions, NUREG/CR-2858 states that the PAVAN computer program does not consider plume meander.

Effluent release points are represented by a conservatively defined release boundary enclosing all potential sources within the plant's nuclear power block, determined using the aggregate power block footprint from all technologies being evaluated for implementation. The EAB is determined by assembling a composite of the EAB distances provided as inputs from the selected technologies to have the limiting EAB distance in every direction (limiting in this case meaning nearest to the potential release points). The outer boundary of the LPZ is assumed to be equivalent to the EAB for the purposes of the evaluation. Table 2.3-50 lists the minimum distances from the perimeter of the release envelope (the power block footprint) for each of the 16 downwind direction sectors for each Plant Complex.

2.3.4.3 Summary of Results and Conclusions

The PAVAN modeling results provide χ/Q values for use in accident dose consequence assessments as required by 10 CFR Part 100. The bounding EAB and LPZ χ/Q values for each Plant Complex are presented in Tables 2.3-51 through 2.3-53 The bounding χ/Q values for each Plant Complex are documented in Table 2.3-54.

2.3.5 LONG-TERM (ROUTINE) DIFFUSION ESTIMATES

2.3.5.1 Purpose and Background

This section presents the methodology and provides the atmospheric dispersion factors (χ/Qs) and deposition factors (D/Qs) for routine releases associated with the Project site. The analysis is prepared in accordance with the guidance provided in NRC RG 1.111, *Methods for Estimating Atmospheric Transport and Dispersion of Gaseous Effluents in Routine Releases from Light-Water-Cooled Reactors*, and uses site-specific meteorological data.

The χ/Q and D/Q factors are calculated at locations as a function of downwind distance from the Project site effluent release points that are located within the north, middle, and south power block areas. The χ/Q and D/Q locations include receptors on the EAB or property line (i.e., site boundary) for each Plant Complex in each of the 16 directional sectors and at two offsite locations, i.e., the nearest resident and nearest vegetable garden (greater than 50 m^2 [538 ft^2]). The minimum distance between the release point and the receptor on the unrestricted area boundary, i.e., the distance to the EAB or to the site boundary, is used as the distance in each sector for χ/Q and D/Q determination. The longest distance from the EAB or site boundary to the power block boundary is used to determine what unrestricted area boundary is used. In addition, general and segmented χ/Q and D/Q factors are calculated radially out to 50 mi. (80.5 km) from the Project site. For all the locations considered, the χ/Q factors are calculated as a ground level release considering the following scenarios: no depletion/no decay, no depletion/2.26-day half-life, and depletion/8-day half-life. The χ/Q and D/Q factors are calculated as average values over a period of one year.

2.3.5.2 Calculation Methodology and Assumptions

The site-specific meteorological data is collected and processed for a time period of one-year from February 7, 2024 to February 6, 2025 to evaluate routine releases at the Project site. RG 1.23 states that for an ESP a consecutive 24-month period of meteorological data that is defendable, representative and complete, but not older than 10 years from the date of the application is required at submittal. Currently, only one year of site-specific data is available. When two years of site-specific meteorological data are available, Duke Energy will update the JFDs for the site and revise the long-term atmospheric dispersion calculation as indicated.

The wind data consists of an hourly JFD of speed, direction, and Pasquill stability class derived from the meteorological tower located at the Project site.

The XOQDOQ code module of the NRCDose, version 2.3.10, computer code is used to calculate the χ/Q and D/Q factors. Using XOQDOQ module contained in the NRCDose computer code implements the assumptions outlined in Section C (excluding C.1.a and C.1.b) of RG 1.111.

The XOQDOQ code module of NRCDose is based on the theory that material released to the atmosphere will be normally distributed (Gaussian distribution) about the plume centerline. In predicting concentrations for longer time periods, the horizontal plume distribution is assumed to be evenly distributed within the directional sector. A straight-line trajectory is assumed between the point releases and all receptors in the models.

The XOQDOQ code uses the JFD to estimates the χ/Q and D/Q factors by default for each of the 16 sectors (22.5°), relative to the release location envelope, extending 50 mi. (80.5 km) radially outward at 22 radial distances for each sector. In the analysis, the release location envelope is at ground level over an area that covers the release point for each Plant Complex at the Project site. The unrestricted area boundary χ/Q and D/Q factors for the 16 sectors for each Plant Complex are conservatively estimated using the minimum distance from the power block boundary to the unrestricted area boundary. Figures 2.3-71 through 2.3-73 present the shortest

distances from the power block boundary to the unrestricted area boundary for each directional sector for the North, Middle, and South Plant Complexes, respectively. Table 2.3-55 presents the distances from the power block boundary to the unrestricted area boundary (i.e., EAB or site boundary) for each direction sector and each Plant Complex.

Many of the dose consequence analyses utilizing the χ/Q and D/Q factors determined in the analysis are prepared to address regulations applicable to the entire project site. Using the bounding χ/Q and D/Q factors for each Plant Complex is overly conservative because the bounding χ/Q and D/Q factors determined for each Plant Complex are not located at the same geological location. Therefore, it is reasonable to determine χ/Q and D/Q factors for each Plant Complex at an unrestricted area boundary Maximally Exposed Location (MEL) that provides less conservative combined χ/Q and D/Q factors than the combined bounding χ/Q and D/Q factors for each Plant Complex. The unrestricted area boundary MEL is a fixed point for a receptor and could be in different sectors for each Plant Complex.

A sensitivity analysis was performed to determine the unrestricted area boundary MEL that results in the maximum combined χ/Q and D/Q factors from each Plant Complex. The unrestricted area boundary MEL is determined to be located along the North Plant Complex EAB, in the northeast sector. The distances from the Middle and South Plant Complex power block boundary to the unrestricted area boundary MEL are shown in Table 2.3-55.

For conservatism, the MEL χ/Q factors for the Middle and South Plant Complex are those for the directional sector that provides the largest χ/Q factors at a distance equal to the MEL distance from the Middle and South Plant Complexes. As can be seen in Tables 2.3-57 through 2.3-60, the bounding χ/Q direction for distances of 0.25 mi. (0.40 km) and greater for the Project site is in the north directional sector. Therefore, the χ/Q factors for the Middle and South Plant Complexes are those in the north directional sector. The bounding D/Q direction for the Project site for distances 0.25 mi. (0.40 km) and greater is the northeast directional sector, which is the sector of the unrestricted area boundary MEL.

In addition, the χ/Q and D/Q factors are estimated for off-site receptor locations from the power block boundary of each Plant Complex. The off-site receptor locations are determined using the guidance from NUREG-1555. As such, per Section 5.4 of NUREG-1555, off-site receptors that are to be considered for evaluation up to 5 mi. (8 km) from the site include the nearest residence, milk animals, meat animals, and vegetable gardens larger than 50 m^2 (538 ft^2). These receptors (nearest resident and nearest vegetable garden) and the associated data are listed in Table 2.3-56. No milk animals or meat animals are identified within 5 mi. (8 km) of the Project site; therefore, locations of milk animals or meat animals are not evaluated.

In accordance with RG 1.111, radiological decay and dry deposition were considered. For conservative estimates of radioactive decay, an overall half-life of 2.26 days is acceptable for short-lived noble gases released to the atmosphere and an overall half-life of eight days is acceptable for iodines released to the atmosphere. In accordance with Regulatory Position 3.c of RG 1.111, wet deposition usually does not have a significant effect on the associated doses. Plume depletion via wet deposition is therefore not modeled in the analysis.

The maximum wind speed utilized in the analysis is 13 m/s (42.65 ft/s). The JFD information

provides the highest wind speed interval that is not closed, referring to any wind in excess of 8 m/s (26.25 ft/s) without specifying the maximum value. The XOQDOQ code requires the minimum and maximum values for the wind speed interval to be specified (closed interval). Per NUREG/CR-2919 (Reference 2.3-34), the maximum speed of an open interval can be assumed to be capped with a value that is 5 units greater than the largest specified interval limit. As such, use of 13 m/s (42.65 ft/s) is appropriate.

No building wake effect is credited in the XOQDOQ model (i.e., the building cross-sectional area for the dispersion analysis is assumed to be zero). Consistent with NUREG/CR-2919 (Reference 2.3-34) no credit for building wake reduces dispersion and is therefore conservative.

The XOQDOQ release model is developed assuming all routine effluent releases occur at ground level. No plume rise is calculated and no elevated terrain corrections are applied. This assumption is conservative because the receptors are located at the ground level, and the ground release model for this scenario provides the bounding values for the χ/Q and D/Q values. The following parameters are utilized in the XOQDOQ model for ground release:

- The vent average velocity is 0 m/s (0 ft/s), consistent with Table 2.1 of NUREG/CR-2919 (Reference 2.3-34) for ground release.
- The vent inside diameter is 0 m (0 ft.), consistent with Table 2.1 of NUREG/CR-2919 for ground release.
- The height of the vent release point is 10 m (32.81 ft.) above plant grade level because XOQDOQ treats a ground release as a release that is 10 m (32.81 ft.) AGL.
- The height of the vent's building is 10 m (32.81 ft.) above plant grade level, which is the same as the release height (for a ground release).
- The wind height used for the vent elevated release is 10 m (32.81 ft.) above plant grade level, consistent with Table 2.1 of NUREG/CR-2919 for ground release.
- The vent heat emission rate is 0 cal/s because this results in no additional plume rise due to buoyancy of the effluent.
- Default open terrain (e.g., recirculation) factors are utilized to represent plume recirculation in calm or light wind conditions.
- The option to correct χ/Q and D/Q values using standard correction factors for open terrain correction is used in the absence of site-specific diffusion test data. This is consistent with NUREG/CR-2919.

2.3.5.3 Summary of Results and Conclusions

The χ/Q and D/Q factors for the Project site unrestricted area boundary for each Plant Complex are provided in Tables 2.3-57 through 2.3-59. The Project site unrestricted area boundary χ/Q and D/Q factors at the MEL for each Plant Complex is provided in Table 2.3-60.

The χ/Q and D/Q factors will be used to determine the radiological consequences of routine airborne releases from the Project site. The offsite receptor χ/Q and D/Q factors for the nearest resident and nearest vegetable garden are provided in Tables 2.3-61 and 2.3-62, respectively.

The general χ/Q and D/Q factors as a function of distance from the release point for each Plant Complex, extending to a distance of 50 mi. (80.5 km), are provided in Table 2.3-63 through Table 2.3-66. The largest values for the χ/Q and D/Q, for all 16 sectors within 50 mi. (80.5 km) of the envelope, are in the north sector for χ/Q factors and in the northeast sector for D/Q factors. χ/Q and D/Q factors for segmented distances out to 50 mi. (80.5 km) from the Project site release envelope are provided in Tables 2.3-67 through 2.3-70.

Table 2.3-22
Classification of Pasquill Atmospheric Stability

Stability Classification	Pasquill Categories	Temperature Change with Height (°C/100 m)
Extremely unstable	A	$\Delta T \leq -1.9$
Moderately unstable	B	$-1.9 < \Delta T \leq -1.7$
Slightly unstable	C	$-1.7 < \Delta T \leq -1.5$
Neutral	D	$-1.5 < \Delta T \leq -0.5$
Slightly stable	E	$-0.5 < \Delta T \leq 1.5$
Moderately stable	F	$1.5 < \Delta T \leq 4.0$
Extremely stable	G	$\Delta T > 4.0$

Notes:
This table is listed as Table 1 in RG 1.23.
ΔT is the 60-10 m Delta-T. Actual DeltaT data must be normalized to a standard 100m vertical separation distance between instrument levels to compare to RG 1.23 ranges for determining stability categories. This may be referred to as the normalized lapse rate, derived from the DeltaT measurements.
Key: °C = degrees Celsius; m = meter

Table 2.3-23
Total Distribution in Each Stability Class for Project Site

Stability Class	Hours	Percentage
A	1799	21.3%
B	453	5.4%
C	485	5.7%
D	2630	31.2%
E	2318	27.5%
F	565	6.7%
G	189	2.2%
Unstable (Classes A-C)	2737	32.4%
Neutral (Class D)	2630	31.2%
Stable (Class E-G)	3072	36.4%

Table 2.3-33
Summary of Meteorological Equipment Used at the Project Site

Meteorological Equipment Upgrade	Specifications[c]	Measurement Levels (AGL)	Meets RG 1.23 Guidance	
			Yes	No
RM Young 05305V Wind Monitor-AQ (wind speed)	±0.2 m/s (±0.45 mph) or 5% of observed wind speed starting threshold < 0.4 m/s (0.89 mph)	60 m and 10 m	X	
RM Young 05305V Wind Monitor-AQ (wind direction)	±5 degree starting threshold < 0.4 m/s (0.89 mph)	60 m and 10 m	X[c]	
RM Young 41342VC Temperature Probe Delta[a]	±0.1 °C (±0.18 °F)	60 m and 10 m	X	
RM Young 41342VC Temperature Probe	±0.5 °C (±0.9 °F)	60 m and 10 m	X	
RM Young 52202-20 Rain Gauge	±10% for a volume equivalent to 2.54 mm (0.1 in.) of precipitation at a rate < 50 mm/hr (<2 in/hr)	Ground	X	
RM Young Aspirated Radiation Shield	Required for NIST	60 m and 10 m	X	
ESC 8864 Data Logger	N/A	N/A	X	
Sierra Wireless Modem – Duke Energy Approved	N/A	N/A	X	
RM Young Model 41382VC Relative Humidity / Temperature[b]	±4%	10 m	X	

Notes:
(a) Delta-T is derived from ambient temperature measurements between 60 m and 10 m. The two temperature probes are matched and calibrated together to achieve higher accuracy for Delta-T (i.e. ±0.1 °C or ±0.18 °F) than would be achievable from using individual temperature readings.
(b) For computation of the dewpoint temperature.
(c) The RM Young specs state that the starting threshold for the wind direction sensor (05305V) is 0.5 m/s at 10 degree displacement, but incorrectly states that 0.5 m/s would be equivalent to 1 mph (0.5 m/s =1.12 mph, so it does not completely meet RG 1.23 guidance for starting threshold). However, the RM Young wind direction does meet guidance in ANS-3.11-2024 for a starting threshold of 0.5 m/s (ref. section 3.1.2 in ANS-3.11-2024) and accuracy of 5 degrees. It would, however, meet the ANS-3.11-2024 guidance for accuracy and starting threshold.

Key: °C = degrees Celsius; °F = degrees Fahrenheit; AGL = above ground level; m = meter; mm = millimeter; mm/hr = millimeters per hour; mph = miles per hour; m/s = meters per second; N/A = not applicable; NIST = National Institute of Standards and Technology; RG = Regulatory Guide

2.4 HYDROLOGIC ENGINEERING

2.4.1 HYDROLOGIC DESCRIPTION

This section describes the site and safety-related SSCs from the standpoint of hydrologic considerations and the project site interface with the hydrosphere.

2.4.1.1 Site and Facilities

The Project site is located at an elevation of approximately 810 ft. (247 m) in North American Vertical Datum of 1988 (NAVD 88) on a peninsula surrounded to the north, east, and west by Belews Lake. Most of the terrain in the vicinity of the Project site (Figure 2.4-1) is characterized by Belews Lake and the foothills of the Blue Ridge mountains to the northwest. Land uses in the vicinity of Belews Lake are primarily residential development, agriculture, and silviculture (timber or forest lands). Belews Lake was formed from Belews Creek, a tributary of the Dan River, under the authorization of the NC Department of Water and Air Resources specifically to provide cooling water to the BCSS. The location of Belews Lake is at the southwest edge of the Dan River Basin. The Dan River rises from springs on Belcher Mountain on the Blue Ridge Plateau in Patrick County, VA, then flows 200 mi. (322 km) across the state border into Stokes County, NC. The lake sits in the foothills of the Blue Ridge Mountains, and the land gradually rises to the northwest. Outcroppings southeast of the Blue Ridge rise into peaks occasionally exceeding 2500 ft. (762 m). The Blue Ridge forms a northeast to southwest barrier about 50 mi. (80 km) from the Project site.

The Sauratown Mountains are located within Stokes and Surry counties and lie west-northwest of the Project site. The range is home to two state parks located within a 25 mi. (40 km) radius of the Project site. Pilot Mountain State Park, which includes Pilot Mountain, peak elevation 2241 ft. (683 m), is approximately 24 mi. (39 km) west, and Hanging Rock State Park, peak elevation is Moore's Knob at 2579 ft. (786 m), is approximately 14 mi. (23 km) northwest of the Project site.

Terrain in the vicinity of the Project site is characterized as alternating ridges and valleys oriented along a northeast to southwest axis. Nearby ridges reach an elevation of 1100 ft. (335 m) AMSL (approximately 300 ft. [91.44 m] above plant grade).

The Project site is a peninsula owned by Duke Energy. It is bounded on the north, east, and west by Belews Lake. The Duke Energy BCSS, an existing dual-fuel coal and natural gas plant capable of generating 2220 MWs of electricity, is located adjacent to the Project site. Units 1 and 2 use once-through cooling in the condenser, with Belews Lake operating as a closed-cycle cooling reservoir. In 2020 and 2021 natural gas was added to the station to allow natural gas co-firing on both units. The station is authorized to pump makeup water from the Dan River into the Belews Lake to maintain the lake level. The proposed location of each Plant Complex is shown in Figure 2.4-1, with a total area of approximately 1187 ac. (480 ha). An existing NS Railroad track heads west from the site, passes the BCSS, and continues west where it intersects with a north-south track that follows the Dan River. These tracks may be used to transport freight to and from the BCSS. There is a short track (approx. 0.7 mi. [1.1 km]) that runs

between the BCSS and the coal pile. Figure 2.4-2 shows the plant grade at the Project site and topography of the surrounding area.

Additional waters located in the vicinity of the site include the Dan River, Belews Creek, and unnamed tributaries. The Dan River is located approximately 2.5 mi. (4.0 km) northwest and Belews Creek is located approximately 3.5 mi. (5.6 km) north-northeast of the Project Site Center Point.

The Project site is to be graded such that runoff is directed away from each proposed Plant Complex to the extent possible. The actual site grading plan will be based on the specific technology selected and the associated site layout plan; additional details will be provided as part of the construction permit or license application.

Flooding from several potential sources has been examined at the site. The potential flooding scenarios applicable and investigated for the site include the following: probable maximum flood (PMF) on streams and rivers, potential dam failures, probable maximum surge and seiche flooding, probable maximum tsunami, flooding due to ice effects, and potential flooding caused by channel diversions. Detailed descriptions of each of these flooding events and how they were estimated are found in Sections 2.4.2 through 2.4.7 and Section 2.4.9.

It is predicted that the highest flood levels at the safety-related structures would result from a local PMP event over the plant site as described in Section 2.4.2.3. Specific flood elevations at safety-related structures are described in Section 2.4.2 and Section 2.4.10. To ensure adequate flood protection, safety-related structures are located above the maximum postulated flood level.

2.4.1.2 Hydrosphere

The Project site is located within the Dan River Basin. The main hydrologic features include the Dan River, Belews Lake, Belews Creek, and the Belews Creek tributaries.

2.4.1.2.1 Dan River Basin

The Dan River rises on the eastern slope of the Blue Ridge Mountains in Patrick County, VA. From there it travels 200 mi. (322 km), passing through Stokes, Rockingham, Caswell, and Pittsylvania counties, before reaching Halifax County, VA, where it enters Kerr Reservoir near the town of South Boston. Along the way, it is fed by five main tributaries — the Smith, Mayo, Sandy, Hyco, and Banister rivers. The Dan River Watershed forms part of the headwaters of the Roanoke River, a major source of the Albemarle Sound in coastal NC, one of the largest estuaries in the U.S. The basin covers 3300 square miles (mi^2) (8547 square kilometers [km^2]), 11,123 linear stream mi. (17,901 km), and 25,042 lake ac. (10,134 ha) and comprises approximately one-third of the Roanoke River Basin.

The nearest stream gauge to the Project site is on the Dan River at Pine Hall, NC, (United States Geological Survey [USGS] 02069000) and is approximately 1.6 mi. (2.6 km) upstream from the confluence of the Dan River with Belews Creek. This gauge station is operated in

cooperation with North Carolina Department of Environmental Quality (NCDEQ). The drainage basin at the stream gauge is 501 mi^2 (1298 km^2) (Reference 2.4-47). There are no major tributaries to the Dan River west of the Project site and before USGS gauge number 02069000. Approximately 10 river mi. (16 km) downstream of Belews Creek is the confluence of the Dan River and the Mayo River. The gauge station Dan River near Wentworth (USGS 02071000) is approximately 8 river mi. (13 km) further downstream. The drainage basin at the Wentworth stream gauge is 1053 mi^2 (2727 km^2) (Reference 2.4-48).

The Dan River Basin is located in a climate region classified as humid subtropical and experiences warm and muggy summers and cold winters with variable snowfall. Rainfall is fairly consistent throughout the year but varies significantly from year to year. Normal annual precipitation in this region (based on data from the KGSO) is 43.95 in. [111.6 cm] July through September have the highest rainfall amounts, while October through December have the least. Summer rainfall is usually from thunderstorm activity that can also bring strong winds and hail. Snow, sleet, glaze, and ice accumulation are rare during the winter months and short-lived when experienced. Snowfall amounts vary greatly, with some winters experiencing only trace snowfall amounts. Glazing is more common in the Piedmont area of NC (where the Project site is located) than the rest of the state but is usually not damaging.

The Dan River and Belews Lake contribute to the water supply for the cooling system for the BCSS. Dan River and Belews Lake will be used as a source of cooling water for the proposed Plant Complexes.

Information on USGS-maintained stream flow gauge stations near the Project site is provided in Table 2.4-1. The information presented includes the location, drainage area, period of record, and the mean, minimum, and maximum average annual flow for the period of record. Streamflow gaging data collected in the basin sporadically since 1987 and data from the NOAA Advanced Hydrologic Prediction Service (AHPS) indicate that flooding events have occurred over the past two decades. Information on the USGS-maintained stream flow gauge station on the Dan River at Pine Hill (USGS stream gauge 02069000) near the Project site is provided in Table 2.4-2. This gauge is missing records for 1991 – 2008. Figure 2.4-3 depicts the location of stream gauges in the vicinity of the Project site.

Drought conditions prevailed across much of NC during 1998 – 2002, resulting in widespread record-low streamflow and groundwater levels in many areas. During this 4-year period, the drought was continuous in areas of western NC, although eastern areas of the state had some periods of relief from tropical storms in 1998 and 1999. New record-low daily mean discharges were set at two gaging stations on the Dan River, Dan River near Francisco (September 5, 1999) and Dan River near Wentworth (August 12, 2002.) (Reference 2.4-53). Table 2.4-3 presents the monthly mean flow data for USGS gauge on the Dan River at Wentworth, NC (02071000) from 1939 to 2024.

In 2007 – 2008, one of the worst droughts on record impacted NC. In 2007 conditions in the state went from no drought to record drought in less than one year. The year 2007 was recorded by the NWS as the driest year in more than 100 years in NC. Another record-breaking

drought occurred in 2010 – 2012 and in early 2016 much of NC was abnormally dry. While central and eastern NC received needed rains in late spring, western NC saw moderate drought begin by early May 2016. Conditions worsened with the western tip of NC reaching the Extreme Drought stage by October 18, 2016, and Exceptional Drought by November 8, 2016 (Reference 2.4-19). Recently, in 2021, NC experienced several periods with more than 80 percent of the state in conditions ranging from abnormally dry to severe drought. The mid-Atlantic started the year with no droughts, but moderate to severe drought developed by June. On December 28, 2021, approximately 87 percent of the state was in moderate to severe drought, with an additional 12 percent being classified as abnormally dry (Reference 2.4-18). These periods of drought are reflected in the monthly mean flows reported at stream gauges located in the region of the Project site (Table 2.4-2 and Table 2.4-3).

No low water records are available from the NWS AHPS for the Dan River at Pine Hall. The AHPS low water records for Dan River near Wentworth show a low of 0.39 ft. (11.9 cm) on August 12, 2002.

Details of flood history for the area are presented in Section 2.4.2. The largest flood on record on the Dan River near Wentworth, NC, occurred on June 22, 1972, as a result of Hurricane Agnes (Reference 2.4-29). The peak streamflow near Wentworth reached 54,200 cubic feet per second (cfs) (1535 cubic meters per second [m^3/s]), and the gauge station recorded a historical crest at 31.60 ft. (9.63 m). Tropical Depression Agnes produced less than 4 in. (100 mm) of rain while moving over the state of Georgia. The interaction with the low-pressure system over NC, however, caused a sharp increase in rainfall. The system produced approximately 150 – 250 mm (6 – 10 in.) of rain over that state with much higher amounts farther north. The record-breaking floods occurred in the Middle Atlantic States in late June and early July 1972. Many streams in the affected area experienced peak discharges several times the previous maxima of record (Reference 2.4-29).

Details of flood history for the area are presented in Section 2.4.2.

There are 11 reservoirs in the Belews Creek Basin in the vicinity of Belews Lake. Figure 2.4-4 shows the Belews Creek watershed upstream of the Belews Lake Dam and includes all the dams within this watershed. Table 2.4-4 provides detailed information for the 11 dams applicable to the site.

The Federal Emergency Management Agency (FEMA) Flood Insurance Study for Stokes County, NC, and Incorporated Areas reports the peak discharges for various flood frequencies on the Upper Dan River Basin and the Upper Yadkin River Basin. The flooding source of Belews Creek from the confluence with Dan River to U.S. Highway 158 was studied by limited detailed methods (Reference 2.4-9). These values are presented in Table 2.4-5. The FEMA 100-year flood inundation map, which represents flood inundation before construction of the Project site, is presented in Figure 2.4-5.

2.4.1.2.2 Belews Lake

Belews Lake is a cooling reservoir completed in 1973 by Duke Power. The reservoir has a

surface area of about 3864 ac. (1564 ha) and an 88 mi. (142 km) shoreline (water level 725.0 ft. [221.0 m]). Water levels in the reservoir vary with a [[
]][CEII] and minimum drawdown level at 720.0 ft. (219.5 m) for current BCSS operation. The reservoir has three main tributaries, West Belews Creek, Belews Creek, and East Belews Creek. The lake is impounded by an earthen dam with a concrete spillway.

Duke Energy has the ability to pump makeup water from the Dan River into Belews Lake to maintain the reservoir level. This pumping has been carried out five times, in Dec 2002 – Feb 2003, Jan 2008 – Mar 2008, Jan 2009 – Mar 2009, Dec 2011 – Mar 2012 and Aug 2012 – Dec 2012. The pumping system is authorized by the “BCSS” 2025 National Pollutant Discharge Elimination System (NPDES) permit “NC0024406” and “the Duke Power” 2009 United States Army Corps of Engineers (USACE) permit SAW-2009-01801. The Plant Complexes, are shown on Figure 2.4-2. The Circulating Water System and the cooling towers will obtain their source water from the Dan River and Belews Lake. Water for the nuclear power plant would be obtained via a new intake on the east side of the site or on the west side of the site, opposite the existing BCSS intake.

Duke Energy owns all the land within and immediately adjacent to Belews Lake. Duke Energy grants shoreline access leases to adjacent property owners for permission to access the reservoir across Duke Energy property. The Belews Creek Basin at its confluence with Dan River is shown in Figure 2.4-6.

2.4.1.2.2.1 Belews Lake Pumping Operations and Lake Elevation

Belews Lake has a makeup water intake structure (MWIS) that provides water from the Dan River, as needed, to maintain an operational level of water. The MWIS minimizes impingement and entrainment by having an approach velocity of less than 0.5 ft/s (0.15 m/s) at the inlet; it is also equipped with a 2 mm (0.08 in.) fine mesh travelling screen with a fish return system.

The drought conditions in the southeastern U.S. in 1998 – 2002, including the Carolinas, led to unprecedented lowering of Piedmont groundwater levels and stream base flows. Declining levels of cooling water in Belews Lake, combined with risks to future operability of BCSS, prompted Duke Energy to obtain regulatory approval to supplement the reservoir with water pumped from the nearby Dan River.

Duke Energy projected that if the surface elevation of Belews Lake dropped below 716.86 ft. (218.5 m) AMSL, BCSS would be unable to operate due to condenser cooling water pump cavitation. In early 2002, structures were added to the condenser cooling water inlets to suppress potential vortices, permitting the plant to operate to a surface elevation of 714.89 ft. (217.9 m) AMSL.

In January 2008 regulatory approval was granted for winter 2008 pumping of Dan River water to aid Belews Lake water management. Pumping from the Dan River commenced January 22, 2008, with the lake surface elevation at 721.78 ft. (220.0 m) AMSL, and terminated on March 31, 2008, with the surface elevation at 724.08 ft. (220.7 m) AMSL. Subsequent springtime tributary inflows further augmented Belews Lake storage volume, with the lake achieving full

pond at 725.07 ft. (221 m) AMSL by April 9, 2008. Pumping from the Dan River and coincident Belews Lake inflows supplied an estimated 8780 acre-feet (ac-ft) (1083 hectare-meters [ha-m]), or about 74% of the volume required to achieve full pond.

In 2012 regulatory approval was granted for pumping of Dan River water to aid Belews Lake water management under certain conditions, including:

- Pumping must not lower the flow in Dan River below 110 cfs (3.1 m^3/s), which is the Division of Water Resources target flow recommendation for this site. River flow at the pumping location must be checked at USGS Pine Hall gauge station (USGS 02069000) prior to each daily pumping event.
- Pumping may occur to a maximum water level in Belews Lake of 724.5 ft. (220.83 m) AMSL.
- Pumping must not occur from April 1 through June 30 of any year to avoid the fish spawning period.
- At least 80% of ambient flow as recorded at the new Pine Hall USGS gauge must be bypassed (i.e., withdraw no more than 20% of flow).

2.4.1.2.3 Belews Creek

There is one stream gauge on the Belews Creek upstream of the Belews Lake near Kernersville, NC (USGS 02069030) (Figure 2.4-3), which has a drainage area of 14.90 mi^2 (38.6 km^2) (Reference 2.4-49). The stream data available is limited to peak stream flow for water years 1954 through 1971. Information for this gauge station is provided in Table 2.4-6.

2.4.1.2.4 Belews Creek Watershed

2.4.1.2.4.1 Lakes

There are a series of small man-made lakes (maximum storage between 30 and 80 ac-ft [3.7 and 9.9 ha-m]) in the Belews Creek Watershed (Figure 2.4-6) (Reference 2.4-38). The associated dams are discussed in Section 2.4.1.2.1.

2.4.1.2.4.2 Streams

There are seven streams that feed into Belews Lake that include Belews Creek, Left Fork Belews Creek, Right Fork Belews Creek (Dean Creek), East Belews Creek, West Belews Creek (Little Belews Creek), Hartley Creek, and Kings Creek (Figure 2.4-6).

2.4.1.2.5 Wetlands

National Wetland Inventory (NWI) maps show that NC has 3.9 million ac. (1.6 million ha) of wetlands. Approximately 94 percent of the wetlands are east of the fall line based on a NC Division of Water Resources wetland program staff assessment (Reference 2.4-16).

Belews Lake is a NWI mapped Waters of the United States (WOTUS). WOTUS, including ponds, streams, and wetlands, are defined in 33 CFR 328.3, and are protected by Section 404 and other applicable sections of the Clean Water Act (CWA) (Title 33 of the U.S. Code 1344). The major drainage feature at the project site is Belews Lake, which is formed by the impoundment of Belews Creek. There are no public wetlands in the vicinity of the Project site (see Figure 2.4-7).

2.4.1.2.6 Water Supply and Canal System

The BCSS withdraws condenser cooling water from the down lake region of Belews Lake and discharges the heated effluent into the West Belews Creek Arm, which is connected to the Belews Creek Arm of the reservoir via a 0.93 mi. (1.50 km) long man-made canal. The man-made canal facilitates the return of heated condenser cooling water effluent from the West Belews Creek Arm to the Belews Creek Arm and back to the intake structure for reuse. Duke Energy constructed a MWIS in 2010. The MWIS withdraws water from the Dan River and Belews Creek and routes it directly to Belews Lake. The system complies with Section 316(b) of the CWA as it was designed to withdraw water via submerged intake pits and through a fine-mesh screen equipped with an aquatic organism return system. The MWIS is designed and permitted to include two 50 cfs (1.42 m^3/s) velocity caps and a four-pump pumping station with a capacity not to exceed 100 cfs (2.83 m^3/s).

The existing pumping station, existing outfall, and existing intake are shown in Figure 2.4-8. The proposed intake and outfall options for Project site are presented in Figures 2.4-9 and 2.4-10, respectively.

2.4.1.2.7 Surface Water Users

The NC Division of Environmental Quality (NCDEQ) maintains records of surface water withdrawals for the state of NC. The NCDEQ Division of Water Resources Water Supply Watersheds online mapping tool shows the Dan River (Madison) Watershed is classified as WS-IV (WS-IV waters are generally in moderately to highly developed watersheds or Protected Areas). A review of the NCDEQ surface water database for the Dan River Water Supply Watershed identified Duke Energy is the only surface water user (Reference 2.4-17). North Carolina's Source Water Assessment Program records public water supply sources on NC OneMap. The Town of Madison and City of Eden are located upstream of the Dan River Combined Cycle Station and downstream of Belews Creek Steam Station. Surface water users and diversion amounts are listed in Table 2.4-7.

2.4.1.2.8 Groundwater and Groundwater Users

The local and regional groundwater characteristics and users are described in Section 2.4.12.

2.4.1.2.9 Climate Change

The first unit at the Project site is expected to be online in the first quarter of 2034, with Units 2 – 6 expected to come online during the period between January 1, 2035, and January 1, 2039

(12-month stagger). The initial operating license for each unit is for 40 years and license renewals could extend that by 40 to 60 years. Initial licensing and extensions could amount to 80 – 100 years of operating life. It is estimated that Unit 1 would be online fin the first quarter of 2034, with Units 2 – 6 expected to come online during the period between January 1, 2035, and January 1, 2039 (12-month stagger). Historical long-term meteorological and hydrological data are considered in the project's impact on the surroundings of the Project site. Though the impact of global climate change is uncertain, projected trends are discussed in this section. Consistent with NRC COL/ESP-ISG-026 (Reference 2.4-28), the normal project lifetime, decommissioning period, and resources that may be impacted by climate change are considered.

The NCCSR (Reference 2.4-14) assesses historical climate trends and potential future climate change in NC under increased greenhouse gas concentrations and provides projected changes for the climate of NC.

The NCCSR also addresses compound events including inland flooding. When analyzing long-term changes in inland flooding, changes in climate conditions, water management practices, and land use and land cover must be considered. Inland flooding in NC encompasses a range of scales, from local urban flooding to medium-size river basins, and a range of topography, from flat to mountainous. Flooding due to tropical cyclones can occur throughout NC. In 1916, 1940, and again in 2004, the remnants of tropical cyclones caused extreme flooding in Western NC, and in 1945 the Piedmont region experienced severe flooding due to a tropical cyclone. The NCCSR projects that it is very likely that NC temperatures and extreme precipitation frequency and intensity continue to increase, and it is likely that the frequency and severity of inland flooding increase statewide (Reference 2.4-14). According to NCCSR, annual average temperature increases relative to the recent climate (1996–2015) for NC are projected to be on the order of 2 – 5 degrees °F (1.1 – 2.8 °C) under a higher scenario (RCP8.5) and 2 – 4°F (1.1 – 2.2 °C) under a lower scenario (RCP4.5) by the middle of this century. By the end of this century, annual average temperature increases relative to the recent climate (1996–2015) for NC are projected to be on the order of 6 – 10°F (3.3 – 5.6 °C) under a higher scenario (RCP8.5) and 2°–6°F (1.1 – 3.3 °C) under a lower scenario (RCP4.5).

The NCSSR also predicts that in the future it is likely that major droughts in their multiple forms become more frequent and severe because of higher temperatures that increase evaporation rates (Reference 2.4-14).

The NCA Report provides detailed information related to the potential effects of climate change on the U.S. by region (Reference 2.4-46). The Project site is located in the southeast region as defined by the report. In general, the NCA report states that the southeast region is vulnerable to sea level rise and coastal flooding, extreme heat events, hurricanes, and tropical cyclones, and increasing wildfire risk (Reference 2.4-46).

The NCA report found that heatwaves in the southeast region are happening more frequently and are occurring during a longer heat season, with some cities also showing increasing trends in heatwave duration and intensity.

The number of extreme warm days (above 95 °F [35 °C]) is expected to continue increasing with every increment of global warming. Further, there have been an increasing number of days that exceed 95 °F (35 °C) and nights that exceed 75 °F (24 °C) and a decrease in the number of "extremely cold" days since 1900 (Reference 2.4-46).

Temperatures have steadily increased across the southeast region since the 1970s. Climate models agree that annual temperatures continue to increase in the future, with an average annual increase of 3 – 5 °F (approximately 1.7 – 2.8 °C) by 2041 – 2070 under higher scenario (RCP8.5). Simulated changes for winter and spring are between 2.5 – 5 °F (1.4 – 2.8 °C), 3.5 – 6 °F (1.9 – 3.3 °C) during the summer, and 3 – 5 °F (1.7 – 2.8 °C) during the fall (Reference 2.4-44). The report also finds that days with maximum temperatures exceeding 95 °F (35 °C) are predicted to increase, and there is likely to be a decrease in days with freezing temperatures (Reference 2.4-46).

The NCA report states that the southeast region is more prone to extreme drought due to higher rates of evapotranspiration than other parts of the eastern United States. Longer-term droughts in the region appear to be currently increasing in severity but do not appear to be occurring more frequently (Reference 2.4-46).

The NCA report states that the souteast region has received increasing precipitation in the fall, but over the past few decades there has been a decreasing trend in rainfall in summer. Most climate models forecast the decrease in summer rainfall to continue with mean annual precipitation expected to decrease across the western portion of the southeast region. Extreme rainfall events have occurred more frequently across the SE in the past 20 years. Average annual precipitation from 2002 to 2021 was 5 percent to 15 percent higher relative to the 1901 – 1960 average in the central and eastern U.S. (Reference 2.4-46).

The NCA has investigated severe weather events, including hurricanes, tropical storms, and tornadoes. The NCA report states that warmer temperature projections would result in a decrease in tropical storms globally, however, there has been a slight increase in the frequency of tropical storms in the Atlantic, and the number of major hurricanes (Category 3 – 5) has increased over the past few decades (Reference 2.4-44). The Project site is located inland and not likely to experience the most severe impacts of hurricanes. However, extreme rain events are a risk with or without tropical systems. The study reports that the number of major tornadoes has increased in the past 50 years, however, there is "no statistically significant trend." The study indicates that the increase in the number of tornadoes reported may be attributable to expanded and better reporting of tornadoes (Reference 2.4-46).

Based on the NCA report, the greatest potential effects of climate change are increased temperatures and reduced water availability for the Project site and its surroundings. At the same time, stormwater from extreme precipitation events may increase. As the models used to develop these projections are based on future estimates of population growth, land use, energy consumption, emissions patterns, etc., there is a level of uncertainty associated with the events and meteorological conditions predicted.

The USEPA climate and weather data maps (Reference 2.4-8) predict change in average annual precipitation under various cases. These projections are under the RCP8.5 scenario and run to 2060. The three cases are:

- Hot/Dry is based on the average of the five climate models that project hotter and drier conditions compared to the other model projections. Based on this case, the site will experience 0.4% annual reduction in precipitation.
- Central is based on the average of the five climate models that project changes in the middle of the distribution of projections. Based on this case, the site will experience 5% annual increase in precipitation.
- Warm/Wet is based on the average of the five climate models that project less warming but increased precipitation relative to other models. Based on this case, the site will experience 11.3% annual increase in precipitation.

While climate impacts are anticipated, they will be actively monitored. In line with established nuclear practices, the Project site will adopt proactive measures to monitor meteorological and environmental conditions throughout the project's life cycle, ensuring compliance with approved operational limits.

2.4.2 FLOODING

2.4.2.1 Flood History

The Project site is situated on a peninsula of Belews Lake, which is part of the larger Roanoke River Basin. The nearest city is Walnut Cove, approximately 4.5 mi. (7.24 km) west of the site (Figure 2.4-3). Belews Lake was constructed in the early 1970s by damming Belews Creek, a tributary to the Dan River. The North Carolina Department of Water and Air Resources authorized the creation of Belews Lake (Reference 2.4-20) specifically to provide cooling water to BCSS, which is owned and operated by Duke Energy. Once constructed, the lake was filled and reached full pond elevation in April 1973. A gated structural spillway [[ ]]^{CEII} and releases outflows to a rock-excavated outlet channel. The excavated channel flows into Belews Creek approximately 0.5 mi. (0.8 km) upstream of its confluence with the Dan River. [[ ]]^{CEII} A pond is located at the toe of the embankment with tailwater elevation of 590 ft. (179.83 m) NAVD 88.

Floods on Belews Creek occur primarily as a result of precipitation runoff over the watershed. However, since construction of the dam, flooding on Belews Creek has been controlled by the dam. Flooding from the Dan River is not applicable to the project site because the site is located at a higher elevation, approximately 220 ft. (67.06 m) above the Dan River.

Stage and streamflow from local gauges (Figure 2.4-3) have been analyzed to determine the intensity of the flood conditions around the site. There are no USGS high-water mark signs located near the site. All the high-water mark signs for NC are located closer to the coast. Only

one historical gauge (station ID 2069030) on Belews Creek was active before the creation of Belews Lake in 1973. Flooding conditions occurred in 1954 (water year 1955) and 1969 with gauge heights reaching 23.98 ft. (7.31 m) and 24.36 ft. (7.42 m), respectively. The average gauge height was 22.50 ft. (6.9 m) (Table 2.4-8). The peak streamflow on Belews Creek, measured in 1969, is 3600 cfs (102 m^3/s, see Figure 2.4-12).

The Dan River is downstream of the site and experiences increased flooding conditions compared to the site location upstream, next to Belews Lake. There are two USGS gauges (station IDs 2069000 and 2071000) on the Dan River close to the site. Although Dan River flooding is not applicable to the site, data from these gauges are presented because they have long periods of record. Dan River near Wentworth, NC (station ID 2071000), is the gauge with the longest period of record of the three gauges discussed in this section. Only the Dan River near Wentworth gauge receives regulated released flow from Belews Lake Dam. However, this released flow contributes only 1 percent of the Dan River's overall streamflow. Flooding conditions downstream of the Belews Lake Dam are more significant and frequent than the upstream flooding. Records are presented in Tables 2.4-9 and 2.4-10. Discharges are graphed and presented in Figures 2.4-13 and 2.4-14.

Flooding events of note that caused the peaks in streamflow data are the Flood of 1940, the "Homestead" Hurricane of 1945, Hurricane Agnes in 1972, Hurricane Florence in September 2018, the February 2020 flood event, and Hurricane Eta in November 2020. Hurricanes can cause intense rainfall in the surrounding areas. The years of the flooding events reflect the peak streamflow statistics from the USGS gauges.

All historical floods within the twentieth century were captured by the Dan River near Wentworth gauge, which has an 85-year period of record. Wentworth gauge data begins in 1908, pauses for 28 years, and resumes continuously in 1937. The gauge datum elevation from USGS 2071000 is 512.3 ft. (156.15 m) from vertical datum NAVD 88.

The average Dan River water depth is 20 ft. (elevation 532.3 ft. [162.25 m] NAVD 88) and average streamflow is 19,859 cfs for the period of record. The flood event with the highest peak stage was Hurricane Agnes in 1972 with a maximum water depth of 31.6 ft. (elevation 543.9 ft. [165.78 m] NAVD 88) and streamflow of 54,200 cfs (1535 m^3/s). This represents an increase of 2.7 times the average streamflow. Out of the five major historical flood events recorded by the USGS in NC's history, two occurred during the 1940s. The "Homestead" Hurricane of 1945 and the Flood of 1940 had peak discharges of 38,100 cfs (1079 m^3/s) and 34,700 cfs (983 m^3/s), respectively, recorded at the Dan River near Wentworth gauge.

Hurricane Florence caused high flows and water levels on the Dan River. Local property was inundated from high water levels, including the 311 Speedway, approximately 1.8 mi. (2.9 km) north of the Belews Lake Dam. The high streamflow was reflected by the Dan River gauges with flows peaking at 28,900 cfs (818 m^3/s) near Wentworth and 20,500 cfs (580 m^3/s) at Pine Hall in September 2018.

The wettest year on record in NC is 2020. Two intense rainfall events occurred in 2020 near the

site. In February of 2020, intense rainfall resulted in the highest streamflow statistics in recent history for both gauges on the Dan River. Hurricane Eta in November of 2020 reflects the second highest water depth and streamflow in recent history for both gauges on the Dan River. The streamflow reached highs of 40,900 cfs (1158 m^3/s) near Wentworth and 26,200 cfs (742 m^3/s) at Pine Hall in February, and 38,500 cfs (1090 m^3/s) near Wentworth and 25,800 cfs (730 m^3/s) at Pine Hall in November. Streamflow was 6.2 percent higher in February than November. Hurricane Agnes in 1972 remains the highest flow near Wentworth with 54,200 cfs (1535 m^3/s), 1.3 times higher than the 2020 flood event.

No historical data exist regarding flooding due to surges, seiches, tsunamis, dam failures, or landslides. River flooding is discussed in Section 2.4.3. Dam failures are discussed in Section 2.4.4. Surge and seiches are discussed in Section 2.4.5. Tsunamis are discussed in Section 2.4.6. Historical information related to icing and ice jams is provided in Section 2.4.7. Channel diversions are discussed in Section 2.4.9.

2.4.2.2 Flood Design Considerations

The types of events evaluated to determine the worst potential flood at the Project site included:

- PMP on the critical watersheds, including potential consequent dam failures, as discussed in Section 2.4.3.
- Cascading and instantaneous failure of all dams at their highest ponding elevation coincident with a 500-year flood event as discussed in Section 2.4.4.
- Local intense precipitation (LIP) as discussed in this section.
- Two-year coincident wind waves as discussed in Sections 2.4.3 and 2.4.4.

The potential events considered but not analyzed included:

- Flooding from Surges and Tsunamis - Specific analysis of Belews Lake flood levels resulting from ocean front surges and tsunamis was not required because of the inland location of the site.
- Flooding from Snow Melt and Ice Jam - Snow melt considerations were also unnecessary because of the temperate zone location of the plant. While there is the potential for ice jams on Belews Creek, based on the section geometry and site elevation at the Project site, an ice jam sufficient to cause Project site flooding is not credible. Further discussion of ice effects is found in Section 2.4.7.
- Flooding from Landslides - Flood waves from landslides into the lake required no specific analysis. A review of the borders of the Belews Lake indicate the absence of major elevation relief. Based on this review, the volume of material entering the lake from potential landslides is not significant compared to the available detention space in the lake. Any waves created from landslides would not result in site flooding due to the large difference in elevation between the normal pool elevation at the lake of 725 ft. (220.98 m) NAVD 88 and the Project site plan elevation of 810 ft. (247 m) NAVD 88.
- Flooding from Seiches - The occurrence of landslides in the area adjacent to Belews Lake is not considered possible due to the low relief of topographic features in the vicinity of the Project site. Therefore, potential seismic events and landslides are not expected to cause

seiches on Belews Lake and, therefore, cannot cause flooding at the Project site. Further discussion of seiches is included in Section 2.4.5.

- Flooding from Migration and Diversion - Belews Lake has been stable for many years with no indication of the potential for migration or diversion. Historical floods have not produced any major changes in the reservoir configuration, so specific analysis of channel diversion was not required. Further discussion of channel diversion is included in Section 2.4.9. As noted above, potential events were evaluated to determine the worst potential flood conditions at the site. The following is a summary of the events considered and their effects. More details for these events are provided in the referenced sections as appropriate.

The potential events considered and analyzed included:

- Flooding from Rivers and Streams - The condition producing the most critical flood level calculated at the Project site is the 10 mi^2 (26 km^2) PMP storm event over the entire Belews Creek watershed. This storm event produces a maximum flood level of 746.4 ft. (227.5 m) NAVD 88. Belews Lake Dam was assumed to not fail even though the dam embankments are overtopped. For more information see Section 2.4.3.
- Flooding from Combined Effects (PMP and Wind Waves) - Wind waves based on a calculated 2-year overwater wind speed of 42.9 miles per hour (mph) (69.0 kilometers per hour [kph]) were assumed to occur coincident with the flood peak. This creates maximum wind waves up to 1.49 ft. (0.45 m) high (trough to crest). When the effects of wind wave and runup were added, the maximum Belews Lake design PMF water level was established to be at elevation 747.86 ft. (227.95 m) NAVD 88. The PMP and wave effect are discussed in Sections 2.4.3.5 and 2.4.3.6.
- Flooding from Dam Breaches and Failures - The calculated water surface elevation (WSEL) at the site resulting from the combined simultaneous failure of all dams coincident with a 500-year flood event reaching its peak at the same time as the lake is [[ ]]^{CEII} NAVD 88 (see Section 2.4.4).
- Flooding from Combined Effects (Dam Failure and Wind Waves) - Wind waves based on a calculated 2-year overwater wind speed of 42.9 mph (69.0 kph) were assumed to occur coincident with the dam failure peak. This creates maximum wind waves up to 1.49 ft. (0.45 m) high (trough to crest). When the effects of wind wave and runup were added, the dam failure water level was established to be at elevation [[ ]]^{CEII} NAVD 88. The dam failure and wave effect are discussed in Sections 2.4.4.5 and 2.4.4.6.
- Local Intense Precipitation - Analysis of the general effects of LIP was also performed based on preliminary site plans. However, the detailed site grades and stormwater conveyance facilities will be designed at the construction permit or license application stage such that LIP does not flood the safety-related SSCs of the plant. For more information see Section 2.4.2.3.

The preliminary Project site plant grade is established at elevation 810 ft. (247 m) NAVD 88, well above the calculated maximum flood level, which is consistent with RG 1.59, Position 1 (see Section 2.4.2.3).

2.4.2.3 Effects of Local Intense Precipitation

The final maximum water levels at buildings expected to result from LIP will be confirmed at the

construction permit or license application stage. However, a preliminary calculation of the flood height resulting from LIP was performed.

Given the physical site topography and the location of the Project site, it is reasonable to expect that the PMP-driven (as described in Section 2.4.2.3.1) Belews Lake floodwater elevation at the locations adjacent to the power block area would be substantially less than that of the Project site plant grade elevation of 810 ft. (247 m) NAVD 88. Therefore, runoff from the Project site is not restrained by tailwater effects at the lake.

The final graded Project site can reasonably take full advantage of the current topography and provide more than adequate runoff capability to the east, west, north, and south with flow directed to Belews Lake. Belews Lake would be affected to a much lesser extent by local intense rainfall events than a PMF event for which the maximum elevation is 745.98 ft. (227.37 m) NAVD 88. The 64 ft. (19.5 m) elevation difference to the plant grade (810 ft. [247 m] NAVD 88) ensures that slopes and drainage systems can be designed to adequately convey LIP-event flows to Belews Lake.

Because Belews Lake is capable of accommodating Project site LIP-event flows without flooding the site, the potential and extent of flooding from a LIP event is dependent upon facility design and final grading and drainage system design. The final Project site drainage systems may employ several techniques, including grading slopes to efficiently convey runoff water, constructing additional drainage channels, etc. Given the existing topography, the Project site power block area is favorably located to allow design of a fully effective site drainage system. It is therefore reasonable to expect that a fully effective drainage system would be designed as part of the construction permit or license application stage.

2.4.2.3.1 Precipitation Distribution

Temporal LIP distribution for the plant was determined from guidance presented in Hydrometeorological Reports No. 51 and No. 52 (HMR-51 and HMR-52) (Reference 2.4-22 and Reference 2.4-23, respectively). The guidelines set forth in HMR-51 and HMR-52 were followed to form the rainfall hyetograph of the 1-hour (hr.), 1 mi^2 (2.6 km^2) PMP for the Project site. The estimated PMP depths presented in HMR-51 are for durations ranging from 6 to 72 hr. and for drainage areas ranging from 10 to 20,000 mi^2 (25 – 51,800 km^2). Using these depths, HMR-52 provides procedures to estimate short-duration point PMP depth (or 1 mi^2 [2.6 km^2]) for durations up to 1 hr.

Figures 24 and 36 in HMR-52 provide point PMP depths of 18.78 in. (477 mm) for a 1-hr. duration and 6.2 in. (157.48 mm) for a 5-minute duration. The 15-minute and 30-minute durations were estimated by applying the point ratios to 1-hr rainfall from Figures 37 and 38 in HMR-52, respectively. The 6-hr rainfall is from Figure 18 of HMR-52. The 15-minute, 30-minute, 60-minute, and 6-hr rainfall depths are 9.7 in. (246.38 mm), 14 in. (355.6 mm), 18.8 in. (477.52 mm), and 29.2 in. (741.68 mm), respectively. Table 2.4-11 presents the 1 mi^2 (2.6 km^2) PMP depths and intensities for various durations used in the analysis at the Project site. The PMP rainfall time series (see Figure 2.4-15) with a 5-minute interval was then constructed following

the guidelines in NRC *Design-Basis Flood Estimation for Site Characterization at Nuclear Power Plants in the United States of America* (NUREG/CR-7046), Appendix B:

- The first time step was set to the highest LIP depth, which is 6.2 in. (157.48 mm).
- The next two 5-minute time steps were set to an incremental precipitation depth of 1.75 in. ([9.7–- 6.2]/2 in.) (44.45 mm).
- Incremental precipitation depths for the subsequent time steps were determined from the cumulative LIP depths shown in Table 2.4-11.

2.4.2.3.2 Runoff Model

The advanced reactor technology and associated site layout and facilities at the Project site have not been finalized. A two-dimensional (2D) FLO-2D model is performed based on the general preliminary site layout as presented in Figure 2.1-5. The following assumptions are made:

1. Because no outside watershed is contributing to the LIP, site cover within the power blocks and laydown areas is assumed to maximize the water levels. High values for Manning's roughness coefficients from Table 2.4-12 are used in the model for the power blocks and areas downstream of the power blocks with the surface covers listed below. Low values from Table 2.4-12 are used for areas upstream of the power blocks. This maximizes the flow toward the power blocks and delays the discharge of flow from the power blocks, resulting in conservative flood levels.
    a. Power blocks: Gravel.
    b. Laydown areas at 840 ft. (256 m) elevation: Gravel cover to maximize tailwater condition.
    c. Laydown areas at 805 ft. (245 m) elevation: Grass cover to maximize tailwater condition.
    d. Laydown areas at 820 ft. (250 m) elevation: Pavement to maximize flow into the power block.
2. No evaporation was considered in the model. This is conservative because stormwater lost due to evaporation could reduce inundation depth and period of inundation.
3. Buildings within the watershed are considered to be solid and impervious. Stormwater must move around buildings and is not removed from the model by flowing into buildings. This assumption is conservative because all rainfall is contained within the model until it can flow out of the model on all sides to Belews Lake.
4. Details for the security barriers (delay barriers and Jersey barriers) are not provided and are not considered. This will be addressed during the construction permit or license application stage.

5. According to hierarchical hazard assessment (HHA) Case 3 of NUREG/CR-7046, all precipitation losses are ignored for all drainage areas. By eliminating the losses attributed to infiltration and initial abstraction, the peak runoff rate increases. This is a conservative assumption.

6. Wind wave analysis is not required for the site LIP calculation. Wind wave calculations are not required for this analysis because there is no flooding from the reservoir during the LIP event and localized ponding is not sufficient to create wind wave action. The configuration of the site structures in areas where ponding is likely also limits the fetch lengths or creates short, narrow fetches that diminish the potential for wind wave impact.

The site is modeled as a flat surface with buildings as obstructions. Three separate FLO-2D models are set up, one for each site boundary. The extent of the FLO-2D models is illustrated in Figure 2.4-17 through Figure 2.4-19. The model boundaries are placed at the edge of the finish grading area away from safety-related SSCs. The FLO-2D models cover an area of approximately 63 ac. (25.5 ha), 57 ac. (23.07 ha), 127 ac. (51.4 ha) for the specific site areas designated for North, Middle, and South Plant Complexes, respectively. In all model domains of this study, runoff is allowed to leave the FLO-2D model at all boundaries. Consequently, any water that reaches a boundary is allowed to flow out of the model in a natural manner by assigning outflow cells along the entire boundary. This reflects actual site conditions because the edge of the developed area is sloped away from the site toward Belews Lake (see Figure 2.1-5). Cell sizes of 10 ft. (3.0 m) were selected to properly identify footprints of the buildings. Fences do not constitute flooding barriers and are not considered in the analysis.

2.4.2.3.3 Flood Elevations

FLO-2D model results show that the maximum LIP flood WSEL in the vicinity of the buildings exceeds the assumed threshold by the amounts shown in Table 2.4-13. A threshold for all buildings and structures of 6 in. (0.15 m) is assumed. These results are based on preliminary site layout and grading. However, these results are considered conservative, as detailed site grades and stormwater conveyance facilities have not yet been developed. These features will be addressed during the construction permit or license application stage to ensure that a LIP does not impact safety-related SSCs.

2.4.2.3.4 Site Drainage System

The site layout and facilities at the Project site have not been finalized. Thus, the location and design of stormwater conveyance facilities have not been determined. These tasks are performed as part of detailed engineering at the construction permit or license application stage. Stormwater is carried away from the plant area by a stormwater collection system comprising appropriate combinations of swales and open channels or a subsurface system of catch basins, pipes and culverts. Runoff is routed to Belews Lake. The finished grade for the site slopes away from buildings and is designed such that the peak discharges from the LIP do not flood safety-related facilities if the subsurface drainage system is plugged.

2.4.3 PROBABLE MAXIMUM FLOOD ON STREAMS AND RIVERS

The design of nuclear power plants includes protection from the adverse effects of flooding. To assist in determining the potential for adverse flooding effects, the NRC provides guidance for estimating design basis floods in *Design Basis Floods for Nuclear Power Plants*, Rev. 2 (RG 1.59) and NUREG/CR-7046. One or an appropriate combination of several hydrometeorological, geoseismic, or structural-failure phenomena causes a design basis flood that results in a hazard to SSCs important to the safety of a nuclear power plant. The PMF due to PMP over the Belews Creek watershed is presented in this section.

American National Standards Institute and the American Nuclear Society (ANSI/ANS) document ANSI/ANS-2.8, Determining Design Basis Flooding at Power Reactor Sites (Reference 2.4-2), and NUREG/CR-7046 (Appendix H), provide three different alternatives for analysis of a flood caused by a precipitation event. They are as follows:

- **Alternative 1** – Combination of the following:
  - Mean monthly baseflow.
  - Median soil moisture.
  - Antecedent or subsequent rain: the lesser of (1) rainfall equal to 40 percent of PMP and (2) a 500-year rainfall PMP.
  - The PMP.
  - Waves induced by 2-year wind speed applied along the critical direction.
- **Alternative 2** – Combination of the following:
  - Mean monthly baseflow.
  - Probable maximum snowpack.
  - A 100-year, snow-season rainfall.
  - Waves induced by 2-year wind speed applied along the critical direction.
- **Alternative 3** – Combination of the following:
  - Mean monthly baseflow.
  - A 100-year snowpack.
  - Snow-season PMP.
  - Waves induced by 2-year wind speed applied along the critical direction.

Alternative 1 was used for this analysis as it is the most conservative and quantifiable. Based on air temperature (T_a) data, the occurrence of snow within the western NC basin and its effect on flood-producing phenomena indicated that snowmelt and antecedent snowpack are not critical factors in the production of floods at the Project site. Therefore, Alternatives 2 and 3 are not considered. Baseflow is not considered for Belews Creek as there are no active or historical gauges upstream of the creek branches for which adequate data were available. Instead,

conservative assumptions are used throughout the analysis to cover the impact of this assumption. To develop the most conservative case, no evaporation was considered in the model. This is conservative because stormwater lost due to evaporation could reduce inundation depth and period of inundation.

2.4.3.1 Watershed Characteristics

The Project site is located on a peninsula surrounded to the north, east, and west by Belews Lake. Belews Lake is formed upstream of Belews Lake Dam and is fed by Belews Creek. As depicted in Figure 2.4-20, the area of Belews Creek watershed upstream of the Belews Lake Dam is 69.33 mi^2 (179.59 km^2).

The hydrology of the Belews Creek watershed upstream of the Belews Lake Dam is characterized by a network of tributaries and streams that contribute to the Belews Lake reservoir in NC. The watershed encompasses a mix of forested, agricultural, and urban landscapes, influencing the flow and quality of water entering the lake. Precipitation is a significant driver of surface runoff and streamflow, with variability linked to seasonal weather patterns. The hydrologic system includes both surface water and subsurface contributions, with groundwater recharge and discharge playing a role in maintaining base flows during drier periods. The dam regulates outflow from Belews Lake, ensuring water availability for downstream uses, power generation, and ecological balance.

2.4.3.2 Probable Maximum Precipitation

Determination of design basis flood levels includes considering the most severe flood conditions that may be reasonably predicted to occur at a site as a result of severe hydrometeorological conditions. The NWS in HMR-51 (Reference 4.2-22) and HMR-52 (Reference 2.4-23) has defined, for the Project site, PMP events for the Belews Creek watershed. The storms defined by the NWS references provide either specific spatial rainfall patterns that reflect orographic effects or idealized elliptical isohyetal patterns with preferred orientation and orographic multipliers.

The stepwise process followed to distribute the storm-area averaged PMF from HMR-51 over the 69.33 mi^2 (179.56 km^2) watershed is described in HMR-52, Section 7. PMP depths for 10 mi^2 to 20,000 mi^2 (25 – 51,800 km^2) basins and durations from 6 hr. to 72 hr. are scaled from Figures 18 through 47 in HMR-51. Using this PMP depth data, curve fits are used to define the area versus precipitation depth relationships for 6-hr., 12-hr., 24-hr., 48-hr., and 72-hr. storm durations. Following the HHA approach from NUREG/CR-7046, instead of considering multiple storm centers and developing multiple PMPs, conservatively, the 10 mi^2 (26 km^2) PMP developed for the site is applied to the entire watershed. This is a conservative consideration because the direct contributing watershed upstream of the dam is 69.33 mi^2 (179.56 km^2) and not every part of the watershed receives the same rainfall at once.

The PMP storm is modeled as a nine-day event. A three-day antecedent storm was postulated to occur three days prior to the three-day PMP storm in the PMF determination. Antecedent storm rainfall depths applied were equivalent to 40 percent of the main storm with a uniform

areal distribution.

Temporal distribution patterns were then adopted based on a 72-hr. PMP distribution provided in HMR-52 (Reference 2.4-23). The distribution places the heaviest precipitation approximately in the end of the antecedent and main storms. The twelve 6-hr. rainfall increments of each 72-hr. storm were ordered from D1 (maximum depth) to D12 (minimum depth). The rainfall increments were applied in each 72-hr. duration in the following sequence: D12, D11, D10, D9 (first 24 hr.), D7, D6, D5, D3 (middle 24 hr.) and D1, D2, D4, D8 (last 24 hr.).

PMP estimations are presented in Table 2.4-14a through Table 2.4-14d. The 10 mi^2, 72-hr. precipitation is 44.2 in. over the watershed. The full PMP hyetograph is presented in Figure 2.4-21.

2.4.3.3 Precipitation Losses

Realistic site-specific Soil Conservation Service (SCS) curve numbers are calculated based on soil type, vegetation, and land use for watershed surfaces and a conservative, yet reasonable, curve number is applied to the watersheds.

The conterminous U.S. land cover (also known as the national land cover database [NLCD]) at a 30 m (98 ft.) spatial resolution with a 16-class legend based on a modified Anderson Level II classification system (Reference 2.4-21) is used. Land cover is further reclassified into four classes, agricultural, forest, medium residential, and water, as presented in Figure 2.4-20.

Soils are classified by the Natural Resource Conservation Service into four hydrologic soil groups based on the soil's runoff potential. The four hydrologic soil groups are A, B, C, and D. Soils classified as A generally have the smallest runoff potential and soils classified as D have the greatest. The Soil Survey Geographic Database is used in this analysis (Reference 2.4-45). Watershed hydrologic soil groups are presented in Figure 2.4-22.

The SCS curve number method is a standard, widely used, and efficient method for determining the amount of runoff from rainfall events. A combination of land use and hydrologic soil group are used to determine curve number. Table 2.4-15 shows the curve number for the corresponding soil group for each land use category. The dominant soil group and land use are B and forest, respectively (Figures 2.4-22 and 2.4-20). Curve numbers applied to the watershed are presented in Figure 2.4-23.

Sensitivity analysis showed that ignoring precipitation losses results in a WSEL 2.5 ft. higher than the scenario with realistic losses. Therefore, the results presented are those obtained by ignoring losses.

2.4.3.4 Runoff and Stream Course Model

A detailed, 2D flood routing model that is developed for the Belews Creek watershed upstream of the dam is used to establish flooding from PMF at the site. This model, Hydrologic Engineering Center River Analysis System (HEC-RAS) 2D, developed by the USACE (Reference 2.4-37), represents all the topographical and man-made features (i.e., buildings,

tanks, and hydraulic structures) that significantly affect runoff at the project site. The project site is represented by a preliminary layout from one of the technologies considered in this ESP.

In flood routing, it is assumed that the Belews Lake dam does not fail when overtopped. This is a conservative assumption as it maximizes the flood level near the site and in the lake by lowering the outflow. This is also a reasonable assumption, as short period of time and limited overtopping should not cause failure of the dam. Limited overtopping often lacks the prolonged hydraulic force necessary to cause significant erosion or undermine the dam's foundation. The duration and intensity of overtopping directly affect its potential to damage the structure. Historical case studies show that dams with robust construction and maintenance often endure short-duration overtopping without catastrophic failure. Failures typically occur when overtopping is sustained, intense, or exacerbated by pre-existing structural weaknesses (Reference 4.2-32). By using a 2D model, floodwater is routed in a natural manner without being "forced" to flow in predefined directions. This allows for a more accurate flood analysis than is possible with one-dimensional (1D) models.

2.4.3.4.1 Model Geometry and Terrain

The Belews Creek watershed is delineated at a point immediately downstream of the Belews Lake Dam, before it joins the Dan River (see Figure 2.4-24). The size of the watershed is 69.33 mi^2 (179.56 km^2). The 2018 1/3 Arc Second (i.e., 10 m [33 ft.]) USGS Light Detection and Ranging (LiDAR) data for NC (Reference 2.4-50) with vertical accuracy of 8 in. [20 cm] at a 95 percent confidence level is used in this analysis. The data were developed using a horizontal datum of North American Datum of 1983 and vertical datum of NAVD 88, both expressed in meters. The watershed topography (see Figure 2.4-25) ranges from 722 ft. (220 m) NAVD 88 at the lake to 1030 ft. (314 m) NAVD 88 at its most upstream point. This detailed LiDAR point data support the construction of a Digital Elevation Model (DEM) for the purposes of this analysis.

The DEM constructed for this analysis (Figure 2.4-26) has a cell size of 5 ft. x 5 ft. (1.5 m x 1.5 m). This cell size is adequate for this analysis because HEC-RAS 2D minimum cell sizes considered in this analysis are 100 ft. x 100 ft. (30.5 m x 30.5 m), with refined areas around the site and the man-made canal using cell sizes of 50 ft. x 50 ft. (15.2 m x 15.2 m). This requires the averaging of 100 or more DEM cells for the 50 ft. (15.2 m) HEC-RAS cell and 400 DEM cells for a 100 ft. (30.5 m) cell. Thus, any additional detail contained in a finer DEM is averaged out in the HEC-RAS grid and does not improve the model.

The extent of the HEC-RAS 2D model is illustrated in Figure 2.4-26. The model boundaries are set to the extent of the watershed to capture the rain on the grid feature of the HEC-RAS 2D. Boundaries are also away from the power block area and safety-related SSCs in order to prevent boundary conditions from affecting flood levels evaluated within the power block area and to ensure the stability of the model.

The HEC-RAS 2D model covers an area of approximately 69 mi^2 (179 km^2); about 13.5 mi. (21.7 km) in the north-south direction and about 6.5 mi. (10.5 m) in the east-west direction. The numerical grid was generated with the RAS Mapper module. The horizontal grid size was 100 ft.

x 100 ft. (30.5 m x 30.5 m) within the entire model domain. The model grid is refined to 50 ft. x 50 ft. (15.2 m x 15.2 m) on the site and in the vicinity of the man-made canal connecting the west part of the lake to the rest of the lake, edges of the embankments, and ditches around the site. The model has 204,696 cells (Figure 2.4-26). Sensitivity analysis on the size of the mesh was performed and confirmed that the selected cell size results in similar output as smaller cells. This is mainly due to the underlying features of HEC-RAS 2D, which considers:

- Volume rating curves of each cell based on detailed LiDAR data within the footprint of each cell.
- Profile along all faces of the cell based on detailed LiDAR data.

The computation interval is used in the unsteady flow calculations. This is probably one of the most important parameters entered into the model. Choosing this value was done with care and consideration as to how it may affect the simulation. The computation interval is based on several factors. First, the interval should be small enough to accurately describe the rise and fall of the hydrographs being routed. A general rule of thumb is to use a computation interval that is equal to or less than the time of rise of the hydrograph divided by 20 (Reference 2.4-37). A second way of computing the appropriate time step is by applying a numerical accuracy criterion called the Courant condition. The Courant condition criterion looks at cross section spacing and flood wave velocity. The basic premise is that the computational interval should be equal to or less than the time it takes water to travel from one cross section to the next. A detailed description of the Courant condition can be found under the Model Accuracy, Stability, and Sensitivity section of this chapter. Use of a time step based on the Courant condition gives the best numerical solution, but it may significantly increase the model's runtime. In this analysis, the sensitivity analysis showed that a 20-second computation interval results in a stable model and captures the hydraulics of the PMP hyetograph.

Model boundary conditions comprise the following:

- **Downstream:** Belews Lake Dam spillway discharge as determined in Section 2.4.3.4.2
- **Entire model domain**: Rain on grid as determined on Section 2.4.3.2.

2.4.3.4.2 Belews Lake Dam Discharge

The dam is an earthen embankment, 170 ft. (51.9 m) in height, constructed on Belews Creek in Rockingham County, approximately 2 mi. (3.2 km) northeast of the proposed plant site. A gated structural spillway, [[ ]]^{CEII} the normal pool at elevation 725 ft. (221 m) NAVD 88. The gate structure consists of two tainter gates 20 ft. (6 m) wide by 15 ft. (4.5 m) high. Each tainter gate is positioned on the [[ ]]^{CEII} The structural spillway releases outflows to a rock-excavated outlet channel. The excavated channel discharges flows into Belews Creek approximately 0.5 mi. (0.8 km) upstream of the confluence with the Dan River.

The gated spillway design of the Belews Lake Main Dam required the use of a hydraulic equation specific to the gated structure. A gate operation element must also be accounted for in the spillway rating curve. [[ ]]^{CEII},

which indicate two operating criteria during storm events. [[

]][CEII]

Accordingly, a spreadsheet developed by Reference 2.4-4 allows for input of gate opening dependent on reservoir WSEL. [[
]][CEII] the normal pool elevation of 725 ft. (221 m). [[

]][CEII]

To determine the spillway capacity, a hydraulic rating curve was developed for each spillway structure. The spillway flow equation, which can be found in the HEC-RAS software manual (Reference 2.4-36), was used to develop a rating curve for the radial crest gates. A weir coefficient of [[ ]][CEII] A weir coefficient of [[
]][CEII] The discharge coefficient for the tainter gate (C), trunnion height exponent (TE), gate opening exponent (BE), and head exponent (HE) values are typical values suggested in the HEC-RAS software manual. The exponent, GE, is a user developed exponent to determine the gate opening height based on the gate operating procedures described above that account for changes in WSEL. The rating curve assumes that the gates are [[

]][CEII] Spillway capacity for the main dam is summarized in Tables 2.4-16a and 2.4-16b. Outflow varies from [[
]][CEII]

2.4.3.4.3 Roughness

Each cell in the model is assigned a Manning's roughness coefficient using land cover categories. Several sources report Manning's roughness coefficients for flow over various surfaces. The following three sources are used in this analysis.

- United States Department of Agriculture (USDA) Natural Resources Conservation Service Technical Release 55 (TR-55) (Reference 2.4-43).
- HEC-RAS Reference Manual (Reference 2.4-36).
- Open-Channel Hydraulics (Reference 2.4-6).

The references listed above provide a range of acceptable values for Manning's roughness coefficients (see Table 2.4-17 only presents roughness values for main features of the model). Manning's roughness values assigned to the entire model are presented in Figure 2.4-27. Roughness varies from 0.05 to 0.2. Sensitivity analysis was performed on roughness by assigning the minimum roughness value from the range provided by the HEC-RAS manual

(Reference 2.4-36). Sensitivity showed that the results are increased by only 6 in. (152 mm), which is bounded by the available margin.

2.4.3.4.4 Hydraulic Structures

Bridges were identified along Highway 158 and 65. Because these bridges are located upstream of the project sites, conservatively, they are assumed to be entirely open. The terrain is modified to simulate an entirely open section for the intersection of roads and Belews Creek.

2.4.3.5 Water Level Determinations

The PMF produces a water elevation of 746.4 ft. (227.5 m) NAVD 88 at the Project site. The maximum WSEL for the entire 2D model domain is presented in Figure 2.4-28. The component of the total vertical extent is 1.5 ft. (0.46 m) (see Table 2.4-22 and Table 2.4-23).

The total vertical extent of the PMF is 747.86 ft. NAVD 88 (Table 2.4-19). This elevation is significantly lower than the site grade elevation of 810 ft. (247 m) NAVD 88 and provides approximately 63 ft. (19 m) of margin. Therefore, it is concluded that safety-related SSCs are not impacted by the PMF and its associated combined effects.

2.4.3.6 Coincident Wind Wave Activity

Wind waves were computed using procedures from the USACE Coastal Engineering Manual (CEM) (Reference 2.4-39). In accordance with EM 1110-2-1614, Equation 2-2 (Reference 2.4-33), and ANSI/ANS-2.8 (Reference 2.4-2), the design wave height, also referred to herein as $H_{1\%}$ (the average wave height of the highest 1% of waves), used for wave runup has the following relationship to the significant wave height (H_s, average wave height of the highest 1/3 of the Waves) (see Equation 2.4.3-1).

$$H_{1\%} \approx 1.67\, H_s \qquad \text{Equation 2.4.3-1}$$

The 2-year mean recurrence interval annual extreme-mile wind speed at 30 ft. (9 m) above ground is 50 mph (80.5 kph) at the site location per Figure 1 of ANSI/ANS-2.8 (Reference 2.4-2) (Figure 2.4-29). The annual extreme-mile wind speed was converted to a 1-hr. duration wind speed using the USACE CEM, Figures II-2-1 and II-2-2 (Reference 2.4-39). The wind speeds were then converted to 10-, 15-, and 20-minute wind speed durations (as appropriate for wave generation for the applied fetches) using USACE CEM Figure II-2-1 (Reference 2.4-39). Calculations are presented in Tables 2.4-20a through 2.4-20e.

Wind-driven waves were calculated using the “Windspeed Adjustment and Wave Growth” module of the Automated Coastal Engineering System (ACES) in the Coastal Engineering Design & Analysis System Version 4.03 (Reference 2.4-40). The shallow restricted option was chosen because the waves are not expected to propagate under a deep-water condition for a significant duration, and the fetch is not unlimited for wave formation; selecting the shallow restricted option, therefore, yields more accurate results. Wind fetch geometry was determined using ArcGIS Pro Version 2.7.1 (Reference 2.4-13). The appropriate wind duration was

determined through an iterative process, as outlined below:

- Depending on fetch, an initial wind duration (10-minute, 15-minute, or 20-minute) was selected and input with the corresponding wind speed into ACES.
- The output wave period was used to calculate wavelength, celerity, and the time required for the wave to travel the fetch based on Dean and Dalrymple (Reference 2.4-7). Sample analyses are presented in Tables 2.4-21a and 2.4-21b.

The resulting time required to travel the fetch was rounded to the nearest five minutes and compared to the wind duration used in the ACES calculation. Five minutes was chosen as an appropriate rounding increment for the wind duration intervals based on the sensitivity and accuracy of the calculation; decreasing the increment to less than five minutes does not significantly change the results.

If the two values were the same, the resulting wave height, period, and wavelength were used. If the two values were different, the resulting time required to travel the fetch was used with the corresponding wind speed as input to the ACES calculation, and the calculation process was repeated. The geographical latitude of observation was input as 36.32 degrees north based on the location of the project site. In this analysis, a duration of 10 minutes with observed wind speed of 42.9 mph (69.0 kph) was selected.

The fetch geometry and average depth along the fetch were determined using the outputs of HEC-RAS 2D combined with the bathymetry of the lake. Average water depth along the fetches was calculated by obtaining the raster water depth information along the fetch line and then averaging these values. Geometry of the lake showed that one fetch is the longest, as shown on Figure 2.4-30. Any other fetch would be shorter than the one selected with shallower water depth. ACES output wave height is H_{mo}, the spectral significant wave height (see Table 2.4-22).

2.4.3.6.1 Wind Setup

Wind setup was calculated along the controlling fetch using U.S. Bureau of Reclamation ACER Technical Memorandum No. 2 (Reference 2.4-42). The calculated wind setup is 0.01 ft. (0.003 m) (Table 2.4-23).

2.4.3.6.2 Wave Runup

The theoretical wave runup was calculated using ACES (Reference 2.4-40) at the edges of the islands where reactor sites are located. Inputs for the runup calculations included design wave height, wave period, and embankment slope. The calculated average wave runup is 1.45 ft. (0.44 m) (Table 2.4-18).

2.4.4 POTENTIAL DAM FAILURES

2.4.4.1 Potential Dam Failure

This section examines the flooding design basis and evaluates the potential hazards to safety-related SSCs as a result of potential dam and on-site pond failures according to the procedure

described in the standard ANSI/ANS-2.8 (Reference 2.4-2), NRC *Guidance for Assessment of Flooding Hazards Due to Dam Failure* (JLD-ISG-2013-01) (Reference 2.4-26), and NUREG/CR-7046.

The Project site is located at an elevation of approximately 810 ft. (247 m) in NAVD 88 on a peninsula surrounded to the north, east, and west by Belews Lake. Most of the terrain in the vicinity of the Project site (Figure 2.4-1) is characterized by Belews Lake and the foothills of the Blue Ridge mountains to the northwest. The location of Belews Lake is at the southwest edge of the Dan River Basin. The Dan River rises from springs on Belcher Mountain on the Blue Ridge Plateau in Patrick County, VA, then flows 200 mi. (322 km) across the state border into Stokes County, NC. The lake sits in the foothills of the Blue Ridge Mountains and the land gradually rises to the northwest.

Upstream dams whose failure has the potential to cause problems at the plant were investigated to determine if their failure would endanger plant safety. Failure of the Belews Lake Dam downstream of the Project site would have no adverse impact on plant safety or shutdown capabilities, as none of the technologies considered require the lake as a safety-related cooling source.

2.4.4.2 Dam and Reservoir Description

There are a total of 10 dams in the Belews Creek watershed and its tributaries upstream of Belews Lake Dam with maximum combined storage capacity of 797 ac-ft. (98.3 ha-m). These dams and reservoirs are owned and operated by different entities for recreation or water supply purposes. Location of these reservoirs with respect to the Project site is shown in Figure 2.4-31. Specific information on these dams relevant to the flood risk assessment of the Project site is summarized in Table 2.4-24 based on data collected from the USACE National Inventory of Dams (NID) (Reference 2.4-38). All dams are earthen type. There are no on-site operational basins requiring analysis for potential dam failure.

There are no current plans to construct dams and reservoirs that could adversely affect flood levels at the Project site.

2.4.4.3 Dam Failure Permutations

Per NUREG/CR-7046, flooding from dam failure should capture the envelope of the following alternatives.

- **Alternative 1** – Combination of the following:
  - A 25-year flood.
  - A flood caused by dam failure resulting from a safe shutdown earthquake, and coincident with the peak of the 25-year flood antecedent or subsequent rain.
  - Waves induced by 2-year wind speed applied along the critical direction.
- **Alternative 2** – Combination of the following:

- The lesser of one-half of the PMF or the 500-year flood.
- A flood caused by dam failure resulting from an operating basis earthquake, coincident with peak flood conditions.
- Waves induced by 2-year wind speed applied along the critical direction.

The NRC has acknowledged that detailed evaluation of a large number of dams in a watershed is difficult and dam failure risk can potentially be evaluated more efficiently with a hierarchical approach. According to JLD-ISG-2013-01 (Reference 2.4-26), certain small dams can be eliminated from further consideration. However, due to the limited number of dams and their small size, screening is not performed in this analysis, and conservatively, all dams in the watershed are included.

According to NUREG/CR-7046, HHA is a progressively refined, stepwise estimation of site-specific hazards that evaluates the safety of SSCs with the most conservative plausible assumptions consistent with available data. The HHA process starts with the most conservative simplifying assumptions that maximize the hazards from the probable maximum event for each natural flood-causing phenomenon expected to occur in the vicinity of a proposed site.

Therefore, regardless of the region's seismic category or dam stability, Alternative 2 is used, which considers cascading failures of all upstream dams. Additionally, instead of seismic dam failure, overtopping dam failure with dams at their maximum storage is conservatively considered to maximize the dam failure impact. Overtopping occurs when a dam reaches its maximum storage capacity, leading to the release of maximum discharge from the structure.

Upon dam failure, the resulting discharge flows toward Belews Lake, over the spillway, and subsequently into the Dan River. This alternative considers the simultaneous failure of all dams while assuming that the downstream Belews Lake Dam remains intact. This assumption results in the highest water level at the Project site.

2.4.4.4 Unsteady Flow Analysis of Potential Dam Failures

In the conceptual dam break flood model, all the dams fail with their reservoir water level at or above the dam crest, thereby releasing the full dam storage. A simplified calculation approach was used to account for the NID volumes under failure conditions. A time to peak of 0.1 hr. was assumed, based on guidelines from the Federal Energy Regulatory Commission (FERC) for the estimation of the dam breach parameter (Reference 2.4-10). A Froehlich approach (Reference 2.4-12) was used to postulate the individual failure hydrograph peak flows. The breach section in the model was represented by a 1 vertical:1 horizontal side slope.

The individual hydrographs were then converted into a triangular hydrograph, ensuring that the entire NID volume was included in the failure flows. Several dams are located within one branch discharging into Belews Lake. These dams are clustered into one dam with the combined storage and average of their surface area used in estimating the breach hydrograph. This is compatible with the guideline provided in JLD-ISG-2013-01 (Reference 2.4-26). A total of two clusters are considered and, therefore, seven hydrographs are generated. Cluster

characteristics are provided in Table 2.4-25.

According to JLD-ISG-2013-01 (Reference 2.4-26), the location of hypothetical (i.e., clustered) dams should be at either the location of the most downstream dam in the cluster or further downstream toward the site. In this analysis, the location of all dams is moved further toward the site as presented in Figure 2.4-31. Breach hydrographs are presented in Figures 2.4-32a through 2.4-32d. Dam breach hydrograph properties and predicted peak discharge are presented in Table 2.4-26. [[

]]CEII

A 500-year, 24-hr uniform rainfall of 10.5 in. (266.7 mm) (Reference 2.3-22) over the entire watershed is applied to represent the coincidental flow. The representative storm is Type II per Reference 2.4-43. To maximize dam failure flooding, the lake is assumed to be [[

]]CEII

Hydrographs were then routed downstream toward Belews Lake using the unsteady, 2D flow option of USACE HEC-RAS version 6.4.1 (Reference 2.4-37).

The unsteady flow runoff and stream course models described in Section 2.4.3.3 were used to evaluate the site flood levels from a combined 500-year, 24-hour rainfall event involving dam failures above the plant.

2.4.4.5 Water Level at the Project Site

The unsteady flow analysis described in Section 2.4.4.4 was performed by applying the dam failure hydrographs (Figures 2.4-32a through 2.4-32d) combined with a 500-year, 24-hour rainfall event. The unsteady flow analysis provides the flow and peak still water levels at the Project site.

The resulting peak dam failure flow combined with the coincident 500-year flood at the location of maximum still water level is [[ ]]CEII (see Figure 2.4-33). The peak timing for the 500-year flood and dam failure hydrographs is matched through sensitivity analysis. The peak still WSEL is [[ ]]CEII NAVD 88. The maximum still WSEL for the entire 2D model domain is presented in Figure 2.4-34. Still water level varies from approximately [[ ]]CEII where the proposed reactor units at the Project site are located. Conservatively, the maximum is considered for all units.

A coincident 50 mph (80.5 kph) (adjusted wind speed, see Section 2.4.4.6) overwater wind was applied, resulting in a wave height of 1.49 ft. (0.45 m) from crest to trough. The maximum WSEL resulting from the combination of the controlling 500-year storm, coincident hydrologic dam failures and wind wave effects is [[ ]]CEII NAVD 88.

The impacts to the Project site from potential flood-causing mechanisms have been evaluated. The site finish grade is 810 ft. (247 m) NAVD 88. This provides approximately [[ ]]CEII Thus, there are no impacts to safety-related SSCs at the Project site.

2.4.4.6 Coincident Wind Wave

Wind waves were computed using procedures of the USACE Coast Engineering Manual (Reference 2.4-39). The calculated coincident design wave height and period are 1.49 ft. (0.45 m) and 1.72 sec., respectively. The wind setup and wave runup associated with an overwater wind speed of 50 mph (80.5 kph) (unadjusted), were 0.01 ft. (0.003 m) and 1.45 ft. (0.44 m), respectively. Calculation details are presented in Section 2.4.3.6.

2.4.4.7 Erosion and Deposition Effects

The effects of the potential movement of erodible material with respect to flood levels at the Project site are shown to be insignificant by taking a very conservative approach. According to EM 1110-2-2300 (Reference 2.4-34), the top width of earthen dams is between [[ ]]^{CEII} Conservatively, a top width of [[ ]]^{CEII} is used for the dams. A side slope of 1 vertical:3 horizontal is used to calculate the bottom width of the dam. The total volume of the material is then calculated as presented in Table 2.4-27. If all the earthen embankments to fail with the highest volume of breached material were to be completely eroded and deposited into the Belews Lake, the storage capacity of Belews Lake is reduced by about [[ ]]^{CEII} According to the elevation-volume curve of the lake (see Figure 2.4-35), this is equivalent to less than a foot rise in Belews Creek with headwater elevation at the peak elevation of [[ ]]^{CEII} NAVD 88. Based on the bounding dam failure results, a rise of less than a foot in Belews Lake is far short of the nearly [[ ]]^{CEII} of rise that would be required to reach the preliminary Project site plant grade.

2.4.5 PROBABLE MAXIMUM SURGE AND SEICHE FLOODING

2.4.5.1 Storm Surge

The Project site is located more than 2300 mi. (3701 km) inland from the Pacific Ocean, approximately 190 mi. (306 km) inland from the Atlantic Coast, and approximately 490 mi. (789 km) inland from the Gulf of America (Reference 2.4-51). The site is located adequately inland such that hurricanes and a Probable Maximum Hurricane are not a source of a potential flood hazard. Therefore, further consideration of storm surge flooding outlined in NRC *The Estimation of Very Low Probability Hurricane Storm Surges for Design and Licensing of Nuclear Power Plants in Coastal Areas*, (NUREG/CR-7134) and NRC *Guidance for Performing a Tsunami, Surge, or Seiche Hazard Assessment* (JLD-ISG-2012-06) (Reference 2.4-27) is not applicable to the site.

Storm surge due to Probable Maximum Wind Storms and squall lines is also not applicable to the Project site because the site is not located on the Great Lakes, as discussed in ANSI/ANS-2.8 (Reference 2.4-2) and JLD-ISG-2012-06 (Reference 2.4-27). Therefore, according to JLD-ISG-2012-06 guidance, determination of hydrostatic and hydrodynamic forces, debris and water-borne projectiles, and effects of sediment erosion or deposition due to storm surge is not necessary because safety-related SSCs at the Project site are not affected by storm surge flood levels (Reference 2.4-27).

2.4.5.2 Seiche

A seiche is defined as “an oscillation of the water surface in an enclosed or semi-enclosed body of water initiated by an external cause” in NUREG/CR-7046. To account for the potential of a seiche due to meteorological effects, the seiche periods for the length and width of Belews Lake were computed. To compute the seiche periods, the lake was assumed to be a rectangular basin with an averaged depth of the lake, which follows the methodologies outlined by Dean and Dalrymple (Reference 2.4-7).

Using the Dean and Dalrymple methodology for seiche periods for Belews Lake, the resulting seiche periods computed were 10.4 minutes for the lake's length and 5.3 minutes for the width of the lake. Seiching at these periods could only occur if an oscillatory force (pressure or wind) excited lake oscillations at one of the seiche periods. The periods calculated for lake oscillation could not be continuously forced by changes in overall weather conditions because these conditions typically fluctuate at time scales of 1 hour or more (Reference 2.4-30). Therefore, seiches due to meteorological effects are dismissed as a source of flooding at the Project site.

Seiches can also occur due to seismic effects and landslides. The Project site is situated in an area of low seismic hazards, according to the American Society of Civil Engineers (ASCE) (Reference 2.4-3). The occurrence of landslides in the area adjacent to Belews Lake is not considered possible due to the low relief of topographic features in the vicinity of the Project site. Therefore, potential seismic events and landslide are not expected to cause seiches on Belews Lake and, therefore, cause flooding at the Project site. Additionally, according to JLD-ISG-2012-06 guidance, determination of hydrostatic and hydrodynamic forces, debris and water-borne projectiles, and the effects of sediment erosion or deposition due to seiche are not necessary because safety-related SSC at the Project site are not affected by seiche flood levels (Reference 2.4-27).

Faults and surface deformation in the vicinity of the Project site (within 25 mi. [40 km] of the site) and in the site region (within 200 mi. [322 km] of the site) are described in Sections 2.5.1 and 2.5.3. Because surge and seiche are not applicable flooding scenarios, the corresponding run-up is also not applicable.

2.4.6 PROBABLE MAXIMUM TSUNAMI HAZARDS

Following the guidance outlined in NRC *Tsunami Hazard Assessment at Nuclear Power Plant Sites in the United States of America – Final Report* (NUREG/CR-6966), and JLD-ISG-2012-06 (Reference 2.4-27), a review was conducted of the NOAA record of historical tsunamis that impacted the east coast of the U.S. and the Gulf of America. The maximum historical water levels due to historical tsunami run-up recorded along the east coast of the U.S. and the Gulf of America is 17.7 ft. (5.4 m), which occurred in Willets Point, New York in 1932 (Reference 2.4-24). Willets Point, New York, is approximately 451 mi. (726 km) from the Project site (Reference 2.4-51), and the closest shoreline that could be subjected to tsunami flooding is approximately 190 mi. (306 km) away. In addition, the Project site’s finish grade is 810 ft. (247 m) NAVD 88, which is significantly higher than the coastal elevations at Willets Point, NY. For these reasons,

the Project site is not subject to tsunami flood levels.

Faults and surface deformation in the vicinity of the Project site (within 25 mi. [40 km]) and in the region (within 200 mi. 322 km]) are described in Sections 2.5.1 and 2.5.3.

According to NUREG/CR-6966 indicates that if regional screening identifies that the site region is not subject to tsunamis, no further analysis for tsunami hazards is required. Additionally, according to JLD-ISG-2012-06 guidance (Reference 2.4-27), the determination of the hydrostatic and hydrodynamic forces, debris and water-borne projectiles, and the effects of sediment erosion and deposition are not considered because the safety-related SSCs of the Project site are not subject to tsunami flood levels (Reference 2.4-27).

2.4.7 ICE EFFECTS

The potential ice effects on the Project site are evaluated in this section. Because the site is located in a region of continental, humid subtropical climate, extreme ice conditions with potential adverse effects on safety-related and risk-significant SSCs are not typically present. Additionally, the advanced reactors under consideration for the Project site do not rely on an external, safety-related water source and therefore are not affected by any potential loss of water supply due to ice conditions in the region.

2.4.7.1 Historical Ice Accumulation

Historical ice accumulations in the site region are evaluated by examining the USACE Ice Jam Database, weather records maintained by NOAA, and other available sources.

The USACE Ice Jam Database, which contains records of ice jam events from 1780 to the access date of December 2024, documents no ice jam event on Belews Creek (Reference 2.4-41).

Records of icing near the Project site are limited. Historical weather data from the nearby airport station (see Figure 2.4-36) indicate that sub-freezing T_a can occur during the winter months in the area (Figure 2.4-37). NOAA NWS records for the North Carolina area, which begin in 1928, document an all-time lowest temperature of -7.96 °F (-22.2 °C) recorded on January 21, 1985 (Reference 2.4-25).

Based on the climatic condition of the area and historical evidence, it can be established that the potential for ice formation and accumulation, including ice jams, exists in the area of the Project site. However, an ice jam sufficient to cause flooding at the Project site is not credible. This is demonstrated by using conservative postulations that are not physically credible, consistent with the HHA approach, as presented below.

2.4.7.2 High and Low Water Levels

The T_a near the Project site have historically fallen below freezing in the winter seasons, as indicated by the mean daily temperatures measured at the Greensboro Piedmont Triad international airport station (Figure 2.4-36 and Figure 2.4-37). This introduces the possibility of

ice blockage of catch basins and drains, causing stormwater runoff to back up to the yard, creating a potential flood risk to the site. However, in evaluating the design basis flood hazard evaluation for the safety-related SSCs at the Project site, in particular the LIP flooding mechanism, it is assumed that all culverts, catch basins, and storm drains are blocked. With this assumption, the site is designed to pass the runoff from the LIP event without adversely impacting any safety-related facility, as presented in Section 2.4.2. The site finished grade at elevation 810 ft. (247 m) NAVD 88, which is above lake level, results in a positive gradient that allows stormwater runoff to gravity flow away from all safety-related SSCs and to prevent backwater flooding due to ice accumulation and ice jam formation in any of the natural water courses. Therefore, flooding of any safety-related SSCs as a result of LIP coincidental with ice formation is precluded.

The breach of an upstream ice dam is one of the considerations in the flood hazard evaluation for the Project site. The flood risk to the site in a breach event would be most critical when the ice jam is formed near the site, where Belews Creek Rd. passes over Belews Lake at three locations (Figure 2.4-42), maximizing the storage that can be impounded behind the jam. A conservative assumption for the height of the ice jam is made to derive a bounding estimate of the impoundment volume, consistent with the HHA approach. It is assumed that the ice jam builds up from the riverbed to 5 ft. (1.5 m) higher than the top of the bridges, which is the maximum dam height that hypothetically can form. The bounding impoundment volume behind the hypothetical ice jam is computed to be approximately 33,329 ac-ft (4111 ha-m). This volume is insignificant in comparison with the combined storage capacities of Belews Lake. Assuming the lake is at normal pool elevation of 725 ft. (221 m) NAVD 88 with an initial volume of 185,000 ac-ft (22,819 ha-m), the added volume from the jam results in an increase in lake level to elevation 734 ft. (224 m) NAVD 88. Combined with the higher available hydraulic heads for the flood waves during a breaching event of the upstream dams, it is concluded that the flooding impact on the Project site from the breach of any upstream ice dam is bounded by the impact from the most limiting dam failure described in Section 2.4.4.

For high water concerns due to backwater caused by ice jams formed downstream of the Project site, a hypothetical worst-case scenario, consistent with the HHA approach, was conservatively assumed with ice buildup to a maximum possible elevation on the Belews Lake Dam (Figure 2.4-36). By reviewing the natural landscape and manmade structures in the river system, it was determined that the worst-case and only backwater flooding at the site would occur when ice is built up at the Belews Lake Dam. The crest level of the dam is at elevation 743 ft. (226 m) NAVD 88. Assuming that an ice jam builds up to the top of the crest elevation, the backwater level behind the ice jam would be of the same order, i.e., approximately elevation 743 ft. (226 m) NAVD 88, which is 18 ft. (5.5 m) above the normal operating level of the lake of 725 ft. (221 m) NAVD 88. Because the site finish grade is at elevation 810 ft. (247 m) NAVD 88, more than 67 ft. (20 m) above the hypothetical maximum ice buildup elevation, it is concluded that no safety-related or risk-significant SSC is affected by the backwater effect of a downstream ice jam.

Low water conditions resulting from ice formation or accumulations that may cause interruption of stream flow in Belews Lake do not impact the site because the advanced reactors being

considered for the Project site do not rely on an external water source for safety-related and risk-significant water supply.

2.4.7.3 Ice Sheet Formation

The advanced reactors being considered for the Project site do not require external water sources for safety-related and risk-significant SSCs and do not rely on any open storage facilities or impoundments to supply or maintain the inventory for safety-related water use. Consequently, a reduction of stream flow in the river or storage volume in an impoundment due to ice sheet formation does not introduce any adverse impacts to safety-related or risk-significant SSCs.

The advanced reactors to be located at the Project site use cooling towers to dissipate the excess heat load from the main steam condensers. The main water structures in the cooling system that have hydrologic interfaces with ice sheet formation are the cooling tower basin at the base of each cooling tower, the Project site discharges, and the makeup water intake structure, located on Belews Lake, which supplies makeup water to the cooling water system.

Because subfreezing T_a can occur during the winter months, ice sheet formation is possible. The ice layer thickness was estimated to evaluate the impact of ice formation on the on-safety-related cooling tower basins and intake structure.

T_a data from the nearby Greensboro Piedmont Triad international airport meteorological station (see Figure 2.4-36 for station location and Figure 2.4-37 for data) was used for the t_i estimation (Reference 2.4-35). The airport meteorological station is located about 16 mi. (26 km) southeast of the site (Figure 2.4-36), and its temperature data is considered to be representative of the site and the nearby region. For this analysis, the station daily weather data from January 1, 1928, through December 9, 2024 (approximately 96 years of data), were used.

The examination of the daily average T_a from the meteorological station for the period of record from 1928 to 2024 (Figure 2.4-37) showed that there were several years in which the daily average temperature fell below freezing for consecutive days during the months of December through February. However, it appears that January and February were generally the months in which t_i reached its maximum (Table 2.4-28).

To predict the maximum t_i that can form at the Project site, an analysis of the temperature data was made to determine the maximum accumulated freezing degree-days (AFDD) for the period of record using the procedures in Reference 2.4-35.

Following the methodology in Reference 2.4-35, the freezing degree day (FDD) value for each day is determined by subtracting the daily average temperature from 32°F (0 °C). The AFDD is then determined by summing the FDD values for each day during the winter. A negative freezing degree day value represents a temperature warmer than freezing, and a positive freezing degree day represents temperatures below freezing. The FDD values for each day of the winter can be summed to determine the net AFDD. The AFDD point is reset to zero whenever the value becomes negative. The peak AFDD value for the period analyzed is 180.3

degree days, which occurred on February 8, 1977.

The t_i was then estimated using a conservative coefficient (C = 0.8), recommended for a windy lake with no snow condition (Reference 2.4-35). Figure 2.4-37 depicts the graph of T_a and AFDD for the period of record. Figure 2.4-38 depicts the temporal variation of the t_i. The maximum t_i was estimated to be approximately 11 in. (28 cm), occurring on February 8, 1977. Figure 2.4-39 shows the T_a and AFDD for the winter of 1976/1977. The estimated t_i over the winter of 1976/1977 is shown in Figure 2.4-40. The yearly maximum ice thickness for the approximate 96-year period is plotted in Figure 2.4-41 and provided in Table 2.4-28.

As demonstrated above, based on the worst winter on record (the winter of 1976-77), ice could build up to a maximum thickness of approximately 11 in. (28 cm) at the Project site and vicinity. Because it is located in a relatively mild climatic region, the plant is not typically subject to extreme ice conditions. Detailed design of the closed-cycle cooling tower and intake structure was not performed to support the ESPA; however, detailed design of the closed-cycle cooling tower and intake structure would consider ice effects, consistent with standard industry practice, to protect against unplanned interruption of the operation of the cooling system.

2.4.7.4 Ice-Induced Forces and Blockages

The advanced reactors being considered for the Project site do not include safety-related or risk-significant SSCs that are subject to ice-induced forces or blockages from either sheet ice or frazil ice. While non-safety-related components may be affected by ice-induced forces or blockages, standard design practices will mitigate the potential impacts of these events.

2.4.7.5 Consideration of Other Site-Related Evaluation Criteria

There is no additional site information that would indicate an icing scenario more severe than has been described above.

2.4.7.6 Consideration of Cold-Region Hydrology

The Project site is located in a region characterized as continental, humid subtropical climate; therefore, impacts associated with cold region hydrologic effects, including permafrost and significant frost, are not applicable to the site. The effect of rain-on-snow, ice and/or frozen soils is addressed, as applicable, in Section 2.4.2 for the LIP flooding evaluation and in Section 2.4.3 for the stream flooding evaluation.

2.4.7.7 Conclusion

Historical and postulated ice conditions applicable to the Project site are evaluated to determine their impact on the safety of the plant. Due to the relatively mild climatic condition at the Project site and the elevated design plant grade above natural drainages, in combination with the advanced reactor plant design that does not rely on external water sources for safety-related water use, it is concluded that ice effects do not cause flooding or water availability concerns for the safety-related and risk-significant SSCs.

2.4.8 COOLING WATER CANALS AND RESERVOIRS

The advanced reactors under consideration for the Project site do not rely on Belews Lake, the Dan River, or any other water source for a safety-related water supply, and the site will not include cooling water canals or new reservoirs to support nuclear generation. As discussed in Section 2.4.7, the Project site will use Belews Lake as the source of makeup water for non-safety-related normal plant cooling. Belews Lake has the ability to be supplemented with makeup water from the Dan River through an installed makeup water system.

2.4.9 CHANNEL DIVERSION

The Project site is located on a peninsula surrounded by Belews Lake. Belews Lake was constructed in the early 1970s by damming Belews Creek, a tributary to the Dan River. The North Carolina Department of Water and Air Resources authorized the creation of Belews Lake specifically to provide cooling water to BCSS, which is owned and operated by Duke Energy. Once constructed, the lake was filled and reached full pond elevation in April 1973. Belews Lake is located approximately 16 mi. (25.6 km) northeast of Winston-Salem in Stokes County, North Carolina. Belews Creek is regulated by the dam spillway, which eliminates the mechanisms by which erosion may cause meandering or encroachment into the intake structure.

Furthermore, the Project site does not rely on Belews Lake or the Dan River to support safety-related and risk-significant SSCs that provide emergency cooling water. However, as noted in Section 2.4.7, the lake is used as a water source for certain non-safety-related SSCs. Additionally, Dan River runs in a southwest-northeast direction downstream of the Belew Creek Dam. There is minimum of 165 ft. (50.3 m) (i.e., 725 ft. – 560 ft.) elevation difference between the Dan River and Belew Lake. Therefore, potential diversion of Dan River will not impact the site. Historical aerial photos of Dan River in the vicinity of pump station feeding Belews Lake from 1985 to 2024 were reviewed. No sign of meandering, erosion, or diversion is observed during the past 40 years. Dan River has experienced both flooding and draught conditions during this period. Therefore, it is highly unlikely that the pump station would be impacted by Channel Diversion. Even if the pump station were impacted, it would not affect site safety functions because the pump station provides no safety-related support functions.

No safety-related water sources are required for operation of the proposed advanced reactors. The lake is the primary source of water for the normal cooling system and water processing plant that feeds the demineralized water systems and liquid radwaste treatment system. Consequently, the safety of the plant is not compromised due to a loss of water supply even in the highly unlikely event of a channel diversion near the site.

It is concluded that a channel diversion is not a necessary design consideration for the Project site. In the unlikely event that channel diversions occur, there is no safety-related impact to the nuclear power plants at the Project site.

2.4.10 FLOOD PROTECTION REQUIREMENTS

Flood protection requirements are specified to protect safety-related and risk-significant SSCs

against postulated design basis external flooding events. The evaluations of the flood hazards applicable to the Project site are described in Sections 2.4.2 through 2.4.7 and Section 2.4.9. Design basis flooding scenarios are discussed in Section 2.4.3. Dam failure scenarios are discussed in Section 2.4.4. Surge and seiche events are discussed in Section 2.4.5. Tsunamis are discussed in Section 2.4.6. Historical information related to icing and ice jams is provided in Section 2.4.7. Channel diversions are discussed in Section 2.4.9. Section 2.4.2 summarizes the maximum flood levels for various flooding scenarios applicable to the Belews Creek Site.

The preliminary Project site grade is established at elevation 810 ft. (247 m) NAVD 88, well above the calculated maximum flood level of 747.86 ft. (227.95 m) NAVD 88 resulting from PMF. It is concluded that the functions of safety-related and risk-significant SSCs are not adversely impacted by the design basis external flooding events. Thus, for all flooding mechanisms other than LIP, no flood protection measures are required at the Project site, and the proposed plant conforms to Regulatory Position 1 of RG 1.59. LIP-specific measures are discussed in Section 2.4.10.2.

2.4.10.1 Flooding History

As detailed in Section 2.4.2.1, the Project site is situated on a peninsula of Belews Lake. Belews Lake was constructed in the early 1970s by damming Belews Creek, a tributary to the Dan River. The risk of floods on Belews Creek in the past was primarily associated with precipitation runoff over the watershed. However, since construction of the dam, flooding on Belews Creek has been controlled by the dam. Flooding from the Dan River does not adversely affect the site as the site is located approximately 250 ft (76.2 m) above the Dan River.

The wettest year on record in NC was 2020. Two intense rainfall events occurred in 2020 near the site. In February of 2020, intense rainfall resulted in one of the highest streamflow statistics in the recorded history for both gauges on the Dan River (see Figures 2.4-13 and 2.4-14). Hurricane Eta in November of 2020 reflects the second highest water depths and streamflow in recent history for both gauges on the Dan River. The streamflow reached highs of 40,900 cfs (1158 m^3/s) near Wentworth with water level of 540.3 ft. (164.7 m) NAVD 88 and 26,200 cfs (742 m^3/s) at Pine Hall in February, and 38,500 cfs (1090 m^3/s) near Wentworth and 25,800 cfs (730 m^3/s) at Pine Hall in November. Streamflow was 1.1 percent higher in February than November. The water levels reached 540.7 ft. (164.8 m) NAVD 88 near Wentworth and 591.2 ft. (180.2 m) NAVD 88 at Pine Hall in February, and 540.3 ft. (164.7 m) NAVD 88 near Wentworth and 590.9 ft. (180.1 m) NAVD 88 at Pine Hall in November.

Hurricane Agnes in 1972 remains the highest flow near Wentworth with 54,200 cfs (1535 m^3/s), 1.3 times higher than the 2020 flood event. Water levels are not available from the 1972 flood. However, scaling from 2020 event, it is estimated that the water level was in the range of 550 ft. (168 m) NAVD 88. The Pine Hall gauge was not in service during the 1972 timeframe.

2.4.10.2 Effects of Local Intense Precipitation

Because Belews Lake is capable of accommodating the water flows from Belews Creek, LIP events are not expected to flood the site. Additionally, in order to protect the Belews Lake Dam,

lake level is controlled procedurally by the dam spillway. The potential of flooding from a LIP event, as described in Section 2.4.2, is dependent upon facility design and final grading and drainage system design. Once the reactor technology has been selected, the site grading and drainage can be designed to prevent the LIP from impacting safety-related SSCs. It is therefore reasonable to expect that a fully effective drainage system is designed as part of the final licensed design.

2.4.11 LOW WATER CONSIDERATIONS

The Project site does not rely on Belews Lake or the Dan River to support safety-related and risk-significant SSCs that provides emergency cooling water. However, Belews Lake, combined with makeup water pumps from the Dan River, is used as a water source for non-safety-related SSCs. It primarily supplies the normal cooling system and the water processing plant that provides demineralized process water for downstream systems and the liquid radwaste treatment system. Figure 2.4-43 shows the location of the site in relation to Belews Lake and the Dan River.

The Project site is located on a peninsula in the middle of Belews Lake, and the supplemental makeup water pumps feeding the lake are located downstream of the Belews Lake Dam on the Dan River (see Figure 2.4-43). The lake was created in 1973 by Duke Energy to provide cooling water for the BCSS, a coal-burning and natural gas power plant currently situated on the lake.

The average withdrawal flow rate from the lake needed to support the nuclear facility at the Project site is estimated to be approximately 30,709 gpm (68.4 cfs, 1.94 m^3/s). The majority is used as makeup water to compensate for evaporation and blowdown losses from the closed-cycle mechanical draft cooling tower system that is used for normal cooling.

There would be return flow back to the lake or the Dan River based on operational needs, via a discharge structure, from cooling tower blowdown and effluents from downstream systems fed by the water processing plant and miscellaneous raw water users. The average discharge rate is estimated to be approximately 3467 gpm (7.72 cfs, 0.22 m^3/s). The net consumptive water use (withdrawal minus discharge) is therefore approximately 27,242 gpm (60.7 cfs, 1.72 m^3/s).

2.4.11.1 Low Flow in Rivers and Streams

The portion of the Dan River in the vicinity of Belews Lake Dam runs from southwest to northeast (Figure 2.4-44). The Dan River is a river of contrasts, originating high along the eastern slopes of the Blue Ridge Mountains in Patrick County, VA, and flowing east until it empties into the 50,000 ac. (20,234 ha) John H. Kerr Reservoir (Buggs Island Lake) near Clarksville, VA. The drainage area for the Dan River upstream of the makeup water pumping station is about 501 mi^2 (1298 km^2). The Belews Creek watershed upstream of Belews Lake Dam has a drainage area of about 69.33 mi^2 (179.59 km^2).

Historical Dan River flow data was gathered for both the 2001 – 2002 (i.e., extreme drought) and the 2011 – 2013 (i.e., typical) time periods from the USGS database (Reference 2.4-52). The typical period is reflective of 2011 – 2013, which were historically slightly drier than average

years, meaning they represent a conservative “typical” scenario. The typical scenario is also representative of normal condition while the extreme drought is a rare condition.

For the 2011 – 2013 period, data from the Pine Hall gauge was available for the entire period, reported in 15-minute intervals. For the 2001 – 2002 period, data from the Pine Hall gauge was not available. Instead, river flow data from the Wentworth gauge (located downstream in the Dan River from the Pine Hall gauge) was collected and flow data at the Pine Hall gauge was estimated. A correction factor was applied by comparing the flow at the two gauges when available for both. Gauge locations are shown in Figure 2.4-3. Streamflow data are presented in Figure 2.4-45.

2.4.11.1.1 Flow Release from Belews Lake Dam

The lake level is controlled by a set of spillway gates that are opened at points to release water. Belews Lake Dam Spillway Operation guidelines state that the lake level control-point (the lake height at which the spillways start releasing water) for winter/spring is 724.7 ft. NAVD 88 (221 m).

2.4.11.1.1.1 Belews Lake Inflows and Outflows

The main inflow contributions to Belews Lake include flow from Belews Creek and its branches, Dan River supplemental makeup flow, direct rainfall, and plant discharge back to the lake. Since the winter of 2002, pumping operations that withdraw supplemental makeup water from the nearby Dan River and deliver it to Belews Lake during periods of low lake level have occasionally occurred. NPDES Permit NC0024406 (Reference 2.4-15) allows for up to 100 cfs (2.83 m3/s) of pumping by the MWIS from the Dan River into Belews Lake. The number of pumps that can be operated at a time is dependent on the flow in the Dan River as well as other conditions. Per the NPDES Permit:

- Pumping from the Dan River must not lower the river flow below 110 cfs (3.11 m^3/s).
- At least 80 percent of the ambient flow must be bypassed (no more than 20 percent of the flow can be withdrawn).
- Pumping may occur to a maximum lake water level of 724.5 ft. (220.83 m) NAVD 88.
- Pumping must not occur from April 1st through June 30th of any year.
- The four-pump pumping station must not exceed a capacity of 100 cfs (2.83 m^3/s).

Outflows from the Belews Lake include primarily withdrawal for the nuclear plant and BCSS, normal spillway operation releases, and flood releases during high flow events. Scenarios are run with and without BCSS in operation. BCSS water demand in scenarios where BCSS is operating is set to the maximum plant usage of 2,257 cfs (1,013,200 gpm, 63.91 m^3/s).

Locations of intake and discharge points are presented in Figure 2.4-46. As there are multiple potential discharge locations, a bounding scenario is analyzed. Common discharge structure is the closest discharge location to the dam spillway and the farthest away from the intake.

Analyses using future plant intake and discharges use common discharge structure and the intake as the two points. This assumption is conservative because it would maximize the residence time of the heated discharge into the lake and thus maximize any related evaporation.

2.4.11.1.1.2 Lake Storage

To evaluate the surface water availability for the site non-safety-related SSCs, the depletion rate of the lake storage below the normal operating pool level was estimated using the stage-storage rating curve for Belews Lake (Table 2.4-30) in conjunction with conservative assumptions about the expected water demands and reservoir inflows and outflows. The scenario selected for evaluation is an extended period of severe drought when inflow to the lake is limited, but all existing users continue their withdrawals.

Since the creation of Belews Lake, sediment has settled at the bottom of the lake, affecting its bathymetry. Based on review of recent lake bathymetry survey against after lake construction bathymetry survey, it is conservatively assumed that, for current scenarios, the bottom 30 ft. (9.1 m) of the lake is filled. This reduces the storage volume of the lake by 1939 ac-ft (240 ha-m). For analysis of long-term scenarios, it is assumed the lakebed continues to experience sedimentation. An additional 10 ft. (3.0 m) is assumed to be filled for future long-term scenarios, equating to an additional 2995 ac-ft (370 ha-m) of volume being removed from the overall lake. This is based on the conservative sedimentation rate of 0.52 ac-ft per mi^2 (3.81 ha-m per km^2) per year (Reference 2.4-31), where the Belews Lake influence area is approximately 70 mi^2 (181 km^2) and the future operation period is 80 years.

2.4.11.1.1.3 Belews Lake Water Level

Belews Lake water levels were analyzed through two different periods: a period of extreme drought years and a period of typical years. The extreme drought period is reflective of 2001 – 2002, which saw the lowest lake levels out of the available 27 years of data.

In total, eight individual scenarios were analyzed using a dynamic water balance model built using the LakeT modeling program (developed by Sargent & Lundy). These analyses reflect four different cases in two different time periods (extreme drought and typical years).

- Extreme drought years (Figure 2.4-47)
  - Case 1: Baseline 1 (BCSS 100 percent, nuclear plant zero percent)
  - Case 2: Baseline 2 (BCSS zero percent, nuclear plant zero percent)
  - Case 3: Near-Term Operation (BCSS zero percent, nuclear plant 100 percent)
  - Case 4: Long-Term Operation (includes predictions for long-term future weather conditions and lake sedimentation, see below) (BCSS zero percent, nuclear plant 100 percent)
- Typical years (Figure 2.4-48)
  - Case 1: Baseline 1 (BCSS 100 percent, nuclear plant zero percent)

- Case 2: Baseline 2 (BCSS zero percent, nuclear plant zero percent)
- Case 3: Near-Term Operation (BCSS zero percent, nuclear plant 100 percent)
- Case 4: Long-Term Operation (includes predictions for long-term future weather conditions and lake sedimentation, see below) (BCSS zero percent, nuclear plant 100 percent)

Table 2.4-29 summarizes the primary differences between each of the four cases and the benchmarked models, with further explanation provided in this section. Predictions for long-term future weather conditions used in the Long-Term Operation case, modeled to the end of the century, show that future temperatures will be 8 °F (4.4 °C) higher, and future precipitation patterns will be 1 percent drier.

Baseline 2 (BCSS zero percent, Advanced Reactor zero percent) models a future lake, beyond advanced reactor operation, where there is no plant operation. As this is a future scenario, future weather conditions are used.

Analysis results for the four cases in typical years are presented in Figure 2.4-48. As shown, the lake level in a typical period follows the same general trend in all plant operation cases and oscillates between the pump trigger point and pump stopping point. Analysis results for the four cases in extreme drought years are presented in Figure 2.4-47. In an extreme drought period, the lake level is able to recover within the time period analyzed in the case with BCSS operation only (Case 1), but not in the cases including nuclear plant operation (Cases 3 and 4).

Differences between the Near-Term Operation models and the Long-Term Operation models are due to global climate change and future sedimentation in the lakebed. Compared to the Near-Term Operation results (Case 3), the Long-Term Operation (Case 4) results show minimal difference in the lowest lake elevation during a typical period (721.64 ft. [219.96 m] vs. 721.31 ft. [219.86 m], see Figure 2.4-48). However, during extreme drought years under future conditions, there is an additional drop of approximately 1.12 ft. in lake level (715.30 ft. [218.02 m] vs. 714.18 ft. [217.68 m], see Figure 2.4-47).

Comparing the lake level with the nuclear plant in operation (Case 3) to with the BCSS only (Case 1) in operation (reflecting current conditions), nuclear plant operation results in an additional approximate 4.4 ft. (1.3 m) drop in lake level during an extreme drought period (719.68 ft. [219.36 m] with BCSS vs. 715.30 ft. [218.02 m] with the nuclear plant, see Figure 2.4-47). In typical years the difference is less than 1 ft. [0.30 m] (722.21 ft. [220.13 m] with the BCSS vs. 721.64 ft. [219.96 m] with the nuclear plant, see Figure 2.4-48).

Additional analyses were performed to determine lake level trends with different pumping capacity. In the nuclear plant operation cases (Cases 3 and 4), the lake level difference is small between the four-pump and two-pump operation scenarios. In the extreme drought period, the difference in minimum lake level is less than 1 ft. (0.30 m) in the worst (Long-Term Operation) case (714.18 ft. [217.68 m] [four-pump] vs. 713.29 ft. [217.41 m] [two-pump]), whereas the lake level in the typical period recovers fully in both scenarios, with the two-pump operation taking slightly longer to reach the pump stopping point.

2.4.11.2 Low Water Resulting from Surges, Seiches, or Tsunamis

There is no safety impact on the Project site due to low water conditions generated by any mechanism because it does not rely on the Belews Lake or Dan River for its safety-related water use. The non-safety-related water supply is also not expected to be affected normally by low water conditions resulting from surges, seiches, tsunamis or other external events. As detailed in Section 2.4.5, there are no conceivable meteorological conditions that would produce a surge or seiche that would reach the Project site grade. It follows that the risk of any surge or seiche event that would cause significant low water concerns is low. Tsunamis are not considered a risk because there are no potential tsunamigenic sources that could affect the site, as indicated in Section 2.4.6.

Based on the evaluation in Section 2.4.7, low water conditions resulting from ice formation or accumulations could cause interruption of flow in Belews Lake under extreme conditions. However, no safety-related or risk-significant SSCs at the site would be impacted.

Similarly, the unlikely failures of the Belews Lake Dam would potentially create a low water condition at the site, but there would be no safety-related or risk-significant impacts.

2.4.11.3 Historical Belews Lake Low Water

Review of historical lake level recordings from 1996 to 2024 indicates that the drought of 2001 – 2002 was one of the worst in recorded Belews Lake history. The other drought of significance was that of 2007 – 2008. Lake water level was reduced to 717.21 ft. NAVD 88 (218.61 m) and 720.7 ft. NAVD 88 (219.67 m) for the 2001 – 2002 and 2007 – 2008 droughts, respectively. Water level variations for these two extreme years are presented in Figures 2.4-49 and 2.4-50.

2.4.11.4 Future Controls

The Project site does not rely upon Belews Lake or the Dan River for safety-related water use and, therefore, there would not be any safety impact as a result of future uses or controls in the lake. For non-safety-related water use, the storage capacity of Belews Lake is adequate to sustain the continuous supply of surface water to meet the needs of the site throughout a drought event equivalent to the drought of record, as discussed in Section 2.4.11.1. Any future water uses of Belews Lake would be controlled by Duke Energy, as the owner and operator, and any future agreements with water users would need to account for Project site water supply requirements. Thus, any future uses of Belews Lake are not expected to affect the water use at the Project site.

2.4.11.5 Plant Requirements

The capability of Belews Lake to maintain a sufficient water level during periods of drought is described in Section 2.4.11.1. The operating pool level at Belews Lake is monitored and maintained at a normal minimum at 724.7 ft. NAVD 88 (220.89 m) (for the winter season). As needed, reservoir operation management measures would be employed to ensure that sufficient water level is maintained in the lake to allow the Project site intake structure to operate.

2.4.11.6 Heat Sink Dependability Requirement

No technologies considered in this application rely on the Belews Lake or Dan River for UHS.

2.4.12 GROUNDWATER

This section was prepared to meet the requirements of NUREG-0800, Section 2.4.12 (Groundwater), and describes the hydrogeologic conditions near the Project site, and the effects of construction and operation of advanced reactors, including advanced reactors, on regional and local groundwater resources. It also summarizes the regional data for the physical and hydrologic characterization of these groundwater resources to evaluate effects on the aquifers of the area.

Regional and local surface water features are described in Section 2.4.1. A geologic overview is presented in Section 2.5.1, and a geotechnical description for plant construction is presented in Section 2.5.4. Note that elevations discussed in this section correspond with NAVD 88. In some cases, cited references may use a different datum.

2.4.12.1 Hydrogeologic Setting

This section describes regional physiography, geology, hydrogeology, groundwater sources and sinks, and sole-source aquifers.

2.4.12.1.1 Physiography and Geomorphology

The Project site is shown in Figure 2.4-51. It is located in southeast Stokes County and in a small portion of northern Forsyth County to the south. Rockingham County lies just to the east, and Guilford County is southeast. The Project site is located adjacent to the existing BCSS. It is 14 mi. (23 km) northeast of Winston-Salem, NC, and 19 mi. (31 km) northwest of Greensboro, NC. This Project site investigation focuses on three separate areas located on a southwest-northeast-trending peninsula that extends into the southwestern portion of Belews Lake. The three areas are referred to as the North Plant Complex, the Middle Plant Complex, and the South Plant Complex and are shown in Figure 2.4-51.

The Project site is in the Piedmont physiographic province, approximately 40 mi. (64 km) east of the Blue Ridge physiographic province (Figure 2.4-52) (Reference 2.4-54). The Piedmont physiographic province extends from Alabama to southern New York (approximately 1000 mi. [1600 km]) and is composed primarily of weathered metamorphic and igneous rocks. Metamorphic rocks include mostly schist and gneiss; igneous rocks are predominantly slightly metamorphosed granite. Structural basins (resulting from faulting) are filled with Mesozoic sediments (Reference 2.4-55).

The Blue Ridge physiographic province extends from Pennsylvania southwest to Georgia, and includes highly deformed metamorphic rocks, mostly Precambrian in age. The primary rock types are schist, gneiss, slate, and quartzite with numerous igneous intrusions (Reference 2.4-56).

The topography along the Project site peninsula is characterized by gently rolling hills and uplands dissected by steep-sided tributary valleys. A maximum elevation of more than 870 ft. (265 m) occurs in interbasinal areas, while the lowest elevations occur along the shoreline of Belews Lake at a typical elevation of 725 ft. (221 m). Prior to inundation, the peninsula was

bound by West Belews Creek to the north and Belews Creek to the south. The bottom elevation of these tributary valleys adjacent to the peninsula that are now flooded by Belews Lake is approximately 620 ft. (189 m), approximately 100 ft. (30 m) below current lake levels (Reference 2.4-57). Land use along the peninsula is predominately woodlands with industrial facilities, including landfills and basins associated with BCSS operations.

2.4.12.1.2 Regional Hydrology

The Project site drains locally into Belews Lake. Overflow from Belews Lake flows into Belews Creek and the Dan River. The Dan River originates along the eastern slopes of the Blue Ridge Mountains in Patrick County, Virginia, and flows east until emptying to the Roanoke River at the John H. Kerr Reservoir, near Clarksville, Virginia (Reference 2.4-58). The Roanoke River eventually drains into the Albemarle Sound of NC (Reference 2.4-59). Surface water bodies located within the Project Vicinity are depicted in Figure 2.4-53; these include the Dan River, Belews Creek, Belews Lake, and Town Fork Creek (Reference 2.4-60). The Dan River is the primary river in Stokes County, and it flows from southwest to northeast across the southeast portion of the county. Belews Lake flows into the Dan River via Belews Creek, just downstream of Belews Lake Dam in Rockingham County. Duke Energy created Belews Lake in 1973 as a cooling basin for the BCSS. The lake has a surface area of 3864 acres (1564 hectares) and reaches a maximum depth of 144 ft. (44 m) deep in the vicinity of the dam (Reference 2.4-61). Belews Lake has a supplemental pumping station that provides water from the Dan River during periods of low lake levels to maintain an operational level of water. During the life of the BCSS, pumping has been carried out four times: in 2002, 2008, 2009, and 2010 (Reference 2.4-62).

Additional discussion on hydrologic features on and near the Project site, surface water supply, and surface water users in the Project Vicinity is provided in Section 2.4.1.

2.4.12.1.3 Regional Geology

Three lithologic-tectonic belts or terranes are mapped within the Project Vicinity: the Milton Belt, Dan River basin, and the Sauratown Mountain Anticline. These features are shown in Figure 2.4-54 (Reference 2.4-63; Reference 2.4-64). The Project site is located within the Milton terrane, which is composed of late Precambrian massive to strongly foliated biotite gneiss and schist, amphibolite, felsic gneiss, and late Paleozoic granite intrusions. The rocks are metamorphosed to amphibolite facies and folded into shallowly plunging recumbent folds (Reference 2.4-65; Reference 2.4-66).

Figure 2.4-55 shows the geology of the Project Vicinity. Four main geologic formations are mapped beneath and adjacent to the Project site (Reference 2.4-63; Reference 2.4-67; Reference 2.4-68), including:

- CZbg - Biotite Gneiss and Schist (520 – 650 million years [my]) - highly metamorphosed and foliated biotite gneiss and schist underlie the Project site and are described as dark colored, medium to coarse grained to porphyroblastic, locally contains hornblende and is chiefly composed of biotite, quartz, potassium feldspar, muscovite, and hornblende. The CZbg formation is interlayered with mica schist and amphibolite and is locally intruded by pegmatite dikes.

- CZfg - Felsic Mica Gneiss (520 – 650 my) - interlayered biotite hornblende gneiss with graphitic mica schist and mica-garnet schist, commonly with kyanite. Underlies the northwest side of Belews Lake.

- PPg - Porphyritic Granite (265 – 325 my) - light gray, medium- to coarse-grained porphyritic granite, granodiorite, and quartz monzonite. Composed of microcline phenocrysts up to 5 inches (in.) (13 centimeters [cm]) in diameter in a matrix of quartz, oligoclase, and biotite. Underlies the area southwest and southeast of the Project site.

- Jd - Diabase Dike (265 – 325 my) - black to greenish dark gray, fine- to medium-grained, dense rock composed of plagioclase, augite, and olivine. Occur as dikes up to 200 ft. (61 m) wide and typically occur as spheroidal weathered boulders with a grayish-brown weathering rind. Diabase dikes typically trend northwest and north and are mapped east of the Project site.

Sedimentary rocks of the Triassic Dan River basin occur northwest of the Milton terrane and trend northeast toward Danville, Virginia. The Chatham Fault Zone separates the Triassic rocks from the metamorphic rocks of the Sauratown Mountain anticlinorium farther to the north and the Milton terrane to the south. The Pinehall Formation, Cow Branch Formation, and Stoneville Formations are mapped within the Triassic-age Dan River basin.

The Sauratown Mountain anticlinorium lies northwest of the Dan River basin. Four stacked thrust sheets or units of Middle Proterozoic basement rocks within the Sauratown Mountain anticlinorium have been pushed one on top of the other through the mountain-building processes that formed the Appalachian Mountains. The thrust sheets include the Forbush gneiss, Miller Creek Complex, Pilot Mountain gneiss, Grassy Creek gneiss, and Volunteer gneiss (Reference 2.4-69).

2.4.12.1.4 Regional Hydrogeology

Figure 2.4-56 shows the principal components of a typical groundwater system in the Piedmont province. The Piedmont groundwater system is characterized by a variably saturated sequence of interconnected and transitional strata (topsoil, residuum, saprolite, and partially weathered rock [PWR]) formed from in-situ weathering of the underlying bedrock parent material. These overlie metamorphic and igneous crystalline bedrock (Reference 2.4-70; Reference 2.4-71). Unconsolidated strata above PWR that primarily function as a porous media aquifer are called overburden (OB). In the boring logs, saprolite is not distinguished; all unconsolidated residual soil is identified as residuum. PWR marks the transition between residuum and unweathered bedrock and can behave as both a porous and fractured rock medium. PWR is designated as a separate hydrogeologic unit, as is fractured bedrock.

Residuum formed from felsic rock types common to the Milton terrane can produce a sandy soil texture. Quartz and muscovite, both common minerals in felsic gneiss and schists, are highly resistant to chemical weathering and remain in the residuum, giving it a sandy texture. Other common minerals such as feldspar, biotite, and amphibole, weather more readily to form silt-sized particles and hydrated clays. Residuum is generally thickest in upland areas and is thin to absent on steeper slopes adjacent to drainage basins (Reference 2.4-70; Reference 2.4-71). As residuum grades downward into PWR, both porous- and fracture-medium characteristics may exist because some of the textural features of the bedrock, including stratigraphic layering,

foliation, and fractures, are retained. With this grading, the degree of weathering decreases with depth (Reference 2.4-72; Reference 2.4-73).

2.4.12.1.5 Groundwater Sources, Sinks, and Recharge

Groundwater is present in the OB and PWR under unconfined or water table conditions and flows in much the same way that surface water runoff flows from topographically high areas to low areas. Groundwater generally travels short distances, discharging to nearby streams, springs, or surface water bodies such as Belews Lake. A portion of the groundwater in the OB flows vertically downward, recharging the underlying bedrock aquifer. In the underlying crystalline bedrock, groundwater is stored and subsequently flows within bedrock fractures. Flow is controlled by the frequency, orientation, and interconnectivity of these fractures, but for the most part, groundwater moves from surface water divides (recharge areas), toward areas of discharge at springs, tributary streams, and rivers or lakes.

Recharge from infiltrating rainfall continually replenishes groundwater. Most of the rainfall returns to the atmosphere by evaporation and transpiration from plants or flows overland to nearby streams. The remainder recharges underlying groundwater aquifers. The amount of water that recharges a groundwater system can be estimated by examining stream flow hydrographs and separating out the contribution from groundwater, called baseflow. It is assumed that over long periods of time, groundwater discharge in a basin in the form of stream baseflow equals groundwater recharge. Baseflow measurements and groundwater recharge estimates from various U.S. Geological Survey (USGS) stream-flow monitoring stations within the Dan River subbasin and in the Project Vicinity indicate an effective average groundwater recharge rate of 8.45 inches per year (in/yr) (21.5 centimeters per year [cm/yr]), or 630 gallons (2385 liters) per day per acre (Reference 2.4-74). Infiltrating groundwater is stored in the underlying residuum, PWR, and bedrock and flows through this aquifer material to eventually discharge to local and regional surface water bodies (Reference 2.4-70).

2.4.12.1.6 Sole-Source Aquifers

The USEPA data confirm no sole-source aquifers in the Project Vicinity. A sole-source aquifer is defined as the sole or principal source of drinking water that supplies 50 percent or more of drinking water for an area, with no reasonably available alternative source should the aquifer become contaminated. Figure 2.4-57 shows the location of sole-source aquifers in the eastern United States (Reference 2.4-75). There are no sole-source aquifers in NC at this time. In Virginia, the most prominent sole-source aquifer is the Columbia and Yorktown-Eastover Multi-aquifer System, which is located east of Chesapeake Bay and supplies drinking water to Accomack and Northampton counties in Maryland. In Maryland, the Piedmont Sole-Source Aquifer supplies drinking water to Montgomery, Howard, and Carroll counties.

2.4.12.2 Site-Specific Hydrogeology

Subsurface information was collected at three Plant Complexes from a total of 15 primary geotechnical borings plus additional offsets (nine of which were subject to geophysical testing), 33 well lithologic borings, 15 shallow monitoring wells, 12 deep monitoring wells, three aquifer pumping test (APT) wells, and 16 sentinel wells. Section 2.5.4 provides a detailed description of the geotechnical investigation, including the locations of borings, logs, and soil testing data. A summary of the field investigation activities related to groundwater characterization is presented below.

- Hydrogeologic cross sections were prepared using lithologic data from the geotechnical and well lithologic borings and groundwater data from monitoring wells. Stratigraphic layers and well screen placements depicted on the cross sections were determined based on field classification of OB, PWR, and bedrock using lithologic observations, Standard Penetration Test (SPT) N-values, and drilling characteristics. Section 2.4.12.2.1 describes development of hydrogeologic cross sections.

- Borehole geophysical logs: Acoustic televiewer (ATV) was completed at boring locations B-1, B-3, B-5, B-6, B-8, B-10, B-11, B-13, and B-15 and/or associated offsets to identify and characterize the orientation, density, and water-producing characteristics of bedrock fractures (Figure 2.4-58 provides boring locations). Fracture fabrics measured by the ATV logs were compared to mapped topographic lineament orientations to provide a better understanding of potential fracture-control and influences on groundwater flow at the Project site. Section 2.4.12.2.2 describes the results of the bedrock fracture fabric analysis, and Section 2.4.12.2.3 summarizes the results of the remote-sensing lineament analysis.

- Groundwater monitoring wells: Twenty-seven groundwater monitoring wells were installed at the three Plant Complexes. Fifteen of the monitoring wells (five at each complex; W-1 through W-15) are shallow wells designed to be screened across or near the water table. Twelve of the monitoring wells (four at each complex; DW-1 through DW-12) are deep monitoring wells screened at various depths within the crystalline bedrock (Figure 2.4-58 depicts well locations). The shallow monitoring wells have total depths ranging from 36 to 99 ft. (11 to 30 m); deep monitoring wells range from 135 to 198 ft. (41.1 to 60.4 m) in depth. Because the water table occurs at various stratigraphic depths across the Project site, shallow wells are screened partially in OB, PWR, and SBR, or a combination of these units. The deep monitoring wells are all screened in DBR. The wells were completed to various depths to provide adequate spatial distribution for determining horizontal and vertical groundwater flow directions and hydraulic gradients based on the encountered groundwater conditions. Sections 2.4.12.2.4, 2.4.12.2.5, and 2.4.12.2.6 describe groundwater flow directions, hydraulic gradients, and temporal groundwater level trends, respectively.

- Slug tests: Single-well field hydraulic conductivity tests (slug tests) were conducted in each of the 27 monitoring wells. Section 2.4.12.3.1 describes the results of the slug tests.

- Packer testing: Five packer tests were performed at three different boring locations. Packer test intervals were selected to target prominent fractures identified from the ATV logs. Section 2.4.12.3.2 describes results of the packer tests.

- APTs: Three APT well clusters were installed (one at each complex). Each cluster consists of one pumping well and several water level sentinel wells. Well clusters were installed in various aquifer depth zones including PWR (PW-2; Middle Plant Complex), the upper crystalline bedrock (PW-1; North Plant Complex), and the deep crystalline bedrock (PW-3; South Plant Complex) at total depths of 72.3 ft. (22.0 m), 90.3 ft.

(27.5 m), and 155.3 ft. (47.3 m), respectively. Section 2.4.12.3.3 describes the APTs. Figure 2.4-58 shows the APT well cluster locations.

Well installations described in this report began in May 2024 and were completed in September 2024. Figure 2.4-58 presents a map of all pumping wells, monitoring wells, sentinel wells, and borings, and Table 2.4-31 presents well construction details. The monitoring wells are segregated into four series based on well depth and well function as follows:

- "W" identifies shallow groundwater monitoring wells. W-1 through W-5 were installed at the North Plant Complex; W-6 through W-10 were installed at the Middle Plant Complex; and W-11 through W-15 were installed at the South Plant Complex. Due to significant topographic and hydrogeologic depth/elevation variability across the three Plant Complexes (including significant variability in depth to water table), the shallow wells were installed in multiple stratigraphic zones, including OB, PWR, and crystalline bedrock.

- "DW" identifies deep groundwater monitoring wells installed within the deeper portions of the crystalline bedrock. DW-1 through DW-4 were installed at the North Plant Complex; DW-5 through DW-8 were installed at the Middle Plant Complex; and DW-9 through DW-12 were installed at the South Plant Complex.

- "PW" identifies pumping wells associated with the three APTs. PW-1 (North Plant Complex) is screened in the shallow bedrock (SBR); PW-2 (Middle Plant Complex) is screened in the PWR; and PW-3 (South Plant Complex) is screened in the deep bedrock (DBR).

- "S" identifies sentinel wells. These wells serve as water level monitoring wells during APTs. Sentinel wells include wells screened in PWR and various depths within the crystalline bedrock.

The hydrogeologic investigation targeted water-bearing strata in the OB, PWR, and crystalline bedrock to characterize hydrogeologic conditions within the upper 200 ft. (61.0 m) below ground surface (bgs), nearly twice the depth of the maximum foundation embedment depth of 125 ft. (38.1 m) of the proposed reactor technologies.

2.4.12.2.1 Hydrogeologic Cross Sections

Hydrogeologic cross sections were prepared using lithologic data from the geotechnical and well lithologic borings, fracture data from the ATV logs, and groundwater data from monitoring wells. Surface profiles were generated using topographic data that included processed USGS LiDAR data. Hydrogeologic layers and well screen placements depicted on the cross sections were determined based on field classification of OB, PWR, and bedrock using lithologic observations, SPT N-values, and drilling characteristics. PWR is defined as residual material with SPT N-values exceeding 100 blows per ft. Top of bedrock is primarily determined from the rate of drilling penetration and other drilling characteristics such as the behavior of the drill rig upon approaching the top of bedrock. Figures 2.4-59 through 2.4-66 present the cross section location map and seven cross sections through the complexes (A-A′, B-B′, C-C′, D-D′, E-E′, F-F′, and G-G′).

Combined OB and PWR (depth to bedrock) thickness from wells and borings range from 14 to 86 ft. (4.3 to 26 m) thick and average 48 ft. (15 m). PWR thickness averages 13 ft. (4.0 m) and OB thickness averages 36 ft. (11 m). PWR is thickest across the northern and eastern portions of the North Plant Complex and is uniformly moderately thin at most other locations. OB is uniformly thick across all three Plant Complexes except in topographically low areas where it thins, likely due to erosion from incised streams. The top of bedrock surface is generally a subdued reflection of the land surface.

The OB consists of mostly moist, silty sand with lesser amounts of clays and sandy silt. Clay layers are more common within the soil profile in the upper 5 ft. (2 m). Trace amounts of gravel-sized rock fragments are commonly observed. PWR consists of silty sand with gravel. The relic rock structure of the parent rock material is commonly associated with PWR. Most of the crystalline bedrock encountered is gneiss and schist, with lesser amounts of granofels.

The water table generally occurs within the OB/PWR and upper 10 to 20 ft. (3.0 to 6.1 m) of the bedrock. In DBR wells, the potentiometric head rises substantially above the screen interval but generally remains within the fractured bedrock aquifer. Groundwater levels in DBR wells are typically at lower elevations than static groundwater elevations in nearby shallow wells, indicating that downward vertical hydraulic gradients prevail in the upland recharge areas of the peninsula.

2.4.12.2.2 Bedrock Fracture Fabric Analysis

An analysis of bedrock fracture fabrics was performed by reviewing the fracture data identified on ATV logs for boring locations B-1, B-3, B-5, B-6, B-8, B-10, B-11, B-13, and B-15 and/or associated offsets (Reference 2.4-76). Fracture density, orientation, and openness were evaluated from the 1,782 total ft. (543.1 m) of ATV logs from the nine borings. Fracture density is qualitatively assessed by observing fracture density in the ATV logs and quantified by calculating the number of fractures divided by the total length of core in each boring. Fracture density is presented in Table 2.4-32 as the identified number of fractures per 100 ft. (30.5 m) of core. The average fracture density for all the borings is 65 fractures per 100 ft. (30.5 m). Borings that intersect a relatively low density of fractures (i.e., 22 to 44 fractures per 100 ft. [30.5 m]) compared with the average fracture density include B-5, B-11, B-13, and B-15. Borings with a high density of fractures (i.e., 65 to 83 fractures per 100 ft. [30.5 m]) include B-1, B-3, B-6, B-8, and B-10.

Figure 2.4-67 shows fracture density and fracture aperture opening width with depth based on the ATV data. Fracture density with depth is keyed to boring depth: six borings are completed to 200 ft. (61.0 m), two borings are completed to 300 ft. (91.4 m), and one boring is completed to 600 ft. (183 m) bgs. Data from the borings drilled to 200 and 300 ft. (61.0 and 91.4 m) appear to indicate a higher fracture density from 60 to 180 ft. (18 to 54.9 m) bgs. Data from the 600 ft. (183 m) boring indicates increases in fracture density between 240 to 250 ft. (73.2 to 76.2 m) bgs and 470 to 530 ft. (143 to 162 m) bgs.

More than 1,150 fractures were identified in the ATV logs. Nearly all (more than 97 percent) of the identified fractures are described as filled or closed with no identified aperture opening. Less than 3 percent (31) of the fractures are identified as open or have open aperture values. Aperture widths range from 0.2 to 6.8 in. (5 to 172 mm), average 1.3 in. (32 mm), and have a median value of 0.9 in. (23 mm). Fractures with open apertures were only recorded in the upper 250 ft. (76.2 m) bgs, as illustrated on Figure 2.4-67. Open fractures identified from the ATV are shown on the hydrogeologic cross-sections.

The dominant fracture orientation identified in the ATV logs strike nearly east-west and dip at low angles toward the south. These sub-horizontal fractures are likely associated with mineralogical and lithological layering in the gneissic and schistose bedrock. Other fracture sets strike northwest and east-west and dip steeply toward the northeast, north, and southwest. These fractures are likely associated with subvertical joints that form perpendicular and oblique to regional geologic strike. The two fractures with the largest open apertures (identified in B-1 at 85 ft. [26 m] bgs and B-8 at 242 ft. [73.8 m] bgs) are sub-horizontal with shallow dips to the southeast and southwest, respectively (Reference 2.4-76).

Because groundwater is stored and transmitted along secondary fracture openings in bedrock aquifers, the density, orientation, and openness of these fractures help determine aquifer properties such as transmissivity (T), hydraulic conductivity (K), storage coefficient (S), yield capacity, fracture interconnectivity, and groundwater flow directions. Most fractures at the Project site are filled or closed or were likely identified by lithologic or mineralogical contrasts in the layering within the rock and are not necessarily fractures capable of conveying groundwater.

Project site data indicates that bedrock is mostly massive with low values of K, T, and S. Because most of the open transmissive fractures are sub-horizontal and occur within the upper 300 ft. (91.4 m), it is assumed that most groundwater flow and storage within the bedrock aquifer is moderately shallow and may be compartmentalized or confined provided there is not sufficient flow and interconnectivity within the bedrock fracture systems. Most groundwater flow likely occurs in the limited number of larger open fractures, which are more likely to be interconnected with regional fracture networks that discharge to available surface water bodies.

2.4.12.2.3 Remote-Sensing Lineament Analysis

Subsurface geologic features such as mineral segregations due to gneissic banding, fracture zones, geologic contacts, jointing, and faults often have ground surface expressions that can be detected through surficial or aerial remote-sensing analysis of photographic and topographic images. Fracture zones or lineaments are important hydrogeologic features because they represent potential areas of increased, localized fracture concentrations.

Fracture zones commonly have enhanced porosity and permeability and therefore represent important pathways for groundwater flow in bedrock. Because fracture zones are typically less resistant to weathering, they are often expressed as natural topographic lows, such as straight stream valley segments, swales, aligned depressions and gaps in ridges, or as linear tonal or vegetative alignments due to variations in soil thickness and moisture. These surface manifestations are referred to as fracture traces or lineaments and were identified for this project by remote-sensing techniques using topographic maps and shaded relief maps produced from digital elevation models (Reference 2.4-77).

A total of 1,408 lineaments were identified within the Project Vicinity and are shown on Figure 2.4-68. Mapped lineaments primarily correspond with tributary stream valleys and other linear topographic depressions. The lineament data were analyzed to display the dominant orientations of the lineaments. The prominent lineament orientations are centered on N30 – 40°W, N20 – 30°E, and N60 – 70°E. Lineament orientations are generally parallel or perpendicular to regional geologic strike (Reference 2.4-69; Reference 2.4-67). Variations are likely caused by changes in local geologic strike and the formation of conjugate fractures at small angles to the principal direction of stress.

The coincidence of the lineaments with known geologic structures and processes suggests that most of the mapped lineaments represent underlying fractures zones that may contribute to groundwater flow within the fractured bedrock aquifer. Lineaments oriented parallel to strike may result from less-resistant interlayered pelitic schist units and therefore may not represent preferential groundwater flow pathways. Across-strike (northwest-trending) lineaments are more likely to represent preferred flow pathways due to their kinematic formation (Reference 2.4-78).

2.4.12.2.4 Groundwater Flow Directions

Historical groundwater level data were evaluated from two nearby BCSS sites; the Craig Road Landfill and the Flue Gas Desulfurization (FGD) landfill. The Craig Road landfill is located approximately 500 ft. (152 m) west of the South Plant Complex. Groundwater flow during the July 2024 sampling event was generally west/northwest, partially radial from areas of high topographic elevation to low, toward Belews Lake. In the deep zone, there was an easterly component to groundwater flow in the eastern portion of the site, downhill, toward an unnamed stream that drains to the canal and Belews Lake. These flow directions are consistent with previous events dating back to 2016 (Reference 2.4-79).

The FGD landfill is located approximately 200 ft. (61.0 m) north of the Middle Plant Complex. Groundwater flow in both the shallow and deep zone during the November 2023 sampling event was generally west/northwest, from areas of high topographic elevation to low, toward Belews Lake. These flow directions are consistent with previous events dating back to 2016 (Reference 2.4-80).

Between May and September 2024, 27 groundwater monitoring wells were installed at the Project site. W-1 through W-15 are shallow monitoring wells screened at or just below the water table. DW-1 through DW-12 are deep monitoring wells screened at various depths within the crystalline bedrock. Five shallow wells and four deep wells were installed at each complex. A well and boring location map is presented as Figure 2.4-58; well construction details are provided in Table 2.4-31. The monitoring wells are used for water level monitoring and slug testing. Groundwater depth measurements were collected monthly for the 12-month period between July 15, 2024, and June 24, 2025, and converted to groundwater elevations after completion of as-built surveying. Groundwater elevation data are presented in Table 2.4-33.

Potentiometric surface maps were prepared that depict groundwater elevations and groundwater flow directions for the shallow and deep monitoring well zones. Depending on variability in site-specific depths to first groundwater, the shallow wells were screened within the unconsolidated OB, PWR, and SBR, or some combination of these units. Deep wells were screened at various depths within the DBR. Bedrock monitoring wells were selected, when possible, to screen more highly fractured intervals.

Figure 2.4-69 (Sheets 1 through 24) presents potentiometric surface maps constructed from water elevation data collected from the shallow and deep monitoring wells on a monthly basis between July 2024 and June 2025. In some cases, water levels did not return to static conditions until several weeks or months following the completion of well development or following a sampling event; these data are included in Table 2.4-33 but were not used for contouring potentiometric surfaces. This condition was observed at monitoring wells W-2, W-3, W-9, DW-3, DW-8, DW-10, DW-11, and DW-12.

The groundwater elevation in DW-8 is an extreme illustration of groundwater levels that likely have still not reached natural equilibrium in the monitoring well. Groundwater elevations gradually increased from approximately 665 to 677 ft. NAVD 88 (203 to 206 m) between September 2024 and June 2025 but remain at least 65 ft. (20 m) lower than other Middle Plant Complex deep monitoring well groundwater elevations. It is assumed that this well was screened within an extremely tight (low-yielding) portion of the crystalline bedrock, which accounts for the extended recovery period.

Groundwater flow direction among both shallow and deep potentiometric surfaces generally follows topography, with flow directions from areas of higher topographic elevations to lower elevations. At the South Plant Complex, groundwater flow is bilinear and radial, toward the northwest, northeast, and southeast toward Belews Lake and the cut-through channel/canal. At the Middle Plant Complex, groundwater flows mostly toward the west and southwest due to influence from the cut-through channel/canal, and in part, to more limited water level data. At the North Plant Complex, near the tip of the peninsula, flow is radial toward the northwest, north, and northeast because Belews Lake surrounds the area on these three sides. Groundwater elevations decrease from the South Plant Complex to the North Plant Complex as proximity to the lake (discharge sink) decreases. This results in a deeper depth to the water table at the North Plant Complex compared with the other two complexes.

2.4.12.2.5 Hydraulic Gradients

Potentiometric surface maps are used to estimate horizontal hydraulic gradients (i_h) at the Project site. For each map, i_h are calculated by drawing a flow line on the potentiometric surface map perpendicular to the contours and determining the difference in hydraulic head (Δh) between isocontour lines (upgradient and downgradient) over the horizontal projection of the flow path length (L) ($i_h = \Delta h/L$). These calculations are summarized in Table 2.4-34 and are presented on the respective potentiometric surface map for each event.

The shallow zone potentiometric map surfaces indicate i_h values range from 5.0×10^{-3} feet per foot (ft/ft) on August 19, 2024, at the North Plant Complex to 9.2×10^{-2} ft/ft on calculated for September 24, 2024, October 11, 2024, and January 8, 2025, at the South Plant Complex, with an overall average value of 3.8×10^{-2} ft/ft. The deep zone potentiometric map surfaces indicate i_h values range from 6.4×10^{-4} ft/ft (April 25, 2025, at the Middle Plant Complex) to 4.4×10^{-2} ft/ft (November 18, 2024, at the North Plant Complex), with an overall average value of 2.7×10^{-2} ft/ft.

Typically, the vertical hydraulic gradient (i_v) is calculated by comparing differences in water level elevations and screened interval depths from nested monitoring wells (i.e., co-located wells screened in different aquifers or aquifer zones). However, at this Project site, the shallow and deep monitoring wells are not co-located; therefore, i_v were modeled using interpolated potentiometric surfaces from the two zones (shallow and deep) and the mid-point of well screen elevation surfaces.

Figure 2.4-70 presents the modeled i_v values for February 7, 2025, because this is the first event with sufficient groundwater elevation data to generate potentiometric surfaces for all three Plant Complexes for both the shallow and deep zones. Modeled i_v results from all monthly water level monitoring events are summarized in Table 2.4-35.

Aquifer systems typically have a downward vertical gradient in groundwater recharge areas that transition to upward vertical gradients in groundwater discharge areas. Vertical gradients measuring greater than zero have a downward flow potential; vertical gradients less than zero have an upward flow potential. Vertical gradients equal to zero are considered flat (i.e., no upward or downward flow potential).

Based on the monthly water level data from the Project site, the following vertical gradient trends were observed:

- All but two vertical gradient calculations demonstrated downward vertical hydraulic gradients (i.e., had positive gradient values).
- Two vertical gradient calculations had upward vertical hydraulic gradients (i.e., had negative gradient values).
- Modeled i_v values ranged from -4.1×10^{-2} ft/ft to 0.64 ft/ft.
- The average modeled i_v value was 0.28 ft/ft.

2.4.12.2.6 Temporal Groundwater Level Trends

Figure 2.4-71 (Sheets 1 through 3) provides hydrographs for wells W-1 through W-15 and DW-1 through DW-12. The hydrographs include plots of groundwater elevation versus time, collected manually between July 15, 2024, and November 10, 2025, and recorded automatically using pressure transducers installed in each monitoring well between November 10, 2024, and November 13, 2025. Daily rainfall measurements from the nearby Dan River at the Pine Hall USGS gauging station (Reference 2.4-81) are also included on the hydrographs. Although not depicted on the hydrographs, lake levels in Belews Lake were collected between July and December 2024 and from July to October 2025. During these periods, lake levels were approximately 724 ft. (221 m).

2.4.12.2.6.1 North Plant Complex

At the North Plant Complex, groundwater elevations range from approximately 725 to 780 ft. NAVD 88 (221 to 238 m) among all monitoring wells, from approximately 746 to 780 ft. NAVD 88 (227 to 238 m) among shallow wells, and from approximately 725 to 769 ft. NAVD 88 (221 to 234 m) among deep wells. The following water level trends are observed in the North Plant Complex monitoring wells:

- Groundwater elevations are typically lower in the deep wells compared with nearby shallow wells indicating a downward hydraulic gradient (recharge area).
- There does not appear to be a direct relationship between rainfall and groundwater level trends.
- Water levels in shallow wells W-2, W-3, and W-5 are mostly flat over the year of hourly transducer measurements, except for episodic declines in water levels in W-2 and W-3 that is directly correlated with purging of these wells during quarterly water quality sampling events. The water levels took several weeks to months to recover after these sampling events.

- Wells W-1, W-4, and DW-4 show a slow steady increase in water levels over the past year and four months since the wells were installed, suggesting that the water levels may still be recovering from well drilling and development activities.

- Deep wells DW-1, DW-2, and DW-3 are the only wells that appear to show a seasonal trend with water levels rising gently through the winter and spring months when groundwater recharge typically occurs and declining water levels starting in May and continuing through the summer months when groundwater recharge typically is not occurring (Reference 2.4-70).

2.4.12.2.6.2 Middle Plant Complex

At the Middle Plant Complex, groundwater elevations range from approximately 750 to 788 ft. NAVD 88 (229 to 240 m) in the shallow monitoring wells, and 664 to 748 ft. NAVD 88 (202 to 228 m) in the deep monitoring wells. The following water level trends are observed in the Middle Plant Complex monitoring wells:

- Groundwater elevations are typically lower in the deep wells compared with nearby shallow wells indicating a downward hydraulic gradient and suggesting the Plant Complex is a groundwater recharge area.

- Most wells appear to show a consistent seasonal trend of declining groundwater levels through the summer months and into early winter, after which water levels level off and rise slightly through the winter and spring before starting to decline again in early summer.

- Episodic declines in water levels were observed in W-9 and appear to be related directly to purging of this well during quarterly water quality sampling events. The water levels took several weeks to months to recover after these sampling events.

- The stableness of the groundwater levels is attributed to the deep depth to groundwater and the stable elevation of the Belews Lake, the main discharge sink for groundwater.

- Groundwater elevations in deep well DW-8 are much lower than all other measured water levels at the Middle Plant Complex. Although water levels continue to show a slow and steady increase, the water levels are still significantly lower than the other Middle Plant Complex wells and suggest that DW-8 did not intersect any significant, connected water-bearing fractures.

2.4.12.2.6.3 South Plant Complex

Groundwater elevations range from approximately 764 to 810 ft. NAVD 88 (233 to 247 m) in the shallow monitoring wells, and 734 to 794 ft. NAVD 88 (224 to 242 m) in the deep monitoring wells. The following water level trends are observed in the South Plant Complex monitoring wells:

- Limited data are available for wells DW-10, DW-11, and DW-12 because these wells required several months to recover to static levels after well development, indicating these wells are in low-yielding fracture zones in the DBR.

- The water level in well W-13 appears not to have recovered after the last quarterly sampling event and remains below the bottom of the screen.

- Groundwater elevations are typically lower in the deep wells compared with nearby shallow wells indicating a downward hydraulic gradient and suggesting the Plant Complex is a groundwater recharge area.

- At the South Plant Complex, groundwater levels are stable showing level to slightly declining trends in essentially all monitoring wells over this period of measurement.

- A typical response to the hydrologic cycle observed at the Middle and North Plant Complexes is not observed at the South Plant Complex with the possible exception of W-15.

- The stableness of the groundwater levels is attributed to the deep depth to groundwater and the stable elevation of the Belews Lake, the main discharge sink for groundwater.

2.4.12.3 Aquifer Properties

The primary hydrogeological properties of interest at the Project site are K, and to a lesser extent, T, S, and effective porosity. The data obtained from the single-well slug tests and packer tests are used to evaluate K, while the multiple-well APTs are used to evaluate T, S, and K for each tested water-bearing zone.

Five packer tests were completed at three different boring locations. Packer test intervals targeted the open fractures identified from the ATV logs. Slug tests were conducted in 27 monitoring wells (15 in the shallow zone, and 12 in the deep zone).

Three APTs were performed between November and December 2024. One test was performed at each complex pumping well cluster. Each cluster consists of one pumping well and several water level sentinel wells. Well clusters were installed in various aquifer depth zones, including PWR (PW-2; Middle Plant Complex), the upper or shallow crystalline bedrock (PW-1; North Plant Complex), and the deep crystalline bedrock (PW-3; South Plant Complex) to total depths of 72.3 ft. (22.0 m), 90.3 ft. (27.5 m), and 155.3 ft. (47.3 m), respectively.

The following definitions are useful for a discussion of aquifer parameters measured from slug testing, packer testing, and APT results (Reference 2.4-70):

- Transmissivity (T) is the capacity of an aquifer to transmit water. It equals the hydraulic conductivity times the aquifer thickness.

- Storage coefficient (S) is the volume of water released from storage in a unit prism of an aquifer when the head is lowered a unit distance.

- Hydraulic conductivity (K) is the capacity of a unit cube of rock to transmit water under a unit gradient through a unit cross-sectional area of an aquifer.

2.4.12.3.1 Slug Test Analysis

K can be estimated from the slug test method, which evaluates the aquifer response to an instantaneous change in water level in the test well. A disadvantage of the slug test method is

that it measures K only in the immediate vicinity of the tested well. However, because the slug test requires minimal equipment and can be performed rapidly, slug testing can be readily performed in multiple wells across the Project site, offering an efficient determination of spatial variability in K.

Slug tests were conducted in 27 monitoring wells (15 in the shallow zone, and 12 in the deep zone). Slug test results based on Plant Complex and aquifer type are presented below and in Tables 2.4-36a – Table 2.4-36c. A summary of the overall sitewide results is provided below and in Table 2.4-37.

- North Plant Complex: The average K for the SBR is 3.31 feet per day (ft/day) (1.01 m/day) and the average K for the DBR is 0.451 ft/day (0.137 m/day). No wells were completed in OB/PWR in part due to the deeper depth of groundwater at the North Plant Complex.

- Middle Plant Complex: The average K for the OB/PWR is 9.07 ft/day (2.76 m/day). The average K for the SBR is 0.174 ft/day (5.30×10^{-2} m/day), and the average K for the DBR is 0.281 ft/day (8.56×10^{-2} m/day).

- South Plant Complex: The average K for the OB/PWR is 3.67 ft/day (1.12 m/day). The average K for the SBR is 0.270 ft/day (8.23×10^{-2} m/day) and 1.58×10^{-2} ft/day (4.82×10^{-3} m/day) for the DBR.

- Overall Project site: K for the OB/PWR ranges from 1.44 ft/day (0.439 m/day) to 16.7 ft/day (5.09 m/day) and averages 6.37 ft/day (1.94 m/day).

- Overall Project site: K for the SBR ranges from 7.09×10^{-4} ft/day (2.16×10^{-4} m/day) to 14.9 ft/day (4.54 m/day) and averages 1.63 ft/day (0.497 m/day). K for the DBR ranges from 5.03×10^{-6} ft/day (1.53×10^{-6} m/day) to 1.80 ft/day (0.549 m/day) and averages 0.249 ft/day (7.59×10^{-2} m/day). K for all bedrock ranges from 5.03×10^{-6} ft/day (1.53×10^{-6} m/day) to 14.9 ft/day (4.54 m/day) and averages 0.908 ft/day (0.277 m/day).

Three methods were used for slug test analysis: Hvorslev, Bouwer-Rice, and Kansas Geological Survey (KGS). Bouwer-Rice is a preferred method for unconfined aquifers, and Hvorslev is a preferred method for confined aquifers (Reference 2.4-82). The KGS method can handle more complex situations, including partial penetration, wellbore skin effects, anisotropy, and transient conditions (Reference 2.4-83). Although all three test methods were used to analyze the slug test data, only K values from the most appropriate methods for the known well and aquifer conditions are used to summarize representative K values in the right-hand column in Table 2.4-36. The Bouwer-Rice method was used as representative K values for clearly unconfined wells where the static water level was within or just above the screen interval and only rising head tests were analyzed due to the storage and gravity drainage effects of the well screen filter pack. The Hvorslev method was used as the representative K values for shallow wells where the water level was not within the well screen, and the KGS curve-matching method was used for the deep partially penetrating bedrock wells.

Table 2.4-37 presents sitewide average K values for each stratigraphic unit based on the slug test results. Figure 2.4-72 (2 Sheets) presents a distribution map of K values across the Project site from the shallow “W” wells and the deep “DW” wells. K values vary by several orders of

magnitude indicating heterogeneous and possibly anisotropic conditions. The low K values in some bedrock wells reflect screen intervals that were not placed adjacent to significant secondary fractures due to the low frequency of such water-bearing fractures and therefore represent the K of unfractured bedrock. Essentially, no groundwater flows through unfractured rock mass. Most groundwater flow occurs where fractures are present, open to transmit water, and interconnected with other fractures. The K distribution map for the shallow wells indicates areas of relatively high K values in central portions of the Plant Complexes that decrease outward toward the perimeter of the Plant Complexes. The K distribution in the deep wells indicates decreasing conductivity downward with depth.

2.4.12.3.2 Packer Test Analysis

Five packer tests were performed using the Lugeon test method at three different boring locations within the consolidated bedrock, one each at the North, Middle, and South Plant Complexes (two tests each were performed at borings B-3 and B-8, and one was performed at boring B-13). Packer test intervals targeted prominent fractures identified from the ATV logs. Packer test results are summarized in Table 2.4-38.

Three of the tested zones (B-3, B-8, and B-13) represented as Zone 1 did not allow significant water penetration, indicating the targeted fracture discontinuities selected were likely closed or filled. The estimated K values for these test intervals range from 2.22×10^{-3} to 9.58×10^{-2} ft/day (6.77×10^{-4} to 2.92×10^{-2} m/day), similar to the range of K values measured from slug testing for wells in consolidated bedrock. The remaining two test intervals required nearly 30 gallons per minute (gpm) (114 liters per minute [lpm]) during testing and had estimated K values of more than 2 ft/day (0.6 m/day). These fractures were open, through-going, and interconnected with other fractures, and may represent potentially significant groundwater flow pathways in an otherwise low permeability unfractured rock mass.

2.4.12.3.3 Aquifer Pumping Test Analysis

Three APT well clusters were installed for aquifer performance testing. Well locations are shown on Figure 2.4-58, and well construction details are provided in Table 2.4-31. These APT well clusters are located at the North, Middle, and South Plant Complexes and target three different aquifer zones as summarized below:

- OB/PWR (Middle Plant Complex): includes pumping well PW-2 and sentinel wells W-6 and S-6 through S-10. All wells are screened within OB/PWR to depths of approximately 70 to 75 ft. (21 to 23 m).

- SBR (North Plant Complex): includes pumping well PW-1 and sentinel wells W-1 and S-1 through S-5. All wells are screened within the SBR to depths of approximately 85 ft. (26 m).

- DBR (South Plant Complex): includes pumping well PW-3 and sentinel wells DW-9 and S-11 through S-16. S-16 is screened in the SBR; all other sentinel wells are screened in the DBR to depths of approximately 150 ft. (45.7 m).

The sentinel wells surrounding each pumping well are arranged in cruciform patterns at approximate distances of 20, 40, and 80 ft. (6.1, 12, and 24 m) away from the pumping well. The PW-2 cluster wells were spaced 15, 30, and 45 ft. (4.6, 9.1, and 14 m) apart. The cross-

shape cluster is oriented northeast-southwest or northwest-southeast, approximately parallel and perpendicular to regional geologic strike to better characterize potential preferred groundwater flow directions and anisotropy associated with bedrock fracture orientations. APT results are presented in Tables 2.4-39a – Table 2.4-39c and summarized below.

PW-2 (Middle Plant Complex, OB/PWR) was pumped at a rate of 3.5 gpm (13 lpm) for approximately 49 hours. The shape of a log-linear time-drawdown plot demonstrates an early-time reduced drawdown slope, which suggests possible gravity drainage effects typical of an unconfined aquifer. Approximately 400 minutes into the test, the drawdown curve steepens and plots as a straight line through the end of the test, indicating that the aquifer is behaving like a confined aquifer and can be analyzed using Theis and Theis recovery methods. These late-time data were analyzed for aquifer properties as being more representative of regional aquifer conditions. Based on the results presented in Table 2.4-39b, it is estimated that the OB/PWR at the Middle Plant Complex has an average T of 132 square feet per day (ft^2/day, 12.3 m^2/day), an average S of 1.99 x 10^{-2}, and an average K of 4.42 ft/day (1.35 m/day) assuming a tested aquifer thickness of 30 ft. (9.1 m) equal to screen length and saturated aquifer above the screen. The aquifer S values suggest the PWR is unconfined to partially confined.

PW-1 (North Plant Complex, SBR) was pumped at a rate of 0.06 gpm (0.2 lpm) for approximately 49 hours. The drawdown plot for the PW-1 APT is similar to the PW-2 APT in that it shows delayed effects of well bore storage and possible effects of limited gravity drainage, suggesting unconfined aquifer conditions. After several hundred minutes of pumping, the log-linear drawdown curve steepens and plots as a straight line through the end of the test. These late-time data were analyzed as confined aquifer conditions following early-time effects of borehole storage and gravity drainage. This portion of the time-drawdown curve is also considered to be more representative of regional aquifer conditions as the drawdown cone spreads away from the pumping well and encompasses greater portions of aquifer material. Distance-drawdown analyses demonstrate that the aquifer behaves heterogeneously with certain wells showing more drawdown than expected while others show less. This could be a function of fracture interconnectedness between the pumping well and certain sentinel wells within the cluster. The excessive drawdown in the pumping well suggests high head loss from turbulent flow likely due to tight fractures near the well interface, possible fracture dewatering, and head loss from cascading flow inside the pumping well. The average aquifer parameters estimated for the SBR aquifer from the test data include an average T of 8.89 ft^2/day (0.826 m^2/day), an average S of 1.06 x 10^{-2}, and an average K of 0.445 ft/day (0.136 m/day). The estimate of K assumes a saturated thickness of 20 ft. (6.1 m) equal to the length of the well screen.

PW-3 (South Plant Complex, DBR) was pumped at a rate of 0.8 gpm (3 lpm) for approximately 49 hours. The drawdown plot does not show evidence of unconfined gravity drainage conditions. After less than 400 minutes, the drawdown plot flattens slightly, indicating that leakage or recharge is occurring. This could be leakage from the overlying saturated OB material recharging bedrock fractures, or a recharge boundary from Belews Lake or the cut-through channel/canal for West Belews Creek. The recharge likely occurs as the drawdown cone expands away from the pumping well and intersects recharge from Belews Lake. Recharge could occur along an open interconnected sub-horizontal fracture(s) that intersects lake bottom sediments or is exposed to the bottom of the lake. Hantush and Theis methods were used to analyze the APT data. The estimated aquifer parameters indicate an average T of 1.40 ft^2/day (0.130 m^2/day), an average S of 1.54 x 10^{-3}, and an average K of 7.02 x 10^{-2} ft/day (2.14 x 10^{-2} m/day) assuming a saturated thickness of 20 ft. (6.1 m) equivalent to the screen

length. The distance-drawdown analysis, which may be more representative of the regional portion of the aquifer, provided a T of 4.29 ft^2/day (3.99x10^{-1} m/day) and K of 0.215 ft/day (6.55 x 10^{-2} m/day). The area of influence based on the distance-drawdown plot at the end of the pump test is slightly over 4000 ft. (1219 m) and covers all three Plant Complexes.

In summary, the following conclusions can be derived by analysis of the APT data.

- Based on the PW-2 test, the OB/PWR behaves as an unconfined to semi-confined aquifer with an average T of 132 ft^2/day (12.3 m^2/day), an average S of 1.99 x 10^{-2}, and an average K of 4.42 ft/day (1.35 m/day).

- Based on the PW-1 test, the SBR behaves as an unconfined to semi-confined aquifer with an average T of 8.89 ft^2/day (0.826 m^2/day), an average S of 1.06 x 10^{-2}, and an average K of 0.445 ft/day (0.136 m/day).

- Based on the PW-3 test, the DBR behaves as a leaky confined aquifer with an average T of 1.40 ft^2/day (0.130 m^2/day), an average S of 1.54 x 10^{-3}, and an average K of 7.02 x 10^{-2} ft/day (2.14 x 10^{-2} m/day). The distance-drawdown analysis, which may be more representative of the regional portion of the aquifer, resulted in a T of 4.29 ft^2/day (0.399 m^2/day) and a K of 0.215 ft/day (6.55 x 10^{-2} m/day).

2.4.12.3.4 Average Linear Groundwater Velocity

The average linear velocity of groundwater is estimated using Darcy's Law as shown below.

$V = K*i_h/\phi_e$

where

V = velocity (ft/day)

K = hydraulic conductivity (ft/day)

i_h = horizontal hydraulic gradient (ft/ft)

ϕ_e = effective porosity (unitless)

The average K from the slug tests and i_h from the monthly manual water levels were used to calculate the average linear velocity for the OB/PWR and the bedrock aquifers separately. Maximum linear velocities were calculated using the maximum i_h for the Project site. Only K values estimated from slug testing were considered in calculating average linear groundwater velocities because the data is more representative of sitewide conditions. Effective porosity values were estimated from reference documents based on grain size distribution and rock type in each stratigraphic unit (Reference 2.4-84; Reference 2.4-85). Average linear groundwater velocity results are summarized in Table 2.4-40.

Results indicate an average linear velocity of 1.2 ft/day (0.37 m/day) and a maximum linear velocity of 2.9 ft/day (0.88 m/day) in the OB/PWR aquifer, an average linear velocity of 3.3 ft/day (1.0 m/day) and a maximum linear velocity of 7.9 ft/day (2.4 m/day) in the SBR aquifer, and an average linear velocity of 0.35 ft/day (0.11 m/day) and a maximum velocity of 0.58 ft/day (0.18 m/day) in the DBR aquifer.

2.4.12.3.5 Hydrogeochemical Characteristics

Groundwater in the Piedmont aquifers typically has moderate mineralization, slightly acidic to neutral pH, and elevated hardness due to weathering of crystalline bedrock. Water quality is generally suitable for drinking, but localized issues include iron, manganese, radon, and occasional nitrate contamination from human activities. These water chemistry characteristics reflect rock-water interactions between infiltrating rainwater and the fractured crystalline rocks (granite, gneiss, schist). Within the Milton Belt, the major ions include calcium, magnesium, and bicarbonate (i.e., calcium-magnesium/bicarbonate type (Reference 2.4-86). Groundwater in the Mesozoic basins to the north of the Project site typically has higher total dissolved solids concentrations locally, and is harder and less acidic than groundwater from the crystalline bedrock aquifer (Reference 2.4-87).

2.4.12.3.6 Hydrogeologic Conceptual Site Model

A hydrogeologic conceptual site model (CSM) has been developed for the Project site from subsurface data collected from a total of 15 primary geotechnical borings plus additional offsets, borehole geophysical tests on 9 borings, 33 well lithologic borings, 15 shallow monitoring wells, 12 deep monitoring wells, three aquifer pumping test (APT) wells, and 16 sentinel wells, along with aquifer coefficient data obtained from 27 slug tests, 5 packer tests, and 3 aquifer pumping tests (one at each Plant Complex in each main hydrogeologic unit), and over one year of groundwater level, hydraulic gradient and groundwater flow direction data. The key aspects of the CSM are as follows:

- The hydrogeologic setting includes crystalline bedrock composed primarily of gneiss with lesser amounts of schist overlain by PWR and OB. The OB is composed of residual soil weathered in-place from the underlying bedrock and described primarily as a silty sand, with lesser occurrences of clay and sandy silt. PWR consists of silty sand with gravel and exhibits the relic rock structure of the parent rock material.

- More than 1,150 fractures were identified in the ATV logs. Based on the ATV logs, fracture density at the Project site ranges from 22 to 83 fractures per 100 ft. (30.5 m) and averages 65 fractures per 100 ft. (30.5 m) and generally declines with depth.

- Over 97 percent of the fractures identified in ATV logs are tight, closed, or filled and likely produce little water. Many of the identified fractures may also represent mineralogical or lithologic discontinuities and are not actually fractures.

- Less than 3 percent of the fractures identified were described as open or had a recorded open aperture width. Aperture widths range from 0.2 to 6.8 in. (5 to 172 mm) and average 1.3 in. (32 mm) with a median value of 0.9 in. (23 mm). Fractures with open apertures were only recorded in the upper 250 ft. (76.2 m) bgs.

- The dominant fracture orientation identified in the ATV logs strike nearly east-west and dip at low angles toward the south. These sub-horizontal fractures are likely associated with mineralogical and lithological layering in the gneissic and schistose bedrock. Other subordinate fracture sets identified in the ATV logs were subvertical and oriented generally northwest and east-west.

- Bedrock fracture orientations coincide reasonably well with more than 1,400 fracture trace lineaments identified within the Project Vicinity that may represent the surface manifestations of underlying subvertical fracture zones. Zones of increased bedrock fracture density may represent preferred pathways for groundwater flow.

- Project site data indicates that bedrock is mostly massive with low values of K, T, and S. Because most of the open transmissive fractures are sub-horizontal and occur within the upper 300 ft. (91.4 m), it is assumed that most groundwater flow and storage within the bedrock aquifer is moderately shallow and may be compartmentalized or confined. Most groundwater flow likely occurs in the largest open fractures, which are more likely interconnected with regional fracture networks and discharge to available surface water bodies.

- Groundwater recharge occurs as direct infiltration of rainfall at land surface that percolates through the unconsolidated OB/PWR into fractured bedrock. Bedrock generally has little primary porosity and permeability. Most groundwater is stored in and flows through a limited amount of secondary fractures with adequate aperture openings formed within the bedrock.

- Groundwater is present in the OB and PWR likely under unconfined or water table conditions and travels short distances, discharging to nearby tributary streams, springs, or surface water bodies such as Belews Lake.

- A portion of the groundwater flows vertically downward, recharging the underlying bedrock aquifer. In the underlying crystalline bedrock, groundwater continues to flow vertically downward and outward or away from topographic divides and toward areas of discharge into nearby creeks, seeps, and surface water bodies (e.g., Belews Lake).

- At the Project site, groundwater flow is bilinear along the spine of the peninsula away from the surface divide and toward Belews Lake and its tributaries. Radial flow occurs partially at all three Plant Complexes as groundwater flows toward Belews Lake and the cut-through channel/canal.

- Overall, groundwater elevations decrease from the South Plant Complex to the North Plant Complex as proximity to the lake decreases. This results in a deeper depth to the water table at the North Plant Complex compared with the other two complexes.

- Hydrographs of groundwater elevation data illustrate that water levels are essentially flat and do not fluctuate from episodic rainfall events or even seasonal changes in groundwater recharge. The stable nature of groundwater levels reflects the relatively deep unsaturated zone and the influence of stable lake levels surrounding the Project site.

- Some site monitoring wells demonstrate an expected seasonal trend with water levels rising gently through the winter and spring months when groundwater recharge typically occurs and declining water levels starting in May and continuing through the summer and fall when groundwater recharge typically is not occurring.

- K varies across the Project site by several orders of magnitude. The average K based on slug test results for OB/PWR is 6.37 ft/day (1.94 m/day) with a maximum of 16.7 ft/day (5.09 m/day). The SBR has an average K of 1.63 ft/day (0.497 m/day) and a maximum K of 14.9 ft/day (4.54 m/day). The K of the DBR is lower than that of the SBR with an average K of 0.249 ft/day (7.59 x 10^{-2} m/day) and a maximum K of 1.80 ft/day (0.549 m/day).

- Three aquifer pumping tests were performed at the Project site at PW-1 (SBR; average K of 0.445 ft/day (0.136 m/day) and average storativity, S, of 1.06 x10^{-2}), PW-2 (PWR; average K of 4.42 ft/day (1.35 m/day) and average S of 1.99 x10^{-2}), and PW-3 (DBR; average 7.02 x10^{-2} ft/day (2.14 x 10^{-2} m/day) and an average S of 1.54 x10^{-3}. Aquifer pump test results show similar but slightly lower K values reflecting the presence of silty sand OB/PWR and low fracture permeability in metamorphosed gneiss and schist bedrock. Storativity values indicate unconfined to semi-confined conditions persist in OB/PWR and SBR, and leaky confined conditions are present in the DBR unit.

- Horizontal groundwater flow velocities using average K values and average and maximum i_h values are highest in the SBR aquifer with an estimated average flow velocity of 3.3 ft/day (1.0 m/day) and a maximum linear velocity of 7.9 ft/day (2.4 m/day). The lowest groundwater flow velocities occur in the DBR aquifer with an average linear velocity of 0.35 ft/day (0.11 m/day) and a maximum velocity of 0.58 ft/day (0.18 m/day).

2.4.12.4 Groundwater Use

2.4.12.4.1 Vicinity Groundwater Use

Groundwater supplies most of the private and public drinking water in the Project Vicinity. Most of the groundwater supply wells are drilled into the underlying bedrock aquifer using air rotary rigs, are typically completed to depths of several hundred feet, and are constructed with 6-in. steel or polyvinyl chloride casing set and grouted into competent rock with the remainder of the borehole open to water-bearing fractures (Reference 2.4-69; Reference 2.4-67). Well yield for crystalline bedrock aquifers is generally low, typically yielding 5 to 35 gpm (20 to 130 lpm) within the fractured bedrock. Above the fractured bedrock, within the surficial aquifer, well yields can increase up to approximately 200 gpm (757 lpm) (Reference 2.4-88). Well yield for Early Mesozoic basins is typically low with an average 11 to 12 gpm (42 to 45 lpm) (Reference 2.4-89). Wells completed in the biotite gneiss and schist unit (CZbg) in the Project Vicinity range in yield from 2 to 93 gpm (8 to 350 lpm) with an average well yield of approximately 40 gpm (150 lpm). Well depths range from 46 to 1,504 ft. (14 to 458.4 m) deep and average approximately 295 ft. (89.9 m) (Reference 2.4-67).

The NC Department of Environmental Quality (NCDEQ) provides historical groundwater use data by category and county. Data are available from 1999 through 2022. The groundwater use categories are agricultural, energy, industrial, mining, public water supply (PWS), and recreational. Groundwater use data were reviewed for the four counties in the immediate Project Vicinity (Stokes, Rockingham, Guilford, and Forsyth). Table 2.4-41 presents the results from 2022 (Reference 2.4-64).

An average of 1.4 million gallons per day (mgd) (5.3 million liters per day [mld]) of groundwater was withdrawn among the four counties. Most of the groundwater withdrawals were for PWS (86 percent), followed by energy (7 percent), recreational (4 percent), and industrial (3 percent).

Groundwater use in Stokes County is relatively limited; 0.10 mgd (0.38 mld) for energy and 0.010 mgd (0.040 mld) for PWS for a total of 0.11 mgd (0.42 mld) for 2022. Between 2007 and 2021, the highest reported average daily groundwater use in Stokes County was 0.040 mgd (0.15 mld) in 2021 (Reference 2.4-88).

The NC Division of Water Resources (NCDWR) Local Water Supply Planning Database identifies three municipalities in the immediate Project Vicinity (Madison, Stokesdale, and Walnut Cove) that have local water supply plans (LWSP) for 2023. These LWSPs are designed to outline the current and projected water supply use and demand up to 2070 for surface water and groundwater.

The LWSP for Walnut Cove projects groundwater demand to increase from 0.31 mgd (1.2 mld) in 2023 to 0.32 mgd (1.2 mld) in 2070. This increase in demand correlates to an increase in overall projected population from 1757 in 2023 to 2000 in 2070. The Madison and Stokesdale LWSPs do not identify groundwater withdrawals for current water use and do not identify groundwater withdrawal use in their projections (Reference 2.4-91).

The NC OneMap, a collaborative geographic information system (GIS) website that presents data from local, state, and federal government agencies, was used to identify PWS near the Project site. OneMap classifies public water systems into three categories:

- Community water system: a public water system that supplies water to the same population year-round.
- Non-transient non-community water system: a public water system that regularly supplies water to at least 25 of the sample people at least 6 months per year (e.g., schools, factories, and hospitals).
- Transient non-community water system: a public water system that provides water in a place such as a gas station or compound where people do not remain for long periods of time.

The NC OneMap query identifies 47 community, 19 transient non-community, and 7 non-transient non-community PWS wells within a 7-mi. (11-km) radius of the Project site. Table 2.4-42 shows the identified PWS wells, and Figure 2.4-73 shows their locations.

Of the 73 identified PWS wells, 59 wells are installed in the Crystalline Rock aquifer, and 14 wells are installed within the Early Mesozoic basin aquifer. Well depths range from 103 to 1504 ft. (31.4 to 458.4 m) bgs in the Crystalline Rock aquifer and from 175 to 1230 ft. (53.3 to 374.9 m) bgs in the Early Mesozoic basin aquifer. Well yields range from 5 to 132 gpm (20 to 500 lpm) in the Crystalline Rock aquifer and from 2 to 200 gpm (8 to 757 lpm) within the Early Mesozoic basin aquifer (Reference 2.4-92).

A private well search of the Environmental Health Departments of the four surrounding counties (Forsyth, Guilford, Rockingham, and Stokes) yielded information from Guilford and Rockingham counties; however, private well information is not readily available from Forsyth and Stokes counties. Identified private water supply wells are presented in Figure 2.4-74. [[ ]]^{WI} private water supply wells within a 7-mi. (11-km) radius of the Project site are identified within Guilford County (Reference 2.4-93).

Private well data provided by Rockingham County identify [[ ]]WI private water supply wells within a 7-mi. (11-km) radius of the Project site. Limited information regarding well yields or depths is available. Based on the available data, well depths range from [[ ]]WI in the Crystalline Rock aquifer and [[ ]]WI in the Early Mesozoic basin aquifer. Well yields range from [[ ]]WI in the Crystalline Rock aquifer, and from [[ ]]WI in the Early Mesozoic basin aquifer (Reference 2.4-94).

The EPA Private Domestic Well online portal estimates the density of private water supply wells for domestic use in Forsyth, Stokes, Guilford, and Rockingham counties using land use data combined with housing units in the area to provide a well count estimate. Figure 2.4-75 shows estimated number of wells per square kilometer (km^2) (well density) for these counties. At the Project site, well density is estimated to be 0 to 25 wells per km^2 (Reference 2.4-95).

Based on the identified well yields and well distances from the Project site, groundwater withdrawals from surrounding areas do not have an influence at the Project site. Similarly, since groundwater is not used at the Project site, there is no impact to nearby groundwater supplies.

2.4.12.4.2 Current On-Site Groundwater Use

The BCSS does not use groundwater as a source for cooling water, potable water, or any other operational needs. Makeup water for the closed-cycle cooling system is derived from an existing surface water intake and conveyance pipeline from the Dan River. Potable water is derived from a local municipal water provider, Winston-Salem/Forsyth County Utilities. The public water is conveyed to BCSS through a water supply line located along the west side of Craig Road leading to the South Gate of the Project site. The only current groundwater pumping is for a groundwater corrective action plan (CAP) remediation system installed as part of ash basin closure activities. The CAP system is located approximately 2.2 mi. (3.5 km) northwest of the Project site and uses a series of 72 extraction wells and 64 clean water infiltration wells.

The total combined water withdrawal amounts for the 72 extraction wells operating as part of the full-scale CAP system are described below:

- Minimum system flow rate: 72 gpm (270 lpm)
- Maximum system flow rate: 98 gpm (370 lpm)
- Average system flow rate: 81 gpm (310 lpm)

Groundwater that is withdrawn is treated and re-infiltrated as clean water into 64 infiltration wells as part of the full-scale CAP system as follows:

- Minimum system infiltration rate: 63 gpm (240 lpm)
- Maximum system infiltration rate: 89 gpm (340 lpm)
- Average system infiltration rate: 75 gpm (280 lpm)

On average, the monthly CAP system withdrawal rate is approximately 3.5 million gallons (13 million liters), and the average monthly infiltration system rate is approximately 3.3 million gallons (12 million liters). Extraction and infiltration wells are screened in residuum and bedrock.

2.4.12.4.3 Projected On-Site Groundwater Use

2.4.12.4.3.1 Groundwater Needs to Support Construction

Even though the water table is moderately deep and the subsurface materials relatively low in permeability, groundwater withdrawal associated with temporary dewatering is expected during excavation and construction of the power block and/or other building foundations. The amount of dewatering required to support the construction of the new advanced reactor plant is unknown because the reactor technology has not been chosen. Because the Project site is surrounded by Belews Lake, impacts from dewatering are expected to be limited to the Project site area of the peninsula. Potential impacts of temporary dewatering are discussed in Section 2.4.12.5.

2.4.12.4.3.2 Groundwater Needs to Support New Plant Operations

Makeup water for reactor operations for closed-cycle cooling system will be sourced from Belews Lake and augmented from the Dan River during periods of low lake levels. Potable water supply needs are supplied by the Winston-Salem/Forsyth County Utilities. Other groundwater supplies are not required to support future advanced reactor plant operations.

2.4.12.5 Dewatering and Post-Construction Groundwater Conditions

2.4.12.5.1 Dewatering and Construction Activities

At this time, the specific reactor technology to be used on the Project site has not been identified; however, the foundation embedment will not exceed 125 ft. (38.1 m) in depth from the finished grade elevation of 810 ft. NAVD 88 (247 m). Based on preliminary site plans, the largest power block and containment structure will be a square roughly 400 by 400 ft. (122 by 122 m) for a total footprint of 160,000 ft^2 (14,864 m^2). The main power block area will be excavated and dewatered to facilitate construction. The dewatering system will likely consist of either DBR wells or sump pumping from a system of shallow excavations to collect groundwater and rainwater, which is then pumped to a discharge point away from the excavation.

The Dupuit equation for steady-state flow in an unconfined aquifer (Reference 2.4-96) is used to estimate dewatering needs based on the rate of groundwater inflow into the excavation. Using site-specific data and excluding recharge from precipitation and Belews Lake, the dewatering pumping rate is estimated to range from approximately 57 gpm (216 lpm) to 370 gpm (1,401 lpm). The radius of influence of the drawdown cone surrounding the foundation excavation is estimated using the modified Theis non-equilibrium equation (Reference 2.4-97; Reference 2.4-98). Based on pumping tests and estimates from this equation, the drawdown cone is predicted to extend up to 4000 ft. (1219 m) during peak dewatering operations. Figure 2.4-76 illustrates the maximum predicted radius of influence from construction dewatering at the three Plant Complexes. As shown, the radius of influence from the North Plant Complex extends across Belews Lake and includes an area of public and private water supply wells. One noncommunity transient public water supply well is located within the predicated radius of influence. The actual drawdown is expected to be reduced by groundwater recharge from precipitation and recharge boundary conditions from Belews Lake. No adverse impacts are

expected. In addition, drawdown from dewatering activities are temporary in nature. Normal groundwater levels are expected to return quickly after construction dewatering ceases.

2.4.12.5.2 Reliability of Groundwater System Used for Safety-Related Purposes

Safety-related systems will not rely on groundwater from the Project site.

2.4.12.5.3 Effects on Plant Foundations

The highest groundwater elevations in the central portion of the North, Middle, and South Plant Complexes are approximately 780 ft. NAVD 88 (238 m), 786 ft. NAVD 88 (240 m), and 810 ft. NAVD 88 (247 m), respectively from shallow monitoring wells W-2, W-8, and W-14. The deepest likely foundation excavation elevation is 685 ft. NAVD 88 (209 m) assuming a finish grade elevation of 810 ft. NAVD 88 (247 m) and maximum excavation depth of 125 ft. (38.1 m). This results in an estimated maximum hydrostatic pressure from groundwater on foundations equivalent to 95 to 125 ft. (29 to 38.1 m) of groundwater or 41 to 54 psi (282 to 372 kPa). Actual hydrostatic pressures on foundations will depend on the actual finished grade and the selected reactor technology.

2.4.12.5.4 Post-Construction Groundwater Conditions

Following decommissioning of the dewatering system, the groundwater will attempt to return to a natural condition. Pavement and structures will likely reduce groundwater recharge, potentially impacting groundwater baseflow discharge into nearby perennial creeks and Belews Lake. Unpaved areas covered by permeable gravel or fill may receive increased recharge, countering impacts of increased impermeable surfaces.

2.4.12.6 Groundwater Flow Model

A numerical groundwater flow model was developed to assist with interpretation of the subsurface hydrogeologic materials and to simulate steady-state groundwater flow conditions.

Due to the complexity of the aquifer system at the Project site, numerical modeling offers the best framework to assess advective flow transport of dissolved constituents within the aquifer and identify location(s) of potential exposure, along with estimating travel times from points of possible accidental release to potential receptors.

The finite-difference three-dimensional groundwater flow model code, MODFLOW-USG Transport (MODFLOW; Reference 2.4-99) was used for numerical modeling. MODFLOW is a standard of the groundwater modeling community and offers a wide range of boundary condition and solver options that satisfy the anticipated demands posed by the facility hydrogeologic setting. The graphical interface for modeling (Groundwater Vistas) was used to create MODFLOW input files and to process and display output data files.

MODFLOW offers a variety of packages for iteratively solving the array of algebraic equations representing the partial differential equations governing fluid flow in a porous medium. The Sparse Matrix Solver (SMS) package employs a nonlinear iterative algorithm to achieve convergence to closure criteria and eventually to observed conditions. SMS can work with the unstructured format of MODFLW-USG Transport, unlike previous solvers. Conservative convergence criteria are specified for SMS, with 0.001 ft. for the maximum absolute change in

head per outer iteration, 1E-05 ft. change per inner iteration, a maximum number of outer loop iterations of 200, and a maximum number of inner loop iterations of 300.

2.4.12.6.1 Model Construction

2.4.12.6.1.1 Model Cell Discretization and Property Conditions

The model domain covers a rectangular area of approximately 230 square miles (Figure 2.4-77) and consists of a parent grid with 165 rows, 95 columns, and 5 layers. The active area of the model is approximately 112 square miles. The parent grid is further subdivided using quadtree refinement into 655,950 total cells (615,265 active cells). Cell spacing ranges from 40 x 40 ft. near the three Plant Complexes to 640 x 640 ft. away from the Project site. The top surface of the model ranges from an elevation of 536 to 1,035 ft. NAVD 88 and is a combined topography-bathymetry surface. A USGS digital elevation model (DEM) was used to represent ground surface outside Belews Lake (Reference 2.4-100). Historical topographic surfaces were used to represent the Belews Lake bathymetry (Reference 2.4-101; Reference 2.4-102).

Five model layers were used to simulate hydrogeologic layers beneath the Project site, including OB, PWR, SBR, DBR, and deepest bedrock (DPR) and are shown in model cross sections (Figure 2.4-78). Note, the DPR layer is not shown in model cross sections. Each layer was assigned average hydraulic conductivity derived from Project site aquifer testing as initial parameter values in the groundwater model. Conductivity values were adjusted during the calibration process but remained within the range of site observed values. The final calibrated model input parameters for K ranges from 2.84 x 10^{-4} ft/day (8.66 x 10^{-3} m/day) to 42.4 ft/day (12.9 m/day).

Groundwater recharge is applied to the uppermost saturated layer present within the model. Recharge values were based on landcover classifications calibrated to a baseflow separation estimate of mean annual recharge for the Dan River Basin of 8.45 in/yr (Reference 2.4-74). Landcover classes thought to represent groundwater discharge areas (wetlands and open water) were set to zero recharge. Medium-intensity and high-intensity developed land was set initially to half and one quarter of the annual recharge estimate to account for impervious surfaces that would facilitate runoff. Recharge property values were adjusted during the calibration process. The final calibrated model input parameters for recharge ranges from 0 to 16.9 in/yr. The average recharge rate over the active model area is 5.84 in/yr. The lower recharge rate is attributed to the large portion of the model area covered by Belews Lake that has an input recharge value of 0 in/yr.

2.4.12.6.1.1.1 Boundary Conditions

Boundary conditions applied in the model include the River, Drain, and No-Flow (Figure 2.4-77). River cells are used to represent Belews Lake and Dan River and other larger perennial streams. River boundaries are head-dependent flux boundaries and can add or remove water from a model, depending on whether the simulated head in the model cell is above or below the assigned threshold value. Drain boundary conditions are used to simulate ephemeral and minor perennial features such as creeks, wetlands and small ponds. Drain boundaries can remove water from a model only. No Flow cells are used to represent inactive portions of the flow model. No Flow cells are set to approximate geographically realistic groundwater flow divides, such as topographic divides at the watershed boundaries. To the west, the Dan River represents a prime groundwater discharge area that would receive flow from both sides of the

river. Accordingly, no-flow cells were set on the west bank of the Dan River. To the north, several sub-catchments were included beyond the Belews Lake impoundment dam to capture any deep flow pathways that may circulate to the north. To limit model size, watersheds to the northeast were filtered to only include adjacent sub-catchments. In addition, the top, bottom and sides of the flow model are also implicit no-flow boundaries.

2.4.12.6.1.1.2 Steady State Conditions

The model is constructed to represent long-term steady-state hydraulic conditions. The available site-wide data set taken in February 2025 is used as a representative example of static conditions. Due to steady lake stages over time and a lack of significant nearby pumping, the assumption of steady-state conditions is likely to hold within the Project site. Other areas of the model domain undergoing construction or other anthropogenic modifications may exhibit temporal changes. However, the distance of potentially variable water levels from the Project site vicinity and dense spatial distribution of boundary conditions enhances the model's ability to meet the steady-state assumption.

2.4.12.6.1.1.3 Model Calibration

Model calibration is an iterative process where initial values of model input parameters are varied within hydrologically and geologically plausible ranges until model results align with constraining observations (i.e., water elevations collected in the field). The modeler, in adjusting parameter values, adheres to reasonable ranges of input parameters based on site-specific or literature values. In the process of adjusting these parameter values, the modeler determines which parameters more strongly affect model outputs. The main calibration targets for this model are water levels, groundwater flow directions, horizontal and vertical hydraulic gradients, and overall water balance.

Water level calibration targets were based on data collected in February 2025 from 24 monitoring wells. Given the range of the water levels, which spanned 83 ft. (25.2 m), a target of 10 percent or 8.30 ft. (2.52 m) was set as the average of the absolute value of the residuals. A match of observed hydraulic gradients and agreement of flow direction in the model compared to the interpreted flow directions from contouring of observed measurements is more important than precise matching of potentiometric target points.

Figure 2.4-79 depicts contoured model-simulated heads compared to interpreted potentiometric surface contours. The model-generated predicted head contours are consistent with measured data obtained across the site. In general, the model conforms to the conceptual site model in that flow directions radiate away from topographic high points on the Project site peninsula, towards Belews Lake, and that shallow unit heads are higher than those of deeper units indicating downward vertical flow gradients.

Figure 2.4-80 presents the residuals plot and a bubble plot of the computed heads versus the observed heads at the target locations. Residual statistics suggest a reasonable fit to the target data. The points lie close to a 1:1 slope line, indicating that the simulated water levels closely match observed water levels. The bubble plots show that positive and negative residuals are randomly distributed throughout the Project site area.

Final calibrated model input parameter values are presented in Table 2.4-44.

2.4.12.6.1.2 Model Water Balance

Details of the water balance for the model are summarized in Table 2.4-43. Water enters the flow model through recharge and river boundary conditions. Water leaves the model through river and drain boundary conditions. The overall internal water balance for inputs versus outputs as computed by MODFLOW is 0.00 percent, indicating a good closure of the model solver and no anomalous numerical behavior.

2.4.12.6.1.3 Model Sensitivity

During the manual adjustments of model input parameters, it became apparent that the most sensitive parameters are horizontal and vertical hydraulic conductivity and recharge for all zones immediately underlying and adjacent to site targets. This is due to the limited geographic extent of targets.

2.4.12.6.1.4 Particle Tracking

Particle tracking was conducted to assess potential groundwater flow pathways and travel times from the potential power block areas (PPBAs) to downgradient discharge areas. Particle tracking utilizes the three-dimensional calculated potentiometric flow field to estimate the path of individual water molecules from a given starting or ending location. This calculation emulates the process of groundwater advective flow. Particle tracks were run in forward mode to a maximum transit time of 10,000 years in the subsurface, or until the particle leaves the model by discharging into a surface water body. Starting locations were placed along the bounding perimeter and at the center of each PPBA. Starting particles were placed at the surface of the water table interface regardless of the layer that occurred.

Particle track simulation results are shown in plan view in Figure 2.4-81 and in cross section view in Figure 2.4-82. Tracks generally run from power blocks radially outward following the topographic and hydraulic gradient away from each PPBA. Some particles travel through shallow OB and/or PWR pathways directly to Belews Lake or ephemeral tributary streams that drain into Belews Lake. Other particles descend into shallow and deep bedrock before rising again to discharge to Belews Lake.

Minimum and median travel times were calculated from a dense particle tracking array with initial particles starting either along the perimeter or the center of the PPBA. Results indicate that the minimum travel times from the perimeter of the North, Middle and South Plant Complexes until discharging into Belews Lake or a tributary are 45.0, 35.3, and 95.6 days, respectively. The forward-tracked particles discharge directly into Belews Lake in the case of the North and Middle Plant Complexes and to an ephemeral tributary in the case of the South Plant Complex. The median simulated travel time from the perimeter of North, Middle, and South Plant Complexes to Belews Lake are 6.7, 8.1, and 7.7 years, respectively. The maximum simulated travel times are 11.3, 27.8, and 15.8 years from the perimeter of North, Middle, and South Plant Complexes to Belews Lake, respectively. The minimum travel times from the center of the North, Middle, and South Plant Complexes until discharging into Belews Lake are 75, 30, and 6.5 years, respectively. The median simulated travel time from the center of the North, Middle, and South Plant Complexes to Belews Lake are 1366, 260, and 72 years, respectively. Estimated minimum and median travel times from each Plant Complex are summarized in Table 2.4-45. Figure 2.4-83 illustrates a box and whisker distribution chart of the numerical groundwater flow model particle tracking results of travel times. Note that all travel times

presented represent saturated groundwater flow only and do not include travel time through the unsaturated vadose zone.

2.4.12.7 Monitoring or Safeguards Requirements

Groundwater level monitoring at the Project site uses the groundwater monitoring wells installed in 2024 for the subsurface investigation. As part of the evaluation for the early site permit (ESP), the groundwater monitoring wells and environmental monitoring program are evaluated with respect to the Nuclear Energy Institute Groundwater Protection Initiative (Reference 2.4-103) and 10 CFR 20.1406 to determine whether any modifications are required to adequately monitor plant effects on groundwater.

Some of the existing monitoring wells are expected to be removed from service before construction activities begin to avoid their inadvertent destruction. For long-term groundwater monitoring purposes, the remaining monitoring wells are evaluated to determine the need for replacement wells. The evaluation forms the basis for the groundwater monitoring program described in the following paragraphs. Considerations to revise the groundwater monitoring program include the following:

- Groundwater Monitoring: Periodic water level measurements in the shallow and deep zone monitoring wells and collection of geochemical samples for analysis are performed in selected monitoring wells. The water level monitoring program objective is to detect changes in flow patterns in the aquifer zones of interest that might affect accident analysis and track temporal trends in groundwater levels that might affect structural stability.

- Operational Monitoring: The process and effluent monitoring program and implementation schedule is described at the construction permit application stage.

Groundwater level measurements in the monitoring wells are collected during construction and after plant startup. The selection of monitoring wells to be included in the program is made before the start of operation. The selection process is based on well condition and position relative to the reactor and other monitoring wells to provide optimal spatial distribution for potentiometric map preparation and hydraulic gradient assessment. Additionally, the long-term viability of monitoring wells (i.e., the likelihood that the well survives construction activities) is considered in the selection process. Monitoring frequency and duration is determined during detailed design at the construction permit or license application stage.

Geochemical groundwater sampling and analysis is performed during construction and after startup. Analysis may include field parameters (e.g., potential of hydrogen [pH], temperature, specific conductance, oxidation-reduction potential, and dissolved oxygen), major cations, major anions, total dissolved solids, and silica. Sampling is performed in supply wells and selected monitoring wells. The monitoring wells to be sampled, the sampling frequency, and the sampling duration are determined later.

Safeguards minimize the potential for adverse impacts to groundwater from the construction and operation of the new reactors. These safeguards include the use of lined containment structures around storage tanks (where appropriate) and hazardous materials storage areas, emergency cleanup procedures to capture and remove surface contaminants, and other

measures deemed necessary to prevent or minimize adverse impacts to the groundwater beneath the Project site.

2.4.13 ACCIDENTAL RELEASES OF LIQUID EFFLUENTS TO GROUND AND SURFACE WATERS

2.4.13.1 Introduction and Release Scenario Description

This section describes a hypothetical liquid accidental release scenario of a volume of water containing radionuclides to groundwater and its subsequent migration to a specified receptor location. Complete design parameters for all technologies considered in this application have not yet been obtained. Specifically, one technology (GVH BWRX-300) has not yet provided a source term for the accidental liquid release scenario, while two of the other technologies (Holtec SMR-300 and NuScale VOYGR) have identified mitigating design features to preclude the release of tank inventories to the environment assuming a postulated failure of the storage tanks. Accordingly, analysis of the liquid effluents to ground and surface waters is limited here to the WEC AP300, X-energy Xe-100, and the TerraPower Natrium technologies. However, conservative assumptions expected to bound any single technology being considered were made in this evaluation. Section 2.4.13.6 summarizes the assumptions used in this analysis. Detailed computations quantifying groundwater conditions, flow direction, velocities, and travel times to potential receptors are described in Section 2.4.12, while potential accidental release parameters and fate of released constituents associated with the assessed technologies are described in this section.

The location(s) of, and travel times to, potential receptors have been determined by forward particle tracking simulating the movement of groundwater by means of the calibrated numerical groundwater flow model. Particles were seeded at the edges of the PPBAs and tracked to the nearest surface water body. Some particles travel through shallow saprolite and/or PWR pathways directly to Belews Lake or a tributary stream draining into Belews Lake. Other particles descend into shallow bedrock before rising again beneath Belews Lake to discharge. The resultant shortest particle travel times are 45.0, 35.3, and 95.6 days from the North, Middle and South Plant Complexes, respectively (Table 2.4-45). The tracked particles discharge directly into Belews Lake in the case of the North and Middle Plant Complexes and to an ephemeral tributary in the case of the South Plant Complex. For particles seeded near the centers of the PPBAs, the median simulated travel times from the North, Middle and South Plant Complexes to Belews Lake are 6.7, 8.1 and 7.7 years, respectively. It is improbable that near any of the Plant Complexes, PWR, or OB strata would be tapped for any reasonable groundwater use or that ephemeral streams would be tapped for surface water use (i.e., there are no potential receptors other than the nearest surface water).

Summaries of isotopes and activities associated with a potential accidental release are listed (by technology) in Table 2.0-5.

The envisioned conservative accidental release scenario includes the following assumptions:

- A worst-case release of liquid waste with composition as listed in Table 2.0-5 (for each technology) is introduced into groundwater. Volumes of potential release are shown in Table 2.4-47.

- The release would occur at the edge of the PPBA, which would be a shorter distance to a receptor location than if the release occurred interior to the PPBA.

- The liquid released is assumed to immediately enter groundwater and move with the groundwater toward a surface water discharge point.

- The released radionuclides move with the general groundwater flow while undergoing attenuation by sorption and radioactive decay. To be conservative, the additional attenuation mechanisms of dilution with groundwater, dispersion along the groundwater flow path, and eventual dilution with surface waters are not initially considered as a basis for comparison to later attenuation effects.

- Ephemeral streams or various points on Belews Lake or the cut-through channel/canal surface water feature between the South and Middle Plant Complexes (West Belews Creek) are the nearest potential receptors identified by the groundwater flow model for groundwater flowing beneath the Plant Complexes.

- Initially, no attenuation mechanisms are assessed as the most conservative scenario. Then, attenuation due to radioactive decay of the parent isotope (progeny decay products excluded) and retardation from sorption are considered (see Sections 2.4.13.2.1.1 and 2.4.13.2.1.2 for details on these attenuation factors).

The potential maximum activity release volume to groundwater varies with technologies and ranges between 883 and 10,000 gal.

Once a technology is selected and site utilization plan developed, further analysis will be conducted and incorporated into additional accidental release modeling and assessment for the construction permit or licensing application of the project.

2.4.13.2 Initial Assessment

The groundwater flow system downgradient of the hypothetical point of release was evaluated to identify potential exposure points and their distances from an accidental release of radionuclides to groundwater. Travel time is conservatively taken as the shortest particle tracking time along a flow path (vertical and horizontal flow) to discharge, which is 35.3 days.

Given the unattenuated travel time estimate of 35.3 days and ignoring both the attenuation of dissolved radionuclides by sorption to aquifer solids and nuclear decay as well as a more indirect path to surface water, this estimate of travel time does not rule out plausible transport and potential for exposure within realistic time periods. This is an overly conservative estimate because the potential release constituents of concern are radioactive and undergo decay, and almost all would be retarded in their transport by interactions with the aquifer solid matrix.

2.4.13.2.1 Attenuated Travel

Sorptive retardation and radioactive decay are attenuation factors affecting the potential release effects at receptor locations. Both factors attenuate (lessen) the potential exposure at receptor locations. Retardation slows the travel time allowing greater decay and spreads out the contaminant mass along the flow path leading to a smaller peak exposure, while radioactive

decay removes contaminants from the system, lessening the total amount of contaminant available and slowing arrival times and concentrations at receptor locations.

2.4.13.2.1.1 Retardation

Using the retardation factors derived from the element-specific solid/liquid partition coefficient (K_d) values for sand, the various retarded travel times for constituents are shown in Table 2.4-48. Site-specific partition coefficient samples are still under analysis and will be incorporated prior to submittal of the construction permit or license application. These retarded travel times are the conservative estimates of when the peak concentration of contaminant arrives at the potential receptor location. Because of element-specific variable spreading of the mass of contaminants in the flow path due to sorption, some of the contaminants arrive earlier than this peak time (but no sooner than the unretarded groundwater flow time [35.3 days]). Also, some of the contaminants arrive later than the peak time. The larger the retardation factor, the more the contaminant mass is spread along the flow path, relatively lessening the peak concentration for an isotope.

2.4.13.2.1.2 Radioactive Decay

Each identified isotope that may be potentially released has a distinct decay rate constant that describes how quickly that isotope's nucleus decays by a certain radioactive decay process. One of the common measures of this mechanism is an isotope's half-life. Half-life is the time needed for half of a given number of atoms to undergo a radioactive decay process and is a constant value under all practical conditions.

Half-life values depend on the isotope. An extensive, authoritative list of isotope half-lives is available from Brookhaven National Laboratory (BNL) (Reference 2.4-104). The half-lives used to determine isotopic concentrations due to groundwater transport were generally taken from this source. When not available from BNL, additional isotope information was obtained from MIRDspecs (Reference 2.4-105).

Given the retarded travel times and radioactive half-lives, the remaining percent of initial activities for individual isotopes of interest for each technology are shown in Table 2.4-48.

2.4.13.2.1.3 Assessment Using Attenuation Factors

The results (maximum remaining concentration) associated with including attenuation factors are shown in Table 2.4-48, and a summary of Unity Rule calculations by technology is provided in Table 2.4-49. Based on NRC standards, the sum of the fractions of the radionuclide concentration to the respective effluent concentration limit (ECL) value from 10 CFR Part 20, Appendix B, Table 2, column 2, should not exceed 1. Based on the Unity Rule calculations, the composition of the initial potential release materials result in sums that are above unity (i.e., exceed 1) for all assessed technologies and are predicted to exceed unity at the receptor location although at a much-reduced value.

2.4.13.3 Sensitivity Analysis

As a conservative measure, K_d values for sandy soils were obtained from AECL-10125 (Reference 2.4-106). In every case, the listed K_d value for sand is the lowest or second lowest value (and still within the same order of magnitude) listed for various soil types. Using these lower K_d values results in a smaller retardation factor and a faster estimated travel time between

an accidental release point and the potential receptor location. Use of any of the more restrictive (greater) retardation factors leads to a longer expected travel time and increased attenuation.

Because retarded travel time plays such a major part in determining the activity of a potential release once it has been transported to the potential receptor, three different travel times (based on particle tracking) were assessed: (1) shortest travel time overall (35.3 days); (2) shortest travel time from the central region of any PPBA (2369 days or 6.5 years); and (3) shortest median (50th percentile) travel time of points release in the central region of one of the three PPBAs (26,238 days or 72 years). Table 2.4-49 presents the effects of these three travel times on Unity Rule values based on the attenuation (retarded travel and radioactive decay).

There are some effects on the final interpretation of Unity Rule values based on the varying travel times. For the shortest overall travel (35.3 days), only X-energy is predicted to be below unity. For the shortest travel from the center of a PPBA (2369 days or 6.5 years), both X-energy and TerraPower are predicted to be below unity. With the median travel time from any PPBA (26,238 days or 72 years), WEC closely approaches unity but is still slightly in excess (1.01 E+00).

This analysis considers the maximum possible concentrations at the receptor (remaining activity divided by release volume) but does not consider the retardation factor's peak spreading, which would spread out the mass along the plume, generally decreasing the actual maximum activity at the reception location.

When both the reactor technology and final location are selected, it may be necessary to re-evaluate the potential impact of an accidental release to groundwater. Furthermore, it may be possible to better quantify greater attenuation due to dilution and/or dispersion. These factors will be affected by the final selected location of the hypothetical release and its flow path length to the nearest surface water.

2.4.13.4 Possible Alternative Conceptual Models

The current evaluation uses the accidental release scenario assumptions described in Section 2.4.13.1. Alternate models could assume the following:

- Different activities or identities of isotopes in accidentally released liquid waste could be considered (which could increase or decrease potential exposure).
- The release could occur elsewhere within the PPBA with or without additional mitigating factors for release control.
- The release could be contained, not mixed with groundwater, and not be transported to eventual release to surface water (which could decrease potential exposure).
- The release could be greatly diluted by mixing with groundwater and/or surface water (which could decrease potential exposure).
- Attenuation by sorption to aquifer matrix might be greater than assumed (site-specific sorption analyses still pending), leading to greater attenuation and reduction of activity at the receptor location (which could decrease potential exposure).

- The volume and/or composition and total activity of the release in the final design could be different (which could increase or decrease potential exposure).

2.4.13.5 Results

The results (maximum remaining concentration) associated with including attenuation factors are shown in Table 2.4-48, and a summary of Unity Rule calculations by technology is provided in Table 2.4-49. Based on NRC standards, the sum of the fractions of the radionuclide concentration to the respective ECL value from 10 CFR Part 20, Appendix B, Table 2, column 2 should not exceed 1.

Based on the Unity Rule calculations:

- The composition of the initial potential release materials yields a sum of ratios of concentrations to respective ECLs that are above unity (i.e., exceed 1) for all assessed technologies.

- WEC is predicted to exceed unity at the nearest receptor location after attenuated travel. TerraPower and X-energy technologies are not predicted to exceed unity at the receptor location after attenuated travel.

- For sensitivity analysis, at one-half the attenuated travel time, only X-energy technology is estimated to be below unity at the receptor location.

- For sensitivity analysis, at double the attenuated travel time, Both TerraPower and X-energy technologies are estimated to be below unity at the receptor location.

Future decisions on placement and choice of technologies may result in the modification of these results and will be incorporated into additional accidental release modeling and assessment for the construction permit or licensing application stage of the project, if necessary, including site-specific partition coefficients.

For some isotopes with short half-lives, the decrease in radioactivity with attenuated travel is substantial. However, such attenuation may not be sufficient in every case to achieve Unity Rule compliance. Unity Rule calculations for isotopes with long half-lives and great exceedances of unity after travel to a receptor location are still expected to exceed ECL acceptable values even when retardation, mixing with groundwater, dispersion, or mixing with the receiving water are considered.

Initially, potential exposure was assessed using no attenuation factors and a conservative (fast) estimate of travel time to assess activities at the surface water locations following an accidental release. Then, refinements, including conservative adsorption values and radioactive decay (crediting retardation), were added to the assessment. Of the radionuclides identified in Table 2.4-32, most have very short half-lives relative to travel time, leading to notable attenuation by radioactive decay. Many isotopes have sufficient time during travel to undergo numerous half-lives of decay time. Future choices of technology and plant placement may also reduce projected radioactivities at potential points of exposure. Additional analyses (including radioactivities of daughter-products produced during transport) will be necessary when final location and reactor technology are chosen.

2.4.13.6 Summary of Conservative Assumptions Employed in the Analysis

The shortest travel time to the closest potential receptor was estimated from particle tracking simulations based on the MODFLOW numerical groundwater flow model. Isotopes, volumes, and activities were obtained from the three technologies that provided these inputs: TerraPower, X-energy, and WEC. The concentration activity (µCi/ml) for each isotope for each technology was provided by the vendor or calculated from the supplied data at the point of potential release. Retardation factors of travel for individual elements' travel due to adsorptive retardation were based on linear sorption assumptions, and K_d values were taken from available literature values, assuming the sand-specific K_d to be least retarding. This retarded travel time was then applied to radioactive decay based on isotope-specific half-lives from literature values. Ignoring the peak-spreading of retarded travel of a solute slug and assuming the remaining radioactive solute would be released to the potential receptor at one time ("maximum possible activity concentration"), the initial release activity concentration was decayed based on the number of half-lives in the retarded travel time. Conservative aspects of these calculations include: (1) all released isotopes are immediately introduced into the groundwater flow regime for transport; (2) the generally least retarding matrix (K_d from sand) was used, leading to the shortest retarded travel time; (3) no peak activity concentration decrease during transport is expected except by radioactive decay (maximum concentration is expected to decrease with retarded travel while peak width increases); and (4) for exposure concentration aggregating (Unity Rule), all isotopes' peak activity concentration (after retarded travel and radioactive decay) are used, even though they will appear at the potential receptor at different times due to different retarded travel rates.

2.4.14 TECHNICAL SPECIFICATIONS AND EMERGENCY OPERATION REQUIREMENTS

Finished site grade is at an elevation of 810 ft. (247 m) NAVD 88. Sections 2.4.2, 2.4.3, 2.4.4, 2.4.5, 2.4.6, 2.4.7, 2.4.8, and 2.4.9 describe controlling hydrological events that may affect the Project site. Section 2.4.10 describes the flooding protection requirements for safety-related SSCs from design basis flood events. As described in Section 2.4.10, the plant will be designed and constructed to prevent flooding that could compromise any SSC in performing their intended safety function.

Accordingly, there are no requirements for emergency protective measures designed to minimize the impact of hydrology-related events on safety-related SSC, and none are incorporated into the technical specifications or emergency operating procedures. The need for such emergency protective measures will be reevaluated at the construction permit or license application stage.

5 minute	1	0.328 (HMR-52 Figure 36)	1-hr., 1-mi^2 PMP	6.2

Key: mi^2 = square mile; PMP = probable maximum precipitation; in. = inch; hr. = hour

Table 2.4-12
Manning's Roughness Coefficients

Manning's Roughness Category	Manning's Roughness Coefficient		
	High[a]	Medium[a]	Low[a]
Grass	0.4[b]	0.2[b]	0.03[c]
Gravel	0.1[b]	0.04[b]	0.02[d]
Pavement	0.05[b]	0.02[b]	0.011[e]

Source: From ADWR's State Standard for Identification of and Development Within Sheet Flow Areas (Reference 2.4-1).From USDA TR-55 (Reference 2.4-43).

Notes:

(a) The categories "high," "medium," and "low" reflect the range of guidance for Manning's roughness coefficients for each land cover type.

(b) From the FLO-2D Reference Manual (Reference 2.4-11).

(c) From Open-Channel Hydraulics (Reference 2.4-6).

Table 2.4-13
Project Site FLO-2D Result Summary

Models	Max. MWSEL (ft. NAVD 88)[(a)]	Site Finish Grade (ft. NAVD 88)	Building Finish Grade (ft. NAVD 88)[(b)]	Max. Flood Depth (ft.)[(c)]
Column ID	**A**	**B**	**C**	**D**
North Plant Complex	811.04	810	810.5	0.54
Middle Plant Complex	811.69	810	810.5	1.20
South Plant Complex	811.17	810	810.5	0.67

Notes:

(a) Maximum water surface elevations (MWSEL) are representative of the majority of the site. There are spots with higher elevations. A detailed study during COLA will identify elevations near safety-related doors of safety-related building(s).

(b) It is assumed that the building finish grades are 6 in. higher than the site finish grade. (COL C = COL B + 6")

(c) Flood depth is calculated by subtracting max water surface elevation from building finish grade. (COL D = COL A – COL C)

Key: MWSEL = maximum water surface elevations; ft. = feet; NAVD 88 = North American Vertical Datum of 1988

Table 2.4-21a
Windspeed Duration Adjustment – ACES

General		
Wind observation type	Shore (windward)	
Wind fetch options	Deep restricted	
Breaking criteria	0.780	
Item	**Value**	**Units**
Elevation of observed wind (Zobs)	30.00	ft.
Observed wind speed (Uobs)	42.90	mph
Air sea temperature difference (dT)	0.00	deg F
Duration of observed wind (DurO)	10.00	minute
Duration of final wind (DurF)		minute
Latitude of observation (LAT)	36.32	deg
Restricted fetch geometry		
Number	**Fetch angle (deg)**	**Fetch length (ft.)**
1	0.00	9370.00
2	10.00	9370.00
Results		
Wind fetch length (F)	6871.33	ft.
Wind direction (WDIR)	10.00	deg
Eq. neutral wind speed (Ue)	38.98	mph
Adjusted wind speed (Ua)	53.97	mph
Mean wave direction (THETA)	7.00	deg
Wave height (Hmo)	0.89	ft.
Wave period (Tp)	1.72	sec.
Wave growth: Deep		

Key: ACES = Automated Coastal Engineering System; deg = degrees; F = Fahrenheit; ft. = feet; mph = miles per hour; sec. = second

Table 2.4-21b
Windspeed Duration Adjustment – Check

	Input	
	Wave Period, T (sec):	1.72
	g (ft/sec^2):	32.2
	Water Depth, h (ft):	126.5
	Fetch Length (ft):	6871.33
	Estimate of Wave Length, L (ft):	15.16
	Calculations	
Equation 3.36	$L = g/(2\Omega)T^2\tanh(2\Pi h/L)$	15.16
	Error (%)	0.00
	Output	
	Celerity, C (ft/sec)	8.81
	Time to Travel Fetch (min)	12.99

Key: ft. = feet; sec. = second

Table 2.4-22
Significant Design Wave Height

Input	
From ACES	H_{mo} = 0.89 ft.
From Dean & Dalrymple	L_p =15.2 ft.
Calculation	
$\varepsilon = 0.25\ H_{mo} / L_p$	0.01 (Equation applicable)
$H_{1/3} = H_{mo}$	0.89 ft.
Design Wave Height $H_{1\%} = 1.67\ H_{1/3}$	**1.49**

Notes:
Spreadsheet calculates the H1% from H_{mo}.
Conversion from H_{mo} to $H_{1/3}$ uses guidance from CETN I-45 (3/91).
Conversion from $H_{1/3}$ to H1% uses guidance from EM 1110-2-1614.
Key: ACES = Automated Coastal Engineering System; ft. = feet; sec. = second

Table 2.4-23
Wind Setup Calculation

Input	
Design Wind Velocity, U (mph)	42.9
Wind Fetch, F (ft)	6871.33
Average Water Depth, D (ft)	126.5
Calculations	
Convert Wind Fetch to Miles	1.30
$S = U^2F/(1400D)$	0.01
Result	
Wind Setup, ft	0.01

Key: ft. = feet; mph = miles per hour

Note:

(a) Coordinates are North Carolina State Plane (United States ft) which is based on North American Datum of 1983 (NAD83); elevations are based on North American Vertical Datum of 1988 (NAVD 88)

Key: bgs = below ground surface; ft. = feet; in. = inches; NP = not present; NR = Not recorded; lithology data collected from three borings (two borings near sentinel wells and one near a shallow or deep well) at each Aquifer Pumping Test (APT) location

Table 2.4-32
Bedrock Fracture Fabric Analysis

Boring Location	Start Depth (ft. bgs)	End Depth (ft. bgs)	Core Length (ft.)	Total # of Fractures	Fracture Density (per 100 ft.)
B-1	85	199	114	92	81
B-3	78	291	213	138	65
B-5	70	189	119	48	40
B-6	47	199	152	115	76
B-8	39	598	559	460	82
B-10	29	199	170	141	83
B-11	57	177	120	26	22
B-13	49	284	235	89	38
B-15	59	159	100	44	44
Total			**1,782**	**1,153**	
Average					**65**

Notes:

(a) Percent of fractures that are filled or closed >97%.

(b) Percent of fractures that are open <3%.

(c) Measured open aperture ranges from 5 to 172 mm, average 32 mm.

(d) Measured open aperture ranges from 0.2 to 6.8 in., average 1.3 in.

Key: bgs = below ground surface; ft = feet; in. = inch; mm = millimeter

Table 2.4-33
Groundwater Elevation Data
(Sheet 10 of 10)

Note:

(a) Indicates pre-development water level, or post-development or post-sampling water level that had not returned to static conditions; data not used in contouring.

Key: BTOC = below top of casing; ft. = feet; NAVD 88 = North American Vertical Datum 1988; NM = Not measured (well had not been installed and/or developed at time of measuring event); TOC = top of casing

Overall Average (Deep) =	**2.7E-02**
Overall Minimum (Deep) =	**6.4E-04**
Overall Maximum (Deep) =	**4.4E-02**

Note:

(a) Δh and L values were obtained from the potentiometric surface maps for the July 2024 through June 2025 events.

Key: ft. = feet; ft/ft = feet per foot; i_h = Horizontal hydraulic gradient; calculated by the formula $i_h = \Delta h/L$; Δh = Difference in hydraulic head between contour lines used to calculate i_h; L = Horizontal distance between contour lines used to calculate i_h; L measured in ArcMap to the nearest 10-ft increment; NC = not calculated

Table 2.4-35

Table 2.4-35
Vertical Hydraulic Gradient Calculations
(Sheet 2 of 2)

Date	Plant Complex	Screen Mid-Point Approach		
		Minimum i_v (ft/ft)	**Maximum i_v (ft/ft)**	**Average i_v (ft/ft)**
6/24/2025	North	0.080	0.48	0.32
	Middle	0.076	0.48	0.31
	South	**-0.029**	0.64	0.19
Overall Minimum i_v = **-0.041**				
Overall Maximum i_v = 0.58				
Overall Average i_v = 0.28				

Notes:

i_v Vertical hydraulic gradient (feet per foot [ft/ft]); positive value represents downward gradient, negative values (**in bold**) represent an upward gradient.

i_v was calculated in ArcMap as: shallow potentiometric surface - deep potentiometric surface/shallow well screen mid-point elevation surface - deep well screen mid-point elevation surface.

Potentiometric and screen elevation surfaces were generated in ArcMap on a six ft by six ft grid for each Plant Complex. Vertical hydraulic gradients are measured at each of the grid nodes from these surfaces.

Key: NA = not available, insufficient data.

Summary of Slug Test Results, South Plant Complex
(Sheet 2 of 2)

Average (South Plant Complex - OB/PWR)	**3.67**
Average (South Plant Complex - SBR)	**2.70E-01**
Average (South Plant Complex - DBR)	**1.58E-02**

Note:

(a) Indicates representative hydraulic conductivity value due to analysis method (see report text for additional information).

Key: "-" = Not analyzed because water levels were still recovering or method was inappropriate, i.e., falling head in unconfined well screen; DBR = deep bedrock (analyzed from DW wells); ft. = feet; ft/day = feet per day; KGS = Kansas Geological Survey, does not include skin effects; OB = overburden; PWR = partially weathered rock; SBR = shallow bedrock (analyzed from W wells)

Table 2.4-37
Summary of Sitewide Hydraulic Conductivity Values

Stratigraphic Unit	Hydraulic Conductivity (K) (ft/day)[(a)]			Wells Tested
	Minimum	Maximum	Average	
OB/PWR Wells	1.44	16.7	6.37	4
All Bedrock Wells	5.03E-06	14.9	9.08E-01	23
SBR Wells	7.09E-04	14.9	1.63	11
DBR Wells	5.03E-06	1.80	2.49E-01	12

Note:

(a) K values from slug tests (Table 2.4.36).

Key: DBR = deep bedrock (analyzed from DW wells); ft/day = feet per day; OB = overburden; PWR = partially weathered rock; SBR = shallow bedrock (analyzed from W wells)

Table 2.4-38
Summary of Lugeon Packer Test Results

Boring Location	Test Interval (ft. bgs)	Average Hydraulic Conductivity (K) (ft/day)	Average Flow (gpm)	Fracture Aperture (in.)
B-3 (North Plant Complex)	Zone 1 (148.4 – 159.6)	4.56E-03	0.06	1.18
	Zone 2 248.4 – 259.6	2.06	27.69	0[(a)]
B-8 (Middle Plant Complex)	Zone 1 165.4 – 176.6	9.58E-02	1.12	1.11
	Zone 2 236.4 – 247.6	2.67	29.56	6.11
B-13 (South Plant Complex)	Zone 1 61.4 – 72.6	2.22E-03	0.01	0.20
Zone 1 Average		**3.42E-02**	**0.4**	**0.83**
Zone 2 Average		**2.37**	**28.63**	**3.06**

Note:

(a) Aperture width was 0, however there are ten fractures shown by acoustic televiewer (ATV) within this test interval; two of the fractures listed as open but had no measured aperture width.

Key: bgs = below ground surface; ft. = feet; ft/day = feet per day; gpm = gallons per minute; in. = inch

.

Table 2.4-39a
Summary of Aquifer Pumping Test Results, North Plant Complex

Well Identification	Distance from PW-1 (ft.)	Maximum Drawdown (ft.)	Aquifer Zone	Test Method	Transmissivity (ft^2/day)	Hydraulic Conductivity[(a)] (ft/day)	Storativity

Table 2.4-39c
Summary of Aquifer Pumping Test Results, South Plant Complex
(Sheet 2 of 2)

Well Identification	Distance from PW-3 (ft.)	Maximum Drawdown (ft.)	Aquifer Zone	Test Method	Transmissivity (ft^2/day)	Hydraulic Conductivity[a] (ft/day)	Storativity
Distance-Drawdown			DBR	Hantush	4.29	2.15E-01	2.49E-06
		Average (DBR)			**1.40**	**7.02E-02**	**1.54E-03**

Note:

(a) K=T/b where K=hydraulic conductivity, T=Transmissivity, and b=saturated aquifer thickness (assumed to be 20 ft equal to screen length).

Key: ft – feet; ft^2/day - square feet per day; ft/day - feet per day; gpm - gallons per minute (pumping rate in pumping well); PW - pumping well; DBR - Deep Bedrock

Table 2.4-40
Average Linear Groundwater Velocity Calculations

Stratigraphic Unit	Hydraulic Conductivity (K)[a] (ft/day)	Average Horizontal Hydraulic Gradient[c] (i_h) (ft/ft)	Maximum Horizontal Hydraulic Gradient[c] (i_h) (ft/ft)	Specific Yield (Effective Porosity, n)	Average Horizontal Flow Velocity[d] (V_{avg}) (ft/day)	Maximum Horizontal Flow Velocity[d] (V_{max}) (ft/day)
Overburden/Partially Weathered Rock (OB/PWR)[b]	6.37	3.8E-02	9.2E-02	0.20	1.2	2.9
Shallow Bedrock (SBR)[b]	1.63	3.8E-02	9.2E-02	0.019	3.3	7.9
Deep Bedrock (DBR)[b]	2.49E-01	2.7E-02	4.4E-02	0.019	0.35	0.58

Notes:

(a) Average K values from slug tests for each stratigraphic unit (Table 2.4.12-7).

(b) K values for SBR and DBR from all three Plant Complexes; K values for OB/PWR from Middle and South Plant Complex only.

(c) Represents average or maximum ih for each stratigraphic unit (Table 2.4.12-4).

(d) Vavg and Vmax calculated using Darcy's Law: V = K*ih/n; Vavg uses average K and average ih and Vmax uses average K and maximum ih.

Key: ft/day - feet per day; ft/ft - feet per foot

Table 2.4-41
Historical Groundwater Use (Vicinity)

County	Recreational	Energy	Industrial	Mining/ Agriculture	Public Water Supply	Total
Forsyth	--	--	--	--	0.22	0.22
Guilford	0.050	-	0.040	--	0.86	0.95
Rockingham	--	--	--	--	0.10	0.10
Stokes	--	0.10	-	--	0.01	0.11
Total (mgd)	**0.050**	**0.10**	**0.040**	**--**	**1.2**	**1.4**
Portion of Overall Use (%)	**4**	**7**	**3**		**86**	

Notes:
Values shown in million gallons per day (mgd) for 2022.
Key: "—" = no water use reported

	7	Deciduous forest	Recharge	2.45	in/yr
	8	Evergreen forest	Recharge	3.87	in/yr
	9	Mixed forest	Recharge	5.86	in/yr
	10	Shrub/Scrub	Recharge	16.9	in/yr
	11	Grassland/herbaceous	Recharge	16.9	in/yr
	12	Pasture/Hay	Recharge	16.9	in/yr
	13	Cultivated crops	Recharge	5.99	in/yr
	14	Woody wetlands	Recharge	0	in/yr
	15	Emergent herbaceous wetlands	Recharge	0	in/yr

Notes:

Hydraulic properties (Kxy, Kz, and Recharge) are represented by zones. Boundary conditions (drains and rivers) are represented by reaches.

All recharge zones and boundary conditions apply to layer 1.

All values rounded to three significant digits.

Key: ft. = feet; in. = inches; yr. = year; Kxy = horizontal hydraulic conductivity; Kz = vertical hydraulic conductivity

Table 2.4-45
Estimated Minimum and Median Particle Travel Times[(a)]

Site	Particle Starting Position	Minimum Particle Tracking Travel Time In Days (Years)	Median Particle Tracking Travel Time In Days (Years)
North Plant Complex	PPBA Perimeter	45.0 (0.12)	2,452 (6.7)
Middle Plant Complex	PPBA Perimeter	35.3 (0.10)	2,961 (8.1)
South Plant Complex	PPBA Perimeter	95.6 (0.26)	2,821 (7.7)
North Plant Complex	PPBA Center	27,253 (75)	498,514 (1,366)
Middle Plant Complex	PPBA Center	10,018 (30)	95,005 (260)
South Plant Complex	PPBA Center	2,369 (6.5)	26,238 (72)

Note:

(a) Based on particle tracking results from the 3D Numerical Groundwater Flow Model.

		WEC	7.13E+02
Median Travel Time (Center PPBAs)	26238	TerraPower	7.04E-04[(a)]
		X-energy	0.00E+00[(a)]
		WEC	1.01E+00

Note:

(a) Values are less than unity (1.0).

2.5 GEOLOGY, SEISMOLOGY, AND GEOTECHNICAL ENGINEERING

This section describes the geology, seismology, and geotechnical engineering characteristics from the Site Region to the Site Location level of detail. As described in Section 2.0, the Project site can accommodate up to three Plant Complexes, each considered for siting a nuclear power facility. A specific technology has not been selected; therefore, a PPE is assigned to the grouping of the three locations.

The following NRC regulatory guidance was used for this section: NRC RG 1.206, *Combined License Applications for Nuclear Power Plants (LWR Edition)*, RG 1.208, *A Performance-Based Approach to Define The Site-Specific Earthquake Ground Motion*, and RG 1.70*, Standard Format and Content of Safety Analysis Reports for Nuclear Power Plants (LWR Edition, Rev. 3).* NRC Technical Report (NUREG) 0800, *Standard Review Plan for the Review of Safety Analysis Reports for Nuclear Power Plants: LWR Edition*, provides guidance for development of Section 2.5.1.

These guidance documents provide the principal seismic and geologic considerations for potential nuclear power plant sites. RG 1.208 stipulates that investigations are performed at four geographic levels: the Site Region (200 miles [mi.] [320 kilometers {km}]), Site Vicinity (25 mi. [40 km]), Site Area (5 mi. [8 km]), and Site Location (0.6 mi. [1 km]) radii. (Table 2.5-1). These distances were measured from the Project site boundary that was defined as the combined North, Middle, and South Plant Complex area. The terms are used in Sections 2.5.1 through 2.5.3 to describe the specific locations of investigation and characterization.

Section 2.5.1 describes the basic geologic and seismic information. Section 2.5.2 describes the vibratory ground motion at the Project site, including an updated seismicity catalog, and seismic sources. Section 2.5.3 describes the potential for surface faulting and deformation in the Site Area and Sections 2.5.4 and 2.5.5 describe the stability of subsurface materials, foundations, and slope stability at the Project site.

A field investigation and laboratory testing program and a literature review of relevant geologic and seismic literature were conducted. The investigations and literature review have not identified geologic or seismic hazards that would screen out the site from consideration for building a nuclear power plant.

2.5.1 GEOLOGIC CHARACTERIZATION INFORMATION

The geologic and seismologic information presented in this section was developed through a review of published scientific literature, interpretation of available scientific figures, a review of other peer-reviewed publications, and analysis of site-specific data. This section demonstrates compliance with the requirements of 10 CFR 100.23(c).

Section 2.5.1 describes the geological and seismological characteristics of the Site Region (200 mi. [320 km]), Site Vicinity (25 mi. [40 km]), Site Area (5 mi. [8 km]), and Site Location (0.6 mi. [1 km]) radii. Section 2.5.1.1 describes the physiographic, geologic, and tectonic characteristics of the Site Region. Section 2.5.1.2 describes the physiographic, geologic, and tectonic characteristics of the Site Vicinity, Site Area, and Site Location. The geological and

seismological information presented in this section was developed in accordance with NRC RG 1.206, RG 1.208, and NUREG-0800.

2.5.1.1 Regional Geology

This section discusses the regional geologic and seismic characteristics within a 200-mi. (320-km) radius of the Project site as captured in Figure 2.5-1. The physiography and geomorphology, geologic setting, stratigraphy, and tectonic setting are described below. The information provided summarizes this broad and complex area and is supported by numerous referenced sources. The Site Region includes the majority of NC, South Carolina, Virginia, and West Virginia, as well as small portions of northeast Georgia, eastern Kentucky, and eastern Tennessee.

2.5.1.1.1 Regional Physiography and Geomorphology

The Site Region is plotted in Figure 2.5-1 with respect to the physiographic provinces and sections as defined by Reference 2.5-1. It comprises the Appalachian Highlands and Atlantic Plain divisions of the United States. The Appalachian Highlands division comprises seven physiographic provinces, four of which are within the Site Region: the Appalachian Plateau, Valley and Ridge, Blue Ridge, and Piedmont provinces. Specifically, the Project site is within the Piedmont Uplands section of the Piedmont province. The southeastern portion of the Site Region encompasses the Coastal Plain province of the Atlantic Plain division, which is oriented parallel to the Atlantic coast shoreline (Figure 2.5-1). The major physiographic provinces are strongly controlled by geologic strata and structures (Reference 2.5-2). As a result, these physiographic provinces provide the basis for organizing the descriptions of geologic features in this section. Descriptions are organized geographically west to east as they are encountered in the Site Region.

2.5.1.1.1.1 Physiography and Topography of the Appalachian Plateaus Province

The Appalachian Plateau physiographic province extends over a length of 960 mi. (1540 km) and laterally extends over 220 mi. (350 km) in places, making it the largest province of the Appalachian Highlands division. It is a synclinal foreland basin that formed during Late Paleozoic time from erosion of a folded crystalline mountain range present to the east. The western portion of the province is underlain by Permian rocks with moderate topographic relief. The eastern margin is a high rim, extending from New York state to northern Alabama that is underlain by thick sequences of sandstone and conglomerate rocks interbedded with shale that are more resistant than the Permian rocks to the west forming higher ridges with more topographic relief. Sedimentary rock sequences are underlain by Precambrian crystalline basement rocks, generally thicken from west to east within the province and range in thickness from approximately 2800 feet (ft.) (850 meters [m]) in the western extent (outside the Site Area) to 25,000 ft. (7620 m) at the Allegheny Structural front (Reference 2.5-3).

Topographically, the province increases in ruggedness gradually from west to east. Topographic relief in Ohio ranges from approximately 295 to 490 ft. (90 to 150 m), while it ranges from 980 to 2950 ft. (300 to 900 m) in the eastern portions of West Virginia. The relief is the result of large rivers dissecting the resistant sandstone caps to form deep gorges, such as the New River Gorge in West Virginia along with several smaller gorges along the West Branch of the Susquehanna River, the Monongahela River, and Tennessee River. The areas surrounding the rivers are characterized by gentle slopes in the base of narrow valleys, with flat, plateau-like

areas restricted to the crests of hills or mountains. The southern reaches of the province in Tennessee and Alabama are more prototypically plateau-like with gently sloping land in the upland sections (Reference 2.5-4).

2.5.1.1.1.2 Physiography and Topography of the Valley and Ridge Province

The Valley and Ridge province is a narrow band east of the Appalachian Plateau that extends more than 1180 mi. (1900 km) from New York state to central Alabama. The province coincides with the outcrop of the folded and faulted rocks of the Appalachian system that were deposited without contemporaneous volcanism. The province is typified by broad valleys underlain by carbonates and shale, while the adjacent ridges are underlain by Silurian to Pennsylvania sandstones with thin shale sequences (Reference 2.5-4).

The entire southeastern edge of the province is an open valley generally termed the Great Valley, or locally called the Shenandoah Valley, the Cumberland Valley, and the Lebanon Valley, among several others. The northwestern edge of the province, particularly from Pennsylvania to southern Virginia, is characterized by high ridges separated by narrow valleys that extend up to 60 mi. (100 km) without being dissected by a stream (Reference 2.5-4).

Fenneman divides the Valley and Ridge province into three distinct sections: the Hudson-Champlain section, which is outside the Site Region, and the central and Tennessee sections within the Site Region (Reference 2.5-5). The central section is up to 80 mi. (130 km) wide and contains a broad sequence of sandstone-cored ridges separated by narrow valleys. Moving south within the central section, the province is more typified by ridges and narrow valleys. The Tennessee section extends from Wytheville, Virginia, to near Tuscaloosa, Alabama. The ridges here were obscured by low angle thrust sheets across Tennessee but reemerge in Alabama until they plunge beneath the Coastal Plain (Reference 2.5-4).

2.5.1.1.1.3 Physiography and Topography of the Blue Ridge Province

The Blue Ridge province is an elongated mountain range extending from Pennsylvania to northern Georgia. Fenneman (Reference 2.5-5) further subdivides the province into two distinctive sections separated by a broad and low gap near Roanoke, Virginia; the Site Region encompasses portions of both sections. The northern section is approximately 250 mi. (400 km) long with an average width of only 9 mi. (15 km) and drains primarily to the Atlantic Ocean. The southern section extends over 350 mi. (560 km), has an average width of approximately 75 mi. (120 km), and drains to the Gulf of America (Reference 2.5-4).

The northern Blue Ridge province occurs on the northwest flank of an anticlinorium with the underlying geology comprising: (1) a thick sequence of quartzite and phyllite rocks; (2) a massive, slightly metamorphosed basalt; and (3) coarse granodiorite. The ridge that extends from Pennsylvania to Roanoke, Virginia, is held up by one or more of the aforementioned rock masses. The anticlinorium core along the southeast face of the Blue Ridge consists primarily of igneous rocks of granitic composition that underlie isolated uplands associated with the adjacent Piedmont province (Reference 2.5-4).

The southern Blue Ridge section transitions from a plateau-like area in the northern portion with an average elevation of about 3000 ft. (910 m) to a more mountainous area in the southern reaches with altitudes of 4920 to 6560 ft. (1500 to 2000 m). The plateau-like reaches are underlain by slaty rocks that are less resistant to erosion than rocks in higher altitudes. The

mountainous areas in the south, such as the Great Smoky Mountains, are underlain by more resistant conglomerate and sandstone rocks. In the high areas of the southern Blue Ridge, long, narrow, steep-sided valleys resemble large trenches. Commonly, but not everywhere, these features crosscut the structural trends of the rocks. One crosscutting trench valley north of Asheville trends east and west for 37 mi. (60 km), crossing two low drainage divides (Reference 2.5-4).

2.5.1.1.1.4 Physiography and Topography of the Piedmont Province

The Piedmont province is between the Atlantic Plain division and the Blue Ridge province, extending from New Jersey to Alabama (Reference 2.5-1). The Project site occurs within the Piedmont province. Near the border with the Blue Ridge province, foothills within the Piedmont rise to an elevation of 2300 ft. (700 m), but the topography is generally gently rolling with an elevation ranging from 980 ft. (300 m) in the northern reaches, to 1500 ft. (450 m) in the southern extent. The Piedmont province slopes eastward to almost sea level in northern Jersey to approximately 790 ft. (240 m) at the most eastern extent in Georgia at the boundary with the Coastal Plain province (Reference 2.5-4).

The Piedmont is characterized by two contrasting terrain types. The bulk of the Piedmont province is underlain by Precambrian to Late Paleozoic igneous and metamorphic rocks and is morphologically characterized by monotonous ridges and ravines dissected in a dendritic pattern. The underlying rocks are mostly weathered to saprolite, a process that preserves the original rock character except the rock strength. Secondarily, from NC northward, several down-faulted Triassic- to Jurassic-aged basins bisect the Precambrian rocks. These Mesozoic basins generally have lower relief than the surrounding Piedmont (Reference 2.5-4). The closest example of this to the Project site is the Dan River basin, approximately 2 mi. (3.2 km) to the northwest. It is a topographic and structural rift basin filled with approximately 5000 ft. (1524 m) of Triassic sediments dipping 30 degrees to the west (Reference 2.5-6).

Most rivers in the Piedmont flow to the southeast, except the Delaware, Susquehanna, Potomac, James, Roanoke, and Coosa. Rivers traversing the Piedmont originate in the Piedmont itself or in the Blue Ridge province. Rivers in the Piedmont typically have narrow drainage basins for their size (Reference 2.5-4).

2.5.1.1.1.5 Physiography and Topography of the Coastal Plain Province

Within the U.S., the Coastal Plain province crosses 19 states to extend from Martha's Vineyard in Massachusetts, south along the Atlantic coast to Florida and west along the Gulf of America to the U.S. – Mexico border (Reference 2.5-1). The Site Region encompasses two of the six sections within the Coastal Plain province: the Embayed section and Sea Island section. The Cape Fear Arch separates the two sections (Reference 2.5-7).

The Coastal Plain is a region of broad, relatively flat terraces of primarily unconsolidated sediments overlying a crystalline basement that dips steeply toward the Atlantic Ocean. Sediments are predominantly siliciclastic and are derived from the erosion of the Piedmont, the Blue Ridge, and Appalachian Mountains. However, a band of Eocene and Oligocene carbonate rocks crop out in south-central NC. Sediments in the Coastal Plain thicken from tens of feet at the Fall Zone to more than 9843 ft. (3000 m) beneath Cape Hatteras, NC. Multiple marine transgressions and regressions since the Cretaceous were preserved as fluvial to marine

sediments. Surficial units are nearly flat-lying in most areas and are generally Miocene or younger in age (Reference 2.5-8).

Drainage within the Coastal Plain is generally toward the Atlantic Ocean and somewhat gentle due to low local relief (less than 99 ft. [30 m]). In the Site Region, drainage patterns are generally northwest to southeast. However, in the vicinity of the Cape Fear Arch to the southeast, the drainage patterns are characterized by deeply incised rivers with non-parallel terraces that resulted from long-term uplift and incision of the Cape Fear Arch river terraces (Reference 2.5-7).

2.5.1.1.2 Regional Geologic History

The geology of the Site Region has been studied intensively, particularly by Reference 2.5-9, Reference 2.5-10, and Reference 2.5-11. The region has experienced multiple phases of tectonic uplift and subsidence, resulting in a complex geological evolution. Numerous mountain-building periods (orogenies) and at least three continental separation events (rifts) have occurred within the region. In addition, other precursor tectonic events affected Laurentia that was initially a separate piece of ancestral North America. Whitmeyer et al. (Reference 2.5-11) describe the early geological events, beginning with the Hadean Eon that dates to at least 4 billion years ago (giga-annum [Ga]) involving the landmass of Laurentia. The oldest rocks of the Early Archean that occur within Laurentia have age ranges from 3.8 to 2.6 Ga. At this early time in the earth's evolution, the magmatic and subduction process of plate tectonics dominated. Whitmeyer et al. (Reference 2.5-11) developed a graphic, captured in Figure 2.5-2, to illustrate the progression of geological events in the development of Laurentia and ultimately the geological characteristics of southeastern North America and the region surrounding the Project site.

Reference 2.5-12 notes five stages of the earth's approximately 4.8 Ga evolution:

1. In the first few tens of millions of years, accretionary processes lead to the formation of the planet and subsequently the core and mantle system

2. Formation of a crustal layer in a pre-plate-tectonic regime until 3.0 Ga

3. High temperature subduction and shallow slab breakoff during an initial plate-tectonic regime from 3.0 to 1.7 Ga

4. Environmental, evolutionary, and lithospheric stability from 1.7 to 0.75 Ga

5. Modern era cold subduction regime from 0.75 Ga to present

During stages three, four, and five, there have been multiple cycles of supercontinent formation and fragmentation, and reassembly.

During the Early Proterozoic, beginning at approximately 2.5 Ga, the protocontinents that either existed or had developed during the Archean began to experience rifting and dispersion. These processes created new ocean crust and developed passive margins. The Grenville orogeny is the earliest orogeny to record geological events within the Appalachians. Prior to the Grenville orogeny, the Trans-Hudson orogeny had occurred farther west and the convergence of landmasses created the supercontinent Nuna/Columbia. The Mesoproterozoic Era, beginning at 1.6 Ga, included the reorganization of Nuna/Columbia and the gradual amalgamation of the

landmass Rodinia by way of the Grenville orogeny, which occurred along the eastern and southern margins of Laurentia (Reference 2.5-11). Swanson-Hysell et al. describe the amalgamation of Laurentia's Archean provinces approximately 1830 million years ago (mega-annum [Ma]). Following was approximately 700 million years (my) of accretionary orogenesis along the active southeastern margin. The accretionary orogenesis was characterized by the subduction of oceanic lithosphere, formation of volcanic arcs and back-arcs, and episodic continental accretion. This period spanned from the Late Paleoproterozoic and Mesoproterozoic Era. The result was n significant accretionary growth of the present-day North American crust. The closure of the Unimos Ocean ended the period of accretion (Reference 2.5-13).

The Grenville orogeny was a major mountain-building event both in physical size of the orogen and the duration of activity, which occurred from approximately 1090 to 980 Ma (Reference 2.5-13). Within the Grenville orogen, the Grenville orogeny caused ductile thrusting, nappe formation, and crustal imbrication associated with high-grade metamorphic conditions. The scale of crustal shortening within the Grenville orogen is indicated by the northwestern extent of deformation, which cuts across the approximately 746-mi.-wide (1200-km-wide) Great Proterozoic accretionary orogen from southwest to northeast at the Grenville Front (Reference 2.5-13).

Figure 2.5-3 shows the position of geological elements resulting from the Grenville orogeny relative to the present-day southeastern U.S. During the Grenville orogeny from 1090 to 980 Ma, the accreted Proterozoic crust was reworked and a large orogenic plateau later experienced extensional collapse prior to the formation of the Grenville Front tectonic zone (Reference 2.5-13). The last major contraction to occur in the Grenville orogeny was the Rigolet phase, which lasted from approximately 1010 to 980 Ma. This phase resulted in the development of the Grenville Front and the parautochthonous belt.

For approximately 200 my after the Grenville orogeny (circa 980 to 780 Ma), Laurentia experienced relative tectonic stability (Reference 2.5-13) until rifting and the emplacement of the associated Gunbarrel large igneous province (circa 778 Ma). After the 778 Ma event, progressive rifting of continents from Rodinia margins continued until the end of the Neoproterozoic Era. The exposed highlands, which developed after the Grenville orogeny, were eroded to sea level by the beginning of the Cambrian. Fault block basins to the north, northwest, and southeast were filled with clastic sediments from the erosion of higher elevation rocks. Sedimentation began as the Grenville highlands were eroded and block fault basins were filled with clastic sediments from the highlands located toward the west, northwest, and southeast (Reference 2.5-9). The Ouachita belt formed as a result of the closure of the Rheic Ocean, followed by the development of the Alleghanian orogen. The Rheic Ocean closure also caused the burial of the Laurentian platform by thick Pennsylvanian clastic wedges that increased in thickness westward (Reference 2.5-14). The Middle Proterozoic granulite terrane was uplifted and eroded due to the initiation of continental rifting at about 700 Ma along trends that eventually became Appalachian structural trends (Reference 2.5-15).

The evolution of the Appalachian region continued with the breakup of the Rodinia supercontinent during the Neoproterozoic at 1.0 Ga. Geologic activity during the Early Neoproterozoic included isolated basin development, which was then followed by large igneous provinces and rifted margins. Stratigraphic analyses have indicated that rifting and volcanism were heterogeneous and diachronous (Reference 2.5-11). The Iapetan margin experienced rifting and the Iapetus Ocean formed at approximately 690 to 570 Ma (Reference 2.5-9). Swanson-Hysell et al. note that a period of approximately 700 my of accretionary orogenesis

occurred along the active southeastern margin of Laurentia (Reference 2.5-13). Processes during this period included the subduction of oceanic lithosphere, the formation of volcanic arcs and back-arcs, and the episodic accretion of continents. During this period, major accretionary crustal growth occurred from active-margin tectonics.

The rifting of Laurentia along its margins during the Neoproterozoic through the Cambrian and the assembly of Gondwana was studied by van Staal and Zagorevski (Reference 2.5-16). The final assembly of Gondwana during the Cambrian was followed by global tectonic plate reorganization that resulted in the beginning of subduction that involved Laurentia, West Gondwana, and Baltica. The accretion of arc terranes along the Appalachian-Caledonian margin of the Iapetus Ocean began at the end of the Cambrian Period (515 to 505 Ma) during the Taconic orogenic cycle, which continued until the onset of the collision of Laurentia, Baltica, Ganderia, and East Avalonia at approximately 430 to 426 Ma. This collision created the Laurussian continent and caused the closure of the Iapetus Ocean. The closure of the Iapetus Ocean in the Appalachians was followed by the Acadian and Neoacadian orogenic cycles that were a result of the accretion of West Avalonia, Meguma, and the Suwanee terranes with Laurentia. The convergence of Laurentia with Baltica and Avalonia continued during the Devonian Period (Reference 2.5-16).

The Cherokee orogeny, a lesser-known orogenic event, has been described by Hibbard et al. (2013) (Reference 2.5-17) and Hibbard et al. (2010) (Reference 2.5-18) as a thermo-tectonic event that affected the Carolina terrane and Carolina. The effects of the Cherokee orogeny are most prominent in central NC with indications also found in Laurentian rocks. The Cherokee orogeny appears to have been contemporaneous with the Salinic orogeny in the northern Appalachians. Age dating using 40Ar/39Ar isotopes places this activity at 450 Ma (Late Ordovician), which is approximately the time of other events such as the Cherokee unconformity on the Laurentian margin at approximately 444 Ma, the supra-subduction zone magmatism in peri-Laurentian rocks at approximately 460 to 430 Ma, and the metamorphic events in peri-Laurentian rocks at approximately 430 Ma. The cause of the orogeny is hypothesized to be a result of the accretion of Carolinia to Laurentia.

The Paleozoic Era hosted the Silurian Salinic orogeny and the Devonian – Carboniferous Acadian and Neoacadian orogenies. The Salinic orogeny was prominent in the northern Appalachians and the Acadian-Neoacadian orogenies were more influential in the central and southern Appalachians. The eastern margin of Laurentia developed into the Appalachian-Caledonian orogenic belts as Laurentia converged with the landmasses of Baltica and West Gondwana. The result was the accretion of the Pangea supercontinent (Reference 2.5-11) and the closure of the Rheic Ocean (Reference 2.5-16). Figure 2.5-4 illustrates the paleogeography at the time of the Alleghanian orogeny prior to the separation that formed the Atlantic Ocean (Reference 2.5-16).

As continental separation occurred, the oceanic crust of the Iapetus Ocean formed. Continental margin and shelf sediments were deposited on the edge of the craton near the beginning of the Cambrian. Crustal compression that preceded the formation of the Appalachian orogen included the amalgamation of exotic (suspect) terranes during the Penobscottian orogeny at approximately 550 to 490 Ma; the Taconian orogeny from approximately 470 to 440 Ma, which included the closing of the Iapetus Ocean and the accretion of previously amalgamated terranes and possibly other terranes to Laurentia; the Acadian orogeny occurring primarily in New England from approximately 400 to 380 Ma; and the Alleghanian orogeny occurring approximately from 330 to 270 Ma in which the accretion of the easternmost terranes, collision

with Gondwana, and westward thrusting of terranes onto autochthonous North America (Reference 2.5-19). The timing and sequence of accreting terranes to Laurentia is illustrated in Figures 2.5-5 and 2.5-6 (Reference 2.5-10).

Reference 2.5-20 describes the aftermath of the Pangea breakup and the fragmentation of eastern North America. The fragmentation created the North American rift system during the Triassic and Jurassic Periods. This rift system consists of a series of exposed and buried basins that range from northern Florida to the Grand Banks of Canada and is divided into three segments: northern, central, and southern. Figure 2.5-7 shows the distribution of the basins and the positioning of the segments.

The basins are typically asymmetric and form a half-graben that is bounded by border faults that involve basement rock. Figure 2.5-8 shows a cross section through the Danville basin, which is proximate to the Project site. The Danville basin actively formed from the Late Triassic through the Middle Jurassic Periods (Reference 2.5-20). Rifting in the southern Appalachians had stopped before the igneous activity and formation of the Central Atlantic Magmatic Province (CAMP) (Reference 2.5-21). The stratigraphy of the Dan River basin, which lies at the southern-most extent of the Danville basin and is approximately 4.5 mi. (7.2 km) east-northeast of the Project site, consists of organic-rich, thermally mature rocks. The rocks include coal, organic mudstone intercalated with siltstone, black organic beds, and siltstone that indicated hydrocarbon outgassing (Reference 2.5-22).

A massive rift zone developed within the Pangean supercontinent, during early Mesozoic time. The rift zone resulted in fragments of Pangea that are separated and preserved on the passive margins of eastern North America, northwestern Africa, and Europe. The fragment on the North American margin, the eastern North American rift system, comprises a series of exposed and buried rift basins extending from northern Florida to the eastern Grand Banks of Canada (Reference 2.5-20).

The eastern North American rift system is divided into three geographic segments: the southern segment encompasses the southeastern United States, the central segment encompasses the northeastern United States and southeastern Canada, and the northern segment encompasses the eastern Grand Banks of Canada. The boundary between the southern and central segments passes through Virginia and Maryland as a diffuse zone. The boundary between the central and northern segments follows the northern faulted margins of the Fundy and Orpheus basins and the Newfoundland fracture zone as a well-defined zone that trends west-southwest to east-northeast. Figure 2.5-7 shows these segments and the rift basins that formed, while Figure 2.5-8 depicts cross sections of the rift basins (Reference 2.5-20).

The presence of growth strata within the rift basin aid in determining the timing of rifting. In general, Late Triassic strata coarsen abruptly near rift basin border faults, which is interpreted to indicate a local source of topographic relief adjacent to the border faults during deposition. Ages of the preserved synrift strata in the three segments of the eastern North American rift system vary. In general, only Late Triassic strata are present in the southern segment, while Late Triassic- to Early Jurassic-aged strata are present in the central segment, and Late Triassic to Early Cretaceous strata are present in the northern segment (Reference 2.5-20).

The vertical sequence of climate-sensitive facies within individual basins indicate as Pangea drifted northward, facies changed as the basins passed from one climate zone to another. The transition from Carnian through Norian-age strata is characterized by apparent drying in eastern

North America (Reference 2.5-20). Figure 2.5-5 from Reference 2.5-10 summarizes the historical timeline of major tectonic events (excluding the Cherokee orogeny).

Whitmeyer et al. summarize the events from the Mesozoic to the present-day (Reference 2.5-23). After the early Mesozoic rift basins formed and faulting occurred in the Proterozoic to Paleozoic rocks of the Piedmont province, mafic dikes intruded in the Piedmont and Blue Ridge, and to a lesser degree, in the Valley and Ridge provinces during the Jurassic. Topographic gaps within the Blue Ridge are indicative of high-angle, northwest-striking faults that crosscut predominantly northeast-trending fabrics throughout the region. Within the Shenandoah River system, subparallel northwest-striking joint sets are frequent and tend to parallel the bends in the river. Also occurring are northeast-trending faults that may be reactivated Paleozoic structures. Whitmeyer et al. note that late overprinting features may be indications of crustal extension related to the breakup of the Pangea supercontinent and the opening of the Atlantic Ocean during the Mesozoic (Reference 2.5-23).

The result of the orogenies is captured in a model cross section, Figure 2.5-9, illustrating the complexity of the regional geological structure and stratigraphy (Reference 2.5-24).

2.5.1.1.3 Regional Stratigraphy

As described in Section 2.5.1.1.2, the Site Region has undergone a complicated geologic history that has been recorded in a complex assemblage of igneous, metamorphic, and sedimentary rocks and their structural relations. Figure 2.5-10 shows the geologic units within a 200-mi. (320 km) radius. The units tend to be distributed in parallel-sided zones that trend northeast to southwest throughout the Site Region. A comparison of the physiographic province map presented in Figure 2.5-1 and the bedrock geology map provided in 2.5-10 suggest that the linear physiographic provinces that trend northeast to southwest have similar stratigraphy, indicating that the provinces have similar geologic histories within each zone. As such, the physiographic regions provide a basis for the discussion of regional stratigraphy in this section.

The stratigraphy is described from west to east across the Site Region. Due to the complex nature of the subsurface geology in the Site Region, the main discussion focuses on the stratigraphy of NC and the geologic terranes recognized in the state, as captured in Figure 2.5-11. These geologic belts have similar rock types and geologic histories in the parts of the Site Region that lie in the adjacent states of Virginia, West Virginia, Kentucky, Tennessee, and South Carolina.

2.5.1.1.3.1 Stratigraphy of the Appalachian Plateaus Province

Rocks of the Appalachian Plateau occur approximately 90 mi. (145 km) northwest of the Project site in eastern Kentucky and the southern portion of West Virginia (Figure 2.5-10). Within the Site Region, the rocks are a thick sequence of Paleozoic sedimentary rocks ranging in age from the Cambrian to the Permian overlying Grenville basement rocks. The sedimentary package ranges in thickness from approximately 13,000 ft. (3962 m) at the northwestern edge of the Site Region to more than 26,000 ft. (7925 m) at the boundary with the Valley and Ridge province in southeastern West Virginia (Reference 2.5-3). In general, sedimentary strata in the western portion of the Appalachian Plateau province are flat lying, while thin-skinned deformation with large-scale thrust faults is recorded in rocks near the Valley and Ridge province (Reference 2.5-3).

The Cambrian to Ordovician rocks underlying the Site Region are primarily a sequence of dolomite and limestone with interbedded siliclastic sequences and lesser amounts of shale (Reference 2.5-3). The main Cambrian formations of the Conasauga Group include the Rome Formation, Pumpkin Valley Shale, Rutledge Limestone, and Rogersville Shale within Kentucky and equivalent formations in West Virginia. The Upper Cambrian comprises the Copper Ridge Dolomite overlain by the Rose Run Sandstone. The Ordovician strata are dominated by the Beekmantown Dolomite overlain by the Trenton-Black River group. In some areas, especially in Kentucky, the St. Peter Sandstone separates the Beekmantown from the overlying Trenton-Black River group. The upper Ordovician is composed of the Reedsville Shale and Juniata Formation (Reference 2.5-3; Reference 2.5-25).

The Silurian strata are predominantly a series of interbedded sandstone, carbonate, and shale rocks. The Lower Silurian is marked by the Tuscarora Sandstone that is pervasive in the Site Region. The Rose Hill Formation, comprising several shale beds, overlies the Tuscorara Sandstone. The Upper Silurian is dominated by carbonate beds of the McKenzie Limestone, Salina group, which is a series of interbedded anhydrites in places, and the Keyser Limestone (Reference 2.5-3; Reference 2.5-25).

The Devonian Rocks in the Site Region are predominantly thick shale with interbeds of shale and, to a lesser extent, limestone. The Helderberg Limestone and the overlying Oriskany Sandstone were deposited during the early Devonian and are overlain by the Onondaga Limestone and the Marcellus Shale within the Middle Devonian. The Upper Devonian is composed of the Brallier Shale, which can locally be subdivided based on organic content in the Rhinestreet Shale, the Hava Formation, and the Ohio Shale. The Brallier Shale is overlain by the Berea Sandstone at the end of the Devonian (Reference 2.5-3; Reference 2.5-25).

Ascending into the Mississippian, the Sunbury Shale is the basal unit marking the beginning of the Early Carboniferous of the Mississippian sequence. Above this shale are at least 30 separate beds that are undifferentiated farther east in the Slade and Borden Formations (Reference 2.5-25). The Late Carboniferous of the Pennsylvanian contains the Breathitt Group in Eastern Kentucky that is equivalent to the Pocohontas Group in West Virginia. The Conemaugh and Conemaugh/Monongahela overlie the Breathitt Group that marks the end of the Late Carboniferous in this area (Reference 2.5-3; Reference 2.5-25).

The lower portion of the Pennsylvanian primarily consists of thick, pebbly to conglomeratic quartzose sandstones of the Kanawha Formation and Pottsville equivalents but becomes more shaley to the east indicating a deep marine depositional setting. The Middle to Upper Pennsylvanian is predominately sequences of siltstone and shale, graywacke, and coal of the Conemaugh and Monongahela (Reference 2.5-26; Reference 2.5-25).

During the entire Permian, only the Elliot County igneous peridotite intrusion was emplaced in the Middle to potentially Upper Permian. Stratigraphically, rocks recording the Triassic, Jurassic, and Lower to Middle Cretaceous are missing in Kentucky. Rocks of the Upper Cretaceous, Paleocene, Eocene, Oligocene, Miocene, and Pliocene are absent in eastern Kentucky. Within the Holocene (last 11,700 years), most of the alluvial floodplain sediments are less than 10,000 years old (Reference 2.5-25).

2.5.1.1.3.2 Stratigraphy of the Valley and Ridge Province

The Valley and Ridge province is captured in Figure 2.5-10 as a series of linear, northeast-trending parallel ridges and valleys. The strata are similar to the Appalachian Plateau in age and lithology; however, the rocks are folded (Reference 2.5-3). Haynes et al. (Reference 2.5-27) presented a general overview of the structural geology and stratigraphy of the Valley and Ridge province, and this narrative is derived from their work.

Within the Valley and Ridge province, the prominent ridges are composed of highly resistant rocks, most often the Tuscarora Sandstone. In some instances, lower elevation ridges are capped by the Devonian Oriskany Sandstone, the Devonian Hampshire Formation, or the Devonian – Mississippian Price Formation. The valleys are typically underlain by rocks susceptible to physical weathering and erosion such as shales, or those susceptible to chemical weathering and erosion such as carbonates. The main valley-forming sequences within the Site Region are the Ordovician Reedsville Shale and the Devonian Marcellus Shale and Mahantango Formation. The main valley-forming carbonate sequences are the Cambro-Ordovician sequences of the Waynesboro and Beekmantown Formations, the Silurian and Devonian carbonate sequences (e.g., the Tonoloway and Helderberg Group), and the Mississipian carbonate sequence (e.g., the Greenbrier Limestone) (Reference 2.5-28).

2.5.1.1.3.3 Stratigraphy of the Blue Ridge Province

Terranes and belts consisting of primarily metamorphic rocks and igneous intrusions make up the Blue Ridge of eastern North America. Tectonostratigraphic terranes are defined as fault-bounded geologic areas that are of regional extent and are characterized by an internally homogeneous stratigraphy and geologic history that is different from that of adjacent terranes (Reference 2.5-15). The Appalachian Mountains have distinct terranes that were accreted to Laurentia at different times by the convergence of tectonic plates. The terranes typically preserve an imprint of past geologic events that have involved compressional, extensional, and translational tectonic forces (Reference 2.5-15). The physiographic province boundaries do not correspond one-to-one with the current understanding of terrane boundaries, and some terranes from the Blue Ridge extend into the Piedmont province.

Hatcher et al. identify the terranes and describe the characteristics of each (Reference 2.5-10). Figure 2.5-11 shows the locations of the terranes for the southern and central Appalachians.

2.5.1.1.3.3.1 Western Blue Ridge (Laurentia)

The Western Blue Ridge is a geologically complicated area and likely composed of several geologic terranes (Reference 2.5-29) including the Trimont Ridge Massif and the Mars Hill Terrane (Reference 2.5-10). The Western Blue Ridge is considered to be part of Laurentia and composed of gneisses that are over 1 Ga and overlain by younger sedimentary rocks (Reference 2.5-15).

2.5.1.1.3.3.2 Central Blue Ridge Terranes

The Central Blue Ridge terranes are similarly complicated to the Western Blue Ridge and are composed of several geologic terranes (Reference 2.5-29), including the Cowrock and Cartoogechaye (Reference 2.5-10). The Cowrock terrane is predominately metasandstone, schists with minor mafic and ultramafic rocks (Reference 2.5-10). The Cartoogechaye terrane is

predominantly metasandstone and ultramafic rocks with Grenville basement that were metamorphosed up to a granulite facies (Reference 2.5-10). The origin of these lithologic assemblages is debated, but Hatcher et al. infer that they were an assemblage of oceanic crust and mantle that was subsequently overlain by oceanic sediments (Reference 2.5-10).

2.5.1.1.3.4 Stratigraphy of the Piedmont Province

Similar to the rocks of the Blue Ridge province to the west, the Piedmont province comprises terranes and belts of primarily metamorphic rocks and igneous intrusions (Reference 2.5-29). Horton et al. (Reference 2.5-15) describe the tectonostratigraphic terranes of the central and southern Appalachians, and Hatcher et al. (Reference 2.5-10) further refined these descriptions. Terrane locations for the southern and central Appalachians are captured in Figure 2.5-11. The following narratives, unless otherwise noted, are primarily based on Horton et al. (Reference 2.5-15).

2.5.1.1.3.4.1 Inner Piedmont Composite Terrane

The Inner Piedmont composite terrane is a stack thrust sheet thought to contain several disrupted terranes of metamorphic rocks, primarily schists, gneisses, amphibolites, and few ultramafic bodies. A more recent study by Merschat and Hatcher (Reference 2.5-30) describes the Inner Piedmont as a composite terrane of the Tugaloo and Cat Square terranes that is highly metamorphosed and extends approximately from the NC – Virginia state line to central Alabama (Figure 2.5-11).

The presence of charnockitic gneiss in NC is interpreted to potentially be Grenville-age basement rock. Other terranes indicate the present of oceanic crust, such as the ultramafic Soapstone Ridge body near Atlanta, Georgia, and the mafic-ultramafic Hammett Grove metaigneous suite in South Carolina. The South Mountains of NC and the Clairmont Formation near Atlanta, Georgia, are diamictite gneisses that may represent metamorphosed mélange complexes. Other parts of the Inner Piedmont have a coherent stratigraphy of metasedimentary and metavolcanic gneisses and schists (Reference 2.5-15).

The Brevard fault zone separates the Inner Piedmont terrane from the Jefferson terrane and is considered a major crustal boundary. The Henderson Gneiss is southeast of the Brevard fault zone and is of the Late Proterozoic or Cambrian age, spanning approximately 74.56 mi. (120 km). There is no indication of the Henderson Gneiss within the Jefferson terrane northwest of the Brevard fault zone. A low-grade metamorphic body, the Chauga belt, at the northwest side of the Inner Piedmont terrane provides a juxtaposition between the Inner Piedmont terrane and the Jefferson terrane in Georgia, NC, and South Carolina (Reference 2.5-15).

The mylonitized Henderson Gneiss in the Brevard fault zone contains zircons that indicate a Uranium-Lead (U-Pb) age of 456 Ma, which has been interpreted as representing the age of mylonite formation during the Taconian orogeny. Granitic gneisses subject to regional metamorphism have indicated a Rubidium-Strontium (Rb-Sr) whole-rock ages of 460 ± 9 Ma, 431 ± 22 Ma, 429 ± 22 Ma, and 427 ± 9 Ma. The onset of Inner Piedmont terrane accretion is placed at approximately 460 Ma within the Middle to Late Ordovician and within the age of the Taconic orogeny in the northern Appalachians. Plutonism associated with the Taconic orogeny carried into the Silurian. Additionally, there is an indication that Acadian metamorphism is dated by 40Ar/39Ar hornblende ages to range from 358 to 333 Ma in the higher-grade metamorphic rock of the Alto allochthon, and ranges from 368 to 327 Ma in the Inner Piedmont terrane and in

lower grade metamorphic rock of the Chauga belt. Researchers disagree about whether the Brevard fault zone is a suture or terrane boundary, but it is possible that the Brevard fault could be a terrane boundary that structurally separates a terrane under the Alto allochthon and the Jefferson terrane (Reference 2.5-15).

2.5.1.1.3.4.2 Smith River Allochthon

The Smith River terrane in NC and Virginia (Figure 2.5-11) primarily comprises two major rock units. The Basset Formation is the lower unit, and it contains fragments from ultramafic and mafic rocks and is interpreted to contain an ophiolitic mélange similar to the Potomac and Jefferson. The upper part of the Bassett is an amphibolite overlain by schist and gneiss of the Fork Mountain Formation. The gneiss unit in the Fork Mountain Formation contains mélange that is similar to mélange in the Potomac terrane (Reference 2.5-15).

The Smith River rocks maintain a characteristic metamorphism that is high prograde, retrograde to greenschist facies, and a secondary prograde to staurolite grade. The metamorphic sequence is similar to that of the Peters Creek Schist of the Potomac terrane. The Bassett and Fork Mountain formations have been intruded by the Martinsville igneous complex, which includes the Leatherwood granite, the Rich Acres Formation (gabbro-diorite), and norite. The Leatherwood granite was dated using U-Pb age dating and Rb-Sr whole-rock dating as Middle Ordovician. The regional amphibolite-facies metamorphism in the Smith River terrane pre-dates the Leatherwood granite and is interpreted as Taconian (Reference 2.5-15).

The Smith River terrane is a fault-bounded synform situated within the Jefferson terrane, northwest of the Sauratown terrane. The Ridgeway thrust bounds the terrane on the west, while the Bowens Creek fault bounds the terrane to the east. However, the synform becomes more compact southeastward, and the bounding faults converge into the Brevard fault zone where the terrane pinches out. Younger rocks of the Martinsville igneous complex are truncated by the Ridgeway thrust, but the thrust is older than the Chatham fault. The Chatham fault divides the Ridgeway fault and juxtaposes the northern end of the Smith River terrane against upper Triassic rocks of the Dan River-Danville basin (Reference 2.5-15).

The Smith River terrane may be infolded and terminate within the Potomac composite terrane, or it may be another thrust slice of the terrane. Smith River terrane rocks may or may not correlate with those in the Inner Piedmont terrane. On aeromagnetic maps, the Smith River terrane appears similar to the Potomac terrane and distinctly different from the Inner Piedmont and Milton terranes. The age of the Smith River terrane metamorphism indicates it was amalgamated with its surrounding terranes during the Taconian orogeny (Reference 2.5-15).

2.5.1.1.3.4.3 Sauratown Mountains Anticlinorium

The Sauratown terrane of NC and Virginia is an elongated foliation dome (Sauratown Mountains) that trends north – northeast and was exposed in an opening of the Jefferson terrane during the Forbush thrust (Figure 2.5-11). The eastern portion of the terrane terminates at the Chatham fault that marks the western edge of the Triassic Dan River-Danville basin. The Chatham fault is interpreted to be coincident with an older ductile shear zone and connect to either the Forbush thrust or the Yadkin fault. The Sauratown Mountains represent the northeastern end of the Brevard fault zone, a linear feature the extends southwest to the Coastal Plain overlap and perhaps farther, which is a distance of more than 373 mi. (600 km) (Reference 2.5-15).

The terrane consists of a Grenville-age continental basement complex and a nonfossiliferous metasedimentary cover. Approximately half of the basement core is biotite gneiss (paragneiss) and schist. In the northern part of the terrane, granitic migmatite of possible Grenville-age is complexly interlayered with the biotite gneiss and schist. South and west of the Sauratown Mountains, the biotite gneiss and schist are typically thin-layered, contain no granitic rock, and are ambiguously related to the basement massif. The basement orthogneisses are 1.17 Ga and correlate to the Blue Ridge orthogneisses to the northwest. Sauratown terrane basement rocks were intruded by Late Proterozoic granites and felsic dikes. The dikes are similar to the Late Proterozoic Crossnore Complex of the Blue Ridge, which is related to Iapetan rifting (Reference 2.5-15).

Cross-bedded muscovitic quartzite that is at least 246 ft. (75 m) thick outcrops for approximately 15 mi. (24 km) along the middle of the Sauratown terrane. Its structural and stratigraphic relationship to the surrounding basement rocks and granite of the Crossnore Complex are possibly part of the cover sequence that may correlate to the Chilhowee Group. The Ashe Formation, which is a gritty biotite-muscovite gneiss containing blue quartz clasts outcrops at one location along the north side of the Sauratown terrane, is interpreted to be unconformably above the Grenville basement. The Ashe Formation is hypothesized to be in thrust contact with the Grenville-age basement rock (Reference 2.5-15).

2.5.1.1.3.4.4 Cat Square Terrane

The Cat Square terrane is bounded by the younger-over-older Brindle Creek fault to the west and the Central Piedmont suture to the east (Figure 2.5-11). It is noted to consist of a sequence of Silurian to Devonian metapsammite and pelitic schist that was intruded by Devonian to Mississippian granitoids that include the Toluca Granite at approximately 378 Ma and the Walker Top Granite at approximately 366 or 407 Ma. Rare mafic and ultramafic rocks occur in the eastern Cat Square terrane. The minimum sediment thickness is estimated at 13,123 ft. (4,000 m). Detrital zircons indicate that Cat Square terrane rocks have a maximum age of approximately 430 Ma, with both Laurentian (2.8, 1.8, 1.4, 1.1 Ga) and peri-Gondwanan (600, 500 Ma) affinities. Deposits on the oceanic crust indicate there are numerous mafic and ultramafic bodies; there is no continental basement in the Cat Square terrane. The Cat Square terrane is interpreted as a remnant ocean basin between Laurentia and the converging Carolina superterrane of peri-Gondwana that lasted for approximately 25 Ma. It was then subducted beneath Laurentia and migrated southward toward the southern Appalachians. The location and southwest migration of a clastic wedge and its structural patterns in the Inner Piedmont indicate that the collision direction was toward the northwest and the basin closed from the northeast to the southwest (Reference 2.5-30).

2.5.1.1.3.4.5 Milton Terrane

The Milton terrane of NC and Virginia has a strongly developed foliation with interlayered felsic and mafic gneisses and minor pelitic schist (Figure 2.5-11). Previously, the rocks had been described as part of the Charlotte belt and that the rocks are higher-grade equivalents of rocks in the Carolina slate belt of the Carolina terrane. The Milton terrane has also been compared to the Inner Piedmont composite terrane based on lithologies, deformational style, and chronology of Paleozoic folding, metamorphism, and igneous activity. Horton et al. note that while the Milton terrane has a similar aeromagnetic character to the Inner Piedmont terrane, the rocks are lithologically distinct from the Carolina slate belt of the Carolina terrane, but it remains a

possibility that a suture zone coincides with the steep metamorphic gradient between the two terranes (Reference 2.5-15).

The northern portion of the Milton terrane is predominantly composed of mafic and felsic metavolcanic rocks, the Shelton Granite Gneiss, and other unnamed biotite gneiss units. A U-Pb crystallization age of approximately 458 Ma from two sources of a meta-rhyolite indicates the presence of Ordovician volcanic rocks in the northern portion of the Milton terrane. In addition to these ages and combined with an age of 450 ± 1.8 Ma from the Old Mill granitic gneiss and the 424 ± 3 and 463 ± 14 Ma ages from the Shelton granite support the Ordovician age for the Milton terrane (Reference 2.5-31).

The rocks from the Milton terrane indicate the involvement of ancient continental crust in the production of these rocks. The presence of Mesoproterozoic xenocrystic zircon documented in the northern portion of the Milton terrane infers a crustal provenance. Additionally, the Chopawamsic terrane rocks have similar trace element concentrations as Milton terrane rocks and are indicative of a volcanic-arc setting. The similarity in rock mineral assemblages, timing of magmatism, and elemental compositions of the Milton and Chopawamsic terranes support the interpretation that they are correlative and were part of an Ordovician arc system built on Iapetan continental crust between 470 and 440 Ma (Reference 2.5-31).

The Milton terrane is structurally characterized by a nearly recumbent antiformal nappe rooted west of the boundary with the Carolina terrane. The Shelton Formation is a leucocratic granitic gneiss that occurs as sill-like bodies throughout the terrane. The sills were emplaced as intrusions either during or after nappe emplacement. The Rb-Sr whole-rock age is 429 ± 7 Ma and indicates that nappe emplacement was probably no later than early Silurian and no later than Taconian. The Milton terrane is bounded to the west by the Chatham fault and to the north by the Brookneal shear zone. To the east, a steep metamorphic gradient marks the transition to the Carolina terrane (Reference 2.5-15).

2.5.1.1.3.4.6 Chopawamsic Terrane

The Chopawamsic terrane includes the Chopawamsic Formation and Ta River Metamorphic Suite in Virginia, the rocks of the Central Virginia volcanic-plutonic belt, and the James Run Formation in Maryland (Figure 2.5-11). The Chopawamsic Formation in Virginia consists of felsic to mafic metavolcanic rocks, interbedded with metagraywacke, phyllite, or schist, and locally intruded by small bodies of plagiogranite and trondhjemite. The Ta River Metamorphic Suite is composed of amphibolite and interlayered biotite schist and gneiss (Reference 2.5-15). The James Run Formation is outside the Site Region.

The Chopawamsic Formation is age-constrained based on U-Pb analyses to approximately 550 Ma (Reference 2.5-31). Rare earth and trace element geochemical characteristics of rocks within the formation are consistent with a tholeiitic island arc suite with some calc-alkaline components. The Ta River Metamorphic Suite has rare earth and trace element characteristics of oceanic tholeiites that indicate the Ta River Formation is a more oceanward facies of the volcanic arc (Reference 2.5-15). The Ellisville and Lahore plutons that have intruded the northern Chopawamsic terrane indicate U-Pb zircon crystallization ages of 440 Ma and 450 Ma for the Ellisville and Lahore plutons, respectively. Other U-Pb ion microprobe analyses from the northern portion of the Chopawamsic Formation yielded Ordovician dates from 445 to 469 Ma (Reference 2.5-31).

To the west, the Chopawamsic terrane has been thrust onto the Potomac terrane along the Chopawamsic fault, and both terranes were subsequently intruded by the Occoquan Granite, which is age-dated at 494 ± 14 Ma. The Chopawamsic and Potomac terranes are interpreted to have amalgamated before the Late Cambrian Penobscottian orogeny. In northern Virginia, the Chopawamsic Formation overlies a sedimentary mélange of the Potomac composite terrane and has the character of the terrane fragments within the Potomac terrane. The Goochland terrane was overthrust onto the Chopawamsic terrane along the Spotsylvania fault in Virginia (Reference 2.5-15).

The middle and upper Ordovician Arvonia Slate and Quantico Formation unconformably overlie the Chopawamsic Formation. Because the Arvonia Slate and Quantico Formation are post-Taconian, the Chopawamsic terrane is overlapped. Mapping has indicated that the Arvonia Slate is very close to overlapping the Milton terrane. The Chopawamsic terrane is interpreted to have amalgamated with the Bel Air-Rising Sun and Potomac terranes in the Penobscottian event of the Late Cambrian. This combined terrane package was overthrust by the Baltimore terrane during the Taconian orogeny (Reference 2.5-15).

2.5.1.1.3.4.7 Carolina Superterrane – Carolina Terrane, Charlotte Terrane

The Carolina terrane is thought to be a composite terrane that includes rocks of the Carolina slate belt and the Charlotte belt (Figure 2.5-11). Additionally included are the Kiokee belt, the Belair belt, and the Battleground Formation of the Kings Mountain belt. Tectonic models indicate that this terrane originated in a volcanic-arc setting; however, there are various hypotheses concerning the direction of subduction, the number of arcs, the crustal type, and the timing (Reference 2.5-15).

The Carolina terrane contains at least two types of volcanic-sedimentary assemblage. The oldest assemblage is a Late Proterozoic andesitic assemblage between Chapel Hill, NC, and the NC – Virginia state line. This assemblage has calc-alkaline differentiation trends within mineral assemblages and is inferred to have formed by subduction along a continental margin. The younger assemblage is Late Proterozoic to Middle Cambrian and consists mostly of interbedded felsic metatuffs and fine-grained marine metasedimentary rocks that formed in a tectonic setting with both continental and oceanic features (Reference 2.5-15).

A potential orogenic event referred to as the Virgilina deformation was interpreted near the Virginia – NC border. The deformation is late Precambrian and Early Cambrian, characterized by folding and faulting, and lacks regional metamorphism. Other studies propose the existence of a major unconformity, referred to as the Virgilina unconformity, in central NC that separated Late Proterozoic rocks affected by the Virgilina deformation from the younger, Late Proterozoic to Middle Cambrian rock sequence occurring to the south. An unnamed fault cuts the Virgilina synclinorium but is crosscut by the 575 ± 20 Ma Roxboro metagranite (Reference 2.5-15).

Multiple lines of evidence support the hypothesis that at least part of the Carolina terrane was accreted to Laurentia during the Taconian orogeny. Earlier tectonic studies that equate the Carolina terrane with Avalonian terranes of the northern Appalachians inferred a Devonian (Acadian) accretion of the Carolina terrane, but this is no longer the predominant understanding. More recent studies measuring whole-rock K-Ar ages for low-grade slates of the Albemarle Group and 40Ar/39Ar whole-rock ages for slates of the Tillery Formation in NC are consistent with a Late Ordovician Metamorphic event. Paleomagnetic studies of the Albermarle Group indicate a paleolatitude of 22 degrees south, which is consistent with a Late Ordovician

timeframe. Higher-grade metamorphic rocks from the Charlotte belt have 40Ar/39Ar ages, consistent with an Ordovician (Taconian) event (Reference 2.5-15).

Calc-alkaline granitoids occur throughout the Carolina terrane, which is common in the Milford-Dedham zone of southeastern New England and Avalon terrane of Newfoundland. The southeastern New England granitoids span 650 to 600 Ma, while Avalon granitoids span 620 to 580 Ma, placing their formation in the Late Proterozoic. The plutons of the Dedham zone and Avalon terrane intrude older metamorphic rocks, but the Carolina terrane does not have a basement identified. The Carolina terrane granitoids lack Lower Cambrian strata overlying the Dedham zone granitoids non-conformably; they also do not have Lower Cambrian red beds overlying them that typify the Avalon terrane (Reference 2.5-15).

The Belair belt is located along the southeastern edge of the Kiokee belt near the Georgia – South Carolina state line (Figure 2.5-11). Belair rocks are composed of greenschist-facies metavolcanic and metasedimentary rocks, whereas Kiokee rocks are an amphibolite facies. The stratigraphic sequences, metamorphic grade, and polyphase structural history of the Belair belt are similar to the Carolina slate belt and are considered part of the Carolina terrane (Reference 2.5-15).

2.5.1.1.3.4.8 Raleigh-Goochland Terrane

The Goochland terrane is located in east-central Virginia (Figure 2.5-11; Reference 2.5-15). More recently, it has been referred to as the Raleigh-Goochland terrane by Hatcher et al. (Reference 2.5-10). It includes the State Farm Gneiss that has a Rb/Sr whole-rock age of 1031 Ma, but with a large uncertainty of ±94 Ma. The State Farm Gneiss is overlain by the Sabot Amphibolite and Maidens Gneiss, which show evidence of a relict granulite-facies metamorphism along with the State Farm Gneiss. Anorthosite intrudes all of these units, which are exposed in three en-echelon, doubleplunging antiforms. The Maidens Gneiss is interpreted to be equivalent to the Po River Metamorphic Suite in northern Virginia and Raleigh gneiss in NC. The Goochland terrane has been traced northward beneath the Coastal Plain into Maryland based on coincident Bouger gravity and magnetic anomalies that were confirmed with a deep well on the Potomac River. A similar Bouger gravity anomaly that extends from the Eastern Shore of Maryland into Delaware and New Jersey has been interpreted as an offset extension of the Goochland terrane.

The Spotsylvania fault separates the Goochland terrane from the Chopawamsic terrane to the west, while the Late Paleozoic Hylas fault zone separates it from the Roanoke Rapids terrane to the east. An interpreted southern extension of the Goochland terrane is overlain by volcanogenic Spring Hope terrane rocks; the boundary between the terrane is a premetamorphic thrust within the Raleigh metamorphic belt. The Goochland terrane is not interpreted to be a piece of Laurentia, but it is considered an exotic accreted terrane (Reference 2.5-15).

2.5.1.1.3.4.9 Brunswick (Charleston) Terrane

The Charleston terrane is equivalent to the older terminologies "Charleston magnetic terrane" and "Brunswick terrane" with some boundary differences (Figure 2.5-11). Also, the Charleston terrane should not be confused with the "Charleston block," which is now generally known as the South Georgia basin. The Charleston terrane is partly covered by overlapping Mesozoic strata of the South Georgia basin and is completely covered by Coastal Plain sediments.

Interpretations of the terrane are entirely limited to subsurface samples obtained during drilling or geophysical data (Reference 2.5-15).

Rock samples obtained from within the terrane are predominantly greenschist-facies metasedimentary and metavolcanic rocks; these samples are interpreted to be similar to the rocks of the Carolina, Spring Hope, and Roanoke Rapids terranes. Short-wavelength circular magnetic and gravity anomalies are interpreted to be both mafic and granitic plutons. A well-known example is the Springfield pluton, which was investigated through a corehole within a circular gravity low. The broad-wavelength magnetic signature in the area of the Charleston terrane is attributed to the eastward dampening of magnetic anomalies caused by the increasing thickness of the non-magnetic Coastal Plain cover to the southeast. The Charleston terrane produces a magnetically high domain that is significantly greater than that of the adjacent Carolina terrane. The high magnetic signature is caused by depth variations to the Moho and is attributed to the nature at the middle to upper levels of the crust. The magnetic and gravity anomalies together show that there is a large volume of mafic plutons and foliated mafic rocks (Reference 2.5-15).

The northwestern boundary of the Charleston terrane is poorly constrained on aeromagnetic data. However, a terrane-bounding suture was interpreted on Consortium for Continental Reflection Profiling (COCORP) seismic reflection data at the continental margin north and southwest of Hatteras. The southeastern boundary of the Charleston terrane is interpreted as south-dipping reflectors penetrating deep into the crust along the Brunswick magnetic anomaly. Three seismic reflection lines at locations in southwestern Georgia confirmed the COCORP interpretations. Observations from shallow drill holes confirmed the suture can be traced from the northern flank of the Brunswick anomaly in Alabama and western Georgia but diverges off the anomaly trend more than 15.5 mi. (25 km) northward in eastern Georgia (Reference 2.5-15).

2.5.1.1.3.4.10 Spring Hope–Roanoke Rapids Terrane

The Spring Hope terrane consists of greenschist-facies felsic to mafic metavolcanic and volcanogenic metasedimentary rocks and their amphibolite-facies equivalents in the Raleigh metamorphic belt (Figure 2.5-11). The terrane is characterized by sequences of metamorphosed mudstone, siltstone, graywacke, and minor conglomerate that are interpreted to be turbidites or reworked pyroclastic-epiclastic deposits. Metavolcanic rocks include felsic crystal and lapilli metatuffs and greenstone-metabasalt, while metagabbro and metadiorite occur as local intrusives. Chemical analyses of terrane rocks indicate a low-potassium tholeiitic suite that is interpreted to mean the Spring Hope terrane formed in a volcanic-arc environment on oceanic crust, but perhaps on a very thin continental crust (Reference 2.5-15).

The age of rocks within the Spring Hope terrane is poorly constrained. Rb-Sr whole-rock ages of metavolcanic rocks are 365 ± 4 Ma and 386 ± 27 Ma, indicating the age is no younger than Devonian. However, high initial Rb/Sr ratios suggest the ages were reset by a Devonian regional metamorphic episode, most likely the Acadian. Metavolcanic rocks within the Carolina superterrane to the west have Rb-Sr whole-rock ages that date them as Ordovician (Taconian) or older (Reference 2.5-15).

The Roanoke Rapids terrane of NC and Virginia is interpreted to be equivalent to the Roanoke Rapids structural block, containing mainly greenschist-facies and epidote-amphibolite-facies metavolcanic and volcanogenic metasedimentary rocks (Figure 2.5-11). The ages of the Roanoke Rapids terrane rocks is poorly constrained. The Fountain pluton in NC contains

granites with Rb-Sr whole-rock ages of 531 ± 60 Ma. It is unknown if pluton intrusion within the surrounding volcanogenic sequence are contemporaneous, but the rocks are at least Cambrian aged, if not older (Reference 2.5-15).

The Fountain pluton has a silicic per-alkalic composition, consistent with rift-related magmatism. Based on the composition and the Rb-Sr age, the Fountain granite compares similarly to the Crossnore Complex in the Sauratown terrane and in the Laurentian terranes of the Blue Ridge tectonic province. Subsequently, the Fountain granite and the Crossnore Complex were possibly emplaced with the late Precambrian and early Paleozoic rifting that formed at the edge of the North American continent (Reference 2.5-15).

2.5.1.1.3.4.11 Mesozoic Rift Basins

During the breakup of Pangea and subsequent opening of the Atlantic Ocean, a series of rift basins, oriented from northeast to southwest, formed in eastern North America (Reference 2.5-32; Reference 2.5-33). The basin closest to the Project site is the Dan River-Danville basin, while the Deep River basin is approximately 60 mi. (96.5 km) southeast of the Project site (Figure 2.5-11). The Dan River-Danville basin is a half-graben that is fault-bounded on the west side and filled with Triassic-Jurassic sediments (Reference 2.5-22).

Strata within the Dan River-Danville basin are reported to be up to 5000 ft. (1524 m) thick (Reference 2.5-6) and are primarily composed of five formations that overlie a dark green to gray-green metamorphic rock that is likely metavolcanic (Reference 2.5-22). From oldest to youngest, the formations are the Pine Hall Formation, Walnut Cove Formation, Dry Fork Formation, Cow Branch Formation, and Stoneville Formation (Reference 2.5-22). The Pine Hall Formation contains mainly fining-upward sequences of medium- to coarse-grained sandstones. Interbedded within the sandstones are several red siltstones and black, organic-rich mudstones with locally persistent coal beds. The overlying Walnut Cove Formation is mainly a dark gray-black organic lacustrine deposit of mudstone, siltstone, and coal. The Dry Form Formation is mostly gray to dark gray siltstone and very fine-grained sandstone (Reference 2.5-22). The Cow Branch Formation is mainly lacustrine, organic-rich rocks of gray to black shale, and the Stoneville Formation is primarily clastics with some lacustrine deposits (Reference 2.5-6).

2.5.1.1.3.4.12 Mesozoic Dikes

Mesozoic Era features in the Site Region include Early Jurassic diabase dikes that occur in a series of dense swarms with systematic, divergent trends throughout the Appalachian Mountains and indicate regional variations in magnetic and chemical characteristics (Figure 2.5-12). The dikes coincide with the Appalachian gravity high and almost exclusively occur east of the Brevard fault zone. The dikes in some areas are overlain by Coastal Plain deposits and are identified by magnetic anomalies. Anomalies have the highest amplitude over the igneous intrusions in the Carolinas and are attributed to a stronger magnetization (Reference 2.5-34).

Burt et al. studied diabase dikes that occur predominately in the eastern Piedmont province of NC (Reference 2.5-35). The dikes tend to be north-trending, up to 37 mi. (60 km) long, and continuous. Two major trends occur from N10°W to N30°W (northwest-trending) and east-trending, and a third, less prominent, group generally trends from east to northeast. The dikes appear more readily in aeromagnetic mapping, but the magnetic signatures are variable, and the highest magnitude signatures are associated with the north-trending dikes. Dikes are narrow and dip steeply, and they are typically emplaced in pre-Triassic crystalline rocks and in

sedimentary rocks in the Triassic basins. The occurrence of dike sills is restricted to Triassic sediments. Dike widths range up to approximately 200 ft. (61 m) with metamorphic contact zones more than 439.40 ft. (12 m) wide. In sedimentary rocks, the contact zones are less than 30 ft. (9 m) wide. The diabase dikes cut cleanly across all structures and may indicate intrusion into tensile fractures. Mineral assemblages of the separate diabase dikes are similar, and most include a chilled border and may or may not show a baked zone or contact aureole (Reference 2.5-35).

The northwest-trending dikes are most common in the sedimentary rocks in the Durham, Deep River, and Wadesboro Triassic basins and north of the Wadesboro basin. A large concentration of north-trending dikes occurs in a zone extending from the South Carolina – NC state line to the NC – Virginia state line. The north-trending dikes are more closely spaced in the south where they are sharply discordant to the northwest-trending dikes and tend to fan out to the east and west as the dikes trend northward. The less prominent dikes that trend east-northeast are located within the Triassic basins, along the basin borders or may be scattered. The north-trending dikes tend to be longer than the dikes that trend northwest or east-northeast. These dikes are typically 0.5 to 15 mi. (0.8 to 24 km) long; none appear to have an uninterrupted length longer than approximately 37 mi (59.5 km). An interrupted dike was found to be more than 100 mi. (161 km) long. The longer dikes are irregularly sinuous with many dikes in the basins terminating into crystalline rock at the basin border or within a short distance of it. As a population, the dikes are not evenly distributed, and large concentrations are present in the central part of the Wadesboro Triassic basin and the Deep River Triassic basin, while areas such as Chatham County have no known dikes. The closest dike to the Site Location is approximately 4 mi. (6.4 km) (Reference 2.5-35; Figure 2.5-16).

2.5.1.1.3.5 Stratigraphy of the Coastal Plain Province

The Coastal Plain strata in the Site Region extend east from the fall line along the boundary with the Piedmont to the Atlantic Ocean (Figure 2.5-10) within Virginia, NC, and South Carolina. Comparing Willoughby et al. (Reference 2.5-36) and Meng and Harsh (Reference 2.5-37) with Weems et al. (Reference 2.5-38) reveals that the Coastal Plain stratigraphy descriptions presented for NC within the Site Region apply to the Coastal Plain of Virginia and South Carolina. Figure 2.5-13 presents a simplified geologic cross section through the coastal plan in Virginia, which is considered to represent the typical wedge-shaped, eastward-thickening Coastal Plain stratigraphy of Cretaceous to Quaternary sediments overlying crystalline basement rocks. The sediments within the Coastal Plain province thicken to a maximum thickness of approximately 9843 ft. (3000 m) at Cape Hatteras (Reference 2.5-8).

The strata of the Atlantic Coastal Plain are divided into five regional supergroups that are currently separated into groups, formations, and members based on stratigraphic relationships. The oldest supergroup that occurs in the NC Coastal Plain is the Cretaceous Minden Supergroup, which is divided into three informal fining-upward sequences. Lack of available fossil data make correlation difficult within the Minden Supergroup, but the units extend from offshore, westward and terminate at a growth fault in Pamlico Sound west of Cape Hatteras. Lower Cretaceous and basal Upper Cretaceous sediments make up the Marquesas (MQ) Supergroup that contains 10 sequences numbered oldest to youngest from MQ-1 to MQ-10. The westward extent of each MQ unit is interpreted to be controlled by a series of growth faults in underlying Paleozoic sediments (Reference 2.5-38).

The Upper Cretaceous, Paleocene, and lower Eocene units consist predominantly of marine siliciclastic sediments that make up the Ancora Supergroup. The middle Eocene through Oligocene units that form the Trent Supergroup are predominantly carbonates. The Nomini Supergroup, which predominantly comprises siliciclastic Miocene to recent sediments and rocks, includes phosphate deposits within the Pungo River Formation. In the Late Cretaceous, sediments of the Clubhouse Formation overstepped all older Coastal Plain deposits toward the northwest to within 50 mi. (80.4 km) of the fall line. The Clubhouse Formation contains calcareous nannofossils and marginal marine dinocysts that indicate marine conditions had extended nearly the entire breadth of the Coastal Plain in northern NC. Middle and upper Miocene strata are locally discontinuous as indicated by the occurrence of anomalously old dinocysts within test boreholes, which reflect reworking of scoured older Miocene sediments into basal Pliocene sediment that began filling the region scoured during the Miocene (Reference 2.5-38).

2.5.1.1.4 Principal Regional Tectonic Structures

The Site Region is characterized by tectonic structures that are the result of multiple Wilson cycles. The region contains orogenies and extensional features resulting from the opening and closing of ocean basins.

2.5.1.1.4.1 Precambrian Tectonic Structures in the Site Region

In the Site Region, the most prominent signature of the assembly of the super continent Rodinia is the New York – Alabama lineament (Reference 2.5-39). The lineament is a magnetic feature interpreted to have been a continental transform fault during the assembly of Rodinia, approximately 1200 Ma (Reference 2.5-39).

Rifting of the supercontinent Rodinia into Laurentia, Baltica, and Amazonia between 700 and 550 Ma led to the formation of the Iapetus Ocean (Reference 2.5-134). Iapetan-age transform and rift faults are mapped in a zone subparallel to the modern Atlantic coastline of the United States (Reference 2.5-39; Figure 2.5-14). Transform faults strike northwest and offset northeast-striking rifts (Reference 2.5-40). In the earliest Cambrian, the rift margin from the Alabama to the New York promontory transitioned to a passive margin. The Rough Creek Graben, Rome trough, and Birmingham Graben also formed at this time as a late synrift extension inward of the rifted margin (Reference 2.5-39).

2.5.1.1.4.2 Paleozoic Tectonic Structures in the Site Region

In the Site Region, the Paleozoic is characterized by three orogenies: the Taconian (Ordovician), Acadian/Neoacadian (Devonian-Mississippian), and Alleghanian (Pennsylvanian-Permian) (Reference 2.5-41; Reference 2.5-204). The Taconian orogeny occurred in the Middle to Late Ordovician and possibly into the Silurian (Reference 2.5-42). Convergence generally progressed northeast with the collision of small plates, islands, and back arc basins, resulting in folds, thrust faults, and nappes (Reference 2.5-42). The Acadian is represented in the region by the Gold Hill fault zone, a Devonian-dextral shear zone that may also have been active in the Late Ordovician with sinistral transpression, possibly related to the accretion of the Carolina zone (Reference 2.5-43).

A series of Paleozoic faults that trend northeast – southwest pass west of the Project site, north through the Central Virginia Seismic Zone (CVSZ). After the 2011 earthquake in Mineral,

Virginia, two of these faults, the Lakeside fault and the Little Fork Church fault, were investigated with ground-penetrating radar and trenched, but no evidence of modern or prehistoric faulting was interpreted. The faults are interpreted to have been reactivated as normal faults during the Mesozoic (Reference 2.5-44).

The Central Piedmont shear zone is interpreted to be a Carboniferous to Permian Alleghanian thrust (Reference 2.5-45). It forms the boundary between the metamorphic rocks of the Piedmont zone and the metaigneous and metasedimentary volcanic-arc rocks of the Carolina zone (Reference 2.5-45).

The Brevard mylonite zone is an up to 3.7-mi.-wide (6-km-wide) zone of mylonitic rocks that contains the up to 0.9-mi.-wide (1.5-km-wide) brittle Brevard fault zone. The Brevard fault zone is interpreted to have formed during the Taconic or Acadian orogenies (Reference 2.5-46). In the modern setting, the Brevard fault strikes northeast – southwest from Alabama to Virginia at the boundary of the Blue Ridge and Piedmont provinces (Reference 2.5-47).

2.5.1.1.4.3 Mesozoic Structures

During the Middle to Late Triassic, Pangea began to break apart. During the breakup and the opening of the Atlantic Ocean, a series of approximately northeast – southwest-oriented rift basins opened (Reference 2.5-32; Reference 2.5-33). The rift basins generally are asymmetric half- grabens (Reference 2.5-33). The basin closest to the Project site is the Dan River-Danville basin. The Chatham fault zone is the primary fault of the half-graben; it trends along the northwest edge of the basin. The fault dips approximately 45° southeast. Smaller, normal faults are also present in the basin (Figure 2.5-15) (Reference 2.5-48). The surface trace of the fault lies approximately 6.2 mi. (10 km) from the Project site (Figure 2.5-15).

The Stony Ridge fault is located approximately 12.4 mi. (20 km) northwest of the Project site and was mapped as forming during the Mesozoic reactivation of the Brevard fault (Reference 2.5-49; Reference 2.5-50; Reference 2.5-51). However, subsequent mapping has been unable to demonstrate measurable displacement on the fault, and the cataclastite associated with the fault may have formed due to hydrothermal alteration (Reference 2.5-49) (Figure 2.5-16).

2.5.1.1.4.4 Cenozoic Structures

2.5.1.1.4.4.1 Fall Lines

Fall lines are zones of increased gradient in rivers that align in a curvilinear trend with similar features in adjacent stream and rivers (Reference 2.5-52). The traditional fall line is the head of tide of navigable rivers, although other fall lines have been identified upstream (Reference 2.5-52). The traditional fall line is mapped as the Coastal Plain-Piedmont boundary (Reference 2.5-53). There are three hypotheses (described below) for the formation of fall lines in the coastal region of Virginia and the Carolinas; these mechanisms may work separately or together (Reference 2.5-52).

1. Differential erosion across linear belts of rock of different hardnesses

2. Climatically driven changes in hydraulic gradient that alter the stream profiles

3. Cenozoic neotectonic uplift

2.5.1.1.4.4.2 Arches

The East Coast of the U.S. is composed of a series of large-scale troughs and rises called arches and embayments (Reference 2.5-54; Figure 2.5-17). The closest feature to the Project site is the Cape Fear Arch, which is a post-rift structural high that trends approximately southeast-northwest across the Coastal Plain and continental shelf of NC (Reference 2.5-55). The axis of the arch runs approximately along the Cape Fear River Valley, and the northeastern flank is steeper than the southwestern flank (Reference 2.5-55). The Cape Fear Arch is interpreted to have experienced intermittent uplift from the Late Cretaceous through apparently the present (Reference 2.5-55). Late Holocene average uplift rates over the last 4000 years are estimated to be 0.24 ± 0.15 mm/yr (0.009 ± 0.006 in/yr) (Reference 2.5-56). The arch was a positive feature during the Cenozoic, and it influenced middle Eocene and Miocene sedimentation patterns (Reference 2.5-57). The U.S. Geological Survey (USGS) Quaternary Fault and Fold Database, last reviewed by USGS in 2002, classifies the Cape Fear Arch as Class C because much of the evidence favors regional warping rather than a narrow zone of near-surface faulting (Reference 2.5-58).

There is no scientific consensus for how the Cape Fear Arch formed. Proposed processes are described below (Reference 2.5-55):

- An ocean fracture zone formed during the opening of the Atlantic.
- A horst between the Cape Fear and Neuse faults.
- Uplift between the Faison and Neuse faults.
- Upwarped dome along the Fountains Creek fault.
- Topography related to the passing of the Bermuda Hotspot.
- Topography related to ongoing mantle upwelling.
- Topography related to delamination of the mantle beneath the arch.

2.5.1.1.4.4.3 Quaternary and Potentially Capable Tectonic Sources

The Site Region contains or connects with two fault sources from the 2023 USGS National Seismic Hazard Map (NSHM) – the CVSZ and the Charleston sources (Figure 2.5-18; Reference 2.5-59). The Site Region additionally intersects or contains three other zones of historical seismic activity that were reviewed for the Senior Seismic Hazard Analysis Committee (SSHAC) Level 2 study performed for the Project site: the Giles County Seismic Zone, the Little River fault, and the Eastern Tennessee Seismic Zone (ETSZ). Additionally, the New Madrid Seismic Zone is discussed because of its regional significance.

2.1.1.4.4.5.3.1 Charleston

On August 31, 1886, an expected moment magnitude (E[**M**]) 6.9 earthquake occurred in the region near Charleston, South Carolina. This earthquake is the largest historical earthquake in the southeastern United States. Paleoliquefaction evidence indicates pre-1886 earthquakes occurred in the same region (Reference 2.5-117, Chapter 6). Multiple faults are identified in the

region; however, there is no scientific consensus on the location of the 1886 rupture (Reference 2.5-61). The Charleston earthquake is included as a source in both the Central and Eastern United States (CEUS) seismic source characterization (SSC) model and the USGS NSHM 2023 (Reference 2.5-117, Chapter 6; Reference 2.5-59; Reference 2.5-62).

Several recent studies have aimed to identify the fault source of the 1886 earthquake and other active faults in the region. Pratt et al. analyzed reprocessed seismic reflection and aeromagnetic data and new ground-penetrating radar data to interpret faults deforming Cretaceous and younger sedimentary units. The faults mapped in their study trend mostly northeast – southwest (Reference 2.5-61). Chapman et al. interpreted a fault striking N6°E with a dip of 43° to the west, based on the occurrence of earthquakes from 2011 to 2012. They interpret the observed seismicity to be aftershocks of the 1886 event on the same fault plane (Reference 2.5-63).

Several recent articles reanalyze historical data related to the 1886 Charleston earthquake (Reference 2.5-64; Reference 2.5-65; Reference 2.5-66; Reference 2.5-67). Hough and Bilham reassess historical accounts of the 1886 earthquake from the near and far field and calculate 1297 Modified Mercalli Intensity (MMI) values and more than 200 not-felt locations (Reference 2.5-67). Using these data and the ground motion models from the Next Generation Attenuation (NGA)-East project, they calculate a M 7.3 for the 1886 event based on the source developed in Bilham and Hough (2023) (Reference 2.5-64). Bilham and Hough (2024) (Reference 2.5-65) reexamined post-1886 earthquake photographs of rail line deformation and concluded the deformation is from dynamic deformation (deformation due to ground motion) instead of the previously interpreted static deformation (coseismic surface deformation). They do not interpret any evidence for faulting in 1886 south of the Ashley River at Rantowles, and they reinterpret the rail line deformation there as the effects of dynamic deformation. Previous studies have interpreted photographs of rail line deformation at Rantowles as evidence for static deformation from shallow strike-slip and thrust faults. Pratt et al. (Reference 2.5-68) wrote a comment on Bilham and Hough (2023) (Reference 2.5-64), taking issue with their proposed location of the 1886 earthquake and interpretation of lack of faulting south of the Ashley River.

2.1.1.4.4.5.3.2 New Madrid

The New Madrid region is the source of the 1811–1812 New Madrid earthquake sequence, which includes the three largest earthquakes in the CEUS in historical time (Reference 2.5-117, Chapter 6). Seismicity is located within a reactivated Precambrian rift zone, the Reelfoot Rift (Reference 2.5-69). A series of three M 7-8 earthquakes occurred in the zone from 1811 to 1812 (Reference 2.5-117, Chapter 6; Reference 2.5-69), and similarly large clusters of earthquakes are interpreted from paleoseismic evidence to have occurred in the Holocene (Reference 2.5-70). The New Madrid region is interpreted to include predominantly strike-slip faults that trend mainly northeast – southwest (Reference 2.5-69; Reference 2.5-59). Although the faults are outside the 200 mi. (320 km) Site Region, following regulatory guidance of NUREG-0800, the historical large magnitude earthquakes in the New Madrid region prompted their inclusion in the review of seismic sources and the inclusion of New Madrid faults as sources in the seismic hazard model (Section 2.5.2).

2.1.1.4.4.5.3.3 Central Virginia Seismic Zone

The CVSZ is a region of higher seismicity rate and includes the 2011 E[**M**] 5.72 Mineral, Virginia, earthquake. Other large historical events include the 1758 E[**M**] 4.95, the 1774 E[**M**]

4.38, and the 1875 E[**M**] 4.77 events. No historical events in the zone are interpreted to be above a E[**M**] 6 (Reference 2.5-71).

Tuttle et al. (Reference 2.5-71; Reference 2.5-72; Reference 2.5-73) documented evidence for paleoliquefaction in the CVSZ. Consistent with previous studies, Tuttle et al. (Reference 2.5-72) found two generations of features, one set historical and one set between 3450 and 2450 years before present. They conclude the younger set of historical features are related to M 5.0–5.5 events, likely the 1758, 1774, and 1875 events, while the older features are likely related to one M 6.5-6.75 event. Tuttle et al. (Reference 2.5-73) give the alternative of the older generation of liquefaction features either being generated by two M 6.25–6.5 or one M 6.5–6.75. There is no conclusive evidence for repeated M 6.5+ earthquakes in the CVSZ.

2.1.1.4.4.5.3.4 East Tennessee Seismic Zone

The ETSZ is a region of elevated historical seismicity in the Valley and Ridge province of Tennessee. Four general explanations have been proposed for the higher rates of earthquakes in the region: (1) the ETSZ is a long-lived aftershock sequence from a prehistoric event; (2) the ETSZ is in a phase of strain release, but the location of strain release (earthquakes) can change; (3) the ETSZ is a zone of weakness that experiences higher strain rates and/or earthquakes; and (4) the seismicity in the ETSZ is the result of the sum of local and regional stresses, resulting in a higher magnitude deviatoric stress tensor (Reference 2.5-74). Stress inversions indicate oblique extension in the ETSZ and long-term deformation (Reference 2.5-74. Historical earthquakes in the region generally have hypocenters between 3 and 16 mi. (5 and 26 km) deep, and magnitudes smaller than M 5 (Reference 2.5-75). The largest instrumental events in the ETSZ are the 1973 E[**M**] 4.01 Alcoa, Tennessee, earthquake and the 2003 E[**M**] 4.57 Fort Payne, Alabama, earthquake (Reference 2.5-76).

Cox et al. (2022) (Reference 2.5-76) summarized recent paleoseismic work in the ETSZ. They interpret a 110-km (68-mi.)-long, northeast-trending corridor, termed the Dandridge-Vonore fault corridor, as a region of Quaternary faulting. Near Alcoa, Tennessee, they interpret sedimentary features in an outcrop as evidence for two thrust-faulting events between 15,000 and 10,000 years ago and two events within 40 thousand years (kyr) were interpreted near Dandridge. Cox et al. (2022) (Reference 2.5-76) conclude there is evidence from outcrop mapping and trenching for at least two, $M_W \geq 6.5$ earthquakes in the last 40 kyr.

Thompson Jobe et al. (Reference 2.5-75) examined the site near Alcoa analyzed in Cox et al. (2018; 2022) (References 2.5-77 and 2.5-76) and the lineaments in the ETSZ. They conclude the outcrops that Cox et al. (2022) (Reference 2.5-76) interpret as coseismic offset are better explained as the result of fluvial deposition. They also reviewed sites near Oak Ridge without firm conclusions, hypothesizing that either fluvial or Quaternary faulting processes could explain the observed scarps and lineaments. Thompson Jobe et al. (Reference 2.5-75) also analyzed light detection and ranging (LiDAR) data and identified lineaments that trend east–west and correlate with other mapped Cenozoic faults. They conclude the faults have apparent left-lateral offset, which agrees with modern earthquake focal mechanisms. The study does not identify any clear evidence for Quaternary surface deformation.

2.1.1.4.4.5.3.5 Giles County Seismic Zone

The Giles County seismic zone is a region of elevated seismicity in southwestern Virginia. The largest historical earthquake in the region is the E[**M**] 5.91 Giles County earthquake that

occurred on May 31, 1897, with a maximum MMI of VIII. The effects of the earthquake included broken chimneys and local landslides (Reference 2.5-78).

Bollinger and Wheeler (1988) (Reference 2.5-79) conclude Giles County seismicity most likely occurs on reactivated Iapetan normal faults. Geologic evidence indicates potential left-lateral faulting, but geophysical and stress analysis indicate oblique-thrust-fault mechanisms in the region of the Giles County seismic zone (Reference 2.5-80).

The Pembroke faults are mapped along an anticlinal trend in the terrace deposits of the New River in the Giles County seismic zone. Extensional cracks in probable Quaternary-age terrace deposits are alternatively interpreted as caused by either subsurface faulting or as the result of dissolution of underlying layers (Reference 2.5-81). These cracks are assigned Class B in the USGS Quaternary Fault and Fold Database (Reference 2.5-82), which is defined as “Geologic evidence demonstrates the existence of Quaternary deformation, but either (1) the fault might not extend deeply enough to be a potential source of significant earthquakes, or (2) the currently available geologic evidence is too strong to confidently assign the feature to Class C but not strong enough to assign it to Class A.”

2.1.1.4.4.5.3.6 Little River Fault

The Little River fault is a recently mapped fault considered to be associated with surface rupture from the 2020 M 5.1 Sparta earthquake in NC (Reference 2.5-83). The fault is located approximately 57 mi. (92 km) west-northwest of the Project site. The Sparta earthquake ruptured an oblique strike-slip fault. The moderate magnitude earthquake occurred at shallow depth (2 km [1.2 mi.]) with a northwest-southeast fault strike based on focal mechanism analysis, perpendicular to the regional structural orientation of the Appalachian Mountains. The earthquake occurred near the town of Sparta, NC, where there is relatively sparse historical seismicity. Geodetic markers and focal mechanism data indicate that the earthquake ruptured on a left-lateral fault at depth with a reverse component near and at the surface (Reference 2.5-83).

Paleoseismic trenches were dug and mapped across the fault scarp. Late Pleistocene surface ruptures with similar displacements to the 2020 earthquake have been interpreted, suggesting similar magnitudes and locations for older events (Reference 2.5-83). Preliminary geochronology and soil horizon analysis by the same authors suggests three earthquake events in the last 40 kyr, indicating an average recurrence interval of 13.3 kyr. Vertical deformation is approximately 3.3 ft. (1 m) in the last 50 kyr, suggesting an approximate vertical slip rate of 0.02 mm/yr during that timeframe (Reference 2.5-83).

2.5.1.1.4.5 Present-Day Tectonic Stress

The Site Region is located within a mid-plate compressive stress province that characterizes the CEUS and extends into Canada and the western North Atlantic basin (Reference 2.5-84). The principal horizontal stress is predominately east – northeast, while the faulting style is predominately compressive, although it transitions to strike-slip in eastern Tennessee (Reference 2.5-85). The cause of the principle horizontal stress direction in the eastern United States is poorly understood as the direction diverges from the plate trajectory. Lundstern and Zoback (Reference 2.5-85) suggest that the stress direction is controlled by sediment loading and flexure along the continental margin.

2.5.1.1.4.6 Regional Gravity and Magnetic Data

Kucks (Reference 2.5-86) provided the primary gravity data reviewed for this application. The data over land were free-air corrected, and a complete Bouguer correction was implemented by removing a gravity reference field within 103.6 mi. (166.7 km) of the measurement location. Figure 2.5-19 presents the Bouguer gravity map for the Site Region. A small portion of the 199-mi. (320 km) Site Region extends offshore into the Atlantic Ocean; that portion of the data was subjected to free-air correction (Reference 2.5-86).

The Magnetic Anomaly Map of North America from Bankey et al. (Reference 2.5-87) provided the primary magnetic data reviewed for this application. Figure 2.5-20 presents the magnetic anomaly map for the Site Region. Details of the specific processing method are presented in Reference 2.5-87. In general, the map is a compilation of digital and analog maps from aeromagnetic surveys completed from 1949 to 2001. For each survey, the definitive magnetic reference field for the survey date was removed, and the data were mathematically processed to an equivalent flight elevation of 1001 ft. (305 m) above terrain, merged, and then filtered (Reference 2.5-87).

2.5.1.1.4.6.1 Gravity Data

Figure 2.5-19 shows Bouguer gravity anomaly data within and surrounding the Site Region. Interpretation of gravity data is complex; general guidelines to interpret gravity patterns are presented below:

- Gravity differences due to subsurface variation in density generally span only a few hundred milligals (mGal) (Reference 2.5-88).
- Lateral variations in rock density give rise to gravity anomalies, but vertical variation in rock density in a flat and layered earth do not produce an anomaly (Reference 2.5-88).
- For igneous rocks, density usually increases with decreasing silica content. For sedimentary rocks, age, depth of burial, and mineral composition are the most important factors for density (Reference 2.5-89).

Figure 2.5-19 identifies key gravity anomalies and/or trends and are described below:

A. A high-gravity anomaly trending northeast to southwest (ranging from approximately -30 to -40 mGal) at the eastern edge of the Cumberland Plateau and Allegheny Mountains. Hatcher et al. (Reference 2.5-90) note that area as underlain by a mafic complex, mainly gabbro, which is denser than the surrounding rocks to the east. The eastern boundary approximately corresponds to the New York–Alabama lineament of Reference 2.5-91.

B. The Appalachian gravity gradient, sometimes referred to as the Piedmont gravity gradient, which is an elongate gravity high that trends northeast to southwest and separates the low (-90 to -70 mGal) gravity anomaly regions from the adjacent high Bouguer (~0 to 25 mGal) gravity in the Piedmont and Coastal Plain. Hatcher et al. infer that the Appalachian gravity gradient most likely represents the eastward thinning of autochthonous continental crust to a buried Iapetus suture (Reference 2.5-90).

C. A gravity low associated with the Triassic Dunbarton basin. Cumbest et al. (Reference 2.5-92) completed extensive research at the Savannah River site southwest of the Project site. The authors interpreted from borehole data and gravity modeling that the gravity low was attributed to granitic plutons bounded to the southeast by corresponding gravity/magnetic highs attributed to mafic intrusive complexes.

D. A gravity low associated with the Lumberton plutonic intrusion as presented in Rankin et al. (Reference 2.5-93). Pratt (Reference 2.5-94) completed a detailed geophysical and coring study in which the gravity low anomaly corresponded to a thick, granite intrusion.

E. The gravity low anomaly studied by Daniels and correlated to a mapped granitic pluton. Adjacent gravity high anomalies corresponded to mafic intrusions (Reference 2.5-95).

F. A gravity low anomaly with unknown origin due to lack of borehole data, but by analogous interpretation to anomalies C-E, it is interpreted to represent a granitic pluton intrusion.

2.5.1.1.4.6.2 Magnetic Interpretations

Figure 2.5-20 presents magnetic anomaly data encompassing the Site Region and surrounding area. The data are a compilation of aeromagnetic surveys published by Bankey et al. (Reference 2.5-87). Similar to gravity data, interpretation of magnetic anomaly data is complex; several guiding principles are presented below:

- The nanotesla (nT) is the standard unit of measure for processing and interpreting magnetic anomaly data (Reference 2.5-96).
- High amplitude anomalies typically reflect lithologic contacts, while anomalies related to structures are more subtle (Reference 2.5-96).
- Magnetic anomalies are caused by lateral changes in the magnetic mineral content of rocks, and so reflect lateral changes in lithology (Reference 2.5-88).

The North American magnetic anomaly map reveals the overall northeast – southwest structural features of the Appalachians. Several large-scale magnetic anomalies in the eastern United States form lineaments that have been associated with seismic zones or basement structures. Figure 2.5-20 identifies key magnetic anomalies and/or trends that are described below:

A. The New York–Alabama lineament occurs on the west side of the Appalachian gravity low. On the northwest side of the lineament, gravity anomalies are north-trending, while on the southeast side of the lineament gravity anomalies are northeast-trending (Reference 2.5-91). Further work by Steltenpohl et al. constrains the southern terminus of the lineament and indicates the feature represents a crustal scale, right-lateral strike-slip fault (Reference 2.5-97).

B. The Clingman lineament lies east of the New York–Alabama lineament and is a magnetic anomaly produced by deep-seated basement structures. These two lineaments, along with the Ocoee lineament that trends between them, are interpreted to be the bounds of the ETSZ (Reference 2.5-97).

C. The Brevard fault zone is also visible in these data. It is interpreted as an aeromagnetic lineament that corresponds with the mapped surface trace of the Brevard fault zone that extends from western NC through eastern Alabama. The aeromagnetic signature continues to the southwest beneath the Coastal Plain in Alabama (Reference 2.5-97).

D. The East Coast Magnetic Anomaly is outside the Site Region, but noteworthy because it marks the present continental/oceanic crustal transition and the Late Paleozoic suture between North America and Africa (Reference 2.5-98).

While not seen on the magnetic anomaly map, multiple prominent, high-frequency magnetic anomalies occur along the eastern portion of the Piedmont and into the Coastal Plain provinces. The magnetic anomalies within the Piedmont are attributed to the presence of an extensive eastern Piedmont fault system that extends southwest into Georgia (Reference 2.5-99; Reference 2.5-100). The series of linear- to arcuate-magnetic anomalies in the Coastal Plain province near the fall line are inferred to represent mafic intrusions on the perimeter of granitic plutons (Reference 2.5-100). Additionally, a similar anomaly is seen farther southwest near the Dunbarton Basin where Cumbest et al. correlated linear magnetic anomalies to mafic intrusions (Reference 2.5-92).

2.5.1.1.5 Regional Geologic Hazards

2.5.1.1.5.1 Karst

In the Site Region, karst and karst-like processes are mainly located in two broad bands. To the east of the Project site, carbonate rocks are located in the Coastal Plain. The Site Region is classified as humid, which results in carbonate bedrock and calcareous sediments at or near the surface as typically being karstic. To the west of the Project site, Weary and Doctor (Reference 2.5-101) mapped the potential for marble in the Sauratown Mountains region. More widespread evidence is available for carbonate units at or near the surface to the northeast of the Project site in the Valley and Ridge province where a band of Cambrian and Ordovician limestones and dolomites follow the general northeast – southwest structural trend (Reference 2.5-51; Reference 2.5-101). Evaporite rocks are not mapped as large-scale units in the Site Region (Reference 2.5-101). Units under the Project site are mapped as quartz-feldspar gneiss (Reference 2.5-51).

2.5.1.1.5.2 Landslide

Most of the mapped landslides in NC are in the Blue Ridge Mountains in the western portion of the state (Reference 2.5-102). Most mapped landslides correspond with the impacts from tropical cyclones or periods of higher rainfall. Landslides also occur more frequently where slopes have been modified by human activities (Reference 2.5-102). Debris flows dominate landslide processes in the southern Appalachian Highlands (Reference 2.5-103). The NC Geologic Survey has not mapped landslides in the counties closest to the Project site (Forsyth, Guilford, Rockingham, and Stokes) from 1990 to 2016 (Reference 2.5-102).

Mirus et al. (Reference 2.5-104) calculated the four counties surrounding the Project site as having a high percentage of landslide-susceptible terrain (66 to 100 percent) but a low rate of mapped landslides (less than 0.01 per km^2). The Coastal Plain region of the Site Region has a low rate of susceptible terrain (less than 33 percent) and a low rate of mapped landslides (less than 0.01 per km^2). The Blue Ridge Mountains have both a high percentage of susceptible

terrain (66 to 100 percent) and a high occurrence of mapped landslides (0.01 to more than 0.1 per km^2).

2.5.1.1.5.3 Volcanic

Prior to the breakup of Pangea, the CAMP, a large igneous province, formed (Reference 2.5-105; Reference 2.5-106). In the Site Vicinity, the CAMP is represented by a series of dikes that trend approximately north to south. Peak activity for the CAMP has been dated to the Triassic-Jurassic boundary, approximately 200 Ma (Reference 2.5-106).

The youngest igneous features within the Site Region are Eocene volcanic dikes, sills, plugs, and diatremes near the West Virginia – Virginia border (Reference 2.5-105), more than 125 mi. (200 km) from the Project site. These features are interpreted to be the result of asthenosphere upwelling related to lithospheric delamination, although other hypotheses are proposed, including plume magmatism and changes in the regional stress field (Reference 2.5-105).

Volcanism is typically associated with plate boundaries and mantle hotspots. Neither setting is present in the Site Region, and there are no mapped Quaternary active volcanoes (Reference 2.5-107; Reference 2.5-108; Reference 2.5-109). There are no Quaternary volcanoes in the Site Region (200 mi. [320 km]) or mapped Quaternary volcanic deposits within Site Vicinity (25 mi. [40 km]) (Reference 2.5-109). Therefore, based on RG 4.26, which specifies if no Quaternary active volcanoes are identified in the Site Region, or Quaternary pyroclastic deposits are located within the Site Vicinity, the volcanic hazard can be screened out from further analysis.

2.5.1.2 Local Geology

The following sections provide a summary of geologic conditions in the Site Vicinity (25 mi. [40 km radius]), Site Area (5 mi. [8 km] radius) and Site Location (0.6 mi. [1 km]) radius. Specifically, the sections present information concerning the physiography, geologic history, stratigraphy, structural geology, non-seismic geologic hazards, and engineering geology. This information is based on a review of geologic literature and geotechnical/hydrogeological field investigations conducted at the Project site.

2.5.1.2.1 Local Physiography

Figure 2.5-21 shows the Site Vicinity and Site Area. The Project site is located in southeast Stokes County, adjacent to the Belews Creek Steam Station (BCSS), near the intersection of four counties: Rockingham County to the east, Guilford County to the southeast, and Forsyth County to the south. The Project site is approximately 14 mi. (23 km) northeast of Winston-Salem and approximately 19 mi. (31 km) northwest from Greensboro, NC. The Project site specifically focuses on three separate sites located on a peninsula that trends southwest – northeast and extends into the southwestern portion of Belews Lake. The three sites are referred to as the North Plant Complex, the Middle Plant Complex, and the South Plant Complex, and they are within the Project site captured in Figure 2.5-21.

The entire Site Vicinity is within the Piedmont physiographic province, approximately 40 mi. (64 km) east of the Blue Ridge physiographic province (Figure 2.5-1). As discussed in Section 2.5.1.1.1, the Piedmont physiographic province extends from New Jersey to Alabama (approximately 994 mi. [1600 km]). Rocks within the Site Vicinity are primarily composed of weathered metamorphic and igneous rocks. Metamorphic rocks include mostly schist and

gneiss; igneous rocks are predominantly slightly metamorphosed granite. Structural basins (resulting from faulting) are filled with Mesozoic sediments (Reference 2.5-4).

The Site Vicinity is within the Yadkin-Pee Dee, Cape Fear, and Roanoke River basins, while the entire Site Area is within the Roanoke River basin. The Yadkin-Pee Dee Rivers flow through west-central NC into South Carolina before emptying into the Atlantic Ocean at Winyah Bay (Reference 2.5-109). The Cape Fear River originates in the northern Piedmont by the confluence of the Haw and Deep Rivers, flows southeast, and then empties into the Atlantic Ocean near Southport, NC (Reference 2.5-110). The Site Area drains locally into Belews Lake, which flows into Belews Creek and the Dan River. The Dan River is part of the Roanoke River basin; which originates along the eastern slopes of the Blue Ridge Mountains in Virginia and flows southeast through Virginia and NC before emptying into the Albemarle Sound of NC (Reference 2.5-111). Average elevations within the Roanoke River basin range from approximately 1000 ft. above sea level near the Dan River in Stokes County to sea level at the mouth of the Roanoke River (Reference 2.5-111). The terrain in the Dan River basin is characterized as rolling and hilly.

2.5.1.2.2 Local Geologic History

The major tectonic events that affected the Site Vicinity are characterized as the Appalachian Wilson Cycle. The sequence of events are outlined by Hatcher et al. (Reference 2.5-10) as follows:

- Formation of Rodinia from 1.2 to 1.0 Ga during the Grenville orogeny
- Rifting of Rodinia ~ 750 Ma
- Failed rifting of Rodinia ~735 Ma
- Rifting of Rodinia ~565 Ma and formation of Pangea
- Taconic orogeny 480-420 Ma
- Neoacadian orogeny 380-355 Ma
- Alleghenian orogeny 325-265 Ma
- Rifting of Pangea

See Section 2.5.1.1.2 for a more detailed discussion of the Site Vicinity tectonic history.

2.5.1.2.3 Local Stratigraphy

Six tectonostratigraphic terranes are mapped within the Site Vicinity: Tugaloo (West of Brevard Zone), Smith River, Sauratown Mountain, Milton, Carolina, and Charlotte. The Mesozoic Dan River basin is approximately 2 mi. (3.2 km) west of the Project site (Figure 2.5-11; 2.5-22). While not depicted on the map, the correlative terranes extend into Virginia as summarized by Bailey (Reference 2.5-112). Section 2.5.1.1.3.4 describes the general rock types and stratigraphy of the aforementioned Piedmont rocks.

At the Site Area level of detail, two lithologic-tectonic belts or terranes are mapped: the Milton Belt and Dan River basin. Figure 2.5-22 shows the tectonostratigraphic boundaries, and Figure 2.5-23 presents the Site Area bedrock geology. The Site Area is located within the Milton terrane, which comprises late Precambrian massive to strongly foliated biotite gneiss and schist, amphibolite, felsic gneiss, and Late Paleozoic granite intrusions. The rocks are metamorphosed to amphibolite facies and folded into shallowly plunging recumbent folds (Reference 2.5-113; Reference 2.5-114).

Four main geologic formations are mapped beneath and adjacent to the Site Area within the Milton terrane (Reference 2.5-115; Reference 2.5-116; Reference 2.5-117). Unit abbreviations are from Figure 2.5-23. Units in parentheses are from Figure 2.5-16:

- CZbg (bc) – Biotite Gneiss and Schist (520 – 650 my) – highly metamorphosed and foliated biotite gneiss and schist underlie the Project site and are described as dark colored, medium to coarse-grained to porphyroblastic, locally contains hornblende and is chiefly composed of biotite, quartz, potassium feldspar, muscovite, and hornblende. The CZbg formation is interlayered with mica schist and amphibolite and is locally intruded by pegmatite dikes.

- CZfg (qgc) – Felsic Mica Gneiss (520 – 650 my) – interlayered biotite hornblende gneiss with graphitic mica schist and mica-garnet schist, commonly with kyanite. Underlies the northwest side of Belews Lake.

- PPg (Pzc) – Porphyritic Granite (265 – 325 my) – light gray, medium- to coarse-grained porphyritic granite, granodiorite, and quartz monzonite. Composed of microcline phenocrysts up to 5 inches (13 centimeters) in diameter in a matrix of quartz, oligoclase, and biotite. Underlies the area southwest and southeast of the Project site.

- TRds, TRdc, TRdp (Trs) Clastic sedimentary rocks of the Dan River Basin

- (TRd) – Diabase Dike (265 – 325 my) – black to greenish dark gray, fine- to medium-grained, dense rock composed of plagioclase, augite, and olivine. Occurs as dikes up to 200 ft. (61 m) wide and typically occurs as spheroidal weathered boulders with a grayish-brown weathering rind. Diabase dikes typically trend northwest and north and are mapped east of the Project site.

Sedimentary rocks of the Triassic Dan River basin occur northwest of the Milton terrane and trend northeast toward Danville, Virginia. The Chatham fault zone separates the Triassic rocks from the metamorphic rocks of the Sauratown Mountain anticlinorium farther to the north and the Milton terrane to the south. The sedimentary rocks within the Dan River basin are mapped as the Pine Hall Formation, Cow Branch Formation, and Stoneville Formations (Reference 2.5-115; Reference 2.5-118); however, Reid and Taylor further subdivide the Pine Hall Formation into the Walnut Cove Formation and Dry Fork Formation (Reference 2.5-6). There is a Mesozoic dike approximately 4 mi. (6.4 km) northwest of the Site Location (Figure 2.5-16).

At the Site Location level, the subsurface was investigated through an exploration program including geotechnical drilling/coring, borehole and surface geophysics, groundwater well installation and aquifer testing, and laboratory analysis of soil/rock samples. Section 2.5.4 presents a detailed description of the exploration program.

Sixteen locations at each of the 3 Plant Complexes were targeted for exploration for a planned total of 48 geotechnical borings. In some instances, 1 to 3 offsets were completed at each location, resulting in 84 geotechnical boreholes. Lithologies were identified in the field and through laboratory testing on samples retrieved using standard penetration testing (SPT), rock coring, sonic drilling, and intact and bulk soil sampling techniques at the locations.

Cross sections were generated as part of an overall effort to understand the Site Location hydrogeologic and subsurface geologic conditions. The cross sections were prepared using lithologic data from the geotechnical and well lithologic borings, fracture data from the acoustic televiewer geophysical logs, and groundwater data from offset monitoring wells. Surface profiles were generated using topographic data that included processed USGS LiDAR data. The lithologic layers and well screen placements depicted on the cross sections were determined based on field classification of overburden; partially weathered rock (PWR); and bedrock using lithologic observations, SPT N-values (the total number of blows required for the 140-pound hammer to drive the sampler the remaining 1 foot [300 mm] depth), and drilling characteristics. PWR is defined as residual material with SPT N-values exceeding 100 blows per foot. Top-of-bedrock is primarily determined from the rate of drilling penetration and other drilling characteristics such as the behavior of the drill rig upon approaching the top of bedrock.

Figures 2.5-24 through 2.5-25 present the cross section location map and seven cross sections through the Plant Complexes (A-A′, B-B′, C-C′, D-D′, E-E′, F-F′, and G-G′).

Combined overburden and PWR (depth to bedrock) thickness from wells and borings range from 14 to 85 ft. (4.3 to 26 m) thick and average 49 ft. (15 m). PWR thickness averages 13 ft. (4.0 m) and overburden thickness averages 36 ft. (11 m). From the cross sections, PWR is interpreted to be thickest at the North Plant Complex and thins south and east within all three Plant Complexes. The top-of-bedrock surface is generally a subdued reflection of the present-day land surface.

The overburden consists of mostly moist, silty sand with lesser amounts of clay and sandy silt. Clay layers are more common within the soil profile in the upper 7 ft. (2 m). Trace amounts of gravel-sized rock fragments are commonly observed. PWR consists of silty sand with gravel. The relict rock structure of the parent rock material is commonly associated with PWR, such as foliations and schistose structures.

2.5.1.2.4 Site Local Structural Geology

2.5.1.2.4.1 Sauratown Mountains Window

The Sauratown Mountains window is northwest of the Project site at the boundary of the Blue Ridge and Piedmont provinces (Reference 2.5-119) and is an exposure of parautochthonous basement through the overlying thrust sheets (Reference 2.5-120; Figure 2.5-26).

A splay of the Brevard fault system terminates to the southwest of the zone (Figure 2.5-26). The window exposes four imbricate, stacked thrust sheets of Middle Proterozoic basement and Late Proterozoic to possibly Early Cambrian metamorphic rocks. Ages of strontium isotopes indicate reequilibrium of basement rocks occurred during the Grenville orogeny but structural textures formed after that time. Five stages of folding are interpreted in the window along with a later stage of brittle deformation that may indicate the reactivation of the Shacktown fault during Mesozoic rifting (Reference 2.5-119).

The following phases of deformation led to the formation of the Sauratown Mountains window (Reference 2.5-49):

- Late Proterozoic margin sedimentation of the Hogan Creek and Sauratown Formations
- Deep burial, metamorphism, and isoclinal folding
- Taconic age faulting along the Forbush thrust
- Taconic age suturing of the Carolina Terrane to North America
- Possibly Alleghanian-age overthrusting along the Danbury thrust
- Formation of the anticlinorium possibly related to duplexing of platform rocks beneath the Blue Ridge and Piedmont thrust sheet
- Mesozoic dike emplacement and hydrothermal activity

2.5.1.2.4.2 Stony Ridge Fault

The Stony Ridge fault is a discontinuous feature that trends northeast – southwest between the Sauratown Mountain window and the Dan River basin (Reference 2.5-51; Figure 2.5-26). The feature had previously been mapped as a fault; however, Hatcher (1988) (Reference 2.5-49) interpreted little to no displacement. Hatcher (1988) (Reference 2.5-49) interpreted the Stony Ridge fault as a Triassic and Jurassic fissure that had been silicified through hydrothermal processes associated with diabase dike emplacement.

2.5.1.2.4.3 Central Piedmont Suture

The Central Piedmont suture separates the rocks of North America from the allochthonous rocks of the Carolina Belt (terrane) (Reference 2.5-49). It is mapped as a terrane boundary from south-central Virginia to west-central Georgia (Reference 2.5-122). In north central NC, the suture is mapped as the Hyco shear zone and the boundary between the Milton and Carolina terrane. The Hyco shear zone is interpreted to be between 335 ± 2 Ma and 320 ± 1 Ma (U-Pb zircon ages) (Reference 2.5-122). The Hyco shear zone has interpreted dextral strike-slip and reverse motion. Hatcher (Reference 2.5-49) interprets the Shacktown fault to the south of the Sauratown Mountain window as the Central Piedmont suture near the Project site (Figure 2.5-26).

2.5.1.2.4.4 The Dan River-Danville Basin

The Dan River-Danville basin is an asymmetric graben (Figure 2.5-26) bounded to the north by the Chatham fault. The Shacktown fault follows the same trend as the Chatham fault, and some interpret the Chatham fault as the northeast extension of the Shacktown fault (Reference 2.5-119). The Dan River basin is one of a series of continental rift basins that formed during the breakup of Pangea from the Permian to the Early Jurassic (Reference 2.5-123). The southeastern boundary of the Dan River basin is bound by onlap via an unconformity, although some short (<1.8 mi. [3 km]) faults are mapped along this boundary (Reference 2.5-123; Reference 2.5-50). CAMP dikes that cross the Dan River basin have not been dated but if assumed to be the same age as other CAMP intrusives they were emplaced around 201 Ma

(Reference 2.5-123). Some dikes cross the Chatham fault and do not appear to be displaced, indicating tectonic subsidence on the fault ceased before dike emplacement (Reference 2.5-123).

2.5.1.2.5 Local Non-Seismic Geologic Hazards

2.5.1.2.5.1 Karst

In the Site Vicinity, rocks of the Sauratown Mountain Anticlinorium (Figure 2.5-22) are considered prone to karst formation, specifically geologic unit CZmg, which is less than a mile from the northwestern edge of the Site Area (Figure 2.5-23). The mapped CZmg unit is a metamorphic graywacke and muscovite-biotite schist with minor amounts of marble (Reference 2.5-115). The presence of marble (a carbonate rock) at or near the land surface, coupled with average annual precipitation of more than 30 in. (76 cm), is the reason the unit is classified as susceptible to karst (Reference 2.5-101). However, there are no known occurrences of karst in the rocks of the Sauratown Mountain Anticline. Additionally, there are no known fissures, tubes, caves, or units such as basalts that can contain tubes and tunnels and behave like karst within the Site Vicinity (Reference 2.5-101).

In the Site Area, no geologic units near the surface are mapped as carbonates or evaporites (Figure 2.5-23). Furthermore, as discussed in Section 2.5.1.2.3, geotechnical borings were advanced at the North, Middle, and South Plant Complexes as part of the subsurface exploration program. The maximum depth of exploration was approximately 299 ft. (91 m) at the North and South Plant Complexes and approximately 600 ft. (183 m) at the Middle Plant Complex. Bedrock at the site is gneiss and schist, which is consistent with the mapped units presented in Figure 2.5-23. Considering the lack of carbonate units within the upper 600 ft. (183 m) at the Site Location, karst is screened out as a site hazard.

2.5.1.2.5.2 Landslides

As discussed in Section 2.5.1.1.5, the area near the site is mapped as susceptible to landslides but with few mapped landslides (Reference 2.5-104). Belair et al. (Reference 2.5-124) developed a landslide susceptibility map for the continental United States (Figure 2.5-27). Slope and 328-ft. (100-m) relief were calculated on 1/3 arc-second digital elevation models (DEMs). Each 295-ft.(90-m) cell is given a rank of 0 to 81 representing how many 32-ft. × 32-ft. (10-m × 10-m) cells within the 90 m cell were calculated to contain landslide-susceptible terrain. In the Site Vicinity, landslide-susceptible terrain increases from southeast to northwest. In general, the terrain formed by the Dan River basin is less susceptible to landslides than the Sauratown Mountains window.

LiDAR DEM data in the Site Area were reviewed for geomorphic features associated with landslides. Typically, landslides can be identified as semi-circular steep scarps, hummocky terrain, and thickened toe-slopes adjacent to areas of higher topographic relief on LiDAR data (Reference 2.5-125). LiDAR data were hill-shaded at multiple angles and examined at various scales. Potential features were compared to an underlying aerial photograph that was used to identify cultural features that caused any anomalous features, such as cut/fill features associated with houses/buildings. No landslides were identified within the Site Area using this method.

2.5.1.2.5.3 Volcanism

As discussed in Section 2.5.1.1.5, volcanic hazards can be screened out due to lack of evidence for Quaternary volcanism in the Site Region (200 mi. [320 km]).

2.5.1.2.6 Site Engineering Geology Evaluation

2.5.1.2.6.1 Engineering Soil Properties and Behavior of Foundation Materials

Engineering soil properties, including index properties, static and dynamic strength, and compressibility were investigated through a detailed geologic, hydrogeologic, and geophysical investigation and are discussed in Section 2.5.4.

2.5.1.2.6.2 Zones of Alteration, Weathering, and Structural Weakness

Section 2.5.4.2 presents a detailed description of the site investigation to identify zones of alteration, weathering, and structural weakness.

In general, the engineering geological stratigraphy at the Project site generally consists of overburden residual soils weathered in place from the parent rock, underlain by PWR and largely unweathered crystalline rock (fractured and sound rock). The intensity of weathering in the residual soils and PWR is highly variable. The upper portion of the rock is fractured to varying degrees and followed at depth by sound rock.

Analysis of core samples collected at the Project site indicates that the recovery and rock quality designation (RQD) values at the site ranged between 0 and 100. The data indicate that the upper portion of the crystalline rock layer is variably fractured as defined by rocks with RQD less than 50. Overall, the thickness varies between borings, with a minimum thickness of 0 ft. and a maximum thickness of 51.3 ft. (15.6 m). At the North Plant Complex, the mean thickness of the stratum identified as fractured rock (see Section 2.5.4.2.2.3) was 14.0 ft. (4.3 m). At the Middle Plant Complex, the mean thickness of the fractured rock stratum was 5.2 ft. (1.6 m). At the South Plant Complex, the mean thickness of the fractured rock stratum was 6.2 ft. (1.9 m).

2.5.1.2.6.3 Deformational Zones

Section 2.5.3.6 presents a detailed analysis of deformational zones within the Site Area. The analysis compares interpretations from the site-specific geotechnical investigation to interpretations from published geologic maps, aerial photography, and a lineament analysis. The borehole data document metamorphic fabrics, folding, and intrusive relationships that are characteristic of Paleozoic to Precambrian tectonism. No evidence of Quaternary or other recent deformation is observed in the core descriptions, geophysical logs, or stratigraphic profiles developed as part of the site investigations.

Fracture and foliation orientations from borehole logging exhibit generally consistent structural patterns across the Site Area. Most boreholes show a dominant northeast – southwest (N30 – 50°E) azimuth fracture orientation with a secondary northwest – southeast (N20 – 40°W) azimuth–orientation, broadly consistent with conjugate fracture sets observed in Piedmont metamorphic rocks. Open and filled fractures were seen in several on-site boreholes, clustering tightly within these primary and secondary fracture orientation modes, whereas others record more dispersed populations that retain a preferred northeast – southwest fracture trend. As

discussed in Section 2.4.12, more than 97 percent of fractures were calculated to be filled or closed based on acoustic televiewer (ATV) logs.

Cross-hole comparisons show that boreholes express one or both of the principal fracture orientations, indicating that the Site Area-scale fracture geometry can likely be attributed to the regional, Site Vicinity, and Region-scale structural grain of the Milton terrane and Charlotte belt. These borehole-scale results correspond directly to the lineament analysis presented in Section 2.5.3.5, which identify prominent lineament orientations centered at N30 – 40°E, N20 – 30°W, and N60 – 70°E. The agreement between borehole fracture orientations and regional lineament trends supports the interpretation that deformation at the Project site reflects inherited Paleozoic – Mesozoic tectonic fabrics, with no evidence of anomalous Quaternary structural trends or through-going fault zones at the Site Location.

In summary, while the Site Area is located within a tectonically complex Piedmont terrane that records multiple Paleozoic and Mesozoic deformation events, none of the mapped structures in the Site Area show evidence of Quaternary reactivation. These structures are not interpreted to be genetically related to the active tectonic sources that define seismicity in the broader CEUS. Subsurface investigations confirm that the Project site is underlain entirely by Cambrian biotite gneiss and schist, with borehole logging documenting consistent fracture and foliation orientations across multiple boreholes. The dominant northeast – southwest and secondary northwest – southeast fracture sets are broadly consistent with Piedmont fabrics and the regional structural grain, indicating that observed fracture geometry reflects inherited tectonic fabrics. The prevalence of mineral-filled fractures further supports the interpretation that these features are ancient and not the result of recent tectonic activity. No evidence of Quaternary-capable faults, anomalous structural orientations, or recent deformation features were identified in borehole core, geophysical logs, or geomorphic datasets. This conclusion aligns with the summary of regional structure ages presented in Section 2.5.1.1.2.

2.5.1.2.6.4 Prior Earthquake Effects

The most recent widely felt earthquake in the Site Region was the 2020 E[**M**] 5.1 Sparta, NC, earthquake. The USGS Did You Feel It? (DYFI) database compiles voluntary submissions of MMI data and aggregates it at the zip code level for events in the United States (Reference 2.5-126). The Project site is located within the Belews Creek (27009) zip code (Table 2.5-2). Based on the DYFI data for the Sparta event, the Belews Creek zip code experienced MMI III effects from the earthquake based on 14 responses. Nearby zip codes also had aggregate DYFI information: zip code 27357 (Stokesdale) MMI III (50 responses), and zip code 27052 (Walnut Cove) MMI IV (53 responses). MMI III to IV is classified as weak to light shaking (Reference 2.5-126). An MMI III is defined as felt indoors, but many do not recognize it as an earthquake. An MMI IV is defined as felt by many indoors and by few people outdoors. Dishes, windows and doors are disturbed (Reference 2.5-127).

The largest recent event in the Site Region was the 2011 E[**M**] 5.72 Mineral, Virginia, earthquake. The USGS DYFI database had an aggregate MMI V in the Belews Creek zip code, which is a moderate shaking intensity with the potential for very light damage – slightly higher than the MMI III from the 2020 Sparta earthquake. Both the Stokesdale and Walnut Cove zip codes were MMI IV based on responses from the Mineral, Virginia, event (Reference 2.5-128).

The Site Vicinity (25 mi. [40 km]) does not include evidence for liquefaction in the paleoseismology database regional data sets compiled for the CEUS SSC Project (Reference 2.5-117, Appendix E).

2.5.1.2.6.5 Effects of Human Activities

Searching public databases for information on oil and gas production, mining, groundwater use, underground fluid injection, and geothermal development yielded the following effects of human activities in the Site Area:

- There have been 129 petroleum exploration holes drilled in NC, with the most recent being drilling to investigate the total petroleum system of the Dan River basin (Reference 2.5-22). There is currently no oil/gas (petroleum) production from any well in NC (Reference 2.5-129; Reference 2.5-130).

- A detailed analysis of the location of mines and mine-like features is presented in Section 2.5.3.6.1.1. Eight mapped features are within the Site Area (5 mi. [8 km]). Six are classified as clay pits, and two are classified as quarries. No underground mining features are mapped in the Site Area. The closest feature is a quarry that is 2.9 mi. (4.6 km) to the northwest of the Project site across the Dan River.

- An evaluation of groundwater use is presented in Section 2.4.12.4.1. The evaluation concludes that groundwater withdrawals do not have an influence at the Project site, and the Project site does not influence nearby groundwater supplies.

- An evaluation of groundwater use at the BCSS is presented in Section 2.4.12.4.2. A series of 72 extraction and 64 clean water injection wells are used for a groundwater system setup as part of the corrective action plan for the ash basin closure. On average, the monthly groundwater system withdrawal rate is approximately 3.4 million gallons (13 million liters), and the average monthly infiltration system rate is approximately 3.3 million gallons (12 million liters). Extraction and infiltration wells are screened in residuum and bedrock.

No commercial geothermal energy plants are located within the Site Area. There are two domestic injection water only geothermal source heat pump sources:

  - 332 Leeward Drive, Stokesdale, NC (Reference 2.5-131).

  - 6375 Carter Farm Road, Belews Creek, NC (Reference 2.5-131).

2.5.2 VIBRATORY GROUND MOTION

This section describes the vibratory ground motion assessments conducted for the Project site.

The NRC considers the CEUS SSC model (Reference 2.5-60), published as NUREG-2115, as an acceptable starting point for seismic analyses at sites in the CEUS. NRC staff evaluated the companion ground motion model (GMM), known as the Next Generation Attenuation (NGA)-East model (Reference 2.5-135), and agree that it provides an appropriate characterization of median ground motion for use in seismic hazard analyses for Central Eastern North America (CENA) sites. Both CEUS SSC and NGA-East models resulted from projects conducted as

Senior Seismic Hazard Analysis Committee (SSHAC) Level 3 studies, ensuring a high level of regulatory compliance. RG 1.208 specifies that the adequacy of the inputs into a seismic hazard analysis must be evaluated considering any new data and interpretations. Following the recommendations in NUREG-2213, a SSHAC Level 2 study is appropriate for the revision (i.e., the modification of one or more components) of models obtained in SSHAC Level 3 studies, such as the CEUS SSC and NGA-East models. A Level 2 study is also appropriate for the application of a regional model to site-specific conditions and is consistent with recommendations in Rodriguez-Marek et al. (Reference 2.5-136) for site response analysis (SRA).

Duke Energy sponsored a SSHAC Level 2 Probabilistic Seismic Hazard Analysis (PSHA) and SRA study for the Project site. The SSHAC Level 2 report forms the basis of the documentation provided in this section of the Site Safety Analysis Report (SSAR). An overview of the study is provided below.

The goal of the SSHAC Level 2 study was to quantify the site-specific vibratory ground motion hazard for the Project site. The study comprised (1) an evaluation and update of the CEUS SSC and NGA-East models to obtain reference rock seismic hazard results; (2) an evaluation of site data and SRA; and (3) calculation of site-specific seismic hazard results. Figure 2.5-28 shows the workflow of the SSHAC Level 2 study. The evaluation and update of the CEUS SSC and NGA-East models are captured on the left side of the diagram (PSHA path, in red). This phase of work occurred while geotechnical and geophysical data were being collected at the site. As the data became available, the SRA part of the study began (SRA path, in blue, on the right side of the diagram). The two paths joined in the site-specific seismic hazard analysis are shown at the bottom of the diagram. As required by SSHAC, the PSHA and SRA parts of the study included (1) an evaluation phase and an integration phase; (2) the generation of databases collecting data, models, and methods; (3) interviews with resource and proponent experts; (4) documentation of analyses and activities. Duke Energy established a participatory peer review panel (PPRP) that was involved for the duration of the study. The PPRP reviewed the SSHAC Level 2 work plan, actively participated in three meetings with the Technical Integration (TI) Team, observed interactions between the TI Team and the resource and proponent experts, and reviewed the draft and final reports.

In the PSHA part of the SSHAC Level 2 study, the TI Team had to determine whether new data, models, and methods post-dating the publication of the CEUS SSC and NGA-East models warranted an update. NUREG-2213 identifies six decision factors to determine whether a model developed as a SSHAC Level 3 study needs to be updated and, if so, what type of update is required. The six factors are:

1. Changes in data, models, or methods
2. Changes in inputs to the hazard analysis
3. Changes in mean hazard results
4. Changes in technical bases
5. Comparisons of calculated mean hazard with current design bases
6. Comparison of risk or performance to target goals

The degree to which new data, models, and methods lead to changes in the input to the hazard analysis and to the hazard results are used to determine whether the study can be used, or whether it needs to be revised, replaced, refined, or corrected. NUREG-2213 defines these terms as follows:

- To “revise” a model means to modify part of it by incorporating new information that only affects that portion of the model.
- To “replace” means to completely abandon a model and develop a new one.
- To “refine” the model means to adapt a regional study to a site by adding information specific to that site.
- To “correct” a model means to rectify the documentation to fix non-technical errors.

As discussed in Section 6.2 of NUREG-2117, the decision to update (or not) a model resulting from a SSHAC Level 3 study is determined by first conducting a careful evaluation of the data, models, and methods that were available at the time the study was conducted. Second, the new data, models, and methods published since the study was completed are evaluated to determine their hazard significance. The criteria for deciding whether an update is necessary involve (1) establishing whether new data, models, and methods would change the center, body, and range (CBR) of technically defensible interpretations (TDIs) and (2) quantifying the changes in seismic hazard results and their importance.

Section 9.4.3 of NUREG-2115 (Reference 2.5-60) provides quantitative criteria to determine whether changes in model parameters are hazard significant. The criteria (provided below) are based on an assessment of the precision of hazard analyses from previous studies to determine minimum estimates of hazard uncertainty.

- Changes of more than 25 percent (absolute value) in mean annual frequency of exceedance (AFE) at the ground motion level corresponding to AFE 1E-4 are significant.
- Changes of more than 35 percent (absolute value) in mean annual frequency of exceedance at the ground motion level corresponding to AFE 1E-6 are significant.

NUREG-2117 also notes that the most important assessment is the confidence that the model captures the CBR of the TDIs, regardless of the effect on the hazard estimates (i.e., even if the change in hazard estimates is small).

The TI Team considered the guidance in NUREG-2117, NUREG-2213, and NUREG-2115 in evaluating the need to update CEUS SSC and NGA-East models based on the availability of data, models, and methods published after the completion of the two studies to determine whether updates were necessary.

The process began with a review of the CEUS SSC and NGA-East documentation to understand what information (data, models, and methods) was available at the time the models were developed and the reasons for modeling choices. As part of the SSHAC Level 2 evaluation phase, the TI Team contacted members of the CEUS SSC and NGA-East teams as resource experts and identified hazard-significant model components during a set of preliminary calculations. The TI Team then explored the key hazard issues by collecting and evaluating new data, models, and methods that became available since the publication of CEUS SSC and

NGA-East. The TI Team identified and contacted resource and proponent experts to clarify the applicability and limitations of new data, models, and methods.

These activities allowed the TI Team to assess the new information against the criteria discussed in the three NUREGs listed above. First, the TI Team considered if the new information determines changes to the CBR of the TDI. To assess new information against this criterion, the TI Team considered all the information (data, models, and methods) available at the time the CEUS SSC and NGA-East models were developed and information that became available after the publication of the models. Considering all the information and using the same criteria that were adopted to develop the CEUS SSC and NGA-East models, the TI Team evaluated whether the data would support different modeling choices that were not considered possible at the time the models were developed.

The TI Team also evaluated the significance of the differences in hazard estimates. If new data, models, and methods determined differences in AFE above the thresholds documented in Chapter 9.3.4 of Reference 2.5-60 listed above, then a refinement is warranted, and the model requires updating for application at the Project site. To use the criteria in Chapter 9 of Reference 2.5-60, the first step is to compute the mean hazard with the model as is. The TI Team was provided with a set of hazard calculations conducted with the CEUS SSC model and NGA-East model. The mean hazard curves were interpolated to obtain the ground motion levels corresponding to AFEs of 1E-4 and 1E-6 (in the following: GM_{1e-4} and GM_{1e-6}). The TI Team then conducted a new set of seismic hazard calculations, changing a model or parameter, and the resulting mean hazard curves were interpolated to find the AFE corresponding to GM_{1e-4} and GM_{1e-6}. Percent differences in AFE between the original model and the updated model were computed and compared to the criteria in Chapter 9 of Reference 2.5-60.

If the changes do not change the hazard results at the Project site and do not modify the CBR of the TDI, they are not implemented but are fully documented in this report.

The TI Team assessments and analyses conducted for the SSHAC Level 2 PSHA and SRA study are used to discuss the following aspects of vibratory ground motion, consistent with NUREG-0800:

- Seismicity (Section 2.5.2.1).
- Geologic and tectonic characteristics of the Site Region (Section 2.5.2.2).
- Correlation of earthquake activity with seismic sources (Section 2.5.2.3).
- PSHA and controlling earthquakes (Section 2.5.2.4).
- Seismic wave transmission characteristics of the site (Section 2.5.2.5).
- Ground motion response spectra (Section 2.5.2.6).

2.5.2.1 Seismicity

The assessment of earthquake recurrence for distributed seismicity zones (area zones) in CEUS relies on a catalog of observed earthquakes. The CEUS SSC project (i.e., NUREG-2115) followed a rigorous SSHAC Level 3 process to compile the earthquake catalog, which was

extensively reviewed. To date, no other compilations of CEUS earthquakes developed for seismic hazard analyses can provide the same level of regulatory assurance. The catalog terminates at the end of 2008; therefore, for the SSHAC Level 2 study, the TI Team assessed if regional earthquake patterns and seismicity parameters required updating. The following sections describe the CEUS SSC earthquake catalog and the update conducted for the SSHAC Level 2 study, provide information on significant earthquakes in the Site Region (200 mi. [320 km]), and discuss human-induced earthquakes.

2.5.2.1.1 CEUS SSC Earthquake Catalog

The CEUS SSC catalog contains records of earthquakes from the earliest available (AD 1534) to the end of 2008 (December 31, 2008) located within the portion of eastern North America that extends from the foothills of the Rocky Mountains at longitude 105°W, to a region of at least 200 mi. (320 km) from the U.S. – Canada border in the north and from the coastline in the south and east.

Earthquake records were collected from publicly available continental-scale catalogs, such as the USGS earthquake catalog or the earthquake catalog from the Geologic Survey of Canada; regional catalogs, such as those developed by local agencies like the southeastern U.S. Seismic Network; and published studies of specific earthquakes in limited geographic areas. The combined records were carefully reviewed to remove duplicate entries, false entries, and nontectonic events. A uniform process was adopted to convert all available magnitudes to the expected moment magnitude (E[**M**]), which considers the uncertainty associated with the magnitude conversion process, as well as statistical errors in magnitude estimation. Equations 3.3.1-9 and 3.3.1-10 of NUREG-2115, reproduced below as Equations 2.5.2-1 and 2.5.2-2 are used to compute E[**M**] and its associated aleatory variability.

$$\mathrm{E}\left[\mathbf{M} \mid \hat{\mathbf{X}}\right] = \left\{ \sum_i \frac{\sigma^2\left[\mathbf{M} \mid \hat{\mathbf{X}}\right]}{\sigma^2\left[\mathbf{M} \mid \hat{X}_i\right]} \cdot E\left[\mathbf{M} \mid \hat{X}_i\right] \right\} + (R-1)\beta\sigma^2\left[\mathbf{M} \mid \hat{\mathbf{X}}\right] \qquad \text{(Equation 2.5.2-1)}$$

$$\sigma^2\left[\mathbf{M} \mid \hat{\mathbf{X}}\right] = \left\{ \sum_i \frac{1}{\sigma^2\left[\mathbf{M} \mid \hat{X}_i\right]} \right\}^{-1} \qquad \text{(Equation 2.5.2-2)}$$

Where:

- $\hat{\mathbf{X}}$ is a vector of observed size measures $\hat{X}_i$
- *R* is the number of observed independent size measures
- *β* is the slope of the magnitude-frequency distribution in natural-log units (*β*=*b*ln(10))
- $\sigma\left[\boldsymbol{M} \mid \hat{X}_i\right]$ is the standard deviation of the statistical uncertainty in the estimate of E[**M**] given the observed size measurement $\hat{X}_i$

For records that have moment magnitudes computed directly from the seismic moment, the expected value of the true moment magnitude obtained from the observed moment magnitude ($E[\boldsymbol{M}|\widehat{\boldsymbol{M}}]$) given its uncertainty $\sigma[\mathbf{M}|\hat{\mathbf{M}}]$ is calculated using Equation 2.5.2-3, which is based on Equation 3.3.1-5 of NUREG-2115.

$$E[\boldsymbol{M}|\widehat{\boldsymbol{M}}] = \widehat{\boldsymbol{M}} - \beta\sigma^2[\boldsymbol{M}|\widehat{\boldsymbol{M}}] \quad \text{(Equation 2.5.2-3)}$$

NUREG-2115 developed a methodology to obtain unbiased earthquake parameters, referred to as the N* approach. The methodology adjusts earthquake counts to account for the uncertainty in the magnitude estimate. By performing statistical tests, EPRI, DOE, and NRC (Reference 2.5-60) showed that the N* approach performs better than the approach previously adopted (e.g., Reference 2.5-137), when the catalog has varying levels of completeness, as is the case for the CEUS SSC catalog. The N* parameter, i.e., the adjusted earthquake count is computed using Equation 3.3.1-12 from NUREG-2115, reproduced below as Equation 2.5.2-4.

$$N^* = exp\{\beta^2\sigma^2[|\boldsymbol{M}|\widehat{\boldsymbol{M}}]/2\}$$
or
$$N^* = exp\{\beta^2\sigma^2[|\boldsymbol{M}|X]/2\} \quad \text{(Equation 2.5.2-4)}$$

Where:

- $\hat{\mathbf{M}}$ is the observed moment magnitude calculated from seismic moment
- X represents a vector of moment magnitudes resulting from conversion of other magnitude types.

2.5.2.1.2 Earthquake Catalog Update

RG 1.208 specifies that the geological and seismological investigations should be conducted within a radius of 200 mi. (320 km) from the site, and NUREG-0800 states that the site PSHA should consider including more distant sources that have a potential for earthquakes large enough to affect the total site hazard. The SSHAC Level 2 study extended the region for updating the earthquake catalog beyond 400 mi. (640 km) of the site center point for two reasons: (1) to capture the concentration of seismicity in the ETSZ; and (2) to account for the low rate of ground motion in the CENA, which causes earthquakes to be felt over wide areas. Earthquake records with reported magnitudes as low as 2.0 were included in the catalog update for consistency with the CEUS SSC. This magnitude threshold is lower than the minimum magnitude of 3.0 or an MMI greater than or equal to IV prescribed in NUREG-0800.

The TI Team followed the methodology outlined in Reference 2.5-60 to update the CEUS SSC catalog in the Site Region. Earthquake records were obtained from the following sources:

- Advanced National Seismic System Comprehensive Earthquake Catalog (ANSS)
- National Earthquake Database of Canada (NEDB)

- Global Centroid Moment Tensor catalog
- Catalog of Moment Tensors for Parts of North America
- New Madrid Earthquake Catalog (Center for Earthquake Research and Information)
- New England Seismic Network
- Ohio Seismic Network
- Pennsylvania State Seismic Network
- South Carolina Seismic Network
- Daniels and Peng (2023) (Reference 2.5-138), catalog of seismicity in the ETSZ.

Duplicate entries (i.e., records of the same earthquake reported by different agencies) are introduced when records from multiple agencies are combined. In these cases, only one record is selected to represent the time and location of the event, while preserving all possible magnitude estimates that are not identical. This approach is consistent with the processing of the CEUS SSC catalog, in which the national catalogs (ANSS and NEDB) are preferred over regional catalogs, and ANSS records are preferred for earthquakes located south of the U.S.-Canada border, while NEDB records are preferred for those earthquakes that occur north of the border.

Table 2.5-3 shows the types of magnitudes present in the earthquake catalog update, the number of occurrences for each, and the magnitude range. The table also shows the equations used to convert these magnitudes, which are obtained from Table 3.3-1 of NUREG-2115 (Reference 2.5-60). The magnitudes for all earthquake records are converted to E[**M**] using Equations 2.5.2-1 to 2.5.2-3 and have a value of N* calculated with Equation 2.5.2-4.

The catalog in E[**M**] is declustered using the process adopted in NUREG-2115. Two versions of the catalog are obtained: one in which only natural (tectonic) events are included (no human-induced or nontectonic events); the other in which natural (tectonic) events and human-induced events are included. Table 2.5-4 lists the mainshocks with E[**M**] ≥ 2.9 reported to have occurred through April 30, 2024, in the region extending to 400 mi. (640 km) of the Project site. Only earthquakes of tectonic origin are included in Table 2.5-4. Table 2.5-5 contains events with E[**M**] ≥ 2.9 identified as potentially human-induced, reported to have occurred through April 30, 2024, in the region extending to 400 mi. (640 km) of the Project site. Section 2.5.2.1.4 describes the identification of human-induced and nontectonic events.

2.5.2.1.3 Significant Earthquakes in the Site Region (200 Mi. [320 Km] Radius)

Most of the seismicity occurring in the Site Region is located along the Appalachian Mountains to the west of the site, and in the CVSZ to the northeast of the site (Figure 2.5-29). As Figure 2.5-30 shows, only four small-magnitude earthquakes are reported to have occurred within 50 mi. (80 km) of the Project site. The closest of these earthquakes occurred on September 25, 1886, at 2:00 a.m. local time and shows an E[**M**] 2.98 computed from felt area. The figure does not include earthquakes identified as nontectonic or human-induced.

Eight earthquakes with E[**M**] ≥ 5.0 are reported within 200 mi. (320 km) of the Project site. The events are described below, from the largest to the smallest.

May 31, 1897, E[**M**] 5.91, Giles County, Virginia. Widespread damage was reported and felt over an area extending from Georgia to Pennsylvania and from the Atlantic coast to Indiana and Kentucky. In the town of Narrows, Virginia, which is approximately 80.7 mi. (130 km) to the north – northwest of the Project site, surface deformation, mudding of waters, and changes in the flow of springs were observed (Reference 2.5-139).

August 23, 2011, E[**M**] 5.72, Mineral, Virginia. The earthquake occurred on a shallow, northeast-striking reverse fault, within the CVSZ (Reference 2.5-140). It was felt from central Georgia to southeast Canada and as far west as Chicago, Illinois (Reference 2.5-140). The strong motion acceleration system at the North Anna Nuclear Power Plant, located approximately 14 mi. (23 km) northeast of the epicenter (Reference 2.5-141), was triggered and registered a peak acceleration of 0.26 g, peak velocity of 13.8 centimeters per second and cumulative absolute velocity of 0.17 g-sec., with duration of the strongest shaking of about 2 to 3 sec. on the north – south horizontal component (Reference 2.5-142).

August 31, 1861, E[**M**] 5.63, near Wilkesboro, Wilkes County, NC. Caused damage to the epicentral area, described as bricks shaken from chimneys, doors jammed open, and stopped clocks (Reference 2.5-139). The earthquake was felt along the Atlantic coast from Washington, D.C., to Charleston, South Carolina, and westward to Tennessee and Kentucky (Reference 2.5-139).

April 29, 1852, E[**M**] 5.21, near Wytheville, Wythe County, Virginia. This severe earthquake affected a large area in southwest Virginia. Damage in the epicentral area included collapsed chimney tops and fallen bricks. The earthquake was felt as far as the District of Columbia, Maryland, New York, Ohio, and Pennsylvania (Reference 2.5-139).

May 2, 1853, E[**M**] 5.16. The earthquake occurred on the border between Virginia and West Virginia. The only available information on this earthquake is a reported MMI of V and felt area of 61,390 mi^2 (159,000 km^2) as reported in Stover and Coffman (Reference 2.5-139).

August 9, 2020, E[**M**] 5.15, Sparta, NC. This earthquake occurred in the Blue Ridge province, which is characterized by prevailing northeast-southwest–trending structures, and west-northwest or east-west lineaments that cross the prevailing structural fabric (Reference 2.5-143). Figueiredo et al. (2022) (Reference 2.5-83) report observing features associated with the co-seismic rupture to the south and southeast of Sparta, stretching for approximately 1.2 mi. (2 km). They observed straight, ~N110° (west-northwest) trending ground ruptures extending ten to hundreds of meters and a co-seismic topographic step associated with a reverse scarp, 8 to 10 cm (3.1 to 3.9 in.) (maximum 9.8 in. [~25 cm]) high. Relocated aftershocks suggest possibly a complex event, with a primary rupture along the southwest-dipping Little River reverse fault that co-seismically ruptured to the surface (Reference 2.5-143). The second structure is interpreted as a sub-vertical fault with left-lateral strike-slip kinematics that had a blind rupture during the mainshock.

The earthquake was felt along the Atlantic coast and westward into Tennessee and Kentucky. In the epicentral area, roads, utility lines, and masonry structures were damaged, including the collapse of walls and chimneys and the cracking and shifting of foundations (Reference 2.5-83).

February 21, 1916, E[**M**] 5.13, near Waynesville, Haywood County, NC. This event was felt over a wide area of the Atlantic coast and westward to Tennessee and Kentucky. Bricks were shaken from chimneys in the epicentral area and as far as 43.5 mi. (70 km) in the northwest direction (Sevierville, Tennessee), according to Stover and Coffman (Reference 2.5-139). Minor damage was also reported in western Tennessee and Virginia. Changes to spring water quality and flow were reported in Wear Cove, Tennessee.

March 10, 1828, E[**M**] 5.08, south of Roanoke, Virginia. This earthquake occurred approximately 43.5 mi. (70 km) south of Roanoke, Virginia. The earthquake has a reported MMI of V and felt area of 189,190 mi^2 (490,000 km^2) according to Stover and Coffman (Reference 2.5-139). No additional information is available about this earthquake.

Consistent with NUREG-0800 requirements, large-magnitude earthquakes that occurred outside the Site Region (i.e., at distances of more than 200 mi. [320 km]) are discussed below. These earthquakes are the New Madrid, Missouri, earthquake sequence of 1811–1812 (approximately 497 mi. [800 km] west of the site) and the Charleston, South Carolina, earthquake of 1886 (approximately 224 mi. [360 km] southeast of the site).

December 16, 1811, E[**M**] 7.17, January 23, 1812, E[**M**] 7.50, and February 7, 1812, E[**M**] 7.80, New Madrid, Missouri. The three earthquakes in the 1811–1812 sequence are the largest earthquakes to have occurred in historical time in the CEUS (Reference 2.5-60). The earthquakes caused extensive ground deformation, including cratering thousands of acres of farmland and covering the surface with ejected sand, subsidence, uplift, and landslides, and opening fissures. Hundreds of thousands of acres of timber were destroyed, and more than 90 percent of the boats near New Madrid were sunk by a river tsunami (Reference 2.5-144). The damage area covered 231,661 mi^2 (600,000 km^2), and the felt area was more than 1,930,510 mi^2 (5,000,000 km^2) (Reference 2.5-139).

September 1, 1886, E[**M**] 6.9, Charleston, South Carolina. The earthquake is one of the most damaging earthquakes to occur in the southeastern United States, causing an estimated $5-6 million in property damage (Reference 2.5-139). Stover and Coffman (Reference 2.5-139) assign an MMI of X and list a felt area of more than 772,000 mi^2 (2,000,000 km^2) based on observations that structural damage was experienced in locations as far as central Ohio, central Alabama, eastern Kentucky, southern Virginia, and western West Virginia, with long period effects reported at locations more than 621 mi. (1000 km) away from the epicentral area. Surface deformation included damaged train tracks, fissures as wide as 3.3 ft. (1 m), cracks, and sand blows. The effects of the earthquake were documented by photographs; among the most famous are those depicting displacements of railroad tracks of the South Carolina Railroad. The aftershock sequence continued through 1889 (Reference 2.5-145), delineating a large aftershock zone extending about 155 mi. (250 km) toward Appalachia.

2.5.2.1.4 Seismicity Associated with Human Activities

The CEUS SSC project identified and removed non-tectonic events from the earthquake catalog. Non-tectonic events include mining and quarrying related blasts, explosions, and rock bursts; reservoir-induced seismicity; chemical explosions; and sonic booms. At the time the CEUS SSC catalog was compiled, earthquakes associated with enhanced oil and gas recovery operations were known to occur; however, the catalog end date (December 31, 2008) precedes the significant seismicity rate increase in the CEUS that began in 2009 with the expansion of recovery operations.

The region covered by the SSHAC Level 2 catalog update includes areas of active surface and underground mining, particularly in West Virginia, Maryland, and Pennsylvania, and areas of active stimulation of hydrocarbon plays, particularly in eastern Ohio and into central West Virginia. Three types of earthquake records are present in the SSHAC Level 2 catalog update: (1) tectonic (natural) earthquakes, including mainshocks and aftershocks; (2) non-tectonic events, such as mine and quarry blasts; and (3) human-induced events, e.g., those associated with hydrocarbon extraction activities.

In the northern Appalachian basin, hydraulic fracturing began in 2009 with targets in the Marcellus Shale. Beginning in 2011, the stratigraphically lower Utica formation was also targeted. A significant increase in seismicity was linked to wastewater disposal and hydraulic fracturing (Reference 2.5-146. Studies conducted by Schultz et al. (Reference 2.5-147) and Brudzinski and Kozlowska (Reference 2.5-146) show that induced seismicity clusters in Appalachia illuminate a set of pre-existing, critically stressed faults that are optimally oriented in the regional stress field.

Figure 2.5-31 is a map of the Appalachian basin showing the depth interval between the stimulated formation and the crystalline basement. Stars indicate known induced seismic sequences. According to Skoumal et al. (Reference 2.5-148), most of the confirmed induced seismic events occurred when the distance between the target shale and the basement is less than 0.6 mi. (1 km). However, it is not the distance itself that controls the occurrence of induced seismicity, rather it is the proximity to favorably oriented, critically stressed, pre-existing faults. In the Appalachian basin, the Precambrian basement satisfies this condition. A possible explanation for the relatively higher frequency of induced earthquakes in Ohio compared to Pennsylvania or West Virginia is the deepening of the Precambrian basement toward the east, such that wells in Pennsylvania and West Virginia target the shallower Marcellus formation instead of the deeper Utica formation. As captured in Figure 2.5-31, evaporites of the Salina Group underlay the Marcellus Shale and could be a barrier to fluid migration toward pre-existing basement faults, thus impeding the transmission of elevated pore-fluid pressures and stress transmission to the faults (Reference 2.5-148).

2.5.2.1.4.1 Induced Seismicity Clusters

This section describes confirmed induced seismicity clusters in Ohio and West Virginia that have occurred since the early 2010s. The clusters are described in chronological order.

A cluster of eight, small-magnitude earthquakes occurred within a few kilometers of an active wastewater injection well in Braxton County, West Virginia, between April and July 2010. The largest earthquake recorded had a magnitude of 3.4. After this cluster, the rate of injection was reduced, until a magnitude 2.8 earthquake occurred in 2012, prompting a reduction in the volume of injection. In 2013, a second magnitude 3.4 earthquake was observed, and the well was shut-in. In total, fifty-four earthquakes were detected between 2010 and 2013; these earthquakes appear to be aligned in a northeast to southwest direction, consistent with the focal mechanism of the largest event (Reference 2.5-148). During the same period, a sequence of small-magnitude earthquakes classified as “probably induced” occurred within 6.2 mi. (10 km) of active wastewater injection wells in Washington County, Ohio (Reference 2.5-149; Reference 2.5-150). The rise in seismicity appears to correlate with increased activity in the Long Run-1 well, located about 3.1 mi. (5 km) from the earthquake epicenters.

In 2011–2012, fluid injection into a deep well near Youngstown, Ohio, produced an earthquake sequence of 109 small events, the largest of which (M_W 3.9) occurred on December 31, 2011 (Reference 2.5-151). The seismicity aligned on an east-northeast to west-southwest trend, consistent with the focal mechanism of the main shock, and helped to identify a subsurface fault close to the injection point (Reference 2.5-151). According to Morris et al. (Reference 2.5-152), the volume of wastewater injection into the Northstar 1 well, combined with the original stress state and a highly anisotropic permeability structure, can reactivate basement structures.

Between July and August 2013, a cluster of 161 small-magnitude earthquakes (up to magnitude 2.7) were reported in Gilmer County, West Virginia. According to Skoumal et al. (Reference 2.5-148), the seismic activity began soon after hydraulic fracturing started and ended soon after the completion of the horizontal wells.

Harrison County, Ohio, experienced a sequence of small-magnitude earthquakes in October 2013. Earthquake epicenters relocated by Friberg et al. (Reference 2.5-153) show a vertical east-west–trending fault in the Precambrian basement directly beneath the Ryser-2, Ryser-3, and Ryser-4 horizontal wells. Using spatial and temporal correlation of the seismicity with the operations in the Ryser wells and the similarity of waveforms of all recorded earthquakes, Friberg et al. (Reference 2.5-153) conclude that the seismic activity was induced by hydraulic fracturing in the Ryser wells.

In 2014, Poland Township, Ohio, experienced 77 small-magnitude earthquakes (M_L up to 3), closely related spatially and temporarily to active hydraulic fracturing operations (Reference 2.5-154). The focal mechanism of the main event and the depth of the seismicity (approximately 1.9 mi. [3 km]) are consistent with the Youngstown, Ohio, sequence.

A sequence of small-magnitude earthquakes was reported in May 2014 near the Kirkwood well pad, near the border of Belmont and Guernsey counties, Ohio (Reference 2.5-146). The sequence was followed in August 2016 by a M_L 2.3 earthquake a few kilometers to the southeast.

In August 2014, a M_L 2.1 event was located within 0.6 mi. (1 km) of two wells in Trumbull County, Ohio. The wells were injecting water into Silurian strata (shallower well) and into sediments approximately 49 ft. (15 m) above the Precambrian basement (deeper well). Earthquake clusters formed an east-northeast to west – southwest trend and north – northeast to south – southwest trend, and the focal mechanism of the largest events (M_L 2.1) indicated a strike-slip mechanism with a north–south fault plane (Reference 2.5-146). Once the injection was halted in both wells, the seismicity stopped. Brudzinski and Kozlowska (Reference 2.5-146) note that the seismicity did not resume after the shallower well returned to operations, indicating a correlation of the earthquakes to the deep well injection.

Between May 2013 and July 2015, 23 earthquakes occurred within 1.9 mi. (3 km) of the Long Run-1 well in Washington County, Ohio. Currie et al. (Reference 2.5-150) identified an additional 319 similar events with magnitudes up to M_L 2.1 and correlated the rate of seismicity with the rate of injection. The seismicity clusters align in the northeast-to-southwest direction, consistent with the trend of low-amplitude folds in Paleozoic rocks overlying the area being stimulated. These folds are interpreted to be generated by basement-involved fault systems that might have provided a path for fluid pressure increases. The earthquakes occurred at depths between 1.9 and 2.7 mi. (3.1 and 4.3 km) in the Cambrian sedimentary strata and in the underlying Precambrian crystalline basement.

Between December 2016 and spring 2017, several small-magnitude earthquakes were reported in Monroe County, Ohio, associated with hydraulic fracturing on the Donato well pad and the nearby Gary Green and Jacobs well pads (Reference 2.5-146).

In June 2017, Noble County, Ohio, experienced two earthquakes, the largest with M_L 2.4, directly below an active horizontal well, followed a few weeks later by a M_L 3.7 earthquake (Reference 2.5-146). The focal mechanism of this earthquake shows an east-west–trending fault plane.

2.5.2.1.4.2 Identification of Human-Induced and Non-Tectonic Events in the Updated Catalog

The TI Team identified non-tectonic events (e.g., explosions, acoustic noise, anthropogenic events, collapses, chemical explosions, rock bursts, induced earthquakes, avalanches, landslides, mine blasts, sonic booms, cryoseisms) from publicly available catalogs and publications, satellite imagery, and databases of active mining operations in various states.

Similarly, the TI Team used maps in published literature and imagery to locate the wells. Earthquakes reported within 1.2 to 1.9 mi. (2 to 3 km) of known hydraulic fracturing or wastewater disposal wells, or that occurred in areas of previously identified induced seismicity clusters and have focal depths consistent with depth of induction, were flagged as probably human-induced.

Figure 2.5-32 compares the focal depth distribution of groups of events identified in the catalog update: tectonic (natural) earthquakes (mainshocks and aftershocks); human-induced earthquakes (i.e., those associated with oil and gas extraction activities); and non-tectonic events (e.g., mine and quarry blasts). Focal depths are used as they appear in the source catalogs, disregarding the quality of the solution. Human-induced earthquakes (red) are concentrated within the top 3.7 mi. (6 km), particularly between 0 and 0.6 mi. (0 and 1 km) and between 2.5 and 3.1 mi. (4 and 5 km). The distribution is truncated at 3.7 mi. (6 km) by choice, following the work of various authors (Reference 2.5-150; Reference 2.5-148) and the approximate depth of the Precambrian basement. Non-tectonic events (black) occur predominantly at very shallow depths (0 to 0.6 mi. [0 to 1 km]), consistent with predominant mining and quarry blasts. Tectonic earthquakes range in depth from very shallow (0 to 0.6 mi. [0 to 1 km]) to deep (24.8 mi. [40 km]). Two peaks, 0 to 0.6 mi. (0 to 1 km) and 2.5 to 3.1 mi. (4 to 5 km), suggest that some human-induced earthquakes may remain in the catalog, and that for many earthquakes, the depth is poorly determined and fixed at 3.1 mi. (5 km).

To evaluate the contamination of the catalog with mining/quarry blasts, the TI Team plotted the time of day when the events are recorded. Figure 2.5-33 compares the local time at which various types of events have occurred: time is converted from Universal Standard Time to Eastern Standard Time or Eastern Daylight Time, depending on the month of the year, and is presented in one-hour intervals. Non-tectonic events occur during daylight hours from about 6:00 a.m. to 6:00 p.m. with maximum frequency in the central part of the working day. Human-induced earthquakes have a similar pattern, while tectonic events are almost evenly distributed between daytime and nighttime. The TI Team noted that the distribution of earthquake occurrence in time (hour of day) seems to indicate that there might still be some contamination of non-tectonic events in the catalog, but tests described in Section 2.5.2.2.2.1 show that the potential contamination does not affect the analysis.

2.5.2.2 Geologic and Tectonic Characteristics of the Site and Region

The CEUS SSC model is the most recent regional SSC model available for the CEUS and is an acceptable starting point for PSHA analyses of sites in the region. Section 2.5.2.2.1 summarizes the CEUS SSC model, describing the logic and salient characteristics of the seismic sources that are used to compute seismic hazard at the Project site. The process of evaluating new information is described in Section 2.5.2.2.2.

Section 2.5.2.2.2 describes new information regarding seismic source zones and seismic fault sources, respectively, and the TI Team evaluation of their effect on seismic hazard. Section 2.5.2.4. summarizes the adopted SSC model for the seismic hazard evaluation of the Project site, informed by the evaluations described in the preceding sections.

2.5.2.2.1 Summary of CEUS SSC Model

The CEUS SSC model covers the portion of central and eastern North America that extends from the foothills of the Rocky Mountains (set at longitude 105°W) in the west, to at least 200 mi. (320 km) from the U.S.-Canada border in the north and from the coastline in the east and south.

The CEUS SSC model includes two types of seismic sources: (1) repeated large-magnitude earthquake (RLME) sources, and (2) distributed seismicity sources, or what are called “background” source zones in Chapter 4 of Reference 2.5-60. RLME sources are used to represent the location of repeated (more than one), large (magnitude **M** ≥ 6.5) earthquakes as inferred from the historical and paleoseismic record (Reference 2.5-60). As discussed in Chapter 1 of Reference 2.5-60, the threshold magnitude **M** 6.5 was chosen because it is usually possible to identify the effects of such earthquakes in the paleoseismological record. Distributed seismicity sources identify regions of diffuse seismicity within which the RLME sources are located.

The CEUS SSC model uses logic trees to represent alternative approaches and conceptual models, and their relative weights. Logic trees are evaluated from left to right, with the left-most nodes (first-order level of the tree) addressing basic conceptual models, followed by subsequent levels that represent the uncertainties in the implementation of each approach. Discrete alternative models or parameters for each level (or node) of the logic tree, are represented by branches and are assigned weights representing their relative credibility.

Figure 2.5-34 shows the CEUS SSC master logic tree: the first (left-most) node is the choice between the models used to define the spatial and temporal distribution of future seismicity in the background sources, respectively Mmax (maximum magnitude) zones and seismotectonic zones. Mmax zones are based on differences in the prior distributions used for assessing maximum magnitude using the Bayesian approach, while seismotectonic zones are delineated using differences in the expected characteristics of future earthquakes beyond Mmax, such as differences in rupture orientation, style of faulting, and focal depth.

RLME sources are tectonic features identified based on clear evidence for Late Quaternary or Holocene RLMEs. RLME sources have (1) the potential to localize future large magnitude (**M** ≥ 6.5) earthquakes; and (2) evidence of recurrence of such earthquakes that differs from that of their host background zone. For these reasons, RLME sources are always included in the model, regardless of how background (diffused) seismicity is represented.

Seismic hazard calculations require recurrence rates of earthquakes associated with each seismic source and the Mmax that each source can produce. A truncated exponential magnitude distribution, defined by rates of earthquakes above a minimum magnitude (known as a-values) and the slope of the magnitude-frequency distribution (known as b-values), is used to model the frequency of earthquakes occurring within the distributed seismicity zones. To capture spatial variations of a- and b-values within source zones, the CEUS SSC project used a smoothing technique known as the penalized-likelihood approach. In applying this technique, the background sources are subdivided in cells along parallels and meridians of either ¼° x ¼° spacing or ½° x ½° spacing for larger zones. Epistemic uncertainty in a- and b-values is modeled by three alternative sets of weighted magnitude intervals, called cases A, B, and E, and eight alternative sets of parameters for each source zone.

Mmax, i.e., the upper truncation of the earthquake recurrence relationship, and its uncertainty were assessed using a combination of two statistical techniques: a Bayesian methodology that employs prior distributions obtained from a database of earthquake magnitudes in stable continental regions; and a mathematical procedure, known as the Kijko method, that uses observed seismicity data and is best applied with large datasets. The application of these methodologies resulted in broad distributions, ultimately represented by five-point discrete approximations for use in hazard calculations.

Following the discovery of an error in the published Mmax distributions for a number of CEUS SSC seismotectonic zones (Paleozoic Extended Zone-Narrow [PEZ-N], Paleozoic Extended-Wide [PEZ-W], St. Lawrence Rift [SLR], Midcontinent-Craton [MidC] A through D, and Illinois Basin Extended Basement [IBEB]), EPRI (Reference 2.5-155) published corrected Mmax distributions for these zones and concluded that the error had a negligible effect on the recurrence parameters, calculated seismic hazard, and ground motion response spectra results.

Aleatory distributions, such as style of faulting, orientation (fault strike) and dip for each style of faulting, and epistemic alternatives (e.g., thickness of the seismogenic crust) are used in the CEUS SSC model to express the characteristics of future earthquake ruptures occurring within distributed seismicity sources. Reference 2.5-60 also provides an empirical equation to compute rupture area as a function of magnitude, and a model for aspect ratio. These equations are used to calculate the dimensions of future earthquake ruptures. Reference 2.5-60 did not develop focal depth distribution or hypocentral depth ratio models because, at the time, these models were not needed for the application of GMMs for central and eastern North America. These distributions are used in the NGA-East Ground Motion Characterization model (Reference 2.5-135) to compute the depth to top of rupture parameter.

Two types of data are used to derive earthquake recurrence for RLME sources: (1) estimated ages of paleoearthquakes, which can be used to calculate the times between consecutive events; or (2) estimates of the number of earthquakes that have occurred post the age of a particular stratigraphic horizon. For most RLME sources, the occurrence of earthquakes in time is modeled to follow a Poisson process, in which the occurrence of an earthquake is independent from the time of the previous event. For two RLMEs, there is sufficient paleoseismological data to indicate that earthquakes may occur in a more periodic fashion than is modeled by a Poisson process. For these RLME sources, a renewal model that considers the time elapsed since the most recent RLME occurrence, was also used to assess the rate of earthquake occurrences. Uncertainties in characterizing the occurrence rates for RLME sources derive from uncertainties in the paleoseismological data (e.g., uncertainties in the number of earthquakes, ages of stratigraphic horizons, and specific ages of earthquakes). Aleatory

variability in the magnitude of individual RLME occurrences is modeled by a uniform distribution over a range of ±0.25 magnitude units centered on the characteristic RLME magnitude. The characteristic RLME magnitude is assessed using various sources of data for each RLME source and the epistemic uncertainty associated with this assessment is expressed by a probability distribution in the logic tree for the source.

2.5.2.2.1.1 Maximum Magnitude Zones

The logic tree for the Mmax zone approach branch captured in Figure 2.5-35 is consistent with the application of the alternative prior distributions for assessing Mmax. Three prior distributions for the calculation of Mmax were developed in Reference 2.5-60: the first distribution is applicable to Mesozoic and younger extended crust (MESE), the second is applicable to non-extended crust, or to crust where the most recent extension occurred before the Mesozoic (called “NMESE”), and the third is a composite distribution for all stable continental regions regardless of presence or absence of Mesozoic extension.

The need to separate crust that underwent Mesozoic extension from older or not extended crust is addressed in the first node of the logic tree, which leads to a branch that models the entire CEUS (the study region [STUDY-R]) as a single zone, and an alternative branch where MESE and NMESE are separated. The approach that uses the separation is preferred (weight of 0.6) over the approach that does not recognize a separation (weight of 0.4) because there is marginal statistical significance for the separation (Chapter 6 of Reference 2.5-60).

The second node of the logic tree in Figure 2.5-35 addresses the uncertainty in the location of the boundary between MESE and NMESE and consists of two interpretations. The narrow interpretation is delineated using only MESE extensional features that are unquestionable, leading to the zones MESE-N and NMESE-N captured in Figure 2.5-36. The wide interpretation includes weaker evidence of extensional features and leads to zones MESE-W and NMESE-W captured in Figure 2.5-37. Discussion in Chapter 6 of Reference 2.5-60 attributes the preference of the narrow interpretation (weight of 0.8) over the wide interpretation (weight 0.2) to the stronger evidence for the boundary location. Figures 2.5-36 and 2.5-37 show that both interpretations of the boundary are within 200 mi. (320 km) of the site. Further discussion of this boundary is given in Section 2.5.2.2.2.3.

The following descriptions of the Mmax zones are summarized from Reference 2.5-60. Full descriptions are provided in that report.

EPRI, DOE, and NRC (Reference 2.5-60) define the western boundary of the interpreted extent of Mesozoic age and younger extensional features using a variety of geologic, geophysical, and seismologic data such as:

- The presence of grabens and basins of Mesozoic age
- The presence of plutonic masses of Mesozoic age and younger
- The presence of faults and dikes of Mesozoic age and younger
- Evidence for MESE uplift and normal faulting

These features are used to define the boundaries of zone MESE-Narrow (MESE-N), which includes the Extended Continental Crust-Atlantic Margin (ECC-AM), Extended Continental Crust-Gulf Coast (ECC-GC), Atlantic Highly Extended Crust (AHEX), Gulf Coast Highly

Extended (GHEX), Reelfoot Rift (RR), SLR, Northern Appalachian (NAP), Great Meteor Hotspot (GMH), and PEZ-N seismotectonic zones. The MESE-Wide (MESE-W) zone adopts the wide alternative geometries for the PEZ-W, RR with Rough Creek Graben (RR-RCG), and IBEB zones.

The largest historical non-RMLE earthquake in the MESE was the E[**M**] 6.25 on September 16, 1732, in the St. Lawrence region of Canada.

The NMESE eastern boundary corresponds to the western boundary of MESE described above. There are two alternative geometries: narrow (NMESE-N) and wide (NMESE-W). The largest historical non-RMLE earthquake in the NMESE-N zone was the E[**M**] 5.91 on May 31, 1897, in Giles County, Virginia; the largest historical non-RLME earthquake in the NMESE-W zone was the E[**M**] 5.72 on May 16, 1909, near the border of North Dakota, Montana, and Canada.

The Study Region (STUDY-R Mmax) zone includes the entire region assessed by the CEUS SSC study. The largest historical non-RLME earthquake in the STUDY-R was the E[**M**] 6.25 on September 16, 1732, in the St. Lawrence region of Canada.

2.5.2.2.1.2 Seismotectonic Zones

Figure 2.5-38 shows the logic tree for seismotectonic zones. The first assessment (first node) pertains to the location of the western boundary of PEZ and matches the uncertainty in the location of the boundary between MESE and NMESE (Figure 2.5-37). The second node explores if the RCG should be included with the RR or with the MidC zone. Four possible interpretations of zone boundaries stem from the combination of the first two nodes, as captured in Figure 2.5-39 to Figure 2.5-42. Three seismotectonic zones are located within 200 mi. (320 km) of the site: PEZ-N, PEZ-W, and ECC-AM (with the site located within the ECC-AM zone).

The potential for hazard contributions from distant earthquakes is considered in the PSHA by incorporating zones located outside the 200 mi. (320 km) radius from the Project site: AHEX, ECC-GC, IBEB, MidC (A through D), NAP, RR, RR-RCG, and SLR.

The seismotectonic zones are presented in alphabetical order below. For each zone, a brief description, summarized from Reference 2.5-60, is provided; full descriptions of the sources are provided in that document.

The AHEX zone marks the transition between the extended, thick continental crust of the ECC-AM to the thin, mafic-oceanic crust of the Atlantic Ocean. In addition to differences in composition of the crust, other characteristics such as the thinner seismogenic crust and sparse seismicity, are used in Reference 2.5-60 to justify separating the AHEX from the ECC-AM. The zone is entirely offshore, and its geometry follows the continental shelf edge from Nova Scotia, Canada, to Georgia.

The ECC-AM is the host zone of the Project site. The zone extends from Nova Scotia, Canada, to Georgia and includes onshore portions of the Piedmont and Coastal Plain provinces and most of the offshore continental shelf region.

The east-dipping Paleozoic basal detachment surface is mapped by seismic reflection profiles at depths of about 3.7 mi. (6 km) at the western flank of the mountains, deepening to about 6.2 mi. (10 km) in the Piedmont, and then steepening to about 21.7 mi. (35 km) in the east. Paleozoic thrust sheets above the detachment are predominantly “thin-skinned” in the west and

"thick-skinned" in the east. The gravity anomaly gradient and other geophysical data show the thinning of the continental crust toward the inferred Late Precambrian-Early Paleozoic continental margin, which lies underneath the Piedmont. The gravity anomaly gradient is taken to define the structural western boundary of the thinned, extension-dominated crust. A major geophysical feature is the East Coast Magnetic Anomaly that runs parallel to the Atlantic margin and is correlated with igneous rocks, marking the transition from continental-rifted crust to mafic-oceanic crust.

The ECC-AM includes multiple shear zones and faults, mostly related to Paleozoic accretion of terrains during the Appalachian orogenies. Normal faults bound Mesozoic rift basins and have been interpreted to be reactivated Paleozoic structures. Cretaceous and younger faults are predominately north – south or northeast – southwest oriented, reverse faults. Some of these faults have experienced Cenozoic activity; however, poor exposure, lack of suitable stratigraphy, small displacement, and low slip rates make the identification of Cenozoic movement difficult. Future earthquakes are modeled to prefer north and northeast orientations, although some weight is assigned to east – west-oriented ruptures.

Seismicity is variable within the ECC-AM, with concentrations of activity in the CVSZ, the greater New York City – Philadelphia area, the Charleston, South Carolina, area, the Piedmont region of South Carolina and Georgia, and in New England. The largest earthquake observed in the ECC-AM was the 1886 Charleston, South Carolina, event, which is associated with the Charleston RLME source. Aside from this earthquake, the largest historical event located in the ECC-AM was the 1755, M 6.1 Cape Ann earthquake. The earthquake was located near the boundary with the NAP zone, and because of the uncertainty in location, two alternative models are used in the calculation of Mmax. In the first model (weight of 0.6), the Cape Ann earthquake is the largest observed earthquake in the ECC-AM. In the second model (weight of 0.4), the Cape Ann earthquake is in zone NAP, and the largest observed earthquake prior to 2011 in the ECC-AM occurred on June 11, 1638 (E[**M**] 5.32).

The Mineral, Virginia, earthquake of August 23, 2011, E[**M**] 5.73, occurred in the ECC-AM and is described in Section 2.5.2.1.3.

The ECC-GC seismotectonic zone delineates areas of thick transitional crust that mark one of the three large crustal domains that formed in the Gulf of America region during the break-up of Pangea. The lack of preferential orientation of structures is used to separate ECC-GC from ECC-AM; differences in seismogenic thickness are used to separate ECC-GC from GHEX (ECC-GC has a thicker crust).

The largest earthquakes in the ECC-GC historical catalog were the October 22, 1882, E[**M**] 5.58 and October 24, 1997, E[**M**] 4.88 earthquakes. Paleoseismic data collected in southeastern Arkansas, northeastern Louisiana, and western Mississippi suggest earthquakes from magnitude 5, potentially up to magnitude 6.5, may occur in the seismotectonic zone, possibly related to the Saline River fault in southern Arkansas. In the CEUS SSC model, the magnitude distribution of paleoearthquakes is used as one of the options to formulate the Mmax posterior distribution for the ECC-GC zone.

The IBEB zone is defined to account for moderate-to-large magnitude earthquakes occurring on deep structures in the Precambrian basement and on Paleozoic faults that extend into the Paleozoic sedimentary rocks. The crust underlying the southern Illinois basin appears to be

different from that of adjacent zones, such that future earthquake characteristics will also be different.

The geometry of the zone is defined to roughly encompass the basement rift sediments and the areas where paleoearthquakes have been identified. Evidence of RLMEs is used to characterize the Wabash RLME source (see Section 2.5.2.2.1.3); however, other paleoseismological evidence exists outside the Wabash Valley, including four paleoearthquakes with approximate **M** 6.2-6.3, as inferred from widely distributed liquefaction features.

The largest historical earthquakes recorded within the IBEB were the September 27, 1891, E[**M**] 5.52; August 15, 1891, E[**M**] 4.97; and April 18, 2008, E[**M**] 5.30 earthquakes. Additionally, four prehistoric earthquakes inferred from the paleoliquefaction studies have estimated magnitudes that are larger than the historical earthquakes. These are the ~**M** 6.3 Vallonia, ~**M** 6.2 Shoal Creek, ~**M** 6.2 Springfield, and **M** 6.2 Waverly earthquakes (Chapter 7, Reference 2.5-60).

The MidC seismotectonic zone is composed of continental crust that has not been involved in orogenic episodes during the Phanerozoic, including the Canadian Shield and the platform. As captured in Figures 2.5-39 to 2.5-42, there are four possible geometries for the MidC zone (A – D) that stem from alternative configurations of the PEZ, RR, and RR-RCG seismotectonic zones.

According to the description in Chapter 7 of Reference 2.5-60, Precambrian basement structures in the MidC zone include northeast-striking shear zones and northwest-trending strike-slip faults interpreted to form fault and fold zones that could be reactivated in the current stress regime. The distribution of seismicity within the MidC zone varies spatially, with concentrations in the Anna Seismic Zone in western Ohio, the Northeastern Ohio Seismic Zone, and the Nemaha Ridge-Humboldt Fault Seismic Zone in Kansas. Paleoseismic investigations in these zones do not identify **M** > 7 earthquakes in the past few thousand years but cannot preclude moderate-sized (**M** 6 to **M** < 7) earthquakes; the data, however, are insufficient to define RLME sources in these areas.

The largest historical earthquakes recorded within the MidC zone were May 16, 1909, E[**M**] 5.72 (although it is noted that the location of the event may be poorly constrained) and the November 15, 1877, E[**M**] 5.50 earthquake (Chapter 7, Reference 2.5-60).

The NAP zone is considered MESE and is separated from the ECC-AM because it does not contain fault-bounded rift basins. Moderate-magnitude, shallow seismicity (depth less than 6.2 mi. [10 km]) occurs above the continental margin within the crust of amalgamated-composite Appalachian terranes. These terranes were formed outboard of the Laurentian margin and post-date Iapetan rifting. For this reason, the NAP zone is separated from the PEZ and SLR zones.

The largest historical earthquakes reported within the NAP have moderate magnitudes: these include the March 21, 1904, E[**M**] 5.73 earthquake, the June 11, 1638, E[**M**] 5.32 earthquake, and the December 24, 1940, E[**M**] 5.6 earthquake. There is some possibility that the 1755 Cape Ann earthquake (E[**M**] 6.1) might be located in the NAP zone rather than in the ECC-AM.

The PEZ zone delineates a region of continental crust of the Iapetan-rifted margin showing some evidence of reactivation during Mesozoic extension, in contrast to the crust of adjacent zones (ECC-AM, ECC-GC, NAP, and SLR) that have strong evidence of Mesozoic reactivation. The two geometries of PEZ (narrow and wide, i.e., PEZ-N and PEZ-W, respectively) are defined on the basis of the evidence for Iapetan rift faults and sediments.

Zones of elevated seismicity within the PEZ include Giles County, Virginia; the ETSZ; and the Clarendon-Linden Fault System. According to EPRI, DOE, and NRC (Reference 2.5-60), paleoseismic investigations in these areas do not provide sufficient data to characterize RLME sources. The largest historical earthquake in the PEZ was the 1897 Giles County earthquake (E[**M**] 5.91) (Chapter 7, Reference 2.5-60).

The August 9, 2020, E[**M**] 5.15 Sparta earthquake occurred in the PEZ and is described in Section 2.5.2.1.3.

The RR seismotectonic zone includes an area of localized tectonic strain interpreted to be a Cambrian aulacogen reactivated during Mesozoic rifting. The rate of earthquakes in this zone is higher than in adjacent zones, and multiple Quaternary active faults have been identified in the zone. The New Madrid Fault System (NMFS), Eastern Rift Margin (ERM), Marianna, and Commerce Geophysical Lineament RLME sources are located inside the RR.

The seismogenic thickness is less in the RR than in the adjacent IBEB zone, as evidenced by focal depths of well-located earthquakes. The RR is differentiated from MidC and ECC-GC based on the orientation of structures (Chapter 7, Reference 2.5-60).

The RCG extends east from the RR and includes faults that formed during the initial phases of rifting and reactivation during the Appalachian-Ouachita orogeny. Figure 2.5-39 through Figure 2.5-42 represent alternative configurations that stem from the uncertainty about the inclusion of the RCG in the RR source zone. The inclusion (zone RR-RCG) receives a lower weight (0.333) compared to the alternative (RCG inside IBEB, weight 0.667) because there is some evidence that Mesozoic reactivation was limited in the RCG (Chapter 7, Reference 2.5-60).

The two largest historical earthquakes reported in the zone that are not associated with RLME sources were the January 5, 1843, and October 31, 1895, **M** 6 (E[**M**] 6.00) earthquakes (Chapter 7, Reference 2.5-60).

The SLR seismotectonic zone is an area of elevated seismicity representing crust that was rifted during the late Proterozoic-early Paleozoic opening of the Iapetus Ocean. Faults were subsequently reactivated during the Paleozoic and Mesozoic. The Charlevoix RLME source area is located within the SLR seismotectonic zone.

The largest historical earthquakes reported in the zone that are not associated with the Charlevoix RLME source include the 1732, E[**M**] 6.25 Montreal earthquake; 1925, E[**M**] 6.18 St. Lawrence earthquake; 1935, E[**M**] 6.08 Timiskaming earthquake; 1944, E[**M**] 5.71 Cornwall-Massena earthquake; 1988, E[**M**] 5.84 Saguenay earthquake.

2.5.2.2.1.3 Repeated Large-Magnitude Earthquake Sources

RLME (**M** ≥ 6.5) sources are included as sources on both the Mmax and the seismotectonic source branches of the master logic tree because they model the occurrence of RLMEs on a specific fault or within a localized area. RLMEs are defined by the historical record, the paleoearthquake record, or a combination of the two. EPRI, DOE, and NRC (Reference 2.5-60) characterize 10 RLME sources, captured in Figure 2.5-43.

The TI Team evaluated the results of the seismic hazard analysis presented in Appendix I of Goulet et al. (Reference 2.5-135) for seven demonstration sites to determine which RLME source may contribute to the seismic hazard at the Project site. The TI Team selected the

Chattanooga demonstration site as a proxy for the Project site because of its relative proximity and similar tectonic environment. The TI Team also evaluated the Savannah demonstration site but concluded that its proximity to the Charleston RLME source obscures the effect of other RLME sources.

The RLME sources that contribute the most to the hazard at Chattanooga are New Madrid and Charleston. Lower contributions are given by the Eastern Rift Margin-South (ERM-S), Wabash Valley and Marianna, Eastern Rift Margin-North (ERM-N), and Commerce RLME sources.

These RLME sources are used in the seismic hazard analysis for the Project site, and their descriptions are taken from the SSHAC Level 2 report. Full descriptions of the RLME sources are provided in Chapter 6 of Reference 2.5-60.

The Charleston RLME source in South Carolina is centered on the coastal city of Charleston (Figure 2.5-44) where in 1886, an E[**M**] 6.9 earthquake was located (see Section 2.5.2.1.3). The earthquake produced high-intensity macroseismic effects (MMI X) in the epicentral area. Paleoseismic evidence, such as sand-blow craters and other paleoliquefaction features along the coast of South Carolina, evaluated by EPRI, DOE, and NRC (Reference 2.5-60) is indicative of RLMEs in this area. Additionally, available geologic and geomorphic evidence suggests that the rate of mid-Holocene to modern seismicity in the Charleston Seismic Zone is transient, alternating periods of activity with periods of quiescence. The Charleston RLME source was modeled as a fault zone within which the earthquake is randomly located because it is not possible to localize the earthquake onto a specific fault. As captured in Figure 2.5-44, the source zone geometry has three configurations: local, narrow, and regional.

- The local geometry is based on the extent of the largest macroseismic intensities, liquefaction features, recorded seismicity, and postulated faults.

- The narrow geometry is designed to encompass a number of postulated faults.

- The regional geometry covers a large area of coastal South Carolina, including the majority of liquefaction features and postulated faults, and extends offshore to include the Helena Banks fault zone.

The Charleston RLME magnitude distribution of future large earthquakes in the CEUS SSC model is based on the range of interpreted magnitudes of the 1886 earthquake and prehistoric earthquakes and assumes that future earthquakes will have similar magnitudes.

The Commerce fault zone RLME source encompasses Late Pleistocene and possible Holocene active faults identified from geophysical, geomorphologic, and geologic data. The Commerce geophysical lineament is defined by gravity and magnetic anomalies and coincides with these tectonic features and with paleoliquefaction features in southeastern Missouri. The data are insufficient to determine whether RLMEs exhibit temporal clustering.

Future earthquake ruptures in the Commerce fault zone RLME source are modeled as vertical, with strike-slip motion and orientation subparallel to the main faults within the zone (Commerce and Penitentiary faults). The northeast and southwest boundaries of the fault zone allow ruptures to extend beyond the zone boundary, while the opposite boundaries (northwest and southeast) do not permit ruptures to extend outside the zone.

The ERM is modeled as a fault zone in which recurrent earthquakes occurred in the Quaternary, with the most recent event in the Holocene. Two independent RLMEs, the ERM-N and the ERM-S are defined on the basis of different timing and the recency of surface deformation. The available data are insufficient to determine whether the RLMEs occur in clusters.

Due to the uncertainty in the dimension of paleoruptures, the two RLME sources have a wide distribution of expected future earthquake magnitudes. The maximum value for the ERM-N is slightly smaller than for ERM-S because of the shorter length of the fault.

The Marianna RLME source is in the southeastern part of the RR seismotectonic zone, outside the NMFS. The source is defined by the presence of earthquake-induced liquefaction features, e.g., large sand blows that predate paleoearthquakes associated with the NMFS. The geometry of the RLME source encompasses the paleoliquefaction sites and structures that have been considered possible causative faults of the paleoearthquakes.

The occurrence of RLMEs is modeled as either “in cluster” or “out of cluster,” with the two models receiving equal weight because there is a possibility that some paleoliquefaction features in the Marianna region might have been caused by earthquakes originating in the ERM RLME sources.

The three largest historical earthquakes in the CEUS occurred in the New Madrid region between December 1811 and February 1812. Three main trends of seismicity are observed in the New Madrid region: two northeast-trending alignments, interpreted to be the location of right-lateral strike-slip faults, and one northwest-trending pattern interpreted as a compressional left-stepover zone.

The December 16, 1811, E[**M**] 7.17 earthquake is believed to have occurred on the southern arm of seismicity (New Madrid South), associated with the Blytheville Arch fault. There are two alternative interpretations for the events of January 23, 1812, E[**M**] 7.50, and February 7, 1812, E[**M**] 7.80. One interpretation is that the January 23, 1812, earthquake occurred on the northern seismicity arm (New Madrid North), and the February 7, 1812, earthquake occurred on the Reelfoot fault. The alternative scenario is that the January 23, 1812, earthquake occurred on the Reelfoot fault, and that the February 7, 1812, earthquake ruptured both the New Madrid North and Reelfoot faults.

The maximum magnitudes of the three earthquakes in the 1811 – 1812 sequence are inferred from macroseismic intensity data and, to a lesser extent, the analysis of paleoliquefaction features. The recurrence of RLMEs in the New Madrid region was obtained from paleoliquefaction studies and analyses of fault-related deformation on the Reelfoot fault. Geodetic, seismological, and geomorphic observations suggest that earthquakes in the NMFS may be temporally clustered, with periods of quiescence separating clusters of activity, and that seismicity migrates within the RR. Based on this, there are three alternative models: (1) future earthquakes on the three faults in the NMFS will occur at the rate inferred from paleoliquefaction studies (weight 0.9); (2) the NMFS is no longer capable of large-magnitude earthquakes and the hazard is modeled by the background seismicity (weight 0.05); and (3) only the Reelfoot thrust is active and is producing RLMEs at a lower rate (weight 0.05).

Uncertainty in the location and extent of the causative faults that ruptured during the 1811 – 1812 earthquake sequence is modeled by the alternative geometries of the three faults that make up the NMFS.

Paleoseismic evidence indicates that at least eight moderate-to-large earthquakes have occurred since the latest Pleistocene time in the Wabash Valley region of southern Illinois and southern Indiana. The two largest paleoearthquakes (**M** ~ 6.7 – 7.8) inferred from the paleoliquefaction data are known as the Vincennes and Skelton earthquakes: their proximity, suggests the existence of an RLME source in the Wabash Valley. There is no clear association of paleoearthquakes with specific tectonic features; therefore, the Wabash Valley RLME source is modeled as a zone where earthquakes are randomly located. The paleoseismic record is insufficient to recognize temporal clustering periods.

2.5.2.2.2 New Information Affecting the Characterization of Seismic Sources

The TI Team's approach to evaluating the need to update the CEUS SSC model is introduced at the beginning of Section 2.5.2. This section summarizes the TI Team's evaluation of new data, models, and methods developed after the completion of the CEUS SSC project (documented in Chapter 6 of the SSHAC Level 2 report). The key issues evaluated by the TI Team and summarized below are:

- Evaluation of the need to update earthquake recurrence rates for distributed seismicity sources (Section 2.5.2.2.2.1)
- Evaluation of the need to update Mmax distributions for seismic source zones (Section 2.5.2.2.2.2)
- Evaluation of the need to update the geometry of the MESE boundary (Section 2.5.2.2.2.3)
- Evaluation of the need to update CEUS SSC RLME sources and to add postulated new faults (Section 2.5.2.2.2.4)

2.5.2.2.2.1 Evaluation of the Need to Update Earthquake Recurrence Rates for Distributed Seismicity Sources

The earthquake catalog described in Section 2.5.2.1 collected an additional 15.3 years of data, including two moderate-sized earthquakes. The TI Team evaluated whether the updated earthquake catalog should be used to update earthquake occurrence rates. The TI Team employed a statistical test that compares the number of earthquakes predicted by the CEUS SSC recurrence rates in 15.3 years with the observed counts of earthquakes observed during the same time interval.

The CEUS SSC model (Reference 2.5-60) uses the Poisson recurrence model to represent the frequency of earthquakes occurring in the distributed seismicity sources. Given the frequency of earthquakes (λ) and the time interval of observation (t), the probability of observing exactly n earthquakes ($P[N=n]$) is given by Equation 2.5.2-5:

$$P[N = n] = \frac{(\lambda t)^n e^{-\lambda t}}{n!} \qquad \text{(Equation 2.5.2-5)}$$

The distributions computed from the CEUS SSC model parameters for distributed seismicity sources can be used to represent uncertainty distributions for the true rate of earthquakes in the region around the Project site. Using a one-sided Poisson test, the TI Team evaluated if the observed number of earthquakes within the portion of CEUS covered by the catalog update (January 1, 2009, to April 30, 2024) is consistent with a tectonic process modeled by the CEUS SSC long-term Poisson rates for the same region. The null hypothesis is that the observed number of earthquakes in 15.3 years (e.g., the duration of the catalog update from January 1, 2009, to April 30, 2024) is consistent with a Poisson process with a "true" rate parameter equal to the recurrence rate in the distribution calculated from the CEUS SSC model.

The one-sided Poisson test is conducted first for the seismicity within 200 mi. (320 km) of the Project site. The probability of observing the actual count of E[**M**] ≥ 2.9, E[**M**] ≥ 3.6, etc., or greater counts, given the true rate λ_i (where λ_i is the mean of the uncertainty distribution for λ calculated from the CEUS SSC model parameters) is computed with Equation 2.5.2-6.

$$P\left[N \geq n_{obs} \middle| \lambda_i\right] = 1 - \sum_{n=0}^{n=n_{obs}-1} P\left[N = n \middle| \lambda_i\right] \qquad \text{(Equation 2.5.2-6)}$$

The test is repeated selecting the region within 400 mi. (640 km) of the Project site. Results are captured in the last two columns of Table 2.5-6 for the region within 200 mi. (320 km) of the Project site, and in in the last two columns of Table 2.5-7 for the region within 400 mi. (640 km) of the Project site. Both tests were conducted with and without human-induced earthquakes as part of the observed counts. Typical statistical test confidence intervals of 5 percent or less are used to indicate significant departures from the null hypothesis. The probability values in Table 2.5-6 and Table 2.5-7 are generally 5 percent or larger, indicating that the observed earthquake counts could be generated by a Poisson process with rate λ equal to the long-term rate predicted by the CEUS SSC model. The TI Team concluded that the observed seismicity does not warrant an update of the earthquake recurrence rates in the region within 400 mi. (640 km) of the Project site because it does not modify the CBR of the TDI.

The TI Team also evaluated the effect of modifications to the earthquake catalog for the southeastern United States introduced by EPRI (Reference 2.5-156), namely the removal of reservoir-induced earthquakes in South Carolina and aftershocks of the Charleston earthquake. The TI Team found that using the revised catalog to compute recurrence rates produces a small percentage decrease in the mean AFE for all magnitudes and concluded that the modification does not affect the CBR of the TDI.

2.5.2.2.2.2 Evaluation of the Need to Update Mmax Distributions for Seismic Source Zones

Section 2.5.2.2.1 introduces the two statistical methods adopted by EPRI, DOE, and NRC (Reference 2.5-60) to compute Mmax distributions for source zones. The TI Team repeated the analysis performed by EPRI, DOE, and NRC (Reference 2.5-60), extending the earthquake dataset with all **M** ≥ 4.3 located within the CEUS SSC source zones that occurred from January 1, 2009, to April 30, 2024. The magnitude threshold of 4.3 was selected to be consistent with the EPRI, DOE, and NRC (Reference 2.5-60) study.

The analysis follows three main steps: (1) application of the Bayesian approach with a set of prior distributions obtained from updated groupings or “superdomains” of stable continental regions with similar crust (age, type of crust, stress state, tectonic history); (2) application of the Kijko statistical approach; and (3) assessment of the relative weights to assign to each method.

2.5.2.2.2.2.1 Bayesian Approach

In the Bayesian approach described in Chapter 5 of Reference 2.5-60, a normal prior distribution is computed from observed data and convolved with a likelihood function to arrive at a posterior distribution of Mmax. The likelihood function is obtained with source-specific information about the number and sizes of observed earthquakes. The likelihood function is zero for all values below the maximum observed magnitude, has a peak near the maximum observed, and then becomes essentially constant at larger magnitudes. The sharpness of the peak and the relative amplitude of the peak compared to the plateau are controlled by the sample size *N*, which is the number of observed earthquakes greater than a threshold magnitude. As *N* increases, the sharpness of the peak increases, and the amplitude of the plateau becomes much less than that of the peak. The last step of the analysis involves representing the continuous posterior distribution by a discrete distribution for use in hazard analysis. In the CEUS SSC model, the chosen representation was a five-point discrete approximation to an arbitrary continuous distribution developed by Miller and Rice (Reference 2.4-157).

Table 2.5-8 lists the number of earthquakes with E[**M**] ≥ 4.3 from earliest available to December 31, 2008, obtained from the CEUS SSC catalog, and the number of earthquakes with **M** ≥ 4.3 from January 1, 2009, to April 30, 2024, inclusive of human-induced earthquakes and aftershocks, obtained by the TI Team from the Global Centroid Moment Tensor Solution catalog and from Saint Louis University. The counts show a notable increase in the number of earthquakes from 2009 onward, particularly in the NMESE and in the MidC zones. These numbers are likely associated with human-induced seismicity in areas of Oklahoma, Texas, and Arkansas. The increased number of earthquakes causes the likelihood function for these source zones to be much more peaked compared to the likelihood function in the CEUS SSC model. For example, Figure 2.5-45 compares the Mmax distribution calculated for zone NMESE-W in the EPRI, DOE, and NRC (Reference 2.5-60) study (part a of the figure) with the recalculated distributions using the extended catalog (part b of the figure). The Bayesian distribution is illustrated by the black histogram for the NMESE prior and is much more peaked and skewed toward lower magnitude values in part b of the figure compared to part a.

2.5.2.2.2.2.2 Kijko Approach

The Kijko approach uses only the observed distribution of earthquakes in a region to determine the Mmax distribution. The method assumes that the earthquake catalog is complete and that the maximum observed magnitude is a true representative of the largest earthquake anticipated to occur within a source zone.

2.5.2.2.2.2.3 Assessment of Relative Weights of Bayesian and Kijko Approaches

EPRI, DOE, and NRC (Reference 2.5-60) show that for sample size *N* less than approximately 100, the cumulative probability function of the Kijko approach reaches a limiting value that is less than unity as the upper-bound magnitude approaches infinity. The limiting value was taken

as an indicator of the probability that the methodology provides meaningful results and was used to assess the relative weight of the Kijko and Bayesian approaches with Equation 2.5.2-7:

$$W_{Kijko} = \begin{cases} 0.5 - P\left(m^u > 8\frac{1}{4} | m^u \geq 5\frac{1}{2}\right) & \text{for} \quad P\left(m^u > 8\frac{1}{4} | m^u \geq 5\frac{1}{2}\right) \leq 0.5 \\ \vdots & \vdots \quad \vdots \\ 0 & \text{for} \quad P\left(m^u > 8\frac{1}{4} | m^u \geq 5\frac{1}{2}\right) > 0.5 \end{cases} \qquad \text{(Equation 2.5.2-7)}$$

Where m^u is the upper-bound magnitude.

From the equation it can be inferred that the Kijko approach works best when the truncated probability mass ($P\left(m^u > 8\frac{1}{4} | m^u \geq 5\frac{1}{2}\right)$) is small, which is the case when the number of observed earthquakes is large. However, when the truncated probability mass is 0.5, the Kijko approach has reached its limit of applicability.

Table 2.5-9 compares the weights of the Kijko approach obtained from Table 5.2.1-5 of Reference 2.5-60 with the weights obtained by the TI Team using the data in Table 2.5-8. Results can be summarized as follows:

- For zones MESE-N, PEZ-N, PEZ-W, the weight assigned to the Kijko approach increases slightly.
- For zones ECC-AM, RR-RCG, and SLR, the weight assigned to the Kijko approach decreases slightly.
- For zones NMESE-W and MidC (all geometries), the weight assigned to the Kijko approach increases substantially due to the large number of earthquakes added to the catalog.
- For all other zones, there are no changes.

The combined effect of larger sample sizes on the resulting composite distribution is to skew the distribution toward lower magnitudes as captured in part b of Figure 2.5-45, where the Kijko distribution is illustrated by the purple histograms, and the resulting composite distribution is illustrated in red.

Using a Miller and Rice (Reference 2.5-157) five-point approximation, the TI Team obtained the Mmax distribution captured in Table 2.5-10, which is compared to the distributions in the CEUS SSC model (as corrected by EPRI [Reference 2.5-155] where necessary). There are small changes for many of the zones that generally tend to lower the average Mmax. To assess the potential hazard significance of this change, the TI Team calculated the annual frequency of earthquakes with E[**M**] ≥ 2.9 for the region encompassing 400 mi. (640 km) of Project site. The TI Team results show that the updated Mmax distributions generate a small decrease in AFE for E[**M**] ≥ 6 (5 to 13 percent). The TI Team does not consider this change to be significant to hazard at the Project site and did not consider the use of updated Mmax.

2.5.2.2.2.3 Evaluation of the Need to Update the Geometry of the MESE Boundary

The Project site is located approximately 3.7 mi. (6 km) west of the “Narrow” interpretation of the western boundary of Mesozoic extension, within crust that did not experience extension during the Mesozoic. Given the proximity of the site to the boundary, the TI Team re-visited the justification for the location of the boundary to determine whether a site-specific refinement is appropriate.

The western boundary of the crust that experienced extension during the Mesozoic is based on the location of a gravity gradient that generally follows the western edge of the Triassic-Jurassic onshore basins or the boundaries of the structural blocks in which they occur. The TI Team used high-resolution datasets mapping Mesozoic basins and concluded that while at a regional scale the western extent of the Mesozoic basins generally coincides with the regional gravity gradient, at a local scale there are two exceptions: the Newark-Gettysburg basin in New Jersey, and the Dan River basin in NC. The Dan River basin is the closest Mesozoic basin to the Project site, and this finding suggests that in the Project site vicinity Mesozoic extension occurred farther west than currently represented in the CEUS SSC model.

Section 2.5.2.2.1 explains that in the CEUS SSC model, MESE crust is separated from NMESE crust because different Mmax prior distributions apply. Given the importance of this boundary and the geologic observations described above, the TI Team postulated an alternative boundary that extends the MESE crust to the western edge of the Dan River basin, as captured in Figure 2.5-46. In this figure, source zone ECC-AM is superimposed on the gravity anomaly gradient map. The geophysical boundary is the western edge of the zone (in blue), and the alternative geologic boundary postulated by the TI Team is illustrated in orange.

The TI Team considers the geophysical (gravity gradient) data and the geologic (basin mapping) data as two possible alternatives to identify the edge of the Mesozoic extensional margin. As captured in Figure 2.5-46, the Project site is in NMESE crust when the geophysical boundary is used but is in MESE crust when the geologic boundary is applied. Hazard sensitivity analyses conducted by the TI Team resulted in 30 to 35 percent differences in AFE for ground motions at the 1E-4 to 1E-6 level, confirming that this site-specific refinement of the CEUS SSC model is warranted.

Given the uncertainty in the datasets and the structural complexity of the fault geometries in the subsurface of which little is known, the TI Team decided to treat the geophysical and geological boundaries as equally weighted epistemic uncertainties. The modification of the boundary affects the geometry of five source zones: ECC-AM, PEZ-N, PEZ-W in the seismotectonic branch, and MESE-N, NMESE-N in the Mmax branch of the CEUS SSC model (see Section 2.5.2.4.1).

2.5.2.2.2.4 Evaluation of the Need to Update CEUS SSC RLME Sources and Add Postulated New Faults

This section summarizes the TI Team’s evaluation of potential changes to the characterization of RLME sources that are included in the CEUS SSC model, and the need to include local sources proposed in recent literature.

The evaluations are described first for RLME sources, followed by postulated new fault sources. The TI Team focused on the two RLME sources with the largest contribution to the hazard at

the Project site, i.e., Charleston, South Carolina, and the RLME sources in the New Madrid region.

Charleston RLME Source. The TI Team reviewed recent studies and found that there is still no consensus on the location of the 1886 Charleston earthquake fault or if that fault is the only Quaternary active fault in the area. Recent studies, however, seem to indicate that the event was within the smaller, “Local” or “Narrow” geometries of the Charleston RLME source. The TI Team evaluated the effect of increasing the weight on the “Narrow” geometry, and results indicate a negligible effect (a few percent increase) on the hazard (see Figure 2.5-47) that does not change the CBR of the TDI. None of the studies reviewed by the TI Team suggest that the magnitude distribution for this source should be updated.

RLME Sources in the New Madrid Region. The TI Team evaluated studies published since the completion of the CEUS SSC model that use paleoseismological and geological investigations to extend the paleoearthquake record and use new LiDAR data to better constrain the length of known faults or identify new ones. The TI Team evaluated the hazard significance of the following modifications:

- Changes in the geometry of the New Madrid South segments (Bootheel and Axial fault sections) and the Reelfoot fault

- Changes in the geometry of the ERM-N and ERM-S RLME sources

- Changes in the geometry of the Commerce RLME source and associated changes in the RLME magnitude distribution

As captured in Figure 2.5-47, these changes produce a small increase (few percents) in hazard, and the TI Team concluded that their inclusion in the seismic hazard model for the Project site is not warranted.

Central Virginia Seismic Zone. The CVSZ is modeled to account for a region of higher seismicity that includes the 2011 E[**M**] 5.72 Mineral, Virginia, earthquake, 1758 E[**M**] 4.95, the 1774 E[**M**] 4.38, and the 1875 E[**M**] 4.77 events. The TI Team reviewed the recent literature and concluded that there is not sufficient paleoseismic evidence for repeated **M** 6.5+ earthquakes in the CVSZ; therefore, based on current knowledge, the TI Team did not consider CVSZ as an RLME source. The TI Team, however, evaluated if the CVSZ should be included in the seismic hazard model as a local source. The TI Team adopted the source characterization published in Thompson-Jobe et al. (Reference 2.5-59), with a modification of the Mmax distribution (**M** 6.5 and **M** 6.75, equally weighted) based on the work of Tuttle et al. (Reference 2.5-72; Reference 2.5-73).

East Tennessee Seismic Zone. The ETSZ is a region of elevated seismicity in the Valley and Ridge province of Tennessee. There are various possible explanations for the higher rates of earthquakes in the region, including being an aftershock sequence from a prehistoric event; a phase of strain release, but the location of strain release (earthquakes) can change; a zone of weakness that experiences higher strain rates and/or earthquakes; local and regional stresses resulting in a higher deviatoric stress tensor.

The TI Team reviewed the recent literature suggesting the presence of Quaternary faulting along a 50-mi. (80-km)-long, northeast-trending corridor, termed the Dandridge-Vonore fault corridor. According to some authors, there is evidence for earthquakes of magnitude greater

than 6.5 in the last 40 kyr, while for others the evidence could be related to fluvial mechanisms. The TI Team concluded that evidence for repeated **M** 6.5+ earthquakes in the ETSZ is insufficient and did not test the hazard significance of such events in the ETSZ for the Project site. The elevated levels of seismicity in ETSZ, compared to the surrounding crust, are captured by the spatially varying seismicity parameters of the CEUS SSC model.

Giles County Seismic Zone. The Giles County Seismic Zone is a region of elevated seismicity in southwestern Virginia. The largest historical earthquake in the region was the E[**M**] 5.91 Giles County earthquake, which occurred on May 31, 1897, with a maximum intensity of VIII. The TI Team did not find published evidence for repeated, **M** 6.5+ earthquakes in the Giles County Seismic Zone. As a result, the Giles County Seismic Zone was not included in the seismic hazard model for the Project site as a distinct seismic source with seismicity rates above those derived from the recorded historical seismicity.

Little River fault. The Little River fault is associated with the surface rupture from the 2020 E[**M**] 5.15 Sparta earthquake. The TI Team evaluated the need to include this fault in the seismic hazard model due to its proximity (approximately 57 mi. [92 km] west-northwest of the Project site). The interpreted fault length based on surface information appears to be insufficient to generate earthquakes of **M** 6.5+, and the TI Team did not find evidence for earthquakes to be repeated. The earthquake rate distribution captured in Table 2.5-11 was obtained by the TI Team using data provided by resource expert Dr. Figueiredo. The TI Team applied the likelihood method adopted in Reference 2.5-60 to develop a five-point distribution of the annual frequency of earthquakes and associated weights.

Saline River. The Saline River fault zone trends northwest-southeast across southeastern Arkansas in the Mississippi Embayment and is interpreted to be a left-lateral strike-slip fault. The TI Team reviewed recent papers describing paleoliquefaction features and trenching studies in the region. While there is no evidence of repeated **M** 6.5+ earthquakes, the TI Team concluded that the contribution of this fault to the total hazard for the Project site should be evaluated. The TI Team adopted the source characterization in Thompson-Jobe et al.(Reference 2.5-59) for the hazard sensitivity analysis.

Figure 2.5-48 shows that the contribution of the new postulated fault sources described above (faults in the New Madrid region, CVSZ, and Saline River) to the total mean seismic hazard at the Project site is not significant (1 percent or less); therefore, the TI Team concluded that its inclusion in the hazard model is not warranted.

2.5.2.3 Correlation of Seismicity with Seismic Sources

Section 2.5.2.1 describes the updated earthquake catalog obtained as part of the SSHAC Level 2 study. Figure 2.5-30 shows that only a few small earthquakes are reported to have occurred within 50 mi. (80 km) of the Project site. The 2020 Sparta, NC, earthquake (E[**M**] 5.15) is associated with the Little River fault, which is located approximately 57 mi. (92 km) west-northwest of the Project site (see Section 2.5.2.2.2.4). The earthquake ruptured on a northwest-southeast–trending fault, perpendicular to the regional structural orientation of the Appalachian Mountains, with an oblique-strike-slip motion. LiDAR data and field mapping indicate a total length of the surface rupture associated with this earthquake of approximately 2.5 mi. (4 km).

Figure 2.5-29 shows that the seismicity appears distributed in specific zones corresponding to the CVSZ (described in Section 2.5.2.2.2.4) to the northeast of the site, scattered along the coast of NC, in South Carolina, and along the Appalachian Mountains.

Earthquakes in South Carolina tend to occur in a cluster around Charleston (see Sections 2.5.2.1.3 and 2.5.2.2.1.3), and around the town of Bowman. Scattered small earthquakes are also reported in the Piedmont region. In the 1970s and 1980s, this physiographic province experienced reservoir-induced earthquakes associated with the impoundments in the basins. Sixteen of these earthquakes were identified during the compilation of the CEUS SSC earthquake catalog and removed. Figure 2.5-29 does not show these earthquakes. After the publication of the CEUS SSC model, EPRI conducted additional reviews of published literature and identified 30 more reservoir-induced earthquakes and 17 aftershocks of the Charleston earthquakes that should have been removed from the catalog (Reference 2.5-156).

In the Southern Appalachian orogen, earthquakes are associated with prevailing northeast-trending structures, particularly in the Valley and Ridge province, which includes the Giles County Seismic Zone in Virginia (north of the site), where the 1897, E[**M**] 5.91 earthquake occurred (see Sections 2.5.2.1.3 and 2.5.2.2.2.4), and the ETSZ (see Section 2.5.2.2.2.4).

2.5.2.4 Probabilistic Seismic Hazard Analysis and Controlling Earthquakes

This section describes the PSHA conducted for the Project site. Section 2.5.2.2 describes the CEUS SSC model, and the evaluations conducted as part of the SSHAC Level 2 study to determine the need to refine the model for site-specific applications. The resulting SSC logic tree is presented in Section 2.5.2.4.1.

Section 2.5.2.4.2 describes the ground motion characterization model by providing a summary of the NGA-East GMM; Section 2.5.2.4.3 summarizes the TI Team's evaluation of the model using new data, models, and methods, and the resulting ground motion characterization logic tree.

Seismic hazard results for reference rock conditions (mean hazard and deaggregation) are presented in Section 2.5.2.4.4 and include sensitivity analyses to illustrate the effect of modeling choices.

2.5.2.4.1 Seismic Source Characterization Model

The SSC model adopted for the SSHAC Level 2 PSHA is presented in Figure 2.5-49. The TI Team evaluation of new data, models, and method concluded that the CEUS SSC model should be refined to include the possibility for an alternative MESE boundary. This is addressed by the first node of the logic tree in Figure 2.5-49, which considers the use of alternative datasets to determine the local geometry of the boundary between MESE and NMESE. As discussed in Section 2.5.2.2.2.3, the TI Team assigned equal weight to the two alternatives because there is no clear choice for a favored interpretation.

The next two nodes of the logic tree in Figure 2.5-49 match the CEUS SSC master logic tree captured in Figure 4.2.1-1 of Reference 2.5-60 and address the basic conceptual models used to characterize the spatial and temporal distribution of future seismicity. These nodes are followed by branches representing uncertainties in the implementation of these models (see Figures 4.2.3-1, 4.2.4-1a and 4.2.4-1b of Reference 2.5-60). The SSHAC Level 2 SSC model

includes Mmax zones and seismotectonic zones that are partly or entirely within a distance of 621 mi. (1000 km) of the Project site: AHEX, ECC-AM, ECC-GC, IBEB, MidC (A through D), NAP, PEZ-N, PEZ-W, RR, RR-RCG, and SLR. As discussed in Section 2.5.2.2.1.3, the RLME sources included in the SSHAC Level 2 SSC model are: Charleston, Commerce, ERM-N, ERM-S, Marianna, New Madrid, and Wabash Valley.

The node addressing the location of the boundary of the Mesozoic extension precedes the CEUS SSC master logic tree because this choice is correlated between Mmax zones and seismotectonic zones. This means that when the geophysical boundary is selected, the original geometry of the MESE-N and NMESE-N zones (from CEUS SSC) is used in the Mmax branch, and the original geometry of zones ECC-AM, PEZ-N, and PEZ-W is used in the seismotectonic branch. Alternatively, if the geological boundary is selected for MESE-N and NMESE-N, the geological boundary is also selected for ECC-AM, PEZ-N, and PEZ-W.

The TI Team obtained a set of earthquake recurrence parameters for the zones affected by the alternative (geologic) MESE boundary (zones ECC-AM, PEZ-N, PEZ-W, MESE-N, and NMESE-N). To ensure consistency between the recurrence parameters associated with the published CEUS SSC model and the recurrence parameters computed for the alternative zone geometry, the TI Team used the computer software ABSMOOTH v. 14, developed by G. Toro of Lettis Consultants International for the EPRI, DOE, and NRC (Reference 2.5-60) study, and used the CEUS SSC earthquake catalog without RLMEs with its published completeness intervals.

2.5.2.4.2 Ground Motion Characterization Model

The NGA-East model (Reference 2.5-135) was adopted as the starting point for the characterization of ground motions for the SSHAC Level 2 study as indicated at the beginning of Section 2.5.2.

The NGA-East project was a multidisciplinary research effort led by the Pacific Earthquake Engineering Center at the University of California, and co-sponsored by the NRC, DOE, EPRI, and USGS. The project, which was conducted over a 10-year period, had two main phases of work: the first phase consisted of a series of scientific research tasks, and the second phase was a SSHAC Level 3 model-building effort.

The ground motion characterization (GMC) model components are summarized in the following sections from the SSHAC Level 2 report.

2.5.2.4.2.1 Median Models

The NGA-East median GMMs are constructed using an innovative approach in which individual GMMs can be thought of as samples from a continuous ground motion space.

A suite of 19 ground motion predictive equations (GMPEs) were developed by a number of different researchers that represented a range of approaches (e.g., stochastic point-source and finite-fault simulations, broadband deterministic simulations, hybrid-empirical approaches, modeling of Fourier spectra of recorded motions). These were used by the NGA-East TI Team to obtain candidate ground motion prediction tables for 374 scenarios resulting from the combination of 11 moment magnitudes (ranging from 4.0 to 8.2) and 34 values of rupture distance (ranging between 0 and 932 mi. [1500 km]). From these predictions, a set of joint continuous distributions of ground motions was developed and constraints were imposed to

guarantee smoothness and physicality of the predictions, as well as the level of uncertainty with magnitude, distance, and frequency.

A model space of 10,000 samples was drawn from these continuous distributions and visualized using the Sammon's map approach that allows representing differences in model prediction using a two-dimensional image. The space was subdivided into an optimal number of cells, determined to be 17, to represent the range of ground motion values. From these 17 cells, Goulet et al. (Reference 2.5-135) obtained 17 median GMMs, weighted based on comparison to empirical CENA ground motion data and density of individual GMPE samples within each cell, with preference (weight 0.8) to density of samples within each cell. The preference for sample density was based on the limited bandwidth of the usable recordings, the magnitude-distance distribution for the CEUS recordings favored relatively low magnitudes at large distances, and large uncertainty in adjusting the recorded motions to the target reference site conditions.

The specified reference site conditions for the NGA-East GMM is a nominal shear wave velocity (V_S) of 9842 feet per second (ft/s) (3000 meters per second [m/s]) and nominal kappa (high frequency seismic waves attenuation parameter) of 0.006 sec. As described in Section 14 of the NGA-East report (Reference 2.5-135), the candidate models used as seed models for NGA-East GMMs were developed for a range of hard rock site conditions, thus incorporating a degree of epistemic uncertainty in the reference rock conditions into the overall epistemic uncertainty in the reference rock median ground motions.

2.5.2.4.2.2 Aleatory Variability Models

The NGA-East TI Team relied on statistical analyses of aleatory variability in motions recorded in CENA and in datasets from active tectonic regions to develop uncertainty distributions for the event-to-event variability (denoted by the symbol τ) and for the single-station within-event variability (denoted by the symbol φ_{SS}). Combining τ and φ_{SS} produces the single-station sigma σ_{SS}. The aleatory variability models were developed independently from the median GMMs.

The form of the aleatory distribution of ground motions was modeled using a lognormal distribution (traditional approach, weighted 0.2) and a mixture of two lognormal distributions (mixture approach, weighted 0.8). For each branch, there are three alternative values for σ_{SS}.

For seismic hazard applications where an ergodic aleatory variability model may be needed, the NGA-East project developed a model for site-to-site variability (φ_{S2S}) based on CENA data with adjustments for the effect of small-magnitude bias and application to hard rock conditions. Epistemic uncertainty in φ_{S2S} was quantified by a three-point discrete distribution like the characterization of uncertainty described above for single-station sigma.

2.5.2.4.2.3 Adjustments

The NGA-East GMM includes three adjustments to the models for median ground motion: (1) attenuation in the Gulf Coast Region (GCR); (2) the effect of source depth; and (3) hanging-wall effect.

The crustal structure and anelastic attenuation in the GCR are different from the Midcontinent Region data on which the NGA-East GMMs are based. NGA-East developed two models to adjust the NGA-East GMMs for GCR attenuation to use in cases where most of the travel path occurs within the GCR.

Goulet et al. (Reference 2.5-135) developed a model for source depth effect because the stress parameter is shown to have a strong dependance on depth for depths shallower than 6.2 mi. (10 km). The source depth effect is parameterized by ΔZ_{TOR} (i.e., the difference between the depth to top of rupture for an individual earthquake rupture [Z_{TOR}], and the magnitude-dependent expected value, $E[\Delta Z_{TOR}]$) and can produce positive or negative adjustments depending on magnitude, frequency, and Z_{TOR}. The adjustment is given by Equation 2.5.2-8:

$$f_{Z_{TOR}} = f_{Z_{TOR,M}} \times \Delta Z_{TOR} \qquad \text{(Equation 2.5.2-8)}$$

Where:

- $f_{Z_{TOR,M}}$ is the magnitude-dependent source depth scaling factor
- ΔZ_{TOR} is the depth deviation from the magnitude-dependent centered Z_{TOR} value.

Equation 2.5.2-9 is used to compute $f_{Z_{TOR,M}}$.

$$f_{Z_{TOR,M}} = \begin{cases} b_1 \ \ for\ \boldsymbol{M} \leq 5.0 \\ b_1 + b_2 \dfrac{\boldsymbol{M} - 5}{1.5} \ \ for\ 5.0 < \boldsymbol{M} \leq 6.5 \\ b_1 + b_2 \ \ for\ \boldsymbol{M} > 6.5 \end{cases} \qquad \text{(Equation 2.5.2-9)}$$

Where:

- b_1 and b_2 are frequency-dependent coefficients given in Table 13-3 of Goulet et al. (Reference 2.5-135)
- **M** is the earthquake moment magnitude

The parameter ΔZ_{TOR} is given in Equation 2.5.2-10:

$$\Delta Z_{TOR} = \begin{cases} Z_{TOR} - E[Z_{TOR}] + 2 \ for\ Z_{TOR} < E[Z_{TOR}] - 2 \\ 0 \ for\ E[Z_{TOR}] - 2 \leq Z_{TOR} \leq for\ E[Z_{TOR}] + 2 \\ \min(10, Z_{TOR}) - E[Z_{TOR}] - 2 \ for\ Z_{TOR} > E[Z_{TOR}] + 2 \end{cases} \qquad \text{(Equation 2.5.2-10)}$$

The NGA-East model documented in Reference 2.5-135 includes focal depth distributions, hypocentral depth ratios (relative depth location of hypocenter within the rupture), and a model for rupture aspect ratio that is conditional on the style of faulting that can be used in estimating Z_{TOR}.

Hanging-wall (HW) effect models are additive terms that adjust ground motions at sites located above dipping rupture planes. These sites are expected to have higher ground motions compared to sites located on the footwall side of earthquake ruptures. These models are generally applicable when the site is in proximity to a known fault. Goulet et al. (Reference 2.5-135) present results of application of HW effects to the hazard from distributed seismicity

sources that show approximately a 2 to 5 percent increase in AFE at the 1E-5 level from application of HW effects to hazard from distributed seismicity sources.

2.5.2.4.3 Evaluation of the Need to Update the NGA-East Model

The process followed by the TI Team to evaluate and determine the need to update elements of the NGA-East model is described at the beginning of Section 2.5.2. The TI Team focused the evaluation of NGA-East in light of new data, models, and methods on the following aspects:

1) The use of an extended set of GMM seeds.

2) Evaluation of NGA-East against an extended database of recordings.

3) Evaluation of aleatory variability model.

4) Evaluation of seismic source parameters for the calculation of Z_{TOR}.

2.5.2.4.3.1 Evaluation of Extended Seed Models

The TI Team evaluated the expanded seed approach adopted for the 2023 update of the National Seismic Hazard Map (NSHM) (Reference 2.5-158). In the NSHM, USGS used the NGA-East models with a weight of 0.667 to represent the ground motion in CEUS and assigned the remaining weight to a subset of the extended NGA-East seed models that included 14 GMMs. The 14 seed GMMs were grouped by their physical characteristics, such as geometric spreading and model type (point source, empirical, hybrid empirical, stochastic), and were weighted based on these groupings. In contrast, the approach used by the NGA-East authors was to develop individual continuous distributions of ground motion in magnitude-distance-frequency space from their seed GMMs, then expand and smooth the resulting distribution beyond what is modeled by the seed GMMs.

To determine whether the use of expanded seeds modifies the CBR of the TDI, the TI Team examined Figure 2.5-50 (Reference 2.5-159). The figure is a representation of the epistemic uncertainty of NGA-East GMMs (red) and updated seed GMMs (green) represented by the range and distribution of median ground motions for a magnitude 7 earthquake. In the top part of the figure, the distance is fixed at 31 mi. (50 km), and the three plots show different spectral periods. At the bottom of the figure, the spectral period is fixed, and the two plots show different distances. The TI Team observation is that:

1. In all cases, the range of epistemic uncertainty in the NGA-East model is much larger than in the 14 seed GMMs.

2. The weighting of the NGA-East models is more similar to a continuous normal probability distribution, whereas the weights assigned to the 14 seed GMMs are random and asymmetric.

Figure 2.5-51(a) (Reference 2.5-160) compares the median ground motion obtained from the NGA-East model (dashed black lines) for a magnitude 5 and a magnitude 7.5 earthquake at a 6.2 mi. (10 km) distance, the extended seed approach (dashed blue lines), and the combination of the two for the 2018 NSHM (red curve). Figure 2.5-51(b) (Reference 2.5-160) compares the median ground motions for a spectral period of 1 sec. as a function of distance for the same two

earthquake magnitudes. The TI Team observation is that the weighted combination of NGA-East and the expanded seed model, illustrated by the red curve, is not significantly different from the prediction obtained using the NGA-East model alone, except for very large magnitude at relatively short distances where the NGA-East prediction is higher than the weighted combination of NGA-East and expanded seed approach.

Based on these evaluations and considering that the NGA-East project examined each sample model drawn from the continuous distributions for physicality and checked that the response spectra resulting from the model are smooth and consistent with physical models of ground motions, the TI Team concluded that the expanded seed model does not improve the representation of the CBR of the TDI.

2.5.2.4.3.2 Comparison of NGA-East with Expanded Database of Recordings

Ramos-Sepúlveda et al. (Reference 2.5-161) studied the compatibility between the NGA-East GMMs and the CENA site amplification model of Stewart et al. (Reference 2.5-162) using an expanded database of observed ground motions that incorporates earthquakes recorded in the CENA region between November 2011 and April 2022. The data were assigned to three regions: (1) Texas-Oklahoma-Arkansas (TOK) with potentially distinct ground motion scaling; (2) Coastal Plain with distinct path effects and relatively deep sediments; and (3) the rest of CENA, which contains the Project site. The updated ground motion database increased the number of recordings at short distances, mostly in the TOK region, but did not extend the magnitude coverage beyond that of the NGA-East database.

The study found a consistent overprediction of ground motions at short periods (0.01 – 0.6 sec.) and underprediction at long periods, with regional variations in the misfit with the TOK region exhibiting larger absolute misfits compared to other areas within the CENA. The authors attribute these discrepancies to two main factors: (1) differences between the site amplification model used during the development of the NGA-East GMMs and the CENA site amplification model by Stewart et al. (Reference 2.5-162); and (2) potential biases in the simulation-based model to adjust hard rock ground motion conditions (V_S approximately 9842 ft/s [3000 m/s]) to site conditions of V_{S30} 2493 ft/s (760 m/s). To address this misfit, the authors propose adjustment factors derived from the expanded CENA database that are added to the natural-log mean ground motions calculated using the NGA-East GMMs.

The TI Team evaluated the work of Ramos-Sepúlveda et al. (Reference 2.5-161) and concluded that the potential bias in the NGA-East GMMs should be addressed in the hazard assessment for the Project. The TI Team decided to conduct further analyses of the residuals between the NGA-East GMMs and CENA-recorded ground motions for conditions specific to the Project site. The site is in the non-TOK, non-Coastal Plain region of the CENA, and is classified as stiff, i.e., $V_{S30} \geq 4921$ ft/s (1500 m/s).

The TI Team extracted peak amplitudes for ground motions from the database compiled by Ramos-Sepúlveda et al. (Reference 2.5-161) recorded from earthquakes with **M** ≥ 4 and distances up to 373 mi. (600 km) in the non-TOK, non-Coastal Plain region. Events classified as potentially induced were not included in the analysis. This selection resulted in a dataset of 23 events (captured in Figure 2.5-52 and Table 2.5-12) and 251 recordings. In Figure 2.5-52, the symbol size is proportional to the earthquake magnitude, the color is based on the number of stiff site recordings available: red for more than 15, white for fewer than 15 recordings. Recorded ground motions were adjusted to hard rock conditions (V_S of 9842 ft/s [3000 m/s])

using the CENA amplification model by Stewart et al. (Reference 2.5-162), and the misfit was calculated as described in Ramos-Sepúlveda et al. (Reference 2.5-161), taking care to adjust the NGA-East GMMs for source depth effects using the values of Z_{TOR} captured in Table 2.5-12 for each earthquake. Figure 2.5-53 illustrates the comparison obtained for the Sparta, NC, earthquake for peak ground acceleration and the spectral acceleration for seven spectral periods ranging from 0.05 to 5 sec. The TI Team obtained similar comparisons for the remaining 22 earthquakes and concluded that the observed ground motions are generally within the range of uncertainty of the NGA-East GMMs.

The TI Team performed a cross-classified mixed-effect analysis to decompose the total residual into mean total residual, event-specific, site-specific, within-event, and within-site components. The analysis was conducted for two ranges of distance to rupture (Rrup): Rrup ≤ 373 mi. (600 km) and Rrup ≤ 249 mi. (400 km). The influence of distance range is not considered significant for spectral periods shorter than 3 s. For longer periods, the TI Team observed greater absolute bias, suggesting the influence of sampling bias. Based on this observation, the TI Team decided to use the misfit calculated for Rrup ≤ 249 mi. (400 km), which is consistent with the distance range used by Ramos-Sepúlveda et al. (Reference 2.5-161) in their evaluations. It is noted that the NGA-East TI Team also limited the distance range of data used for assessing model weights to ≤ 249 mi. (400 km) for the same reason. The mean total residual and the corresponding standard error are captured in Figure 2.5-54 by the blue dots and error bars. In the development of the NGA-East GMMs, the NGA-East authors imposed strong smoothing to ensure that the reference rock response spectra would conform to the expected spectral shapes. To maintain this behavior, the TI Team imposed a strong smoothing on the mean total residual by computing an average constant value for the period range of 0.005 sec. (peak ground acceleration) to 0.2 sec., and a broad triangular smoothing window encompassing 19 adjacent periods for periods longer than 0.2 sec. The corresponding 5th and 95th percentiles were similarly smoothed. The smoothed values are captured in Figure 2.5-54 by the thick black lines. Table 2.5-13 captures the values of mean error and corresponding standard deviation.

2.5.2.4.3.3 Evaluation of Aleatory Variability Models

The TI Team reviewed recently published literature and found no new significant work on aleatory variability beyond that represented in the NGA-East GMM. Consequently, the TI Team adopted the NGA-East partially non-ergodic model for use in the seismic hazard calculations for the Project site. The partially nonergodic model is selected because epistemic uncertainty in site amplification is explicitly incorporated into the analysis in developing site-specific ground motions.

The TI Team also conducted a seismic hazard sensitivity analysis to evaluate the effects of using the weighted combination of lognormal and mixture models to represent the form of the aleatory variability distribution versus using the models individually. The results of the test indicate that using a lognormal or mixture model produces a small difference in hazard at the AFEs of interest (1E-4 to 1E-6): the mixture model produces results that are 0.5 percent to 1.6 percent higher than the total mean hazard obtained as a weighted combination of lognormal and mixture models. Therefore, the TI Team decided to simplify the implementation of the NGA-East model by using only the mixture model.

2.5.2.4.3.4 Evaluation of Seismic Source Parameters for the Calculation of Z_{TOR}

As discussed in Section 2.5.2.4.2.3, the NGA-East GMMs include an adjustment for depth effect that is quantified by the parameter Z_{TOR}. The NGA-East authors developed a relationship to obtain the rupture area as a function of magnitude, focal depth distributions, aspect ratio models, and hypocentral depth ratio distributions for use in calculating Z_{TOR} in the PSHA. The TI Team compared the relationship between rupture area and magnitude with recently published relationships and with observations from the Ramos-Sepúlveda et al. (Reference 2.5-161) extended dataset of recordings and concluded that the relationship between rupture area and magnitude published with the NGA-East model remains valid.

Similarly, the TI Team compared the focal depth distribution obtained by the NGA-East TI Team with updated distributions obtained from the catalog update described in Section 2.5.2.1 and found that, in general, the distribution of depths is consistent between the data prior to 2009 (from the CEUS SSC model) and the data after 2009 (from the updated catalog in Section 2.5.2.1), except for a large number of very shallow earthquakes (depths less than 1.2 mi. [2 km]) in the post-2009 data. These differences are indicative of a potential residual contamination of induced earthquakes in the catalog update. Based on this observation, the TI Team concludes that the focal depth distribution in the NGA-East model is applicable to the seismic hazard for the Project site for the purpose of calculating Z_{TOR}.

2.5.2.4.3.5 Application to the Project Site

Figure 2.5-55 shows the ground motion characterization logic tree adopted for the reference rock hazard calculations. The first node of the logic tree addresses the need to adjust the NGA-East model for bias (see Section 2.5.2.4.3.2): one branch does not include the bias adjustment, i.e., the NGA-East model is used as published; the alternative branch includes the bias adjustment. The TI Team applied equal weighting (maximum uncertainty) to the two branches because there is no clear basis, at this point in time, to determine how much of the bias stems from the NGA-East GMMs and how much from the site amplification model.

The second node of the logic tree applies only if the bias adjustment is selected. The node represents epistemic uncertainty in the amount of adjustment, which is represented by using the median plus or minus the epistemic uncertainty (smoothed 5th and 95th percentiles captured in Figure 2.5-54).

As discussed in Section 2.5.2.4.3.3, the partially non-ergodic aleatory variability model is appropriate for use in the PSHA for the Project site, but only the mixture model is used. This is captured in the last two levels of the logic tree.

Following the discussion in Section 2.5.2.4.2.3, adjustments for GCR are not applicable because there are no travel paths through the GCR from seismic sources of significance to the site hazard. Adjustments for HW effects are assessed to be essentially zero at an AFE of 1E-4 and at most 2 to 5 percent increases in ground motions at an AFE of 1E-5. Including the HW effects from distributed seismicity sources is shown to produce only a small percentage increase (2 to 5 percent) in the range of AFEs of interest. Finally, as discussed in Section 2.5.2.4.3.4, the TI Team found that the parameters required for the calculation of Z_{TOR} provided with the NGA-East model can be used in estimating seismic hazard at the Project site.

2.5.2.4.4 Seismic Hazard Results for Reference Rock

This section describes the PSHA results for reference rock hazard (V_S 3000 m/s, approximately 9842 ft/s) obtained using the SSC model captured in Figure 2.5-49 and the ground motion characterization model captured in Figure 2.5-55.

The minimum magnitude for hazard calculations is 5.0, and the cumulative absolute velocity filter is not applied. Reference rock hazard calculations were conducted for a single location in the center of the Project site. The coordinates of this center point are latitude 36.27295°N, longitude -80.0558°E. The analyses were conducted for peak ground acceleration (PGA) and spectral acceleration response spectral ordinates at frequencies of 100, 50, 40, 33.33, 25, 20, 13.33, 10, 6.67, 5, 4, 3.33, 2.5, 2, 1.33, 1, 0.67, 0.5, 0.33, 0.25, 0.2, 0.13, and 0.1 Hz (periods of 0.01, 0.02, 0.025, 0.03, 0.04, 0.05, 0.075, 0.1, 0.15, 0.2, 0.25, 0.3, 0.4, 0.5, 0.75, 1, 1.5, 2, 3, 4, 5, 7.5, and 10 sec.). The results extend to cover, as a minimum, to AFE 1E-8.

Figures presented in this section illustrate the effect of elements of the SSC and GMC model for four spectral frequencies (PGA and 10 Hz, 1 Hz, and 0.1 Hz, or spectral periods of 0.1, 1, and 10 sec.) representative of high, medium, and low frequency ranges. Figure 2.5-56 shows the relative contribution to the total mean hazard (black) from distributed seismicity sources (blue) and RLME sources (red). At the annual frequencies of interest (1E-4 to 1E-5), the hazard is controlled by the distributed seismicity sources for high frequency motions (PGA to 10 Hz), while the RLMEs become the dominant contributors to the hazard for low frequency motions.

The total mean reference rock hazard is deaggregated to show the distributions of magnitude-distance-epsilon (number of standard deviations in the ground motion) combination that contributes to hazard. Deaggregation histograms are captured in Figure 2.5-57 to Figure 2.5-60 for AFEs of 1E-4, 1E-5, 1E-6 (return periods of 10,000, 100,000, and 1 million years, respectively). As discussed above, the hazard for high frequency motions (PGA and 10 Hz [0.1 sec.] spectral acceleration) at AFE 1E-4 is contributed primarily by distributed seismicity sources, which cover a broad range of magnitude and distances within 62 mi. (100 km) of the site, with smaller contributions by RLME sources, which are large-magnitude earthquakes at distances of 186 mi. (300 km) or more from the site. For annual frequencies of exceedance smaller than 1E-4, the RLME contribution decreases. This is evident in Figure 2.5-57 and Figure 2.5-58 for return periods of 100,000 and 1 million years (parts [b] and [c] of each figure), where the hazard is dominated by distributed seismicity sources.

For 1 Hz (1 sec. period) spectral acceleration (Figure 2.5-59), the largest contributions to the total mean hazard at AFE 1E-4 to 1E-6 are associated with the Charleston RLME source, as illustrated by a peak contribution centered around magnitude 7.5 at distance of about 186 mi. (300 km). For 0.1 Hz (10 sec.) spectral acceleration (Figure 2.5-60), the hazard is dominated by the New Madrid RLME source, as shown by the peak centered around magnitude 7.8 at a distance of more than 311 mi. (500 km).

Sensitivity analyses explore the effect of specific modeling alternatives on the total hazard. In these analyses, the total mean hazard is obtained by systematically assigning a weight of 1.0 to one branch of the logic tree and zero to the other alternatives at a specific node, while keeping the rest of the logic tree unaltered. The elements of the logic tree that have been tested for sensitivity include the alternative geometry of the MESE boundary and the choice of including the bias adjustment and its epistemic uncertainty. These nodes represent the refinements to the

published CEUS SSC (Reference 2.5-60) and NGA-East (Reference 2.5-135) models introduced by the SSHAC Level 2 TI Team.

Figure 2.5-61 shows the effect of using alternative boundaries for MESE: the site hazard computed using the geologic boundary is represented by the red curve, while the hazard computed using the geophysical boundary is represented by the green curve. The geophysical boundary corresponds to the published CEUS SSC model and places the Project site in the PEZ seismotectonic zone, and the geologic boundary places the Project site in the ECC-AM seismotectonic zone. As Figure 2.5-61 shows, the effect of introducing an alternative boundary is to reduce the hazard for high frequency motions, compared to using the CEUS SSC model as published. Low frequency motions are not affected by the alternative MESE boundary because the hazard is dominated by RLME sources.

Figure 2.5-62 shows the effect of introducing bias adjustments to compensate for the potential misfit between NGA-East predictions and recorded ground motions. The mean hazard curve obtained without applying the bias correction is illustrated in green: this corresponds to a direct implementation of the published NGA-East model. The solid blue curve represents the hazard obtained when the bias adjustment is applied, and the dashed curves represent the epistemic uncertainty on how large the adjustment for bias should be. As Figure 2.5-54 shows, the level of bias adjustment is frequency-dependent, meaning that for high frequencies (between PGA and 5 Hz [0.2 sec.]) the adjustment is constant, with median and 5th percentile (in lognormal scale) being less than zero and the 95th percentile being greater than zero. As frequency decreases (between 5 Hz [0.2 sec.] and 0.33 Hz [3 sec.]), the bias adjustment progressively increases, although the median and 5th percentile remain less than zero and the 95th percentile remains greater than zero. Only for very low frequency (0.2 Hz [5 sec.] to 0.1 Hz [10 sec.]) the mean and 95th percentiles are both greater than zero, while the 5th percentile remains less than zero. This behavior is reflected in the curves on Figure 2.5-62, where PGA and 10 Hz (0.1 sec.) are similar (parts (a) and (b) of the figure), 1 Hz (1 sec.) shows a larger difference between the “no bias” and the upper branch of the bias adjustment (part (c) of the figure), and for 0.1 Hz (10 sec.), the bias adjustment is higher than the “no bias” results because both median (labeled “Bias Central” in the legend) and 95th percentile (labeled “Bias Upper” in the figure) are greater than zero.

Variance histograms show the combined effect of the range in hazard and the weights assigned to the various branches in the logic tree. The fractional contributions of the variance from each level of the logic trees in Figure 2.5-49 and Figure 2.5-55 to the total variance are captured in Figure 2.5-63 for PGA and 10 Hz (0.1 sec.) spectral acceleration and in Figure 2.5-64 for 1 Hz (1 sec.) and 0.1 Hz (10 sec.) spectral acceleration. Histograms are obtained for AFEs of 1E-4 (blue), and for AFE 1E-5 (red). Histograms for the two AFEs are similar: the single largest variance is always associated with the uncertainty in the median NGA-East model. For high frequency motions (Figure 2.5-63), the nodes of the logic tree associated with uncertainty in the earthquake recurrence and Mmax on the distributed seismicity zones have contributions between 5 and 20 percent, larger contributions for AFE 1E-5. For low frequency motions (captured on Figure 2.5-64), the nodes associated with magnitude and frequency of RLMEs contribute about half or more of the total variance. The bias adjustment and the alternative basis for the MESE boundary do not have significant variance contributions, just a small percentage at high frequency motions.

2.5.2.5 Seismic Wave Transmission Characteristics of the Site

This section describes the data available to characterize the propagation of seismic waves from the reference rock condition of the NGA-East ground motion models to the control point depths of the technologies being considered for each Plant Complex. These data are used to develop the site response model and site amplification functions that compute performance-based response spectra (see Section 2.5.2.6).

Section 2.5.2.5.1 contains a description of the location and the configuration of the Plant Complexes, including a description of the topography and planned site grading. A summary of the parameters used in SRA, such as velocity profiles, modulus reduction and damping curves, properties of the fill materials, unit weights, and site attenuation parameter kappa, is also presented in Section 2.5.2.5.1.

A description of the approach and logic tree for SRA analyses opens Section 2.5.2.5.2, which continues with discussions of the profile randomization, calculation of conditional mean spectra (CMS), and derivation of site amplification functions (SAFs).

The final part of this section discusses topographic effects and summarizes the design recommendations.

2.5.2.5.1 Site Conditions

The site geology is described in detail in Section 2.5.1 and can be summarized as consisting of the inner Piedmont Cambrian Gneiss and Schist and residual soils (sand, silt, and some clay) of the Cecil-Appling-Pacolet soil series. The TI Team developed cross sections of the Project site, generally following the axis of the peninsula and extending into Belews Lake. The cross section in Figure 2.5-65 shows the main rock and soil units present at the Project site. As captured in the figure, the topography is moderately steep, with ridge slopes at angles of 11 degrees to 18 degrees. The depth to top of bedrock and thickness of overburden and partially weathered rock vary across the site. Across the site, i.e., at the center of the ridge and along the slopes, the average depth to bedrock and variability of that depth to bedrock are similar, as illustrated on Figure 2.5-66.

Ground surface elevations range from 760 ft. (232 m) to 850 ft. (259 m) in the three complex areas, with the toe of the ridge slope at an elevation of about 720 feet. Figure 2.5-67 part (b) shows the elevation of the planned finished grade (yellow) and the estimated bedrock surfaces based on the median depths to rock from boring data (solid blue curve), and one standard deviation (dash-dotted curves), for the North Plant Complex. The location of the cross section is shown in Figure 2.5-67 part (a). Similar plots are captured in Figure 2.5-68 for the Middle Plant Complex, and in Figure 2.5-69 for the South Plant Complex. As the figures show, varying amounts of cut and fill are needed to grade each Plant Complex to reach the planned pad elevation of 810 ft. (247 m).

Figure 2.5-70 shows in more detail the topography of the North Plant Complex in the area where future safety-related structures may be located. The safety-related area (black polygon) is approximately 800 ft. x 1800 ft. (244 m x 549 m), and the planned pad elevation is 810 ft. (247 m). To capture the variability in ground surface, soil/fill thickness, and corresponding depth to bedrock, the TI Team determined that site response analyses should be performed for three 300 ft. x 300 ft. (91 m x 91 m) areas (red squares in the figure) representing the approximate

spatial dimension of nuclear facilities (Reference 2.5-163): one located in a central ridge location, one located in the upper slopes, and one located farther down the slope at the corner of the area. These locations give rise to two possible scenarios: one in which the materials above the target pad elevation of 810 ft. (247 m) are removed (labeled "cut,") the other in which fill material must be added to reach the target pad elevation (called "fill"). Depending on the ground surface elevation, the amount of material that must be cut varies, as Table 2.5-14 shows. The table summarizes the different site conditions for the three locations selected for SRA in the North Plant Complex. The TI Team conducted a sensitivity analysis to determine whether the two site grading cases (cut and fill) were sufficient to capture variability in site amplification across the site, or if additional cases should be added to capture intermediate conditions. Figure 2.5-71 shows an example of this analysis for the North Plant Complex for a scenario magnitude of 7 along with two alternative velocity profiles (see Section 2.5.2.5.2). On each plot, the purple and red curves correspond to the cut and fill cases, while the blue curve is obtained using velocity profiles for the site that do not include any amount of cut or fill. The TI Team concluded that the site grading cases tested for the North Plant Complex result in very similar amplifications at the top of partially weathered rock (PWR). For the control point at the surface, the results generally capture the range of possible site amplifications. The TI Team included a case with 10 ft. (3 m) of cut to obtain a smoother transition between the amplification peaks produced by various cases.

The TI Team used similar considerations to determine the site grading cases to use in SRA for the Middle and South Plant Complexes. Figure 2.5-72 and Figure 2.5-73 show the safety-related areas (black polygons) and site areas for SRA (red boxes) in the Middle and South Plant Complexes, respectively. The size of the red boxes is the same in the Middle and South Plant Complexes as in the North Plant Complex; the size of the safety-related area (black polygon) in the South Plant Complex is approximately 1500 ft. x 1800 ft. (457 m x 549 m). As described for the North Plant Complex, there are two possible site grading scenarios (cut or fill), and different amounts of material (removed or added), as Table 2.5-15 shows for the Middle Plant Complex and Table 2.5-16 shows for the South Plant Complex.

The TI Team noted that the depth to bedrock is generally shallower for the Middle Plant Complex (40 ft. [12 m]) compared to the average depth to bedrock for the North and South Plant Complexes (50 ft. [15 m]). The site grading scenarios applicable to the Middle Plant Complex are very similar to those obtained from North Plant Complex.

As Table 2.5-16 shows, the amount of cut and fill necessary to reach the planned pad elevation is greater in the South Plant Complex compared to the North and Middle Complexes. For this reason, TI Team used five scenarios to capture the variability in the topography for the South Plant Complex: three scenarios correspond to the three scenarios for the North and Middle Plant Complexes and two scenarios capture the larger amounts of cut (38 ft. [11.5 m]) and fill (40 ft. [12 m]) present in the South Plant Complex.

2.5.2.5.2 Velocity Profiles

This section describes the development of V_S profiles representative of the North, Middle, and South Plant Complex areas using the velocity data collected at the site, as well as suspension logging, downhole measurements, and Spectral Analysis of Surface Waves (SASW) testing. Section 2.5.4 discusses the velocity data in more detail.

Figure 2.5-74 compares V_S profiles obtained with different datasets: solid curves represent profiles obtained from suspension logs, and dashed curves are the profiles obtained from SASW measurements. The black dash-dotted curve on each plot is the velocity profile from downhole measurements at the deep borehole in each Plant Complex. As shown, the downhole and suspension log data have large gradients in the velocity around a depth of 50 ft. (15.2 m) at the soil-to-bedrock transition zone and higher velocities in the rock of around 8000 to 10,000 ft/s (2438 to 3048 m/s). The TI Team compared the depth to rock for each boring with geophysics to the depth of the large gradient in the suspension log data for each boring and found the depths to be similar. The SASW data differ in that they show a thicker lower velocity PWR layer with V_S around 2000 to 2500 ft/s (610 to 762 m/s), and lower velocities (about 6000 to 8000 ft/s [1829 to 2438 m/s]) for the rock.

The red square symbols are laboratory unconfined free-free (Fr-Fr) measurements from samples collected at each complex area. The majority of Fr-Fr testing results have velocities similar to the suspension log and downhole datasets, although three samples have lower velocities, around 2000 to 2500 ft/s (610 to 762 m/s), with one of those samples located in the upper portion of the bedrock and the other sampled from about 160 ft. (48.8 m) in depth. One of the three samples is located in the PWR and shows similar velocities to those obtained from suspension logs in the PWR.

Figure 2.5-75 compares the V_S profiles along the 12 SASW arrays and includes an average SASW profile (solid black curve). The figure shows that velocities are generally similar in the three complexes.

The TI Team evaluation of suspension log data is illustrated in Figure 2.5-76. Part (a) of the figure shows the data collected at each Plant Complex, color-coded to identify the location of the boreholes: blue dots are individual measurements from boreholes located in the North Plant Complex, orange dots are from the Middle Plant Complex, and green dots are from the South Plant Complex. The red line represents the average shear wave velocity profile obtained combining measurements from the three Plant Complexes. The deepest log (at B-8 in the Middle Plant Complex) measured a consistent V_S of more than 10,000 ft/s (3000 m/s) below a depth of about 275 ft. (84 m). The TI Team used this observation to place the reference rock halfspace at that depth for the three Plant Complexes. Part (b) of Figure 2.5-76 shows the average V_S profiles evaluated for each Plant Complex using three suspension logs for each profile and the average V_S profile obtained using all the data.

The TI Team made two observations from Figure 2.5-76. The first is that the transition to higher velocities occurs at a shallower depth in the Middle Plant Complex compared to the other two Plant Complexes. Given that the site grading scenarios are the same for the North and Middle Plant Complex, the TI Team conducted a sensitivity analysis to determine whether the difference in velocity profiles yields significantly different SAFs between the North/South and Middle Plant Complexes. An example of the sensitivity analysis is captured in Figure 2.5-77 for a magnitude 7 scenario, for control points at the surface and at the top of the PWR: the red curves are SAFs obtained using velocity profiles derived for the North Plant Complex and the blue curves are SAFs obtained using velocity profiles derived for the Middle Plant Complex. The TI Team concluded that the variability in results between the North and Middle Plant Complex is smaller than the larger variability resulting from epistemic uncertainty in input model parameters. Consequently, the TI Team calculated one set of SAFs applicable to North and Middle Plant Complexes. The second observation made by the TI team on Figure 2.5-76, is that the variations between the average V_S profiles obtained within each Plant Complex were within the

range of variations observed across the entire Project site. The TI Team concluded that the overall average V_S profile obtained by combining all the suspension logs is appropriate for use in SRA. The suspension logging V_S profile is listed in Table 2.5-17.

The TI Team compared downhole V_S measurements to the suspension log data for the same borehole and found that the velocities were similar; therefore, the TI Team did not develop an average velocity profile for the downhole data.

SASW measurements conducted at the Project site included four arrays in each Plant Complex. The V_S profiles for the 12 arrays vary from the V_S measurements from suspension log and downhole data as captured in Figure 2.5-74, with generally lower velocities, particularly for the PWR and upper rock portions of the profiles. The TI Team noted that these differences are present even for those arrays that are located adjacent to boreholes with suspension logging testing. The TI Team evaluated whether the ground surface elevations and direction of source input for the SASW arrays could be correlated to changes in the V_S profiles, but no correlations were found. The SASW V_S profile is captured in Table 2.5-18. The TI Team placed the halfspace reference rock elevation at the average bottom depth of the SASW-derived profiles (540 ft. [164.6 m]) to capture the uncertainty in the depth of the reference rock horizon. The velocity of the halfspace was assumed to be the same as for the suspension log profile because the SASW data did not reach layers with velocities above 9000 ft/s (2743 m/s).

The TI Team compared the dispersion curves computed for the mean profile derived from suspension log data and those calculated for the mean profile derived from SASW with the experimental dispersion data. This comparison is captured in Figure 2.5-78: data points represent experimental dispersion data, while the solid red and green curves are the dispersion curves from suspension logging and SASW velocity profiles, respectively. The mean and three standard deviation bounds of the compacted dispersion curves from SASW are also illustrated on the figure. The comparison shows relative agreement between the mean and standard deviation of the dispersion curves from the velocity profiles and the experimental data. TI Team used this comparison to conclude that the suspension log profile appears to be consistent with the upper part of the dispersion curve dataset for the site and that both the suspension log and SASW profiles are reasonable interpretations of the subsurface conditions at the Project site.

To account for a reduction or increase in isotropic confining pressure (σ_0) based on either a cut or fill scenario, the TI Team adjusted the V_S in the soil using data from resonant column torsional shear (RCTS) testing of eight intact soil specimens. Figure 2.5-79 shows the variation in the small-strain V_S with increasing (normally consolidated range) or decreasing (overconsolidated range) confining pressure. The adjustments range from reductions of about 50 to 250 ft/s (15 to 76 m/s) for cut scenarios that use the overconsolidated range and increases of about 100 to 450 ft/s (30 to 137 m/s) for the fill scenarios that use the normally consolidated range.

2.5.2.5.3 Evaluation of Site Kappa

The TI Team computed the site attenuation parameter kappa (κ_0) in two ways: (1) using the Anderson and Hough (Reference 2.5-164) waveform-based estimation; and (2) using empirical relationships.

For the first approach, the TI Team obtained recordings of recent earthquakes from stations with geologic conditions similar to the Project site. Table 2.5-19 shows the list of stations in NC and

Virginia from the N4 (Central and Eastern U.S. Network) and Transportable Array networks that the TI Team evaluated. Of the stations with similar geology to the Project site, only two, N4.T57A and N4.U56A, had ground motion records with high signal-to-noise ratio. The stations are located within approximately 62 mi. (100 km) of the Project site. Each station recorded 12 earthquakes, and the TI Team used these records to compute kappa.

The TI Team downloaded the horizontal components of these recordings from the data center of the Incorporated Research Institutions for Seismology and processed the recordings by correcting for instrument response and then by removing the mean. The value of kappa was computed from the smoothed and unsmoothed Fourier amplitude spectra (FAS) of each horizontal component using the Anderson and Hough (Reference 2.5-164) acceleration slope methodology, in which a line is fitted to the natural logarithm of FAS as a function of frequency. Kappa is obtained from the slope of the fitted line. Three frequency ranges were used to derive kappa: 15 – 35 Hz; 20 – 35 Hz; and 15 – 30 Hz. These ranges are similar to those used in Reference 2.5-136 to estimate kappa from recordings.

Figure 2.5-80 shows the average of kappa from two horizontal components calculated using the widest reliable frequency range, plotted as a function of distance. The TI Team excluded records with a difference of more than 20 percent between the kappa values computed from the two horizontal components and records with distances greater than 373 mi. (600 km). Following Anderson and Hough (Reference 2.5-164), a linear trend was fitted to the data and used to remove the distance dependence for kappa. The resulting kappa ranges between 0.03 and 0.04 sec., and the TI Team concluded that a value of 0.033 sec. was appropriate to represent the range.

For the second approach, the TI Team considered the empirical relations of Campbell (Reference 2.5-165), Van Houtte et al. (Reference 2.5-166), and Xu et al. (Reference 2.5-167), which are applicable to stable continental regions according to Rodriguez-Marek et al. (Reference 2.5-136). Campbell (Reference 2.5-165) developed an equation to estimate kappa by modifying the general model for kappa in Hough and Anderson (Reference 2.5-168) and propose four models to capture the variability of the effective quality factor at depth. The TI Team obtained a kappa value for each of the four models and computed the geometric mean of kappa, which is 0.010 s. The empirical equation from Van Houtte et al. (Reference 2.5-166) was developed using data from the NGA database, the Kiban Kyoshin Network (KiK-net), and previous literature. Using this method, the TI Team obtained a site kappa of 0.040 s. Xu et al. (Reference 2.5-167) derived their model for kappa using data from 51 sites from the KiK-net. The resulting site kappa calculated by the TI Team is 0.020 s.

Table 2.5-20 summarizes the values of kappa calculated by the TI Team and the assigned relative weights. The highest weight (0.5) is assigned to the kappa value obtained with the Campbell (Reference 2.5-165) empirical relationship because the model is derived for CENA and is based on a more robust dataset than the waveform analysis conducted by the TI Team. The kappa from waveform analysis is given weight of 0.3 because the values are evaluated from site-specific data at recording stations located on similar geologic units as the Project site. Kappa values based on Xu et al. (Reference 2.5-167) and Van Houtte et al. (Reference 2.5-166) receive weights of 0.16 and 0.04, respectively, because these empirical equations are derived from data from the Japanese KiK-net database, which is not directly applicable at the Project site. The higher weight assigned to Xu et al. (Reference 2.5-167) compared to Van Houtte et al. (Reference 2.5-166) is because the Xu et al. model (Reference 2.5-167) incorporates the depth to the 2.5 km/s (3281 ft/s) V_S horizon. The weighted average site kappa for the Project site is

0.02 s, which is consistent with kappa estimates (0.018 s) in the Piedmont region of South Carolina near Lake Monticello obtained by Chapman et al. (2003)(Reference 2.5-169).

EPRI (Reference 2.5-163) recommends an epistemic uncertainty in site kappa of $\sigma\left(ln(\kappa_0)\right) = 0.4$; Xu et al. (Reference 2.5-167) reports instead an uncertainty of $\sigma\left(ln(\kappa_0)\right) = 0.22$. The TI Team applied the $\sigma\left(ln(\kappa_0)\right) = 0.22$ value to each value of kappa from Table 2.5-20 and derived the cumulative density function (CDF) for kappa, from which they extracted the 10th, 50th, and 90th percentiles. Following recommendations in EPRI (2013) (Reference 2.5-163), the TI Team assigned weights of 0.3, 0.4, 0.3 to the three percentiles. A sensitivity analysis showed that sampling five branches from the CDF instead of three does not provide a better representation of the uncertainty in site kappa. The site kappa model for use in SRA is given in Table 2.5-21.

2.5.2.5.4 Shear Modulus Reduction and Damping

The TI Team derived two sets of shear modulus reduction and damping curves (material curves) to capture the uncertainty in the residual soils. Note that the upper soils, which are likely to be removed during grading operations, were not included in the analyses.

The first set of material curves for residual soils was derived using the RCTS results, which were fit with a power function similar to Darendeli (2001) (Reference 2.5-170). The fitted curve was then used to derive modulus reduction curves for five different confining stresses that represented the range of possible depths for the residual soils. Even though the RCTS testing was performed on samples in the upper 24 feet of the residual soils, the derived material curves are applicable to all depth ranges because the residual soils had consistent soil types across all depths, and the material curves are extrapolated to higher confining stresses to be appropriate for the deeper residual soils. The five different confining stresses represented approximately 15-foot-thick layers going from an average depth of 7.5 ft. (2.3 m) to about 67.5 ft. (20.6 m). These modulus reduction curves are captured in the top part of Figure 2.5-81. To confirm that the higher strain portion of the curves is representative of the shear strength of the residual soils based on lab strength testing, the TI Team plotted the shear strain versus shear stress curves for the lab-derived modulus reduction curves, evaluated using the approximate V_S values for the residual soils. The shear strength data showed no trend with depth of the sample tested; therefore, the data were compared to material curves for various depth ranges. Also captured on Figure 2.5-81 are the undrained shear strength results for residual soils from the unconfined compressive strength and unconsolidated-undrained triaxial compression tests for the Project site. These test results are plotted at an arbitrary 2 percent shear strain for comparison to the curves. The TI Team concluded that the lab strength data generally match the range of shear strengths interpreted from the modulus reduction curves, especially considering that the lab data are obtained from samples at shallower depths than about 20 ft. (6 m). Consequently, the TI Team did not adjust the modulus reduction curves at high strains.

A similar process was used to derive the damping curves from the RCTS lab testing for the residual soils. The TI Team fitted the minimum damping (Dmin) versus the confining stresses values from laboratory testing with a power function, which results in an average Dmin of about 1.8 percent for the residual soils. The TI Team found that the RCTS results for damping were adequately matched using the standard coefficients from Darendeli (Reference 2.5-170). Figure 2.5-82 shows the lab-derived damping curves for the residual soils.

The second set of material curves for residual soils is directly based on the Darendeli (Reference 2.5-170) equations for modulus reduction and damping using a plasticity index of 0,

consistent with the results of laboratory testing and other standard parameters. The modulus reduction and damping curves for the residual soils are captured in Figure 2.5-83(a). The TI Team did not adjust the high strain portions of the Darendeli (Reference 2.5-170) curves because the interpreted shear stress versus shear strain curves are similar to those captured in Figure 2.5-83(b) at strains above about 1 percent.

The TI Team used two sets of curves to capture uncertainty in the material curves for the rock layer (i.e., PWR and rock). The curves were evaluated for lower reference strain and higher reference strain sets. For PWR, the TI Team adopted the curves for unweathered shale from Stokoe et al. (2003) (Reference 2.5-171) and EPRI (2013) (Reference 2.5-163) rock for a depth of 2000 to 5000 ft. (610 to 1524 m). These curves are captured in Figure 2.5-84. For rock layers with V_S less than 8000 ft/s (2438 m/s) the TI Team assumed the rock to be linear for the more linear set of curves and used the unweathered shale Stokoe et al. (Reference 2.5-171) curves for the less linear set. The TI Team assumed rock layers with V_S above 8000 ft/s (2438 m/s) to be linear for both sets of reference strains.

Rodriguez-Marek et al. (Reference 2.5-136) indicate that the cumulative impact of small-strain damping (Dmin) must be compatible with the assigned values of kappa for the site. The TI Team adjusted the small-strain portion of the damping curves to match the kappa values in Table 2.5-21 using the approach presented in Xu et al. (Reference 2.5-167). First, the TI Team used the models from Campbell (Reference 2.5-165) to obtain Dmin values in the rock layers, based on the V_S profile from suspension logging (see Table 2.5-17). The resulting Dmin values ranged from 0.7 percent to 0.9 percent. The TI Team then conducted linear site response analysis using the calculated Dmin values in the rock, the lab-derived material curves for the residual soils (Dmin of 1.8 percent), and the Stokoe et al. (Reference 2.5-171) unweathered shale curve for the PWR (Dmin of 1.0 percent). This calculation produced a kappa value of 0.012 sec. for the surface output FAS. The TI Team found that the halfspace and intrinsic profile kappa was equal to 0.007 s, and that the remaining 0.005 sec. were the contribution of the profile damping. The TI Team considers the calculated scale factors to be in the range of scale factors reported in Xu et al. (Reference 2.5-167). For the 10th percentile kappa value of 0.007 s, the profile should have insignificant damping; therefore, the TI Team imposed a Dmin of 0.1 percent in all layers to limit the damping to a small value. The resulting scaled Dmin values for various soil and rock units for the range of kappa values are captured in Table 2.5-22. The small-strain damping values for the highest kappa value of 0.035 sec. are very high compared to the original damping values and the damping values for a kappa value of 0.014 sec. The TI Team noted that these values represent the upper 90th percentile Dmin values and thus represent the upper range of enhanced wave scattering effects on the damping. Given the relatively thin soil profile for the Project site, these high Dmin values are necessary to achieve kappa values that correspond to those obtained from inversion of earthquake recordings for similar geologic conditions. Figure 2.5-85 shows two examples of the adjustments to the small-strain damping to match the site kappa. The top part of the figure shows the adjustments to the lab-derived damping curves for residual soils (0 to 15 ft. [0 to 4.6 m] in depth) and the bottom part shows the adjustments applied to the Stokoe et al. (Reference 2.5-171) unweathered shale curve for PWR. For site kappa of 0.007 sec. (orange curves in Figure 2.5-85), the TI Team used the small-strain damping values for shear strains of 0.0005 percent to 0.001 percent, beyond this level the curve is smoothly transitioned to the original (unadjusted) curve (dashed curves in Figure 2.5-85). For the other kappa values, the damping is constant in the low shear strain portion until the original curve is reached.

2.5.2.5.5 Dynamic Properties for Fill Materials

The dynamic properties of fill materials are described in Section 2.5.4. Table 2.5-23 contains the V_S profiled developed by the TI Team, which includes a top layer with V_s of 1000 ft/s (305 m/s). To define how the velocity in the fill would increase with depth, the TI Team relied on equations from Seed et al. (1984) (Reference 2.5-172) and prior experience with granular fill. Material curves for the fill are based on the range of curves from Seed and Idriss (1970) (Reference 2.5-173), Rollins et al. (1998) (Reference 2.5-174), and on experience with granular fill with gravel.

2.5.2.5.6 Layer Unit Weights

The TI Team developed unit weight for the upper residual soils and the rock units using data from lab testing. An average value of 100 pounds per cubic foot (pcf) (1602 kilograms per cubic meter [kg/m^3]) was evaluated for the upper residual soils and an average value of 170 pcf (2723 kg/m^3) was evaluated for the rock layers. The TI Team reviewed boring logs that indicated that residual soils below about 20 to 30 ft. (6 to 9 m) in depth had higher blow counts than soils above that depth. Consequently, the TI Team assigned a unit weight of 115 pcf (1842 kg/m^3) to the residual soils below depths of about 20 to 30 ft. The TI Team relied on prior experience to assess a unit weight of 135 pcf (2162 kg/m^3) to the PWR. Fill materials are assigned a unit weight of 120 pcf (1922 kg/m^3).

2.5.2.5.7 Site Response Analysis

The TI Team conducted site response analyses to develop amplification functions that capture the uncertainty in the location of future reactors and control point depths. The TI Team conducted a series of sensitivity analyses to evaluate the base depth and base elevations of the technologies considered for deployment at each Plant Complex (summarized in Table 2.5-24 and captured in Figure 2.5-65 by the dashed red lines). The parameters in Table 2.5-24 were provided to the TI Team in the Hazard Products Document and included only five technologies. The TI Team did not evaluate the sixth technology (TerraPower); however, it has a similar base elevation to Technology 4 in Table 2.5-24, such that design response spectra (DRS) applicable to Technology 4 can also be considered valid for TerraPower. Examples of these analyses results are captured in Figure 2.5-86 for alternative velocity profiles, alternative site grading cases, AFEs, and earthquake magnitudes. The TI Team concluded that the control points for technologies 2 and 3 in Table 2.5-24 could be represented by a single depth of 85 ft. (26 m) for the purpose of conducting site response analyses, except for the South Plant Complex, where the control point at depth of 115 ft. (35 m) was also analyzed separately. The combination of control points and alternative site grading conditions (see Table 2.5-14 to Table 2.5-16) gives rise to 21 site response analysis cases, which are summarized in Table 2.5-25.

The TI Team developed a logic tree for conducting site response analysis, which is captured in Figure 2.5-87. The first node addresses the methodology used to conduct SRA. The TI Team chose the equivalent linear (EQL) Random Vibration Theory (RVT) approach to site response analyses, which was originally implemented in the code Strata (Reference 2.5-175). The version of the code used by the TI Team implements RVT site response analysis with Vanmarcke's (Reference 2.5-176) peak factor formulation and Boore and Thompson (Reference 2.5-177) oscillator duration adjustment for CENA. In each SRA, the input motion is applied at the base of the profile as an outcropping motion. For each epistemic alternative case, the TI Team used 60 randomized profiles and sets of properties. The input FAS are obtained by calculating broadened CMS (Reference 2.5-178) and then inverting the response spectra to Fourier

amplitude using Inverse Random Vibration. Outputs of the SRA are response spectra at the control point elevations and peak shear strains and strain compatible properties in each layer. To address the underprediction of the high-frequency components of motion at large strains, Xu and Rathje (Reference 2.5-179) proposed a kappa correction to the FAS computed from EQL site response analysis. The National Center for Research on Earthquake Engineering (Reference 2.5-180) modified this kappa correction method so that the EQL FAS remains unmodified below a specified transition frequency. This kappa correction approach is designated the kappa2 approach. The transition frequency is based on the frequency at which the EQL FAS decreases below some fraction of its peak. The TI Team used the values recommended in Rodriguez-Marek et al. (Reference 2.5-136), i.e., 0.05, 0.11, and 0.17 with weights of 0.2, 0.6, and 0.2. This is captured in the second node of the logic tree in Figure 2.5-87. The kappa2 approach (kappa-corrected EQL) receives a weight of 0.7 compared to the unadjusted EQL (weight 0.3). TI Team assigned a weight of 0.3 to the unadjusted results following indications in Rodriguez-Marek et al. (Reference 2.5-136) that the unadjusted amplification (without using the kappa2 approach) could still be valid.

Xu and Rathje (Reference 2.5-179) observed that kappa does not vary systematically with the induced shear strain but remains at its small-strain value. Their study also demonstrates motions computed using the small-strain kappa as κ_{target} in a kappa-corrected EQL analysis are more consistent with recorded motions. Following Rodriguez-Marek et al. (Reference 2.5-136) and Xu and Rathje (Reference 2.5-179), the small-strain kappa values evaluated from linear site response runs for each analysis (randomized profile and input motion combination) were used as the target kappa for each analysis. The TI Team applied the kappa2 approach after the calculation of iterated equivalent linear site response, with the modifications only applied to the output FAS. Subsequently, the modified site response FAS at the target horizons are converted back to response spectral values for use in computing site amplification factors. The kappa2 approach is only applied to the output when the peak shear strain in the profile is above 0.1 percent (i.e., the minimal level at which, according to Zalachoris and Rathje (Reference 2.5-181), the equivalent linear analysis may not be reliable). The kappa2 approach adjustments are not applied to periods above 1 sec. because EQL analyses are reliable at higher periods. Preliminary site response analyses show that the effect of the kappa2 approach is generally small (negligible at frequencies below about 2 Hz and at lower ground motion levels) and that the correction is needed when the maximum shear strains in the rock is above 0.1 percent. The kappa2 approach was not implemented for control point elevations in the rock, i.e., top of PWR; reactor base depths of 44 ft. (13 m) and below for the cut locations (number 1, 2, and 4 from Table 2.5-24); reactor base depth of 85 ft. (25.9 m) and below for the thinner fill location (number 3 in Table 2.5-24); reactor base depth of 115 ft. (35 m) and below for the thicker fill location (number 5 in Table 2.5-24).

The third node of the logic tree addresses the uncertainty in the velocity profile (see discussion in Section 2.5.2.5.2). The TI Team conducted a sensitivity analysis to evaluate whether the results obtained with the two velocity profiles captured a range of amplification and to determine the variability of the results. Figure 2.5-88 shows examples of the SRA sensitivity analyses that the TI Team conducted. The plots compare a site amplification function calculated with the velocity profile obtained using suspension log data (in purple) and one calculated with the velocity profile obtained with SASW data (in green). Plots are presented for cut and fill scenarios and for control points at the surface and at the top of the PWR (interface). The TI Team determined that the results capture a range of amplifications and that large differences between the results occur, in particular for the control point at top of PWR. The V_S profile from suspension logging receives a higher weight compared to the SASW profile because the

velocities from suspension log data, downhole data, and URC Fr-Fr testing are consistent. Additionally, the boring logs also indicate higher velocity at shallow depths, consistent with the P-S profile.

The fourth level of the logic tree addresses the uncertainty in alternative material curves. As discussed in Section 2.5.2.5.3, the TI Team developed two sets of curves: one based on laboratory testing results on samples collected at the site (called “site-specific set” in Figure 2.5-87), the other based on the Darendeli (Reference 2.5-170) curves. The TI Team preference for the site-specific set is motivated by the fact that the curves are derived using site-specific RCTS data and should, therefore, represent the nonlinear behavior of site soils better than the Darendeli (Reference 2.5-170) curves.

The fifth and final level of the logic tree in Figure 2.5-87 addresses the uncertainty in site kappa, which is described in Section 2.5.2.5.3.

2.5.2.5.7.1 Randomization of Velocity Profiles and Material Curves

The V_S profiles and material curves described in Sections 2.5.2.5.2 and 2.5.2.5.4 were randomized to represent spatial variability in the wave paths and material properties and to smooth out sharp resonance peaks produced by deterministic profiles. For each logic tree branch, the TI Team obtained 60 randomized profiles using the layer velocity correlation model developed by Toro (Reference 2.5-182) with parameters for firm sediments (USGS Site Class C). Site Class C was chosen because the site is essentially a sequence of flat-lying sediments, though most have become rock. Layer thicknesses were randomized based on the variation of thickness of each layer from the site investigation geophysical data. The velocities between the fill (when present) and the underlying rock were not correlated. Similarly, the velocities between soil and PWR were not correlated. For the cut cases, the profile was first randomized, then adjusted to remove the materials above the pad elevations, such that the variation of the existing ground surface in each area is modeled. For fill cases, the fill layer thicknesses are varied to capture the total variation of the fill thickness for each area.

Following the randomization of the V_s profiles, dispersion curves of the 60 randomized profiles were compared to the SASW dispersion curves to confirm all randomizations are realistic. Figure 2.5-89 shows an example of the 60 randomized velocity profiles (gray) and their median (blue) compared to the target velocity profile (red), on the left-hand side of each figure. On the right-hand side, the standard deviation of the log of the velocity from the simulations (blue) is compared to the target (red). The randomization was rerun until the p-values between the target median V_S profile and the median of the 60 randomized profiles reached a minimum value of 0.1 and an average above 0.5.

For each logic tree branch, 60 randomized sets of material properties were also obtained. Randomization of the modulus reduction (G/Gmax) curves was performed assuming a Beta distribution, which is limited to the range of 0 to 1. The parameters of the Beta distribution are adjusted to produce the target sigma of ln(G/Gmax) of 0.15 in the vicinity of shear strain $3x10^{-2}$ percent. Randomization of damping curves was performed assuming a target sigma of 0.3. Randomized damping values were limited to a maximum of 15 percent in the vicinity of shear strain $3x10^{-2}$ percent following guidance given in Appendix E of RG 1.208 and guidance for development of dynamic properties for soil structure interaction analyses given in Section 3.7.2 of NUREG-0800 and Section C5.2 of the American Society of Civil Engineers, Structural Engineering Institute (ASCE/SEI) 4-16 (Reference 2.5-183). A correlation coefficient of -0.7

between modulus reduction and damping curves was used in the randomization process. Figure 2.5-90 shows an example of the randomized material curves.

2.5.2.5.7.2 Broadened Conditional Mean Spectra

The use of broadened CMS extends the concept of low frequency and high frequency "controlling earthquakes" discussed in RG 1.208 and reduces the tendency to overdrive the site profile by using broad-banded input motions scaled to high levels. To calculate the broadened CMS, first the reference rock hazard was deaggregated for 14 levels of motion equally spaced in log space between AFE 1E-2 and 3E-9. Input rock motion scenarios for **M** 5, 6, 7, and 8 earthquakes and mean distance of contributing events for each AFE were generated using the ground motion characterization model used in the reference rock hazard calculations. This ensured consistency between the CMS and the reference rock hazard results.

The CMS was calculated for five period ranges (0.005 to 0.1; 0.03 to 0.3; 0.15 to 1; 0.4 to 3; and 1.5 to 10) using the correlation model by Baker and Bradley (2017) (Reference 2.5-184) adjusted for CENA high-frequency rich motions. The CMS are converted to FAS using inverse RVT and the significant duration (i.e., the duration between the 5th and 95th percent of the Arias intensity) obtained with the empirical model by Reference 2.5-185. Figure 2.5-91 shows the resulting CMS on separate plots for **M** 5, 6, 7, and 8 earthquake scenarios. On each plot, AFEs ranging from 1E-3 (return period 1000 years) to 1E-7 (return period of 10 million years) are represented by curves of different colors. Different line types are used to represent the uniform hazard response spectrum (UHRS) that the CMS is equal to for various ranges of conditioning frequencies. The CMS are shown with slightly darker colors compared to curves of the same AFEs.

2.5.2.5.7.3 Amplification Fitting

The amplification functions were obtained by dividing the output response spectra by the input response spectra for each randomized profile, each CMS input motion, and site response case from Table 2.5-25. These data points were then fit by a piecewise-linear function to define the median magnitude-dependent probabilistic SAF and the corresponding standard deviation in amplification. Figure 2.5-92 shows an example of fit to the site amplification data for PGA at the ground surface, obtained using the suspension log velocity profile for 24 ft. (7.3 m) of cut, the site-specific set of G/Gmax and damping curves, a site kappa of 0.014, and using a kappa2 correction factor (i.e., fraction of the FAS peak) of 0.11. The four plots correspond to CMS magnitudes 5, 6, 7, and 8. On each plot, the gray circles are amplification values for individual randomized profiles and material properties, while the red curves show the fitted median (solid), 5th and 95th (dashed) percentile SAFs.

The TI Team applied two adjustments to the SAFs. The first adjustment focuses on the standard deviation in ln(SAF). As noted by Rodriguez-Marek et al. (Reference 2.5-136), at low ground motion levels, the variability in ground motions caused by site properties is already accounted for in the evaluation of single-station sigma because recorded motions are generally at low ground motion levels. The standard deviation increases at higher ground motion levels because of variability in nonlinear response, which is not well represented in the empirical data used to develop single-station sigma values. Therefore, following Reference 2.5-136, the standard deviation obtained in the piecewise-linear fit was replaced by Equation 2.5.2-11:

$$\sigma_{non-linear} = \sqrt{\sigma_{fit}^2 - \sigma_{linear}^2} \quad \text{(Equation 2.5.2-11)}$$

Where $\sigma^2{}_{linear}$ is the variance computed at low levels of input motion where minimal levels of nonlinear behavior are manifested in the site amplification analyses. The level of motion is taken to be at the point where there is minimal variability in the SAFs. The minimum value of $\sigma_{non\text{-}linear}$ is set to 0.001.

The second adjustment focuses on the epistemic uncertainty in the SAFs. The aleatory variability model from the NGA-East project is a partially non-ergodic or single-station sigma model. Incorporating this model into PSHA necessitates including epistemic uncertainty in the site amplification analysis. Rodriguez-Marek et al. (Reference 2.5-186; Reference 2.5-136) suggested that a minimum level of epistemic uncertainty should be applied to account for unmodeled uncertainties in developing SAFs using 1-D site response analysis. Rodriguez-Marek et al. (Reference 2.5-136) recommend a value of $\sigma_{\ln\,(SAF_epistemic)}$ = 0.15 for the minimum epistemic uncertainty. Bahrampouri and Rodriguez-Marek (2023) (Reference 2.5-187) quantified modeling error in 1-D site response for a large set of KiK-net stations in Japan. The modeling error was assessed as a function of the assumed uncertainty in site properties, with modeling error decreasing with increasing assumed uncertainty in site properties. Their results suggest a minimum epistemic uncertainty of 0.2. The TI Team adopted the minimum of 0.2 suggested by their analysis, which was incorporated by expanding the epistemic distribution of SAFs resulting from the branches of the SRA logic tree in Figure 2.5-87. The expansion was achieved by scaling each amplification function resulting from the SRA analysis by $\exp(\pm 1.645\sigma_{additionl\ epistemic})$ with $\sigma_{additional\ epistemic}$, as captured in Equation 2.5.2-12:

$$\sigma_{additional\ epistemic} = \sqrt{\max\,(0, 0.20^2 - \sigma_{\ln SAF_epistemic}^2} \quad \text{(Equation 2.5.2-12)}$$

The weights assigned to the additional amplification curves are based on the Keefer and Bodily (1983) (Reference 2.5-188) discrete approximation to a normal distribution and are 0.185, 0.63, and 0.185 for the 5th, 50th, and 95th percentile values, respectively.

2.5.2.5.8 Topographic Effects

Topographic effects refer to the phenomenon where seismic waves interact with the shape of the ground surface, particularly when the shape deviates significantly from being flat. The effects can result from various mechanisms, including wave interference caused by reflections off convex or concave surfaces, sensitivity to the angle of wave incidence, and scattering or reflection from sharp topographic features. In some cases, resonance may also occur, depending on the shape and size of the terrain. Topographic effects are highly frequency-dependent, with the most significant amplification occurring when the seismic wavelengths are similar in scale to the topographic features. This amplification tends to diminish at longer periods, as long-period waves are generally unaffected by smaller-scale surface features.

As described previously, the three Plant Complexes are situated on a ridge sloping toward Belews Lake with slope angles of approximately 15 degrees. From Figure 2.5-67, the TI Team estimated that in the North Plant Complex, the main ridge slopes range from 5:1 to 4:1

(horizontal to vertical ratio) or 11 degrees to 14 degrees with a height of about 90 ft. (27 m) to the planned pad elevation. In the Middle Plant Complex (Figure 2.5-68), the main ridge slopes range from 4:1 to 3:1 (horizontal to vertical ratio) or 14 degrees to 18 degrees with a height of about 90 ft. (27 m) to the planned pad elevation. In the South Plant Complex (Figure 2.5-69), the main ridge slopes range from 4:1 to 3:1 (horizontal to vertical ratio) or 14 degrees to 18 degrees with a height of about 90 ft. (27 m) to finished grade elevation on the lake slope, but only about 50 ft. (15 m) on the west side.

The TI Team reviewed several models to estimate potential topographic amplification effects at the site. The European Seismic Code Eurocode 8 Part 5 (Reference 2.5-189) introduces frequency-independent amplification factors up to 40 percent based on simplified two-dimensional geometries. Cauzzi et al. (2010, 2012) (References 2.5-190 and 2.5-191) use three-dimensional numerical modeling to provide amplification factors for the 5 percent-damped elastic displacement response spectrum. Their model is designed to capture three-dimensional topographic effects associated with reliefs having relatively small width-to-length aspect ratios. Rai et al. (Reference 2.5-192) analyze intra-event residuals from the Chiou and Youngs (Reference 2.5-193) ground motion model using the NGA-West2 database. Rai et al. (Reference 2.5-192) focus on the correlation between residuals and geomorphologic parameters like relative elevation, slope, and curvature. The Ashford and Sitar (Reference 2.5-194) and Ashford et al. (Reference 2.5-195) model is based on two-dimensional simulations using the generalized consistent transmitting boundary method. The model computes topographic amplification factors at multiple receiver locations along a slope.

Of the models evaluated, the TI Team considered the Cauzzi et al. (2010, 2012) (References 2.5-190 and 2.5-191) models not to be applicable at the Project site for three main reasons: (1) the vertical relief at the Project site is much less than the modeled relief; (2) the frequency range is limited to 2 Hz, which does not capture the decrease in amplification expected at higher frequencies; and (3) the model was limited to a single ground motion scenario. The remaining three models were used to derive topographic amplification factors at each Plant Complex and are captured in Figure 2.5-93. Note that the Rai et al. (2017) (Reference 2.5-192) produces no topographic amplification at the South Plant Complex; therefore, it is not shown in the figure. The final topographic amplification factors for each complex were determined by combining the results from these different models, with equal weight assigned to each model. The amplification factors are listed in Table 2.5-26 and are captured in Figure 2.5-94. These factors should be multiplied by the applicable DRS (see Section 2.5.2.6) if a facility is constructed near the edge of the graded site pad.

2.5.2.6 Ground Motion Response Spectra

This section describes the development of the horizontal and vertical site-specific ground motion response spectra (GMRS). The section is organized to first describe the approach adopted to compute mean and fractile site-specific hazard (Section 2.5.2.6.1); magnitude and distance deaggregation of the site-specific hazard and calculation of controlling earthquakes (Section 2.5.2.6.2); performance-based horizontal DRS (Section 2.5.2.6.3); and vertical-to-horizontal (V/H) spectral ratios (Section 2.5.2.6.4). The site-specific seismic hazard results for the North and Middle Plant Complexes are presented next (Section 2.5.2.6.5), followed by the results for the South Plant Complex (Section 2.5.2.6.6). Sensitivity analyses showing the effect of elements of the SRA are presented in Section 2.5.2.6.7 and the section is concluded with a brief summary guidance for future use of the site-specific hazard results (Section 2.5.2.6.8).

2.5.2.6.1 Mean and Fractile Site-Specific Hazard Curves

The approach used to compute site-specific hazard results requires convolving the reference rock horizontal hazard described in Section 2.5.2.4.4, with the SAFs described in Section 2.5.2.5.7. This approach is identified as "Approach 3" in NUREG/CR-6728 (Reference 2.5-196) and its mathematical formulation is presented in Equation 2.5.2-13.

$$G_{Z,S}(z_k; m_i) = \sum_j P\left(SAF_S \geq \frac{z_k}{x_j} | x_j, m_i\right) \cdot p(x_j; m_i) \qquad \text{(Equation 2.5.2-13)}$$

Where:

- $G_Z(z_k;m_i)$ is the annual frequency of exceeding ground motion level z_k for magnitude m_i and SAF_S.
- SAF_S is the s-th branch of the logic tree in Figure 2.5-87, combined with the additional epistemic uncertainty described in Section 2.5.2.5.7.3.
- $p_X(x_j; m_i)$ is the discretized rock hazard curve giving the annual frequency of ground motions on rock of x_j (values near x_j).
- $P\left(SAF_S \geq \frac{z_k}{x_j} | x_j, m_i\right)$ is the probability that site amplification SAF_S for magnitude m_i at reference rock ground motion level x_j is greater than or equal to $\frac{z_k}{x_y}$.

Following McGuire et al. (2001) (Reference 2.5-196) and Bazzurro and Cornell (2004) (Reference 2.5-197), the site amplification SAF_S is assumed to be lognormally distributed, such that Equation 2.5.2-14 defines the probability term inside Equation 2.5.2-13:

$$P\left[SAF_S \geq \frac{z_k}{x_j} | x_j, m_i\right] = 1 - \Phi\left\{\frac{ln\left(\frac{z_k}{x_j}\right) - \overline{ln[SAF_s(x_j, m_i)]}}{\sigma_{lnSAF_s(x_j,m_i)}}\right\} \qquad \text{(Equation 2.5.2-14)}$$

Where:

- $\overline{ln[SAF_s(x_j, m_i)]}$ is the median (mean log) amplification of SAF_s for magnitude m_i at reference rock ground motion level x_j
- $\sigma_{lnSAF_s(x_j,m_i)}$ is the value of standard deviation for SAF_S or magnitude m_i at reference rock ground motion level x_j removing the linear component assumed to be contained within the single station aleatory variability.
- $\Phi[\ ]$ is the cumulative normal distribution function.

The approach to compute fractiles of the site-specific seismic hazard using Approach 3 follows the methodology presented in INL (Reference 2.5-198) and Rodriguez-Marek et al. (Reference 2.5-136). The reference rock hazard results in Section 2.5.2.4.4 consist of AFEs calculated for a discrete set of 20 ground motion values resulting from all possible paths along the SSC and

GMC logic trees. The epistemic uncertainty in the rate of exceeding each ground motion level is represented by the distribution of AFEs resulting from each logic tree path. A set of 100 hazard curves are obtained from this distribution of reference rock hazard. SAFs developed for the Project site are magnitude-dependent, introducing a level of complexity into the analysis. The INL (Reference 2.5-198) solution is to interpolate the magnitude-dependent SAFs defined for **M** 5, 6, 7, and 8 over the entire magnitude range covered by the hazard calculation (from **M** 5.0 to 8.2, using a 0.1-magnitude unit interval). This step results in 33 magnitude-dependent SAFs. Each SAF is then scaled by its relative contribution to the total mean site-specific hazard at a given ground motion level to obtain a mean magnitude-independent SAF and its uncertainty. Approach 3 can then be applied to obtain a set of site-specific fractile hazard curves from the reference rock fractiles and the mean hazard-weighted SAF.

2.5.2.6.2 Magnitude-Distance Deaggregation and Controlling Earthquakes

NUREG-0800 specifies that applications for new reactors meet the requirements of 10 CFR 100.23 when the PSHA includes a discussion of the high- and low-frequency controlling earthquakes at the site, as defined in RG 1.208. Appendix D of RG 1.208 contains a methodology to obtain magnitude-distance deaggregation tables and the magnitude and distance of the controlling earthquake from the deaggregation of the seismic hazard. INL (Reference 2.5-198) describes how to deaggregate site-specific hazard when Approach 3 is used and SAFs are magnitude-dependent. The INL (Reference 2.5-198) methodology involves five steps:

1. Obtain a set of mean magnitude-dependent amplification functions (one for each spectral frequency), interpolated to add 100 points between each consecutive ground motion level. Using the naming convention introduced in INL (Reference 2.5-198), this vector of reference rock ground motion values is called *rsa*. The magnitude-dependent amplification functions interpolated to *rsa* are then further interpolated to magnitudes between **M** 5.0 and **M** 8.2, with a step of 0.1 moment magnitude units, consistent with the magnitude range used in the PSHA. Using the INL (Reference 2.5-198) naming convention, the resulting mean magnitude-dependent amplification functions are called $mSAF_{Mi}$.
2. Obtain magnitude-dependent equivalent reference rock ground motions. This step involves finding, for each magnitude between **M** 5.0 and **M** 8.2 and each target AFE, the values of reference rock motions (called $rsa_{Mi,\ AFE}$) that, when multiplied by $mSAF_{Mi}$, produce the magnitude-dependent site-specific ground motion at the specified AFE (called $ssa_{Mi,\ AFE}$). Following RG 1.208, the target AFEs are 1E-4, 1E-5, and 1E-6, corresponding to return periods of 10 thousand years, 100 thousand years, and 1 million years. To compute rsa_{Mi}, the interpolated reference rock motions (*rsa*) are multiplied for each $mSAF_{Mi}$ to obtain ssa_{Mi}. Then, using the UHRS at the target AFE, ssa_{Mi} are interpolated to find $rsa_{Mi,\ AFE}$.
3. Obtain the distance contribution by deaggregation of the reference rock hazard for each magnitude-dependent equivalent reference rock ground motion. This produces 33 (one for each magnitude between **M** 5.0 and **M** 8.2) magnitude-distance deaggregation tables for each AFE.

4. Obtain magnitude contributions to total site-specific hazard. Site-specific hazard curves for each magnitude between **M** 5.0 and **M** 8.2 can be interpolated to obtain the AFE corresponding to the site-specific UHRS values for each spectral period and used to calculate the relative contribution of each magnitude to the total site-specific hazard.
5. Combine the distance deaggregation from step 3 with the magnitude deaggregation from step 4. For each spectral period of interest (per RG 1.208 these are: 0.1 sec., 0.2 sec., 0.4 sec., 1 sec., frequencies of 10 Hz, 5 Hz, 2.5 Hz and 1 Hz), the distance deaggregation obtained for each magnitude and AFE (step 3) is scaled first by rsa_{M_i}, AFE, then by the hazard contribution computed for magnitude $\mathbf{M}_i$ (step 4). This produces tables of magnitude and distance deaggreagation for each spectral period and AFE of interest.

INL (Reference 2.5-198) cautions that the approach is valid under the assumption that the distance is not affected by the convolution of the reference rock hazard with the magnitude-dependent SAFs. This assumption is supported by NUREG/CR-6728 (Reference 2.5-196), which recognizes that the level of reference rock motion and magnitude govern the site-specific hazard, while distance does not have a significant effect. Consequently, calculating the distance deaggregation from the reference rock hazard is possible.

Once the magnitude-distance deaggregation tables are calculated, Appendix D of RG 1.208 can be used to obtain the required tables of magnitude and distance deaggregation and controlling earthquakes. Deaggregation step 2 in RG 1.208 requires a deaggregation of the PSHA for each of the spectral accelerations (frequencies of 10 Hz, 5 Hz, 2.5 Hz, and 1 Hz, or periods of 0.1 sec., 0.2 sec., 0.4 sec., 1 sec.) and annual probability levels (AFEs of 1E-4, 1E-5, and 1E-6) and provide a table such Table D.1 for each of the 12 cases.

Appendix D of RG 1.208 also contains the procedure for calculating controlling earthquakes. The first step consists of a review of the magnitude-distance distribution for the average of 1 and 2.5 Hz to determine whether the contribution to the hazard for distances of 100 km (63 mi.) or greater is substantial, i.e., on the order of 5 percent or greater (RG 1.208, Section D.4, Step 1). The next step to determine controlling earthquakes is to calculate the mean magnitude and distance of the controlling earthquake associated with the ground motions determined in the first step of the deaggregation (above) for the average of 5 and 10 Hz. The mean magnitude of the controlling earthquake is computed using results of the entire magnitude-distance bins matrix using Equation 4 of RG 1.208, which is reproduced below as Equation 2.5.2-15.

$$M_c(5-10\ Hz) = \sum_m m \sum_d P(m,d)_2 \qquad \text{(Equation 2.5.2-15)}$$

Where:

- M_c(5-10 Hz) is the mean magnitude of the controlling earthquake for the high-frequency range.
- m is the central magnitude value of each magnitude bin.
- d is the centroid distance value for each distance bin.

The mean distance of the controlling earthquake is determined using results of the entire magnitude-distance bins matrix using Equation 5 of RG 1.208, reproduced below as Equation 2.5.2-16.

$$Ln\{D_c(5-10\ Hz)\} = \sum_d Ln(d) \sum_m P(m,d)_2 \qquad \text{(Equation 2.5.2-16)}$$

Where:

- D_c(5-10 Hz) is the mean distance of the controlling earthquake for the high-frequency range.
- m is the central magnitude value of each magnitude bin.
- d is the centroid distance value for each distance bin.

Similar calculations are repeated to obtain the controlling magnitude in the low-frequency range (M_c(1-2.5 Hz)) and the controlling distance (D_c(1-2.5 Hz)) for distances less or equal to 100 km (62 mi.) and for distances greater than 100 km (62 mi.).

2.5.2.6.3 Methodology to Obtain Performance-Based Response Spectra

RG 1.208 provides instructions to calculate performance-based GMRS using the 1E-4 and 1E-5 UHRS. The methodology is based on ASCE/SEI Standard 43-05 (Reference 2.5-199) approach for defining a risk-consistent DRS. ASCE/SEI 43-19 (Reference 2.5-200) updated the process to obtain DRS; however, for Seismic Design Category 5 structures, such as nuclear reactors, the two approaches are equivalent, as discussed in Section C2.2 of ASCE/SEI 43-19 (Reference 2.5-200) and NRC (2022) (Reference 2.5-201). This means that the DRS presented in Sections 2.5.2.6.5 and 2.5.2.6.6, which are calculated using RG 1.208, are identical to those that would be obtained using ASCE/SEI 43-19 (Reference 2.5-200).

The DRS is obtained from the site-specific UHRS using the expression provided in Equation 2.5.2-17.

$$DRS(f) = DF(f) \times UHRS(f) \qquad \text{(Equation 2.5.2-17)}$$

Where:

- $DF(f)$ is the Design Factor.
- $UHRS(f)$ is ground motion value with a mean AFE of 1E-4.

The Design Factor is defined based on the ratio of the ground motion amplitudes for mean AFEs of 1E-4 and 1E-5, and it ensures that the site-specific response spectrum is equal to or greater than the mean AFE 1E-4 UHRS. The hazard curve slope factor (AR) is determined from Equation 2.5.2-18.

$$AR = \frac{SA(0.1 \cdot H_D)}{SA(H_D)}$$ (Equation 2.5.2-18)

Where:

- *SA(H_D)* is the spectral acceleration at the target UHRS mean exceedance frequency H_D of 1E-4.
- *SA(0.1 H_D)* is the spectral acceleration at 0.1 H_D, which is equivalent to mean AFE of 1E-5.

The *DF(f)* for each spectral frequency is the maximum of two parameters: DF_1, which has a value of 1.0, and DF_2, which is calculated using Equation 2.5.2-19.

$$DF_2 = 0.6 \cdot AR^{0.8}$$ (Equation 2.5.2-19)

RG 1.208 imposes a minimum value of the DRS equal to 45 percent of the mean 1E-5 UHRS, when AR exceeds 4.2.

Table 2.5-24 shows the base depths of the control points. Section 2.5.2.5.7 discusses the TI Team evaluation that some of these control points can be grouped for the purpose of SRA. A different number of DRS are generated for each Plant Complex. Section 2.5.2.6.8 provides guidance on how to apply the DRS to various technologies. The DRS are:

- GMRS for ground surface (elevation 810 ft. [247 m]), equivalent to Performance-Based Surface Response Spectrum for the North, Middle, and South Plant Complexes.
- Foundation Input Response Spectrum (FIRS) for depth of 44 ft. (13 m) (elevation 766 ft. [234 m]) for the North, Middle, and South Plant Complexes.
- FIRS for a depth of 85 ft. (26 m) (elevation 725 ft. [221 m]) for the North, Middle, and South Plant Complexes.
- FIRS for a depth of 115 ft. (35 m) (elevation 695 ft. [211.8 m]) for the South Plant Complex only.
- Performance-Based Interface Response Spectrum (PBIRS) for the top of PWR for the North, Middle, and South Plant Complexes.

DRS are obtained by first enveloping the UHRS for each applicable site grading and average cut/fill thickness. This step is completed for both the 1E-4 UHRS and the 1E-5 UHRS, which are then used to calculate the DRS using the procedure in RG 1.208 as discussed above. In this fashion, the resulting performance-based response spectra represent a PPE.

A similar process is applied to obtain the vertical performance-based DRS: first, the horizontal 1E-4 and 1E-5 UHRS are multiplied by V/H (described in Section 2.5.2.6.4), then, the vertical 1E-4 UHRS and vertical 1E-5 UHRS are each enveloped and the DRS are calculated applying the procedure in RG 1.208.

2.5.2.6.4 Approach to Calculate Vertical-to-Horizontal Spectral Ratios

The TI Team adopted two empirical V/H models to derive the mean V/H ratios: Pezeshk et al. (Reference 2.5-202) and EPRI (Reference 2.5-203).

Pezeshk et al. (Reference 2.5-202) developed a V/H model using the NGA-East database of CENA recordings with magnitude **M** ≥ 3.4 and rupture distance (R_{rup}) < 1000 km (621 mi.), excluding those that occurred in the Gulf Coast region. The parametric model is applicable for a spectral period range from PGA to 10 sec. and provides values of V/H as a function of magnitude, source-to-site distance, and V_{S30}. Implementation of the Pezeshk et al. (Reference 2.5-202) model requires calculating V_{S30} for each control point depth, site-grading case (i.e., various amounts of cut or fill), and velocity profile. The average V_{S30} was calculated as the total thickness (98 ft. [30 m]) divided by the ratio of the total layer thickness and total shear wave travel time through that layer. The resulting V_{S30} values for the alternative profiles and control point elevations are listed in Table 2.5-27.

The functional form of the Pezeshk et al. (Reference 2.5-202) V/H model is captured in Equation 2.5.2-20:

$$ln\left(\frac{V}{H}\right) = a_1 + a_2\boldsymbol{M} + a_3\boldsymbol{M}ln\left(\sqrt{R_{rup}^2 + h^2}\right) + a_4 ln(V_{S30}) + a_5 + \Delta_{es} \quad \text{(Equation 2.5.2-20)}$$

Where:

- Coefficients a_1 to a_5 were obtained by the TI Team from Dr. Pezeshk, who indicated that the published coefficients do not reflect the final model. The TI Team interpolated the coefficients in log-linear space to produce coefficients for four periods: 0.025 sec. (40 Hz), 0.75 sec. (1.33 Hz), 4 sec. (0.25 Hz), and 7.5 sec. (0.13 Hz) to match the 24 spectral periods at which the reference rock hazard is calculated.
- **M** is the mean magnitude obtained by the TI Team from the site-specific hazard at AFE of 1E-4 and 1E-5 for each case.
- R_{rup} is the mean rupture distance obtained by the TI Team from the site-specific hazard at AFE of 1E-4 and 1E-5 for each case.
- h is depth.
- V_{S30} is the time-averaged V_S in the upper 30 m (98 ft.). In the application of Equation 2.5.2-20, the TI Team limited the V_{S30} values from Table 2.5-27 to 2000 m/s, which is the upper limit of the data used to develop the Pezeshk et al. (Reference 2.5-202) model.
- Δ_{es} represents the variations around the median prediction of V/H ratios.

The TI Team converted the median values of V/H to mean V/H for application to the DRS using Equation 2.5.2-21 (Reference 2.5-203).

$$mean\ /H\ =\ median\ V/H\ \times\ \exp\left(\sigma_{lnV/H}^2/2\right) \quad \text{(Equation 2.5.2-21)}$$

Where:

- $\sigma_{lnV/H}$ is the standard deviation calculated using the model in Pezeshk et al. (Reference 2.5-202) given in Equation 2.5.2-22.

$$\sigma = \sqrt{\tau^2 + \varphi_{S2S}^2 + \varphi_{SS}^2} \quad \text{(Equation 2.5.2-22)}$$

In Equation 2.5.2-22:

- τ is the standard deviation of between-event residuals.
- φ_{S2S} is the standard deviation of the site-to-site within-event residuals.
- φ_{SS} is the standard deviation of the single-station within-event residuals.

The V/H ratios obtained with this model show a sharp decrease at low frequencies, which the TI Team interpreted as being caused by the limited data available to develop the model in this frequency range. The TI Team observed that other V/H models developed with datasets that include larger magnitude earthquakes do not show this effect and opted to set the coefficients for frequencies < 0.33 Hz (periods > 3 sec.) equal to the coefficients for 0.33 Hz (period of 3 sec.).

The second model used by the TI Team to develop V/H is that published by EPRI (Reference 2.5-203), which updates the V/H model for hard rock in NUREG/CR-6728 (Reference 2.5-196). EPRI (Reference 2.5-203) developed V/H ratios for active tectonic regions from the horizontal and vertical GMPEs of Campbell and Bozorgnia (2003) (Reference 2.5-204) and the Gülerce and Abrahamson (2011) (Reference 2.5-205) V/H model. To account for the difference in frequency content between CEUS motions and those in active tectonic regions, the V/H ratios for active regions were shifted upward in frequency by a factor of 3.33. The frequency-shifted Campbell and Bozorgnia (Reference 2.5-204) and Gülerce and Abrahamson (Reference 2.5-205) V/H ratios were then combined with those of McGuire et al. (Reference 2.5-196) to produce V/H ratios for a range of site conditions.

EPRI (Reference 2.5-203) also describes a process to extend the V/H for soil conditions. The approach uses the V_{S30} (calculated from the velocity profile used to obtain the site DRS) together with the PGA to determine the site class from a table of values. Mean V/H ratios for different frequencies are provided in tabular form for different site classes. As explained in EPRI (Reference 2.5-203), the mean V/H ratios are generic because they do not consider plant-specific site conditions and are appropriate for general investigations or screening purposes.

The TI Team decided to develop scaling factors to adjust the EPRI (Reference 2.5-203) models for rock conditions (i.e., models A-Hard to D-Hard) to the Project site conditions. Scale factors were developed for each possible V_{S30} (Table 2.5-27), and PGA (values for AFE of 1E-4 and 1E-5). Figure 2.5-95 compares the weighted average V_{S30} from Table 2.5-27 and the corresponding horizontal DRS PGA at AFE 1E-4 (blue dots) and at AFE 1E-5 (orange dots). Also shown for comparison are the V_{S30} values obtained from the P-S profile (open triangle and open circle). After inspecting the figure, the TI Team determined that PGA values of 0.3 g and 0.85 g are representative of the site-specific hazard at AFE 1E-4 and AFE 1E-5 for a V_{S30} equal

to 1100 m/s (3609 ft/s). The TI Team assumed that for the AFE 1E-4 level, the C-Hard (PGA about 0.3 g) is appropriate for scaling, and for the AFE 1E-5 level, the appropriate EPRI (Reference 2.5-203) V/H model to scale is D-Hard (PGA about 0.45 g).

The V/H model by Gülerce and Abrahamson (2011) (Reference 2.5-205) was then used twice: first, to obtain V/H ratios for a rock condition (i.e., V_{S30} of 1000 m/s [3280 ft/s]) and for the PGA of 0.3 g or 0.45 g; second, to obtain V/H for each site-specific V_{S30} value and PGA values of 0.3 g and 0.85 g for AFEs of 1E-4 and 1E-5, respectively.

The ratio between the Gülerce and Abrahamson (2011) (Reference 2.5-205) V/H for Project-specific site conditions and the Gülerce and Abrahamson (Reference 2.5-205) V/H for rock conditions is the scale factor used in adjusting EPRI (Reference 2.5-203). Note that the ratio between the Gülerce and Abrahamson (Reference 2.5-205) V/H values at 100 Hz and PGA was applied to the 100 Hz EPRI (Reference 2.5-203) values to derive the V/H value at 200 Hz (0.005 sec.).

In addition to V_{S30}, **M**, rupture distance, and PGA, Gülerce and Abrahamson (Reference 2.5-205) uses the dominant style-of-faulting (which is strike-slip for the Project site), and the depth to top of rupture (Z_{TOR}), which is calculated using Equation 5 of Chiou and Youngs (2014) (Reference 2.5-193) for strike-slip and normal faulting. As previously described for the Pezeshk et al. (Reference 2.5-202) model, the TI Team interpolated the coefficients of the Gülerce and Abrahamson (Reference 2.5-205) model to match the 24 (CEUS) spectral frequencies used in the site-specific hazard analysis and considered EPRI (Reference 2.5-203) correction of the frequency when applying models derived for the western U.S. to CEUS.

Additionally, the TI Team noted that the constant portion of the EPRI (Reference 2.5-203) V/H models is equal to the Gülerce and Abrahamson (2011)(Reference 2.5-205) value at some frequency greater than 20 Hz for the “Hard” (V_{S30}=1000 m/s) site. Similarly, for the “Intermediate” site (V_{S30}=400 m/s), the constant part of the EPRI (Reference 2.5-203) V/H equals the Gülerce and Abrahamson (Reference 2.5-205) value at about 17 Hz. Using this observation, the TI Team decided that for frequencies of 20 Hz and below the appropriate Gülerce and Abrahamson (Reference 2.5-205) coefficients to use are:

1) Those for period of 0.15 sec. (equivalent to 22.2 Hz for CEUS sites) for $V_{S30} \geq 1000$ m/s.
2) Those for period of 0.2 sec. (equivalent to 16.7 Hz for CEUS sites) for V_{S30} of 400 m/s.
3) Log-linear interpolated coefficients for intermediate values of V_{S30}.

The final V/H ratios are calculated for each control point, site grading, and AFE using the logic tree in Figure 2.5-96. The Pezeshk et al. (Reference 2.5-202) model is given a lower weight because the database consists primarily of recordings from **M** < 5 earthquakes, while the primary interest in the hazard calculations is for **M** ≥ 5 events. The weights assigned to the velocity profiles are discussed in Section 2.5.2.5 and match the logic tree in Figure 2.5-87.

Figure 2.5-97 shows examples of V/H ratios obtained for the 10 ft. (3 m) of cut case and AFE of 1E-4 at two control points: ground surface (top) and top of PWR (bottom). On each plot, the long-dash curves show the mean V/H ratios for suspension log (P-S) and SASW profiles obtained with the EPRI (Reference 2.5-203) model; the short-dash curves (also for P-S and SASW profiles) are the V/H obtained with Pezeshk et al. (Reference 2.5-202). The solid gray line and the solid green line correspond to the weighted V/H ratios for P-S and SASW profiles,

resulting from the weighted combination of the results from the EPRI (Reference 2.5-203) and Pezeshk et al. (Reference 2.5-202) model, i.e., combining the branches on the first node of the logic tree in Figure 2.5-96. The solid red curve is the final V/H model for this case, which is obtained by combining the second node of the logic tree. The V/H values are presented in Table 2.5-28 through Table 2.5-37. Each table represents a control point depth and AFE and contains the V/H obtained for various site grading conditions using the suspension log (P-S) and SASW profiles and their weighted average.

Based on their review of a study exploring V/H ratios at depth versus at the surface, the TI Team concluded that the V/H ratios developed using the methods described above are applicable to the target depths.

2.5.2.6.5 Seismic Hazard Results for the North and Middle Plant Complexes

Seismic hazard results for the North and Middle Plant Complexes are identical. Results are obtained for three site grading cases (two cut cases and one fill case) and four control point elevations as Table 2.5-25 shows. Examples of mean and fractile hazard curves are captured in Figure 2.5-98 for PGA, 10 Hz and 1 Hz spectral acceleration. The curves represent the same site grading case (24 ft. [7 m] of cut) but different control point depths: surface grade (top row); depth of 44 ft. (13 m) (second row); depth of 85 ft. (26 m) (third row); and top of PWR (bottom row). On each plot, the mean site-specific hazard is illustrated by the solid black curve, and the 5th, 16th, 50th, 84th, and 95th site-specific hazard fractiles are shown in different colors. The figures also include, for comparison, the mean reference rock hazard, represented by the dashed black line. The site-specific hazard is generally higher than the corresponding reference rock hazard, with larger differences for high-frequency motions (PGA and 10 Hz spectral acceleration), particularly at ground surface. Note that these figures are also applicable to the South Plant Complex as shown in Table 2.5-25.

The horizontal 1E-4 site-specific UHRS and the 1E-5 site-specific UHRS obtained for the North and Middle Plant Complexes for each control point and site grading case are captured in Figure 2.5-99. Subplots in the figure contain the UHRS for control points at the surface (Figure 2.5-99a); depth of 44 ft. (13 m) (Figure 2.5-99b); depth of 85 ft. (26 m) (Figure 2.5-99c); and top of PWR (Figure 2.5-99d). Solid lines are used for the 1E-4 UHRS, and solid lines with dots are used for the 1E-5 UHRS. To calculate performance-based response spectra representative of PPE, the UHRS obtained for different site grading conditions are enveloped. The thicker, dashed blue and green spectra in Figure 2.5-99 are the enveloped 1E-4 and 1E-5 UHRS, respectively. The horizontal DRS is calculated from the enveloped UHRS using Equations 2.5-17 to 2.5-19 and is illustrated by the solid black line. The vertical UHRS for AFE 1E-4 and 1E-5 and for different site grading conditions and control point depths are obtained multiplying the envelope horizontal UHRS captured in Figure 2.5-99 by the corresponding weighted average V/H ratios (from Table 2.5-28 to Table 2.5-37). The enveloped 1E-4 and 1E-5 vertical UHRS are then used to compute the vertical DRS as described in Section 2.5.2.6.3. Figure 2.5-100 compares the horizontal and vertical DRS for control points at the surface (Figure 2.5-100a); depth of 44 ft. (13 m) (Figure 2.5-100b); depth of 85 ft. (26 m) (Figure 2.5-100c); and top of PWR (Figure 2.5-100d).

Tabulated values of the enveloped horizontal and vertical 1E-4 UHRS and 1E-5 UHRS, and corresponding horizontal and vertical DRS are provided in Table 2.5-38 for the control point at the surface (GMRS); in Table 2.5-39 for the control point at 44 ft. (13 m) depth (FIRS); in Table 2.5-40 for the control point at 85 ft. (26 m) depth (FIRS); and in Table 2.5-41 for the control point

at the top of PWR) (PBIRS). These response spectra are calculated for the set of 24 spectral ordinates at which the NGA-East GMMs are defined; however, RG 1.208 requires the performance-based response spectra be defined for a minimum of 30 spectral frequencies to ensure a smooth spectrum. To meet this requirement, horizontal and vertical GMRS, FIRS, and PBIRS are interpolated to add six more spectral frequencies. The interpolated horizontal and vertical DRS for the North and Middle Plant Complexes are listed in Table 2.5-42.

The process described in Section 2.5.2.6.2 was used to obtain magnitude-distance deaggregation tables and the high-and low-frequency controlling earthquakes for each control point and site grading. Figure 2.5-101 shows an example of magnitude-distance deaggregation for high- and low-frequency motions at AFEs of 1E-4, 1E-5, and 1E-6 for the 24 ft. (7 m) cut case and a control point at ground surface.

Table 2.5-43 summarizes magnitude and distance of the controlling earthquakes for AFE 1E-4 and 1E-5. The contribution of earthquakes located at distances greater than 100 km (62 mi.) is always greater than 5 percent for low-frequency motions at these AFEs, therefore, two sets of values are provided: one obtained for earthquakes located at distances smaller than 100 km (62 mi.), and the other for earthquakes located at greater distances. As captured in the table, there are minor variations in the magnitude and distance of controlling earthquakes for each control point and possible site grading such that controlling earthquakes for the North and Middle Plant Complexes can be summarized as follows:

- High frequency (mean of 5 and 10 Hz): **M** 6.4, R_{rup} 71 km (44 mi.) for AFE 1E-4; **M** 6.3 R_{rup} 23 km (14 mi.) for AFE 1E-5. These earthquakes are consistent with the magnitude and distance range of background seismicity in the host zone.
- Low frequency (mean of 1 and 2.5 Hz) for distance less than 100 km (62 mi.): **M** 6.3, R_{rup} 25 km (16 mi.) for AFE 1E-4; **M** 6.5 R_{rup} 17 km (11 mi.) for AFE 1E-5. These earthquakes are consistent with background seismicity in the host zone.
- Low frequency (mean of 1 and 2.5 Hz) for distance greater than 100 km (62 mi.): **M** 7.3, R_{rup} 323 km (201 mi.) for AFE 1E-4; **M** 7.4 R_{rup} 300 km (186 mi.) for AFE 1E-5. These values are consistent with the Charleston RLME source.

2.5.2.6.6 Seismic Hazard Results for South Plant Complex

Seismic hazard results for the South Plant Complex are obtained for five site grading cases (three cut cases and two fill cases) and five control point elevations as captured in Table 2.5-25. The seismic hazard curves in Figure 2.5-98 are applicable to the South Plant Complex as discussed previously. Figure 2.5-102 compares PGA, 10 Hz, and 1 Hz spectral acceleration seismic hazard curves for a site grading case (40 ft. [12 m] of fill) that is unique to the South Plant Complex and for different control points: surface grade (top row); depth of 44 ft. (13 m) (second row); depth of 85 ft. (26 m) (third row); depth of 115 ft. (35 m) (fourth row); and top of PWR (bottom row). On each plot, the mean site-specific hazard is shown by the solid black curve, and the 5th, 16th, 50th, 84th, and 95th site-specific hazard fractiles are shown in different colors. The figures also include, for comparison, the mean reference rock hazard, represented by the dashed, black line. As observed for the North and Middle Plant Complexes, the site-specific hazard is generally higher than the corresponding reference rock hazard, with larger differences for high-frequency motions (PGA and 10 Hz spectral acceleration), particularly at ground surface.

The horizontal 1E-4 site-specific UHRS and the 1E-5 site-specific UHRS obtained for the South Plant Complex control point and site grading case are captured in Figure 2.5-103. Subplots in the figure contain the UHRS for control points at the surface (Figure 2.5-103a); at a depth of 44 ft. (13 m) (Figure 2.5-103b); a depth of 85 ft. (26 m) (Figure 2.5-103c); the top of PWR (Figure 2.5-103d); and a depth of 115 ft. (35 m) (Figure 2.5-103e). Solid lines are used for the 1E-4 UHRS, and solid lines with dots are used for the 1E-5 UHRS. The approach to calculating performance-based response spectra that are representative of the PPE is described in Section 2.5.2.6.3. The thicker, dashed blue and green spectra in Figure 2.5-103 are the enveloped 1E-4 and 1E-5 UHRS, respectively. The horizontal DRS is calculated from the enveloped UHRS and is shown by the solid black line. The envelope horizontal UHRS are multiplied by the respective V/H ratios to obtain vertical UHRS for different site grading cases. The enveloped vertical UHRS are then used to compute the DRS as previously described. Figure 2.5-104 summarizes the results for the South Plant Complex by showing only the horizontal and vertical DRS.

Tabulated values of the enveloped horizontal and vertical 1E-4 UHRS and 1E-5 UHRS, and corresponding horizontal and vertical DRS are provided in Table 2.5-44 for the control point at the surface (GMRS); in Table 2.5-45 for the control point at 44 ft. (13 m) depth (FIRS); in Table 2.5-46 for the control point at 85 ft. (26 m) depth (FIRS); in Table 2.5-47 for the control point at the top of PWR (PBIRS); and in Table 2.5-48 for the control point at 115 ft. (35 m). To meet the requirements of RG 1.208, the horizontal and vertical GMRS, FIRS, and PBIRS are interpolated for six additional spectral frequencies. The interpolated spectra are captured in Table 2.5-49.

Magnitude-distance deaggregation tables and tables of high-and low-frequency controlling earthquakes for each control point and site grading were obtained following the procedure described in Section 2.5.2.6.2. Table 2.5-50 summarizes magnitude and distance of the controlling earthquakes for AFE 1E-4 and 1E-5. The contribution of earthquakes located at distances greater than 100 km (62 mi.) is always greater than 5 percent for low-frequency motions; therefore, two sets of values are provided: one obtained for earthquakes located at distances less than 100 km (62 mi.) and the other for earthquakes located at greater distances. The table shows minor variations in the magnitude and distance of controlling earthquakes for each control point and possible site grading such that controlling earthquakes for the South Plant Complex can be summarized as follows:

- High frequency (mean of 5 and 10 Hz): **M** 6.4, R_{rup} 70 km (43 mi.) for AFE 1E-4; **M** 6.3 R_{rup} 23 km (14 mi.) for AFE 1E-5. These earthquakes are consistent with the magnitude and distance range of earthquakes in the host zone.
- Low frequency (mean of 1 and 2.5 Hz) for distance less than 100 km (62 mi.): **M** 6.3, R_{rup} 25 km (16 mi.) for AFE 1E-4; **M** 6.5 R_{rup} 17 km (11 mi.) for AFE 1E-5. These earthquakes are consistent with background seismicity in the host zone.
- Low frequency (mean of 1 and 2.5 Hz) for distance greater than 100 km (62 mi.): **M** 7.3, R_{rup} 323 km (201 mi.) for AFE 1E-4; **M** 7.4 R_{rup} 300 km (186 mi.) for AFE 1E-5. These values are consistent with the Charleston RLME source.

2.5.2.6.7 Sensitivity Analysis

The TI Team generated tornado plots to illustrate how individual branches and nodes of the site characterization logic tree in Figure 2.5-87 influence the site-specific hazard. In a tornado plot, the ground motion corresponding to the hazard at a specified AFE is represented by a vertical

line. The vertical axis lists the logic tree levels, ranked from top to bottom in order of decreasing effect on the ground motion value. In this manner, the model components that produce the largest variability in ground motion at a given AFE are at the top, and those that produce the smallest variability are plotted at the bottom.

Figures were generated for the South Plant Complex at the surface target elevation, for PGA, and spectral acceleration at 10 Hz and 1 Hz, and for AFE of 1E-4 and 1E-5. The TI Team found that the three levels of the logic tree that influence the hazard the most are the V_S profile, site kappa, and additional epistemic uncertainty. Site kappa produces the largest variability in ground motion for PGA because it influences the damping in the sediments above bedrock. For shorter spectral frequencies, the stiffness of the site determines less variability in amplification from the velocity profile, such that the additional epistemic uncertainty is shown to produce the largest variability in ground motion at 1 Hz. This is captured in Figure 2.5-105, showing tornado plots for PGA at AFE 1E-4, and in Figure 2.5-106, which shows tornado plots for 1 Hz spectral acceleration at AFE 1E-5. Each figure presents five subplots arranged in two rows: the top row (three subplots) shows results for the three cut cases applicable to the South Plant Complex, while the bottom row (two subplots) shows the results for the two fill cases applicable to the South Plant Complex. The tornado plots also show that results are generally consistent for different control point depths.

2.5.2.6.8 Implementation Instructions

As described in previous sections site-specific seismic hazard curves were obtained for each possible combination of site grading and control point depth. The hazard curves were then interpolated to obtain UHRS, which were enveloped to represent the PPE site conditions. Horizontal and vertical GMRS, FIRS, and PBIRS were developed from the enveloped UHRS and captured possible variations in seismic wave transmission characteristics across the site.

In summary, the DRS obtained in this section are as follows:

- Horizontal and vertical GMRS in Table 2.5-42: applicable to all technologies in the North and Middle Plant Complexes.
- Horizontal and vertical PBIRS in Table 2.5-42: applicable to all technologies in the North and Middle Plant Complexes.
- Horizontal and vertical FIRS for depth 44 ft. (13 m) in Table 2.5-42: applicable to Westinghouse AP300 in the North and Middle Plant Complexes.
- Horizontal and vertical FIRS for depth 85 ft. (26 m) in Table 2.5-42: applicable to Holtec SMR-300, X-energy Xe-100, TerraPower Natrium, and GVH BWRX-300 in the North and Middle Plant Complexes.
- Horizontal and vertical GMRS in Table 2.5-49: applicable to all technologies in the South Plant Complex.
- Horizontal and vertical PBIRS in Table 2.5-49: applicable to all technologies in the South Plant Complex.
- Horizontal and vertical FIRS for depth 44 ft. (13 m) in Table 2.5-49: applicable to Westinghouse AP300 in the South Plant Complex.

- Horizontal and vertical FIRS for depth 85 ft. (26 m) in Table 2.5-49: applicable to Holtec SMR-300 and NuScale VOYGR in the South Plant Complex.
- Horizontal and vertical FIRS for depth 115 ft. (35 m) in Table 2.5-49: applicable to X-energy Xe-100, TerraPower Natrium, and GVH BWRX-300 in the South Plant Complex.

The DRS should be adjusted to account for topographic amplification if the technologies are to be located near the edge of the graded site pad. Table 2.5-26 contains the multiplicative factors to apply to the DRS.

In all cases, the magnitude and distance of controlling earthquakes is as follows:

- High frequency (mean of 5 and 10 Hz): **M** 6.4, R_{rup} 70 km (44 mi.) for AFE 1E-4; **M** 6.3 R_{rup} 23 km (14 mi.) for AFE 1E-5.
- Low frequency (mean of 1 and 2.5 Hz) for distance less than 100 km (62 mi.): **M** 6.3, R_{rup} 25 km (16 mi.) for AFE 1E-4 and **M** 6.5 R_{rup} 17 km (11 mi.) for AFE 1E-5.
- Low frequency (mean of 1 and 2.5 Hz) for distance greater than 100 km (62 mi.): **M** 7.3, R_{rup} 323 km (201 mi) for AFE 1E-4 and **M** 7.4 R_{rup} 300 km (186 mi.) for AFE 1E-5.

2.5.3 SURFACE DEFORMATION

This section evaluates the potential for tectonic and non-tectonic deformation at or near the ground surface for the Belews Creek, North Carolina (NC) site (Project site). This section has been developed in accordance with RG 1.208 and NUREG-0800. The tectonic and nontectonic deformation evaluated in this section includes the following:

- Potential surface deformation associated with bedrock faults.
- Other potential geologic sources of surface deformation, including karst collapse, salt tectonics, and volcanism.
- Human-induced causes of surface deformation, including the potential for mine collapse.

Consistent with these requirements, the investigations assess whether any geologic structures within the Site Area (5 mi. [8 km] radius), Site Vicinity (25 mi. [40 km] radius), or Site Region (200 mi. [320 km] radius) can be classified as capable tectonic sources that may produce surface deformation. The assessment draws on the geologic, seismologic, and tectonic framework presented in Section 2.5.1, which describes the stratigraphy, tectonic structures, and regional geologic hazards of the Piedmont and adjacent provinces. Particular emphasis is placed in this section on evaluating known structures in proximity to the Project site, including the Chatham fault zone, Stony Ridge fault, Little River fault, the Central Piedmont suture, and the Dan River – Danville basin. In addition, other mapped regional features, such as the Brevard fault zone and the ETSZ, are also evaluated.

Published geologic maps from the USGS and NC Geological Survey (NCGS), regional seismicity catalogs including the CEUS SSC project, remote-sensing datasets like high-resolution LiDAR, and paleoseismological studies were reviewed. Also evaluated were nontectonic features that may cause surface deformation, such as karst and legacy mining.

Methods and conclusions presented herein are integrated with the vibratory ground motion characterization in Section 2.5.2 and the regional tectonic framework in Section 2.5.1; this integration provides traceable consistency across data sources and regulatory guidance (RG 1.208; NUREG-0800).

2.5.3.1 Geological, Seismic and Geophysical Investigations

This section summarizes published investigations and datasets used to evaluate the potential for tectonic and nontectonic surface deformation in the Site Vicinity and provides broader tectonic context from the Site Region. The reviewed information includes (1) regional and local geologic mapping; (2) remote-sensing and geomorphic datasets; (3) seismicity and paleoseismic studies; and (4) datasets for nontectonic deformation such as karst and mining.

Where applicable, site-specific reconnaissance (e.g., aerial imagery review, LiDAR-based hillshade, and slope products) has been cross-checked against published maps to verify feature locations and assess whether any unmapped Quaternary scarps or collapse features may be present within the Site Vicinity.

2.5.3.1.1 Geologic Mapping

Geological mapping in the area surrounding the Project site documents the presence of Piedmont metamorphic units and the adjacent Mesozoic Dan River – Danville rift basin. USGS and NCGS maps show the Site Area underlain by gneissic and schistose rocks of the Milton and Charlotte terranes, while the Dan River basin to the north and northeast is expressed as a half-graben bounded on the northwest by the Chatham fault system. Numerous Triassic – Jurassic diabase dikes transect both basin and basement rocks (Reference 2.5-51; Reference 2.5-133; Reference 2.5-114; Reference 2.5-17). The Piedmont Region is located east of the Blue Ridge Mountains and is characterized by rolling relief (Reference 2.5-206). Geologic units in the Piedmont Region are mainly metamorphic rocks that are intruded by igneous rocks and, in some locations, faulted and filled with Triassic-age sediments (Reference 2.5-207). Metamorphic rocks are interpreted to have accreted onto Laurentia in the Early to Middle Ordovician (Reference 2.5-43). Collectively, these mapping datasets provide the basis for evaluating bedrock structures and tectonic setting in the Site Vicinity. Sections 2.5.1.1.4 and 2.5.1.2.3 to 2.5.1.2.4 provide a detailed narrative of terrane architecture, the Dan River – Danville basin geometry, and mapped fault systems used here as the structural context for surface-deformation screening.

Geophysical surveys summarized in Section 2.5.1 complement geologic mapping. Regional aeromagnetic data delineate major terrane boundaries and diabase dike swarms, which appear as linear magnetic highs trending northeast-southwest across the Site Region. Gravity datasets similarly highlight the Dan River – Danville basin as a negative anomaly relative to surrounding metamorphic basement, corroborating its geometry as a half-graben. Seismic reflection profiles across portions of the basin (Reference 2.5-123) constrain the thickness of Triassic – Jurassic sediments and confirm fault-bounded margins along the Chatham fault zone. However, no focused geophysical campaigns (e.g., local reflection surveys or seismic arrays) have identified Quaternary-capable structures in the Site Vicinity.

High-resolution LiDAR data acquired statewide from 2015 to 2016 (0.5 to 1 meter [m] (1.6 to 3.3 ft.) DEMs) (Reference 2.5-208) enable reconnaissance for potential Quaternary tectonic landforms. Hillshade and relative-relief analyses reveal no sharp, laterally continuous scarps of

probable Quaternary tectonic origin within the Site Area. Observed lineaments are consistent with mapped bedrock foliation, lithologic contacts, and diabase dike trends (discussed further in Section 2.5.3.5).

2.5.3.1.2 Earthquake Catalogs and Regional Seismicity

Regional seismicity was reviewed using the project earthquake catalog and the CEUS SSC project report as the standard regional source model for nuclear facility hazard studies (Reference 2.5-60). These resources provide historical and instrumental seismicity in the Site Region and the basis for characterizing background sources and recurrence in the CEUS as discussed in Section 2.5.2.

An important modern reference event is the August 9, 2020, earthquake (E[**M**]5.1), approximately 60 mi. (95 km) northwest of the Project site in Sparta, NC. Detailed field and LiDAR studies document a short reverse-sense surface rupture along the Little River fault with up to approximately 9.8 inches (in.) (25 centimeters [cm]) of vertical offset, the first well-documented historical surface rupture in the eastern United States outside the New Madrid seismic zone, underscoring that moderate intraplate events can produce localized surface deformation (Reference 2.5-83). The Sparta earthquake was not felt at the BCSS but was recorded in the turbine generator vibration monitoring system.

In addition to earthquake catalogs and as discussed in Section 2.5.2, seismic monitoring in the southeastern United States has been enhanced by broadband and short-period seismometer networks operated by the USGS and regional universities (Reference 2.5-209).

The Site Region catalog review also considers historical events in the CVSZ, ETSZ, and Giles County zone to evaluate whether any sequences or mapped trends project toward the Site Vicinity (see Section 2.5.3.2).

2.5.3.2 Geologic Evidence for Surface Deformation

There are several zones of Quaternary seismicity in the Site Region based on paleoseismology and historical seismicity (Reference 2.5-59; Figure 2.5-107); however, in many of these zones, the link between seismicity and any surface deformation is less defined (Reference 2.5-210; Reference 2.5-82; Reference 2.5-65). A summary of these zones is provided below, and Section 2.5.1 describes them in more detail.

2.5.3.2.1 Charleston

On August 31, 1886, an E[**M**] 6.9 earthquake occurred in the region near Charleston, South Carolina. It is the largest known historical earthquake in the eastern United States. Paleoliquefaction evidence indicates pre-1886 earthquakes have occurred in the same region in the last 5500 years (Reference 2.5-60). The Charleston source area remains the most robust CEUS example of repeated strong earthquakes in the late Holocene based on extensive paleoliquefaction databases (Reference 2.5-60). Multiple near-surface faults have been identified in the region; however, there is no scientific consensus on the location of the 1886 rupture(s) (Reference 2.5-61). Recent studies continue to debate the location of coseismic deformation from the 1886 event (Reference 2.5-68; Reference 2.5-211), while other studies have mapped potentially seismogenic faults in the zone that did not rupture in 1886 (Reference 2.5-61; Reference 2.5-212). These mapped structures do not project toward the Site Vicinity.

2.5.3.2.2 Central Virginia

The CVSZ has elevated rates of seismicity relative to the surrounding region in Virginia. Measured seismicity in the zone includes the 2011 E[**M**] 5.72 Mineral, Virginia, earthquake. Other large historical events in this zone include the 1758 E[**M**] 4.95, the 1774 E[**M**] 4.38, and the 1875 E[**M**] 4.77 events. No historical events in the zone are interpreted to exceed E[**M**] 6 (Reference 2.5-71). Pazzaglia et al. (Reference 2.5-213) interpreted differential uplift along river terraces in the region near the Mineral, Virginia, earthquake. They concluded that the area has undergone 30 to 94 meters per million years of tectonically driven river incision consistent with low intraplate strain rates. In the CVSZ, river-terrace geomorphology and geochronology indicate long-term differential uplift but do not document through-going Quaternary surface rupture. Paleoliquefaction features attributed to late Holocene earthquakes are recognized regionally, yet available trenching and geomorphic work in the CVSZ has not identified a specific Quaternary-rupturing fault trace (Reference 2.5-71).

2.5.3.2.3 Eastern Tennessee

The ETSZ is a region with an elevated historical seismicity rate in Tennessee (Reference 2.5-74).. The region exhibits one of the higher instrumental seismicity rates in the CEUS, and recent field studies have evaluated potential Quaternary deformation. Cox et al. (Reference 2.5-76) reported outcrops and deposits interpreted as coseismic deformation in Holocene alluvium; however, subsequent reexamination by Thompson Jobe et al. (Reference 2.5-210) reinterpreted several key exposures as fluvial features. Thompson Jobe et al. (Reference 2.5-210) did, however, interpret east-west trending lineaments from LiDAR DEMs, but conclude that these lineaments lack corroborating evidence for Quaternary surface rupture. Together, these results support the characterization of the ETSZ as an intraplate region with distributed microseismicity but without demonstrated, mappable Quaternary fault scarps.

2.5.3.2.4 Giles County

The Giles County seismic zone has an elevated historical seismicity rate in southwestern Virginia. The largest historical earthquake in the region was the E[**M**] 5.91 Giles County earthquake, which occurred on May 31, 1897. The earthquake has an estimated maximum MMI of VIII. (Reference 2.5-78).

The Pembroke faults are mapped within the Giles County seismic zone. These faults are associated with extensional cracks in fluvial terrace deposits. They are classified as having evidence of Quaternary deformation, but it is not conclusive if the deformation is related to tectonic faulting or dissolution of underlying carbonate layers (Reference 2.5-82; Reference 2.5-81).

2.5.3.2.5 Little River Fault

Within NC, the August 9, 2020, Sparta earthquake (E[**M**] 5.1) produced a short, reverse-sense surface rupture on the Little River fault, the first well-documented historical surface rupture in the eastern United States outside the New Madrid region (Reference 2.5-83). Maximum observed offset height of approximately 9.8 in. (25 cm) was documented by field mapping and LiDAR differencing. The rupture length (~2 km [1.2 mi.] at the surface) was shorter than the subsurface rupture length from focal depth data (approximately 4.35 mi. [7 km]), illustrating that moderate intraplate events can generate localized surface breaks (Reference 2.5-83). No

Sparta earthquake-related structures project toward the Project site area (see Section 2.5.1.1.4).

2.5.3.3 Timing of Deformation

The most recent regional and intense deformation in the Site Vicinity was Permian to Early Jurassic rifting associated with the breakup of Pangea in the Dan River basin (Reference 2.5-123). Dikes associated with the Central Atlantic magmatic province (CAMP) volcanics (approximately 201 million years [Ma]) that cross the rift are not displaced by the basin-bounding Chatham fault. This geological relationship indicates that movement on the fault occurred before dike emplacement (Reference 2.5-123; Reference 2.5-50).

Other mapped faults, such as the Brevard fault, are older than the Dan River basin. The Chatham fault that bounds the Dan River basin is mapped as Devonian to Mississippian in age (Reference 2.5-214). No published evidence indicates post-Miocene reactivation of mapped Site Vicinity structures; thus, by RG 1.208 criteria, these features do not meet the definition of capable tectonic sources.

2.5.3.4 Correlation of Earthquakes with Tectonic Features

There are no earthquake events above expected moment magnitude (E[**M**]) 2.9 in the Project Earthquake Catalog within the Site Vicinity 25 mi. (40 km) radius (Figure 2.5-107). E[**M**] 2.9 is the lowest value used by the CEUS SSC model for recurrence (Reference 2.5-60). This project uses the CEUS SSC project catalog updated through the end of April 2024 applying the same methodology used for the CEUS SSC (Section 2.5.2).

The closest project catalog earthquake greater than E[**M**] 5 to the Project site was the 2020 E[**M**] 5.1 Sparta earthquake with an epicenter 59 mi. (95 km) to the northwest (Figures 2.5-107; 2.5-108). The earthquake generated an average coseismic topographic step of 3.1 to 3.9 in. (8 to 10 cm) (maximum approximately 9.8 in. [25 cm]) associated with a reverse-fault scarp on the Little River fault. The scarp was mapped to be approximately 2 km [1.2 mi.] long (Reference 2.5-83). The Sparta event is the first well-documented surface rupture in the eastern United States outside the New Madrid region, and it demonstrates that moderate intraplate earthquakes can result in localized deformation. However, the Little River fault is outside the Site Vicinity, and no mapped Quaternary structures project toward the Project site (see Section 2.5.1.1.4).

Two earthquakes with epicenters located more than 77 mi. (125 km) from the Project site are associated with the Giles County seismic zone (Figure 2.5-108). The April 29, 1852, E[**M**] 5.21 and the May 31, 1897, E**[M**] 5.91 earthquakes caused damage to local structures and were felt in the greater Virginia region (Reference 2.5-139). Because both earthquakes were pre-instrumental and there is no conclusive evidence of surface deformation in their source area (Reference 2.5-82), they are not associated with a specific known-geological structure. Smaller, instrumentally recorded earthquakes in the area are interpreted to occur on reactivated Precambrian or Cambrian Iapetan normal-slip faults. These faults are below the Appalachian thrust complex (Reference 2.5-82).

The project earthquake catalog separates natural seismicity from human-induced events such as those associated with hydrocarbon extraction and waste injection. There are no induced events within the Site Vicinity. The closest rocks with hydrocarbon potential are the sedimentary

rocks in the Dan River basin. As of 2023, NC did not produce any natural gas or oil (Reference 2.5-215).

The evaluation of the correlation to earthquakes with capable tectonic sources shows:

1. No earthquakes ≥ E[**M**] 2.9 are recorded within the Site Vicinity.

2. The nearest surface-rupturing earthquake, the 2020 Sparta event, occurred approximately 59 mi. (95 km) away and has no known structural connection to the Project site.

3. Regional earthquake epicenters (Giles County, CVSZ, ETSZ, and Charleston) are located more than 25 mi. (40 km) away and lack demonstrable Quaternary surface ruptures in their source areas.

4. Induced seismicity is absent in the Site Vicinity because of the lack of hydrocarbon production or wastewater injection.

Accordingly, there is no evidence to correlate earthquakes with capable tectonic sources at or near the Project site. Regional seismicity contributes to background hazard but does not indicate the presence of capable Quaternary faults in the Site Vicinity.

2.5.3.5 Relationship of Geologic Features in the Site Vicinity (25 Mi. [40 Km]) to Regional Geologic Features

The most prominent feature in the Site Vicinity is the Mesozoic Dan River basin (Figures 2.5-109, 2.5-110; 2.5-111). The basin is a half-graben, bounded to the northwest by the Chatham fault or Dan River fault zone and to the southeast by a nonconformity (Reference 2.5-123; Reference 2.5-50). The fault is 35 mi. (56 km) long. It was originally named the Chatham fault in Virginia and the Dan River fault zone in NC (Reference 2.5-50). The Dan River basin is one of a series of continental rift basins that formed during the breakup of Pangea from the Permian to the Early Jurassic (Reference 2.5-123; Reference 2.5-50). The southeastern boundary of the Dan River basin is bound by sedimentary onlap via a nonconformity, although some short length (up to 3 mi. [4.8 km]) faults are mapped along this boundary (Reference 2.5-123; Reference 2.5-50; Figure 2.5-109). Since deposition, the sedimentary units of the Dan River basin have been tilted to the northwest and gently folded (Reference 2.5-50). Approximately north-south trending Triassic and Jurassic age diabase dikes transect both basin margins (Reference 2.5-123; Reference 2.5-133). Some of the dikes that cross the border fault do not appear offset (Reference 2.5-123), which indicates that the dikes were likely emplaced after movement ceased on the fault and the fault has not been reactivated since the Mesozoic. There is no association between the Dan River basin and the seismicity pattern from the project earthquake catalog (Section 2.5.2; Figure 2.5-107).

The Project site is within the Charlotte terrane, one of a series of northeast-southwest trending metamorphic geologic units (Reference 2.5-51; Reference 2.5-17; Figure 2.5-111). In the Site Area, the geology can be separated into the Milton terrane and Charlotte belt with the Project site sitting on the Milton terrane. This is based on interpreted differences in lithology that were not originally mapped (Reference 2.5-114; Figure 2.5-110). To the south of the Project site and within the Site Vicinity is the Carolina Slate Belt. The Sauratown Mountain anticlinorium, the Brevard fault zone, the Smith River allochthon, and the Blue Ridge Belt are mapped north of the

Project site (Reference 2.5-51; Reference 2.5-133). The Brevard fault is the closest of these features to the Project site at more than 45 mi. (75 km) away. The Brevard fault zone is mapped as Devonian to Mississippian in age (Reference 2.5-214).

The Stony Ridge fault is located approximately 12.5 mi. (20 km) northwest of the Project site (Reference 2.5-51). The Stony Ridge fault was mapped as forming during the Mesozoic reactivation of the Brevard fault (Reference 2.5-49; Reference 2.5-50); however, subsequent mapping was unable to demonstrate appreciable displacement on the fault, and the cataclasite associated with the fault may have formed from local hydrothermal alteration (Reference 2.5-49). The Stony Ridge fault can be seen as a positive feature in the LiDAR data (Figure 2.5-112) and is mapped in the geologic map (Figure 2.5-111; Reference 2.5-51). It is not a topographic step that could indicate recent offset along the fault, but the observed geomorphology is likely due to differential erosion of the more resistant cataclasite.

Prominent topographic features in the Site Vicinity are interpreted to be related to changes in underlying lithology. Approximately 9.3 mi. (15 km) northeast of the Project site, two hogback ridges in the Dan River basin between Madison and Stonewall consist of interbedded, well-indurated siltstone and sandstone (Reference 2.5-50). East of the site, a linear feature trending northeast-southwest from Belews Lake toward Gold Hill coincides with the boundary between Precambrian to Paleozoic muscovite and biotite schists and mica and gneiss schist (Reference 2.5-133; Figure 2.5-111; Figure 2.5-112, labeled as “lithologic boundary”). The contact as mapped is irregular and is not interpreted as a fault contact (Reference 2.5-133).

2.5.3.6 Potential for Surface Deformation at the Site

The Site Area lies within the Piedmont Province with rocks recording multiple Paleozoic orogenic events and Mesozoic continental rifting (Reference 2.5-17; Reference 2.5-10). As described in Section 2.5.1, the Piedmont is bounded to the northwest by the Blue Ridge Province and to the southeast by the Coastal Plain, and it contains sutures such as the Central Piedmont shear zone and Brevard fault zone. These regional features are located more than 45 mi. (75 km) from the Project site.

The tectonic structures mapped within the Site Area consist primarily of lithologic contacts, foliation-parallel fabrics, and intrusive diabase dikes within the Milton terrane (Reference 2.5-51; Reference 2.5-133; Reference 2.5-114). No Quaternary-capable faults are mapped in the Site Area (Reference 2.5-82; Reference 2.5-59). The nearest mapped fault is the Chatham fault zone, which bounds the Dan River – Danville basin approximately 2 mi. (3.2 km) northwest of the Project site (Reference 2.5-50; Reference 2.5-123). This fault was active during times of Late Paleozoic to Early Mesozoic rifting, but cross-cutting relationships with CAMP dikes indicate that slip ceased prior to approximately 201 Ma (Reference 2.5-123). Thus, tectonic structures within the Site Area are older features that do not exhibit evidence of Quaternary reactivation. Therefore, the local geologic structures in the Site Area do not show evidence of being linked to any regional Quaternary-capable earthquake sources. The mapped metamorphic foliation, intrusive dikes, and rift-basin faults are consistent with regional tectonic trends (northeast-southwest orientation) but display no geomorphic or geologic evidence of recent activity.

Aerial photographs of the Site Area were reviewed; however, the tree canopy prevented meaningful geological assessments for parts of the area (Reference 2.5-216; Figure 2.5-113). LiDAR data with a spatial resolution of 3 ft. (1 m) collected in 2015 and 2016 (Reference 2.5-

208; Figure 2.5-112) was developed into a DEM for the project (Reference 2.5-208). The aerial photographs and LiDAR DEM were compared with geologic maps of the area (Reference 2.5-133; Reference 2.5-51). Of the two maps (Reference 2.5-133 and Reference 2.5-51), Carpenter (Reference 2.5-133) mapped more subunits and lithologic changes.

Three prominent northeast-southwest trending features are identified on the DEM. Two features in the Dan River basin align with the general location of hogbacks ridges mapped by Thayer (Reference 2.5-50). The third feature trends northeast-southwest and crosses into the Site Area, aligning with the boundary between Precambrian to Paleozoic muscovite and biotite schists and mica and gneiss schist (Reference 2.5-133; Figures 2.5-111 and 2.5-112). The location of mapped faults from the geologic maps was reviewed in both the aerial and LiDAR data. Within the Site Area (5 mi. [8 km]), the only mapped fault is the Chatham fault, which does not have a strong geomorphic signature in the LiDAR DEM. No sharp linear features were identified in the LiDAR or aerial photographs that could indicate recent faulting in the Site Area.

A lineament map covering the Site Area was developed as part of the ground water analysis for the Project site (Section 2.4.12; Figure 2.5-114). A total of 1408 lineaments were identified with prominent lineament orientations centered on N30-40°W, N20-30°E, and N60-70°E. Lineament orientations are generally parallel or perpendicular to regional geologic trends. Variations are likely caused by changes in local geological unit's strike and the formation of conjugate fractures at small angles to the principal direction of stress. Most interpreted lineaments are shorter than 2 mi. (3.2 km). The longest lineament follows the Dan River valley to the northwest of the Project site. This portion of the Dan River generally follows the contact between the Mesozoic Dan River basin and the older metamorphic units. No lineaments longer than 2 mi. (3.2 km) are mapped in the Project site, including when lineaments are projected across the lake to the other shore to connect features disrupted by the datasets used for the lineament analysis that do not image the lake floor. Geologic mapping performed from 1966 to 1971 (Reference 2.5-51) maps rock surface beneath the lake location and do not show any faults or lineaments crossing the Project site.

Karegar et al. (Reference 2.5-217) conducted a regional study using Global Positioning System (GPS) data with average record lengths of 8.5 years per station from the U.S. Atlantic Coast region (Figure 2.5-115). Data from the study show the Piedmont region is generally subsiding at a rate of 0.06 to 0.02 inches per year (1.5 to 0.5 mm/yr). Three GPS stations in the Site Vicinity (25 mi. [40 km]) are subsiding within the range of the general rates for the Piedmont region. There are no indications from the regional dataset that the Site Vicinity is behaving differently from the rest of the Piedmont in NC and southern Virginia.

Within the Site Location (1 mi. [1.6 km]), the subsurface exploration study confirms that the Project site is entirely underlain by the CZbg unit, a Cambrian-age biotite gneiss and schist, which is metamorphosed to amphibolite facies and intruded locally by pegmatitic dikes. Lithologies and structures observed in boreholes are consistent with previously published regional geologic mapping (Reference 2.5-114; Reference 2.5-115). The borehole data document metamorphic fabrics, folding, and intrusive relationships characteristic of Paleozoic to Precambrian tectonism. No evidence of Quaternary or other recent deformation was observed in the core descriptions, geophysical logs, or stratigraphic profiles developed as part of this investigation.

Fracture and foliation orientations documented from borehole logging (boreholes 1, 3, 5, 6, 8, 10, 11, 13, and 15, as expressed in rose diagrams in Figure 2.5-116) exhibited generally

consistent structural patterns across the Site Area. Field data did not differentiate between joints and fractures and therefore, the more general term of “fractures” is used in this section. Most of boreholes showed a dominant northeast-southwest (N30–50°E) azimuth orientation with a secondary northwest-southeast (N20–40°W) azimuth orientation broadly consistent with conjugate fracture sets observed in Piedmont metamorphic rocks.

Several boreholes (B5, 10, 11, 13) displayed both open and filled fractures clustering tightly within these modes, whereas others (B3 and 3A, 6, 15A and B) recorded more dispersed populations that retain a preferred northeast-southwest trend.

Cross-hole comparisons show that nearly all boreholes express one or both of the principal fracture orientations, indicating that Site Area-scale fracture geometry can likely be attributed to the regional Site Vicinity and Site Region-scale structural grain of the Milton terrane and Charlotte belt. These borehole-scale results correspond directly to the lineament analysis presented in Section 2.5.3.5 (Figure 2.5-114), which identifies prominent lineament orientations centered at N30–40°E, N20–30°W, and N60–70°E. The agreement between borehole fracture orientations and regional lineament trends supports the interpretation that deformation at the Project site reflects inherited Paleozoic – Mesozoic tectonic fabrics, with no evidence of anomalous Quaternary structural trends or through-going fault zones at the Site Location.

In summary, while the Site Area is located within a tectonically complex Piedmont terrane that records multiple Paleozoic and Mesozoic deformation events, none of the mapped structures in the Site Area show evidence of Quaternary reactivation. These structures are not interpreted to be genetically related to the active tectonic sources that define historical and instrumental seismicity in the broader CEUS. Subsurface investigations confirm that the Project site is underlain entirely by Cambrian biotite gneiss and schist, with borehole logs documenting fracture and foliation orientations that are consistent across multiple boreholes. The dominant northeast-southwest and secondary northwest-southeast fracture sets are broadly consistent with Piedmont fabrics and the regional structural grain, indicating that observed fracture geometry reflects inherited tectonic fabrics. The prevalence of mineral-filled fractures further supports the interpretation that these features are ancient and not the result of recent tectonic activity. As discussed in Section 2.4.12, more than 97 percent of fractures were calculated to be filled or closed based on ATV log data. No evidence of Quaternary-capable faults, anomalous structural orientations, or recent deformation features were identified in borehole core, geophysical logs, or geomorphic datasets. This conclusion aligns with the summary of regional structure ages discussed in Section 2.5.1.

2.5.3.7 Non-Tectonic Hazard Screening (Mining, Volcanism, Karst, and Evaporites)

2.5.3.7.1 Mining

The location of mines and mine-like features that could collapse or result in surface deformation at the Project site was performed using data from the USGS Prospect- and Mine-Related Features from USGS 7.5- and 15-Minute Topographic Quadrangle Maps of the United States dataset (Reference 2.5-218, version 10 [May 2023]). This database includes prospect pits, mines, adits, dumps, and tailings, compiled from USGS topographic maps.

Forty-four mapped features within the Site Vicinity (25 mi. [40 km]) appear in the database (Figure 2.5-117). All but one are pits and quarries. The single adit, identified as “Tory’s Den” is mapped as a cave in Hanging Rock State Park (Reference 2.5-219). Mine and cave entrances

can share a symbol on topographic maps (Reference 2.5-220) and the classified adit is at the location of the cave. Based on the data contained in Horton and San Juan (Reference 2.5-218) and the interpretation of the adit as a cave entrance, the Site Vicinity contains no mapped underground mine features.

Eight mapped features are within the Site Area. Six are classified as clay pits and two are classified as quarries. No underground mining features are mapped in the Site Area. The closest feature is a quarry that is 2.8 mi. (4.5 km) to the northwest of the Project site across the Dan River. It is visible in the LiDAR DEM (Figure 2.5-112).

Aerial photographs in the Site Area were reviewed for evidence of underground mines such as tailings piles (Figure 2.5-113). Quarry features and the coal ash basin from the Belews Creek Steam Station are visible on the aerial photographs, indicating other tailing features could be mapped, although tree cover and the age of the features may make them less recognizable on aerial photographs. Topographic maps and LiDAR data were also reviewed for symbols associated with mining or topographic features.

Data compiled by Horton and San Juan (Reference 2.5-218) and analysis of aerial photographs do not indicate subterranean mining in the Site Vicinity that could lead to tunnel collapses and surface deformation at the Project site.

2.5.3.7.2 Volcanism

Prior to the breakup of Pangea, the CAMP, a large igneous province had formed (Reference 2.5-106). In the Site Vicinity, the CAMP is represented by a series of dikes that trend approximately north-south. Peak activity for the CAMP has been dated to the Triassic – Jurassic boundary, approximately 200 Ma (Reference 2.5-106). The youngest igneous features within the Site Region are Eocene volcanic dikes, sills, plugs, and diatremes near the West Virginia – Virginia border (Reference 2.5-105), more than 125 mi. (200 km) from the Project site.

Recent volcanism is typically associated with plate boundaries and mantle hotspots. Neither setting is present in the Site Region, and there are no mapped Quaternary active volcanoes (Reference 2.5-107; Reference 2.5-108; Reference 2.5-109). There are no Quaternary volcanoes in the Site Region (200 mi. [320 km]) or mapped Quaternary volcanic deposits within Site Vicinity (25 mi. [40 km]) [Reference 2.5-109]). Therefore, based on RG 4.26, which specifies if no Quaternary active volcanoes are identified in the Site Region (200 mi [320 km]), or Quaternary pyroclastic deposits within the Site Vicinity (25 mi. [40 km]), the volcanic hazard can be screened out of further analysis.

2.5.3.7.3 Karst and Evaporites

Tobin and Weary (Reference 2.5-221) compiled data for the USGS of locations in the United States of potential karst and karst analogous features. In NC, most karst-susceptible units are carbonate rocks in the Coastal Plain region. The Project site is not within a region identified to have fissures, tubes, caves, or units such as basalts that can contain tubes and tunnels and behave like karst.

Espenshade et al. (Reference 2.5-51) mapped the Project site geology as gneiss and schist of the Charlotte belt. Profile B-B' maps the unconformity at the southeast margin of the Triassic basin dipping away from the Project site (Figure 2.5-111). In Figure 2.5-111, the Project site is

projected onto the cross section that trends northwest-southeast, which, at its closest, is approximately 4.5 mi. (7.2 km) south of the Project site. The Project site projects into the unit Pzc - granitic rock; however, the Project site sits on the mapped bc unit - gneiss and schist. No evaporites or carbonate units are mapped in the Site Area (5 mi. [8 km]) (Reference 2.5-51; Reference 2.5-133). Rock units in the Triassic Dan River basin are mapped as clastic sedimentary rocks of nonmarine origin (Reference 2.5-51).

Borings and data collected at the Project site did not identify carbonate or evaporite units, or voids. LiDAR DEM data in the Site Area were reviewed for geomorphic features associated with karst and salt dissolution such as enclosed depressions, sinking streams, and other indications of karst (Reference 2.5-222; Figure 2.5-112; Reference 2.5-223). Sinkholes are the most common hazard in karst areas (Reference 2.5-224). No closed depressions or other karst features are identified in the Site Area.

2.5.4 STABILITY OF SUBSURFACE MATERIALS AND FOUNDATIONS

This section provides the details of the subsurface materials and foundation conditions for the Project site. It was prepared based on guidance presented in the relevant sections of NUREG-0800.

The Project site consists of three Plant Complexes – the North, Middle, and South Plant Complexes. At each complex, six different reactor technologies are under consideration as part of the ESPA. Table 2.5-51 provides a summary of the technologies and their anticipated bearing depth and base elevations. Additional site-specific studies will be performed during the construction permit or license application phase once a final selection on reactor technology is made.

The information presented in this section is based on results of the site-specific subsurface investigation program implemented at the Project site as part of the ESPA, and evaluation of the collected data, unless stated otherwise. NC State Plane Coordinate System (North Zone), North American Datum of 1983 (NAD 1983) is used to establish horizontal datum. North American Vertical Datum of 1988 (NAVD 88) is used to establish vertical datum, unless stated otherwise.

This section presents the required information in the following sequence:

- Section 2.5.4.1 - Geologic Features
- Section 2.5.4.2 - Properties of Subsurface Materials
- Section 2.5.4.3 - Foundation Interfaces
- Section 2.5.4.4 - Geophysical Surveys
- Section 2.5.4.5 - Excavation and Backfill
- Section 2.5.4.6 - Groundwater Conditions
- Section 2.5.4.7 - Response of Soil and Rock to Dynamic Loading
- Section 2.5.4.8 - Liquefaction Potential
- Section 2.5.4.9 - Earthquake Design Basis
- Section 2.5.4.10 - Static and Dynamic Stability

- Section 2.5.4.11 - Design Criteria
- Section 2.5.4.12 - Techniques to Improve Subsurface Conditions

2.5.4.1 Geologic Features

Section 2.5.1.1 addresses the regional physiography, geologic history, stratigraphy, structures, and tectonic setting and provides related maps, cross sections, and references.

Section 2.5.1.2 describes the physiographic, geologic, and tectonic characteristics of the Project site vicinity and Project site area using related maps, figures, and references.

The three locations explored as part of the Belews Creek, NC site ESPA investigation are referred to as the North Plant Complex, Middle Plant Complex, and South Plant Complex. Together, these are referred to as the Project site and are located in southeast Stokes County, near the intersection of four counties: Rockingham County to the east, Guilford County to the southeast, and Forsyth County to the south. The Project site is located within the Piedmont physiographic province, a distinct physiographic province that extends from New Jersey to Alabama (approximately 1000 mi. or 1600 km) (Reference 2.5-4).

Geologically, the Piedmont physiographic province is characterized by distinct tectonostratigraphic terranes. Tectonostratigraphic terranes are defined as fault-bounded geologic areas of regional extent, characterized by an internally homogeneous stratigraphy and geologic history that is different from that of adjacent terranes (Reference 2.5-15). These distinct terranes have been accreted to the ancient continent of North America (Laurentia) at different times by the convergence of tectonic plates. The terranes typically preserve an imprint of past geologic events that involved compressional, extensional, and translational tectonic activity (Reference 2.5-15). The Project site is entirely located within the Milton terrane, which is composed of Late Precambrian massive to strongly foliated biotite gneiss and schist, amphibolite, felsic gneiss, and Late Paleozoic diabase and granite intrusions. Milton terrane rocks are metamorphosed to amphibolite facies and folded into shallow, plunging, recumbent folds (Reference 2.5-115; Reference 2.5-15).

The site is underlain entirely by the CZbg unit, a Cambrian biotite gneiss and schist that ranges from approximately 520 to 650 million years old (Reference 2.5-117; Reference 2.5-116; Reference 2.5-227). The CZbg unit is a highly metamorphosed and foliated biotite gneiss and schist, described as dark colored, medium- to coarse-grained to porphyroblastic, locally contains hornblende, and is chiefly composed of biotite, quartz, potassium feldspar, muscovite, and hornblende. The CZbg formation is interlayered with mica schist and amphibolite and is locally intruded by pegmatite dikes.

Lithologies encountered during drilling operations are consistent with the published maps and reports as described above.

2.5.4.2 Properties of Subsurface Materials

The engineering stratigraphy at the Project site generally consists of overburden residual soils weathered in place from the parent rock, underlain by PWR and crystalline rock (fractured and sound rock). The degree of weathering in the residual soils and PWR is highly variable. The

upper portion of the rock is fractured to varying degrees and underlain by sound rock. The properties of subsurface materials are discussed in the following sections:

- Section 2.5.4.2.1 summarizes the Project site subsurface investigation. Section 2.5.4.2.2 describes the various strata encountered during the subsurface investigations.

- Sections 2.5.4.2.2, 2.5.4.2.3, and 2.5.4.2.4 describe the subsurface conditions and the derived geotechnical engineering properties (both static and dynamic) of the strata encountered with depth. Tables and figures referenced in these sections present the derived geotechnical engineering properties for these strata.

2.5.4.2.1 Subsurface Investigation

The subsurface investigation for the Project site was performed in accordance with the guidance outlined in RG.132 “Geologic and Geotechnical Site Characterization Investigations for Nuclear Power Plants”. This guidance was used in preparing a work plan, which formed the basis for the subsurface investigation. Deviations are identified at point of use, and alternatives and/or bases for deviations are provided. The subsurface investigation was conducted from April 2024 through March 2025. Figure 2.5-118 shows the locations of the geotechnical investigation field tests for the North, Middle, and South Plant Complexes. Figures 2.5-119 through 2.5-121 show the geotechnical investigation field tests relative to the surface and borehole geophysical explorations performed at the North, Middle, and South Plant Complexes, respectively. A summary of the geotechnical field tests is provided in Table 2.5-52. Because a specific reactor technology has not yet been selected, the locations of the boreholes were selected to be as representative of the overall site conditions as possible as part of the ESPA while considering the three potential complexes and six different technologies/layouts.

Before initiating drilling activities, the public utility service (NC 811) located and marked the underground utilities. A private utility locating subcontractor was also engaged to locate and mark underground utilities. Appropriate methods, such as ground penetrating radar, were employed to locate subsurface utilities within a 20-ft. (6.1 m) radius of each staked boring location. Soft dig excavations in the form of hand auger borings were conducted at boring and well locations to verify the absence of subsurface utilities to a depth of 5 ft. (1.5 m) or until encountering refusal on rock. No overhead utilities were found to conflict with the proposed boring locations.

Upon completion of field tests, surveying was conducted to establish the horizontal and vertical locations of investigation and testing points. The as-built survey was completed using a combination of survey-grade GPS methods and traditional differential leveling. Survey-grade GPS used for horizontal coordinates and elevations had an accuracy of 0.1 ft. (0.03 m), and differential leveling used for elevations had an accuracy of 0.02 ft. (0.006 m). The coordinates and elevations of the geotechnical field tests are captured in Table 2.5-52.

In total, 84 boreholes were completed – 26 of these boreholes were in the North Plant Complex, 28 were in the Middle Plant Complex, and 30 were in the South Plant Complex. The subsurface investigation is categorized into four series based on the primary function and is summarized below:

- "B" series borings were the primary geotechnical and geophysical borings. Forty-seven B-series borings were performed, including the offset borings that were drilled a short distance away (typically less than 10 ft. [3.0 m]) from the parent boring for rock coring or obtaining samples for laboratory testing (designated as A, B, C, or D, depending on the number of offset borings performed). Borings B-1, B-1A, B-1B, B-1C, B-2, B-2A, B-3, B-3A, B-3B, B-4, B-5, and B-5A were at the North Plant Complex; B-6, B-6A, B-6B, B-6C, B-7, B-7A, B-7B, B-8, B-8A, B-8B, B-8C, B-9, B-9A, B-9B, B-10, and B-10A were at the Middle Plant Complex; and B-11, B-11A, B-11B, B-11C, B-11D, B-12, B-13, B-13A, B-13B, B-13C, B-14, B-14A, B-14B, B-14C, B-15, B-15A, B-15B, B-15C, and B-15D were at the South Plant Complex.

- "W" series borings were performed for the shallow groundwater monitoring wells. Nineteen W-series borings were performed – W-1A, W-1B, W-2A, W-2B, W-3A, W-4A, W-5A, and W-5B were at the North Plant Complex; W-6A, W-7A, W-8A, W-9A, W-9B, and W-10A were at the Middle Plant Complex; and W-11A, W-12A, W-13A, W-14A, and W-15A were at the South Plant Complex.

- "DW" series borings were performed for the deep groundwater monitoring wells. Twelve DW-series borings were performed – DW-1A through DW-4A were at the North Plant Complex; DW-5A through DW-8A were at the Middle Plant Complex; and DW-9A through DW-12A were at the South Plant Complex.

- "S" series borings were performed for the sentinel wells (which served as water level monitoring wells during aquifer pumping tests). Six S-series borings were performed – S-1A and S-5A were at the North Plant Complex; S-7A and S-10A were at the Middle Plant Complex; and S-11A and S-15A were at the South Plant Complex.

A rig geologist (a geologist or an engineer) was assigned to each drill rig. The rig geologist was responsible for supervising/observing the drilling activities performed by their assigned crew, performing daily site equipment checks, preparing boring logs, documenting work activities, and implementing applicable sections of the work plan. The rig geologist also supervised subcontractor operations, such as borehole geophysical testing, for conformance to specified procedures and instructions.

The primary method of advancement through overburden soils was mud rotary drilling as described by ASTM D5783-18 (Reference 2.5-228) with SPT sampling. However, other methods of drilling were also employed, including rotosonic drilling (Reference 2.5-229) for some well lithology borings, and hollow-stem augers (Reference 2.5-230) for bulk soil sample collection. Upon encountering refusal on rock, borings were advanced using coring techniques.

All boreholes except for DW-11A and borings W-3A through W-15A, which were advanced using a sonic bit, had SPT split-spoon sampling. Disturbed soil samples were obtained using 1.5-in. (3.8-cm) inside diameter split-spoon samplers in conjunction with the SPT, as described by ASTM D1586 (Reference 2.5-231). The split spoon sampler was driven a minimum of 18 in (46 cm) or to refusal. The sampling interval was 2.5 ft. (0.76 m) to 5 ft. (1.5 m). The recovered soil samples were visually described and classified by the rig geologist in accordance with ASTM D2488-17e1 (Reference 2.5-232).

In addition, 24 undisturbed samples (using Shelby push tubes) were collected from the overburden soils. Undisturbed samples were obtained in accordance with ASTM D1587 (Reference 2.5-233) using nominal 3-in. (7.6-cm) outside diameter, 30-in. (76-cm)-long Shelby tubes. The samples were preserved and prepared for transport to the laboratory for subsequent testing in accordance with ASTM D4220/D4220M-14 (Reference 2.5-234).

Hollow-stem auger borings (Reference 2.5-230) collected bulk soil samples for laboratory testing. Bulk samples were taken from auger cuttings brought to the surface (approximately 100 pounds) from specified sampling intervals and stored in multiple, clean, 5-gallon buckets with lids along with separate jar samples to preserve the moisture of the material.

All geotechnical borings performed during the field investigation program penetrated into the rock layer. Rock coring was initiated once the rig geologist confirmed the presence of rock. Rock coring used the diamond core drilling method in accordance with ASTM D2113-14 (Reference 2.5-235) and water or a low-solids, high-polymer drilling mud and a wireline triple-tube, ball-bearing, swivel-type, HQ core barrel with a split inner barrel and hydraulic extrusion fittings. Core runs were generally 5 ft. (1.5 m) in length. The recovered rock samples were visually described and classified by the rig geologist in accordance with ASTM D5434-12 (Reference 2.5-236). Routine-care rock samples were wrapped following ASTM D5079-08 (Reference 2.5-237). Any special-care rock core samples as defined by ASTM D5079-08 were identified by the rig geologist or lead geologist and preserved as soon as practical after coring to preserve their in situ characteristics.

Photographs were taken of split-spoon and rock core samples. Undisturbed samples were sealed in steel tubes and therefore could not be photographed. An on-site, secure, temperature-controlled sample storage facility for soil and rock samples was established prior to initiating the field exploration program. Field samples were delivered to the sample storage facility daily. Split-spoon samples were placed into glass jars with moisture sealing screw-type lids and were transported in compartmentalized cardboard boxes. Bulk soil samples were placed in plastic buckets secured with snap-on lids. Undisturbed (intact) Shelby tube samples were temporarily capped in the field near the test location, transported in a vertical orientation to the on-site sample storage where they were cleaned and sealed, and then secured in a vertical position in custom wood racks. All samples were labeled on the containers to identify the samples and logged into the sample storage facility using a sample inventory log. Material storage and handling were in accordance with ASTM D4220/D4220M-14 (Reference 2.5-234) and ASTM D5079-08 (Reference 2.5-237) for soil and rock samples, respectively.

2.5.4.2.1.1 Standard Penetration Test Measurements and Hammer Energy Calibration

Soil samples were collected from the borings by means of SPT split-spoon and Shelby tube samples. SPT resistance (N) values were measured during the sampling and recorded on the boring logs.

Energy measurements were made on the auto-hammer-rod system on each of the drill rigs used during the field investigation in accordance with ASTM D4633 (Reference 2.5-238). A Pile Driving Analyzer was used to acquire and process hammer energy data. Table 2.5-53 summarizes the measured energies. The average energy transfer ratio measurements, defined as the ratio of the maximum recorded energy transfer to the theoretical hammer energy, ranged from 88 to 89 percent.

The SPT N-value used in correlations with engineering properties is typically the value corresponding to 60 percent hammer efficiency. The measured field SPT N-values were adjusted based on the energy measurements by applying the obtained energy transfer ratio from hammer energy measurements for each drilling rig to the measured SPT N-values. The measured SPT N-values from each boring were adjusted using the energy transfer ratio value captured in Table 2.5-53 depending on the drill rig used for a particular borehole.

Energy-corrected SPT N-values (N_{60}) ranged from 1.5 blows/ft (bpf) to 138 bpf (1.5 blows/0.3 m to 138 blows/0.3 m), with an average measured N_{60} value of approximately 31 bpf (31 blows/0.3 m) in the overburden soils, indicating typically medium dense consistency. The N_{60} value in the PWR layer was more than 100 bpf. The variability of N_{60} values across the entire site is presented in Figure 2.5-122. The figure indicates a generally increasing N_{60} value with depth; however, the variability is significant as is common in Piedmont residual soils.

2.5.4.2.1.2 Rock Core Data

The rig geologist visually described the rock core including lithology and discontinuities and distinguished mechanical breaks from natural breaks where possible. The rig geologist also calculated core recovery (CR) and RQD prior to moving the core from the drill site. RQD was measured and recorded for each core run in compliance with ASTM D6032/D6032M-17 (Reference 2.5-239).

The CR and RQD values at the site ranged between 0 percent and 100 percent. The data indicate that the upper portion of the crystalline rock layer is fractured to varying degrees. For engineering stratigraphy purposes, fractured rock for this project has been defined as cored rock with RQD values less than 50 percent. At the North Plant Complex, the mean thickness of the stratum identified as fractured rock (see Section 2.5.4.2.2.3) was 14 ft. (4.3 m) (with a standard deviation of 15 ft. [4.6 m]). At the Middle Plant Complex, the mean thickness of the fractured rock stratum was 5.2 ft. (1.6 m) (with a standard deviation of 8.4 ft. [2.6 m]). At the South Plant Complex, the mean thickness of the fractured rock stratum was 6.2 ft. (1.9 m) (with a standard deviation of 7.4 ft. [2.3 m]).

2.5.4.2.1.3 Laboratory Tests

The laboratory investigation of soils and rocks was performed in accordance with the guidance outlined in RG 1.138, *Laboratory Investigations of Soils and Rocks for Engineering Analysis and Design of Nuclear Power Plants*. Laboratory testing included the following:

Soil Tests:

- Classification of Soils for Engineering Purposes – ASTM D2487-17e1 (Reference 2.5-240)
- Laboratory Determination of Water (Moisture) Content of Soil and Rock by Mass – ASTM D2216-19 (Reference 2.5-241)
- Liquid Limit, Plastic Limit, and Plasticity Index of Soils – ASTM D4318-17e1 (Reference 2.5-242)

- Amount of Material Finer than 75-µm (No. 200) Sieve in Soils by Washing – ASTM D1140 17 (Reference 2.5-243)
- Particle-Size Distribution (Gradation) of Soils Using Sieve Analysis – ASTM D6913/D6913M 17 (Reference 2.5-244)
- Particle-Size Distribution (Gradation) of Soils Using Hydrometer Analysis – ASTM D7928 21e1 (Reference 2.5-245)
- Specific Gravity of Soil Solids by Water Pycnometer – ASTM D854-23 (Reference 2.5-246)
- One-Dimensional Swell or Collapse of Soil – ASTM D4546-21 (Reference 2.5-247)
- One-Dimensional Consolidation Properties of Soils Using Incremental Loading – ASTM D2435/D2435M-11 (Reference 2.5-248)
- Unconfined Compressive Strength of Cohesive Soil – ASTM D2166/D2166M-16 (Reference 2.5-249)
- Unconsolidated-Undrained Triaxial Compression Test on Cohesive Soils – ASTM D2850-23 (Reference 2.5-250)
- Consolidated-Undrained Triaxial Compression Test for Cohesive Soils – ASTM D4767-11 (2020) (Reference 2.5-251)
- Laboratory Determination of Density and Unit Weight of Soil Specimens – ASTM D7263-21 (Reference 2.5-252)
- Laboratory Compaction Characteristics of Soil Using Modified Effort – ASTM D1557-12 (2021) (Reference 2.5-253)
- X-Ray Radiography of Soil Samples – ASTM D4452/D4452M-22 (Reference 2.5-254)
- Resonant Column Torsional Shear (RCTS) - University of Texas Procedure
- Determination of Thermal Conductivity of Soil and Rock by Thermal Needle-Probe Procedure – ASTM D5334-22ae1 (Reference 2.5-255)
- Water (Moisture) Content, Ash Content, and Organic Material of Peat and Other Organic Soils – ASTM D2974-20e1 (Reference 2.5-256)
- Chemical analyses:
  - pH of Soil Used in Corrosion Testing – ASTM G51-18 (Reference 2.5-257)
  - Water-Soluble Sulfate Ion Content of Soil – ASTM C1580-20 (Reference 2.5-258)
  - Water-Soluble Chloride Ion Content of Soil – AASHTO T291-22 (2022) (Reference 2.5-259)

Rock Tests:

- Direct Shear Strength Tests of Rock Specimens Under Constant Normal Force – ASTM D5607-16 (Reference 2.5-260)
- Compressive Strength and Elastic Moduli of Intact Rock Core Specimens under Varying States of Stress and Temperatures – ASTM D7012-23 method B (Reference 2.5-261)
- Compressive Strength and Elastic Moduli of Intact Rock Core Specimens under Varying States of Stress and Temperatures – ASTM D7012-23 method C (Reference 2.5-261)
- Compressive Strength and Elastic Moduli of Intact Rock Core Specimens under Varying States of Stress and Temperatures – ASTM D7012-23 method D (Reference 2.5-261)
- Unconfined Free-Free Resonant Column (URC) - University of Texas Procedure
- Resonant Column Torsional Shear (RCTS) - University of Texas Procedure

For all strength tests performed on rock core, specimens were prepared in accordance with ASTM D4543-19 (Reference 2.5-262). The number and types of tests were selected to be representative of the conditions encountered at the site and to allow for adequate characterization of the pertinent soil and rock properties.

- Table 2.5-54 provides a summary of the laboratory tests and specifications used for the laboratory testing program.
- Table 2.5-55 provides a summary of the index test results.
- Table 2.5-56 provides a summary of the soil consolidation and swell/collapse test results.
- Table 2.5-57 provides a summary of the soil strength test results.
- Table 2.5-58 provides a summary of the unit weight determinations on undisturbed soil samples.
- Table 2.5-59 provides a summary of the Modified Proctor test results.

In addition to the routine tests commonly performed in typical soil and rock testing laboratories, specialty tests not covered in regulatory guides were also performed for the Belews Creek site exploration. These included RCTS and unconfined Free-Free (Fr-Fr) unconfined resonant column URC tests, which were performed at the University of Texas. These tests also included constant strain rate triaxial compression of rock samples, constant strain rate uniaxial compression of rock samples, and direct shear testing of rock that were performed by RESPEC, a specialty geotechnical consultant.

The following sections provide a summary of each test, describing the most important and relevant results.

2.5.4.2.1.3.1 Soil and Rock Classification

Soil samples were classified in the laboratory using the Unified Soil Classification System (USCS) in accordance with ASTM D2487-17 (Reference 2.5-240).

2.5.4.2.1.3.2 Grain Size Distribution, Moisture Content, and Atterberg Limits

Grain size distribution tests and moisture content tests were performed as part of index tests on select samples of overburden soils in accordance with ASTM D422-63 (Reference 2.5-322) and ASTM D2216-19 (Reference 2.5-241), respectively. Select soil samples were also tested to evaluate their plasticity characteristics in accordance with ASTM D4318-17e1 (Reference 2.5-242). The results of these tests were used for classification and correlation purposes. The results of these tests were used for classification and correlation purposes. The overburden soils were generally classified as silty sands (SM) and non-plastic silts (ML), except for some near-surface fill soils (typically in the upper 10 ft. [3 m]) that were noted to be plastic (MH, CL, or CH). The Plasticity Index (PI) of the plastic samples from index tests ranged from 10 percent to 59 percent, with a mean of 24 percent. The natural moisture content of the samples from index tests ranged from 5.4 percent to 52.8 percent, with a mean of 23.3 percent. The fines content of the samples from index tests ranged from 18.4 percent to 95 percent, with a mean of 50.1 percent.

2.5.4.2.1.3.3 Specific Gravity

Specific gravity tests were performed on select overburden soil samples in accordance with ASTM D854-23 (Reference 2.5-246). The specific gravity of the soil samples ranged from 2.61 to 2.87, which is consistent with typical values of specific gravity of soils that tend to lie in a relatively narrow range of 2.7 ± 0.2.

2.5.4.2.1.3.4 Unit Weight Determination

Unit weight determinations were made on undisturbed samples of soil in accordance with ASTM D7263-21 (Reference 2.5-252) using the direct measurement method. Unit weight measurements were also made on the RCTS soil samples using calibrated calipers and scales, as well as on rock samples during Fr-Fr and RCTS tests and during unconfined compressive strength tests.

The dry unit weight of the undisturbed residual soil samples ranged from 66.8 to 90.5 pcf, with a mean of 78.6 pcf. The moisture content associated with the unit weight determinations ranged from 19.0 to 42.4 percent, with a mean of 30.3 percent. The corresponding total unit weight was between 82.2 and 117.0 pcf, with a mean of 102.3 pcf. The undisturbed samples were typically obtained from relatively looser/softer zones of overburden soils (all but one were from Stratum I as described in Section 2.5.4.2.2.1); as such, the relatively low unit weights indicated by the unit weight determinations most likely underestimate the unit weights of the deeper, more competent overburden residual soils.

The Fr-Fr and RCTS tests on rock samples indicated total rock unit weights ranging from 153.8 to 181.8 pcf, with a mean of 169.8 pcf. Rock specimens that were tested under unconfined (uniaxial) and confined (triaxial) conditions ranged from 161.9 to 195.3 pcf with a mean of 169.6 pcf.

2.5.4.2.1.3.5 Thermal/Chemical Tests

Chemical testing was performed on select samples and included pH (Reference 2.5-257), chloride ion content (Reference 2.5-259), and sulphate content (Reference 2.5-258). These tests provide information related to the potential for chemically induced corrosion of foundation materials, such as concrete and reinforcing steel.

Measurements of pH on 14 samples indicated average pH values (taken as the average of three readings) ranging from 5.0 to 6.9. Chloride ion content measurements made on 14 samples indicated water soluble chlorides ranging from 5 to 19 milligrams per kilogram (mg/kg). Sulfate content measurements made on 14 samples indicated water soluble sulfates ranging from <10 to 60 mg/kg.

2.5.4.2.1.3.6 Unconfined Compressive Strength and Unconsolidated-Undrained Triaxial Compression Test

Unconfined Compressive Strength (UCS) tests were performed on two undisturbed soil samples (Reference 2.5-249). The tests indicated undrained shear strengths of 2.6 pounds per square inch (psi) and 8.3 psi.

Unconsolidated-undrained (UU) triaxial compression tests with pore water pressure measurements were performed on eleven undisturbed overburden samples in accordance with ASTM D2850-23 (Reference 2.5-250). The tests indicated undrained shear strengths ranging from 7.6 psi to 21.0 psi.

2.5.4.2.1.3.7 Consolidated-Undrained Triaxial Compression Test with Pore Pressure Measurements

Consolidated-undrained (CU) triaxial compression tests with pore water pressure measurements were performed on select undisturbed overburden samples in accordance with ASTM D4767-11 (Reference 2.5-251). Eight tests were performed on undisturbed residual soil samples to determine their strength parameters. In addition, three tests were performed on remolded samples compacted to 95 percent of their Modified Proctor maximum dry density to provide the strength parameters for as-compacted on-site residual soils.

For the undisturbed samples tested, the laboratory data indicate total stress parameters of undrained cohesion (c) ranging from 3.3 psi to 6.6 psi and undrained friction angle (ϕ) ranging from 1.9 degrees to 35.3 degrees. The effective stress parameters of effective cohesion (c') and effective stress friction angle (ϕ') were found to range from 0 psi to 1.4 psi and from 27.5 degrees to 36.4 degrees, respectively. These results exclude the result of the sample from Boring B-11D, which was deemed unreliable for use in the analyses (possibly due to a high level of sample disturbance) and was therefore omitted.

For the remolded on-site residual soil samples tested, the laboratory data indicate total stress parameters between 6.0 psi and 9.4 psi for c and 24.9 degrees and 34.5 degrees for ϕ, and effective stress parameters between 1.76 psi and 3.41 psi for c' and 26.1 and 30.2 degrees for ϕ'.

Section 2.5.4.2.3 provides additional details on the use of the laboratory test data in developing static soil engineering properties for the project. Section 2.5.4.10.3 provides additional details on the strength characteristics of remolded on-site residual soils.

2.5.4.2.1.3.8 One-Dimensional Consolidation Test

One-dimensional consolidation tests were performed on 11 undisturbed overburden samples in accordance with ASTM D2435-11 (Reference 2.5-248) to determine stress history and compressibility parameters of residual soils. The residual soil samples tested for their consolidation characteristics included silty sands (SM), elastic silts (ML), and high plasticity silts (MH). The interpretation of the consolidation test results requires consideration of the unique process for the formation of residual soils.

The initial void ratio (e_0) of the samples tested ranged from 0.814 to 1.466. The average coefficient of consolidation (C_v) was approximately 1.1 square feet per day. The test results indicate apparent pre-consolidation pressures ranging from 3.4 tons per square foot (tsf) to 8.3 tsf for the residual soils as indicated by the Casagrande graphical construction method for evaluating pre-consolidation pressures. The recompression indices (C_r) ranged from 0.03 to 0.09, and the compression indices (C_c) ranged from 0.31 to 0.78. Using an alternate interpretation based on the simplified graphical construction method, the test results indicate apparent pre-consolidation pressures ranging from 0.9 to 2.6 tsf. The recompression indices ranged from 0.05 to 0.13, and the compression indices ranged from 0.31 to 0.77.

It is not uncommon for different graphical interpretation methods to produce different results when evaluating consolidation test data. Further, interpretation of consolidation results in Piedmont residual soils is particularly challenging due to the mode of formation, soil fabric effects, and the sand-like nature of the silty sands and non-plastic silts. Section 2.5.4.10.3 provides additional details on the consolidation characteristics of the on-site residual soils.

2.5.4.2.1.3.9 One-Dimensional Swell/Collapse Test

One-dimensional swell/collapse tests were performed on three undisturbed overburden samples in accordance with ASTM D4546-21 (Reference 2.5-247) to determine swell or collapse potential of residual soils after wetting. Using an overburden pressure of 0.25 tsf, one sample experienced a heave of -1.0 percent (negative value indicating downward compression) after adding water, while the other two samples experienced heave between +0.6 and +0.7 percent (positive value indicating upward swell). The measured swell pressures for the two samples that experienced positive heave ranged from 0.3 to 1.4 tsf. The test results indicate low swell or collapse potential of the soils.

2.5.4.2.1.3.10 Compaction Testing

Select bulk samples of overburden residual soils were tested in accordance with ASTM D1557-12 (Reference 2.5-253) to determine the maximum dry density and optimum moisture content using the Modified Proctor procedure. The results are used in assessing the compaction characteristics of soils to evaluate their suitability as backfill.

The maximum dry density of the samples tested ranged from 101.8 to 125.9 pcf, with optimum moisture contents between 9.3 percent and 23.4 percent. In general, the high-plasticity silt (MH) samples exhibited lower maximum dry density and higher optimum moisture content. The

results also show that the natural moisture content of the samples is, at times, much greater than the optimum moisture contents, indicating that significant moisture conditioning may be required prior to the use of on-site residual soils as backfill. Section 2.5.4.5.2.1 provides additional details on the compaction characteristics of the on-site residual soils.

2.5.4.2.1.3.11 Unconfined and Confined Compressive Strength of Rock

Unconfined (uniaxial) compressive strength (UCS) and confined (triaxial) compressive strength (TCS) tests were performed on representative rock core specimens to determine their compressive strength in accordance with ASTM D7012-23. The UCS tests were performed at a constant rate of strain and zero confinement pressure on specimens that were approximately 2.4 inches (61.0 mm) in diameter with length-to-diameter ratio equal to approximately 2.0. The TCS tests were performed under constant strain rate conditions and various confining pressures ranging between 75 psi and 750 psi on specimens that were approximately 2.0 in. (50.8 mm) in diameter with length-to-diameter ratio equal to approximately 2.0.

Forty-two samples (6 schist and 36 gneiss) were tested for UCS, and 68 samples (4 schist and 64 gneiss) were tested for TCS. Elastic modulus and Poisson's ratio measurements were also made in all 68 TCS samples and 25 of the 42 UCS samples.

The UCS of all the samples tested ranged between 1580 and 28,440 psi, with a mean of 14,324 psi and a standard deviation of 6170 psi. For the schist samples, the mean UCS was 7890 psi with a standard deviation of 4307 psi. For the gneiss samples, the mean UCS was 15,396 psi with a standard deviation of 5803 psi. The TCS of all the samples tested, as indicated by the peak deviatoric stress observed during testing, ranged between 6170 and 41,490 psi, with a mean of 20,347 psi and a standard deviation of 6772 psi. For the schist samples only, the mean TCS was 14,020 psi with a standard deviation of 819 psi. For the gneiss samples only, the mean UCS was 20,743 psi with a standard deviation of 6785 psi.

The elastic modulus of all the samples tested ranged between 4.09E+05 psi and 1.02E+07 psi, with a mean of 5.15E+06 psi and a standard deviation of 1.83E+06 psi. The Poisson's ratio of all the samples tested ranged between 0.01 and 0.19, with a mean of 0.08 and a standard deviation of 0.04. For the schist samples, the mean elastic modulus was 3.48E+06 psi with a standard deviation of 1.74E+06 psi, and the mean Poisson's ratio was 0.06 with a standard deviation of 0.01. For the gneiss samples, the mean elastic modulus was 5.25E+06 psi with a standard deviation of 1.80E+06 psi and the mean Poisson's ratio was 0.08 with a standard deviation of 0.04.

Section 2.5.4.2.3 provides additional details on the use of the laboratory test data in developing static rock engineering properties for the project.

2.5.4.2.1.3.12 Direct Shear Testing of Rock

Direct shear tests were performed on 26 representative rock core samples to determine their strength under constant normal force conditions in accordance with ASTM D5607-16 (Reference 2.5-263). The direct shear tests were performed on natural, open joints and intact rocks using the multi-stage method, with the sample initially sheared at a normal stress representative of the in-situ stress conditions to evaluate peak and residual shear strengths,

followed by shearing the same rock specimen under increasing normal stresses. After the initial shearing stage, the joint surfaces were brushed clean, and the test specimen was reset to its original position. The normal stresses during tests were between 51 psi and 564 psi.

The test results indicate peak friction angles (with cohesion taken as zero) between 33.3 degrees and 79.3 degrees with a mean of 55.0 degrees and a standard deviation of 12.8 degrees, and residual friction angles (with cohesion taken as zero) ranging between 24.7 and 49.0 degrees with a mean of 35.8 degrees and a standard deviation of 5.4 degrees.

Section 2.5.4.2.3 provides additional details on the use of the laboratory test data in developing static rock engineering properties for the project.

2.5.4.2.1.3.13 Resonant Column Torsional Shear Test

RCTS tests were conducted according to the procedure developed by the University of Texas at Austin. Eight tests were performed on undisturbed residual soil specimens, and three tests were performed on select rock samples. The focus of the RCTS testing program was to evaluate the dynamic properties (mainly, stress and strain-dependent shear modulus and damping) of the overburden soils and rock for use in site response and other relevant dynamic analyses. Sections 2.5.4.2.4 and 2.5.4.7 discuss how the RCTS test results are used for the dynamic analyses.

2.5.4.2.1.3.14 Free-Free Unconfined Resonant Column Test

Fr-Fr URC tests were conducted according to the procedure developed by the University of Texas at Austin. Sixteen Fr-Fr tests were performed on special care rock samples retrieved from various boring locations. The term "Free-Free" is used to differentiate from the "Fixed-Free" condition of the typical resonant column test, meaning that one end of the sample is fixed, while the other is free to rotate or displace. No confining pressure is used in this test. Fr-Fr testing in torsional and longitudinal motion is used to measure shear wave and compression wave velocities, V_S and V_P, respectively, and damping at small strains, from which initial (maximum) shear modulus (G_{max}), Young's modulus of elasticity (E_{max}), and the minimum damping ratio (D_{min}) can be determined. The Poisson's ratio (ν) of the specimen can also be calculated using the relationship between V_S and V_P. A discussion of how the Fr-Fr testing results are used for the dynamic analyses is presented in Sections 2.5.4.2.4 and 2.5.4.7.

2.5.4.2.1.4 Geophysical Tests

Geophysical data collected at the site included suspension P-S velocity logging, downhole wave velocity profiling, SASW surveys, and electrical resistivity (ER) surveys. Figure 2.5-119 through Figure 2.5-121 capture the locations of each test for the North, Middle, and South Plant Complexes, respectively. Table 2.5-60 summarizes the surface geophysics (SASW and ER) locations. In addition, induction/natural gamma, three-arm caliper/natural gamma, electric log/natural gamma, and acoustic televiewer/borehole deviation data were collected in the P-S suspension velocity logging boreholes. The tests are described in detail in Section 2.5.4.4.

2.5.4.2.2 Description of Subsurface Materials

As discussed in Section 2.5.1.2, the Project site is located in the Piedmont physiographic province. The overburden soil at the site is composed of residual soils that formed in-place from weathering of the parent bedrock. Some fill soils were also encountered in the upper 10 ft. (3 m) of a few of the borings; however, soils identified as fill will be removed as part of the plant construction, and their properties were not considered. Below the residual soils is typically a zone of PWR, which is underlain by crystalline metamorphic rocks. The upper portion of the rock is fractured to varying degrees and becomes more sound with depth.

Figure 2.5-118 depicts the location of the geotechnical investigation borings at the North, Middle, and South Plant Complexes. Each boring log was inspected with a primary emphasis on soil types and field SPTN-values for the overburden soils, and CR and RQD for the rock layers. Based on evaluation of the characteristics and consistencies of the soil and rock encountered in the borings, the subsurface conditions at the site are defined by the following five strata:

- Stratum I (Residuum 1) – Residual soil with field SPT N-values of 15 bpf or less
- Stratum II (Residuum 2) – Residual soil with field SPT N-values greater than 15 bpf and less than 50 blows for 0.5 ft. (6 in.) of penetration (100 bpf)
- Stratum III (Partially Weathered Rock) – (PWR) – Residual material with field SPT N-values of 100 bpf or greater; for lithologic borings drilled using sonic rigs, this stratum was identified based on field descriptions of the material and drilling difficulty
- Stratum IV (Fractured Rock) – Cored rocks with RQD less than 50 percent
- Stratum V (Sound Rock) – Cored rocks with RQD equal to or greater than 50 percent

Tables 2.5-61 through 2.5-63 provide a summary of thicknesses and elevations for each strata, including minimum, maximum, and average values based on the subsurface investigation findings for the North, Middle, and South Plant Complexes, respectively. While the strata are delineated to represent in situ conditions, differential weathering, common in the Piedmont physiographic province, typically results in variations of the materials and properties within each stratum. This variation is depicted on the equally spaced fence diagrams captured in Figure 2.5-123 and 2.5-124 for the North Plant Complex, Figure 2.5-125 and 2.5-126 for the Middle Plant Complex, and Figure 2.5-127 and 2.5-128 for the South Plant Complex. These figures show the average stratum elevation overlaid on the individual fence diagrams for each boring to help visualize the variability between the average stratum elevations and the different stratum elevations at the individual boring locations.

2.5.4.2.2.1 Stratum I and II (Residuum)

Stratum I consists primarily of residual soils with lower relative densities compared to Stratum II and field SPT N-values of 15 bpf or less. The mean N_{60}-value was 13.6 bpf with a standard deviation of 0.5.3 bpf, 14.0 bpf with a standard deviation of 3.9 bpf, and 13.7 bpf with a standard deviation of 4.3 bpf in the North, Middle, and South Plant Complexes, respectively. In the North Plant Complex, Stratum I materials exhibit a mean thickness of 7.0 ft. (2.1 m) and

extend to an average base elevation of 809.0 ft. (246.6 m) NAVD 88. In the Middle Plant Complex, Stratum I materials exhibit a mean thickness of 18.9 ft. (5.8 m) and extend to an average base elevation of 789.5 ft. (240.6 m) NAVD 88. In the South Plant Complex, Stratum I materials exhibit a mean thickness of 21.0 ft. (6.4 m) and extend to an average base elevation of 799.5 ft. (243.7 m) NAVD 88. The thickness of Stratum I varies significantly between borings, with a minimum thickness of 0 ft. and a maximum thickness of 32.5 ft. (9.9 m).

Stratum II consists primarily of residual soils with higher densities compared to Stratum I, with field SPT N-values greater than 15 bpf but less than 100 bpf. The mean N_{60}-value was 57.2 bpf with a standard deviation of 27.4 bpf, 39.0 bpf with a standard deviation of 18.0 bpf, and 45.7 bpf with a standard deviation of 21.7 bpf in the North, Middle, and South Plant Complexes, respectively. In the North Plant Complex, Stratum II materials exhibit a mean thickness of 27.1 ft. (8.3 m) and extend to an average base elevation of 784.0 ft. (239.0 m) NAVD 88. In the Middle Plant Complex, Stratum II materials exhibit a mean thickness of 20.2 ft. (6.2 m) and extend to an average base elevation of 772.0 ft. (235.3 m) NAVD 88. In the South Plant Complex, Stratum II materials exhibit a mean thickness of 18.4 ft. (5.6 m) and extend to an average base elevation of 780.5 ft. (237.9 m) NAVD 88. The thickness of Stratum II also varies between borings, with a minimum thickness of 0 ft. and a maximum thickness of 72.7 ft. (22.2 m). This degree of differential weathering is not uncommon in the Piedmont physiographic province. The engineering challenges associated with this differential weathering profile are addressed in the subsequent report sections.

The residual soils of Strata I and II were generally classified as silty sands (SM) and non-plastic silts (ML), except for some near-surface fill soils, typically in the upper 10 ft. (3 m), that were noted to be plastic (high plasticity silts [MH], low plasticity clays [CL] or high plasticity clays [CH]). Of the 141 samples tested for their plasticity characteristics, only 23 were noted to be plastic and of those, only three samples below 10 ft. (3 m) were plastic. The plasticity index of the plastic soils in index tests ranged between 10 percent and 59 percent, with a mean of 24 percent. The natural moisture content in index test samples was between 5.4 percent and 52.8 percent, with a mean of 23.3 percent. The fines content of the index test samples tested was between 18.4 percent and 95 percent, with a mean of 50.1 percent.

Due to difficulties with Shelby tube sampling in the denser residual soils, most of the undisturbed samples were obtained from Stratum I. The dry unit weight of the undisturbed residual samples tested from Stratum I ranged from 66.8 to 90.5 pcf, with a mean of 78.1 pcf. The corresponding total unit weight was between 82.2 and 117.0 pcf, with a mean of 101.7 pcf. The only undisturbed sample from Stratum II (B-6B, UD-2) indicated a dry unit weight of 87.4 pcf and a corresponding total unit weight of 113.4 pcf.

UU triaxial compression tests and UCS tests indicate undrained shear strengths between 2.6 and 21.0 psi. Non-plastic residual soils, such as those typically encountered at the Project site, are normally analyzed as drained (using effective stress strength parameters); therefore, the undrained shear strengths should be used with caution.

CU triaxial compression tests with pore water pressure measurements were performed on eight undisturbed residual soil samples and three remolded residual soil samples compacted to 95 percent of their Modified Proctor maximum dry density. For the undisturbed samples tested, the laboratory data indicate total stress strength parameters, cohesion (c) and total stress friction angle (ϕ), between 3.3 psi and 6.6 psi for c and between 1.9 and 35.3 degrees

for ϕ and effective stress parameters, effective cohesion (c') and effective stress friction angle (ϕ'), between 0 and 1.4 psi for c' and 27.5 and 36.4 degrees for ϕ'. These results exclude the results of the sample from Boring B-11D, which showed results deemed unreliable for use in the analyses (possibly due to a high level of sample disturbance) and therefore were omitted. Using an alternate Mohr-Coulomb interpretation with c' equal to 0 would yield slightly higher values of ϕ'. The strength parameters are generally consistent with published values for Piedmont residual soils (Reference 2.5-264; Reference 2.5-265; Reference 2.5-266).

For the remolded samples tested that were compacted to 95 percent of their Modified Proctor maximum dry density then tested under saturated conditions, the laboratory data using a Mohr-Coulomb interpretation indicate effective stress parameters between 1.76 and 3.41 psi for c' and 26.1 and 30.2 degrees for ϕ'.

Consolidation testing performed on undisturbed samples of residual soils indicate an initial void ratio between 0.814 and 1.466. The average coefficient of consolidation was approximately 1.1 square feet per day. The test results indicate pre-consolidation pressures between 3.4 tsf and 8.3 tsf for the residual soils as indicated by the Casagrande graphical construction method for evaluating pre-consolidation pressures. The recompression indices ranged from 0.03 to 0.09, and the compression indices ranged from 0.31 to 0.78. Using an alternate interpretation based on the simplified graphical construction method, the test results indicate pre-consolidation pressures between 0.9 tsf and 2.6 tsf. The recompression indices ranged from 0.05 to 0.13, and the compression indices ranged from 0.31 and 0.77. It is not uncommon for different graphical interpretation methods to produce different results when evaluating consolidation test data. Further, interpretation of consolidation results in Piedmont residual soils is particularly challenging due to mode of formation, soil fabric effects and the more sand-like nature of the silty sands and non-plastic silts.

One-dimensional swell/collapse tests were performed on three undisturbed overburden samples in accordance with ASTM D4546-21 (Reference 2.5-247) to determine swell or collapse potential of residual soils after wetting. Using an overburden pressure of 0.25 tsf, one sample experienced a heave of -1.0 percent (negative value indicating downward compression) after adding water, while the other two samples experienced heave between 0.6 and 0.7 percent (positive value indicating upward swell). The measured swell pressures for the two samples that experienced positive heave ranged from 0.3 to 1.4 tsf. The test results indicate low swell or collapse potential of the samples.

The compaction characteristics of the in situ residual soils are discussed in Section 2.5.4.5.2.1. The consolidation and swell/collapse characteristics of the in situ residual soils are discussed in Section 2.5.4.10.3.

2.5.4.2.2.2 Stratum III (Partially Weathered Rock)

This stratum consists of residual materials with field SPT N-values of 100 bpf or greater. For lithologic borings drilled using sonic rigs, this stratum was identified based on field descriptions of the material and drilling difficulty. In the North Plant Complex, Stratum III materials exhibit a mean thickness of 19.2 ft. (5.9 m) and extend to an average base elevation of 764.5 ft. (233.0 m) NAVD 88. In the Middle Plant Complex, Stratum III materials exhibit a mean thickness of 9.6 ft. (2.9 m) and extend to an average base elevation of 762.5 ft. (232.4 m) NAVD 88. In the South Plant Complex, Stratum III materials exhibit a mean thickness of 6.3 ft. (1.9 m) and extend to an average base elevation of 774.0 ft. (235.9 m)

NAVD 88. The thickness of Stratum III varies between borings, with a minimum thickness of 0 ft. and a maximum thickness of 78.4 ft. (23.9 m). This degree of differential weathering is not uncommon in the Piedmont physiographic province. The engineering challenges associated with this differential weathering profile are addressed in the subsequent report sections.

No undisturbed samples were obtained from Stratum III due to their high relative density; therefore, relevant engineering properties were estimated based on empirical correlations and engineering judgment.

2.5.4.2.2.3 Stratum IV (Fractured Rock) and Stratum V (Sound Rock)

Stratum IV consists of cored rocks with RQD less than 50 percent. In the North Plant Complex, Stratum IV materials exhibit a mean thickness of 14.0 ft. (4.3 m) and extend to an average base elevation of 750.5 ft. (228.8 m) NAVD 88. In the Middle Plant Complex, Stratum IV materials exhibit a mean thickness of 5.2 ft. (1.6 m) and extend to an average base elevation of 757.5 ft. (230.9 m) NAVD 88. In the South Plant Complex, Stratum IV materials exhibit a mean thickness of 6.2 ft. (1.9 m) and extend to an average base elevation of 768.0 ft. (234.1 m) NAVD 88. The thickness of Stratum IV varies between borings, with a minimum thickness of 0 ft. and a maximum thickness of 51.3 ft. (15.6 m).

Stratum V consists of mostly intact gneiss and schist rocks with RQD values equal to or greater than 50 percent. The thickness of this stratum was not determined because the borings were terminated at varying depths within this stratum. Typically, the CR and RQD values were 100 percent, indicating a high quality and largely intact rock mass with soundness increasing with increasing depth.

As discussed in Section 2.5.4.2.1.3.11, the UCS of all the rock samples tested ranged between 1580 and 28,440 psi, with a mean of 14,324 psi and a standard deviation of 6170 psi. For the schist samples, the mean UCS was 7890 psi with a standard deviation of 4307 psi. For the gneiss samples, the mean UCS was 15,396 psi with a standard deviation of 5803 psi. The TCS of all the samples tested, as indicated by the peak deviatoric stress observed during testing, ranged between 6170 and 41,490 psi, with a mean of 20,347 psi and a standard deviation of 6772 psi. For the schist samples , the mean TCS was 14,020 psi with a standard deviation of 819 psi. For the gneiss samples, the mean UCS was 20,743 psi with a standard deviation of 6785 psi.

The elastic modulus of all the samples tested ranged between 4.09E+05 psi and 1.02E+07 psi, with a mean of 5.15E+06 psi and a standard deviation of 1.83E+06 psi. The Poisson's ratio of all the samples tested ranged between 0.01 and 0.19, with a mean of 0.08 and a standard deviation of 0.04. For the schist samples, the mean elastic modulus was 3.48E+06 psi with a standard deviation of 1.74E+06 psi, and the mean Poisson's ratio was 0.06 with a standard deviation of 0.01. For the gneiss samples, the mean elastic modulus was 5.25E+06 psi with a standard deviation of 1.80E+06 psi, and the mean Poisson's ratio was 0.08 with a standard deviation of 0.04.

As discussed in Section 2.5.4.2.1.3.12, the direct shear tests performed on natural, open joints and intact rocks using the multi-stage method indicate peak friction angles (with cohesion taken as zero) between 33.3 degrees and 79.3 degrees with a mean of 55.0 degrees and a standard deviation of 12.8 degrees, and residual friction angles (with cohesion

taken as zero) between 24.7 and 49.0 degrees with a mean of 35.8 degrees and a standard deviation of 5.4 degrees.

The measured UCS, elastic moduli and Poisson's ratio are generally within the typical range of reported values for gneiss and schist (Reference 2.5-268; Reference 2.5-321). Section 2.5.4.2.3 provides additional details on the use of the laboratory test data in developing static engineering properties of rock for the project.

2.5.4.2.3 Static Soil and Rock Engineering Properties

The static engineering properties of the five engineering strata identified were determined by laboratory testing and empirical correlations based on in situ test results, as well as comparison to values in published literature and engineering judgment. Because of the similarities in subsurface conditions for the identified strata, the provided parameters represent the corresponding strata at all three Plant Complexes.

For Stratum I and II (residual soils), the field SPT N-values were corrected for hammer energy, borehole diameter, rod length, sampling method, and overburden pressure effects to establish hammer energy corrected N_{60}-values and fully corrected $(N1)_{60}$-values (Reference 2.5-267). For empirical estimates of engineering properties in these strata, a lognormal distribution was used for the SPT N-values, with the lower bound, best estimate, and upper bound values taken as 5th percentile, 50th percentile, and 95th percentile, respectively. These N-values were then used in empirical correlations (Reference 2.5-268; Reference 2.5-269; Reference 2.5-270; Reference 2.5-271; Reference 2.5-272; Reference 2.5-273) for estimation of the relevant static soil properties, and the results were compared against the published literature and laboratory test results where applicable (Reference 2.5-274; Reference 2.5-275; Reference 2.5-276; Reference 2.5-277; Reference 2.5-264; Reference 2.5-265; Reference 2.5-266; Reference 2.5-278; Reference 2.5-279; Reference 2.5-280) to establish the final lower bound, best estimate, and upper bound values.

For Stratum III, the engineering properties were based on empirical correlations (Reference 2.5-268; Reference 2.5-269; Reference 2.5-270; Reference 2.5-271; Reference 2.5-273) and published literature (Reference 2.5-274; Reference 2.5-266; Reference 2.5-278) due to lack of laboratory tests in this stratum (which was too dense to sample but too weak to core).

For Stratum IV and Stratum V, the engineering properties were based on laboratory test results, empirical correlations and published literature. For Stratum IV, based on review of the conditions indicated on the boring logs and using the Geologic Strength Index (GSI) criteria as outlined in Hoek (Reference 2.5-321), the rock surface conditions were judged to range from "Poor" to "Fair," and the rock structure was judged to range from "Disintegrated" to "Blocky/Disturbed/Seamy.". This resulted in a GSI range of 14 to 45. For Stratum V, the rock surface conditions were judged to range from "Fair" to "Very Good," and the rock structure was judged to range from "Blocky" to "Intact/Massive." This resulted in a GSI range of 44 to 95. The static engineering properties were then determined using the intact rock properties (as measured from the laboratory tests) to calculate equivalent Mohr-Coulomb rock mass parameters for strength and rock mass deformation moduli as discussed in Hoek (Reference 2.5-321). Lower bound, best estimate, and upper bound values were established based on the weaker schist and the range of GSI values, as well as consideration for the variability in the strength and deformation properties of the rock samples.

Table 2.5-64 summarizes the static properties for Stratum I, II and III (residual soils and PWR); Table 2.5-65 summarizes the static properties for Stratum IV and V (fractured and sound rock). The static properties for structural backfill are discussed in Section 2.5.4.5.2.2. The best estimate engineering properties (strength and deformation) of the rock mass at the Project site, conservatively based on the weaker schist, indicate that the rock mass is stronger and less compressible than the structural backfill. Structural backfill is used as the bounding scenario for the static stability analyses described in Section 2.5.4.10.1 and 2.5.4.10.2; therefore, the Project site is expected to meet the static stability requirements (bearing capacity and settlement) with the proposed reactors supported on either structural backfill or bedrock. Ground improvement techniques for the various proposed reactor technologies are described in Section 2.5.4.12.

2.5.4.2.4 Dynamic Soil and Rock Engineering Properties

As part of the dynamic analyses discussed in Section 2.5.4.7, representative shear wave velocity (V_S) and compression wave velocity (V_P) profiles were determined, incorporating the results from downhole, P-S suspension logging, and SASW surveys as well as laboratory testing. The best-estimate wave velocity profiles from the SASW surveys and P-S suspension logging were used to establish the range of low-strain dynamic elastic property recommendations for use in more routine engineering calculations. The best-estimate V_S and V_P profiles used in determining the low-strain dynamic elastic properties are captured in Figure 2.5-129 and Figure 2.5-130, respectively. The SASW surveys generally indicate a slower wave velocity profile compared to the P-S suspension logging results; therefore, the dynamic properties associated with the SASW survey results are more conservative. The calculated low-strain dynamic elastic properties using the P-S logging and SASW velocities are summarized in Table 2.5-66 and 2.5-67, respectively.

While the values presented in Tables 2.5-66 and 2.5-67 are based on the best-estimate wave velocity profiles, the dynamic analyses described in Section 2.5.4.7 consider the variability of these parameters through randomization of the layer thicknesses, as well as shear modulus and damping curves as a function of shear strain.

2.5.4.3 Foundation Interfaces

The planned finish plant grade is at an elevation (EL.) of approximately 810 ft. (247 m). The reactor base elevations for the six different technologies under consideration are summarized below:

- EL. = 766 ft. (233.5 m) for Westinghouse (embedment depth = 44 ft. [13.4 m])
- EL. = 727 ft. (221.6 m) for NuScale (embedment depth = 83 ft. [25.3 m])
- EL. = 724 ft. (220.7 m) for Holtec (embedment depth = 86 ft. [26.2 m])
- EL. = 696.8 ft. (212.4 m) for TerraPower (embedment depth = 113.2 ft. [34.5 m])
- EL. = 695 ft. (211.8 m) for X-energy (embedment depth = 115 ft. [35.1 m])
- EL. = 685 ft. (208.8 m) for GVH (embedment depth = 125 ft. [38.1 m])

Based on the above-mentioned base elevations and the conditions encountered at those elevations, all reactor technologies except Westinghouse are anticipated to bear on competent rock. The subsurface investigation indicates the potential for the presence of residual soils, PWR, and/or fractured rock at or below the Westinghouse reactor-bearing elevation. For the Westinghouse technology, any pockets of weaker residual soils or PWR encountered at the bottom of the base mat excavation would be over-excavated and replaced with structural backfill or lean concrete. Static and dynamic stability of the reactor base mats is discussed in Section 2.5.4.10, while techniques to improve the ground below the reactor base mats are described in Section 2.5.4.12.

2.5.4.3.1 Subsurface Uniformity

Soil-structure interaction and foundation design are a function of the uniformity of the soil and rock below the structures. As discussed in Section 2.5.4.2.2, differential weathering has resulted in variable subsurface conditions in the overburden residual soils and PWR. As discussed in Section 2.5.4.3, all reactor technologies except Westinghouse are anticipated to be founded on competent rock due to their embedment depths. All residual soils and non-uniform PWR will be excavated and removed from below the reactor base mats and replaced with structural backfill or lean concrete as discussed in Section 2.5.4.12. The best estimate V_S profiles as discussed in Section 2.5.4.2.4 indicate V_S greater than 2000 feet per second (ft/s) (610 meters per second [mps]) below the highest proposed reactor base-mat elevation of 766 ft. (233.5 m) for the Westinghouse reactor. The minimum V_S for structural backfill if required below the reactor base mat is 1000 ft/s (305 mps) per Section 2.5.4.5.2.2.

As an additional check, the layer dips between borings were evaluated at the site. For subsurface layers that dip less than 20 degrees from horizontal, a generic analysis using horizontal layers is applicable as described in NUREG/CR-0693. The analysis indicates dip angles of less than 20 degrees from horizontal in the fractured rock and sound rock layers in all cases except two instances (out of the 1080 boring pairs considered for all three Plant Complexes, based on 16 borings in each Plant Complex area resulting in 360 unique combinations per complex). These dip angles exceeding 20 degrees were encountered between adjacent borings located near each other. At these close spacings, relatively small differences in the subsurface conditions due to differential weathering exaggerate the calculated dip values and thus can be disregarded relative to the assessment of site uniformity because the values are not considered representative of the subsurface conditions across the site.

Once the final reactor technology and site are selected, additional closely spaced borings and geophysical explorations will be performed in the safety-related structure footprints to further evaluate subsurface uniformity.

2.5.4.3.2 Coefficient of Interface Sliding Friction

Unified Facilities Criteria (UFC) (Reference 2.5-280) provides recommendations for ultimate coefficient of interface static sliding friction between dissimilar materials. For mass concrete on sound rock, the friction factor is given as 0.7. For mass concrete on clean gravel, gravel-sand mixtures, or coarse sand, the ultimate coefficient of interface static sliding friction is between 0.55 and 0.60.

Duncan and Mokwa (Reference 2.5-270) recommend 0.76 x ϕ (soil friction angle) for a conservative estimate of the ultimate concrete-sand interface friction angle. For PWR with a

best-estimate friction angle of 43 degrees per Section 2.5.4.2.3, this results in a coefficient of 0.64. For structural backfill with a minimum friction angle of 40 degrees per Section 2.5.4.5.2.2, this results in an ultimate coefficient of interface static sliding friction of 0.59.

Base mats of the safety-related structures will not be founded on the in situ residual soils (i.e., Stratum I or Stratum II); therefore, no ultimate coefficient of interface static sliding friction values are provided for those strata.

2.5.4.4 Geophysical Surveys

Geophysical data collected at the site included borehole geophysical surveys (Reference 2.5-281) using suspension P-S velocity logging and downhole wave velocity profiling, as well as surface geophysics using SASW surveys and ER surveys. Additional data were also collected in the P-S suspension velocity logging boreholes, including natural gamma, dual induction (conductivity), long- and short-normal resistivity, three-arm caliper, acoustic televiewer, and borehole deviation.

The location of each test is captured in Figure 2.5-119 through Figure 2.5-121 for the North, Middle, and South Plant Complexes, respectively. Figure 2.5-131 presents the V_S obtained from the different methods (including laboratory measurements for comparison) for all the complexes, with the range of the proposed reactor base mat elevations shown for reference. The V_S are also captured separately in Figures 2.5-132 through 2.5-134 for the North, Middle, and South Plant Complexes, respectively.

The details of suspension P-S velocity logging, downhole V_S profiling, SASW surveys, and ER surveys are provided below.

2.5.4.4.1 Suspension P-S Velocity Logging

Suspension P-S velocity logging was performed in accordance with GEOVision procedure for OYO P-S Suspension Seismic Velocity Logging, Rev. 1.5 (Reference 2.5-282). P-S logging measures S-waves and P-waves generated by a source on the P-S logging probe within the borehole to determine wave travel times upward past multiple receivers on the probe and subsequently S- and P-wave velocities of the subsurface materials. The receivers that detect the waves and the source that generates the waves are moved as a unit in each boring, which produces a relatively constant amplitude signal at all depths. The testing is performed in a fluid-filled borehole, with both V_S and V_P measurements taken at 1.64-ft. (0.5-m) intervals.

P-S suspension logging velocity data were collected in boreholes B-1A, B-3/B-3A, B-5, B-6, B-8/B-8A, B-10/B-10A, B-11A/B-11B, B-13/B-13A, and B-15A/B-15B. Boreholes B-1, B-3/B-3A, and B-5 are in the North Plant Complex. B-6, B-8/B-8A, and B-10/B-10A are in the Middle Plant Complex, and B-11A/B-11B, B-13/B-13A, and B-15A/B-15B are in the South Plant Complex. The survey in Borehole B-8/B-8A was extended to a depth of 588.9 ft. (179.5 m) below the existing ground surface to allow for deep shear and compression wave profiling in at least one of the boreholes.

As part of the P-S data collection, additional data were also collected in the boreholes, including natural gamma, dual induction (conductivity), long- and short-normal resistivity, single-point resistance, three-arm caliper, spontaneous potential, ATV, and borehole deviation. Natural gamma (Reference 2.5-283) records the amount of natural gamma

radiation emitted by the materials surrounding the borehole. Natural gamma sensors were onboard the dual induction, three-arm caliper, and E-log probes. Dual induction (conductivity) (Reference 2.5-284) uses an electromagnetic induction probe consisting of transmitter and receiver coils to create eddy currents in the subsurface materials that give rise to a secondary electromagnetic field. The secondary electromagnetic field generates an alternating electrical current that is measured by the receiver coils and is proportional to the conductivity of the formation. Formation conductivity is the reciprocal of formation resistivity. Long- and short-normal resistivity measurements are made via a low-frequency, bi-directional electric current from a source electrode on the probe and returns through the formation to the probe. Potentials from this current flow are measured on various electrodes on the probe with respect to a voltage reference located at the surface. These measurements are converted to apparent formation resistivities within the probe and transmitted to the surface. Three-arm caliper (Reference 2.5-285) measurements use caliper logs to record borehole diameter at different depths. Changes in borehole diameter are related to boring construction, such as casing or drilling bit size, and to fracturing, caving, or breakouts along the borehole wall. The caliper tool consists of three arms that are spring-loaded to contact the borehole sides. The movement of the arms is converted into a voltage recorded by the probe. ATV (Reference 2.5-286) provides a continuous and oriented 360-degree view of the borehole wall from which the character, relation, and orientation of lithologic and structural planar features, such as discontinuity orientations; dip directions, and aperture widths; and fracture frequency, can be defined. The televiewer also measures borehole inclination and deviation from vertical using an accelerometer in the probe.

2.5.4.4.2 Downhole Velocity Tests

Downhole seismic testing was performed in boreholes B-3/B-3A (North Plant Complex), B-8/B-8A (Middle Plant Complex), and B-13/B-13A (South Plant Complex) in accordance with ASTM D7400/D7400M-19 (Reference 2.5-287). Downhole logging obtains direct measurements of S- and P-waves generated from an elastic-accelerated, high-energy impulsive surface source. These measurements are used to determine wave travel times to a downhole receiver and subsequently S- and P-wave velocities of the subsurface materials. The logging system orients the downhole receiver parallel to the axis of excitation at the surface to ensure that signals received at the downhole geophones are of maximum amplitude and are not subject to errors in travel time caused by incorrect phase of first arrival picks.

The boreholes were cased and pumped dry prior to testing, with both V_S and V_P measurements taken at 3.28 ft. (1.0 m) intervals. The downhole velocity test data were interpreted using a layered approach for comparison to the P-S suspension logging results in the same boreholes.

2.5.4.4.3 Spectral Analysis of Surface Waves Arrays

Twelve SASW arrays were performed across the Project site, with four arrays at each Plant Complex (North, Middle, and South). SASW is a nondestructive and nonintrusive seismic method that uses the dispersive nature of Rayleigh-type surface waves propagating through layered materials to determine the S-wave velocity profile. Dispersion of the surface waves occurs because of changes in stiffness of the soil or rock layers with depth. A high-frequency surface wave that propagates with a short wavelength stresses material only near the exposed surface and thus only samples the properties of the shallow, near-surface material.

A low-frequency surface wave with a long wavelength stresses material to a greater depth and thus samples the properties of both shallow and deeper materials. Spectral analysis is used to separate the waves by frequency and wavelength to determine the composite experimental (field) dispersion curve. An analytical, forward-modeling procedure is then used to theoretically match the field dispersion curve with a one-dimensional layered system of varying layer stiffnesses and thicknesses. The profile that generates a theoretical dispersion curve that most closely matches the field dispersion curve is presented as the S-wave velocity profile.

SASW testing in the field involved generating surface waves at one point on the surface and measuring the motions perpendicular to the surface created by the passage of the waves past multiple receivers (geophones). The receivers were arranged on the surface along a single radial path from the source. Successively longer spacings between the source and receivers were used to measure progressively longer wavelengths. The number and progression of the receiver spacings was selected to measure progressively longer wavelengths and to produce significant overlap of the individual dispersion curves to enhance test reliability. Hammers or metal plates were generally used to generate surface waves for shorter receiver spacings, and a large mobile vibrator was used for larger receiver spacings.

SASW differs from P-S logging and downhole velocity testing in that it is a surface-wave based method that provides a non-destructive, area-based assessment. P-S logging and downhole velocity testing provide depth-specific, interval-based measurements. As such, it is not considered atypical for the different methods to produce varying subsurface profiles.

2.5.4.4.4 Electrical Resistivity Arrays (Not Safety-Related)

Field ER testing was performed using four-pin Wenner resistivity arrays to determine the in-place ER of the subsurface materials at the site. Testing followed ASTM G57-20 (Reference 2.5-288) and was completed along two traverses at each complex. For each traverse, resistance and apparent resistivity measurements were recorded at electrode spacings (A-spacings) of 1, 1.5, 2, 3, 4.5, 7, 10, 15, 20, 30, 50, 70, 100, 150, 200 ft. (0.3, 0.5, 0.6, 0.9, 1.4, 2.1, 3.0, 4.6, 6.1, 9.1, 15.2, 21.3, 30.4, 45.7, and 61.0 m).

2.5.4.4.5 Geophysical Characteristics

Figure 2.5-131 presents the shear wave velocities obtained from the different methods (including laboratory measurements for comparison) for the three complexes, with the proposed reactor base mat elevations shown for reference. The shear wave velocities are also captured separately in Figures 2.5-132 through 2.5-134 for the North, Middle, and South Plant Complexes, respectively.

In general, V_S and V_P determined from the suspension P-S logging tests in geophysical boreholes near the SASW arrays were found to be higher than V_S and V_P determined from the SASW arrays. This can be attributed to the SASW involving a larger rock mass volume than the localized downhole tests. Based on the proposed reactor base mat elevations, all technologies except (Westinghouse at EL. 766 ft [233.5 m]) are underlain by geomaterials with V_S greater than 1000 ft/s (305 m/s). Section 2.5.4.12 discusses techniques for ground improvement.

Section 2.5.4.7 provides more specific discussions on the use of the geophysical measurements for response of soil and rock to dynamic loading.

2.5.4.5 Excavation and Backfill

A combination of temporary excavation (cut slopes), fill slopes, and retaining structures will be used to facilitate construction of below-grade portions of the plant. The materials anticipated to be excavated are overburden residual soils, PWR, fractured rock, and sound rock.

Based on the existing site elevations, significant cuts and fills are anticipated to achieve the proposed finished plant grade. The planned final plant grade is at an elevation of approximately 810 ft. (247 m). The reactor base elevations for the six different technologies under consideration are 766 ft. (233.5 m) for Westinghouse, 727 ft. (221.6 m) for NuScale, 724 ft. (220.7 m) for Holtec, 697 ft. (212.4 m) for TerraPower, 695 ft. (211.8 m) for X-energy, and 685 ft. (208.8 m) for GVH. Depending on the technology selected, the reactor building excavation varies between approximately 44 ft. (13.4 m) and 125 ft. (38.1 m) in depth from finished grade elevation.

Because a reactor technology has not yet been selected and final site grading plans have not been developed, this section provides a general discussion on the anticipated extent of excavations and methods, backfill sources and quality control, and compaction characteristics of backfill.

Stability of permanent excavations, fill slopes and retaining structures are addressed in Section 2.5.5.

2.5.4.5.1 Excavation Extents and Methods

2.5.4.5.1.1 Excavations in Soil and Partially Weathered Rock

Temporary excavations up to 20 ft. (6 m) in depth can typically be graded by open cut in accordance with Occupational Health and Safety Administration (OSHA) 1926, Subpart P – Excavations guidelines (Reference 2.5-319). Limitations of the shallow, open cut slopes are as follows:

- For unsaturated residual soils, typically classified as Type C soil, the cut slopes are no steeper than 1.5 horizontal (H):1.0 vertical (V).
- For unstable rock, such as PWR and fractured rock in dry conditions, typically classified as Type B, the slopes are no steeper than 1.0H:1.0V.
- For unstable rock, such as PWR and fractured rock in saturated or submerged conditions, typically classified as Type C, the slopes are no steeper than 1.5H:1.0V.

Alternatively, the infinite slope theory can be used to approximate the maximum slopes for temporary excavations in residual soils and PWR. For partially saturated soils (i.e., no porewater pressure), and conservatively assuming apparent cohesion of zero (this is conservative because partially saturated residual soils tend to exhibit matric suction that increases their shear strength), the factor of safety (FS) for the slope, according to the U.S. Army Corps of Engineers (Reference 2.5-320) can be calculated as shown in Equation 42.5.4-1:

$$\mathrm{FS} = \frac{\tan(\phi')}{\tan(\beta)} \qquad \text{(Equation 2.5.4-1)}$$

Where:

1) ϕ' is the Effective stress friction angle (deg)
2) β is the slope angle (deg) = $\text{atan}\left(\frac{V}{H}\right)$, with V = vertical rise and H = horizontal run

Based on Section 2.5.4.2.3, the best-estimate of effective stress friction angle is 31 degrees for the upper residual soils (Stratum I), 36 degrees for the lower residual soils (Stratum II), and 43 degrees for the PWR (Stratum III). In the infinite slope theory formulation, FS = 1.0 (unity) implies a stable slope; however, to account for variations in soil properties, FS = 1.1 is targeted for temporary excavations herein, resulting in a maximum slope of 1.8H:1.0V for Stratum I, 1.5H:1.0V for Stratum II, and 1.2H:1.0V for Stratum III. These slopes are generally flatter than indicated by OSHA guidelines; however, as previously noted, partially saturated residual soils often exhibit apparent cohesion (Reference 2.5-266; Reference 2.5-289), which if accounted for would slightly lower the FS determined using the infinite slope method. Final temporary excavation slope dimensions will be determined once a reactor technology is selected and final grading plans are developed at the construction permit or license application phase. Regular inspections of temporary excavations and the adjacent areas will be performed to identify potentially hazardous conditions.

Deeper excavations will likely require earth-retaining system(s). Alternatively, earth-retaining system(s) can be used to reduce the lateral extent of excavations. Commonly used methods in the Piedmont physiographic province include soil nail walls, soldier piles and timber lagging, and secant or tangent walls. If needed, earth-retaining systems will be designed once a reactor technology is selected and final grading plans are developed at the construction permit or license application phase.

2.5.4.5.1.2 Excavations in Rock

Stable sound rock is typically graded using a maximum slope at or near vertical. A typical P-wave velocity of 3500 ft/s is the boundary between conventional means and ripping, and 6000 ft/s is the boundary between ripping and blasting (Reference 2.5-273). Figures 2.5-135 through 2.5-137 capture the measured compression wave velocities from suspension P-S logging and SASW surveys at the North, Middle, and South Plant Complexes, respectively.

The compression wave velocities from suspension P-S logging for the North and Middle Plant Complexes indicate that the rock excavation for the Westinghouse reactor (base elevation of 766 ft. [233.5 m]) can generally be achieved using conventional means or ripping, whereas the other five reactor technologies (base elevations ranging from 727 ft. [221.6 m] to 685 ft. [208.8 m]) likely require blasting. The compression wave velocities from suspension P-S logging for the South Plant Complex indicate rock blasting is likely for all six technologies. On the other hand, SASW results indicate that the rock excavation for all six proposed technologies can be achieved using conventional means or ripping. This difference is attributed to the global versus local nature of SASW testing compared to suspension P-S logging, and differential weathering resulting in variable subsurface conditions even within short horizontal distance, which is common in the Piedmont physiographic province. Variability in excavation difficulty is anticipated during construction.

If required, typical blasting methods include presplit and production blasting. Production blasting uses large explosive, widely spaced charges that are designed to fragment a large amount rock between the existing slope face and the blasthole. This method is the most efficient way to

remove large rock burdens but typically creates radial fractures that reduce the strength of the remaining rock mass and increase susceptibility to slope raveling and rockfall. Controlled blasting is generally used for removing material along the final slope face, or in some cases, to create an artificial fracture along the final cut slope to prevent radial fractures caused by production blasting (Reference 2.5-290). The use of rock bolts or retaining structures (such as secant walls) may be required to stabilize the near-vertical rock slope faces or to facilitate reactor construction.

Geologic mapping will be needed as the excavation proceeds. In addition, the rock excavations will require monitoring for movement during and after the excavation.

2.5.4.5.2 Backfill Sources

2.5.4.5.2.1 On-Site Residual Soils

Residual soils will be excavated as part of site grading and/or power block construction. The compaction and strength characteristics of residual soils were evaluated via a series of Modified Proctor and triaxial tests. Eleven samples were tested to evaluate their compaction characteristics using the Modified Proctor method, and three samples were tested using the CU triaxial method to evaluate their strength characteristics at the as-compacted densities.

The maximum dry density of the samples tested ranged from 101.8 to 125.9 pcf, with optimum moisture contents between 9.3 and 23.4 percent. In general, the high-plasticity silt (MH) samples exhibited lower maximum dry density and higher optimum moisture content. The results also show that the natural moisture content of the samples is at times much greater than the optimum moisture content, indicating that significant moisture conditioning may be required prior to the use of residual soils as non-safety-related backfill.

CU triaxial tests were performed on three bulk samples remolded to 95 percent of the Modified Proctor maximum dry density. Because the maximum shear stress was not clearly defined (i.e., the samples did not show a clear peak even at ultimate strain), alternate interpretations of the Mohr-Coulomb parameters c' (effective stress cohesion) and ϕ' (effective stress friction angle) were performed at reference strain levels of 5 and 10 percent. A Mohr-Coulomb envelope with c' = 200 pounds per square foot (psf) and ϕ' = 30 degrees was selected as the best estimate for all interpretations at various strain levels. This estimate can be used for stability analyses of earth structures (such as new fill slopes) constructed using the excavated residual soils compacted to 95 percent of their Modified Proctor maximum dry density, with a best estimate total unit weight of 130 pcf.

The parameters described above are generally consistent with the typical values of c' and ϕ' for compacted soils from the literature. The Federal Highway Administration (2017) (Reference 2.5-291) indicates that for SM, ML, and CL soils, the best-estimate of c' under saturated conditions is 400 psf, 200 psf, and 300 psf, respectively, with best estimate ϕ' of 34 degrees, 32 degrees, and 28 degrees, respectively.

Compacted residual soils are commonly used as construction materials; however, Blight and Simmons (2012) (Reference 2.5-292) indicate there are various challenges associated with compaction of residual soils, including:

- Relatively high in situ moisture contents

- Soil structures that are lightly cemented
- Weathered particles that break down under compaction effort
- Minerals that are affected by wetting and drying

Because the parent rock is usually variable in composition, the degree of weathering is also variable, which can create challenges with selection of representative samples for testing and quality control during placement and compaction. Additionally, drying of the soil from the in situ moisture content can change both its index and physical properties, including compaction properties. Further, moisture control during compaction has important implications on the compacted soil behavior. Compacted soils in a partially saturated condition, compacted well dry of the optimum moisture content, have a potential to collapse when wetted (Reference 2.5-292). Alternatively, as the water content of compacted residual soils reaches an equilibrium with the surrounding environment (which often means an increase in water content after placement), a reduction in strength and volume change can occur due to loss of suction/surface tension between particles with increasing water content.

More specifically for Piedmont residual soils, the mica content has an effect on shear strength and compressibility characteristics of compacted fills. Studies have shown that the presence of mica can alter the soil packing to increase compressibility and reduce compacted densities and strength (Reference 2.5-293; Reference 2.5-294; Reference 2.5-266; Reference 2.5-295; Reference 2.5-296). In some cases, ultimate compression (settlement) has also been shown to increase with the degree of saturation (Reference 2.5-293).

The inherent variability of Piedmont residual soils and their sensitivity to moisture and mica content create challenges with the selection of representative samples for testing and quality control during placement and compaction and their use as structural backfill where strength and compressibility are of primary concern. This is also evident from the relatively low strength parameters indicated by the previously described triaxial tests performed on residual soil samples compacted to 95 percent of the Modified Proctor maximum dry density. As such, the use of residual soils as backfill will be limited to non-safety-related areas of the Plant Complex, provided screening and compaction control techniques are implemented.

2.5.4.5.2.2 Structural Backfill

Some of the reactor technologies may be founded on structural backfill in cases where unsuitable materials are encountered below the base mat that require excavation and replacement with compacted structural backfill. A structural backfill source had not yet been identified at the time of the ESPA investigation. Granular structural backfill is expected to consist of Unified Soil Classification System soil type GW (well-graded clean gravels, gravel-sand mixtures) to provide high-strength, low-deformation characteristics and compactability. Lean concrete is also suitable for use as structural backfill.

Based on published literature (Reference 2.5-297), past experience with structural backfill materials, and the project requirements, the following static properties are assumed for granular structural backfill. These properties will be reevaluated and verified during the final design phase once the reactor technology is selected and a backfill source identified. Other materials may also be suitable for use as structural backfill based on additional testing and final technology selection / design requirements.

- A minimum dry unit weight of 125 pcf

- A minimum total unit weight of 135 pcf
- A minimum effective stress friction angle of 40 degrees
- A minimum elastic modulus of 2000 kips per square foot (ksf)
- A minimum shear wave velocity of 1000 ft/s

2.5.4.5.3 Compaction Specifications, Monitoring, and Quality Control

Fill placement and compaction control procedures are addressed in a technical specification prepared during the detailed design stage of the project, which includes requirements for suitable fill, testing to address potential material variations, and in-place density and moisture content testing frequency. The technical specification also includes requirements for an on-site testing laboratory for quality control, especially material gradation and plasticity characteristics, the achievement of specified moisture-density criteria, fill placement/compaction, and other requirements to ensure that the fill operations conform to the earthwork specifications for the project. The soil testing company is required to be independent of the earthwork contractor and to have an approved quality program. A sufficient number of laboratory tests are required to ensure that variations in the fill material are accounted for. A trial fill program is normally conducted to determine an optimum number of compactor passes, the maximum loose lift thickness, and other relevant data to achieve the specified moisture-density criteria.

Piedmont residual soils commonly have less than 5 percent organic content by weight, a maximum particle size of 3 in. (76 mm) and consist of materials classified as either SC, SM, SP, SW, GC, GM, GP, or GW per ASTM D2487. Based on past experience with similar soils and laboratory test results from the ESP investigation, the excavated residual soils used as non-structural backfill in non-safety-related areas of the plant are expected to be classified as SM, ML, or CL, with a plasticity index no greater than 15. Soils classified as plastic silts (MH), high-plasticity clays (CH), organic silts (OL), organic clays (OH), or highly organic clays/peat (PT) are not suitable for use as backfill.

Fill is typically placed in maximum 8-in. (203-mm)-thick horizontal, loose lifts, and compacted to at least 95 percent of maximum dry density per ASTM D1557 (Reference 2.5-253), the Modified Proctor test procedure, at moisture contents within 2 percent of its optimum moisture. The degree of compaction is typically increased to a minimum of 98 percent of the Modified Proctor maximum dry density for the upper 1 ft. (0.3 m). Fill placed in landscape, non-structure support, and non-pavement areas is typically compacted to at least 90 percent of the Modified Proctor maximum dry density.

Excavated SM, ML, or CL soils can be difficult to compact if too wet or too dry. As a result, the ability to use such soils depends on their moisture contents. Soils that are too wet to properly compact can be dried by aeration or mixed with an additive such as cement or lime to stabilize the soil and facilitate compaction.

2.5.4.6 Groundwater Conditions

2.5.4.6.1 Groundwater Measurements and Elevations

Section 2.4.1.2 provides detailed descriptions of the hydrogeologic and groundwater conditions.

Per Section 2.4.1.2, the water table interface at the Project site generally occurs within the overburden/PWR and upper 10 to 20 ft. (3.0 to 6.1 m) of the bedrock. For foundation stability analyses, the groundwater levels (GWT) were further evaluated by reviewing measurements from the monitoring wells across the site, as well as considering the Probable Maximum Flood (PMF) elevation provided in Section 2.4.3.5, given as elevation 747.9 ft. (227.9 m).

The saturation state of the residual soils was assessed by comparing GWT (taken as the highest reading from each well) and PMF elevation with the elevation of the top of PWR as described in Section 2.5.4.2.2. The GWT is below the top of PWR in all wells, indicating that the residual soil is unsaturated, except for wells W-7, W-11, W-12, W-14, and W-15 (and for W-12 and W-14, the GWT is near the residual soil – PWR interface). Similarly, the PMF elevation is below PWR in all wells except W-15. No SPT data were available for Wells W-7, W-11, W-12, W-14, and W-15; therefore, the elevation of the top of PWR at these locations is uncertain. As such, the residual soils at the Project site are judged to be in a predominantly partially saturated state.

Pavement and structures following construction will likely reduce groundwater recharge, potentially affecting groundwater baseflow discharge into nearby perennial creeks and Belews Lake. Unpaved areas covered by permeable gravel or fill may receive increased recharge, countering effects of increased impermeable surfaces. As a whole, the on-site residual soils are expected to remain partially saturated as long as adequate drainage measures are provided during and after construction of the reactors to prevent net positive water infiltration into the soils in the power block. Localized areas of saturated residual soils may occur near the residual soil – PWR interface, but they are not anticipated to affect overall site/foundation stability. The groundwater level for stability considerations was taken as at the interface of residual soils and PWR.

Additional groundwater measurements from the existing monitoring wells, as well as data from additional wells that may be installed as part of the final site investigation after a reactor technology is selected, will be used for assessment of groundwater conditions during the final design phase.

2.5.4.6.2 Construction Dewatering

Even though the water table is typically at or below the interface of residual soils and PWR and the subsurface materials are relatively low in permeability, temporary dewatering is expected during excavation and construction of the power block and potentially other building foundations. The amount of dewatering required to support the construction of the new advanced reactor plant is unknown because the reactor technology has not been selected.

The dewatering system will likely consist of either deep bedrock wells or sump pumping from a system of shallow excavations to collect groundwater and rainwater, which is then pumped to a discharge point away from the excavation. A series of groundwater monitoring wells are typically used to monitor the effectiveness of the dewatering system in reducing the groundwater level. Some of the existing monitoring wells may be used to monitor the effectiveness of dewatering. Additional monitoring wells will likely be installed to provide adequate monitoring on all four sides of the excavations.

The general sequence of excavation and dewatering for the reactor is expected as follows. First, the overburden soils are removed, then the excavation proceeds down through PWR, fractured rock, and/or sound rock until the planned reactor base elevation is reached. A gravity-based

system such as sumps and sump pumps in the bottom of the excavation can be used to keep the groundwater elevation below the floor of the excavation. Alternatively, dewatering wells can be installed around and within the excavation area. If dewatering wells are used, effluent from the dewatering systems will most likely need to be routed through a temporary storage pond or holding tanks. The required pumping rate will partially depend on when the dewatering system is implemented and how fast the excavation proceeds downward. Section 2.4.12 estimates a dewatering system designed for the deepest foundation excavations will likely require temporary pumping between 57 and 370 gallons per minute. Stormwater runoff into the excavations will also need to be considered for final dewatering design to prevent intense rain events from creating ponding in the excavations.

Following decommissioning of the dewatering system, the groundwater will attempt to return to a natural condition. Pavement and structures will likely reduce groundwater recharge, potentially affecting groundwater baseflow discharge into nearby perennial creeks and Belews Lake. Unpaved areas covered by permeable gravel or fill may receive increased recharge, countering effects of increased impermeable surfaces.

For reactor technologies sited below the groundwater table, permanent dewatering using wells may be required if the reactor structure is unable to resist hydrostatic uplift pressures. As an example, the GVH reactor technology has a foundation depth of 125 ft. (38.1 m), corresponding to a base mat bottom elevation of 685 ft. (208.8 m), relative to the proposed finished plant grade elevation of 810 ft. (247 m). For the North Plant Complex, the groundwater level from the monitoring wells was observed between approximate elevation 725 ft. (221 m) and 780 ft. (237.7 m), which would result in a hydrostatic pressure of (780 –685 ft.) x 62.4 pcf (unit weight of water) = 5928 psf for the upper-bound scenario and (725 – 685 ft.) x 62.4 pcf = 2496 psf for the lower-bound scenario.

2.5.4.7 Response of Soil and Rock to Dynamic Loading

The seismic history of the area and the Project site, including any prior history of seismicity, is addressed in Sections 2.5.2.1 and 2.5.3.3. Liquefaction is addressed in Section 2.5.4.8. Detailed descriptions of the development of the GMRS and the associated PSHA are included in Section 2.5.2. Additional descriptions on site-specific geophysical methods and results are discussed in Section 2.5.4.4.

2.5.4.7.1 Wave Velocity Profiles

The Project site is divided into three main areas: the North, Middle, and South Plant Complexes. As part of the geotechnical site investigation, boreholes were drilled to depths of up to 300 ft. (91 m) in the North and South Plant Complexes, and up to 600 ft. (183 m) in the Middle Plant Complex.

To characterize dynamic soil properties, a combination of geophysical methods was employed:

- Suspension P-S logging was conducted in 15 boreholes, resulting in 9 velocity profiles (three per Plant Complex).
- Downhole velocity measurements were performed in 6 boreholes, consolidated into 3 profiles (one per Plant Complex).
- SASW testing was carried out using 12 arrays (four per Plant Complex).

Sections 2.5.4.2.1.4 and 2.5.4.4 provide additional details on geophysical methods and data interpretation.

Figure 2.5-138 compares V_S profiles (by depth) derived from various data sources, including P-S suspension logging profiles (solid lines), SASW profiles (dashed lines), downhole velocity profiles (black dash-dotted lines), and laboratory Fr-Fr resonant column measurements (red square symbols). As shown, the suspension logging and downhole data exhibit consistent large velocity gradients near the soil-rock transition zone at approximately 50 ft. (15.2 m) depth, with rock V_S ranging from 8000 to 10,000 ft/s (2438 to 3048 m/s). The depth of the velocity gradient observed in the suspension log data corresponds closely with the depth to the top of rock identified in the boring logs, indicating agreement between geophysical and geologic interpretations. In contrast, SASW data indicate a thicker layer of PWR with lower V_S of 2000 to 2500 ft/s (610 to 762 m/s), and underlying rock V_S of 6000 to 8000 ft/s (1829 to 2438 m/s). The suspension P-S logging results also generally indicate higher V_S compared to the SASW results. This difference is attributed in part to the global versus local nature of SASW testing compared to suspension logging.

Most Fr-Fr laboratory results are consistent with suspension and downhole data, though three samples (from borings W-1, B-6, and DW-11) show lower velocities between 1200 and 2500 ft/s (366 to 762 m/s), attributed to their location in upper, more fractured rock layers.

2.5.4.7.1.1 Suspension P-S Logging Profiles

Suspension P-S logging data from boreholes across the three Plant Complexes are color-coded in Figure 2.5-139a: blue for the North Plant Complex, orange for the Middle Plant Complex, and green for the South Plant Complex. The solid red line represents the V_S profile compiled from all measurements. Each Plant Complex includes two boreholes to approximately 280 ft. (85 m), while the Middle Plant Complex includes a deeper approximately 590-ft. (180-m) borehole. This deeper suspension log recorded consistent V_S values exceeding 10,000 ft/s (3048 m/s) below 275 ft. (84 m), supporting the selection of this depth as the reference rock half-space for the site.

Following excavation to the planned final plant grade of 810 ft. (247 m), the remaining soil profile exhibits a V_S of approximately 1000 ft/s (305 m/s). The deepest soil layer is about 5 ft. (1.5 m) in thickness with V_S around 1500 ft/s (457 m/s), underlain by a 4-ft. (1.2-m)-thick PWR layer with velocities ranging from 2400 to 3400 ft/s (732 to 1036 m/s).

Figure 2.5-139(b) presents average V_S profiles for each Plant Complex, based on three suspension logs per complex, along with an overall average profile derived from all nine logs. The Middle Plant Complex shows a transition to higher velocities at shallower depths, consistent with boring log data. Variations between the average V_S profiles for each complex were found to be within the range of variability observed within each complex. Therefore, the overall average V_S profile was selected.

Table 2.5-68 summarizes this average suspension V_S and V_P profiles, which have a weighted average V_S to 30 m ($V_{S\text{-}30}$) of 1807 ft/s (551 m/s). Downhole V_S measurements closely match the suspension log data for corresponding boreholes. As a result, a separate average profile for the downhole data was not developed.

2.5.4.7.1.2 Spectral Analysis of Surface Waves Profiles

Figure 2.5-140 compares V_S profiles from 12 SASW arrays and an average SASW profile captured as a solid black curve. In general, V_S values from SASW testing are lower than those from suspension logs, particularly within the PWR and upper rock layers. The SASW data indicate a thicker low-velocity PWR layer, approximately 100 ft. (30.4 m) thick with V_S between 2000 and 2500 ft/s (610 to 762 m/s), compared to the much thinner PWR layer (approximately 4 ft. [1.2 m]) identified in suspension logs. Additionally, the lower rock V_S from SASW ranges from 6000 to 8000 ft/s (1829 to 2438 m/s), whereas suspension logs show higher velocities of 8000 to 10,000 ft/s (2438 to 3048 m/s).

Table 2.5-69 summarizes the average SASW V_S and V_P profiles. To account for uncertainty in the depth to reference rock, the SASW-derived half-space was placed at an average depth of 540 ft. (164.6 m), which is significantly deeper than the depth indicated by suspension logs. Because the SASW data do not reach layers with velocities exceeding 9000 ft/s (2743 m/s), the velocity of the half-space was assumed to match that of the suspension log-based profile.

Layer thicknesses were converted to elevations by averaging the borehole elevations where suspension logging was performed for the suspension logging-based analysis, and by averaging the elevations of the array center and endpoints for the SASW-based analysis.

The best-estimate V_S and V_P profiles derived from suspension log and SASW data are presented in Figure 2.5-129 and Figure 2.5-130, respectively.

2.5.4.7.1.3 Dispersion Curves

Figure 2.5-141 compares dispersion curves derived from the mean V_S profiles obtained through suspension P-S logging and SASW data with experimental dispersion measurements. The figure also includes compacted dispersion curves (i.e., the averaged evaluated dispersion curves for each array), and their mean and ±3 standard deviation bounds. The mean and standard deviation bounds for the compacted curves are similar to the mean and bounds for the dispersion curve data points.

The comparison indicates that the suspension logging-derived profile aligns well with the upper portion of the observed dispersion data. Overall, both the suspension log and SASW profiles are considered reasonable representations of subsurface conditions because their modeled dispersion curves fall within the bounds defined by the dispersion curve data for the SASW profiles at the site.

2.5.4.7.1.4 Adjustment of Analysis Velocity Profiles for Cut/Fill

V_S in soils were adjusted to account for changes in isotropic confining pressure (σ_0) due to cut or fill conditions. These adjustments were based on RCTS testing of eight intact soil specimens at the Project site that evaluate V_S variation under increasing (normally consolidated, NC) and decreasing (over-consolidated, OC) confining pressures. The relationship between V_S and σ_0 was modeled using Equation 2.5.4-2:

$$V_s = A_s \times (\sigma_0 / P_a)^{n_s} \qquad \text{(Equation 2.5.4-2)}$$

Where:

3) A_S is shear wave velocity at σ_0 equal to one atmosphere
4) σ_0 is total isotropic confining pressure
5) P_a is atmospheric pressure (one atmosphere)
6) n_S is dimensionless exponent

Average values of n_S were 0.11 for over-consolidated conditions and 0.23 for normally consolidated conditions. These values were applied to adjust V_S for cut (over-consolidated) and fill (normally consolidated) scenarios, respectively. Resulting adjustments ranged from reductions of 50 to 250 ft/s (15 to 76 m/s) for cut scenarios and increases of 100 to 450 ft/s (30 to 137 m/s) for fill scenarios.

2.5.4.7.2 Shear Modulus Reduction and Damping Material Curves

Atterberg limit testing indicates that the residual soils at the Project site are generally non-plastic, with only a few samples from the upper few feet showing plasticity index values greater than zero. These upper soils are expected to be removed during grading and are therefore excluded from further analysis.

Despite the non-plastic results from Atterberg testing (except for one sample), the RCTS test results (Figures 2.5-142 and 2.5-143) resemble modulus reduction and damping curves typically associated with higher plasticity soils. To account for uncertainty in soil behavior, two sets of modulus reduction and damping curves were developed for the site: site-specific curves and original Darendeli curves.

Site-specific modulus reduction curves were developed using lab-derived data. For each test, the fitted reference strain was plotted against the corresponding confining stress. The data were fitted using a power function consistent with Darendeli (Reference 2.5-170), and new site-specific coefficients for Darendeli's modulus reduction equations were derived based on this relationship. Using these validated coefficients and an average 'a' value of 1.013, site-specific modulus reduction curves were generated for five confining stress levels representing the range of possible depths for the residual soils (i.e., approximately 15-ft. [4.6 m]-thick layers, from depths of 7.5 to 67.5 ft. [2.2 to 20.6 m]). The site-specific modulus reduction curves are presented in Figure 2.5-144 with the RCTS test results.

In addition, evaluation of shear strength from the modulus reduction curves indicates that the high-strain portion of the site-specific modulus reduction curves reasonably represents the shear strength of the residual soils based on lab strength data, and no adjustments to the curves are needed.

A similar process was used to derive the site-specific damping curves from the RCTS lab testing for the residual soils. For each test, the D_{min} was plotted against the corresponding confining stress. The data were fitted using a power function consistent with Darendeli (Reference 2.5-170), and new site-specific coefficients for Darendeli's damping curves were derived based on this relationship. Using these validated coefficients, the site-specific damping curves were generated for the same five confining stress levels and are presented in Figure 2.5-145. The fitted power function results in an average D_{min} of about 1.8 percent for the residual soils. Table 2.5-70 presents the site-specific modulus reduction and damping curves for the residual soils.

2.5.4.7.2.1 Darendeli Material Curves for Residual Soils

The second set of modulus reduction and damping curves for the residual soils was developed directly using Darendeli's equations (Reference 2.5-170), incorporating a plasticity index of 0 based on laboratory test results and other standard input parameters. Figures 2.5-146 and 2.5-147 present these curves. Table 2.5-71 presents the Darendeli modulus reduction and damping curves for the residual soils.

2.5.4.7.2.2 Material Curves for Partially Weathered Rock and Rock

To account for uncertainty in the material properties of the crystalline rock (fractured rock and sound rock) layer, two sets of curves were evaluated for both PWR and rock. For PWR, there are no available published curves for this type of material so the selected curves include unweathered shale (Reference 2.5-298) and EPRI rock (Reference 2.5-299) at depths of 2000 to 5000 ft. (609.6 to 1524 m). For rock layers with shear wave velocities less than 8000 ft/s (2438 m/s), two sets of curves were used: linear curves and unweathered shale curves from Stokoe et al. (Reference 2.5-298). For rock layers with velocities greater than 8000 ft/s (2438 m/s), linear behavior was assumed for both sets. The curves are captured on Figures 2.5-148 and Figures 2.5-149. Tables 2.5-72 and 2.5-73 present the two sets of modulus reduction and damping curves for the PWR and rock.

2.5.4.7.3 Low-Strain Dynamic Properties for Residual Soils, Partially Weathered Rock, and Rock

See Section 2.5.4.2.4.

2.5.4.7.4 Dynamic Properties for Fill

To raise portions of the site to the required final plant grade of 810 ft. (247 m), up to 50 ft. (15.2 m) of granular fill will be placed and compacted to 95 percent Modified Proctor, with a minimum shear wave velocity of 1000 ft/s (305 m/s) per Section 2.5.4.5.2.2. The shear wave velocity profile for the fill was developed using prior experience and Reference 2.5-172 equations, assuming a surface V_S of 1000 ft/s (305 m/s) and increasing with depth. Table 2.5-74 presents the derived V_S profile.

Material curves for the proposed granular fill were assumed based on published curves from Seed and Idriss (Reference 2.5-173), Rollins et al. (Reference 2.5-300), and prior experience with gravelly soils. Figures 2.5-150 and 2.5-151 show the assumed modulus reduction and damping curves, which are more nonlinear than the EPRI (Reference 2.5-163) shallow soil curves due to the expected higher gravel content in the fill.

2.5.4.7.5 Randomization of Material Properties

To capture spatial variability and reduce resonance effects, velocity profiles and material curves were randomized using Toro's (Reference 2.5-182) correlation model for firm sediments (USGS Site Class C), appropriate for the site's flat-lying sedimentary structure. For each logic tree branch, 60 randomized profiles were generated.

Layer thicknesses were randomized based on the variation of thickness of each layer from the site investigation geophysical data. Velocity correlations were not applied between fill and underlying rock, or between soil and PWR materials. For cut scenarios, profiles were trimmed to

pad elevations after randomization to model the variation in existing ground surface across different areas. For fill scenarios, fill thicknesses were varied to reflect observed site conditions.

Figure 2.5-152 shows an example of the 60 randomized velocity profiles (gray) generated for each logic tree branch, along with their median (blue) compared to the target velocity profile (red) on the left side. The right side displays the standard deviation of the logarithm of the velocities from the simulations (blue) versus the target (red). The randomization process was iterated until statistical criteria were met: a minimum p-value of 0.1 and an average p-value above 0.5 between the target median V_S profile and the median of the 60 randomized profiles.

2.5.4.7.6 Site Response Spectra

Site-specific DRS were developed for the North, Middle, and South Plant Complexes in accordance with RG 1.208 and ASCE/SEI 43-05. These include:

- GMRS at the surface (elevation 810 ft. [247 m]), which are equivalent to performance-based surface response spectra for the North, Middle, and South Plant Complexes.

- Foundation input response spectra (FIRS) at depths of 44 ft. [13.4 m] (elevation 766 ft. [233.5 m]) and 85 ft. [25.9 m] (elevation 725 ft. [221 m]) for all complexes, and at 115 ft. [35.1 m] (elevation 695 ft. [211.8 m]) for the South Plant Complex Only.

- Performance-based interface response spectra (PBIRS) at the top of the PWR for each complex.

The GMRS, FIRS, and PBIRS were derived from site-specific uniform hazard response spectra (UHRS) for annual frequencies of exceedance (AFE) of 1E-4 and 1E-5. Horizontal UHRS were enveloped across site grading cases and scaled using design factors to produce the DRS. Vertical response spectra were calculated by applying weighted vertical-to-horizontal (V/H) spectral ratios to the horizontal UHRS.

See Sections 2.5.2.6.1 through 2.5.2.6.4 for details on mean and fractile site-specific hazard curves, V/H spectral ratios, magnitude-distance deaggregation, and controlling earthquakes.

2.5.4.7.6.1 Seismic Hazard Results for Plant Complexes

Seismic hazard results for the North and Middle Plant Complexes are identical. Results were obtained for three site grading cases, including two cut cases (10 ft. [3 m] and 24 ft, [7.3 m]) and one fill case (15 ft. [4.6 m]), and for four control point elevations: surface, 44 ft. [13.4 m], 85 ft. [25.9 m], and the top of the PWR. For the South Plant Complex, seismic hazard results were developed for five site grading cases, three cut cases (10 ft. [3 m], 24 ft. [7.3 m], and 38 ft. [11.6 m]) and two fill cases (15 ft. [4.6 m] and 40 ft. [12.2 m]), and five control point elevations: surface, 44 ft. [13.4 m], 85 ft. [25.9 m], 115 ft. [35.1 m], and the top of the PWR.

The horizontal 1E-4 and 1E-5 site-specific UHRS for the North and Middle Plant Complexes and South Plant Complex were developed for each control point and site grading case and are presented in Figures 2.5-153 and 2.5-154, respectively. Subplots include control points at the surface (a) at depths of 44 ft. [13.4 m]; (b) 85 ft. [25.9 m]; and (c) 115 ft. [35.1 m]

(Figures 2.5-154e), and at the top of the PWR (Figure 2.5-153d and Figure 2.5-154d). Solid lines represent the 1E-4 UHRS, while solid lines with dots represent the 1E-5 UHRS.

To develop performance-based response spectra representative of the PPE, the UHRS for different site grading conditions were enveloped for each Plant Complex. For the North/Middle and South Plant Complexes, the enveloped 1E-4 and 1E-5 horizontal UHRS are shown as the thicker dashed blue and green curves in Figures 2.5-153 and 2.5-154, respectively. DRS were calculated from the enveloped UHRS and are shown by the solid black lines in the figures.

Vertical UHRS were obtained by multiplying the enveloped horizontal UHRS by the corresponding weighted average V/H spectral ratios, as provided in Section 2.5.2.6.4. These vertical UHRS were then used to compute the vertical DRS. Figures 2.5-155 and 2.5-156 present the results by comparing horizontal and vertical DRS across all control points for the North/Middle and South Plant Complexes, respectively.

Tabulated values of the enveloped horizontal and vertical 1E-4 and 1E-5 site-specific UHRS, along with the corresponding horizontal and vertical DRS, are provided for the North and Middle Plant Complexes in Table 2.5-75 (surface – GMRS), Table 2.5-76 (44 ft. [13.4 m] depth – FIRS), Table 2.5-77 (85 ft. [25.9 m] depth – FIRS), and Table 2.5-78 (top of PWR – PBIRS). These spectra were initially calculated for 24 spectral ordinates defined by the Next Generation Attenuation-East ground motion models. However, to meet the RG 1.208 requirement for a minimum of 30 spectral frequencies to ensure a smooth spectrum, horizontal and vertical GMRS, FIRS, and PBIRS were interpolated to include six additional frequencies. The interpolated spectra are presented in Table 2.5-79.

For the South Plant Complex, tabulated values of the enveloped horizontal and vertical 1E-4 and 1E-5 UHRS, and the corresponding horizontal and vertical DRS, are provided in Table 2.5-80 (surface – GMRS), Table 2.5-81 (44 ft. [13.4 m] depth – FIRS), Table 2.5-82 (85 ft. [25.9 m] depth – FIRS), Table 2.5-83 (top of PWR – PBIRS), and Table 2.5-84 (115 ft. [35.1 m] depth – FIRS). To satisfy the RG 1.208 requirement for 30 spectral frequencies, the horizontal and vertical GMRS, FIRS, and PBIRS were interpolated similarly, with results captured in Table 2.5-85.

2.5.4.8 Liquefaction Potential

Soil liquefaction is a process by which loose, saturated, primarily granular deposits lose a significant portion of their shear strength due to pore pressure buildup resulting from cyclic loading, such as that caused by an earthquake. During liquefaction, pore water pressure increases and soil particles lose contact, causing the soil to behave more like a liquid than a solid. Soil liquefaction occurrence (or lack thereof) depends on geologic age, state of soil saturation, density, gradation, plasticity, and earthquake intensity and duration. In addition to loss of strength, liquefaction can cause settlement of the overlying layers as the liquefying layer densifies following earthquake shaking.

The reactor base mats will be founded either on structural backfill, lean concrete, or competent rock. Structural backfill or lean concrete are not susceptible to liquefaction. Nevertheless, RG 1.198, *Procedures and Criteria for Assessing Seismic Soil Liquefaction at Nuclear Power Plant Sites*, was used as a guide for assessing liquefaction potential of the on-site residual soils at the Project site for conservatism.

RG 1.198 states that earthquake-induced liquefaction is most commonly observed in (but not restricted to) fluvial-alluvial deposits, eolian sands and silts, beach sands, reclaimed land, and uncompacted hydraulic fills. Also, per RG 1.198, most liquefaction risk is associated with recent Holocene deposits and uncompacted fills, and soils with dual Unified Soil Classification system designations including SM-SC or GM-GC are potentially liquefiable. Additionally, RG 1.198 states that "if it can be demonstrated that any potentially liquefiable soil types present at a site (1) are currently unsaturated (e.g., are above the water table), (2) have not been saturated previously (e.g., are above the historic high water table), and (3) cannot reasonably be expected to become saturated, such soils can be considered to pose no potential liquefaction hazard." For water levels to be considered in assessing liquefaction, RG 1.198 states that groundwater tables or pool elevations should be assumed to lie at the maximum or the minimum of the range that can be expected at the site of the facility, in the direction that is most critical to the analysis, including consideration of the water levels governed by flood conditions.

The presence of sandy soil layers (typically classified as SM/SC) at the Project site indicates a potential for liquefaction under seismic loading based on soil type. As discussed in Section 2.5.4.6, the water table at the Project site is predominantly located at or below the soil-rock interface, and residual soils are expected to remain partially saturated as long as adequate drainage measures are provided during and after construction of the reactors to prevent net positive water infiltration into the soils in the power block. Accordingly, these soils are considered to pose no potential liquefaction hazard based on RG 1.198.

An analysis based on V_S was performed that considers the groundwater table to be at the plant final grade elevation of 810 ft. [247 m] (critical case) using the V_S based methodology outlined in Reference 2.5-267. Unlike SPT measurements that can fail to adequately capture soil fabric/microstructure-related phenomena contributing to strength and stiffness (manifested as cyclic resistance), V_S measurements can more accurately represent the in situ state of soils including aging effects (Reference 2.5-301; Reference 2.5-302). The best-estimate V_S profiles as described in Section 2.5.4.2.4 were used in this assessment. The V_S values were corrected for overburden pressure (V_{S1}) and indicate a minimum of 827 ft/s (252 m/s) below elevation 810 ft. [247 m]. Based on Reference 2.5-267, V_{S1} greater than 200 m/s (656.1 ft/s) for soils with fines content greater than 35 percent (as is typical for the Project site) for a moment magnitude of 7.5 indicate no potential for liquefaction. The mean magnitudes for the surface site-specific hazard range from 5.9 to 7.3 for AFEs of 1E-4 and 1E-5 for frequencies of peak ground acceleration to 1 Hz, thus the mean magnitudes are less than 7.5 for the critical AFEs and frequencies for liquefaction hazard for the site, and the 200 m/s value is a conservative liquefaction susceptibility limit for the site. As the minimum V_{S1} value for the residual soils is greater than 200 m/s, the residual soils pose no potential liquefaction hazard based on RG 1.198 if even saturated.

2.5.4.9 Earthquake Design Basis

The site GMRS is derived and discussed in detail in Section 2.5.2.6.

2.5.4.10 Static and Dynamic Stability

The following sections discuss general static aspects of stability. Dynamic aspects of the foundation interface will be discussed in Sections 3.7 and 3.8, once a reactor technology is selected and a more site- and technology-specific study is conducted at the construction permit or license application phase.

Once the excavation to reach the base of safety-related structures is completed, the base of the excavation will be evaluated for any areas of residual soils or weak rock that may need further excavation and replacement with structural backfill or lean concrete. As such, all safety-related structures will be founded on either structural backfill, lean concrete, or competent rock.

2.5.4.10.1 Bearing Capacity

The bounding scenario for bearing capacity is reactor base mats founded on structural backfill. Based on the anticipated base mat elevations, the Westinghouse reactor technology has the highest proposed base mat elevation of 766 ft. (233.4 m) and will likely be founded on structural backfill or lean concrete. Per Section 2.5.4.5.2.2, the minimum effective friction angle for structural backfill is 40 degrees. All other reactor technologies have a deeper base mat embedment and will be underlain by more competent materials (typically sound rock).

The ultimate bearing capacity (q_{ult}) for a strip footing (with a length-to-width ratio greater than 10) can be evaluated, in terms of effective stress or drained analysis, using Terzaghi's general shear bearing capacity expression included below as Equation 2.5.4-3:

$$q_{ult} = c\,N_c + q\,N_q + 0.5\,\gamma\,B\,N_\gamma \qquad \text{(Equation 2.5.4-3)}$$

Where:

- c is effective stress cohesion
- q is effective vertical stress at the bearing elevation
- B is footing width
- L is footing length
- γ is effective unit weight of soil
- N_c, N_γ, and N_q are bearing capacity factors that depend on the friction angle

For a reactor base mat bearing on structural backfill with zero cohesion, and conservatively ignoring the foundation embedment effects, the equation above simplifies to Equation 2.5.4-4:

$$q_{ult} = 0.5\,\gamma\,B\,N_\gamma \qquad \text{(Equation 2.5.4-4)}$$

The above-calculated q_{ult} values further need to be adjusted for L/B ratios less than 10 by applying a shape correction factor (s_γ). The final equation (Equation 2.5.4-5) used to calculate ultimate bearing capacity is thus:

$$q_{ult} = 0.5\,\gamma\,B\,N_\gamma s_\gamma \qquad \text{(Equation 2.5.4-5)}$$

As indicated by this equation, the ultimate bearing capacity increases with increasing width for foundations bearing on granular materials (such as structural backfill). A reactor base mat width and length of 100 ft. (30.4 m) were used for bearing capacity calculations, which is conservative because the length and width of the base mats associated with the six proposed reactor technologies are all wider than 100 ft. (30.5 m). Per Section 2.5.4.5.2.2, the total unit weight of

structural backfill is 135 pcf. Assuming groundwater to be at the reactor base mat (most conservative assumption), the effective unit weight is:

$$\gamma = 135 \text{ pcf} - 62.4 \text{ pcf} = 72.6 \text{ pcf}$$

Different bearing capacity and shape correction factors have been established by various researchers (e.g., Terzaghi, Meyerhoff, Hansen). The more conservative bearing capacity and shape correction factors proposed by Hansen, as given in Reference 2.5-280, were used for the calculations, resulting in N_γ = 80 and s_γ = 0.6. The ultimate bearing capacity is then calculated as:

$$q_{ult} = 0.5\ (72.6 \text{ pcf})\ (100 \text{ ft})\ (80)\ (0.6) = 174{,}240 \text{ psf} = 174.2 \text{ ksf}\ (8.3 \text{ MPa})$$

As a comparison, this is much greater than the required minimum ultimate bearing capacity of 75 ksf (3.6 megapascals [MPa]) for NuScale as indicated in Section 2.5.4 of the NuScale Final Safety Analysis Report (Reference 2.5-303). The ultimate bearing capacity associated with the NuScale technology is considered bounding for the other technologies for the purposes of the ESPA. The ultimate bearing capacity of the final reactor technology will be calculated once a selection is made at the construction permit or license application phase; however, ultimate bearing capacity is not anticipated to be the controlling factor for the reactor base mats.

2.5.4.10.2 Elastic Settlement

The bounding scenario for elastic settlement is base mats underlain by the thickest compressible materials. Residual soils below the reactor base mats will be excavated; therefore, the compressible materials are structural backfill and PWR. The compressibility of the fractured and sound rock is considered negligible. This assumption is justified because the best-estimate elastic moduli of fractured rock and sound rock layers are approximately 10 to 100 times that of the structural backfill/PWR, respectively.

The subsurface profile used for elastic settlement estimation purposes is based on the conditions indicated by boring B-4 in the north complex. Based on a mat bearing elevation of 766 ft. (233.5 m) corresponding to the reactor technology with the highest reactor base mat elevation and the bottom of Stratum III (PWR) at elevation 712.8 ft. (217.3 m), there is 53.2 ft. (16.2 m) of structural backfill and/or PWR below the base mat at this location which represents the thickest combination of compressible materials (structural backfill and/or PWR) below the base mat bottom.

Settlement analyses typically assume the following form as shown in Equation 2.5.4-6 (Reference 2.5-274):

$$\Delta H = \varepsilon\, H = \sum_{H_i}^{H_{i+1}} \frac{\Delta q_i}{E_{si}} \quad (i = 1 \text{ to } n) \qquad \text{(Equation 2.5.4-6)}$$

Where:

- ΔH is settlement
- ε is axial strain
- H = thickness of compressible layer
- Δq = stress increase at the mid-point of each layer due to net load imposed by the base mat
- E_s= elastic modulus

In other words, the total settlement is the sum of the strain in each layer multiplied by the layer thickness. Per Section 2.5.4.5.2.2 and Section 2.5.4.5.2.2, the minimum and best estimate elastic modulus for the PWR and structural backfill are both 2000 ksf (95.8 MPa). This means that elastic settlement estimates will be identical even if all the PWR is excavated and replaced with structural backfill or if some PWR remains in-place.

A flexible foundation was assumed such that the applied loads can be represented as a uniform soil bearing pressure at the base of the mat. Reactor-specific design pressures were not provided at the ESP phase. A net mat pressure of 6 ksf (0.29 MPa) was assumed. The net pressure considers the effects of the overburden stress removed due to excavation of the materials above the base mat; for example, a mat with a gross bearing pressure of 10 ksf (0.48 MPa) bearing at a depth of 44 ft. (13.4 m) below final grade (such as the Westinghouse reactor) would impart a net pressure of 5.6 ksf (0.27 MPa) on the excavation bottom assuming a unit weight of 100 pcf for the excavated overburden soils. Reactor base mats that are embedded deeper may experience no net bearing pressure increase or associated settlement if the overburden stress removed due to excavation is the same or greater than the gross mat bearing pressure, creating a “compensated” condition. Because the in situ residual soils below the reactor base mat will be over-excavated and replaced with compacted structural backfill, there was no need to evaluate potential time-dependent consolidation settlements.

Stress increase in layers below the loaded foundation is typically modeled using various stress distribution methods (e.g., Boussinesq, Westergaard, 2:1 assumption, Schmertmann). Because stresses will be distributed over a wider footprint than that of the base mat as depths increase, the stress increase in subsequent layers decreases as depth increases. It is conservatively assumed that the underlying layers will be subject to stress increase the same as the net base mat pressure (i.e., no load distribution). The difference in surcharge due to replacing the excavated in situ residual soils with compacted structural backfill (i.e., due to difference of total unit weights) is considered negligible.

Accordingly, the uniform elastic settlement of the base mat can be calculated as:

$$\Delta H = \left(\frac{\Delta q}{E_s}\right) \text{ x } H = \left(\frac{6 \text{ ksf}}{2000 \text{ ksf}}\right) \text{ x } 53.2 \text{ ft} = 0.16 \text{ ft} = 1.9 \text{ in } (4.8 \text{ cm})$$

A time influence factor was used for added conservatism to consider the time rate of development of settlement in coarse-grained layers, which may occur in the structural backfill and PWR layers. The work by Liu et al., contained in Reference 2.5-304, builds on previous work done by several other researchers (e.g., Reference 2.5-305; Reference 2.5-306), suggests the following relationship (Equation 2.5.4-7) for computing a time influence correction factor (f_t):

$$f_t = 1 + R_{ref} + R \text{ x } \log\left(\frac{t}{0.1 \text{ x } T_0}\right) \quad \text{(Equation 2.5.4-7)}$$

Where:

7) $R_{ref} = 0.1 - 0.015 \text{ x } \log(F)$ (F is the factor of safety)
8) $R = 0.182 - 0.043 \text{ x } \log(F)$
9) t is time in years
10) T_0 is duration of load application

Conservatively assuming F = 3 (actual factor of safety is likely much higher) and using T_0 = 1 year, this relationship gives a time influence correction factor of approximately 1.25 after t = 1 year and 1.58 after t = 100 years. There is no guidance on what value of t to use in the calculations; using t = 100 years is likely overly conservative whereas using t = 1 years is likely insufficient. An f_t value of 1.5 was used in this calculation.

The total elastic settlement including time effects is then calculated as:

$$\Delta H_t = f_t \text{ x } \Delta H = (1.5) \text{ x } (1.9 \text{ in}) = 2.9 \text{ in } (7.4 \text{ cm})$$

The settlement requirements for the NuScale technology, as indicated in Section 2.5.4 of the NuScale Final Safety Analysis Report, are a maximum allowable total settlement of 4 in. (101.6 mm) along the base mat, and a settlement tilt limit of 1 in. (25.4 mm) total in any direction or half an inch per 50 ft. of building length (Reference 2.5-303). Assuming similar total settlement criterion for the other reactor technologies, the estimated upper-bound total settlement of 2.9 in. (73.7 mm) is satisfactory. The settlement tilt was not evaluated because it is a function of mat rigidity and final site/technology selection. Because the reactor base mats of all other technologies are located deeper and/or underlain by more competent materials, the total settlement for the other technologies is expected to be smaller. Using the above approach, a sensitivity analysis was also performed to estimate total elastic settlement (in inches) for various net mat pressures between 2 and 10 ksf and compressible layer thicknesses between 10 and 100 ft. The results are summarized in Figure 2.5-157. From this figure, as one example for a potential reactor base mat bearing at elevation 800 ft. (243.8 m) with a net mat pressure of 5 ksf (0.24 MPa), and considering the conditions in boring B-4 with the bottom of the compressible materials at elevation 712.8 ft. (217.3 m) resulting in a total compressible material thickness of 87.2 ft. (26.6 m), the total elastic settlement is approximately 4 in. (101.6 mm).

2.5.4.10.3 Consolidation and Swell/Collapse Potential

None of the base mats for the six different reactor technologies under consideration will be underlain by in situ residual soils that are subject to potential time-dependent consolidation, collapse, or swell. There may be other shallow structures associated with the nuclear plant supported on residual soils; however, because a specific reactor technology has not been selected at this time and the locations of various structures associated with a specific plant configuration are not known, the test results are interpreted to provide a preliminary evaluation and demonstration of the general consolidation and collapse/swell characteristics of the in situ residual soils at the subject site. Once a reactor technology is selected and structure locations are identified at the construction permit or license application phase, there will be additional structure-specific subsurface investigations and laboratory testing performed.

Piedmont residual soils are formed in-place from weathering of the parent rock and are not subject to some of the typical mechanisms that result in over-consolidation of natural deposits, with the exception of water level changes and subsequent desiccation. The term “apparent OCR” is commonly used to refer to the apparent pre-consolidation pressure inferred from consolidation test results from Piedmont residual soils (Reference 2.5-264; Reference 2.5-307; Reference 2.5-266). In addition, Piedmont residual soils are prone to sample disturbance and stress release upon extrusion from sampling tubes in the laboratory because of the high fine sand fraction and/or presence of mica minerals (Reference 2.5-264). As such, it is challenging to interpret the characteristic of compressibility of the Piedmont residual soils based on results of the consolidation tests because, for example, there may not be a well-defined yield point on the typical e-log p plots used to present consolidation data (Reference 2.5-308), and the estimation of pre-consolidation stress in Piedmont residual soils requires considerable engineering judgment (Reference 2.5-307).

The residual soil samples tested for their consolidation characteristics included silty sands (SM), elastic silts (ML), and high plasticity silts (MH). The liquid limit of the plastic samples tested ranged between 57 and 69, and plasticity index ranged between 13 and 24. The initial void ratio ranged between 0.814 and 1.466 with a mean of 1.133. The average coefficient of consolidation was approximately 1.1 square feet per day.

Using the Casagrande method, the recompression index ranged from 0.03 to 0.09, and the compression index ranged from 0.31 to 0.78. The estimated pre-consolidation pressures ranged from 6.8 ksf to 16.6 ksf. The calculated apparent OCR based on the estimated pre-consolidation pressures ranged from 5.2 to 98.6. When excluding the shallow samples (in the upper approximate 8 ft. [2.4 m]) that are subject to frequent moisture content fluctuations/desiccation, the pre-consolidation pressures ranged from 6.8 ksf to 16.6 ksf, and the calculated OCR values ranged from 5.2 to 14.6. These pressures are significantly greater than the typical pre-consolidation pressures of 1 to 5 ksf and apparent OCR values of 1 to 4 reported in literature for Piedmont residual soils (Reference 2.5-264; Reference 2.5-266; Reference 2.5-308).

Using the Simplified Method (Reference 2.5-309) (where the straight portion of the initial recompression curve is projected forward and the straight portion of primary consolidation curve is projected backward, with the intersection point representing the pre-consolidation pressure and the slope of the projected lines representing the recompression and compression indices), the recompression index ranged from 0.05 to 0.13, and the compression index ranged from 0.31 to 0.77. The estimated pre-consolidation pressures ranged from 1.8 ksf to 5.2 ksf. The calculated over-consolidation ratio based on the estimated pre-consolidation pressures ranged from 1.8 to 26.6. The pre-consolidation pressures estimated using the Simplified Method are in good agreement with the typical pre-consolidation pressures of 1 to 5 ksf. The calculated apparent OCR values are generally higher than the typical values; however, when excluding the shallow samples (in the upper approximate 8 ft. [2.4 m]) that are subject to frequent moisture content fluctuations/desiccation, the calculated apparent OCR values of 1.8 to 3.5 are in better agreement with the typical values for Piedmont residual soils.

Alternative interpretation methods for one-dimensional consolidation tests can yield different results with respect to the pre-consolidation pressure/OCR as well as recompression and compression indices (Reference 2.5-310; Reference 2.5-311; Reference 2.5-312). This is particularly the case in Piedmont residual soils as previously discussed. Therefore, the interpretation and use of consolidation parameters from laboratory oedometer tests on Piedmont residual soils require significant care, and in most cases, the use of sound

engineering judgment. In addition, conventional consolidation tests have been shown to overpredict settlements in Piedmont residual soils, and SPT-based and elastic modulus-based methods are frequently used instead for predicting settlement (Reference 2.5-273).

2.5.4.10.4 Displacement Monitoring

For structures founded on structural backfill, competent PWR, or crystalline rock, elastic displacement is expected during load additions for construction. A displacement (settlement) monitoring plan will be developed to monitor rebound/heave in the subsurface soil and rock due to excavation, changes in pore pressures due to excavation and dewatering, and settlement due to construction of the structures. The displacement monuments will be monitored on a regular basis and will include conventional survey, electronic instrumentation, and possibly remote telemetry. The tilt and differential movement of the structures will be a monitoring priority.

2.5.4.10.5 Lateral Earth Pressures

2.5.4.10.5.1 Residual Soils and Backfill

Below grade walls are subject to lateral earth pressures based on the state of stress of the soil behind the wall and the movement experienced by the wall. For rigid walls that experience little to no movement (typical for buried safety-related structures), the “At-Rest” earth pressure is typically used. Conservatively assuming no friction between the wall and the backfill, Rankine’s method (Equation 2.5.4-8) can be used to estimate the lateral at-rest earth pressures for a vertical wall as follows (Reference 2.5-313):

$$\sigma'_h = \gamma' \cdot h \cdot K_0 \qquad \text{(Equation 2.5.4-8)}$$

Where:

11) σ'_h is Static horizontal effective stress
12) γ' is Effective unit weight (buoyant unit weight below the water table, and total unit weight above)
13) h is Depth below the top of wall
14) K_0 is Coefficient of at-rest earth pressure where ϕ' is the effective stress friction angle of the backfill

$$K_0 = (1 - \sin(\phi'))(1 - \sin(\beta)) \text{ for normally consolidated soils}$$

$$K_0 = (1 - \sin(\phi')) \times OCR^{\sin(\phi')} \text{ for overconsolidated soils}$$

Where β is the slope angle of backfill surface behind retaining wall. For unrestrained retaining walls where wall movement away from the backfill can occur, the coefficient of at-rest earth pressure in Equation 2.5.4-8 can be replaced with the coefficient of “Active” earth pressure (K_A) in Equation 2.5.4-9 for estimating active earth pressures (for $\beta \leq \phi'$):

$$K_A = \cos(\beta)\frac{\cos(\beta) - \sqrt{\cos^2(\beta) - \cos^2(\phi')}}{\cos(\beta) + \sqrt{\cos^2(\beta) - \cos^2(\phi')}} \qquad \text{(Equation 2.5.4-9)}$$

For a non-sloping backfill, the expression above can be simplified to Equation 2.5.4-10:

$$K_A = \frac{1 - \sin(\phi')}{1 + \sin(\phi')} \quad \text{(Equation 2.4.5-10)}$$

Lastly, for walls where movement occurs into the backfill (e.g., in front of the wall footing), the coefficient of "Passive" earth pressure (Equation 2.5.4-11) can be used (for $\beta \leq \phi'$):

$$K_P = \cos(\beta)\frac{\cos(\beta) + \sqrt{\cos^2(\beta) - \cos^2(\phi')}}{\cos(\beta) - \sqrt{\cos^2(\beta) - \cos^2(\phi')}} \quad \text{(Equation 2.5.4-11)}$$

For a non-sloping backfill, the expression above can be simplified to Equation 2.5.4-12:

$$K_P = \frac{1 + \sin(\phi')}{1 - \sin(\phi')} \quad \text{(Equation 2.5.4-12)}$$

For cases where interface friction between the wall and the backfill is considered, Coulomb's method is sometimes used to estimate the active and passive lateral earth pressure coefficients as follows in Equation 2.5.4-13 and 2.5.4-14:

$$K_{A(C)} = \frac{\cos^2(\phi' - \omega)}{\cos^2(\omega)\cos(\delta + \omega)\left[1 + \sqrt{\left(\frac{\sin(\delta + \phi')\sin(\phi' - \beta)}{\cos(\delta + \omega)\cos(\omega - \beta)}\right)}\right]^2} \quad \text{(Equation 2.5.4-13)}$$

$$K_{P(C)} = \frac{\cos^2(\phi' + \omega)}{\cos^2(\omega)\cos(\delta - \omega)\left[1 - \sqrt{\left(\frac{\sin(\delta + \phi')\sin(\phi' + \beta)}{\cos(\delta - \omega)\cos(\beta - \omega)}\right)}\right]^2} \quad \text{(Equation 2.5.4-14)}$$

Where:

15) the subscript "(C)" denotes Coulomb

16) ω is the wall face inclination from vertical

17) δ is the interface friction angle between the wall and the backfill

18) β is the backfill slope angle as previously defined

However, subsequent studies have shown that using the Columb method for estimating K_P can produce unconservative values, and that the log-spiral method is more suitable for calculating passive pressures (Reference 2.5-280). For a vertical wall with non-sloping backfill, the coefficient of passive pressure using the log-spiral method ($K_{P(LS)}$) can be estimated by Equation 2.5.4-15:

$$\ln\left(K_{P(LS)}\right) = \ln\left(\frac{1+\sin(\phi')}{1-\sin(\phi')}\right)\left[1.443\left(\frac{\delta}{\phi'}\right)\sin(\phi')+1\right] \quad \text{(Equation 2.5.4-15)}$$

For cases involving non-vertical walls and/or inclined backfill, design charts can be used to determine the $K_{P(LS)}$ values (Reference 2.5-280).

The selection of the effective stress friction angle used in lateral earth pressure calculations also needs to consider the potential for interaction with the in situ soils where the annular (filled) space between the wall and the backfill is small, where the lesser of effective stress friction angles between the backfill material and in situ materials would control.

Additional lateral forces to be considered for buried walls include:

- Hydrostatic pressure (below the water table)
- Lateral pressures induced by other structures or equipment
- Seismically induced pressure

Once a reactor technology is selected, additional assessment of the lateral earth pressures will be performed at the construction permit or license application phase, including dynamic soil-structure interaction analyses considering the site-specific foundation input response spectra.

2.5.4.10.5.2 Rock

The annular space between the excavation in fractured and sound rock and the reactor structure wall is typically backfilled with lean concrete. For unjointed massive hard rock, only water pressure typically needs to be accommodated once post-excavation elastic strain has developed. For fractured or bedded rock masses, the lateral earth pressures depend on the nature of and movement along the discontinuities (Reference 2.5-314).

For fractured rock, the lateral earth pressures can be conservatively estimated as described in Section 2.5.4.10.5.1, assuming a friction angle of 43 degrees (consistent with the best estimate for the PWR as described in Section 2.5.4.2.3). For sound rock, the lateral earth pressures can be considered negligible (but with consideration for the hydrostatic pressure below the water table and lateral pressures induced by other structures or equipment).

Additional assessment of the stresses in rock will be performed following additional data collection once a reactor technology is selected at the construction permit or license application phase.

2.5.4.11 Design Criteria

Foundation design criteria were available for only one of the six potential reactor technologies (Reference 2.5-303). Once a final reactor technology is selected at the construction permit or license application phase, the applicable design criteria will be used to further assess foundation stability.

2.5.4.12 Techniques to Improve Subsurface Conditions

The Westinghouse reactor has a proposed embedment depth of 44 ft. (13.4 m) where variable subsurface conditions were encountered. The remaining five reactor technologies (NuScale, Holtec, TerraPower, X-energy, and GVH) are anticipated to be supported on competent rock due to their relatively deep embedment depths and the subsurface conditions encountered at the proposed base mat elevations.

For the Westinghouse technology, variable subsurface conditions including residuum, PWR, fractured rock, and sound rock were encountered at the proposed base mat bottom elevation. Once the excavation reaches the proposed base mat elevation, the conditions need to be evaluated to identify areas of unsuitable materials (such as residuum) below the base mat. Excavation and replacement with structural backfill, “dental concrete” treatment where lean concrete is used to backfill excavated areas of unsuitable materials, or high-mobility (cement slurry) rock grouting are potential ground improvement alternatives to achieve a relatively uniform-bearing surface to promote even stress distribution. However, there is a risk with this approach that this remedial work may not be able to identify and address deeper layers of weaker residual soils that may be interbedded within the PWR due to differential weathering common in the Piedmont physiographic province. Such conditions were identified in several of the borings (in particular, at the North Plant Complex).

As an alternative, the excavation can be extended to a predetermined depth and backfilled with structural fill. The exact depth of this potential over-excavation is not known at this time. Per Section 2.5.4.2.2, the average bottom elevation of the PWR layer was identified as elevation 764.5 ft. (233 m), 762.5 ft. (232.4 m),and 774 ft. (235.9 m) for the North, Middle, and South Plant Complexes, respectively; however, the standard deviations for these elevations are on the order of 21 to 27 ft. (6.4 to 8.2 m). Additional subsurface investigation to be performed during the final design phase can be used to determine the final excavation depth once a reactor technology is selected at the construction permit or license application phase.

Another alternative to achieve a uniform bearing surface is through the use of a load transfer platform (LTP) below the mat. Also referred to as a “bridging layer,” a LTP often consists of a select well-graded granular backfill to provide adequate strength and promote arching (Reference 2.5-315). The thickness of the LTP is typically on the order of 2 to 4 ft. (0.6 to 1.2 m). Geosynthetic reinforcement is also sometimes used within the LTP to increase resistance to lateral spreading and/or to increase global stability. Lastly, the use of piles to create a pile-supported mat can also be considered. Drilled piers will most likely be used for this purpose because of the challenges associated with driving piles in highly variable subsurface conditions.

For the NuScale, Holtec, TerraPower, X-energy, and GVH technologies, ground improvement will likely consist of dental concrete to address areas of fractured or weak rock that may be identified once the excavation bottom is reached.

Detailed ground improvement plans, including the installation of piles if needed, will be addressed once a final reactor technology is selected and plans, including ancillary structure locations, are available.

2.5.5 STABILITY OF SLOPES

This section discusses the site characteristics and parameters concerning the stability of earth and rock slopes, both natural and manmade, whose failure could adversely affect the safety of the Site.

Specifically, this section evaluates the dynamic and static stability of the planned slopes and embankments at the Project site, addressing the following elements:

- Slope Characteristics (Section 2.5.5.1)
- Design Criteria and Design Analyses (Section 2.5.5.2)
- Site Investigations Boring Logs (Section 2.5.5.3)
- Properties of Borrow Material (Section 2.5.5.4)

Final grading plan will depend on advanced reactor technology selected in the construction permit or license application phase. Therefore, specific locations of safety-related slopes are not known at the ESPA phase. The site grading plan and the stability of any safety-related slopes will be evaluated in the construction permit or license application phase.

2.5.5.1 Slope Characteristics

The Project site consists of three separate areas located on a peninsula that trends southeast - northeast and extends into the southwestern portion of Belews Lake. The three Plant Complexes within the Project site are shown in Figure 2.5-158.

Based on the existing site elevations, significant cuts and fills are anticipated to achieve the proposed finished plant grade, which is planned at an approximate elevation of 810 ft. (247 m). As a result, the perimeter of each power block will primarily consist of compacted fill slopes downward and away from the critical structures. This grading will not result in significant upward slopes that could impact the facilities.

The final location of safety-related structures and their proximity to these fill slopes will be established in the final design. At this time, the safety-related structures are a minimum of 100 ft. (30.5 m) from the crest of the nearest slope.

Figures 2.5-159 through 2.5-161 present a preliminary grading plan for each of the three Plant Complexes. Also indicated are the critical slope sections that have been evaluated. Figures 2.5-162 through 2.5-171 present the cross-section of each slope considered.

The excavations to achieve the proposed plant grade will generally encounter existing overburden residual soils, partially weathered rock, fractured bedrock, and sound bedrock. These materials are discussed in Section 2.5.5.3.

The constructed slopes are designed with nominal slopes of 3 horizontal to 1 vertical (3H:1V). They will be constructed with the material excavated to establish the site grade. This construction will include:

- Removal of organic and otherwise unsuitable soils.
- Establishing a firm and unyielding subgrade prior to fill placement.
- Grading the exposed subgrade to provide terraces to key the new fill into the natural soils.
- Placement of moisture conditioned fill in nominal-maximum 8-in. (203-mm)-thick horizontal, loose lifts.
- Compaction of each lift to a minimum 95 percent of maximum dry density per ASTM D1557 (Modified Proctor test), with moisture contents within 2 percent of its optimum moisture as determined by ASTM D1557.
- Testing of compaction and moisture content to validate construction procedures.
- Establishing vegetation or aggregate surfacing to control soil erosion from the fill slopes.

Based on the explored condition, compacted fill consisting of the residual soils (generally consisting of silty sand (SM), sandy silt (ML) and lean clay (CL)), is considered to result in less desirable engineering properties than fill consisting of compacted partially weathered rock, fractured bedrock or sound bedrock (following crushing and processing). Thus, the use of residual soil is appropriately conservative for this evaluation.

Laboratory testing of residual soils obtained from the Site are discussed in Section 2.5.4.2.1. Based on this testing, a Mohr-Coulomb envelope with c' = 200 pounds per square foot (psf) and ϕ' = 30 degrees was selected as the best estimate for all interpretations at various strain levels. These values are used for stability analyses of slopes constructed with the excavated residual soils when compacted to 95 percent of their Modified Proctor maximum dry density.

Section 2.4.12 provides detailed descriptions of the hydrogeologic and groundwater conditions, while Section 2.5.4.6.1 concludes that the residual soils at the Project site are judged to be in a predominantly partially saturated state.

The engineering stratigraphy and properties of the natural materials below the future fill are discussed in Sections 2.5.4.2.2 and 2.5.4.2.3, as well as Table 2.5-64.

In general, groundwater levels are higher in the wells located farther from the natural slope crests and decrease as they approach the crests. In this evaluation, groundwater levels are considered to remain constant from the natural slope crests to the fill slope crests, then decrease along the slope faces to the water level of Belews Lake. These constant groundwater levels are used as average groundwater elevations for each site area and are depicted on each cross section (Figures 2.5-162 through 2.5-171). Using average groundwater levels across the slope crests is considered conservative, since well monitoring data indicate that most groundwater elevations near slope crests were lower than these average values.

The horizontal PGA are 0.432g (gravitational acceleration) for three Plant Complexes; the vertical PGAs are 0.317g for North and Middle Plant Complexes and 0.326g for the South Plant Complex, as provided with Section 2.5.2.6.8.

Peak ground motions occurring in both horizontal and vertical directions are considered in the slope stability analyses. However, it is unlikely that the PGAs in all directions occur simultaneously. Based on NUREG/CR-0098 (Reference 2.5-323), pages 29 to 30, it is conservative to take the combined effects as 100 percent of the effect due to motion in one direction and 40 percent of the effects corresponding to the two directions of motion at right angles to the principal motion considered. In the slope stability analyses, one horizontal motion is considered 100 percent with the remaining two motions considered 40 percent. The resultant horizontal PGA is 0.465 g (for three Plant Complexes). The corresponding 40 percent vertical PGAs are 0.127 g (North and Middle Plant Complexes) and 0.130 g (South Plant Complex). The vertical PGA of 0.130 g is used in all three Plant Complexes as a conservative value representative of the Project Site.

In a pseudo-static slope stability analysis, the ground shaking is performed by applying seismic coefficients in SLOPE/W software. The Federal Highway Administration suggests that a seismic coefficient equal to 50 percent of the design PGA be used (Reference 2.5-324). Thus, the horizontal, vertical seismic accelerations used are:

- Horizontal Direction: 0.233
- Vertical Direction: -0.065 (upward)

2.5.5.2 Design Criteria and Analyses

The slope stability analysis methodology used in the evaluations is based on limit equilibrium analysis. This involves calculating a factor of safety (FS) by comparing the resisting (stabilizing) forces within the mass of the structure to driving (destabilizing) forces. The main destabilizing factor is the self-weight of the slope mass. The FS is the ratio of the resisting forces to driving forces.

A number of limit equilibrium methods have been developed to analyze slope stability. Depending on the complexity of the assumptions made in deriving the FS equations, different methods provide varying levels of accuracy. The Spencer method, considered one of the more robust analytical tools, was used to perform the slope stability analysis.

The slope stability was analyzed using SLOPE/W Version 8.0 for Windows. The computer software is developed by GeoStudio, and the program has been appropriately verified and validated.

Two critical load cases are analyzed for slope stability as follows:

- Steady-state Condition: This analysis considers that the proposed slopes will exist a sufficient length of time after construction to develop hydrostatic conditions. In this analysis, the normal operating pool elevation of El. 725.0 ft. (221.0 m) is used. The phreatic lines through the embankment slope are conservatively considered. A surcharge load of 250 psf is considered under the steady-state loading condition to represent non-heavy-construction traffic loading. This surcharge is applied to the slope crest with a 5-ft distance from the edge.

- Pseudo-static Condition: This analysis considers the stability of the slopes under the ground shaking of a seismic event. This analysis is applicable for locations that do not

include soils that will liquefy or cyclically soften under the design seismic event. For this analysis, the ground shaking is performed by applying a seismic coefficient into SLOPE/W software.

The normal operating pond elevation is at El. 725.0 ft. (221.0 m) and the probable maximum flood (PMF) flooding elevation is at 747.86 ft. (227.95 m). As shown in Figures 2.5-156 through 2.5-165 (cross-section of each slope considered), the naturally formed partially weathered rock extends above the normal operating as well as the PMF elevations. As there is such a negligible effect on the fill slope and given the engineering properties of the partially weathered rock, it is appropriate to forgo evaluations for flood surcharge and rapid drawdown loading conditions.

Because the slopes are located more than 100 ft. (30.5 m) from safety-related structures and non-safety-related with special treatment (NSRST) structures, the acceptance criteria for this structural assessment of slope stability are in general accordance with the required safety factors on the United States Society on Dams (Reference 2.5-325) as follows:

- The calculated static FS under the long-term, drained condition must equal or exceed 1.5.
- The calculated seismic FS using pseudo-static analysis approach must equal or exceed 1.1

Considering the slope and geotechnical characteristics described herein, the minimum FS against failure for fill slopes has been determined by engineering calculations outlined in Table 2.5-86.

2.5.5.3 Boring Logs

Section 2.5.4.5 of this SSAR presents the requirements of the fill material to be used to raise the site.

2.5.5.4 Compacted Fill

Section 2.5.4.5 of this SSAR presents the requirements of the fill material to be used to raise the site.

2.5.5.5 Human Induced Surface Deformation

Human-induced causes of surface deformation, such as dewatering of the natural groundwater levels or anticipated construction activities, are not considered to have a significant impact on the safety of the slopes that are located well away from the safety-related structures.

Table 2.5-1
Scale Area and Range of Distances for Characterization

Table 2.5-20
Computed Site Kappa Values

Model	κ_0	Weight
Waveform analysis	0.033	0.3
Campbell (2009) (Reference 2.5-165)	0.010	0.5
Van Houtte et al. (2011) (Reference 2.5-166)	0.040	0.04
Xu et al. (2020) (Reference 2.5-167)	0.020	0.16

Key: κ_0 = site attenuation parameter (kappa)

Table 2.5-21
Site Kappa Values For Use In Site Response Analysis

Logic Tree Branch	κ_0	Weight
10th percentile	0.007	0.3
50th percentile	0.014	0.4
90th percentile	0.035	0.3

Key: κ_0 = site attenuation parameter (kappa)

Table 2.5-22
Site Kappa Values and Corresponding Profile Small-Strain Damping Values

Material Curve/Layer Type	κ_0		
	0.007	**0.014**	**0.035**
	Small-Strain Damping (%)		
Residual Soil	0.1	2.5	10.0
PWR	0.1	1.4	5.6
Rock, V_S<8000 ft/s	0.1	1.3	5.0
Rock, V_S>8000 ft/s	0.1	1.0	3.9

Key: κ_0 = site attenuation parameter (kappa); *D*min = small-strain damping; ft/s = foot per second; PWR = partially weathered rock; V_S = shear wave velocity

Table 2.5-23
Shear Wave Velocity Profile for Fill Materials

Layer	Thickness (ft.)	Shear Wave Velocity (ft/s)	Shear Wave Velocity (m/s)
1	3	1000	305
2	3	1090	332
3	3	1149	350
4	3	1205	367
5	3	1220	372
6	3	1243	379
7	6	1271	387
8	6	1301	397
9	10	1331	406

Key: ft. = foot; ft/s = foot per second; m/s = meter per second

Table 2.5-24
Base Depths And Base Elevations of Proposed Technologies

Technology	Base Depth (ft.)	Base Depth (m)	Base Elevation (ft.)	Base Elevation (m)
1	44	13.4	766	233.5
2	83	25.3	727	221.6
3	86	26.2	724	220.7
4	115	35.1	695	211.8
5	125	38.1	685	208.8

Note: Base depth and base elevations are determined with respect to the final plant grade elevation of 810 ft. (247 m).

Key: ft. = foot; m = meter

Table 2.5-25
Site Response Analysis Cases

Plant Complex	Grading	Control Point Depth
North, Middle, South	Cut – 24 ft.	Surface
North, Middle, South	Cut – 24 ft.	44 ft.
North, Middle, South	Cut – 24 ft.	85 ft.
North, Middle, South	Cut – 24 ft.	Top of PWR
North, Middle, South	Cut – 10 ft.	Surface
North, Middle, South	Cut – 10 ft.	44 ft.
North, Middle, South	Cut – 10 ft.	85 ft.
North, Middle, South	Cut – 10 ft.	Top of PWR
North, Middle, South	Fill – 15 ft.	Surface
North, Middle, South	Fill – 15 ft.	44 ft.
North, Middle, South	Fill – 15 ft.	85 ft.
North, Middle, South	Fill – 15 ft.	Top of PWR
South	Cut – 38 ft.	Surface
South	Cut – 38 ft.	44 ft.
South	Cut – 38 ft.	85 ft.
South	Cut – 38 ft.	Top of PWR
South	Fill – 40 ft.	Surface
South	Fill – 40 ft.	44 ft.
South	Fill – 40 ft.	85 ft.
South	Fill – 40 ft.	115 ft.
South	Fill – 40 ft.	Top of PWR

Key: ft. = foot; PWR = partially weathered rock

Table 2.5-26
Topographic Amplification Scale Factors

Key: AFE = annual frequency of exceedance; ft. = foot; km = kilometer; **M** = moment magnitude; mi. = mile; PWR = partially weathered rock; Rrup = rupture distance

Table 2.5-51
Summary of Reactor Base Mat Embedment Depths and Elevations

Technology	Base Depth (ft.)	Base EL.[(a)] (ft.)
Westinghouse	44	766
NuScale	83	727
Holtec	86	724
TerraPower	113.2	696.8
X-energy	115	695
GVH	125	685

Note: EL = elevation; ft: = feet

(a) Based on a final plant grade of Elevation 810 feet.

Table 2.5-52
Testing Summary – Borings
(Sheet 7 of 7)

Notes:

Coordinates are North American Datum (NAD) 83 State Plane North Carolina FIPS 3200 (US Feet); elevations are North American Vertical Datum (NAVD) 1988.

(a) SPT - Standard Penetration Test

(b) UD - Undisturbed Sample (Shelby Tube Sampler)

(c) E-log includes single-point resistance, self-potential, long-normal, and short-normal resistivity, and electrical conductivity.

Below is a list of geotechnical borings terminated prior to planned depth or portion of depth rejected due to quality or mechanical constraints:

B-1: Boring terminated at 120.1 ft. due to tooling stuck in the hole. Re-assigned in offset as B-1A using the same drill rig to complete rock coring.

B-9A: Boring terminated at 45.7 ft. due to auger refusal. Sample was discarded and resampled in B-9B.

B-9B: Boring terminated at 45.8 ft. due to auger refusal.

B-10: Boring terminated at 55.1 ft. due to casing installation complications from a possible boulder. Re-assigned in offset as B-10A using the same drill rig

B-11: Boring terminated at 3.9 ft. due to tricone refusal. Re-assigned in offset as B-11A using the same drill rig.

B-11A: Boring terminated at 50.2 ft. due to tricone refusal and potential difficulties coring through PVC casing. Re-assigned in offset as B-11B using the same drill rig.

B-15: Boring terminated at 81.7 ft. due to complications with PVC casing during coring. Re-assigned in offset as B-15A using the same drill rig.

Key: ft = foot; SPT = standard penetration test

Table 2.5-53
Drilling Equipment

Driller	Drill Rig Model	Carrier Type	Owner	Auto Hammer	Hammer Serial Number	Auto Hammer Energy Ratio (%)	Rig Use
G. Owens	Geoprobe 8140LS	Track	Geologic Exploration	NA	NA	NA	Geotechnical (Rotosonic)
C. Lackey	CME 550X	All-terrain vehicle	Premier	Yes	336353	88	Geotechnical (Mud Rotary)
C. Maddox	CME 750X	All-terrain vehicle	Premier	Yes	323438	89	Geotechnical (Mud Rotary)
J. Messick	Diedrich D-70	Track	Geologic Exploration	Yes	047	89	Geotechnical (Mud Rotary)
B. Thomas	Geoprobe 3230DT	Track	Geologic Exploration	NA	NA	NA	Well Installation (Air Hammer)

Key: NA = Not Applicable

Table 2.5-54
Summary of Geotechnical Laboratory Testing

Test Standard	Test Description
ASTM D854-23	Specific Gravity of Soil Solids by Water Pycnometer
ASTM D1140-17	Amount of Material Finer than 75-µm (No. 200) Sieve
ASTM D1557-12(2021)	Laboratory Compaction Characteristics of Soil Using Modified Effort
ASTM D2166-16	Unconfined Compressive Strength of Cohesive Soil
ASTM D2216-19	Determination of Water (Moisture) Content of Soil and Rock by Mass
ASTM D2435/D2435M-11(2020)	One-Dimensional Consolidation Properties of Soils Using Incremental Loading
ASTM D2487-17e1	Classification of Soils for Engineering Purposes
ASTM D2850-23	Unconsolidated-Undrained Triaxial Compression Test
ASTM D2974-20e1	Water (Moisture) Content, Ash Content, and Organic Material of Peat and Other Organic Soils
ASTM D4318-17e1	Liquid Limit, Plastic Limit, and Plasticity Index of Soils
ASTM D4546-21	One-Dimensional Swell or Collapse of Soil
ASTM D4767-11(2020)	Consolidated-Undrained Triaxial Compression Test for Cohesive Soils
ASTM D5334-22ae1	Determination of Thermal Conductivity of Soil and Rock by Thermal Needle-Probe Procedure
ASTM D6913/D6913M-17	Particle-Size Distribution of Soils Using Sieve Analysis
ASTM D7012-23 Method C	Compressive Strength and Elastic Moduli of Intact Rock Core Specimens under Varying States of Stress and Temperatures
ASTM D7263-21	Laboratory Determination of Density and Unit weight of Soil Specimens
ASTM D7928-21e1	Particle-Size Distribution (Gradation) of Soils Using Hydrometer Analysis
ASTM G51-18	pH of Soil Used in Corrosion Testing
ASTM D4452-14	X-Ray Radiography of Soil Samples
ASTM D5607-16	Direct Shear Strength Tests of Rock Specimens Under Constant Normal Force
ASTM D7012-23 Method B	Compressive Strength and Elastic Moduli of Intact Rock Core Specimens under Varying States of Stress and Temperatures
ASTM D7012-23 Method C	Compressive Strength and Elastic Moduli of Intact Rock Core Specimens under Varying States of Stress and Temperatures
ASTM D7012-23 Method D	Compressive Strength and Elastic Moduli of Intact Rock Core Specimens under Varying States of Stress and Temperatures
AASHTO T291-94(2018)	Water-Soluble Chloride Ion Content of Soil
ASTM C1580-20	Water-Soluble Sulfate Ion Content of Soil
RCTS	Resonant Column Torsional Shear Testing
URC	Unconfined, Free-Free Resonant Column Testing

Notes:

(a) Preconsolidation pressure was estimated using Casagrande Graphical Method for Estimating Preconsolidation Pressure; see Section 2.5.4.10.3 for discussion on consolidation parameters.

(b) Initial and final dry unit weight and moisture obtained as part of consolidation testing.

(c) Negative values indicate samples experienced compression (collapsed) after adding water.

Key: ft. = foot; UD = undisturbed sample; BK = bulk sample; N/A = not applicable; pcf = pounds per cubic foot; tsf = tons per square foot

Notes:

(a) The coordinates and ground elevation for the parent boring are shown. The offset boring is within 10 ft. (distance), with less than 1-ft. **elevation difference relative to the parent boring.**

Cells with dashed lines ("--") indicate the boring did not have standard penetration test (SPT) and/or rock coring performed; thus, no contact elevation was identified.

Key: EL = elevation; ft. = foot; max = maximum; min = minimum; PWR = partially weathered rock; Std Dev = standard deviation

	Best Estimate	***65***	***150***	***1,000***
	Upper Bound	*105*	*300*	*2,000*
Concrete-Soil Ultimate Interface Friction Factor, tan(δ)[f]	**Best Estimate**	***--***	***--***	***0.64***

Notes:

(a) Based on lognormal distribution assumption; lower bound taken as 5th percentile, best estimate as 50th percentile and upper bound as 95th percentile.

(b) As measured during unit weight determinations.

(c) Majority of samples tested were non-plastic; values shown are for the plastic samples only.

(d) For slope stability analyses only for cut slopes in Stratum I and/or Stratum II under unsaturated conditions. If there is a potential for the residual soils in the cut slope to become saturated, then effective cohesion should be zero.

(e) For undrained slope stability analyses during Rapid Drawdown conditions.

(f) No value shown for Stratum I and II because safety-related structures will not be founded on these strata. Per Section 2.5.4.3.2, structural backfill with a minimum friction angle of 40 degrees has an ultimate coefficient of interface static sliding friction of 0.59

Key: bpf = blows per foot; PWR = partially weathered rock; SPT = standard penetration test; psf = pounds per square foot; tsf = tons per square foot; USCS = Unified Soil Classification System

Table 2.5-65
Summary of Static Rock Engineering Properties for Strata IV and V
(Sheet 1 of 2)

Parameter	Description	Stratum IV – Fractured Rock	Stratum V – Sound Rock
Total Unit Weight, γ_{total} (pcf)	Lab Testing	161.9 – 195.3 (Avg. 169.6)	
	Best Estimate	*170*	
Unconfined Compressive Strength, UCS (psi)	Lab Testing	1,580 – 28,440 (Avg. 14,324)	
	Best Estimate[(a)]	*7,890*	
Elastic Modulus of Intact Rock, E_i (psi)	Lab Testing	4.09E+05 – 1.02E+07 (Avg. 5.15E+06)	
	Best Estimate[(a)]	*3.48E+06*	
Poisson's Ratio of Intact Rock, v	Lab Testing	0.01 – 0.19 (Avg. 0.08)	
	Best Estimate	*0.10*	
Rock Quality Designation, RQD (%)	Field Testing	0 - 49	50 - 100
Geologic Strength Index, GSI	Lower Bound	14	44
	Best Estimate	30	70
	Upper Bound	45	95
Equivalent Rock Mass Mohr-Coulomb Strength Parameters, c and ϕ[(a)]	Lower Bound	c = 0 psi, ϕ = 40 deg	c = 51 psi, ϕ = 47 deg
	Best Estimate	**c = 34 psi, ϕ = 41 deg**	**c = 157 psi, ϕ = 55 deg**
	Upper Bound	c = 53 psi, ϕ = 48 deg	c = 888 psi, ϕ = 55 deg

Table 2.5-65
Summary of Static Rock Engineering Properties for Strata IV and V
(Sheet 2 of 2)

Parameter	Description	Stratum IV – Fractured Rock	Stratum V – Sound Rock
Rock Mass Deformation Elastic Modulus, E_{rm} (psi) [(a)]	Lower Bound	44,800	345,250
	Best Estimate	153,155	1,522,260
	Upper Bound	368,480	2,481,610
Rock Mass Deformation Shear Modulus, G_{rm} (psi) [(a)]	Lower Bound	20,365	156,930
	Best Estimate	69,615	691,935
	Upper Bound	167,490	1,128,005
Concrete-Soil Ultimate Interface Friction Factor, tan(δ)	Best Estimate	0.70[(b)]	0.70

Note:

(a) Values shown based on the weaker schist.

(b) Following ground improvement as discussed in Section 2.5.4.12

3.5 MISSILE PROTECTION

3.5.1 Missile Selection and Description

3.5.1.6 Aircraft Hazards

NUREG-0800, *Standard Review Plan for the Review of Safety Analysis Reports for Nuclear Power Plants: Light Water Reactor (LWR) Edition*, establishes an acceptable method for applicants to demonstrate that the risks from aircraft hazards are sufficiently low. The NUREG establishes proximity-based screening criteria that allow an applicant to assess risk consequences by inspection. However, as noted below, the Belews Creek, North Carolina (NC) site (Project site) does not meet these criteria. In such cases, the NUREG requires a more detailed review of aircraft hazards. Specifically, NUREG-0800, Section 3.5.1.6, Rev. 4, “Aircraft Hazards,” provides that aircraft accidents that could lead to radiological consequences in excess of the exposure guidelines of Title 10 of the Code of Federal Regulations (CFR) Part 100, with a probability of occurrence greater than an order of magnitude of 10^{-7} per year (yr.), should be considered in the design of the plant. The NUREG establishes the expected rate of exposure identified in 10 CFR 50.34(a)(1) dose guidelines as it relates to the requirements identified in 10 CFR 100.20(b) should be about an order of magnitude of 10^{-6} per yr. If it can be shown with rigorous analysis, using realistic assumptions and reasonable arguments, that the estimated probability could be lower, then, in accordance with NUREG-0800, Section 2.2.3, Rev. 3, “Evaluation of Potential Accidents,” the risk level is considered acceptable.

The aircraft facilities and airways are described in Section 2.2.2.7. A screening evaluation was first performed to determine if the probability is considered to be less than an order of magnitude of 10^{-7} per yr. by inspection in accordance with the proximity criteria set in NUREG-0800. The evaluation determined there are two airports within five statute miles (mi.) (eight kilometers [km]) of the Project site – Meadow Brook Field (N63) and DS Butler Farm and Airfield (N83). Additionally, there is one airport with projected operations in 2050 that are greater than that allowed by the screening criteria – Piedmont Triad International (GSO). The evaluation further determined there are multiple federal airways (V-20/T-224, V-45, and V-103) whose edges are closer than two statute mi. (3.2 km) to the Project site. The Project site is approximately 1.9 statute mi. (3.0 km) from the centerline of airway V-20/T-224, 3.1 statute mi. (5.0 km) from the centerline of airway V-45, and 3.5 statute mi. (5.6 km) from the centerline of airway V-103. Additionally, approach pattern, approach and landing (AL)178 to Runway 14 of the Piedmont Triad International (GSO) airport does not meet the two statute mi. (3.2 km) criteria. Therefore, due to the airports, airways, and an approach pattern that fail the screening criteria in NUREG-0800, a detailed review of aircraft hazards was performed to determine whether the accident frequency is less than an order of magnitude of 10^{-7} per yr.

Details of the aircraft hazards analysis are provided in Section 2.2.2.7 and follow the methodology in DOE-STD-3014-2006 (Reference 3.5-1). To demonstrate acceptability, further evaluation is required to show the expected rate of occurrence of potential exposures resulting in radiological dose in excess of the guidelines identified in 10 CFR 50.34(a)(1), as it relates to the requirements identified in 10 CFR 100.20(b), is on the order of magnitude of 10^{-6} per yr. and the realistic probability is lower, based on qualitative arguments. The accident frequency evaluation in Section 2.2.2.7 utilizes a set of bounding building dimensions (i.e., with a safety-related footprint diagonal, R, less than or equal to 216 feet [ft.] [65.8 meters {m}], height less than or equal to 176 ft. [53.6 m], and footprint area less than or equal to 20,700 square [sq.] ft.

[1920 sq. m]). These dimensions, as well as the aircraft's wingspan, skid distance, and impact angle define the effective area used in the accident frequency calculation as explained in DOE-STD-3014-2006 (Reference 3.5-1). The bounding building dimensions associated with the selected reactor technology will be confirmed at the time of the construction permit or license application.

When the technology vendor is selected, further assessments will be performed to confirm that the risk of a radiological release due to an aircraft accident satisfies NUREG-0800, Section 3.5.1.6 acceptance criteria. The results of these assessments will be documented in the construction permit or license application.

Chapter 11 Radioactive Waste Management

11.2 LIQUID WASTE MANAGEMENT SYSTEM

11.2.3 Liquid Radioactive Releases

This section describes the liquid radiological impacts of normal plant operation from the Belews Creek, North Carolina (NC) site (Project site) to members of the public. Section 11.2.3.1 describes the exposure pathways by which radiation from radiological liquid effluents could be transmitted from the Project site to members of the public. Section 11.2.3.2 estimates individual and collective doses to members of the public from radiological liquid effluents and evaluates the impact of these doses by comparing them to regulatory limits.

11.2.3.1 Exposure Pathways

During normal operation of the Project site, radiological liquid effluents are expected to be discharged to the environment. The Project site will release small quantities of treated and diluted radioactive liquid effluent into the Dan River. The liquid effluent pathways associated with the Dan River are analyzed to estimate the potential doses from liquid releases during normal operation. The major pathways of concern are those that could yield the highest radiological doses for a given receptor. The pathways are determined from the type and amount of radioactivity transported, the transport mechanism, and the consumption or usage factors of the receptor.

The exposure pathways considered for the Project site are analyzed and estimated for the maximally exposed individual (MEI) and the general population surrounding the Project site. The MEI is the member of the public who is positioned to receive the maximum possible calculated dose. The doses estimated for the Project site are based on United States (U.S.) Nuclear Regulatory Commission (NRC) Regulatory Guide (RG) 1.109, Rev. 1, *Calculation of Annual Doses to Man from Routine Releases of Reactor Effluents for the Purpose of Evaluating Compliance with 10 CFR Part 50, Appendix I*. These estimated doses are used to confirm that anticipated releases, associated with normal operation of the plants (being considered for the Project site) will result in doses that are within the dose limits to the public described in Title 10 of the Code of Federal Regulations (CFR), Part 50, (10 CFR 50), Appendix I; 10 CFR Part 20, and 40 CFR Part 190, the U.S. Environmental Protection Agency (USEPA) limits on dose to the public.

The LADTAP II module of the NRCDose computer code implements the methodology discussed in RG 1.109, Rev. 1 to estimate doses from liquid effluents from the Project site (Reference 11.2-1). The code estimates the dose to the MEI and to the average individual through the following pathways:

- Internal exposure from ingestion of aquatic foods.
- Internal exposure from ingestion of drinking water.
- Internal exposure from ingestion of milk and meat from livestock consuming pasture feed from farms irrigated by contaminated water.
- Internal exposure from ingestion of vegetables and fruits from farms irrigated by contaminated water.

- External exposure to shoreline sediments.
- External exposure from boating and swimming.

The reactor effluent discharge flow rate of 7.35 cubic feet per second (cfs) (0.208 cubic meters per second [m^3/s]) and a mean flow rate for the Dan River of 498.4 cfs (14.11 m^3/s) is utilized for the analysis. Additionally, transit time from liquid discharge to the Dan River is assumed to be zero. This is conservative since the Dan River is greater than 2.24 miles (mi.) (3.6 kilometers [km]) from the Project site, and thus some decay will occur before it is discharged into the river.

The shoreline, swimming, and boating usage is determined by multiplying the 50 mi. (80 km) radius population for the year 2079 (Table 11.2.3-3) by the average shoreline usage rate. The fish consumption is similarly determined by multiplying the 50 mi. (80 km) radius population for the year 2079 (Table 11.2.3-3) by the average adult fish consumption; however, the only identified location of commercial fish supply within 50 mi. (80 km) of the Project site produces 250,000 pounds of tilapia per year. Therefore, the average adult fish consumption is reduced by 50 percent to account for the fraction of consumption attributed to the Dan River.

The drinking water usage rate is determined using the survey conducted in 2024, which shows that the Dan River is used as drinking water for two locations (i.e., city of Eden and town of Madison in NC). The 2025 population for both locations (i.e., 17,581) was used and scaled appropriately to 2079, using the same scale factors (i.e., 1.39) used for the projected 2079 50 mi. (80 km) radius population.

The milk production, meat production, and produce production that utilized irrigation from the Dan River, downstream of the radioactive liquid effluent discharge location, is determined using the survey conducted in 2024 and consumption rates from the GASPAR II Technical Manual. Using the survey, the sum of the fractions of irrigated cropland is determined to be 0.0153. Additionally, the ratio of total cropland from counties using irrigation to the total cropland within 50 mi. (80 km) is identified to be 0.585. For the analysis, the national irrigation usage rate in 2024 of 38.1 liters/m^2/month is utilized. Using this information and the consumption rates in Table 11.3.3-3, the production rates for milk, meat and produce that use Dan River water for irrigation, are determined.

Table 11.2.3-1 contains an overview of the liquid pathway parameters used by LADTAP II. Table 11.2.3-2 contains the fish and invertebrate consumption rates and aquatic recreation usage rates used for the MEI and average individual. The consumption factors (infant, child, teen, or adult) from RG 1.109, Rev. 1 are used to determine the doses to the average individual and MEI. Additionally, these consumption factors are multiplied by the projected population (Table 11.2.3-3) within 50 mi. (80 km) of the Project site.

Additionally, since Duke Energy has not yet selected a technology for the Project site, the activity assumed to be released for the site is based on an enveloping approach to bound the technologies considered in this application. The bounding liquid release activity utilized for the Project site is provided in Table 11.2.3-4.

A pump station located roughly three miles downstream from the discharge location can pump river water into Belews Lake in accordance with permitted limitations related to river flow and season. However, any dose contributions from the pathways associated with the Belews Lake would be negligible due to the distance from the discharge location, additional dilution from the Dan River and Belews Lake, and the assumption that liquid radioactive effluent is released in

intermittent batch releases and could be discharged when the pump is not operating.

Population doses for the Project site are calculated for the year 2079, which is projected to be approximately 40 years from starting normal operation. The projected population within 50 mi. (80 km) of the Project site for the year 2079 is provided in Table 11.2.3-3.

11.2.3.2 Liquid Pathway Doses

Table 11.2.3-5 converts the liquid bounding release activity to concentrations to compare against the effluent concentration limits (ECLs) of 10 CFR Part 20, Appendix B, Table 2, Column 2. The bounding release activity is converted to concentrations by dividing by the reactor effluent discharge flow rate and the dilution factor. As shown in Table 11.2.3-5, the bounding release activity concentrations are within the liquid ECLs of 10 CFR Part 20, Appendix B, Table 2, Column 2.

Table 11.2.3-6 provides the resultant doses for the Project site from LADTAP II to the MEI at each pathway location determined. These results are based on the inputs in Tables 11.2.3-1, 11.2.3-2, and 11.2.3-4. Table 11.2.3-7 compares 10 CFR Part 50, Appendix I, dose limits for liquid effluents to the MEI doses for a single unit. The MEI doses calculated from liquid effluents for the Project site are compared to 40 CFR Part 190 and 10 CFR 20.1301(e) dose limits, as shown in Table 11.3.3-8. Table 11.2.3-8 provides the collective population doses from liquid effluents to individuals living within a 50 mi. (80 km) radius of the Project site.

As can be seen from Tables 11.2.3-7 and 11.3.3-8, the estimated liquid effluent doses to the MEI for a single unit are within design objectives of 10 CFR Part 50, Appendix I; and the estimated gaseous and liquid effluent doses to the MEI are within 40 CFR Part 190 and 10 CFR 20.1301(e) dose limits; respectively.

Table 11.2.3-1
Liquid Pathway Parameters

Parameter	Value
Water Type	Fresh Water
Discharge Rate	7.35 cfs
Dilution Factor	68
Transit Time to Receptor	0 hour
Impoundment Reconcentration Model	None
Shore-Width Factor	0.2
Population within 50 miles	3,057,906
50-mi Shoreline Usage (person -hr/yr)	39,141,197
50-mi Swimming Usage (person -hr/yr)	39,141,197
50-mi Boating Usage (person -hr/yr)	39,141,197
50-mi Sport Fishing Harvest (kg/yr)	10,549,775.7
50-mi Commercial Fishing Harvest	0
50-mi Sport Invertebrate Harvest	0
50-mi Commercial Invertebrate Harvest	0
Drinking Water Population	24,500
Milk Production using Dan River as Irrigation (L/yr)	10,947,915.1
Meat Production using Dan River as Irrigation (kg/yr)	3,010,676.6
Produce Production using Dan River as Irrigation (kg/yr)	18,994,632.6

Key: cfs = cubic feet per second; hr/yr = hours per year; kg/yr = kilograms per year; L/yr = liters per year; mi. = mile

Table 11.2.3-2
Fish and Invertebrate Consumption Rates and Aquatic Recreation Usage Rates

Consumption Factor	MEI Annual Rate				Average Annual Rate				Average Rate
	Adult	Teen	Child	Infant	Adult	Teen	Child	Infant	
Fish Consumption (kg/yr)	21	16	6.9	0	6.9	5.2	2.2	0	5.9
Invertebrate Consumption (kg/yr)	0	0	0	0	1.0	0.75	0.33	0	0.85
Shoreline Usage (hr/yr)	12	67	14	0	8.3	47	9.5	-	12.8
Swimming (hr/yr)	12	67	14	0	8.3	47	9.5	-	12.8
Boating (hr/yr)	12	67	14	0	8.3	47	9.5	-	12.8
Drinking Water Consumption (L/yr)	730	510	510	330	370	260	260	-	-

Key: hr/yr = hours per year; kg/yr = kilograms per year; L/yr = liters per year; MEI = maximally exposed individual

11.3 GASEOUS WASTE MANAGEMENT SYSTEM

11.3.3 Gaseous Radioactive Releases

This section describes the gaseous radiological impacts of normal plant operation from the Project site to members of the public. Section 11.3.3.1 describes the exposure pathways by which radiation from radiological gaseous effluents could be transmitted from the Project site to members of the public. Section 11.3.3.2 estimates individual and collective doses to members of the public from radiological gaseous effluents and evaluates the impact of these doses by comparing them to regulatory limits.

11.3.3.1 Exposure Pathways

During normal operation of the plants considered for the Project site, radiological gaseous effluents are expected to be discharged to the environment. Exposure to the radiological effluents from normal operation is dependent on the radiological exposure pathways. A radiological exposure pathway is the vehicle by which a receptor may become exposed to radiological releases from nuclear facilities. The major pathways of concern are those that could yield the highest radiological doses for a given receptor. These pathways are determined from the type and amount of radioactivity transported, the transport mechanism, and the consumption or usage factors of the receptor. Environmental transport mechanisms for gaseous effluents consider the historical meteorological characteristics of the area that are defined by windspeed and wind direction. Additional factors such as location of homes, use of cattle for milk, and gardens for vegetable consumption are considered when evaluating exposure pathways.

The exposure pathways considered for the Project site are analyzed and estimated for the MEI and the general population surrounding the Project site. The MEI is the member of the public who is positioned to receive the maximum possible calculated dose. The doses estimated for the Project site are based on RG 1.109 and RG 1.111, Rev. 1, *Methods for Estimating Atmospheric Transport and Dispersion of Gaseous Effluents in Routine Releases from Light-Water-Cooled Reactors*. The estimated doses are used to confirm that anticipated releases associated with normal operation of the plants considered for the Project site are within the dose limits to the public described in 10 CFR Part 50, Appendix I; 10 CFR Part 20; and 40 CFR Part 190, the USEPA limits on dose to the public.

Section 2.3.5 contains discussion regarding the atmospheric dispersion (χ/Q) and ground deposition (D/Q) factors for the Project site. The χ/Q factors in Section 2.3.5 are determined using the XOQDOQ computer code, which implements RG 1.111 methodology (Reference 11.3-1). Table 11.3.3-1 contains the χ/Q and D/Q values for the maximally exposed location (MEL) and offsite receptors that are utilized for the evaluation.

The GASPAR II module of the NRCDose computer code implements the methodology discussed in RG 1.109, Rev. 1 to estimate doses from gaseous effluents from the Project site (Reference 11.3-2). The code calculates the radiation exposure to people through the following potential pathways:

- External exposure to airborne radioactivity
- External exposure to deposited activity on the ground

- Inhalation of airborne radioactivity
- Ingestion of contaminated agricultural products

Table 11.3.3-2 contains an overview of the gaseous pathway parameters used by GASPAR II. The fraction of the year that leafy vegetables are grown, and milk and meat animals are on pasture is based on site-specific conditions. NC experiences all four seasons; therefore, it is not expected that vegetables are grown all year, and milk and meat animals are on pasture all year.

Figure 2.2 in the GASPAR II technical manual (Reference 11.3-2) is used to determine the length of the growing season. In the case of the Project site, the growing/pasture season is 8 months. The GASPAR II Technical Manual states to add one month for goats for nine total months and to subtract three months for leafy greens for five months.

The fraction of the maximum individual's vegetable intake that is from their own garden is expected to be lower than the default GASPAR II value. The land survey conducted in December of 2024 identified the nearest vegetable garden as a soybean farm. Furthermore, the survey found that the crop production within 2 miles of the Project site is comprised of corn, sorghum, soybeans, tobacco, winter wheat, triticale, and hay. The crop production within 2 miles also appears to be operations that would require the crops to be processed and shipped outside of the project area. As such, it is not reasonable to assume that 76 percent (i.e., the value from Table E-15 of RG 1.109) of vegetables consumed are from an individual's garden. Therefore, it is reasonable, and still conservative to assume that an individual consumes roughly a third of their vegetable intake (i.e., 0.35) for 42 percent (i.e., 5 months) of the year from their own garden.

Table 11.3.3-3 contains food consumption rates for the average individual and the MEI within 50 mi. (80 km) of the Project site. The table is based on the most conservative consumption factor (infant, child, teen, or adult) from Reference 11.3-2 which is used to determine the dose to the average individual and the MEI. Additionally, these consumption factors are multiplied by the projected population (Table 11.2.3-3) within 50 mi. (80 km) of the Project site. Because milk and meat animals are not identified to be within 5 mi. (8 km) of the Project site, dose contributions from milk and meat animals do not contribute to the MEI dose.

Additionally, since Duke Energy has not yet selected a technology for the Project site, the activity assumed to be released from the site is based on an enveloping approach to bound the technologies considered in this application. The bounding gaseous release activity utilized for the Project site is provided in Table 11.3.3-4.

As noted in NUREG-2226 (Reference 11.3-3), direct radiation from sources within a light-water reactor (LWR) is primarily due to nitrogen-16. Because the primary coolant of an LWR is contained in a heavily shielded area, dose rates in the vicinity of LWRs are generally undetectable and less than 1 mrem/yr at the unrestricted area boundary. Some plants (mostly boiling-water reactors) do not have completely shielded secondary systems and may contribute some measurable offsite doses. Additionally, since the dose rates discussed in NUREG-2226 and NUREG-1437 relate more to units that are larger than the advanced reactors considered in the analysis, the dose is expected to be less for the technologies considered for the Project site. Therefore, a dose rate for direct radiation of 1 mrem/yr at the unrestricted area boundary is utilized. However, since 40 CFR Part 190 applies to the MEI, which is located at the nearest resident, and since the nearest resident is located farther from the unrestricted area boundary, any contributions to the MEI from direct radiation are expected to be negligible.

Population doses for the Project site are calculated for the year 2079, which is projected to be approximately 40 years from starting normal operation. The projected population within 50 mi. (80 km) of the Project site for the year 2079 is provided in Table 11.2.3-3.

11.3.3.2 Gaseous Pathway Doses

Table 11.3.3-5 converts the gaseous bounding release activity to concentrations for the Project site to compare against the Gaseous ECLs of 10 CFR Part 20, Appendix B, Table 2, Column 1. As can be seen from Table 11.3.3-5, the bounding release activity concentrations for the Project site are within the ECLs of 10 CFR Part 20, Appendix B, Table 2, Column 1. To convert the bounding release activity to a concentration, each radionuclide is multiplied by the unrestricted area boundary MEL χ/Q factor for each plant. The activities utilized for each Plant Complex are determined by multiplying the per unit activities by the expected number of units at each Plant Complex, as discussed in Section 1.11. Since the bounding release activity is primarily based on technologies that would build two units at each Plant Complex, it is reasonable to multiply the per unit activities by two. The resulting concentrations for each Plant Complex are summed to obtain the bounding site gaseous release concentrations and are compared against the ECLs of 10 CFR Part 20, Appendix B, Table 2, Column 1.

Table 11.3.3-6 provides the results for the Project site from GASPAR II to the MEI at each pathway location. These results are based on the inputs in Tables 11.3.3-2 and 11.3.3-3. Table 11.3.3-7 compares 10 CFR Part 50, Appendix I, dose limits for gaseous effluents to the MEI doses for a single unit. The MEI doses calculated from gaseous and liquid effluents for the Project site are compared to 40 CFR Part 190 and 10 CFR 20.1301 dose limits, as shown in Table 11.3.3-8. Table 11.3.3-9 provides the collective population doses from gaseous effluents to individuals living within a 50 mi. (80 km) radius of the Project site.

As can be seen from Tables 11.3.3-5, 11.3.3-7, and 11.3.3-8, the bounding site gaseous release concentrations are within the ECLs of 10 CFR Part 20, Appendix B, Table 2, Column 1; the estimated gaseous effluent doses to the MEI for a single unit are within design objectives of 10 CFR Part 50, Appendix I; and the estimated gaseous and liquid effluent doses to the MEI are within 40 CFR Part 190 and 10 CFR 20.1301(e) dose limits, respectively.

Chapter 13 Conduct of Operations

13.3 EMERGENCY PREPAREDNESS

This section, along with the Part 5, Emergency Plan, of the early site permit application (ESPA), describes emergency preparedness to support the addition of new nuclear power Plant Complexes at the Belews Creek, North Carolina (NC) site (Project site). In accordance with Title 10 of the Code of Federal Regulations (CFR) Part 52, Section 52.17(b)(2)(i), this plan describes major features of a performance-based emergency preparedness program and addresses pertinent requirements contained in 10 CFR 50.160, *Emergency Preparedness for Small Modular Reactors, Non-Light Water Reactors, and Non-Power Production or Utilization Facilities* and associated guidance contained in Regulatory Guide (RG) 1.242, Rev. 0, *Performance-Based Emergency Preparedness For Small Modular Reactors, Non Light-Water Reactors, and Non-Power Production or Utilization Facilities*. The Emergency Plan meets the applicable requirements of 10 CFR 50.47(a)(1) as delineated by 10 CFR 50.160.

To maintain consistency throughout the Duke Energy fleet, the Project site Emergency Plan references applicable emergency preparedness processes that are described in the existing Duke Energy Common Emergency Plan. The Duke Energy Common Emergency Plan has been approved by the U.S. Nuclear Regulatory Commission (NRC) to support all of the Duke Energy operating nuclear facilities in Safety Evaluation Report dated August 26, 2021 (Reference 13.3-1).

Duke Energy has not selected a reactor technology to be built at the Project site. However, six advanced reactor technologies are being considered. These include four small modular reactors (SMRs) (BWRX-300, VOYGR, SMR-300, and AP300) and two non-light water reactors (non-LWR) (Natrium and Xe-100):

- GVH BWRX-300
- NuScale VOYGR
- Holtec SMR-300
- WEC AP300
- TerraPower Natrium
- X-energy Xe-100

The reactor technology options currently under consideration incorporate design features that provide inherent improvements in safety and security, relying more upon passive processes.

As described in Section 13.3.3.1, the Duke Energy ESPA is establishing the aggregate of the three-Plant Complex exclusion area boundaries (EABs) as the plume exposure pathway emergency planning zone (EPZ). Once a reactor technology has been selected, Duke Energy will be required to provide a confirmatory analysis of the EPZ at the construction permit or license application phase.

Establishment of the plume exposure pathway EPZ at the EABs will not require off-site planning activities including,

- Contacts and arrangements with federal, state, and local government agencies.
- Development of off-site state/county emergency plans.
- Initial/follow-up notifications to state/county organizations (unless required).
- Annual dissemination of public information materials.
- An off-site facility to coordinate on-site/off-site emergency response.
- Off-site dose projections (unless required) and protective actions recommendations.
- Preparatory activities such as evacuation time estimates and contacts and arrangements (agreements with federal, state, local, and tribal governmental agencies).

Duke Energy has established a performance monitoring program at the Project site to demonstrate the effectiveness of the Emergency Plan to carry out effective response to emergency and accident conditions. The framework of the performance monitoring program is based on the current Duke Energy Drill and Exercise Program which describes all objectives and evaluation criteria that may be used for a drill or exercise. Specific performance metrics and objectives for each of the emergency response functions have been developed and are used for evaluation to demonstrate capabilities of the emergency response organization to maintain and perform the emergency response functions described in 10 CFR 50.160 and RG 1.242. Specific details pertaining to performance monitoring and maintenance are contained in Part 5, Section III of the ESPA.

As discussed previously, when Duke Energy chooses a design technology and moves forward in the construction permit or license application phase, the Emergency Plan will be revised to address additional site-specific emergency preparedness requirements. These include determination of Emergency Action Levels (EALs) used to establish emergency classifications, on-site staffing and augmentation time requirements, and locations of emergency response facilities. Additionally, emergency preparedness-specific inspections, tests, analysis, and acceptance criteria will be developed during the construction permit or license application phase. Duke Energy will adopt an EAL scheme similar to NEI 99-01, Rev. 7, *Development of Emergency Action Levels for Non-Passive Reactors*, which has been approved by the NRC. Staffing and augmentation time requirements will be based on a staffing analysis performed in accordance with NEI 10-05, Rev. 0, *Assessment of On-Shift Emergency Response Organization Staffing and Capabilities*, or a similar staffing assessment.

13.3.1 PHYSICAL CHARACTERISTICS

13.3.1.1 Site Description

The proposed Project site is located primarily in Sauratown Township, in the southeastern corner of Stokes County, NC, with a small portion in Belews Creek Township, Forsyth County, NC. All proposed nuclear units will be in Stokes County, while support facilities, such as laydown areas, will be in Forsyth County. The Project site, adjacent to Belews Lake, is approximately 14 miles (mi.) (22.5 kilometers [km]) northeast of Winston-Salem, NC, and approximately 19 mi. (30.6 km) northwest of Greensboro, NC. The total site is approximately 1187 acres (ac). Access to the Project site is available by road using the Duke Power Steam Plant Rd, via Pine Hall Rd, or using Craig Rd, via State Highway 65.

Chapter 2 provides information regarding the physical characteristics of the proposed site, including the preliminary site layout, population distribution, and potential hazards in the site vicinity.

Figure I-1 in Part 5 of the ESPA provides a Project site layout map depicting the proposed reactor design technologies under consideration and site access.

13.3.1.2 Area Population

The resident population has been estimated based on the year 2020 U.S. Census Bureau (USCB) decennial census data (Reference 13.3-2). The resident population distribution within 50 mi. (80.5 km) of the Project site was computed using ArcGIS Pro by overlaying the 2020 USCB block group data on the grid of segments and summing the population of the block group(s) within, or partially intersecting, each segment. The ArcGIS Pro geoprocessing tool was used to calculate overlapping areas (Reference 13.3-3). The tabulate intersection tool was used to calculate the overlapping area of each block group-segment intersection. The block group populations in the segment were grouped and summed to calculate a total segment population. In 2020, the residential population within 5 mi. (8.0 km), 10 mi. (16.1 km), and 20 mi. (32.2 km) of the Project site was 16,951, 74,442, and 675,829, respectively.

The transient population within a 20-mi. (32.2-km) region surrounding the Project site was estimated via a variety of public sources associated with major employers, schools, medical facilities, lodging facilities, and recreational areas and venues. The public sources included government and corporate websites, federal databases, tourism sites, and aggregators of service provider records for the region. Raw transient population estimates were weighted according to the length of time each population group was expected to be in the 20-mi. (32.2-km) area. Weighted transient population estimates were rounded to the nearest whole number to avoid estimating a fraction of a person. Projected transient populations were computed with the same methodology used to develop the resident population projections. The transient population estimates were assumed to be reflective of 2020. The transient population within the 20-mi. (32.2-km) area both unweighted and weighted is estimated to be 230,756 and 116,790, respectively.

13.3.2 EMERGENCY PLAN

Part 5 of the ESPA contains the Project site Emergency Plan with all available information at the time of submittal.

13.3.3 EMERGENCY PLANNING ZONES

Duke Energy is developing a performance-based emergency preparedness program using 10 CFR 50.160 and applying for an Early Site Permit under 10 CFR Part 52. Discussion on the plume exposure pathway EPZ and ingestion response planning is provided below.

13.3.3.1 Plume Exposure Pathway Emergency Planning Zone

In accordance with the 10 CFR 50.160, performance-based approach, the plume exposure pathway EPZ is the area within which public dose is projected to exceed 1 roentgen equivalent man (rem) total effective dose equivalent (TEDE) over the first 96 hours from the release of radioactive materials from the facility as specified in 10 CFR 50.33(g)(2)(i). The criterion considers accident likelihood and source term, timing of the accident sequence, and meteorology. In addition, the plume exposure pathway EPZ is the area in which predetermined, prompt protective measures are necessary. This is consistent with the guidance in EPA-400/R-17/001, January 2017, *PAG Manual: Protective Action Guides and Planning Guidance for Radiological Incidents*. Due to the state of the reactor designs of the technologies being

considered in this ESPA, the analysis used to determine whether the criteria in 10 CFR 50.33(g)(2)(i)(A) and (B) are met, and if they are met, the size of the plume exposure pathway EPZ, is not available from the reactor technology vendors. When Duke Energy makes its technology selection for the Project site, the selected reactor technology vendor will be required to provide a confirmatory acceptance analysis at the construction permit or license application phase. This analysis will confirm that the public dose, as defined in 10 CFR 20.1003, does not exceed the limit of 10 millisievert (mSv) (1 rem) TEDE over 96 hours from the release of radioactive materials from the facility considering accident likelihood and source term, timing of the accident sequence, and meteorology per 10 CFR 50.33(g)(2). This will result in the plume exposure pathway EPZ being within the aggregate of the three-Plant Complex EABs defined in Section 2.1.2 and Figure 2.1-5. The analysis will be performed in accordance with the methodology described in RG 1.242, Appendices A and B. With the plume exposure pathway EPZ located within the EABs, evacuation of the public during the first 96 hours of the accident is not required. As such, the Emergency Plan focuses primarily on on-site planning activities.

13.3.3.2 Ingestion Response Planning

Although the Project site plume exposure pathway EPZ is bounded by the EABs, ingestion response planning is required to protect the food ingestion pathway in the event of a radiological release at the site. The probability of such a release is considered very low due to the design of advanced reactors, which include SMRs and non-LWRs, currently under consideration, and strict operational guidelines enforced by the NRC. In the event of a radiological release, the principal exposure sources are contaminated water or food, such as milk or fresh vegetables.

Ingestion response is not required in the early phase of an emergency, because the ingestion of contaminated foods and water is a longer-term concern. Local, state, and federal resources are available for the intermediate and late phases of emergency response and can support intermediate and long-term monitoring, analysis, interdiction, or embargo, when warranted, for products identified as part of the site's food and water ingestion pathway. Additional details can be found in ESPA, Part 5, Section I.F.

13.3.4 EVACUATION TIME ASSESSMENTS

As discussed earlier, Duke Energy is establishing the EABs as the plume exposure pathway EPZ at this time. Therefore, in accordance with 10 CFR 50.160 and the guidance in RG 1.242, an Evacuation Time Estimate (ETE) study is not required, and the Emergency Plan is focused on on-site planning activities.

13.3.5 CONTACTS AND AGREEMENTS

The proposed plume exposure pathway EPZ is aligned with the EABs. As such, the need for off-site contracts, agreements, and certifications is not required in accordance with 10 CFR 50.160 and the guidance in RG 1.242.

13.6 PHYSICAL SECURITY

The Project site is located in the southeastern corner of Stokes County, NC, just north of Belews Creek Township, NC, extending slightly into the northeastern corner of Forsyth County, NC. The Project site is owned by Duke Energy. Duke Energy proposes to construct up to three nuclear power Plant Complexes on the Project site; each complex may contain multiple advanced reactors. The specific reactor technology has not been selected.

The Project site is located on a peninsula surrounded by Belews Lake to the north, east, and much of the western sides. Belews Lake is also owned by Duke Energy and was constructed in the early 1970's as a cooling reservoir for the adjacent Belews Creek Steam Station. The site may be accessed from either Pine Hall Road from the west or Craig Road from the south. For a detailed description of the Project site, refer to Section 2.1.

As required by 10 CFR 100.21(f), the characteristics of the Project site are such that adequate security plans and measures can be developed and implemented. The following highlights key site characteristics of the proposed site.

The configuration of the Project site is suitable for implementing the requirements of 10 CFR 73.55, ensuring adequate separation between structures and security boundaries, as well as deterring both land-based and waterborne threats. The natural topography presents no unusual features that would impede implementation of necessary physical barriers and other protection measures. Site layouts are arranged to maintain sufficient spatial separation to facilitate effective security measures. The reactor technologies under consideration incorporate defense-in-depth measures to mitigate the risk of radiological sabotage, including controls for exclusion, protected, and vital areas. The proposed site layout is provided in Figure 1.2-3. A topological map of the site is presented in Figure 2.1-1.

In accordance with 10 CFR 100.21(f), Duke Energy will ensure that site characteristics are such that adequate security plans and measures can be developed and implemented. During the construction permit or license application phase, the specific design features will be reviewed to ensure site physical protection measures comply with 10 CFR 73.55 requirements. A detailed security assessment will be provided during the construction permit or license application phase, which will address site-specific design features of the selected reactor technology that support site security and will describe the key features of the physical protection plan. These features include descriptions of the security monitoring systems, threat detection and deterrence measures, physical barriers to be provided for protected and vital areas and vehicle control measures, personnel screening requirements, security equipment testing and maintenance, and communication requirements.

Vehicle access is limited to the west and south sides of the property because the Project site is bordered by Belews Lake. A railroad spur connects the Project site to the Norfolk Southern Railway. No major highways, railroads, or waterways traverse the proposed exclusion, owner-controlled, or protected areas. Further, an EAB will be established to mitigate security threats from both land and water. Exclusion area authority and control is discussed in more detail in Section 2.1.2. Therefore, accidental explosion from the nearby transportation routes is not expected to be a credible scenario.

While the Project site is in a relatively rural location, the region surrounding the site contains a significant population associated with the Piedmont metropolitan area. Major metropolitan areas include Winston-Salem, NC (14 mi.) and Greensboro, NC (19 mi.). The moderately close

proximity of the site location to the metro areas ensures the availability of material, equipment, or services needed to maintain and support the security systems and operations. Refer to Section 2.1 for additional details on the demography surrounding the Project site.

The effects of acute and prolonged exposure to severe weather and resulting environmental conditions such as flood and drought will not challenge the engineered and administrative controls for security operations. Engineered and administrative controls will not be challenged in the event of flooding or low water conditions at the Project site. Minimum standoff distances will not be impacted by flooding or low water conditions. Additional details regarding site hydrological features are provided in Section 2.4.

The geological and seismology characteristics for the Project site have been determined to be suitable for nuclear plant construction. The identified regional seismic characteristics do not challenge or pose an impediment to the engineered and administrative controls required for a physical protection system. Security plans and measures will be developed and implemented to comply with applicable codes and standards for the reactor technology selected. The specific reactor technologies under consideration have robust seismic design specifications which provide reasonable assurance that nuclear safety-related systems, structures, and components as well as the security features will remain available under design-basis seismic conditions. Additional details regarding the site seismic and geological features are provided in Section 2.5.

Review of nearby facilities, including nearby chemical/industrial facilities, pipelines, transportation routes (railroads, waterways, airways), and military facilities (military bases, training bases, munitions storage) reveals no potential hazards associated with off-site explosions, flammable vapor clouds, and fires in the vicinity of the Project site that pose a security concern. Additionally, toxic vapor clouds do not pose a security concern for the Middle or South Plant Complex power blocks. However, that same risk may pose a design-basis hazard to the North Plant Complex power block and additional refinement, or mitigating features may need to be employed once a final reactor technology is selected. Additional assessments on nearby site hazards are provided in Section 2.2.

Because the detailed site layout design has not been finalized at this ESPA stage, Duke Energy has not identified possible planned culverts or unattended openings that could extend from the outside to the inside of the designated Protected Area to render a potential security breach. The site-specific security assessment conducted for the construction permit or license application phase will identify and describe the specific security features implemented to address planned culverts or unattended openings. The resulting security plan will describe the measures taken to ensure assessment, observation, detection, and surveillance requirements are met, and appropriate barriers, as necessary, are installed to prevent potential exploitation of any planned culverts or unattended openings.

Chapter 15 Accident Analysis

15.1 ACCIDENT SELECTION

As discussed in Section 1.11, Duke Energy is considering several nuclear technologies for potential construction and operation on the Belews Creek, North Carolina (NC) site (Project site). A specific technology has not yet been selected. Accordingly, Duke Energy is employing a Plant Parameter Envelope (PPE) approach in the Duke Energy Belews Creek Early Site Permit Application (ESPA). As discussed in Section 1.11, the advanced reactor technologies considered in development of the PPE for this ESPA include enhanced design and passive safety features expected to improve overall reactor safety compared to current operating reactors. These technologies include:

GVH BWRX-300	An advanced boiling-water reactor (BWR) design with passive safety features that uses standard light-water reactor (LWR) fuel and generates 870 megawatts thermal (MWt).
NuScale VOYGR	An advanced, integral pressurized-water reactor (PWR) design with passive design features that uses standard LWR fuel with a shorter fuel assembly length, with up to 12 reactors generating 250 MWt each, with the containment of each reactor submerged in the Reactor Building pool.
Holtec SMR-300	An advanced PWR design that includes passive safety features, uses standard LWR fuel, and generates approximately 1000 MWt.
WEC AP300	An advanced PWR design that includes passive safety features, uses standard LWR fuel, and generates 990 MWt.
TerraPower Natrium	An advanced, metal fueled, pool-type sodium fast reactor with passive design features that generates 840 MWt and uses sodium-bonded metallic fuel with high chromium martensitic steel cladding, that operates at near atmospheric pressures and includes a molten salt energy storage system.
X-energy Xe-100	An advanced high-temperature gas-cooled reactor that includes passive safety features. Each reactor generates 200 MWt. The X-energy Xe-100 uses TRi-structural ISOtropic (TRISO) particle fuel. The reactor and steam generator are located inside the containment structure.

As discussed in U.S. Nuclear Regulatory Commission (NRC) Regulatory Guide (RG) 1.206, Rev. 1, *Applications for Nuclear Power Plants*, Section C.1.2, “Safety Analysis Report, for an ESPA, “Chapter 15 is analogous to a COL FSAR for the potential reactor designs but is limited to Section 15.0.3 addressing the evaluation of the radiological consequences of design basis.” [accidents].” Accordingly, this chapter is limited to evaluation of the radiation doses at the exclusion area boundary (EAB) and low population zone (LPZ) for the technologies considered in the development of the PPE. For the Project site, the EAB and LPZ are established at the same boundary.

NUREG-0800, *Standard Review Plan for the Review of Safety Analysis Reports for Nuclear Power Plants: LWR Edition*, (SRP) 15.0.3, “Design Basis Accident Radiological Consequence

Analyses for Advanced Light Water Reactors," March 2007, states the following in Section I.3, for an ESPA employing a PPE approach:

> *A PPE is a set of plant design parameters that are expected to bound the characteristics of a reactor or reactors that may be constructed at a site, and it serves as a surrogate for actual reactor design information. The PPE values are selected by the applicant to bound a range of possible current and future reactor designs. The PPE values and associated information in the ESP application must contain sufficient information for the staff to make a determination regarding the acceptability of the proposed site using the radiological consequence evaluation factors identified in 10 CFR 50.34(a)(1).*

Nuclear Energy Institute (NEI) document NEI 10-01, Rev. 1 (Reference 15.1-1), Section 4, "Development of Normal and Accident Source Terms for a PPE-Based ESP," recognizes that radiation dose calculations for accidents require input from multiple release pathways, radionuclide removal mechanisms, and dispersion factors, which differ among various nuclear technologies. NEI 10-01, Rev. 1, recognizes further that based on the maturity of the technology design, all factors potentially affecting off-site doses for all postulated events may not yet have been sufficiently developed to support definitive projections of the dose consequences for every postulated event. Specifically, NEI 10-01 states:

> *Accident analyses model the time-dependent transport of radionuclides out of the reactor core through several pathways, each with different time-dependent removal mechanisms for radionuclides. Each reactor design has different release pathways, and each pathway has different release rates and different radionuclide removal mechanisms. Given the differences in the reactor designs, it is not possible to develop a bounding analysis for use in PPE based ESP.*
>
> *In addition, the applicant using a PPE may not know the site layout and building configuration making it impossible to model near field atmospheric dispersion around buildings in order to determine doses in the main control room and other areas where habitability is required post accident. Detailed accident analyses are more appropriately performed in the COLA, when a technology is selected and the orientation of the plant onsite is known.*

In the most recently approved Early Site Permit (ESP), ESP No. ESP-006, issued to Tennessee Valley Authority (TVA) for the Clinch River Nuclear site, the NRC accepted the above approach. In Section 15.0.3 of the Final Safety Evaluation Report for the ESPA for the Clinch River Nuclear site (Reference 15.1-2), the NRC noted:

> *SSAR Chapter 15 describes the applicant's assessment of the offsite radiological consequences of DBAs for a surrogate plant, as bounded by the PPE (TVA 2017-TN5387). The U.S. Nuclear Energy Institute 10-01, "Industry Guidance for Developing a Plant Parameter Envelope in Support of an Early Site Permit," notes that accident analyses model the time-dependent transport of radionuclides out of the reactor core through several pathways, each with different time-dependent removal mechanisms for radionuclides (NEI 2010-TN5866). As the applicant notes in SSAR Section 15.1, "Accident Selection," different reactor designs have different release pathways, and each pathway has different release rates and different radionuclide removal mechanisms (TVA 2017-TN5387). Given these differences, the applicant chose to use the DBA*

> *radiological consequence analyses from the design that resulted in the highest post-accident offsite doses in its assessment of the radiological consequences of DBAs at the CRN Site.*

Consistent with the above approach, Duke Energy has selected a source term (radioactivity released to the environment) expected to yield the highest post-accident doses at the EAB/LPZ as the surrogate for the purpose of evaluating the Project site against the site radiological consequence evaluation factors set forth in Title 10 of the Code of Federal Regulations (CFR) Part 52, Section 10 CFR 52.17(a)(1)(ix) and 10 CFR 50.34(a)(1)(ii)(D). The surrogate accident source term selected for analysis represents an instrument line break accident (ILBA) associated with one of the LWRs (GVH BWRX-300) considered in this application. The ILBA assumes a non-isolable circumferential break of a primary cooling system instrument line located outside of primary containment, discussed in further detail in Section 15.2 below.

Using the surrogate source term, doses have been calculated for a two-hour period following initiation of the accident for the EAB, and for the 30-day period following initiation of the accident for the LPZ. The doses calculated using the surrogate accident source term are expected to bound the accident doses of the technologies under consideration in this ESPA at the site EAB/LPZ over any two-hour period and the 30-day period following initiation of the accident.

15.2 SOURCE TERM

The surrogate accident source term (radioactivity released to the environment) used in evaluating the Project site EAB/LPZ doses is provided in Section 2.0, Table 2.0-3. Based on the information currently available, and as discussed above, a primary cooling system ILBA postulated by one of the LWRs was selected as the surrogate accident for the Project site.

The surrogate design-basis accident (DBA) source term was developed by first evaluating information provided by reactor technologies whose designs were sufficiently mature to enable adjusting doses provided to the site conditions. Those technologies included NuScale, X-energy, and TerraPower. To obtain doses for the three Project site Plant Complexes described in Section 2.1.2, doses of these three technologies were scaled using the methodology applied in the Clinch River Nuclear site ESPA. Specifically, the technology vendor doses were divided by the short-term atmospheric dispersion factors (χ/Qs) assumed by the technology vendors and multiplied by the Project site short-term χ/Qs to obtain the site-specific doses for these technologies for the three Plant Complexes. The resultant doses for those technologies were well within the 10 CFR 52.17(a)(1)(ix) and 10 CFR 50.34(a)(1)(ii)(D) dose limits.

Note 1 of 10 CFR 52.17 states:

> *The fission product release assumed for this evaluation should be based upon a major accident, hypothesized for purposes of site analysis or postulated from considerations of possible accidental events. Such accidents have generally been assumed to result in substantial meltdown of the core with subsequent release into the containment of appreciable quantities of fission products.*

X-energy did not assume a fission product release for the hypothesized major accident due to substantial meltdown of the core because for the Xe-100, core meltdown is not credible at the temperatures experienced in its non-metallic core. NuScale assumed a beyond design basis event core damage accident, and TerraPower postulated a fuel fault DBA resulting in fuel assembly failure.

Of the three remaining technologies, all of which are LWRs, only one vendor (GVH) had advanced their accident analyses sufficiently to provide source terms for their postulated spectrum of accidents. Of the two remaining technologies, one was able to provide an estimated dose which is bounded by the surrogate accident dose; the other has not yet provided either a dose estimate or source term.

GVH BWRX-300 provided source term information regarding multiple line break accidents (feedwater line break accident, main steam line break accident, isolation condenser system line break accident, and instrument line break accident).

Accordingly, site-specific dose assessments of the accidents postulated by GVH were performed, using conservative assumptions. Based on these dose assessments, the ILBA, which does not assume core damage, was determined to be the bounding accident for the technology. The doses for the ILBA were higher than the core damage accident postulated by NuScale and TerraPower.

In addition to the conservative assumptions used in developing the χ/Qs for the Project site discussed in Section 15.3 below, the dose assessment included the following conservative assumptions:

- The accident was modeled assuming a pre-incident iodine spike.
- Although creditable under NRC RG 1.183, the accident is postulated to result in release of primary coolant activity to the atmosphere with no credit for holdup, filtration, or plateout of the effluent in any plant building.
- It is assumed that relevant daughter products are included in the activities released to the environment.

Based on the conservative methodology discussed above, Duke Energy has concluded that the source term developed is a reasonable surrogate for analysis of DBAs for the Project site.

15.3 EVALUATION METHODOLOGY AND CONCLUSIONS

Doses for the bounding DBA at the limiting EAB/LPZ boundary are shown in Table 15.3-1. The limiting two-hour EAB short-term χ/Q is conservatively applied to the LPZ dose determination because the EAB and the LPZ boundary are the same, the release is an instantaneous release, and the 0-to-2-hour EAB short-term χ/Q is larger than the LPZ short-term χ/Qs.

Key inputs to determination of the doses in Table 15.3-1 include:

- As discussed in Section 2.3.4, the greater of the short-term χ/Q values calculated for the directionally dependent (0.5% maximum sector) or the directionally independent (5% overall site) for the Project site is used.

- Use of the surrogate accident source term to calculate doses at the EAB/LPZ.

As discussed in Section 2.3.4, the Project site short-term dispersion factors were calculated using conservative assumptions:

- No building wake effects were credited.

- Effluent release points are assumed to occur at the perimeter of each of the technology composite footprints depicted as power block areas in Figure 2.1-5. This adds additional conservatism as the actual releases in most cases occur at the perimeter of the reactor building, located well inside of the perimeter of each vendor's technology plot footprint.

- As discussed in Section 2.3.4, the short-term dispersion factors for the Project site have been calculated in accordance with the guidance contained in NRC RG 1.45, Rev. 1, using the PAVAN code. Use of the ARCON code in accordance with NRC RG 1.249, Rev. 0, would likely reduce the Project site dispersion factors, and thus reduce the calculated doses by up to an order of magnitude.

- It is assumed that the LPZ dose is equal to the 0-2 hour EAB dose for the instantaneous release since the EAB and the LPZ are the same boundary. This is conservative as the 0-8 hour LPZ χ/Q is smaller than the 0-2 hour EAB χ/Q factor, which would result in a smaller dose at the LPZ. Since an instantaneous release is assumed, it is acceptable to utilize the 0-2 hour EAB χ/Q as the 0-8 hour LPZ χ/Q.

Based on the conservatisms applied in development of both the surrogate source term and the short term χ/Qs for the project site, Duke Energy is reasonably confident that the doses calculated for the surrogate accident will bound the two remaining technologies that have not yet provided sufficient information to validate this conclusion. However, for any technology selected, descriptions of each of the postulated DBAs and their associated dose consequences will be provided in the construction permit or license application.

The resulting accident doses are expressed as total effective dose equivalent (TEDE), consistent with 10 CFR 52.17(a)(1)(ix) and 10 CFR 50.34(a)(1)(ii)(D). As shown in Table 15.3-1, the accident doses of the technologies considered in the development of the PPE are below the 25 rem TEDE limits specified in 10 CFR 52.17(a)(1)(ix) and 10 CFR 50.34(a)(1)(ii)(D) at the EAB/LPZ for the Project site.

Table 15.3-1
Belews Creek Bounding Accident Doses

Location	Time (hr)	Dose (rem TEDE) [(a)(b)]
EAB	0 - 2	18.3
LPZ	0 - 720	18.3(c)

Notes:

(a) As compared to the 25 rem Total Effective Dose Equivalent (TEDE) limit specified in 10 CFR 50.34(a)(1)(ii)(D).

(b) Doses for the 0-2 hour time are for the worst two hours and not necessarily the first two hours.

(c) The two-hour EAB short-term atmospheric dispersion factor is conservatively applied to the LPZ dose determination because the EAB and the LPZ boundary are the same, the release is an instantaneous release, and the 0-to-2-hour EAB short-term atmospheric dispersion factor is larger than the zero to eight-hour LPZ short-term atmospheric dispersion factor.

Key: EAB = exclusion area boundary; hr = hour; LPZ = low population zone; rem = roentgen equivalent man; TEDE = Total Effective Dose Equivalent

Chapter 17 Quality Assurance Program Description

17.5 QUALITY ASSURANCE PROGRAM DESCRIPTION – DESIGN CERTIFICATION, EARLY SITE PERMIT, AND NEW LICENSE APPLICANTS

17.5.1 INTRODUCTION

The Quality Assurance Program implemented during the development of this Early Site Permit Application (ESPA) for safety-related activities is described in the Duke Energy Topical Report, *Quality Assurance Program Description Operating Fleet*, DUKE-QAPD-001 (hereby referred to as QAPD). The QAPD and associated procedures provide for control of Duke Energy's activities that have the potential to affect the quality of safety-related structures, systems, and components (SSCs) of the proposed advanced reactors at the Belews Creek, North Carolina (NC) site (Project site).

17.5.2 SUMMARY

The QAPD is the top-level quality assurance (QA) document that applies to Duke Energy's fleet and that defines the quality policy and assigns major functional responsibilities. The QAPD applies to Duke Energy's personnel, organizations, and contractors performing activities within the scope of the QAPD that could affect the quality of safety-related SSCs at Duke Energy's nuclear plants. The QAPD applies to design, construction, testing, operation, maintenance, repair, replacement, and modification of Duke Energy's nuclear facilities. The QAPD also addresses the site-related activities associated with the preparation of the ESPA.

The QAPD applies to site suitability quality assurance activities associated with the ESPA, including designing, procuring, handling, testing, siting, inspecting, storing, training, and shipping. The QAPD is based on American National Standards Institute (ANSI) N18.7 and the ANSI N45.2 series standards in lieu of ANSI / American Society of Mechanical Engineers (ASME) Nuclear Quality Assurance (NQA)-1. The following addresses specific areas of NUREG-0800, *Standard Review Plan for the Review of Safety Analysis Reports for Nuclear Power Plants: LWR Edition*, specifically Sections A through V under Section 17.5, "Quality Assurance Program Description - Design Certification, Early Site Permit and New License Applicants."

17.5.3 EVALUATION

Title 10 of the Code of Federal Regulations (CFR) 52.17(a)(1)(xii) requires an evaluation of the site against applicable sections of the NUREG-0800 revision in effect six months before the docket date of the application. NUREG-0800, Chapter 17, Section 17.5, Rev. 1, "Quality Assurance," is based on 10 CFR Part 50, Appendix B, and reflects alignment with Duke Energy's QAPD, which the NRC staff found acceptable for meeting the requirement of Appendix B. The Duke Energy QAPD reflects alignment with an earlier set of standards, ANSI N18.7 and ANSI N45.2, considered by the NRC to be acceptable methods for complying with the provisions of 10 CFR 50, Appendix B. The QAPD is approved by the NRC to govern QA activities at multiple operating nuclear plants.

The QAPD has been evaluated in relationship to NUREG-0800, Section 17.5 and found to be in compliance with the Standard Review Plan (SRP) with following two exceptions:

- Section S, Items 2 and 3 – Per the QAPD, the Chief Nuclear Officer (CNO) is responsible for quality assurance and is the highest level of management responsible for establishing Duke Energy Corporation's nuclear policies, goals, and objectives. The qualifications of the CNO meet the intent of Section S, Item 2 qualifications for management of the implementation of the QA plan. Section S, Item 3 individuals responsible for planning, implementing, and maintaining the QA plan are qualified in accordance with the QAPD and are the same personnel for the operating plants. These qualifications meet the intent of Section S, Item 3 of the SRP.

- Section V, Item 1e – The QAPD does not commit to NRC Generic Letter (GL) 91-05, *Licensee Commercial-Grade Dedication Programs*. The QAPD commits to other dedication guidelines, such as GL 89-02, *Actions to Improve the Detection of Counterfeit and Fraudulently Marked Products*, and Regulatory Guide (RG) 1.164, *Dedication of Commercial-Grade Items for Use in Nuclear Power Plants*. The current QAPD meets the intent of Section V, Item 1e of the SRP.
