2. For a full core off-load (157 assemblies off-loaded), maintain the Spent Fuel Pool Water temperature to less than 150.97°F using 2 SFC heat exchangers. This peak temperature is due to a heat load based on decay heat generation from 157 assemblies with exposures of 30.25 GWD/MTU (13 assemblies), 52.25 GWD/MTU (72 assemblies) and 55 GWD/MTU (72 assemblies) cooled for 72 hours, and moved to the SFP in exactly 20 hours; plus 1565 assemblies with exposures up to 55 GWD/MTU and cooled for 18 months, or more. All fuel assemblies discharged through 1996 are assumed to have been burnt at 2775 MWt. All fuel assemblies discharged after 1996 are assumed to have been burnt at 2900 MWt. The maximum net heat load coincident with peak bulk temperature for this case is 40.16 MBTU/HR, considering passive heat losses (including evaporative cooling effects) of 0.95 MBTU/HR.
3. For a full core off-load (157 assemblies off-loaded), maintain the Spent Fuel Pool Water temperature to less than 170°F using 1 SFC heat exchanger with an augmented Spent Fuel cooling system water flow rate of 2400 gpm. This peak temperature is due to a heat load based on decay heat generation from 157 assemblies with exposures of 30.25 GWD/MTU

(13 assemblies), 52.25 GWD/MTU (72 assemblies) and 55 GWD/MTU (72 assemblies). Cooling times are calculated as a function of the component cooling water temperature into the SFC heat exchanger, which is varied from 85°F to 105°F, and range from 58 hours (85°F cooling water) to 146 hours (105°F cooling water). The full core off-load is moved into the SFP in exactly 20 hours; with the SFP already containing 1565 assemblies with exposures up to 55 GWD/MTU and cooled for 18 months or more. All fuel assemblies discharged through 1996 are assumed to have been burnt at 2775 MWt. All fuel assemblies discharged after 1996 are assumed to have been burnt at 2900 MWt. The maximum net heat load coincident with peak bulk temperature for this case is 40.74 MBTU/HR, considering passive losses (including credit for evaporative cooling effects of 1.77 MBTU/HR.

4. An abnormal fuel off-load is one where a full core is off-loaded 36 days after 72 assemblies were placed in the spent fuel pool. For an abnormal off-load, maintain the SFP water temperature to less than 149.53°F using 2 SFC heat exchangers. This peak temperature is due to a heat load based on decay heat generation from 157 assemblies with exposures of 2778 MWD/MTU (72 assemblies), 31884 MWD/MTU (72 assemblies) and 53884 MWD/MTU (13 assemblies), cooled for 72 hours and moved to the SFP in exactly 20 hours; plus 1565 assemblies with exposures up to 55 GWD/MTU and cooled for 19 months or more. The maximum net heat load coincident with peak bulk temperature for this case is 38.84 MBTU/HR, considering passive losses (including evaporative cooling effects) of 0.90 MBTU/HR, and single failure does not have to be considered.
5. Transfer water between the RWST and the refueling cavity.
6. Maintain the purity and clarity of water in the spent fuel pool and/or the refueling cavity at acceptable levels by means of skimming, filtering and/or demineralizing the water to remove corrosion and fission products.
7. Provide means for adding boric acid to the spent fuel pool to maintain the boron concentrations at a nominal 2000 ppm.
8. Provide means to add demineralized water to the spent fuel pool to make up for evaporation losses.
9. Monitor spent fuel coolant for excessive radioactivity due to defective fuel elements.
10. Provide for filtering and/or demineralization to clean the water in the RWST.
11. Maintain a water shield above the spent fuel elements to limit radiation levels in the area of the pool to less than 2.5 mr/hr.

The components of the system are classified as Safety Class 2b, except for equipment and piping associated with the spent fuel purification pump, spent fuel cooling demineralizer and spent fuel purification filters; and radiation monitor, RM-L4. These components are not safety-related. The RWST is Safety Class 2a.

Safety Class 2a piping, valves and equipment are designed, fabricated, tested and inspected in accordance with the ASME Code, Section III, Class 2.

Safety Class 2b piping, valves and equipment are designed, fabricated, tested and inspected in accordance with the ASME Code, Section III, Class 3.

Isolation of nonessential portions of the spent fuel cooling system is provided.

9.1.3.2 System Description

A spent fuel cooling system diagram is included as Figure 9.1-3.

The spent fuel cooling system consists of three basic loops: The spent fuel cooling loop; the spent fuel cooling and transfer loop; and the spent fuel purification loop.

The spent fuel cooling loop provides for cooling of the spent fuel pool. Cooling water is removed from the pool through four 6 inch lines, is pumped by the spent fuel cooling pump through spent fuel heat exchanger A and is returned to the pool through four 6 inch lines.

The spent fuel cooling and transfer loop serves as an alternate or supplement to the spent fuel cooling loop when required. It also serves to transfer water between the several storage volumes associated with the fuel handling and storage systems, including the RWST, fuel transfer canal, refueling cavity, and the cask loading area. The loop consists of the spent fuel cooling and transfer pump, spent fuel heat exchanger B, and interconnecting piping as shown on Figure 9.1-3.

Loop seal piping is installed to ensure the minimum required Technical Specification RWST volume is protected from potential line breaks in the non-safety portion of the purification loop.

The major components of the purification loop are the spent fuel purification pump, spent fuel cooling demineralizer, and two spent fuel purification filters in parallel. Normally the purification loop takes suction from the spent fuel pool skimmers, pumps the water through the spent fuel cooling demineralizer and the spent fuel purification filters, and returns the water to the spent fuel pool. This loop can also take suction from the spent fuel pool, RWST, cask loading area skimmer, refueling cavity, fuel transfer canal drain or cask loading area drain. The purification loop can also discharge to the RWST, fuel transfer canal, refueling cavity, and the return line to the cask loading area.

The RWST is included in the spent fuel cooling system. It is an atmospheric storage tank in an open Seismic Category 1 structure. It is equipped with an overflow line, one vent line to the Auxiliary Building plant vent, and heat tracing. Outdoor system piping connecting to the tank is equipped with separate, redundant heat tracing circuits.

The RWST vent is piped directly to the auxiliary building charcoal exhaust system. The vent line is of 8 inch, schedule 40 pipe with runs of approximately 2 feet vertically, 25 feet horizontally and 4 feet sloping higher by 2-1/2 feet where it enters the auxiliary building. This vent piping is designed to Quality Related Standards to ensure that the vent piping remains functional following design wind and seismic loading. Since normally there is no air flow in the RWST vent line, it has been concluded that no appreciable amount of moisture could accumulate in the line. Therefore, the probability of blockage due to freezing is considered negligible.

Component data are presented in Table 9.1-1.

9.1.3.3 Safety Evaluation

Equipment, piping and components of the spent fuel cooling system are housed in Seismic Category 1 structures. Piping lines entering and exiting from the spent fuel pool are located at elevation 460’-3" and are provided with anti-siphoning holes to preclude draining the pool below this level. This low water level was established to satisfy the requirements of the following criteria:

1. Minimize the dose rate at the pool surface during spent fuel transfer in the unlikely event of a coincident pipe break in a line entering or exiting the spent fuel pool.
2. Assure that the Technical Specification requirement of 23 feet of water is maintained over the top of irradiated fuel assemblies located in the spent fuel pool storage racks.
3. Not to exceed the 10 CFR 71.73 cask drop design criterion for the spent fuel cask, a minimum water height above the cask loading area is required so that a cask drop through air and water will not generate a calculated impact velocity greater than 44 ft/sec.

   At the start of fuel handling operations, the water level in the cask load area is the same as and is controlled by the spent fuel pool water level. Therefore, at the design low water level of the pool, a minimum water level of 40.5 feet above the bottom of the cask load area is available to satisfy the cask drop design criterion. It has been determined that the cask drop through 3.75 feet of air plus 40.5 feet through water will generate an impact velocity of less than 44 ft/sec at the cask load area floor.

The suction lines inside the spent fuel pool are positioned to take suction approximately 4 feet below the normal water level to minimize vortexing and the possibility of floating debris entering the system. The return cooling lines from the spent fuel heat exchangers are located inside the pool such that cooled water is discharged downward. This ensures adequate dispersion of the cold water around the stored spent fuel assemblies. Each suction and return line in the pool is provided with a small anti-siphoning hole (approximately 1/2 inch) located 1 foot, three inches below the normal water level (460'3") to prevent draining the pool below the design low water level in the event of a postulated pipe break occurring outside the pool below the low water level.

Also, there are no drain lines connected to the spent fuel pool. The suction and return lines are located on opposite sides of the pool to prevent channeling and to obtain maximum circulation of the pool water. During fuel handling operations with the pool at the normal water level, about 10 feet of water shielding is available during the transfer of spent fuel elements.

Normal makeup water to the pool is available from the demineralized water storage tank. Emergency makeup water to the pool is available from the RWST, which is Safety Class 2a, or from the reactor makeup water storage tank (RMWST), which is Safety Class 2b. Pumps from three separate systems: spent fuel cooling and purification pumps, Reactor Makeup Water pumps, and demineralized water transfer pumps are available for the transfer of water.

The spent fuel pool water is cooled by either one of two redundant spent fuel cooling water loops. Each loop contains a pump, heat exchanger, piping, valves and instrumentation. The pumps can be powered from separate emergency (diesel) power sources.

Typical refueling practice is to perform a full core off-load with two spent fuel cooling pumps in operation. For a full core offload, the spent fuel cooling system is required to maintain the spent fuel pool water below a temperature of 170°F (which is the limit of the structural integrity analysis) during normal operation with one spent fuel cooling loop in operation and at or below the bulk boiling temperature during an emergency (i.e., abnormal full core offload with both spent fuel cooling loops in operations). The design assumptions and peak SF Pool water temperatures are described in Section 9.1.3.1 and preserved through plant procedures that require the following:

1. Prior to the start of core offload, both SFC loops be available with a minimum of one loop in operation.
2. If the indicated pool temperature is ≥ 120°F,
   a. Both spent fuel cooling loops be in operation, or
   b. In the event of a spent fuel pump is unavailable, flow in the operating cooling loop is increased to ≥ 2400 gpm.
3. Multiple reliable sources of electric power be maintained to the SF pumps, including at least one diesel generator backed, safety related electrical bus for spent fuel pool cooling at all times that spent fuel is being moved and while the full core is off-loaded.

Although two SFP cooling loops are typically functional and are supplied by 1E electrical buses, administrative controls provide for an ESF bus outage when spent fuel is being moved or while the full core is offloaded. If 1E power is not available to one of the cooling loops, contingency plans allow for one of the spent fuel cooling pumps to be quickly connected to a reliable source of offsite power. In the unlikely case that all SF cooling is lost, sufficient time exists to provide makeup water to the pool to preclude the fuel from becoming uncovered.

The degree of conformance of the design of the spent fuel cooling system and the fuel handling system with the recommendations of Regulatory Guide 1.13 is addressed in Appendix 3A.

9.1.3.4 Inspection and Testing Requirements

Testing requirements of this system are satisfied through system operation. The spent fuel cooling pump and spent fuel cooling and transfer pump are alternated during normal cooling to equalize wear. Routine inspections of system piping and components are made during system operation.

9.1.3.5 Instrumentation Requirements

Measurement and monitoring of radiation, pressure, level, flow rate, and temperature are performed for purposes of indication, alarm, control, and record maintenance. A leakage

detection system is provided to detect leakage from the spent fuel pool and determine the location of the leakage.

9.1.3.5.1 Radiation Measurement

See Section 11.4 for details.

9.1.3.5.2 Pressure Measurement

Pressure gages provide local indication for the following points in the system: inlets to suction strainers, suctions and discharges of spent fuel cooling and transfer pump and spent fuel cooling pump, suction and discharge of spent fuel purification pump, and inlet and outlet of spent fuel purification filters.

Pressure test connections are provided on the outlet of each spent fuel heat exchanger.

9.1.3.5.3 Level Measurement

During transfer of spent resin to the spent resin storage tank from the spent fuel cooling demineralizer, Health Physics verifies that all resin has been flushed to the spent resin storage tank using radiation surveys.

RWST level measurement consists of four independent level channels, each having control room indication. These loops perform a post accident monitoring function (see Section 7.5 for more detail); provide annunciator inputs of maximum fill, minimum fill, low-low, and empty liquid levels; and analog input to the plant computer. Each loop is independent and physically separated from the other.

Safety classification of these loops is Class 1E for equipment which provides the post accident monitoring function.

The spent fuel pool has two level measurement loops, each having control room indication and one loop inputting to the plant computer. High and low pool levels are annunciated in the control room and locally. These level loops are physically separated.

The fuel transfer canal, refueling cavity, and cask loading area each have a level loop providing control room indication and control room annunciation of high and low water levels. Additionally, the fuel transfer canal and cask loading area level inputs are sent to the plant computer.

9.1.3.5.4 Flow Rate Measurement

The spent fuel cooling and the spent fuel cooling transfer piping loops each have flow rate measurement instrumentation providing control room indication, low flow annunciation in the control room (not actuated unless spent fuel cooling or transfer pump breaker is closed) and analog input to the plant computer. These flow loops are physically separated.

The purification piping loop has a local flow indicator which is located downstream of the purification filters.

9.1.3.5.5 Temperature Measurement

RWST temperature measurement consists of two temperature loops. Each loop provides control room indication and one loop provides analog input to the TSC computer.

The spent fuel pool has two temperature measurement loops, each providing control room indication and annunciation of high temperature. In addition, one of the loops provides analog inputs to the plant and TSC computers. These channels are physically separate and redundant.

The refueling cavity has a temperature loop which provides control room indication and high temperature annunciation in the control room.

Spent fuel heat exchangers A and B both have local temperature indicators on the inlet and outlet.

In the spent fuel purification demineralizer inlet piping there is a temperature switch with input to the control room annunciator for high temperature.

9.1.4 Fuel Handling System

9.1.4.1 Design Bases

The Fuel Handling System (FHS) consists of equipment and structures utilized for the refueling operation in a safe manner meeting General Design Criteria 61 and 62 of 10 CFR 50, Appendix A.

The following design bases apply to the FHS.

1. Fuel handling devices have provisions to avoid dropping or jamming of fuel assemblies during transfer operation.
2. Handling equipment has provisions to avoid dropping of fuel handling devices during the fuel transfer operation.
3. Handling equipment used to raise and lower spent fuel have a limited maximum lift height so that the minimum required depth of water shielding is maintained.
4. The Fuel Transfer System (FTS), where it penetrates the containment, has provisions to preserve the integrity of the containment pressure boundary.
5. Criticality during fuel handling operations is prevented by geometrically safe configuration of the fuel handling equipment.
6. Handling equipment will not fail in such a manner as to preclude the safety function of Seismic Category 1 equipment in the event of a SSE.

7. The inertial loads imparted to the fuel assemblies or core components during handling operations are less than the loads which could cause damage.
8. Physical safety features are provided for personnel operating fuel handling equipment.

9.1.4.2 System Description

The FHS consists of the equipment needed for transporting and handling fuel from the time it reaches the station until it leaves the station. Basically this equipment is comprised of fuel assemblies, core component and reactor component hoisting equipment, fuel handling equipment, and the FTS. The structures associated with the fuel handling equipment are the refueling cavity, the refueling canal, the fuel transfer canal, the spent fuel pool, and the new fuel storage area.

New fuel assemblies received for initial fuel loading are removed one at a time from the shipping container and stored in both the new and spent fuel storage racks. Normally, new fuel assemblies received after the initial fuel loading are stored in the new fuel storage racks located in the new fuel storage area.

A new fuel assembly is delivered to the reactor by removing a new fuel assembly from the storage rack, placing it into the new fuel elevator, lowering it into the fuel transfer canal, rotating to horizontal and transferring it through the FTS.

The fuel handling equipment is designed to handle the spent fuel assemblies underwater from the time they leave the reactor vessel until they are placed in a cask for removal from the Fuel Handling Building (for either transfer to the ISFSI for dry cask storage or for shipment from the site). Underwater transfer of spent fuel assemblies provides an effective, economic, and transparent radiation shield, as well as a reliable cooling medium for removal of decay heat. The boric acid concentration in the water provides an additional margin to preclude criticality.

The associated fuel handling structures may be generally divided into: the refueling cavity, the refueling canal and fuel transfer canal which are flooded during plant shutdown for refueling, the spent fuel pool which is kept full of water and is accessible to operating personnel, and the new fuel storage area. The refueling canal and the fuel transfer canal are connected by a fuel transfer tube. This tube is fitted with a blind flange on the refueling canal end and a gate valve on the fuel transfer canal end. The blind flange is in place except during refueling to ensure containment integrity. Fuel is carried through the fuel transfer tube on an underwater transfer car.

During Dry Cask Storage operations in the Fuel Handling Building, the fuel transfer canal and the cask loading pit are flooded for cask loading and unloading.

Fuel is moved between the reactor vessel and the refueling canal by the refueling machine. A rod cluster control changing fixture is located in the refueling canal for transferring control elements from one fuel assembly to another fuel assembly. The FTS is used to move fuel assemblies between the reactor building and the fuel handling building. After a fuel assembly is placed in the fuel container, the lifting arm pivots the fuel assembly to the horizontal position for passage through the fuel transfer tube. After the transfer car transports the fuel assembly through the fuel

transfer tube, the lifting arm at that end of the tube pivots the assembly to a vertical position so that the assembly can be lifted out of the fuel container.

In the spent fuel pool and the fuel transfer canal, fuel assemblies are moved about by the fuel handling machine. When lifting spent fuel assemblies, the hoist uses a long handled tool to assure that sufficient radiation shielding is maintained. A shorter tool is used to handle new fuel assemblies initially, but the new fuel elevator must be used to lower the assembly to a depth at which the fuel handling machine, using the long handled tool, can place the new fuel assemblies into or out of the fuel storage racks.

Decay heat, generated by the spent fuel assemblies in the spent fuel pool, is removed by the spent fuel cooling system. After a sufficient decay period, the spent fuel assemblies are removed from the spent fuel racks and loaded into casks for removal from the Fuel Handling Building.

9.1.4.2.1 Refueling Procedure

The refueling operation follows a detailed procedure which provides a safe and efficient refueling operation. Before refueling operations the reactor coolant system is borated and cooled down to refueling shutdown conditions as specified in the Technical Specifications. Criticality protection for refueling operations, including a requirement for checks of boron concentration, at least once per 72 hours is specified in the Technical Specifications. The following significant points are assured by the refueling procedure:

1. The refueling water and the reactor coolant contain over 2000 ppm boron. This concentration, together with the negative reactivity of control rods, is sufficient to keep the core reactivity less than or equal to 0.95 K_{eff} during the refueling operations. A reactivity penalty for the withdrawal of the highest worth rod is included in the reactivity calculation.
2. The water level in the refueling cavity is high enough to keep the radiation levels within acceptable limits when the fuel assemblies are being removed from the core.

The refueling operation is divided into four major phases: 1) preparation, 2) reactor disassembly, 3) fuel handling, and 4) reactor assembly. A general description of a typical refueling operation through the four phases is given below:

1. Phase I Preparation

   The reactor is shutdown and cooled to cold shutdown conditions with a final $K_{eff} \leq 0.95$ (all rods in minus 1). Following a radiation survey, the reactor building is entered. At this time, the coolant level in the reactor vessel is lowered to a point slightly below the vessel flange. Checking of the fuel transfer equipment and refueling machine for proper operation is begun in this phase.

2. Phase II - Reactor Disassembly

   All cables, air ducts, and insulation are removed from the vessel head. The refueling cavity is then prepared for flooding by sealing off the reactor cavity; checking of the underwater lights, tools, and finishing checks of the fuel transfer system and continuing checks of the refueling machine; closing the refueling canal drain holes; and removing the blind flange from the fuel transfer tube. With the refueling cavity prepared for flooding, the vessel head is taken to its storage pedestal. Water from the refueling water storage tank is pumped either into the fuel transfer canal and the refueling cavity by the Spent Fuel Cooling system, or into the reactor coolant system by the residual heat removal pumps causing the water to overflow into the refueling cavity. When the water reaches a safe shielding depth, (see Section 9.1.4.3.4) the control rod drive shafts are disconnected and, with the upper internals, are removed from the vessel. The fuel assemblies and rod cluster control assemblies are now free from obstructions and the core is ready for refueling. Checking of the refueling machine is completed at this time.

3. Phase III - Fuel Handling

   The refueling is accomplished by either a full core off-load and re-load to and from the Spent Fuel Pool or a core shuffle. The full core off-load removes all of the fuel from the reactor vessel to the spent fuel pool. There, the rod cluster control assemblies are shifted between fuel assemblies as necessary, by a portable rod cluster control changing tool suspended from the fuel handling machine. When ready, the fuel assemblies are loaded into the vessel in the designed pattern. New fuel assemblies are usually pre-staged in the spent fuel pool to expedite the reload, but can be moved from the new fuel pit into the fuel container with the new fuel elevator and fuel handling machine. The core shuffle moves fuel assemblies within the reactor vessel, only removing those most depleted to the spent fuel pool and replacing them with new or only partially depleted fuel assemblies brought from the spent fuel pool or new fuel pit. The rod cluster control assemblies are shifted between fuel assemblies as necessary by the rod cluster control changing fixture, which is in the refueling canal of the reactor building.

   The following describes the steps of a core shuffle:

   a. The refueling machine is positioned over a fuel assembly in the core.
   b. The fuel assembly is lifted by the refueling machine to a predetermined height sufficient to clear the reactor vessel and still leave sufficient water covering the fuel assembly to eliminate any radiation hazard to the operating personnel.
   c. If the removed assembly contains a rod cluster control assembly, the assembly is placed in the rod cluster control changing fixture by the refueling machine. The rod cluster control assembly is removed from the spent fuel assembly and put in a new fuel assembly or in a partially spent fuel assembly previously placed in the changing fixture.
   d. The fuel transfer car is moved into the refueling canal from the fuel transfer canal.
   e. The fuel assembly container is pivoted to the vertical position by the lifting arm.

f. The refueling machine is moved to line up the spent fuel assembly with the FTS.

g. The refueling machine loads a spent fuel assembly into the fuel assembly container of the transfer car.

h. The fuel assembly container is pivoted to the horizontal position by the lifting arm.

i. The fuel assembly container is moved through the fuel transfer tube to the fuel transfer canal by the transfer car.

j. The fuel assembly container is pivoted to the vertical position. The spent fuel assembly is unloaded by the spent fuel handling tool attached to the fuel handling machine.

k. The spent fuel assembly is moved into the spent fuel pool and placed in a spent fuel storage rack by the fuel handling machine.

l. The new fuel assembly is taken from the new fuel storage rack and loaded into the new fuel elevator by the fuel handling building crane. The fuel handling machine takes the fuel from the new fuel elevator and places it in the fuel assembly container. Alternatively the new fuel is pre-staged in the spent fuel pool and is moved to the fuel assembly container by the fuel handling machine.

m. The fuel assembly container is pivoted to the horizontal position and the transfer car is moved back into the refueling canal.

n. Partially spent fuel assemblies are relocated in the reactor core, and new fuel assemblies are added to the core.

o. Any new assembly or transferred fuel assembly that is placed in a control position is first placed in the rod cluster control changing fixture to receive a rod cluster control from a spent fuel assembly.

p. This procedure is continued until refueling is completed.

4. Phase IV - Reactor Assembly

   Reactor assembly, following refueling, is essentially achieved by reversing the operations given in Phase II - Reactor Disassembly.

9.1.4.2.2 Component Description

9.1.4.2.2.1 Refueling Machine

The refueling machine (see Figure 9.1-4) is a rectilinear bridge and trolley system with a vertical mast extending down into the refueling water. The bridge spans the refueling cavity and the refueling canal and runs on rails. The bridge and trolley motions are used to position the vertical mast over a fuel assembly in the core. A long tube with a pneumatic gripper on the end is lowered down out of the mast to grip the fuel assembly. The gripper tube is long enough so that the upper end is still contained in the mast when the gripper end contacts the fuel. A winch mounted on the trolley raises the gripper tube and fuel assembly up into the mast tube. The fuel is transported while inside the mast tube to its new position.

The refueling machine uses a single variable frequency drive mounted in the motor control console to control the speeds of the bridge, trolley and main hoist motors. This is an electronic device that provides step-less variable speeds from zero to full speed.

All controls for the refueling machine are mounted on a console in the trolley. The bridge is positioned on a coordinate system laid out on one rail. The trolley is positioned with the aid of a scale on the bridge structure. The drive for the bridge, trolley and main hoist provides for variable speeds and includes the ability for setting separate frequencies for setting jogging (inching) speeds for the bridge, trolley and main hoist. The maximum speed for the bridge is 65 fpm, 45 fpm for the trolley and 21 fpm for the main hoist. The auxiliary monorail hoist on the refueling machine has a two step magnetic controller to give hoisting speeds of approximately 7 and 20 fpm.

Refueling machine interlocks and permissives are provided by a Programmable Logic Controller (PLC) that is mounted inside the Control Console on the trolley. PLC interlocks and limit switches prevent damage to the fuel assemblies. The PLC tracks the inner mast position in order to stop the hoist from being raised above a safe shielding depth; this function is backed up with a physical limit switch. In an emergency, the bridge, trolley and main hoist can be operated manually using handwheels on the respective motors.

The refueling machine mast is equipped with hardware to support in-mast sipping - a failed fuel detection process.

9.1.4.2.2.2 Fuel Handling Machine

The fuel handling machine (see Figure 9.1-5) is a wheel-mounted walkway, spanning the spent fuel pool, the fuel transfer canal, and cask loading pit, which carries an electric monorail hoist on an overhead structure. The fuel handling machine is used for handling fuel assemblies within the spent fuel pool, the fuel transfer canal and the cask loading pit by means of a long handled tool suspended from the hoist. The hoist travel and tool length are designed to limit the maximum lift of a fuel assembly to a safe shielding depth.

The fuel handling machine has a 2 step magnetic controller for the bridge and hoist. The bridge speeds are 11 and 33 fpm and the hoist speeds are 7 and 20 fpm. A hydraulic coupling is used in the bridge drive to limit starting acceleration.

The hoist trolley is hand operated by a chain drive.

9.1.4.2.2.3 New Fuel Elevator

The new fuel elevator (see Figure 9.1-6) consists of a box-shaped assembly with its top end open, sized to house one fuel assembly that is raised and lowered by a winch and cable.

The new fuel elevator is normally used to lower a new fuel assembly to an elevation where it can be handled by the fuel handling machine with a long-handled spent fuel handling tool. The new

fuel assembly can then be moved to the fuel basket of the transfer system during core loading or to the spent fuel pool to stage the assembly for core loading at a later date.

The new fuel elevator is also used as a work platform for holding an irradiated fuel assembly. An example of this would be fuel assembly top nozzle reconstitution referred to in FSAR chapter 4. In this process, the irradiated fuel assembly is loaded into the New Fuel Elevator with the spent fuel handling tool and fuel handling machine and the elevator at the bottom of its travel. The elevator is then raised to a level with about 10 feet of water shielding available above the fuel. The New Fuel Elevator controls have been modified and administrative controls are also used to control the process to ensure that radiation dose rates to personnel remain within acceptable limits.

9.1.4.2.2.4 Fuel Transfer System

The FTS (see Figure 9.1-7) is a transfer car that runs on tracks extending from the refueling canal through the fuel transfer tube and into the fuel transfer canal. The car is moved along the track via a cable/winch system. A hydraulically actuated lifting arm is at each end of the fuel transfer tube. The fuel container in the refueling canal receives a fuel assembly in the vertical position from the refueling machine. The fuel assembly is then lowered to a horizontal position for passage through the fuel transfer tube. After passing through the tube, the fuel assembly is raised to a vertical position for removal by a tool suspended from a hoist mounted on the fuel handling machine. The fuel handling machine them moves to a storage loading position and places the spent fuel assembly in the spent fuel storage racks.

During reactor operation, the transfer car is stored in the fuel transfer canal. A blind flange is bolted on the refueling canal end of the fuel transfer tube to seal the containment. The terminus of the tube outside the reactor building is closed by a gate valve.

9.1.4.2.2.5 Rod Cluster Control Changing Fixture

The rod cluster control changing fixture is supplied for periodic rod cluster control element inspections and for transfer of rod cluster control elements from one fuel assembly to another (see Figure 9.1-8). The major subassemblies which comprise the changing fixture are the frame and track structure, the carriage, the guide tube, the gripper, and the drive mechanism. The carriage is a moveable container supported by the frame and track structure. The tracks provide a guide for the 4 flanged carriage wheels and allow horizontal movement of the carriage during changing operation. The positioning stops on both the carriage and frame, locate each of the three carriage compartments directly below the guide tube. Two (2) of these compartments are designed to hold individual fuel assemblies and the third is made to support a single rod cluster control element. Situated above the carriage and mounted on the refueling canal wall is the guide tube. The guide tube provides for the guidance and proper orientation of the gripper and rod cluster control element as they are being raised and lowered. The gripper is a pneumatically actuated mechanism responsible for engaging the rod cluster control element. It has two flexure fingers which can be inserted into the top of the rod cluster control element when air pressure is applied to the gripper piston. Normally the fingers are locked in a radially extended position. Mounted on the operating deck is the drive mechanism assembly which consists of the manual carriage drive mechanism,

the revolving stop operating handle, the pneumatic selector valve for actuating the gripper piston, and the electric hoist for elevation control of the gripper.

9.1.4.2.2.6 Spent Fuel Assembly Handling Tool

The spent fuel assembly handling tool (see Figure 9.1-9) is used to handle new and spent fuel assemblies in the fuel transfer canal and the spent fuel pool. It is a manually actuated tool, suspended from the fuel handling machine, which uses four cam actuated latching fingers to grip the underside of the fuel assembly top nozzle. The operating handle to actuate the fingers is located at the top of the tool. When the fingers are latched a pin is inserted into the operating handle, which prevents the fingers from being accidentally unlatched during fuel handling operations.

9.1.4.2.2.7 New Fuel Assembly Handling Fixture

The new fuel assembly handling fixture (see Figure 9.1-10) is used to lift and transfer new fuel assemblies from the new fuel storage area to the new fuel elevator. It is a manually actuated tool suspended from the fuel handling building crane, which uses 4 cam actuated latching fingers to grip the underside of the fuel assembly top nozzle. The operating handles to actuate the fingers are located on the side of the tool. When the fingers are latched, the safety screw is turned in to prevent the accidental unlatching of the fingers.

9.1.4.2.2.8 Reactor Vessel Head Lifting Rig

The original Reactor Vessel Head lifting rig has been replaced with a special lifting device integrated into the Integrated Head Assembly (IHA), typically referred to as the reactor head service structure. This lifting rig assembly is part of the IHA and stays installed on the IHA during both refueling activities and normal power operations. This device complies with ANSI 14.6-1978 design requirements as documented in the IHA Design Report.

9.1.4.2.2.9 Cranes

1. Polar Crane

   The reactor building polar crane is a single trolley, electric, overhead crane with a main hoist capacity of 360 tons and an auxiliary hoist capacity of 25 tons. The polar crane is used to lift the reactor vessel head and reactor internals prior to refueling operations.

   The Polar Crane has two loading conditions, a “Construction” load, and a “Normal Operation” load. The “Construction” loading is 360 ton and does not consider seismic interaction. The “Normal Operation” loading is 157.5 ton and does consider seismic forces (i.e., crane will continue to hold a suspended load during and after a seismic event). During normal plant shutdown for refueling, seismic interaction is considered when loads, such as the reactor vessel head assembly, are suspended above irradiated fuel in the reactor vessel.

2. Fuel Handling Building Crane

   The fuel handling building crane is a single trolley, electric, overhead crane with a main hoist capacity of 125 tons and an auxiliary hoist capacity of 15 tons. The fuel handling building crane is used to remove and replace the spent fuel pool gate; unload and transfer new fuel assemblies; and move, load, and unload casks during spent fuel transfer operations.

   The Fuel Handling Building overhead bridge crane is a single-failure-proof crane with a capacity of 125 tons as described in Section 3.12.4.3. The crane is designed to hold the full rated capacity during and after a postulated seismic event.

9.1.4.2.2.10 Reactor Vessel Internals Lifting Device

The reactor vessel internals lifting device (see Figure 9.1-11) is a structural frame positioned by the polar crane. The frame is lowered onto the guide tube support plate at the internals, and is mechanically connected to the support plate by 3 breech lock type connectors. Bushings on the frame engage guide studs in the vessel flange to provide guidance during removal and replacement of the internals package.

9.1.4.2.2.11 Reactor Vessel Stud Tensioner

The stud tensioners are employed to secure the head closure joint at every refueling. The stud tensioner is a hydraulically operated device that uses oil as the working fluid.

9.1.4.3 Safety Evaluation

9.1.4.3.1 Safe Handling

9.1.4.3.1.1 Design Criteria for the Fuel Handling System

1. The primary design requirement of the equipment is reliability. A conservative design approach was used for all load bearing parts. Where possible, components are used that have a proven record of reliable service. Throughout the design, consideration was given to the fact that the equipment will spend long idle periods stored in an atmosphere of 80°F and high humidity.
2. Except as otherwise specified the refueling machine and fuel handling machine are designed and constructed in accordance with Crane Manufacturer Association of America (CMAA) Specification 70.
3. The design load for the refueling machine and fuel handling machine was the normal dead and live loads plus the maximum hoist load.
4. The allowable stresses for the refueling machine and fuel handling machine structures supporting the weight of the fuel, are as specified in Subarticle XVII-2200 of Appendix XVII of the ASME Code, Section III, 1974 Edition.

Hoisting components loaded in simple tension have an allowable stress of 0.20 ultimate stress maximum.

5. All components critical to the operation of the equipment or located so that parts can fall into the reactor are assembled with the fasteners positively restrained from loosening under vibration. Spring or tooth type lock washers are not considered as positive restraints. If positive restraint cannot be achieved on fasteners on purchased components above the water line, then the fasteners must be lockwired, tack welded or backed out, coated with locking compound and retightened.

9.1.4.3.1.2 Industrial Codes and Standards Used in the Design of the Fuel Handling Equipment

1. Refueling Machine and Fuel Handling Machine: Applicable sections of CMAA Specification 70.
2. Structural: ASME Code, Section III, Appendix XVII, Subarticle XVII-2200, 1974 Edition.
3. Electrical: Applicable standards and requirements of IEEE Standard 279, National Electric Code, NFPA #70, and NEMA Standards MGI and ICS are used in the design, installation, and manufacturing of all electrical equipment.
4. Materials: Materials conform to the specifications of the ASTM standard.
5. Safety: OSHA Standards 29 CFR 1910, and 29 CFR 1926 including load testing requirements, the requirements of ANSI N18.2, Regulatory Guide 1.29 (see Appendix 3A) and General Design Criteria 61 and 62.

9.1.4.3.1.3 Refueling Machine

The refueling machine design includes the following provisions to ensure safe handling of fuel assemblies:

1. Electrical Interlocks

   a. Bridge, Trolley and Hoist Drive Mutual Interlocks

      The bridge, trolley, and hoist are interlocked such that only one motor can be operated at any one time either by the master or jog switches. If any one of the master or jog switches are actuated, all others are inactivated and have no effect on the current operating mode of the machine. The logic checks for actual motor operation and motor control relay status, and thus can stand a single failure.

   b. Bridge Trolley Drive - Gripper Tube Up

      With a fuel assembly attached, bridge and trolley motions are prevented except when the Gripper Tube Up interlock is actuated. The interlock is redundant and can withstand a single failure.

c. Gripper Interlock

Interlocks exists that prevent the solenoid valve that supplies air to the gripper actuator for disengagement to open except if both the mast is at the elevation that corresponds to Gripper Tube Down and a Slack Cable condition exists.

As backup protection for this interlock the mechanical weight actuated lock in the gripper prevents operation of the gripper under load, even if air pressure is applied to the operating cylinder. This interlock is redundant and can withstand a single failure.

d. Excessive Suspended Weight

The load control system (integral to the PLC) will stop the hoist when overloads or underloads occur. A six way selector switch on the Control Console allows the operator to select between light and heavy assemblies and varying levels of overload. A master overload is programmable, yet non-bypassable and is set at a value to ensure fuel is protected. For underload, each of the positions on the selector switch has one value for hoist cut-out.

e. Hoist-Gripper Position Interlock

An interlock in the hoist drive circuit in the up direction, permits the hoist to be operated only when either the open or closed indicating switch on the gripper is actuated. The hoist-gripper position interlock consists of two logic paths that work parallel such that one path must be closed for the hoist to operate. If neither one of the gripper position limit switches are actuated, audible and visual alarms on the console will actuate. The interlock, therefore, is not redundant but can withstand a single failure since both an interlocking path and the monitoring path must fail to cause a hazardous condition.

2. Bridge and Trolley Hold-Down Devices

Both the refueling machine bridge and trolley are horizontally restrained on the rails by two pairs of guide rollers, one pair at each wheel location on one truck only. The rollers are attached to the bridge truck and contact the vertical faces on either side of the rail to prevent horizontal movement. Vertical restraint is accomplished by anti-rotation bars located at each of the four wheels for both the bridge and trolley. The anti-rotation bars are bolted to the trucks and, for the bridge restraints, extended under the rail flange, while for the trolley restraints, extended beneath the top flange of the bridge girder which supports the trolley rail. Both horizontal and vertical restraints are adequately designed to withstand the forces and overturning moments resulting from the SSE.

3. Design Load

The design load for structural components supporting the fuel assembly is the dead weight plus 4800 pounds (3 times the fuel assembly weight).

4. Main Hoist Braking System

   The main hoists are equipped with 2 independent braking systems. A solenoid release-spring set electric brake is mounted on the motor shaft. This brake operates in the normal manner to release upon application of current to the motor and set when current is interrupted. The second brake is a mechanically actuated load brake internal to the hoist gear box that sets if the load starts to overhaul the hoist. It is necessary to apply torque from the motor to raise or lower the load. In raising, this motor cams the brake open. In lowering, the motor slips the brake allowing the load to lower. This brake actuates upon loss of torque from the motor for any reason and is not dependent on any electrical circuits.

5. Fuel Assembly Support System

   The main hoist system is supplied with redundant paths of load support such that failure of any one component will not result in free fall of the fuel assembly. Two wire ropes are anchored to the winch drum and carried over independent sheaves to a load equalizing mechanism on the top of the gripper tube. In addition, supports for the sheaves and equalizing mechanism are backed up by passive restraints to pick up the load in the event of failure of this primary support. Each cable system is designed to support 13,750 pounds or 27,500 pounds acting together.

   The working load of a fuel assembly, with a Rod Cluster Control Assembling (RCCA) plus gripper is approximately 2000 pounds.

   The gripper itself has four fingers gripping the fuel, any two of which will support the fuel assembly weight.

   The gripper mechanism contains a spring actuated mechanical lock which prevents the gripper from opening unless the gripper is under a compressive load.

   During each refueling outage and prior to removing fuel, the gripper and hoist system is routinely load tested to at least 3250 pounds.

9.1.4.3.1.4 Fuel Transfer System

The following safety features are provided for in the FTS.

1. Transfer Car Permissive Switch

   The transfer car controls are located in the fuel handling building and conditions in the reactor building are, therefore, not visible to the operator. The transfer car permissive switch allows a second operator in the reactor building to exercise some control over car movement if conditions visible to him warrant such control. Transfer car operation is possible only when both lifting arms are in the down position as indicated by the limit switches. The permissive switch is a backup for the transfer car lifting arm interlock. Assuming the fuel assembly container is in the upright position in the reactor building and the lifting arm interlock circuit fails in the permissive condition, the operator in the fuel handling building still cannot operate the car because of the permissive switch interlock. The interlock, therefore, can withstand a single failure.

2. Lifting Arm - Transfer Car Position

   Two redundant interlocks allow lifting arm operation only when the transfer car is at the respective end of its travel and therefore can withstand a single failure.

   Of the two redundant interlocks which allow lifting arm operation only when the transfer car is at the end of its travel, one interlock is a position limit switch in the control circuit. The backup interlock is a frame down limit switch which not allow the car to traverse until both frame down limits are closed. Additionally, the lifting arm will not operate while the car is traversing.

3. Transfer Car - Valve Open

   A remote panel has been installed at the valve operator location which is equipped with lights which show the position of the valve. When the valve is full open only the red light is illuminated. While the valve is changing position (open - closed or closed - open) the red and green lights are illuminated. When fully closed the green light is illuminated. Tied to the red light only illumination (valve full open) is the traverse permissive. The carriage will not traverse with the valve not full open. In addition to the remote light indicating panel XPN5556, the control panel is equipped with a red light - valve open.

4. Transfer Car - Lifting Arm

   The transfer car lifting arm is primarily designed to protect the equipment from overload and possible damage if an attempt is made to move the car when the fuel assembly container is in the vertical position. This interlock is redundant and can withstand a single failure.

The basic interlock is a position limit switch in the control circuit. The backup interlock is a mechanical latch device that is opened by the weight of the fuel assembly container when in the horizontal position.

5. Lifting Arm - Refueling Machine

   The refueling canal lifting arm is interlocked with the refueling machine. Whenever the transfer car is located in the refueling canal, the lifting arm cannot be operated unless the refueling machine mast is in the fully retracted position or the refueling machine is over the core.

   The circuits which interlock the refueling canal lifting arm with the refueling machine are redundant.

6. Lifting Arm - Fuel Handling Machine

   The lifting arm is interlocked with the fuel handling machine. The lifting arm cannot be operated unless the fuel handling machine is not over the lifting arm area. The interlocks are redundant.

7. Additional protective devices designed into the Raytheon modification:
   1. Load sensitive bases which open circuits if an underloaded or overload torque is sensed on the car.
   2. Overcurrent protection on the winch motors.
   3. Overtravel programmed limits to backup primary limits in case of failures. Additionally, hard stops are provided to create overtorque in case limit controls fail.

9.1.4.3.1.5 Fuel Handling Machine

The fuel handling machine includes the following safety features.

1. The fuel handling machine controls are interlocked to prevent simultaneous operation of the bridge drive and hoist.
2. Bridge drive operation in the normal 2 speeds is permitted only when the hoist is in the full up position. The bridge can be jogged in increments of less than one inch, at low speed, in timed intervals when the hoist is in other than the full up position.
3. An overload protection device is included on the hoist to limit the uplift force which could be applied to the fuel storage racks. The protection device limits the hoist load to 125 percent of the rated hoist capacity.
4. The design load on the hoist is the weight of one fuel assembly (1600 lbs), the weight of one failed fuel container (1000 lbs), and the weight of the tool which gives it a total weight of approximately 3000 lbs.
5. Restraining bars are provided on each truck to prevent the bridge from overturning.

9.1.4.3.1.6 Fuel Handling Tools and Equipment

All fuel handling tools and equipment handled over an open reactor vessel are designed to prevent inadvertent decoupling from machine hooks (i.e., lifting rigs are pinned to the machine hook and safety latches are provided on hooks supporting tools).

Tools required for handling internal reactor components are designed with fail safe features that prevent disengagement of the component in the event of an operating mechanism malfunction. These safety features apply to the following tools.

1. Control rod drive shaft unlatching tool: The air cylinders actuating the gripper mechanism are equipped with backup springs which close the gripper in the event of loss of air to the cylinder. Air operated valves are equipped with safety locking rings to prevent inadvertent actuation.
2. Spent fuel assembly handling tool: When the fingers are latched a pin is inserted into the operating handle and prevents inadvertent actuation. The tool weighs approximately 385 pounds and is preoperationally tested at 125 percent the weight of one fuel assembly (1600 lbs).
3. New fuel assembly handling fixture: When the fingers are latched a safety screw is screwed in preventing inadvertent actuations. The tool weighs approximately 100 pounds and is preoperationally tested at 125 percent the weight of one fuel assembly (1600 lbs).

9.1.4.3.1.7 Polar Crane

The reactor building polar crane is safety-related and is designed to Seismic Category 1 requirements. This crane is equipped with two completely independent and automatically operated brake systems. Each brake system is capable of stopping the rated crane load at any speed up to 150 percent of the rated speed.

9.1.4.3.1.8 Fuel Handling Building Crane

The fuel handling building crane is safety-related and is designed to Seismic Category 1 requirements. This crane is equipped with two completely independent and automatically operated brake systems. Each brake system has a minimum capacity of 125 percent of that required to hold the design rated loads. The fuel handling building crane rail installation allows operation over the cask loading pit, decontamination and new fuel storage area, but excludes operation over the spent fuel pool. Structural stops are provided at each end of the rails.

9.1.4.3.2 Seismic Considerations

The safety classifications for all fuel handling and storage equipment are listed in Table 3.2-1. These safety classes provide criteria for the seismic design of the various components. Safety Class 1 and 2a equipment is designed to withstand the forces of the OBE and SSE. For normal conditions plus OBE loadings, the resulting stresses are limited to allowable working stresses as defined in the ASME Code, Section III, Appendix XVII, Subarticle XVII-2200 for normal and

upset conditions. For normal conditions plus SSE loadings, the stresses are limited to within the allowable values given by Subarticle XVII-2110 for critical parts of the equipment which are required to maintain the capability of the equipment to perform its safety function. Permanent deformation is allowed for the loading combination which includes the SSE to the extent that there is no loss of safety function.

The Safety Class 2b and 3 fuel handling and storage equipment satisfies the Safety Class 1 and 2a criteria given above for the SSE. Consideration is given to the OBE only in so far as failure of the Safety Class 2b and 3 equipment might adversely affect Safety Class 1 or 2a equipment.

For Non-Nuclear Safety equipment, design for the SSE is considered if failure might adversely affect a Safety Class 1, 2a, 2b, or 3 component.

Design for the OBE is considered if failure of the Non-Nuclear Safety component might adversely affect a Safety Class 1 or 2a component.

9.1.4.3.3 Containment Pressure Boundary Integrity

The fuel transfer tube which connects the refueling canal (inside the reactor building) and the fuel transfer canal (outside the reactor building) is closed on the refueling canal side by a blind flange at all times except during refueling operations. Two seals are located around the periphery of the blind flange with leak-check provisions between them.

9.1.4.3.4 Radiation Shielding

During all phases of spent fuel transfer, the gamma dose rate at the surface of the water is 2.5 mr/hr or less. This is accomplished by maintaining the spent fuel pool level at the normal elevation of 461’-6", thus providing a nominal 10 feet of water shielding above the active fuel assembly during all handling operations.

The two fuel handling devices used to lift spent fuel assemblies are the refueling machine and the fuel handling machine. The refueling machine contains positive stops which prevent the top of a fuel assembly from being raised to within a nominal 10 feet of the normal water level in the refueling cavity. The hoist on the fuel handling machine moves spent fuel assemblies with a long handled tool. Hoist travel and tool length likewise limit the maximum lift of a fuel assembly to within a nominal 10 feet of the normal water level in the spent fuel pool.

9.1.4.3.5 Spent Fuel Shipping Cask Handling

The spent fuel shipping cask is designed to withstand a drop, in air, of 30 feet without release of the solid contents of the cask. Restrictive administrative procedures are followed during cask handling operations to minimize cask impact loadings in the event of a cask drop. The only area where the drop height exceeds 30 feet is above the cask loading pit. However, as discussed in Section 9.1.3.3, a cask drop into the flooded cask loading pit does not violate the 30 foot drop criteria since the calculated impact velocity of the cask at the floor of the cask loading pit is less than 44 ft/sec. The velocity of 44 ft/sec is the impact velocity generated by a 30 foot cask drop in

air onto an unyielding surface. Water level in the cask loading pit is continuously controlled whenever the cask is placed in or removed from the pit. Therefore, for a cask drop into the flooded cask loading pit, there is no release of the solid contents of the cask.

To minimize the consequences of a cask drop, the cask is moved at a height of 1 foot above the operating floor by the fuel handling building crane. Handling of the cask in the plant proper is performed with the bottom impact limiter removed from the cask.

Since handling of the cask in the plant does not violate the 30 foot drop criterion, cask integrity is maintained and there is no release of the contents of the cask. Therefore, a design basis analysis of the radiological consequences of a spent fuel cask drop accident is not required.

The area of fuel handling building crane coverage precludes damage to safety-related equipment should a cask drop occur. There are no safety related systems or components located under the travel path of the fuel transfer cask. In addition, cask handling in this limited area will not violate the 30 foot drop criteria.

9.1.4.4 Tests and Inspections

As part of normal plant operations, the fuel handling equipment is inspected for operating conditions prior to each refueling operation. During the operational testing of this equipment, procedures are followed that will affirm the correct performance of the FHS interlocks.

9.1.5 Spent Fuel Dry Cask Storage

9.1.5.1 System Description

The Virgil C. Summer Nuclear Station (VCSNS) has established an Independent Spent Fuel Storage Installation (ISFSI) located approximately 500 feet west of the Unit 1 Fuel Handling Building (FHB) and northeast of warehouses A and B in the plant Protected Area as shown on Figure 1.2-1. The ISFSI concrete pad has a capacity for 98 vertical spent fuel storage casks.

Spent Fuel Dry Cask Storage operations at the VCSNS are conducted under a general license in accordance with Subpart K of 10 CFR Part 72. The general license issued by 10 CFR 72.210 authorizes a 10 CFR Part 50 nuclear power plant licensee to store spent fuel at an onsite ISFSI. Subpart K of 10 CFR Part 72 also includes 10 CFR 72.212, “Conditions of general license issued under §72.210,” which requires the use of a dry cask storage system that is pre-approved by the Nuclear Regulatory Commission, as evidenced by its listing in 10 CFR 72.214.

The VCSNS ISFSI uses the Holtec HI-STORM Flood and Wind (FW) vertical cask storage overpack, the Holtec MPC-37 multi-purpose canister (MPC), and the HI-TRAC Variable Weight (VW) transfer cask as described in the HI-STORM FW MPC Storage System FSAR and approved by the Nuclear Regulatory Commission in HI-STORM FW Certificate of Compliance No. 1032, which includes the Technical Specifications for the HI-STORM FW MPC Storage System.

The MPC provides the confinement boundary for the stored fuel. The MPC is a welded, cylindrical canister with a honeycombed cell fuel basket to contain the spent fuel assemblies. All MPC confinement boundary components are made entirely of stainless steel. The honeycombed cell fuel basket construction includes the neutron absorbing material that provides criticality control. The MPC also provides axial shielding at the top and bottom ends.

The HI-STORM FW storage overpack provides additional radiation shielding and structural protection of the MPC during storage. The HI-STORM FW overpack design includes a lid which incorporates the air outlet duct. The overpack is a heavy-walled steel and concrete, cylindrical vessel whose side wall consists of non-reinforced concrete enclosed between inner and outer carbon steel shells. The carbon steel shells are coated on the exposed surfaces for corrosion protection. The overpack has eight air inlets at the bottom and a near 360 degree (excluding the support plates) air outlet at the top to allow air to circulate naturally through the cavity to cool the MPC inside. The inner shell has guide tubes attached to its interior surface to guide the MPC during insertion and removal and allow cooling air to circulate through the overpack.

The HI-TRAC VW is a metal transfer cask that provides a means to lift and handle the MPC. The Hi-TRAC VW provides shielding of the spent fuel assemblies in the MPC and structural protection of the MPC during loading, unloading, and movement of the MPC from the cask loading area to the storage overpack. The HI-TRAC VW is a multi-walled (carbon steel/lead/carbon steel) cylindrical vessel which utilizes a neutron shielding water jacket and a removable bottom lid used during MPC transfer operations.

9.1.5.2 Operations in the Fuel Handling Building

Loading the MPC-37 canisters with spent fuel assemblies takes place in the FHB. An empty MPC-37 canister is brought into the FHB rail bay in a HI-STORM FW overpack situated on top of a Low Profile Transporter (LPT). The empty MPC is loaded into the HI-TRAC VW transfer cask that is supported in the decontamination area by a Cask Support Pedestal. The HI-TRAC VW containing the empty MPC is lifted by the FHB single-failure-proof overhead crane, using a HI-TRAC lift yoke, from the decontamination area and placed in the cask loading pit of the spent fuel pool for spent fuel loading operations. A Variable Elevation Cask Staging Pedestal (VECASP) assembly is located on the floor of the cask loading pit. Using the lift yoke and a lift yoke extension, the HI-TRAC VW containing the empty MPC is moved to the lower position inside the VECASP in the cask loading pit.

The MPC is then loaded with spent fuel assemblies utilizing the fuel handling machine. The HI-TRAC VW and loaded MPC are transferred by the FHB crane to the stainless steel lined decontamination area, where the MPC is decontaminated, welded shut, drained, dried, and backfilled with helium. The HI-TRAC VW containing the MPC is then lifted and placed on top of the HI-STORM FW overpack inside the FHB rail bay so that the MPC can be transferred from the HI-TRAC to the HI-STORM. After the MPC has been placed in the HI-STORM, the loaded HI-STORM is transported out of the FHB on the LPT, where the loaded HI-STORM is lifted from the LPT by a vertical cask transporter (VCT), moved along the haul path by the VCT to the ISFSI pad, and placed in its storage location.

Critical load handling operations in the FHB associated with dry cask loading or unloading activities are conducted using single-failure-proof handling systems, which include the main hoist on the FHB overhead crane and lifting devices meeting the enhanced safety factors of ANSI N14.6 or ASME B30.9. These lifting devices and other cask handling system components meet the applicable requirements of ANSI N14.6, NUREG-0554, and applicable guidelines of NUREG-0612 per the VCSNS heavy loads program described in FSAR Section 3.12.

9.2 WATER SYSTEMS

9.2.1 Service Water System

The Service Water System (SWS) provides water from the Service Water pond, a Seismic Category 1 impoundment adjacent to Monticello Reservoir, for cooling of the emergency diesel generators, Component Cooling heat exchangers, HVAC (Heating Ventilating and Air conditioning) mechanical water chiller condensers and the Service Water pump house cooling coils. The system also cools the reactor building cooling units (RBCUs) under: post accident or high containment pressure conditions, loss of non-Class 1E power; loss of industrial cooling water or during testing. In addition, this system is the backup water source for the Emergency Feedwater System and Component Cooling Water System. The system consists of two independent (A and B) full capacity loops with the capability of valving a third swing Service Water pump into either loop. The system is safety-related and is designed so that a single failure denies cooling to only 1 of the redundant loops.

9.2.1.1 Design Bases

The SWS is designed in accordance with the requirements of General Design Criterion 44, to provide sufficient redundant and independent capacity to ensure that cooling water is available to safety systems and components necessary to achieve and maintain a safe shutdown from normal plant operation or following a design basis accident.

SWS redundancy is protected through physical separation of equipment, barriers and double valving at interconnections of redundant loops. Physical separation is provided wherever possible to eliminate the potential for damage to both SWS headers by a missile which could be generated by equipment in the vicinity of the headers. Where physical separation is not feasible missile protection walls are employed where necessary.

SWS piping and components are classified as Safety Class 2b, except those portions of SWS piping conveying cooling water to the Digital Rod Position Indication System cooling unit, Service Water pump house cooling coils, and water jet air exhausters used to remove air from the line interconnecting the Circulating Water pumphouse and the Service Water pumphouse. Reactor Building penetrations, isolation valves and intermediate piping are classified as Safety Class 2a. The portions of SWS piping conveying cooling water to the Digital Rod Position Indication System cooling units and water jet air exhausters are classified as non-nuclear safety class and non-Seismic Category 1. The remaining system components are classified as Seismic Category 1.

The capacity of the SWS, with both redundant loops in operation, is adequate during a normal plant shutdown to reduce the RCS temperature to 140°F within 24 hours after reactor shutdown following an extended full power run at the current licensed RTP of 2900 MWt. With 1 of the 2 SWS loops inoperable (single failure), satisfactory cooldown can be achieved, except that the time to reduce the RCS temperature to 140°F will be extended. The SWS is capable of limiting the CCWS temperature to 105°F at the end of the 24 hour cooldown period is achieved through operation of both loops, the SWS is capable of limiting the CCWS temperature to 120°F with a

single failure of the SWS. At no time during the cooldown does the CCWS temperature exceed 120°F.

The system is capable of satisfying these performance requirements with Service Water temperature at the design maximum of 95°F.

The control room operator is able to monitor the cooling performance of system components by means of instrumentation which indicates flows, temperatures and pressures or actuates alarms. Should the operating equipment fail to satisfy cooling requirements, the operator is able to place a redundant loop in service. Instrumentation for each heat exchanger and pump loop is applied so that abnormal operating conditions are identifiable by the operator.

Piping and pressure retaining components for this system satisfy the requirements of the ASME Code, Section III, Class 2 or 3, as applicable, except the non-nuclear safety class portions.

Piping and pressure retaining components of non-nuclear safety class portions of the SWS satisfy the requirements of ANSI B16.5 and ANSI B31.1.

9.2.1.2 System Description

System diagrams for the SWS are provided as Figures 9.2-1 and 9.2-2 (Sheets 1 through 4). Service water is supplied to the system by three, 100% capacity, vertical, wet pit pumps, each equipped with a two-speed motor which is permanently locked in the high speed position. Three (3) traveling water screens, each with independent controls, screen wash system and associated piping, valves, instrumentation and controls as shown by Figure 9.2-1 are also provided. The Service Water pumps can be controlled manually from the control room, the control room evacuation panel, locally or automatically as described in Section 9.2.1.3.

During normal plant operation, 1 of 3 Service Water pumps is in service at all times. A second SW pump may be run to limit biofouling in the inactive loop and is available for emergency use. The third Service Water pump is provided as an installed spare and its circuit breaker(s) is racked out. The spare pump can be aligned in parallel with the running Service Water pump in either loop through crossover connections. In the event of malfunction of the running Service Water pump, the spare pump is manually started to replace the running pump. The automatic start capability of the Service Water pumps is not used.

If 1 pump is out of service for maintenance, its circuit breaker must be placed in the test/maintenance position. The third pump must be aligned electrically and mechanically to replace the out of service pump.

Piping of the Service Water pump C is arranged so that it can be manually valved into either the A or B loop in place of Service Water pump A or B, as required. The interconnecting piping between Service Water pump C discharge and both A and B loops contains double manual valves to ensure the required double isolation between A and B loops.

Each Service Water pump has a corresponding traveling screen, screen wash system, and screen control system. The screen wash system take their water supply from the corresponding Service Water pump discharge header. Screen wash is provided using only the Service Water pumps discharge. This has been found to provide adequate screen wash force.

The diesel generator cooler in the operating SWS loop receive cooling water flow continuously, even though the diesel is not in operation. The plant Fire Protection System serves as a standby means of cooling the diesel generators. This includes automatic opening of the cross connect valves on high lube oil temperature or high jacket water temperature when the diesel is operating in the emergency mode.

Provision is made to supply Service Water to the Emergency Feedwater System through remotely operated valves if required. The 8” SW lines that provide backup flow to the Emergency Feedwater System are lined with a cured-in-place pipe lining to prevent MIC and general corrosion. Also, upon receipt of a “lo-lo” Component Cooling water surge tank level signal, Service Water is automatically provided for Component Cooling water makeup (see Sections 9.2.2 and 10.4.9).

SWS piping at the Component Cooling heat exchangers is arranged to allow back flushing of the heat exchangers, if required, by manual positioning of the valves.

A portion of the Service Water flow from each loop goes to a water jet exhauster. These air exhausters remove air that may be released from solution in the 36 inch pipe which interconnects the circulating water pumphouse and the Service Water Pumphouse.

Cooling water flow to the HVAC mechanical water chiller condensers is provided when the chiller is operating. The motor operated inlet valves open when their associated chillers are operating. Manual valves are available at the chiller outlets for isolation of these heat exchangers if required.

The RBCUs receive water from the Service Water booster pumps and the Digital Rod Position Indication System cooling unit is isolated from the Reactor Building cooling units by closing the isolation valves under safety injection, loss of non-Class 1E power, or test conditions. Upon receipt of a safety injection signal, the ESFLS starts the inactive loop at high speed. A description of safety injection actuation signals is presented in Section 7.3. The Service Water booster pumps, with throttling orifices in the discharge piping, maintain system pressure inside the Reactor Building above peak post accident pressure when Service Water flow is maintained to 2 RBCUs.

During normal operation, cooling water flow to the RBCUs and the Digital Rod Position Indication System cooling unit is provided by an industrial cooling system.

Valves XVB-3107A(B)-SW and XVB-3106A(B)-SW have been designed and interlocked to other equipment controls to mitigate two scenarios in which a pipe water hammer could occur. The first water hammer scenario was postulated to occur when the RBCUs are operating in their normal lineup where they are being cooled by the nonsafety Industrial Cooling Water System and the Service Water booster pumps (SWBP) are started during normal swap over to the SW system

for or after a Loss Of Offsite Power (LOOP). The second water hammer scenario is postulated to occur when the SW system is aligned to provide cooling for the RBCUs and a LOOP occurs.

To minimize the effects of the first water hammer scenario vacuum relief valves XVV-13143A(B)-SW downstream of valve XVB-3107A(B)-SW will replace, with air, any vacuum void downstream of closed valves XVB-3107A(B)-SW that may be formed due to gravity drain down of water to the SW pond. Upon the start of the SWBPs and opening of valves XVB-3107A(B)-SW, the air in the piping will act as a cushion to minimize any water hammer affects that could occur downstream of XVB-3107A(B)-SW. The opening logic of valves XVB-3107A(B)-SW has a delayed opening after valve XVB-3106A(B)-SW begins to open. The delay allows fluid flow momentum to build to assure that additional void formation in the RBCU piping inside containment will not occur during swap over to the SW system.

To minimize the effects of the second water hammer scenario XVB-3107A(B)-SW, fast closing air operated butterfly valves, close in seven seconds upon de-energizing of the SWBPs. During times that the RBCUs are aligned with the SW system, if a LOOP were to occur, the fast valve closure will trap water in the high points above the valve and prevent void formation due to gravity drain down of the water to the SW pond. Interface logic is provided to equipment controls that tie the start of the respective SWBP to the closed position of the respective valve XVB-3107A(B)-SW. The controls prevent a SWBP start if the respective valve XVB-3107A(B)SW failed to close within 10±1 seconds, allowing drain down of the water to the SW Pond.

A check valve with controlled closing speed is installed at the Service Water booster pump discharge to minimize water hammer in the event that electrical power to the pump and associated motorized discharge valve is momentarily interrupted.

Effluent from the SWS is returned to the Service Water pond by the 2 independent (A and B) loops. Motorized valves at the pump discharge and check valves at the system discharge prevent siphoning of the Service Water pond back into the system in the event of a major line rupture within the plant.

A biocide injection system was installed in the Service Water System for organic fouling control.

A chemical injection system was installed to treat the Service Water System for corrosion and silt disposition.

Information concerning major SWS components is presented in Table 9.2-1.

9.2.1.3 Safety Evaluation

The Service Water System is safety-related and is used to remove heat released during the postulated loss of coolant accident (LOCA).

Three (3) 100% capacity Service Water pumps, located in the Service Water intake structure, take suction from the Seismic Category 1 Service Water pond. Thus, a positive supply of cooling water is assured.

Under emergency conditions, power is supplied to loop A and B Service Water pumps by emergency diesel generators A and B, respectively.

The Service Water pumps are vertical, wet pit pumps housed in the Service Water intake structure and are supplied with water from the Service Water pond. The Service Water pond is connected to Monticello Reservoir through an interconnecting pipe system between the circulating water intake structure and the Service Water intake structure. Piping is installed so that the flow path is interrupted if Monticello Reservoir is drawn down below elevation 415' coincident with the isolation valve being open for some unforeseen reason. The minimum required submergence, to the bottom of the suction bells, for the Service Water pumps is 5 feet. At minimum Service Water pond level, the available submergence to the bottom of the suction bell, is approximately 21 feet. A discussion of low Service Water pond level considerations is presented in Section 2.4.11.

The Service Water intake structure also has a weir to ensure that the water level in the intake structure does not drop below elevation 399', the bottom of the Service Water pump suction bell is at elevation 394'. Water may be supplied to the Service Water intake structure from Monticello Reservoir through the interconnecting pipe and thereby maintain the minimum 5 foot submergence requirement.

The Service Water pumps are valved to discharge into either of the 2 main headers supplying cooling water to the nuclear portion of the station. System design assures that a single failure does not result in loss of more than 1 of the redundant Service Water loops. Table 9.2-2 presents a SWS failure analysis. The 2 Service Water loops are designed so that all cross connections between the loops are double valved. At least 2 valves in series are closed during normal operation.

During a postulated LOCA, the 2 Service Water booster pumps supplying Service Water to the RBCUs are started. Throttling orifices in the return lines control back pressure to maintain Service Water pressure above long term post accident Reactor Building ambient pressure. This favorable pressure differentiated in conjunction with the leak-tight integrity of the RBCU coils and associated SWS piping, minimize the potential for transport of radioactive materials outside of containment in a postulated post-accident situation.

The RBCUs are normally used for Reactor Building temperature control. Normal cooling water supply to the RBCUs is provided by cooled water from the Industrial Cooling Water System.

In the event of a safety injection signal, both A and B Service Water loops, including the Service Water booster pumps are started to satisfy redundancy requirements. Each Service Water booster pump is supplied with power from the appropriate (A or B) emergency diesel generator.

During normal operation, and a postulated LOCA, 1 Service Water pump operates to supply up to 16,800 gpm of water at temperatures up to 95°F. This flow is adequate to provide sufficient cooling to one SWS loop. A second SW pump may be run to limit biofouling of the inactive loop.

During the postulated LOCA or upon receipt of a safety injection signal, the Digital Rod Position Indication System cooling unit is isolated from the RBCUs by closing the isolation valves.

Missile protection is discussed in Section 3.5. Pipe rupture considerations are discussed in Section 3.6.

The SWS is generally protected from radioactive contamination by 2 physical boundaries. Systems which contain radioactive materials are cooled by the Component Cooling Water System which is, in turn, cooled by the SWS. The SWS also cools the HVAC mechanical water chiller condensers where Service Water is separated from the potentially radioactive fluid by at least 3 physical barriers. The single application where Service Water is separated from radioactive fluid by only 1 physical barrier is post accident Reactor Building cooling. However, in this case, the Service Water booster pumps maintain Service Water pressure inside the Reactor Building above long term Reactor Building pressure. Reactor Building pressure exceeds SWS pressure for only a short time interval in the post accident case in the event that an individual RBCU is isolated in one or both trains.

The RBCU cooling coils, and associated SWS piping are classified as moderate energy components, in accordance with applicable pipe rupture rules. Therefore, only through wall leakage cracks may be postulated, in the long term, following a design basis accident. However, SWS pressure remains above Reactor Building pressure in the long term following a design basis accident.

The Service Water pumps can be manually controlled from the control room or from the control room evacuation panel.

The Service Water booster pumps can be manually controlled from the control room. The Service Water booster pumps automatically start upon receipt of a safety injection signal via the ESFLS. During an undervoltage condition on bus 1DA or 1DB the respective Service Water booster pumps are tripped and then loaded on the emergency diesel generator by the ESFLS. The low suction pressure trip is blocked when the booster pump starts in response to a safety injection signal.

Service water pump discharge valves are automatically driven open when their respective pumps start and are driven closed when their respective pump is shutoff. There are no operator controls provided for these valves on the main control board. The Service Water booster pump discharge valves, are automatically driven open when their respective pumps start, and close when the Service Water Booster Pump stops.

Differential pressure across each traveling screen is measured by 2 bubbler probes. Upon receipt of a high differential pressure signal from either bubbler probe (indicating dirty screens), the screen wash system is started and the screen wash isolation valve is opened. This provides high pressure water to the screen wash spray nozzles. Pressure in the spray nozzle header is sensed and provides a starting signal to the screen drive motor. This control scheme ensures that the screen wash systems do not start unless sufficient suction pressure is available and the screen is not driven unless sufficient pressure exists at the spray nozzles to ensure complete washing.

A timer ensures that the screen is washed and driven for a period corresponding to a minimum of 1-1/3 revolutions of the screen.

Capacity for local manual operation using a jog button is provided. Flow to the screens is not interrupted during the self-cleaning cycle. Upon receipt of a safety injection or loss of non-Class 1E power signal via the ESFLS, the normal screen controls are isolated and the screens cease rotation.

9.2.1.4 Tests and Inspections

The SWS is operated during all plant operating phases. Operation is alternated between the 2 loops during normal power operation; although a SW pump may be run to provide flow to the inactive loop to limit biofouling. Thus, normal operation verifies the operability and performance of the Service Water pumps. Therefore, no periodic testing of the pumps is necessary. Automatic startup of the system in response to a safety injection or loss of non-Class 1E power signal is verified periodically.

System actuation tests are performed during the refueling period when a loop is inactive. These tests check the automatic startup circuitry and operation of the actuation relays and associated components. One of the SWS loops is in operation throughout the refueling period.

Other system verifications are also performed periodically. Closure of the industrial cooler containment isolation valves in response to the applicable ESF signals during each refueling shutdown. Also, these valves are checked to verify their leak tightness (see Section 6.2.6).

9.2.1.5 Instrumentation Requirements

SWS instrumentation provides the necessary inputs for control, operation and performance/status monitoring of the system. This instrumentation is shown on Figures 9.2-1 and 9.2-2 (Sheets 1 through 4). In addition, indicators and/or controls are located on the control room evacuation panel, on local panels and near the components.

9.2.1.5.1 Pressure Measurement

1. Pressure Indicators

   Direct reading pressure indicators are provided on the discharge side of the Service Water pumps, on the suction side of the Service Water booster pumps, and on the discharge side of the Service Water screen wash system.

2. Pressure Transmitters

   Pressure transmitters located on the discharge side of the Service Water and Service Water booster pumps and in the exit of the RBCUs provide signals for control room indication and low pressure alarms. In addition, the transmitters on the discharge side of the Service Water pumps provide auto-start signals for the Service Water pumps; however, auto-start on low pressure is no longer used because the standby concept has been replaced by an installed spare concept.

3. Pressure Switches

   Switches located at the spray nozzle header provide contacts for the traveling screen start signal. Switches located on the suction side of the Service Water booster pumps provide contacts for an alarm. One switch is located on the suction side at the DRPI cooling unit booster pump providing interlock contacts which prevent the pump from starting and which trip the pump if suction pressure is not sufficient.

4. Pressure Test Connections

   Pressure test connections are located throughout the system for use during performance testing.

5. Differential Pressure Switches

   Two (2) independent differential pressure switches located across each traveling screen provide contacts for the respective screen wash isolation valve opening.

9.2.1.5.2 Liquid Level Measurement

Two (2) level transmitters located in the Service Water pond provide signals for control room indication and low level alarm.

9.2.1.5.3 Flow Rate Measurement

Direct reading flow indicators (locally mounted) are provided for cooling water flow to the upper and lower motor bearings for each Service Water pump A, B, and C. A flow element is provided on both the A and B 30" diameter Service Water pump discharge headers (IFE-4586 for A pump discharge; IFE-4587 for B pump discharge). The flow elements are mounted downstream of the tee in each respective discharge header which connects the header with the C pump discharge pipe. A locally mounted flow indictor (IFI-4586 or IFI-4587) is provided for flow indication for each flow element.

Flow transmitters located on the outlet side of the diesel generator coolers, Component Cooling heat exchangers and HVAC mechanical water chiller condensers provide signals to the Yokogawa units on the main control board (see Section 9.2.1.5.5), which provide both component low flow alarms and indication.

Flow transmitters located on the discharge side of the Service Water booster pumps and in the discharge loop headers from the RBCUs provide signals for control room indication and low flow alarms.

9.2.1.5.4 Temperature Measurement

1. Temperature Indicators

   Direct reading temperature indicators are provided on the outlet side of the diesel generator coolers, Component Cooling heat exchangers, Digital Rod Position Indication System cooling unit, HVAC mechanical water chiller condensers, and Service Water pump house cooling coils.

2. Temperature Elements

   Temperature elements (thermocouples) located on the outlet side of the diesel generator coolers, Component Cooling heat exchangers and HVAC mechanical water chiller condensers provide signals to the control room Yokogawa Recorders (see Section 9.2.1.5.5) which provide both high temperature alarms and indication. Temperature elements which provide input through signal converters to control room indicators are located in each loop header from the reactor building cooling units and in each loop supply header. Temperature elements providing computer input are located at the motor inboard, outboard, thrust bearings and motor stators of each Service Water pump.

3. Temperature Test Connections

   Test wells are conveniently located throughout the system for use during performance testing.

9.2.1.5.5 Monitors

For those cooling heat exchangers which do not have individual flow and/or temperature indicators, Yokogawa Recorders are provided. These recorders, mounted on the main control board, accept analog signals from the individually measured temperatures and flows. For every measured variable there is an individual alarm condition window with capability provided to set an alarm condition signal limit from the measured variable. For every 20 measured temperature or flow signals, an indicator is provided in temperature degrees or flow gallons per minute (GPM). Abnormal conditions are annunciated. If, at a sensor location, the temperature exceeds its maximum setpoint limit, or if the flow drops below its minimum setpoint limit, the event is alarmed. The operator checks the actual reading and takes appropriate action. To prevent unnecessary alarm attendance by the operator, the variable signals are grouped so that when one Service Water loop is inactive, all of the temperature and flow variable alarms on that loop can be defeated together. Since HVAC mechanical water chiller C can be used with either Service Water loop A or loop B, flow readings appear on both A and B Yokogawa Recorders units to satisfy separation criteria.

9.2.1.5.6 Special Instrumentation

The main control board ESF monitor lights (see Section 7.5 for a more detailed explanation) provide an easily recognizable indication of the status of essential components and equipment.

Included among the monitor lights for this system are status (position) indication of the containment isolation valves, the Service Water pump discharge valves and the valves in the return paths.

An audible and visual alarm is annunciated on the main control board if manual action by the operator deliberately bypasses the operation of the SWS.

The Service Water booster pump discharge flow and Service Water temperature in and out of the Reactor Building are part of the post accident monitoring instrumentation (see Section 7.5 for a more detailed explanation).

9.2.1.5.7 Instrumentation Qualifications

Sections 3.10, 3.11, and 7.1 outline the qualifications and diversity of the instrumentation utilized in this system.

9.2.2 Component Cooling Water System

The Component Cooling Water System (CCWS) serves as an intermediate, closed loop cooling system to transfer heat from components important to safety including those which may contain radioactive or potentially radioactive fluids to the Service Water System. These components are the residual heat removal (RHR) pumps, RHR heat exchangers, charging pump gear/oil coolers and Component Cooling water pump motors.

The CCWS is also utilized during normal plant operation to transfer heat from various systems and components that are not important to safety. This latter service is subsequently referred to as “nonessential”. Use of the CCWS precludes release of radioactivity in the event of malfunction of one of the nonessential components. Nonessential recipients of Component Cooling water supply are as follows:

1. Reactor coolant drain tank heat exchanger.
2. Excess letdown heat exchanger.
3. Reactor coolant pumps (bearings and thermal barrier cooler).
4. Spent fuel heat exchangers.
5. Letdown heat exchanger.
6. Seal water heat exchanger.
7. Recycle evaporator package.
8. Waste evaporator package.
9. Waste gas compressors.
10. Sample heat exchangers.
11. Waste Process System recombiners.

Operation of the CCWS is required during all phases of normal plant operation, including startup through cold shutdown and refueling, as well as during emergency operation following a LOCA. Significant heat removal functions of the system are as follows:

1. Remove the excess heat generated during a plant startup.
2. Provide cooling of the letdown flow during normal power operation.
3. Remove residual and sensible heat from the Reactor Coolant System (RCS) during and after a plant shutdown.
4. Remove the residual heat released in the reactor during refueling operations and from the stored spent fuel.
5. Provide cooling to the components important to safety following a LOCA to achieve a safe shutdown or maintain a safe reactor operating condition.

9.2.2.1 Design Bases

The CCWS is designed to satisfy the requirements of General Design Criterion 44. Sufficient redundant and independent capacity ensures that cooling water is available to achieve and maintain a safe shutdown from normal plant operation, following an accident combined with a loss of offsite power and any single failure (including failure of one diesel generator). The redundancy within the CCWS is consistent with redundancies within other safety-related systems.

The basic CCWS is classified as Safety Class 2b except for the following:

1. The chemical injection system, portions of the surge tank makeup water systems and piping downstream of system relief vent and drain valves are non-nuclear safety class.
2. Penetration isolation valves and associated intermediate piping are classified as Safety Class 2a.

The basic CCWS is classified as Seismic Category 1, except for the following:

1. Radiation monitor instrument lines downstream of the seismic isolation root valves.
2. The Recycle Evaporator Package Sample Cooler and the Waste Evaporator Package Sample Cooler flow indicator’s instrument lines downstream of the seismic isolation root valves.

The various systems supplied with Component Cooling water, corresponding required flow rates and heat loads associated with various plant operational modes are listed in Tables 9.2-3 through 9.2-10.

With both loops in operation, the CCWS capacity is adequate during a normal plant shutdown to reduce the RCS temperature to 140°F within 24 hours after reactor shutdown following an extended full power run at the current licensed RTP of 2900 MWt. With a single failure within the CCWS, satisfactory cooldown can be achieved, except that the time to reduce the RCS temperature to 140°F may be extended depending upon the failure. During the cooldown, the

system is capable of limiting the CCWS temperature to 105°F at the end of the 24 hour cooldown period with both loops in operation. After an RCS temperature of 140°F at the end of the 24 hour cooldown period is achieved with both loops, the CCWS is capable of limiting the CCWS temperature to 120°F with a complete failure of either loop. At no time during the cooldown does the CCWS temperature exceed 120°F. The system is capable of meeting these performance requirements when provided with Service Water at a maximum temperature of 95°F.

The pressure on the Component Cooling water side of the CCWS heat exchanger is maintained at a pressure less than the pressure on the Service Water side to prevent CCW leakage into the Service Water pond should a tube leak develop within the heat exchanger. This is a non-safety related requirement.

CCWS components are accessible for necessary manual operations and maintenance. The post LOCA situation will render some of the CCWS inaccessible but will not neutralize the safety function of the system. The CCWS installation is removed or shielded from possibly radioactive process systems to preclude unacceptable personnel exposure.

CCWS components satisfy the intent of Regulatory Guide 1.48 (see Appendix 3A) and are seismically qualified.

Single failure incidents within the CCWS have been analyzed and analytical results demonstrate that no single failure precludes performance of the safety function of the system. Table 9.2-11 presents the single failure analysis.

9.2.2.2 System Description

The CCWS consists of 2 independent loops, providing 100% redundancy in the supply of cooling water for the safety-related systems, and a common supply for the nonessential systems.

System diagrams for the CCWS are included as Figures 9.2-4 through 9.2-7.

The ECCS components supplied with cooling water by the CCWS are as follows:

1. Residual heat removal pumps.
2. Residual heat removal heat exchangers.
3. Centrifugal charging pumps.

These components are parts of redundant, independent systems served by redundant, independent CCWS loops. Thus, upon loss of 1 CCWS cooling loop, or portion thereof, cooling water remains available to the redundant component in each of the safety-related systems.

As required by General Design Criterion 44, the same emergency power bus delivers power to essential components and essential elements in the same CCWS loop. Should a loss of offsite power, combined with failure of 1 onsite emergency power supply occur, the CCWS loop

supplying cooling water to safety-related components receiving power from the operating emergency power supply remains operable.

The common circuit for the nonessential systems is connected to both CCWS loops through crossover connections and can be supplied from either CCWS loop. Normally, isolation valves (2 valves in series) in the crossover connections to 1 loop are closed and the circuit is aligned to receive Component Cooling water only from the operating loop. This alignment provides complete isolation between the 2 loops. Valve position status lights are provided in the control room. The crossover connections to both loops are open simultaneously only during a normal switchover operation. The crossover connections to both loops can be closed at the main control board by operator action for isolation of the nonessential circuit from both CCWS loops during safety injection or recirculation operating modes if cooling water is not required for the spent fuel pool cooling heat exchanger.

A third CCWS pump is provided which is aligned in parallel with the running pump in either loop through crossover connections. Two (2) valves in series are provided in each crossover header to maintain isolation and independence between the 2 loops. Incorrect valve alignment is alarmed in the control room. This third pump is normally aligned with the running loop and serves as a standby to the running pump. Should pressure decrease below a certain level due to a malfunction of the running pump, the standby pump is automatically started to maintain operation of the loop. The standby pump does not start as a result of a safety injection signal without loss of offsite power but remains as a backup to the running pump during subsequent operations.

If there is a loss of offsite power, the standby pump is locked out to ensure against its inadvertent startup during the restarting of the running pump by the engineered safety features load sequencer (ESFLS). It does not provide automatic backup to the running pump during subsequent operation. A manual electrical circuit realignment is performed if standby pump operation is required.

If one pump is out of service for maintenance, its circuit breaker must be placed in the test/maintenance position. The third pump must be aligned electrically and mechanically to replace the out of service pump.

Redundant valves (2 valves in series) are used in all cross connections between the two CCWS loops to ensure isolation or the capability for isolation of 1 loop from the other. Use of 2 valves ensures against loss of isolation in the event of valve pressure boundary failure or a line failure between valves combined with a valve functional failure.

The Component Cooling pumps have 2 speed capability. Operation of the pump at high speed is initiated only by manual operator action and is administratively permitted only when the nonessential circuit is connected to the loop and the RHR heat exchanger circuit is open. Only the low speed pump operating mode is associated with the CCWS safety function. One pump operating in the high speed mode satisfies normal shutdown criteria under design conditions but the capability of achieving a safe shutdown for normal operation or following an accident is not contingent upon availability of the high speed mode. Operation of a CCWS loop with the pump at high speed is an option available to the operator at any time subject to the previously noted restrictions.

The CCWS is operated during all phases of plant operation:

1. Startup.
2. Normal power operation.
3. Shutdown.
4. Refueling.
5. Under hot standby conditions.
6. Following an accident (including a LOCA).

The 2 loops are operated independently and can be operated singly or simultaneously. One (1) loop has the flow capacity to satisfy cooling water requirements under normal plant operating conditions except during normal shutdown. During normal shutdown, operation of the second loop is necessary to support operation of the second RHR pump and RHR heat exchanger to cool the reactor coolant system from 350°F to 140°F within 24 hours after reactor shutdown. A satisfactory cooldown of the Reactor Coolant System can be achieved with only 1 loop operating; however, this would extend the cooldown time.

Upon the occurrence of an accident resulting in a safety injection signal, both CCWS loops are activated. The active loop continues to operate in the normal mode. The pump in the inactive loop is automatically started in the low speed mode to provide cooling water flow through the RHR heat exchanger circuit and to its assigned safety-related pumps. If 1 loop does not operate in response to the safety injection signal, the other loop provides cooling water to the safety-related systems necessary to achieve a safe shutdown.

If 1 Component Cooling pump is out of service for repair or maintenance, its breaker must be placed in the test/maintenance position and each of the 2 remaining pumps is connected to a different loop. This maintains redundant, independent capacity for supplying cooling water to safety-related components. The valves in the crossover connections between the nonessential circuit and the inactive loop are closed.

A surge tank maintains adequate net positive suction head (NPSH) to each Component Cooling pump, provides makeup water to each loop as needed and provides compensation for fluid thermal expansion. The bottom half of the tank is partitioned such that each half serves 1 CCWS loop. Thus, a loss of water in 1 loop does not affect the other loop. Isolation and independency of the loops is thereby maintained.

Cooling water is demineralized and treated with corrosion inhibiting chemicals and an alkaline agent. Demineralized makeup water is automatically supplied to each compartment of the surge tank. An operator actuated chemical injection system prepares and injects chemical additives into the CCWS water as needed.

A connection to the pump suction piping for each loop is provided from the SWS for emergency makeup water supply to the CCWS. Emergency makeup is provided when leakage is in excess of the maximum demineralized water makeup rate of 50 gpm, or when normal makeup is not

available. Breaks in miscellaneous non-nuclear safety related instrument lines as a result of seismic event would result in a maximum leakage rate of 153 gpm. A signal resulting from a lo-lo level in 1 of the baffled surge tank compartments would automatically open the Service Water isolation valve connected to that compartment.

Radiation monitors, located in each CCWS loop, detect leakage into the loop from those components containing radioactive fluid and initiate an alarm in the control room. The source of the leakage is identified by analyzing cooling water samples from the heat exchanger of each served component. The source of leakage is then isolated by closing the valves in the cooling water supply and return lines to that particular heat exchanger.

Excessive leakage of Component Cooling water is detected by pressure changes, flow rate changes, an increase in the frequency and/or duration of surge tank water makeup cycles or visual inspection of the system.

Valves are provided in the CCWS distribution circuits so that a particular circuit can be isolated from the CCWS in case of leakage or for maintenance of the heat exchanger supplied by that circuit. Also, manual shutoff valves are provided in each CCWS loop to permit isolation of a pump or Component Cooling heat exchanger for maintenance.

The CCWS loop and heat exchanger for the reactor coolant pump thermal barriers create a pressure head significantly greater than the other cooling circuits. To provide adequate pressure head for this circuit, booster pumps are utilized to create the additional pressure head required. Three (3) booster pumps are provided in a parallel arrangement. During normal operation, 1 of the pumps is operating. A second pump is in a standby condition to back up the operating pump and is started automatically if the discharge pressure decreases below a predetermined limit. The third pump is provided to maintain backup capability should 1 pump be out of service for repair or maintenance.

Since operation of the booster pumps is not a CCWS safety function requirement and the thermal barrier cooler serves only as a backup to flow from the charging pumps for reactor coolant pump seal cooling, the booster pumps receive electric power from the non-Class 1E supply buses. In the event of a safety injection signal, the operating booster pump continues to operate and the backup booster pump remains in a standby condition. However, in the event of a loss of offsite power, the operating booster pump stops and the booster pumps remain inoperable. (The reactor coolant pumps also stop if a loss of offsite power occurs.)

Flow rates, pressure and temperatures are measured in each of the CCWS circuits. At the Component Cooling heat exchangers, residual heat removal heat exchangers, RHR pumps and components necessary for normal operation, high temperature and low flow alarms are activated in the control room by the measurement systems. An alarm is also activated if a high RHR heat exchanger flow rate occurs to provide protection against excessive tube vibration. An excessive RHR heat exchanger flow can be reduced by throttling the manual valve in the CC system outlet line from the heat exchanger (XVB-9507A, B-CC).

Motor operated valves are located in the discharge lines from the reactor coolant pump thermal barrier coolers. These valves close in response to a high flow rate from the coolers and, in conjunction with a check valve upstream of the cooler, provide isolation of the CCWS from over pressurization in the event of a tube failure in the thermal barrier cooler. Corresponding isolation elements are provided in the CCWS circuit serving the excess letdown heat exchanger to isolate the balance of the CCWS from the effects of a failure in this heat exchanger.

Throttling and balancing capability is provided within each loop and within each CCWS supply circuit to balance loop flow characteristics to pump characteristics for either pump operating speed and to balance each parallel flow circuit so that it receives the required cooling flow. Likewise, if a circuit is removed from service, the other circuits and the loop balances must be adjusted accordingly. Pressure reducing orifices are used where throttling of a circuit is required under all operating conditions. Where the requirement for throttling depends upon the plant (or CCWS) operating mode, various valves in the circuits are used for temporary trim throttling.

The CCWS loops are each capable, with the pump operating at high speed, of supplying peak flow rate of approximately 11,700 gpm of water. At the beginning of plant cooldown with a maximum temperature of 120°F, the CCWS (with both loops operating) transfers a peak heat load of 251.8 x 10^6 BTU/hr (includes spent fuel pool load) to Service Water with a maximum temperature of 95°F. At a maximum CCWS temperature of 120°F and total flowrate of 7325 gpm, one CCWS Heat Exchanger can transfer 140.7 x 10^6 BTU/hr to the SWS assuming 95°F SW and 7680 gpm SWS flow. During the recirculation phase, the heat load on one CCWS loop is estimated to be 72.8 x 10^6 BTU/hr and 59.5 x 10^6 BTU/hr on the other.

Information concerning major CCWS components is presented by Table 9.2-12.

9.2.2.3 Safety Evaluation

Those portions of the CCWS required to ensure performance of safety-related functions are designed to satisfy Safety Class 2a or 2b and Seismic Category 1 requirements. All Safety Class 2a components are built in accordance with the ASME Code, Section III, Subsection NC. All Safety Class 2b components are built in accordance with the ASME Code, Section III, Subsection ND.

A single failure analysis is presented by Table 9.2-11. This analysis demonstrates that sufficient redundancy is provided with the system to ensure that safety-related functions are performed.

Protection of the CCWS from the dynamic effects of pipe rupture is discussed in Section 3.6.

Sections 9.2.2.3.1 through 9.2.2.3.3 describe CCWS operation during safety injection, recirculation and shutdown, respectively.

9.2.2.3.1 Safety Injection

Following the occurrence of a safety injection signal, the CCWS provides cooling water to both centrifugal charging pumps and RHR pumps. In subsequent phases, removal of heat from the RHR heat exchanger may be accomplished through operator action which depends upon the accident or event causing the safety injection signal.

Both CCWS loops operate during safety injection. This provides Component Cooling water to the centrifugal charging pumps and RHR pumps which ensures that the minimum safety function of these pumps is available under any accident condition, including loss of offsite power and any single failure.

Upon receipt of a safety injection signal (without loss of offsite power), the active CCWS loop continues to operate. The safety injection signal does not start the standby Component Cooling pump. However, the standby pump continues to remain active and starts automatically if there is a malfunction of the running Component Cooling pump resulting in a decrease in the loop pressure.

The inactive CCWS loop is activated in response to the safety injection signal. The supply and return lines to the RHR heat exchanger are normally open in this loop. The non-running Component Cooling pump is started automatically by the ESFLS. The loop operates to circulate cooling water through the RHR heat exchanger circuit, charging pump oil coolers, and to the RHR pump aligned with the loop.

If there is a loss of offsite power in conjunction with or subsequent to the safety injection signal, the running loop pump stops and is then restarted by the ESFLS. The pump in the non-running loop likewise stops and is restarted by the ESFLS if the loss of offsite power was preceded by a safety injection signal. The standby pump is locked out when a loss of offsite power occurs and does not start automatically if there is a subsequent malfunction of the running pump. The operating booster pump stops and the booster pumps remain inoperable.

The supply of Component Cooling water to the nonessential systems continues (unless terminated by the operators) except, if a containment, phase B isolation signal occurs, the CCWS containment isolation valves in the lines to and from the Reactor Building are closed terminating the cooling water supply to the reactor coolant pumps, the reactor coolant drain tank heat exchanger and the excess letdown heat exchanger.

The RHR heat exchanger circuit remains closed on the active loop during the injection phase. When operation of the heat exchanger is necessary for reactor cooldown or for recirculation, the RHR heat exchanger circuit is activated by the operator. The valves in the crossover connections to the nonessential circuit can be closed as the RHR heat exchanger circuit is activated and pump operation may be continued at low speed. However, if the nonessential circuit is not shut off when the RHR heat exchanger circuit is activated, the pump is switched to the high speed mode by the operator. An alternate arrangement is to isolate all of the components on the nonessential circuit except the spent fuel pool cooling heat exchanger and operate the pump at low speed. In anticipation of switchover, during the injection phase, the CC flow to the RHR Hx may be initiated in the active loop with the CC pump in slow speed; however, subsequent to completion

of the switchover procedure (Table 6.3-3), the CC pump in the active loop will be placed in fast speed provided that the swing pump is available.

No operator action is required for normal operation of the CCWS during safety injection. Alarms are actuated in the event of an abnormal condition within either of the two loops. Following the occurrence of a safety injection signal, the operator may modify the operation of the system.

9.2.2.3.2 Recirculation

The post LOCA safety injection phase is followed by the recirculation phase during which the water collected in the Reactor Building from the accident and the safety injection phase is recirculated through the RHR heat exchanger and the Reactor Coolant System by the RHR pumps. During this phase the CCWS loops must transfer the heat load from the RHR heat exchangers, as well as provide cooling to the respective RHR and charging pumps.

The normally inactive loop operates during the safety injection phase with the RHR heat exchanger circuit open. Therefore, no change is necessary in the operation of this loop when recirculation is initiated. In the active loop, the RHR heat exchanger circuit is normally shut off throughout safety injection. The shutoff valve must be opened by manual operator action to activate the RHR heat exchanger for the recirculation phase. When the RHR heat exchanger circuit is opened, the operator either shuts off the nonessential supply circuit, switches the pump to the high speed mode or manually isolates the individual components on the nonessential circuit except for the spent fuel pool cooling heat exchangers. If required, the spent fuel heat exchanger may be temporarily removed from service. In anticipation of switchover, during the injection phase, the CC flow to the RHR Hx may be initiated in the active loop with the CC pump in slow speed; however, subsequent to completion of the switchover procedure (Table 6.3-3), the CC pump in the active loop will be placed in fast speed provided that the swing pump is available.

9.2.2.3.3 Shutdown

Shutdown is a transient condition which takes the plant from the hot, critical, minimum load condition to cold shutdown. During the initial shutdown period residual and sensible reactor heat are removed from the Reactor Coolant System through the steam generators. CCWS operation is continued through this initial period with no change from the normal power operation mode. After approximately 4 hours (when reactor coolant temperature and pressure are reduced to approximately 350°F and 400 psig) the cooldown heat removal function is transferred to the CCWS through the RHR heat exchangers.

Maximum heat removal demand is placed on the CCWS at this time. After maximum core operating life, the peak heat load of approximately 107 x 106 BTU/hr is transferred to the CCWS through each RHR heat exchanger to maintain the normal reactor cooldown rate. An additional heat load of approximately 38 x 106 BTU/hr is added from the RHR pumps and the nonessential systems. To handle this heat load, operation of both CCWS loops is necessary. The RHR heat exchanger circuit is opened on the operating loop and the pump is switched to the high speed mode. This loop supplies cooling water for the nonessential systems, assigned RHR pump and 1 RHR heat exchanger. Operation of the other loop in the low speed mode is initiated to supply

cooling water to one RHR heat exchanger and the assigned RHR pump. Trim throttling of the high speed loop may be necessary to rebalance flows and meet temperature limits of components in the circuits for the high speed operating mode.

9.2.2.4 Tests and Inspections

The CCWS is operated during all plant operating phases. Operation is alternated between the two loops during normal power operation. In addition, the low speed mode is tested in accordance with ASME Code, Section XI. The operability and performance of the 2 Component Cooling pumps at low speed is therefore verified. Automatic startup of the system in response to a safety injection signal is verified periodically. Satisfactory startup and operation of each pump at low speed is verified prior to plant startup after each refueling period.

System tests are performed as required by Tech Specs. These tests check the automatic startup circuitry and operation of the actuation relays and associated components. One (1) of the loops is in operation throughout the refueling period.

Other system verifications are also performed periodically. Closure of the containment isolation valves in response to a "high-high" containment pressure signal is checked during each refueling shutdown. Also, these valves are checked to verify their leak tightness (see Section 6.2.6). Closure of the isolation valves in the thermal barrier discharge lines in response to a high flow signal from the downstream flow meter is verified periodically.

9.2.2.5 Instrumentation Requirements

Measurement and monitoring of radiation, pressure, liquid level, flow rate and temperature are performed for purposes of indication, alarm, control and record maintenance as required by the CCWS.

9.2.2.5.1 Radiation Measurement

A radiation monitor in each CCWS loop provides control room indication if either CCWS loop has become contaminated from the following:

1. Thermal barrier cooler leakage.
2. Tube leakage from heat exchangers with contaminated fluid served by the CCWS.

An excessive radiation level actuates control room alarms and closure of the valve in the surge tank vent line. The radiation monitoring system which performs these measurements is discussed in Section 11.4.

9.2.2.5.2 Pressure Measurement

Pressure measuring devices monitor the discharge header pressure from the Component Cooling pumps and Component Cooling booster pumps. These devices provide control room indication,

alarms and automatic start of the backup Component Cooling pump when there is a decrease in discharge header pressure. Local pressure gages are used to indicate suction and discharge pressure for all CCWS pumps and the pressure in the surge tank vapor space.

9.2.2.5.3 Liquid Level Measurement

Surge tank liquid level is monitored on both sides of the baffle. High, low and low-low levels cause alarms in the control room. The low level indication causes the demineralized water makeup valve to the affected side of the tank to open. A low-low level indication causes the emergency Service Water makeup valve to the affected side of the tank to open. Clearing of low level indication causes the demineralized water makeup valve to close. Operator action is required to close the Service Water valve.

9.2.2.5.4 Flow Rate Measurement

Flow rate measurement is performed in both the essential and nonessential loops.

Identical instrumentation measures Component Cooling water flow rates in CCWS essential loops A and B. Flow rate measurements are made in the Component Cooling pump discharge headers, RHR heat exchanger inlet lines and the discharge lines from the RHR pump seals. The essential CCWS measurements provide control room indication of Component Cooling water flow to essential components.

Redundant safety related flow transmitters are provided in the supply header to the upper and lower reactor coolant pump bearings. These transmitters provide signals for flow indication and actuation of low flow alarms in the control room should CCWS flow to the pump bearings decrease to less than that required to serve three reactor coolant pumps. Redundant safety related flow transmitters are also provided in the supply header from the CCWS booster pumps to the reactor coolant pump thermal barriers. These transmitters provide signals for flow indication and actuation of low flow alarms in the control room should flow to the thermal barriers decrease to less than that required to serve three reactor coolant pumps.

Nonessential CCWS flow measurements provide the operator with flow information for each reactor coolant pump thermal barrier and bearing cooler outlet line, the waste evaporator heat exchanger package, the recycle evaporator package and the individual nonessential heat exchangers (except sample coolers) served by the CCWS. For the monitored nonessential components, an alarm is initiated when the cooling water flow rate falls below a preset limit.

9.2.2.5.5 Temperature Measurement

Temperature measurements are backup indications for control of flow measurements for both the essential and nonessential CCWS loops. For each analog flow signal transmitted to the control room (and its associated low flow limit alarm), there is a corresponding analog temperature signal transmitted to the control room and a corresponding high temperature limit alarm. Additional high temperature alarms from temperature switches are also provided. For certain analog temperature transmitting devices, there is either a local thermometer or a locally indicating temperature switch

which permits local indication for checking and, in some cases, remote alarms or computer logging. By removing the adjacent thermometer or temperature switch from its thermal well, the well can be used as a reference to check the calibration of the adjacent analog temperature transmitting device. In addition, test wells are located throughout the system to allow checking of heat exchanger efficiencies.

9.2.2.5.6 Special Instrumentation

The main control board ESF monitor lights (see Section 7.5 for more detailed explanation) provide an easily recognizable indication of the status of essential components and equipment. Included among the monitor lights for this system are status (position) indication of the containment isolation valves.

An audible and visual alarm is annunciated on the main control board if manual action by the operator deliberately bypasses the operation of the CCWS.

9.2.2.5.7 Instrumentation Qualification

Sections 3.10, 3.11 and 7.1 outline the qualification and diversity of instrumentation utilized in this system.

9.2.3 Demineralized Water Makeup System

The Demineralized Water System is composed of the cycle makeup pretreatment system, which clarifies and filters raw water from Monticello Reservoir, and the cycle makeup demineralization system which demineralizes water from the cycle makeup pretreatment system for distribution to the Nuclear Steam Supply System (NSSS), the secondary (turbine) cycle, and for other miscellaneous uses.

9.2.3.1 Design Bases

The Demineralized Water System is designed to satisfy the makeup water requirements of the Reactor Coolant System and secondary (turbine) cycle systems.

The system is nonsafety-related. Piping and equipment is designed and fabricated in accordance with applicable American National Standards Institute, American Society of Testing and Materials and American Water Works Association codes and standards and the ASME Code, Section VIII.

9.2.3.2 System Description

Figures 9.2-8 and 9.2-9 show the Demineralized Water Makeup System.

In the cycle makeup pretreatment system, raw water from Monticello Reservoir is treated with a suitable flocculant and chlorine to precipitate suspended matter, remove color and adjust pH. The clarified water is filtered through automatic gravity filters and is force fed into a 1,000,000 gallon

filtered water storage tank. The filtered water is then pumped to miscellaneous pump seals, industrial cooler makeup, and through carbon filters to cycle makeup demineralization system. The carbon filters remove organic matter and excess chlorine as well as objectionable taste and odor. A portion of the carbon filter effluent used to serve as sterile water makeup for potable water service. The sterile water system includes provision for chemical treatment to disinfect and control the alkalinity of the system. Sterile water supply is modified to be fed from the same OWS source as potable water, see Section 1.2.3.8.4.

The cycle makeup demineralization system purifies water from the cycle makeup pretreatment system. Rated capacity of the cycle makeup demineralization system is 375 gpm (per train) and is based upon 1.5% of rated steam flow.

Two trains of plant installed demineralizer units and a vendor supplied portable demineralizer system are used. Each train includes a cation unit, anion unit and a mixed bed polishing unit. Since experiencing a sulfuric acid leak that damaged the discharge nozzle of the sulfuric acid tank, it has not been possible to regenerate the resin beds in the installed cycle makeup demineralization system. Therefore, the vendor supplied portable demineralizer system operates normally. The equipment associated with the cycle makeup demineralization system remains installed in the plant, isolated from the Filtered Water System and the Demineralized Water Storage Tank. The vendor supplied system is aligned in parallel with the original two trains. The portable equipment consists of a demineralizer trailer, a carbon activated skid, and a resin polishing skid. The trailer includes a series of a cation and an anion unit. The demineralized water produced is stored in the 500,000 gallon Demineralized Water Storage Tank and pumped to the following major use points:

1. To a vacuum degasifier for primary plant cycle makeup (recycle makeup water system).
2. To miscellaneous nuclear related uses, such as resin sluicing and Component Cooling water makeup.
3. To the main condenser for secondary cycle makeup.
4. To laboratories and sampling rooms.
5. To Auxiliary Steam (AS) System Condensate Return Unit.

When the resin is spent in the vendor supplied system, the trailer and skids are unhooked and replaced with a new system with the same specifications. If the cycle makeup demineralization system equipment is used, regeneration of the installed plant demineralizer units is accomplished automatically after pushbutton initiation, using dilute sulfuric acid and dilute sodium hydroxide solution. Regenerant wastes are discharged to the neutralization waste basin for neutralization with sulfuric acid and sodium hydroxide. Neutralized wastes are pumped to Monticello Reservoir through the circulating water discharge.

9.2.3.3 Safety Evaluation

The Demineralized Water System is nonsafety-related and, therefore, is not required to operate under accident conditions.

Proper precautions are taken in the handling, storage and mixing of chemicals used in the cycle makeup pretreatment and demineralization systems. Leaks and accidental spills are confined and treated prior to disposal.

9.2.3.4 Testing and Inspection Requirements

The Demineralized Water System is tested and inspected in accordance with applicable codes and standards and vendor recommendations. Periodic monitoring of equipment controls, periodic inspection of system piping and components and testing and adjustment of equipment as suggested by the manufacturers are performed during normal operation.

9.2.3.5 Instrumentation Requirements

Measurement and monitoring of conductivity, silica, dissolved oxygen, sodium, pressures, levels, flow rates and temperatures are performed for purposes of indication, alarm, control and record maintenance at the equipment and at the local control panel.

9.2.4 Potable and Sanitary Water Systems

The original potable water source and its treatment are described in Section 9.2.3: from the pressurized sterile water tank, potable water is distributed to plumbing fixtures, showers, laboratory units, laundry and emergency shower and eyewash facilities throughout the plant. The modified source of potable water is obtained from the Off Site Water Treatment System (OWS); see Section 1.2.3.8.4. No potable water is provided to potentially radioactive equipment. No radiological contamination of this system is expected during normal operation or during an accident.

9.2.5 Ultimate Heat Sink

A safety class impoundment, referred to as the Service Water pond, is constructed in a small arm of Monticello Reservoir to perform ultimate heat sink functions under various conditions. The Service Water pond is created by three earth dams and the site embankment areas (see Figure 1.2-1) which are designed and constructed to meet the most severe natural phenomena as described in Chapter 2. The volume of water stored within the impoundment and the surface area related to water elevation are shown in Figure 2.4-13.

9.2.5.1 Design Bases

A description of the design bases for the ultimate heat sink is presented in Section 2.4.8.

9.2.5.2 System Description

The Service Water pond supplies water for the Service Water System under normal and emergency operating conditions. The intake for the Service Water System is located along the northwest shoreline of the pond on the west embankment. A discharge structure for this system is provided along the southwest edge of the pond and also on the west embankment.

The Service Water intake structure, as shown schematically in Figure 2.4-11, provides adequate water from either the Service Water pond or Monticello Reservoir through an interconnecting pipe and isolation valve. It is possible to safely shut down the plant using only the Service Water pond without reliance upon Monticello Reservoir. Hydraulic performance of the Service Water pond is described in Section 2.4-8.

9.2.5.3 Safety Evaluation

9.2.5.3.1 Analytical Model

A time dependent computer model developed to predict the thermal performance of the ultimate heat sink (Service Water Pond). The model used to describe the temporal and spatial thermal distribution within the Service Water pond (SWP) contained three coupled major components:

- Heat transfer between the pond and the atmosphere
- Transport of heated water discharged near the pond's surface
- Internal movement of heat within the pond (vertical transport)

Field studies of the thermal and flow characteristics of the SWP were conducted in October 1997, before and after Refueling Outage #10, the results of which were used in validating the computer model methodology. These studies included top to bottom temperature measurements to evaluate thermal stratification and dye studies to characterize the circulation patterns within the SWP.

9.2.5.3.2 Design Bases for Safety Evaluation

The Service Water pond is designed to satisfy the following requirements:

1. Service Water Flow Requirements
   a. For normal operation - 12,000 - 24,000 gpm.
   b. Under loss of coolant accident (LOCA) conditions - 32,000 gpm.
   c. For normal shutdown - 12,000 - 26,000 gpm.

   The normal operation and normal shutdown design basis SWP thermal study assumed two trains of Service Water in operation since this results in the limiting SWP temperatures for these modes.
2. Service Water System Heat Rejection
   a. During normal operation - 57.35 x 10^6 BTU/hour.
   b. Under LOCA conditions - (see Figure 9.2-10).
   c. During normal shut down - (see Figure 9.2-11).
3. Service Water Pond Levels
   a. Normal operation (mean level) - elevation 422.0’.

b. Under LOCA conditions - elevation 414.75' - 415.0’.

c. Normal shutdown - elevation 414.75' - 415.0’.

4. Service Water Pond Area and Capacity
See Figure 2.4-13.

9.2.5.3.3 Analyses

The Service Water pond serves as the ultimate heat sink for the Virgil C. Summer Nuclear Station. The method used to determine the calculated heat loads for the ultimate heat sink was to sum the heat loads served by the Service Water System for the design basis LOCA. These heat loads are transferred to the Service Water System from other cooling systems as follows:

1. Component Cooling Water System

   The Component Cooling Water System (CCWS) provides cooling for the residual heat removal (RHR) heat exchangers, spent fuel cooling and other NSSS auxiliaries. The RHR heat exchangers remove decay heat and sensible heat from the NSSS during the recirculation mode of Emergency Core Cooling System operation. The RHR heat duty following a LOCA is shown by Figure 9.2-10. Spent fuel cooling heat loads are included in the CCWS heat load transferred to the Service Water System following a LOCA and are listed in Table 9.2-9.

2. Reactor Building Cooling Units

   The reactor building cooling units remove heat from the Reactor Building atmosphere following a LOCA and transfer it to the Service Water system. This heat load is shown by Figure 9.2-10.

3. Diesel Generator Coolers

   The heat rejected from the diesel generators to the Service Water System is 21.36 x 106 BTU/hr, based upon two diesel generators operating at the 7 day load rated capacity. This heat load is assumed to remain constant over the 30 day period.

4. HVAC Mechanical Water Chillers

   The Chilled Water System provides cooling for numerous safety related cooling coils. The HVAC mechanical water chillers reject the total heat load from the refrigeration system to the Service Water System. The heat load from two HVAC chillers plus compressor heat rejection is 9.9 x 106 BTU/hr assumed to remain constant throughout the 30 day period.

The analysis of the thermal performance of the Service Water pond is based upon the heat loads described in items 1 through 4, above, with added design margins, and the meteorological conditions described in Section 9.2.5.3.1. The analytical results indicate that the Service Water pond provides sufficient heat dissipation to limit Service Water intake temperature to a maximum

value of less than 95°F under the most adverse conditions by restricting the pre-incident Service Water intake structure temperature to 90.5°F and the SWP level to 416.5' (Reference 6).

9.2.5.3.3.1 Normal Operation

For the initial condition in the LOCA studies, it was considered appropriate to evaluate the thermal performance of the Service Water pond for normal meteorological and plant operating conditions.

Average monthly climatological data for a 32 year period of record (1965 through 1996) at Columbia, S. C., provided the bases for the generation of daily meteorological data for normal operation. The data included dry bulb temperatures, dewpoint temperatures and wind speeds. There are two other climatological recording stations in the vicinity of the site: Parr and Little Mountain. These stations are closer to the site than Columbia Station but do not have complete data. The nearest source of consistent and sufficiently complete data for analytical purposes is Columbia. For the parameters measured at Parr and Little Mountain, there is little difference from the Columbia data. Therefore, the Columbia data was used for the analysis. The operational conditions existing prior to RF-10 were used in the SWP computer model to estimate the SWP temperatures for the entire 32 year period. Rolling averages, over periods of 1 hour and 1 hour to 50 days, of the intake temperatures from the SWP were calculated for the 32 year period. The results indicated that the meteorological conditions from the time periods July to August 1968, 1986, and 1993 will provide the most restrictive intake temperatures.

9.2.5.3.3.2 Loss of Coolant Accident and Normal Shutdown Conditions

To study the effects of LOCA and normal shutdown heat rejection rates on the thermal performance of the Service Water pond, it is hypothesized that the most critical cases would occur if Monticello Reservoir failed completely, coincident with the interconnecting pipe isolation valve in the open position. This would cause the Service Water pond water surface elevation to drop to a minimum of elevation 415.0’. To establish the operating characteristics necessary to evaluate the thermal performance of the Service Water pond, it is further assumed that the reservoir failed instantaneously and the Service Water pond surface elevation dropped from its normal mean level at elevation 422.0’ to elevation 415.0’ instantaneously. An additional loss of 0.25' is included to account for seepage from the SWP.

The ultimate heat sink has been analyzed for a minimum water surface elevation of 414.75’. The volume evaporated from the surface of the SWP during the 10 day and 30 day period following the postulated LOCA initiation was determined to be $4.96X10^5$ ft^3 and $1.56X10^6$ ft^3, respectively. There are no drift losses from the pond.

The meteorological data described in Section 9.2.5.3.3.1 was used as input for LOCA cases.

9.2.5.3.4 Summary of Analytical Results

Based upon generated meteorological data and the proposed operating conditions, the analytical results show that the Service Water pond is an adequate heat sink and source of cooling water

under the most adverse conditions with the pre-incident Service Water intake structure temperature limited to 90.5°F and the SWP level limited to 416.5' (Reference 6). The maximum Service Water intake temperatures are summarized in Table 9.2-15. Vertical temperature distributions for the LOCA studies are provided on Figure 9.2-22.

Figure 2.4-1 shows the location of Service Water intake and discharge structures. The topography of the pond is also shown by this figure.

In the analysis it is assumed that the discharge to the Service Water pond is completely mixed with an equal flowrate of pond water. However, the Service Water discharge structure is designed to limit entrance mixing and encourage hot surface layer development. Figure 3.8-64 presents details of the discharge structures. This should improve the actual thermal structure by developing more satisfaction and reducing the extent of the epilimnium. It should also result in the withdrawal of cooler water at the level of the Service Water intake structure.

9.2.5.4 Testing and Inspection Requirements

Ultimate heat sink testing and inspection requirements include only periodic visual inspection of riprap.

9.2.5.5 Instrumentation Requirements

The instrumentation associated with the ultimate heat sink is described in Section 9.2.1.

9.2.6 Condensate Storage Facilities

9.2.6.1 Design Bases

The condensate storage system is designed to provide and store sufficient demineralized water to satisfy secondary cycle makeup requirements.

The condensate storage system is designed to ensure that a reserve of condensate quality water is dedicated for use by the emergency feedwater system (EF). To accomplish this function, the condensate storage tank (CST) is designed to provide the EF a sufficient amount of water to refill the steam generators to no load program level plus the amount required to replenish the steam released from the steam generators through the MSSVs and PORVs. Under the uprated plant conditions with the Model Δ75 Steam Generators, the required CST volume to maintain Hot Standby for 2 hours followed by a 4 hour cooldown to RHR operation is 152,550 gallons; the required volume to maintain Hot Standby for an 11 hour period is 158,570 gallons. Therefore, 158,570 gallons is the minimum required CST inventory that is dedicated and available to the EF. The actual CST volume that is dedicated and available to the EF based on the physical configuration of the tank from the bottom of the condensate to condenser nozzle to the top of the emergency feedwater suction nozzle is 160,054 gallons. There is an additional unusable volume of 19,794 gallons below the top of the emergency feedwater suction nozzle.

Since the condensate storage tank is the primary source of emergency feedwater, it is a safety-related component. Therefore, this tank is designed, fabricated, inspected, tested and stamped in accordance with the requirements of the ASME Code, Section III, for Class 3 tanks.

9.2.6.2 System Description

The condensate storage tank and cycle makeup scheme are shown on the system diagram, Figure 10.4-8. The emergency feedwater supply is shown by Figure 10.4-16.

The system consists of one condensate storage tank, with a capacity of 500,000 gallons of condensate, and the associated makeup and distribution systems. The condensate storage tank is located outside, adjacent to the Water Treatment Building. Of the condensate storage tank capacity, 160,054 gallons is reserved for use by the emergency feedwater system. This reserve is the volume between the bottom of the condensate to condenser nozzle and the top of the emergency feedwater suction nozzle. It is maintained by having the tank connections, except those required for instrumentation, emergency feedwater pump suction, chemical analysis and tank drainage, above the level providing 160,054 gallons to the EF system. The tank is field fabricated of carbon steel, lined with an inert material. Table 9.2-16 presents tank physical details. A check valve in the drain line of the tank is provided to allow for nitrogen sparging as a method of controlling CST water oxygen levels; the sparging operation is not allowed in modes 1 - 3.

Makeup to the condensate storage tank is supplied from the 500,000 gallon demineralized water storage tank. The makeup water is routed through the main condenser for deaeration. As the makeup water enters the condenser, it increases the hotwell level. A level control valve then opens to permit condensate, from the discharge of the condensate pumps, to flow into the condensate storage tank. Makeup is cyclical in nature. The makeup control valve opens when the low tank level is reached, and closes at the high tank level.

Emergency feedwater pump recirculation lines also return water to the condensate storage tank when the emergency feedwater system is used during startup or any time an emergency feedwater pump is in a recirculating mode.

9.2.6.3 Safety Evaluation

The water contained in the condensate storage tank is normally supplied from the demineralized water storage tank through the main condenser. Radiological considerations are not a factor in design or tank location.

To assure the availability of the condensate storage tank contents, it is constructed in accordance with the ASME Code, Section III. The tank foundation is designed to satisfy Seismic Category 1 requirements. The location of the condensate storage tank ensures that releases of the stored water due to any unforeseen failure does not affect any safety-related equipment.

Freeze protection is not required for the condensate storage tank. During normal plant operation, recirculation between the condensate storage tank and the condenser hotwell may be

accomplished. This technique may be used to maintain the temperature of the condensate storage tank contents well above freezing.

Freeze protection is provided, by means of electric heat tracing, for safety-related piping and instrument lines connected to the condensate storage tank, including the suction line to the emergency feedwater pumps. This line is heat traced at all exposed locations.

9.2.6.4 Tests and Inspections

Testing of this system includes operability tests associated with the tank level monitoring instrumentation that initiates the automatic transfer of the suctions of the emergency feedwater pumps on low suction pressure. Inspections are limited to periodic visual examinations of welds and connections to the tank.

9.2.6.5 Instrumentation Requirements

The condensate storage tank is provided with level instrumentation necessary for control of makeup to maintain an adequate tank operating level. Level switches initiate alarms in the control room upon detection of high level and if level decreases below that required for use by the Emergency Feedwater System. Level instrumentation associated with the Emergency Feedwater System is discussed in Section 10.4.9.

9.2.7 Reactor Makeup Water Supply System

The reactor makeup system provides for storage of tritiated but not aerated, recycled primary coolant grade water.

9.2.7.1 Design Bases

The Reactor Makeup Water Supply System is designed to perform the following functions:

1. Supply water to the Chemical and Volume Control System (CVCS).
2. Supply makeup water to the spent fuel pool at a rate of 150 gpm.
3. Provide a backup water supply for spray cooling in the pressurizer relief tank, capable of supplying 150 gpm.
4. Provide a water supply for makeup to and flushing of reactor auxiliary systems.
5. Provide storage capacity equal to or greater than the total 84,000 gallon capacity of the recycle holdup tanks for recycle primary coolant grade water produced in the boron recovery system and Liquid Waste Processing system.

The portion of the Reactor Makeup Water Supply System between the reactor makeup water storage tank and the CVCS and Spent Fuel Cooling System is safety related and is classified as Safety Class 2b. The remainder of the system is not safety related.

Two (2) isolation valves in series and monitor and control instrumentation ensure that flow related failures in nonsafety related portions of the system do not jeopardize the functional capability of the safety related portions.

Safety Class 2b piping, valves and equipment are designed, fabricated, tested and inspected in accordance with the ASME Code, Section III, Class 3. Nonsafety related piping and equipment satisfy the requirements of ANSI B31.1.0 and the ASME Code, Section VIII, as applicable.

9.2.7.2 System Description

Figure 9.2-24 is the Reactor Makeup Water Supply System flow diagram. Data for major system components is presented in Table 9.2-17.

The initial supply of primary coolant grade water is provided by the demineralized makeup water system. Subsequent primary grade makeup water requirements are satisfied from the 100,000 gallon capacity reactor makeup water storage tank. The principal source of makeup water in the reactor makeup water storage tank is the demineralized water system using the system vacuum degasifier transfer pumps. The boron recovery system evaporators and the liquid waste processing system evaporators are a secondary source of makeup water in the reactor makeup water storage tank when in operation. This water contains tritium. Therefore, its use is limited to reactor auxiliary systems containing radioactive fluid.

Water supplied to the boric acid blender for reactor coolant makeup is automatically controlled by the reactor coolant makeup control system, a part of the CVCS. Water is provided for the following upon demand by manually starting one of the two reactor makeup water pumps:

1. Makeup for evaporative losses from the spent fuel pool.
2. Flushing of boric acid and waste evaporator units, drumming station, demineralizers, resin fill hopper, reagent tanks, catalytic recombiner packages and gas decay tanks.
3. Transport of resin to and from the spent resin storage tank.
4. Dilution in the chemical mixing tank and boric acid batching tank.
5. Makeup for seal water losses in the waste gas compressors.
6. Cooling water to the pressurizer relief tank in the event of safety valve discharge.

The reactor makeup water storage tank is located outside the plant in the tank area adjacent to the Auxiliary Building. This tank and all outdoor system piping connecting to the tank are insulated and heat traced to maintain a minimum temperature at 40°F. The reactor makeup water pumps and most system piping are located in the Auxiliary Building.

9.2.7.3 Safety Evaluation

The portion of the reactor makeup water storage system that supplies water to the CVCS and the Spent Fuel Cooling System is Safety Class 2b since it supplies reactor coolant makeup required

for normal plant shutdown, as well as makeup to the spent fuel pool. System operation is not required for ANS 18.2 (Reference 4) Condition III and IV events.

Two (2) valves in series are provided to isolate the safety-related portion of the system from the nonsafety related portion. A flow switch and a low pressure alarm provide means for detection of malfunction or operation of the nonsafety related portion of the system that could jeopardize the functional capability of the safety-related portion.

Two (2) 100% capacity reactor makeup water pumps assure that an adequate supply of water is available when required.

9.2.7.4 Inspection and Testing Requirements

Major components of the reactor makeup water system are in use during normal plant operation. The two reactor makeup water pumps are alternated during normal system operation to equalize wear. Routine observations of system piping and components are made during normal operation. Periodic tests are not required.

9.2.7.5 Instrumentation Requirements

Measurement and monitoring of pressure, temperature, level and flow are performed for purposes of indication, alarm, control and record maintenance.

9.2.7.5.1 Pressure Instrumentation

Pressure transmitters with local indicating meters are located on the discharge of each reactor makeup water pump. These transmitters provide control room indication for monitoring pump operation. A pressure transmitter with local indicating meter is also located in the supply line from the demineralized water makeup system for purposes of control and indication.

A pressure switch located in the supply line to nonsafety related portions of the reactor makeup water system actuates an alarm in the control room should a pipe break or other malfunction occur which could cause loss of pressure. This alarm is interlocked with a low flow switch to preclude this alarm function when there is no flow in this line.

Test connections on the suction side of each pump are provided for measurement, in conjunction with the pressure transmitters, of differential pressure to check pump performance.

9.2.7.5.2 Temperature Instrumentation

Direct reading local temperature indicators are provided to permit monitoring of pump motor coolers. Redundant temperature elements in the reactor makeup water storage tank provide indication and actuate a low temperature alarm in the control room. Heat tracing circuits on the tank are automatically energized to maintain a minimum temperature of 40°F.

9.2.7.5.3 Level Instrumentation

Redundant level transmitters with local indicating meters are provided on the reactor makeup water storage tank to provide indication and high, low, and lo-lo level alarms in the control room.

9.2.7.5.4 Flow Instrumentation

A high/low flow switch with local indicating meter is provided in the supply line to the nonsafety related portions of the reactor makeup water system. The high flow switch actuates the two isolation valves in series whenever flow exceeds 150 gpm, the capacity of one reactor makeup water pump. The low flow switch provides an interlock to the low pressure switch in the non-safety related supply line to preclude the low pressure alarm when there is no flow in that line (i.e., when the header is isolated). A flow element with local indicating meter is located in the pump recirculation line from the common discharge header to the reactor makeup water storage tank to permit checking of pump performance.

(5) Essential Load
{ } Units receiving CCWS flow.

Table 9.2-11
Component Cooling Water System Single Failure Analysis

	Component	Malfunction	Components and Consequences
1.	Component Cooling Pumps	Rupture of Pump casing	The casing is designed for 200 psig and 200° F. The pump is protected from over pressurization by a relief valve in the discharge line. The pumps are inspectable and are located in the Intermediate Building, protected against credible missiles. All pumps can be isolated from the system.
2.	Component Cooling Pump	Standby pump fails to start	The pump in the inactive loop is started to ensure that required safety functions of the system are satisfied.
3.	Component Cooling Heat Exchanger	Shell or tube rupture	A very unlikely event. However, the heat exchanger can be isolated from the system.
4.	Piping	Pipe Crack	Since this system is low energy, only through wall leakage cracks are postulated. The maximum postulated pipe crack size would require isolation of one CCW loop. The other loop will remain operable to provide cooling water to system heat loads. (Per BTPAPCSB3-1, a failure in the redundant train need not be postulated.)

9.3 PROCESS AUXILIARIES

9.3.1 Compressed Air Systems

The compressed air systems include the Station Service Air System, Instrument Air System, the condensate polisher compressed air system (see Section 10.4.6) and Reactor Building Instrument Air System. The Station Service Air System provides air for general plant use. The Instrument Air System provides air for instruments and controls. The Reactor Building Instrument Air System provides clean, dry air for Nuclear Steam Supply System (NSSS) instruments and valves inside the Reactor Building. Breathing air, when required, is obtained from the backup instrument air compressor.

9.3.1.1 Design Bases

The compressed air systems are designed to satisfy NSSS and balance of plant (BOP) requirements for compressed air. Piping and valves associated with the compressed air systems, except for Reactor Building penetrations, are designed, fabricated, inspected and erected in accordance with ANSI B16.5 (Reference 1) and ANSI B31.1 (Reference 2). Piping and valves between and including containment isolation valves are designed, fabricated, inspected and erected in accordance with the requirements of the ASME Code, Section III, Class 2. Receiver tanks are designed, fabricated, inspected and erected in accordance with ASME Code, Section VIII, Division 1, requirements.

Seismic classification of compressed air system components is as follows:

1. Seismic Category 1

   Reactor Building piping penetrations and process piping between and including containment isolation valves.

2. Nonseismic Category

   Remaining Service Air System piping and Instrument Air System piping.

Containment isolation valves are provided on each Reactor Building penetration for isolation during a postulated loss of coolant accident (LOCA). Isolation valves are provided on equipment and components for maintenance purposes.

Air compressors are supplied with electric power from 480 volt buses.

9.3.1.2 System Description

Figures 9.3-1 through 9.3-3a provide compressed air system diagrams. Design parameters for major system components are presented in Table 9.3-1.

Two (2) electric motor driven, full capacity, oil-free rotary screw compressors located in the turbine room supply compressed air to the Station Service Air System and Instrument Air System. The air compressors take suction locally and discharge to the common air receiver. Each air compressor motor receives electric power from a different non-safety related 480 volt bus and is controlled locally or from the control room. Control switches permit placing 1 air compressor in operation and the other in standby. The standby air compressor is activated by a pressure switch mounted on the air receiver if air receiver pressure decreases to less than a predetermined value.

A normally open valve (with limit switches) interconnects the Instrument Air System with the instrument air system backup compressor, including its air receiver, filter and dryer. This provides the Instrument Air System with a third compressor, and each is a standby to the other with similar controls.

When required, the instrument air backup compressor is isolated from the system and its output is totally dedicated to breathing air.

The instrument air backup compressor receives electric power from a 480 volt diesel bus which is isolated in the event of loss of offsite power or safety injection. In the event of a loss of offsite power, this compressor can be manually loaded onto the diesel bus after the operator has determined that all automatically sequenced loads have started. The instrument air backup compressor is an air cooled unit.

A diesel driven, full capacity, oil-free rotary screw compressor located outside of the Turbine Building is provided with an underground pipe connection to the main air receiver discharge. A moisture separator is installed inside the Turbine Building to protect the air system from moisture slugs. This connection allows the diesel driven compressor to supply the Station Service Air or Instrument Air System and provides an additional back-up air supply. The line from the compressor is provided with a check valve to prevent air loss if the compressor fails. The diesel driven compressor is activated by a pressure switch mounted downstream of the check valve if instrument air pressure decreases to less than a predetermined value.

Station Service Air is distributed to quick disconnect hose connections for use throughout the plant. A backpressure regulated valve is provided in the line supplying station service air to isolate the Station Service Air System in the event of low pressure in the Instrument Air System. Reactor Building service air is supplied by the Station Service Air System through a removable spool piece. The only anticipated need for service air within the Reactor Building is for the performance of maintenance during outages. During normal operation, the Reactor Building service air line is disconnected from the service air piping by closing the containment isolation valve and removing the spool piece.

Instrument air is filtered to remove particles larger than 5 microns and dried to a dew point of -40°F at 100 psig. Each of the two dryers have a prefilter and afterfilter which are provided for ease of maintenance. The dryer is of the electrically heated, dual chamber, desiccant type with full flow automatic bypass piping. The Instrument Air System serves as a backup for the Reactor Building Instrument Air Services.

Two (2) electric motor driven, full capacity, nonlubricated, reciprocating type air compressors located in the penetration access area supply air for the Reactor Building Instrument Air System. The air compressors take suction from the Reactor Building and discharge to air receivers.

Each Reactor Building instrument air compressor receives electric power from a different 480 volt, nonessential bus and is controlled locally or from the control room. Switches are provided which allow either constant speed control or automatic start/stop air compressor operation. Under constant speed control, when demand decreases, the air compressor continues to operate but is unloaded. When automatic start/stop is selected, the air compressor stops when demand decreases and starts when demand increases.

Reactor Building instrument air is filtered to remove particles larger than 5 microns and dried to a dew point of 35°F at 100 psig. Two (2) full capacity, refrigerated type dryers with integral moisture separators are provided for this service. Condensate drains from the dryers, moisture separators and air receivers are piped to the nuclear drain system for sampling and disposal, due to the possibility of radioactive contamination of the system. If Reactor Building instrument air system pressure decreases to less than 90 psig, the backup instrument air valve automatically opens to supply air from the Instrument Air System.

Cooling water required for the station service and instrument air compressor water jackets and interstage coolers is supplied from the turbine building closed cycle cooling water system. Cooling water required for the reactor building instrument air compressor water jackets and aftercoolers is supplied from the Industrial Cooling Water System.

9.3.1.3 Safety Evaluation

Neither the Station Service Air System, the Instrument Air System, Instrument Air Backup System nor the Reactor Building Instrument Air System is required to mitigate the consequences of a LOCA or to achieve safe shutdown. Instruments and controls served by the Instrument Air System and the Reactor Building Instrument Air System are: 1) non-nuclear safety class and are either not required to function during a LOCA or to achieve safe shutdown; 2) nuclear safety class and fail in a safe position after loss of air supply. The only air operated devices which do not fall into one of the 2 categories described above are the feedwater isolation valves, the control room outside air dampers, the emergency feedwater system control valves and the turbine driven steam isolation valve. These air operated devices are equipped with safety related air volume tanks or accumulators.

The fire service to diesel generator cooling water isolation valves are equipped with quality related air accumulators.

Reactor building instrument air system containment isolation valves are normally open. Status lights are provided in the control room to indicate the position of these valves. Automatic closure of these containment isolation valves is initiated by receipt of a containment isolation Phase A signal.

The reactor building service air line is normally disconnected from the service air piping by a closed isolation valve and removal of the spool piece. No outleakage through the reactor building service air line is anticipated during a LOCA or under other emergency conditions.

The breathing air system containment isolation valves are normally locked closed. They will be permitted to be opened under administrative control during refueling and maintenance shutdown periods.

9.3.1.4 Testing and Inspection

Operability and performance of the air compressors is verified during normal operation of the systems.

Air compressors are subjected to manufacturer's performance testing. In addition, the completed compressed air systems are subjected to preoperational testing under design conditions.

9.3.1.5 Instrumentation Requirements

Instrumentation and controls for the compressed air systems are provided, as shown by Figures 9.3-1 through 9.3-3a to control and monitor system operation and the performance of equipment.

Local control panels are provided in the Turbine Building for the station service and instrument air compressors and in the penetration access area for the reactor building instrument air compressors. Operational control devices and monitoring instruments, as well as numerous alarms are provided on these control panels. In addition, air pressure and air flow rate are continuously monitored by local pressure indicators and flow elements mounted on the system piping. The presence of any alarm condition at one of the local panels or switches results in annunciation at a common alarm in the control room. The Breathing Air System has a carbon monoxide monitor to monitor the breathing air for carbon monoxide concentration when breathing air is in use. An alarm results in a local alarm, a remote alarm in the Health Physics Laboratory and a compressor trip and subsequent alarm in the control room.

A local control panel is provided in the yard beside the diesel driven compressor. An operational control switch for the auto-start of the compressor is provided on this panel.

An additional panel is provided on the compressor skid. This panel provides additional operational control devices and alarms.

A control switch for each compressor except the diesel driven compressor is provided in the control room to permit remote operation.

9.3.2 Process Sampling System

Fluid system sampling capabilities are available at numerous local sampling points located throughout the plant. Samples requiring cooling and depressurization and which are, or may be, radioactive (and therefore require frequent monitoring) are piped to the nuclear sample room

through the Nuclear Sampling System. This system also provides continuous, automatic analysis of steam generator secondary side water (see Section 10.3.5 for details). In addition, the Nuclear Sampling System provides centralized sampling of vital process fluids. For turbine cycle sampling, see Section 10.3.5. The system also has the capability to sample the Reactor Coolant System during post-accident conditions.

9.3.2.1 Design Bases

The design bases for the nuclear sampling system are as follows:

1. Cool and depressurize liquid samples.
2. Provide a minimum delay of 60 seconds for reactor coolant samples, thus allowing sufficient time for N16 to decay to acceptable levels prior to leaving the Reactor Building.
3. Provide a hooded sample sink suitable for sample collection and disposition of wastes to the waste holdup tank.
4. Provide ample ventilation to protect personnel from inhalation of radioactive gases and vapors.
5. Provide demineralized rinse water.
6. Provide sufficiently high fluid velocity during purging of the lines and during sampling to retain solid particles in suspension.
7. Use lines as small as possible to control purge volumes.
8. Provide for obtaining all samples manually in accordance with a specified schedule.
9. Provide capability for purging sample lines and equipment so that representative samples are obtained. Plateout of samples is reduced by maintaining sample velocities of 2.0 ft/sec.
10. Provide for measurement of temperature, pressure and purge flow rate for each sample point.
11. Provide passive flow restriction by use of 3/8 inch OD (0.245 inch ID) tubing which restricts flow sufficiently that a passive failure of a downstream component does not prevent a safety system function required for a Condition III or Condition IV event.
12. Provide a special sampling panel for reactor coolant and RHR systems which allows for post accident sampling of these systems.
13. Provide shielding for personnel protection consistent with GDC-19.

System equipment and components are classified in accordance with the safety classifications discussed in Section 3.2. Construction of safety class equipment and components is in accordance with the ASME Code, Section III. Seismic design and safety classification of sampling lines and components conform to the classification of the system to which each sampling line is connected. The degree of compliance with Regulatory Guides 1.26 and 1.29 is discussed in Appendix 3A. Components and piping downstream of the second isolation valve are designed to non-nuclear safety class and non-Seismic Category 1 requirements. Radiation shielding is provided to protect personnel from exposure to lines or equipment containing radioactive fluids for all types of sampling (See FSAR Appendix 12A for radiation exposure and shielding discussion).

Provision is made for continuous flow through the sample lines from the steam generator secondary sides. Shutoff valves, which close upon receipt of a containment isolation signal (Phase A), are provided. These valves are also interlocked such that they close upon receipt of an emergency feedwater start signal, but these interlocks may be overridden by operation of a switch located at the sampling rack. This switch does not, however, override the containment isolation signal (Phase A).

9.3.2.2 System Description

The Nuclear Sampling System diagram is presented by Figures 9.3-4 and 9.3-20. Points sampled by the system are tabulated in Table 9.3-2.

Tubing from each of the nuclear sampling system sample points is routed to the nuclear sample room, located at the northwest corner of the nuclear control access area at elevation 412'. Shielding is provided for these lines where required to minimize personnel exposure.

The sampling system for obtaining a reactor coolant sample following a TMI-2 type accident will have sufficient shielding to limit general plant personnel whole body exposure to significantly less than 70 mr/hr during use of the system.

Operators of the sampling system will be protected from excessive radiation by the use of lead shielding as for example, the on-line monitors will have a 4 inch thick lead brick wall to limit whole body exposure to significantly less than 70 mr/hr. Transportable sample bombs containing the diluted liquid sample and the containment air sample may be shielded to minimize exposure to radiation during transport to the Radio-Chem Laboratory or count room for the required analyses. Slightly higher exposure may be experienced by the operators at the hands and fingers when the sample bombs are removed from their attachment point.

Dilution of the sample will minimize exposure of laboratory personnel to radiation during analysis of the samples.

System isolation valves, penetration isolation valves, test connections and reactor coolant N16 delay coils are located in the Reactor Building. Residual heat removal system isolation valves, the chemical and volume control system N16 delay coils, test vent connections and penetration isolation valves are located in the Auxiliary Building. The majority of the balance of valves and equipment are located in the nuclear sample room in the Control Building. Samples from the following extraction points are cooled using heat exchangers served by the Component Cooling Water System:

1. Residual heat removal loops (2 points).
2. Pressurizer liquid and steam spaces (2 points).
3. Reactor coolant loop B (hot leg).
4. Reactor coolant loop C (hot leg).
5. Steam generator A, secondary water (shell and blowdown).

6. Steam generator B, secondary water (shell and blowdown).
7. Steam generator C, secondary water (shell and blowdown).

An auxiliary cooler is provided for points 1 through 4 to assure samples are at required temperatures during periods of high sample flow rates.

Samples from points 5 through 7 and from accumulators A, B and C are depressurized by use of globe type throttle valves located where flashing of the sample fluid to steam does not occur.

Samples from the reactor coolant loops pass through a delay coil designed to allow sufficient time for decay of N16 prior to leaving the Reactor Building. Sample lines from extraction points 5 through 7, above, provide continuous flow of secondary fluid from the steam generators (see Section 10.3.5).

All liquids are routed to the sample sinks where purging samples can be individually collected. Mixing of primary and secondary fluids is prevented by the use of separate subsystems without interties as shown by Figures 9.3-4 and 9.3-20. Purge volumes from primary extraction points are routed to the volume control tank or waste holdup tank and for the accident case, to the pressurizer relief tank. Upon completion of purging, samples can be routed to the sample sink. Sufficient volume is drawn into the sink prior to taking the sample to purge the line from the normal purge path to the sink to assure a representative sample. The liquid in the sample sink from purging and sampling is routed to the waste holdup tank. Purge volumes from secondary system extraction points are routed to a separate sink and thence to the nuclear blowdown holdup tank.

Extraction points 1 through 4 are directed through a special sampling panel which is designed to be used for both normal and post-accident sampling. Liquid can be analyzed for dissolved solids and isotopes. Dilution of the liquid sample can be accomplished.

In addition to the sample points which require cooling and depressurization, as previously described, there are numerous local sample points throughout the plant. Local sample points on tanks are either on the discharge side of the corresponding pump or the tank has the capability of being recirculated to ensure that samples are representative. Sample lines are purged for a sufficient period of time prior to sample extraction to remove sediment deposits and air and gas pockets.

Remote manual, fail closed, solenoid valves are the primary functional valves used during sampling and for shutoff of sample lines leaving the Reactor Building and certain other high pressure, high temperature extraction points. These valves are located close to the point where the process system is tapped. Air operated valves, located in the nuclear sample room are used for throttling, shutoff and sample routing. All containment isolation valves fail closed and are closed upon receipt of a containment isolation signal (Phase A). Test connections and test vents are provided in appropriate locations to permit leak testing of the containment isolation valves.

The special sampling panel has pneumatically operated valves for control of the sampling flow path.

For sampling of gases, refer to ANSI N13.1(Reference 3).

Component data are presented in Table 9.3-3.

9.3.2.3 Safety Evaluation

Those portions of the Nuclear Sampling System which interface with safety class systems or perform a containment isolation function are designated as Safety Class 3 or 2a. These portions of the system are designed in accordance with appropriate codes and standards as discussed in Section 3.2. The Nuclear Sampling System performs no additional safety related functions.

The seismic design and safety classification of sampling lines and components conform to the classification of the system to which each sampling line is connected. The degree of compliance with Regulatory Guides 1.26 and 1.29 is discussed in Appendix 3A. Components and piping downstream of the second isolation valve are designed to non-nuclear safety class and non-Seismic Category 1 requirements.

The system is designed to provide radiological protection consistent with GDC-19 and protection from industrial safety risks which could result from the high temperatures and pressures of some samples.

9.3.2.4 Testing and Inspection Requirements

Containment isolation valves are tested and inspected as described in Sections 6.2.4 and 6.2.6. Inservice inspection of ASME Class 2 and 3 components is discussed in Section 5.7.

Routine preventive maintenance requirements are stated in the station maintenance procedures.

9.3.2.5 Instrumentation Requirements

Nuclear sampling system instrumentation provides the signals required for reliable operation, control and performance/status monitoring of the system. Functional descriptions of system instrumentation are as follows:

1. Pressure Indicators

   Pressure indicators located throughout the system permit monitoring of the sample lines.

2. Temperature Indicators

   Temperature indicators located throughout the system permit monitoring of sample lines.

3. Flow Indicators

   Flow indicators permit monitoring of sample flow.

4. Radiation Monitor

   The radiation monitor, RM-L1, shown in Figure 9.3-4, measures gross gamma activity from the reactor coolant letdown line. An increase in the activity level in this line may be indicative of a fuel clad failure. This condition also causes an alarm in the control room.

   The radiation monitor RE 6992 shown in Figure 9.3-20 measures gross gamma activity from extraction points 1 through 4, as described in Section 9.3.2.2.

9.3.3 Equipment and Floor Drainage System

9.3.3.1 Design Bases

To preclude backflooding as a cause of degradation of any safety related equipment or piping, an extensive network of 4 inch floor drains is provided in all buildings. Drain headers terminate in a series of sumps or tanks which are equipped with high level alarms. All sumps except the east penetration access, waste holdup tank room, chemical feed equipment drains and IB sump D-battery room sumps have automatic, redundant sump pumps. Engineered safety features equipment and piping areas are provided with floor drain sumps which are instrumented to actuate alarms in the control room when flow into the sumps exceeds the maximum expected flow of 45 to 50 gpm (alarm drains). All such alarms are audible at the main control board. Measurements, such as reactor building sump level, are displayed on the main control board. Separate drain systems are provided for reactor grade and low level waste depending upon the location served. These separate systems distribute drain flow to the proper sump or tank. Exact locations of equipment and piping and associated drain systems are shown by Figures 9.3-5 through 9.3-15 and are described in Section 9.3.3.2. Portions of the system which contain additional safety features are also discussed in Section 9.3.3.2. Reactor coolant leakage detection is discussed in Section 5.2.7.

Technical Requirements for steam propagation barriers/components (SPB) in the equipment and floor drainage system required to maintain area environmental conditions for equipment qualification (EQ) purposes are provided in plant procedures. These procedures specify the technical criteria for design, procurement, installation /maintenance and inspection of these QR components. Components may include orifice plates, check valves, or loop seals designed to segregate EQ zones to ensure that the conditions for which the equipment qualification were based on are not exceeded.

9.3.3.2 System Description

The equipment and floor drainage system and related sump pumping systems are shown by Figures 9.3-5 through 9.3-15.

1. Reactor Building

Reactor grade or low activity leakage may originate from equipment inside the Reactor Building. All floors above the basement, inside the Reactor Building, are interconnected by grating or are individual structural platforms which support equipment. Consequently, safety related equipment located at these levels cannot be backflooded during normal operation. In addition, floor drains and equipment drains are installed to isolate any leakage to the local floor area concerned. These drain headers, in addition to the ones in the basement, terminate inside and below the floor opening of the reactor building sump. The refueling cavity liner seepage detection trough is part of this system.

The incore instrument sump at elevation 387’-6" collects any leakage that occurs directly around the reactor vessel and instrument chase. This affords protection for the bottom of the hot reactor vessel and instrument cable bundles.

A removable spool piece is installed in the discharge line from the incore instrumentation sump to facilitate removal of reactor cavity leakage to the reactor coolant drain tanks during refueling outages.

The accumulated drainage or leakage flows in the Reactor Building or incore instrument sump are normally sent to the floor drain tank. If increased activity is detected, the flow is aligned to the waste holdup tank.

2. Fuel Handling Building

Four inch floor drains in the Fuel Handling Building discharge to a header in the Auxiliary Building. Normal low level effluent from this header flows to the Auxiliary Building sump. The spent fuel pool liner seepage detection trough is part of this system.

The Excess Liquid Waste System, located in a separate area of the Fuel Handling Building, has its own sump system which collects floor and equipment drains. No safety class equipment is contained in this area. The sump system includes three sumps, one for each of the decontamination pit collecting tank and excess waste holdup tank cubicles and one for the general area. All sump pumps discharge to the 10,000 gallon decontamination pit collecting tank or the 10,000 gallon excess waste holdup tank, both integral to the system. The sump system also collects low level effluent from the hot machine shop decontamination room trench drain.

3. Penetration Access Area

Floor and equipment drains in the penetration access areas flow to the 10,000 gallon floor drain tank located at the lowest level (elevation 374’-0") in the Auxiliary Building. This system contains alarm drains.

The component cooling surge tank, the reactor building instrument air compressors and dryers are all on the operating floor. The component cooling surge tank and the reactor building instrument air compressors are located in the personnel access area. The air dryers are in an area monitored by alarm drains. Main steam relief valve compartments on the mezzanine have floor drains. The basement penetration access area has floor drains and several alarm drains for leakage detection. Floor drains in the east penetration access area flow to a common sump in the basement. The sump pump discharges to the floor drain tank.

4. Auxiliary Building

   a. Drains to Waste Holdup Tank

      Reactor grade equipment drains and tank overflows in the Auxiliary Building flow to the 10,000 gallon waste holdup tank at the lowest level in the building. There are no floor drains or alarms associated with this system. Equipment drains in the sub-basement flow to the 1000 gallon miscellaneous waste drain tank. A small centrifugal pump empties this tank to the waste holdup tank at the same floor elevation.

   b. Drains to Floor Drain Tank

      Low activity floor and equipment drains above the mezzanine and approximately one-half of all floor and equipment drains at or below the mezzanine flow directly to the 10,000 gallon floor drain tank. Alarm drains for this portion of the system alert the operator to leakage from piping above shield slabs at elevations 426’-6" and 400’-0", residual heat removal heat exchangers at elevation 412’-0" and Safety Injection System low head piping and valve chambers at floor elevation 397’-0".

   c. Drains to Auxiliary Building Sump

      The balance of floor and equipment drains at or below the mezzanine flow to the 1,945 gallon Auxiliary Building sump at elevation 374’-0". Alarm drains for this portion of the system protect the gas decay tank valve gallery and the charging pumps at elevation 388’-0" and the reactor building spray pumps at elevation 374’-0". Sump pumps discharge to the floor drain tank.

   d. Other Auxiliary Building Sumps

      The boron recycle holdup tank room sump pumps at elevation 388’-0" discharge to the liquid waste holdup tank. The liquid waste holdup tank room area sump at elevation 374’-0" is pumped to the floor drain tank.

      Residual heat removal pump room sump B sump pumps at elevation 374’-0" normally discharge to the floor drain tank. Pump flow may be aligned to the waste holdup tank if necessary. Residual heat removal pump room sump A and the waste evaporator feed pump room sump contain no sump pumps. They drain to the residual heat removal pump room sump B.

      The Nuclear Blowdown System reservoir, at elevation 374’-0", collects effluent from the system demineralizers and floor drains at elevation 452’-6".

      Blowdown monitor and holdup tanks with demineralizers and pumps at elevation 436’-0", along with basement equipment and floor drains for this system also flow to the reservoir. Steam generator blowdown samples from the nuclear sampling room are drained to this reservoir. Reservoir sump pumps discharge to the blowdown holdup tank at elevation 436’-0".

5. Outside

The refueling water storage tank and reactor makeup water storage tank, located in an enclosure outside the Auxiliary Building at elevation 412’-0", are protected by sump pumps which discharge to a waste monitor tank.

The refueling water storage pit drain tank, installed on elevation 436’-0" northwest of refueling water storage tank sump, discharges the contents to a waste monitor tank if contents show unacceptable level of radioactivity, or to yard drainage system if contents show acceptable for release.

The sodium hydroxide storage tank is located in a cubicle outside the Auxiliary Building at elevation 412’-0". It is protected by sump pumps which discharge to the 10,000 gallon neutralization waste tank trench.

6. Intermediate Building

   The alarm drains from the shield slab which run between the penetration access areas at elevation 422’-3" flow to the east penetration access area sump. The contents of this sump are pumped to the floor drain tank.

   Three (3) Intermediate Building basement sumps contain a total of 6 pumps, each rated at 75 gpm. These sumps protect the component cooling water pumps and heat exchangers at the same level by discharging to the Turbine Building sump. Two (2) out of 3 sump high level alarms cause the main feedwater isolation valves and other valves to close and eliminate the most probable cause of flooding in this area (see Section 7.6).

7. Control Building

   Lavatories within the normal radiation control area, hot showers, hot laundry and the floor drains in these areas flow to the laundry and hot shower tank at elevation 374’-0" in the Auxiliary Building. Fume hood sinks in the radiochemical laboratory flow to the chemical drain tank, also at elevation 374’-0" in the Auxiliary Building. The sample sink and panel drains for steam generator blowdown empty into the nuclear blowdown reservoir. The primary sample sink drainage flows to the waste holdup tank. Floor and equipment drains for the 482’-0" elevation, (except the charcoal filter plenum drains) drain via the Turbine Building sump system. The charcoal plenums, most of the floor drains, sinks in the health physics laboratory and equipment drains in the radiochemical laboratory flow to the floor drain tank.

8. Tendon Access Gallery

   The tendon access gallery is provided with floor sumps which drain to a building sump. This building sump is equipped with sump pumps to pump sump contents to the Turbine Building sump.

9. Turbine Building Drains

The 250 gpm turbine room sump pumps discharge to the 6000 gallon (normal operating capacity) industrial and sanitary waste collection sump. This sump is located north of the substation fence. Releases to this system, associated with the remote possibility of low level activity spillage in the Turbine Building, are discussed in Section 11.2.7. Figure 9.3-15 illustrates this connection.

10. Valve Packing Box Leakage

    Valve packing box leakage is monitored by directing any leakage from 12 groups of packing boxes to level switches. The valve groups are illustrated by Figures 9.3-13 and 9.3-13a. Each of the 12 level switches actuates a local alarm annunciator and causes a common alarm in the control room if leakage from any valve in the associated group is detected.

11. Service Water Pump House

    Wall drains are provided in the piping pits on the 425’ level of the Service Water Pump House to allow the relief of internal flooding. A total of three drains, one in each piping pit, are at an elevation of 426’-11” and limit the height of internal flooding to below the height of any essential equipment in the pits. The drains release into the Service Water Bay and can be plugged in case of an external flooding event.

9.3.3.3 Safety Evaluation

The equipment and floor drain system has no active valves except for the Reactor Building sump drain system which is provided with containment isolation valves. These valves close automatically upon receipt of a Phase A containment isolation signal rendering the Reactor Building sump drains essentially inoperable.

Leakage detection floor alarm drains are provided to identify the most probable location of a leaking component or pipe line. These are located in those areas which contain safety class equipment and systems which are most important to safe plant operation. Alarm response time for leakage in excess of the maximum expected (i.e., 45 to 50 gpm) ranges from a few seconds for the alarm drains to less than 4 minutes for residual heat removal pump room B sump.

Alarm systems for greater than 1 gpm and greater than 10 gpm flow to the Reactor Building sump and an unidentified leakage indication alarm for the Incore Instrument Sump are provided. Level instruments are provided for the Reactor Building sump. The residual heat removal pump room sumps and the waste evaporator feed pump room sump are each equipped with alarms actuated by a flow of greater than 45 gpm to the sump. The residual heat removal pump rooms have a 1 foot high curb at the access openings and thus have the capacity to contain a 50 gpm leak in either room for greater than 30 minutes, without flooding equipment, if the sump pumps should fail. If the contents of either the recycle holdup tank or waste holdup tank should flood either tank compartment, the spillage into the recycle holdup tank compartment is pumped to the waste holdup tank and spillage into the waste holdup tank compartment is pumped to the floor drain tank. If sump pumps are inoperative, each compartment is designed to hold the tank contents.

The plant drain system assures that spillage is collected and can be processed before being recycled or released to the environment.

9.3.3.4 Testing and Inspection Requirements

The drain system is given an extensive check for leakage and proper routing prior to actual operation. Pumps are checked for level switch control and operation. Valves in sump pump systems are aligned as shown on various system flow diagrams. Systems can be checked periodically by utilizing local control switches. Alarms are calibrated locally and checked in the control room.

9.3.3.5 Instrumentation Requirements

Display instrumentation in the control room which is related to the reactor coolant pressure boundary leakage detection system is described in Section 5.2.7 as are the information displayed and allowance for operator action. Section 7.6 discusses system instrumentation in further detail.

9.3.4 Chemical and Volume Control System

The Chemical and Volume Control System (CVCS) is shown in Figure 9.3-16 (Sheets 1 through 5). It is designed to provide the following services to the reactor coolant system (RCS):

1. Maintenance of programmed water level in the pressurizer, i.e., maintain required water inventory in the RCS.
2. Maintenance of seal-water injection flow to the reactor coolant pumps.
3. Control of reactor coolant water chemistry conditions, activity level, soluble chemical neutron absorber concentration and makeup.
4. Emergency core cooling (part of the system is shared with the Emergency Core Cooling System).
5. Provide means for filling, draining and pressure testing of the RCS.

9.3.4.1 Design Bases

Quantitative design bases are given in Table 9.3-4 with qualitative descriptions given below.

9.3.4.1.1 Reactivity Control

The CVCS regulates the concentration of chemical neutron absorber (boron) in the reactor coolant to control reactivity changes resulting from the change in reactor coolant temperature between cold shutdown and hot full power operation, burnup of fuel and burnable poisons, buildup of fission products in the fuel, and xenon transients.

9.3.4.1.1.1 Reactor Makeup Control

1. The CVCS is capable of borating the RCS through either 1 of 2 flow paths and from either 1 of 2 boric acid sources.
2. The amount of boric acid stored in the CVCS always exceeds that amount required to borate the RCS to cold shutdown concentration assuming that the control assembly with the highest reactivity worth is stuck in its fully withdrawn position. This amount of boric acid also exceeds the amount required to bring the reactor to hot shutdown and to compensate for subsequent xenon decay.

9.3.4.1.1.2 Boron Thermal Regeneration

The load following capabilities of the Boron Thermal Regeneration System were removed by plant modification MRF 21511. The system continues to be used as deborating demineralizers to reduce reactor coolant boron concentration towards the end of core life. The Boron Thermal Regeneration System (BTRS) also is used to cool the letdown flow for enhanced RCP seal performance and to clean up the RCS before shutting down the reactor.

9.3.4.1.2 Regulation of Reactor Coolant Inventory

The CVCS maintains the coolant inventory in the RCS within the allowable pressurizer level range for normal modes of operation including startup from cold shutdown, full power operation and plant cooldown. This system also has sufficient makeup capacity to maintain the minimum required inventory in the event of minor RCS leaks (see Technical Specifications for a discussion of maximum allowable RCS leakage).

9.3.4.1.3 Reactor Coolant Purification

The CVCS is capable of removing fission and activation products, in ionic form or as particulates, from the reactor coolant in order to provide access to those process lines carrying reactor coolant during operation and to reduce activity releases due to leaks.

9.3.4.1.4 Chemical Additions for Corrosion Control

The CVCS provides a means for adding chemicals to the RCS which control the pH of the coolant during initial startup and subsequent operation, scavenge oxygen from the coolant during startup, and counteract the production of oxygen in the reactor coolant due to radiolysis of water in the core region.

The CVCS is capable of maintaining the oxygen content and pH of the reactor coolant within limits specified in Table 5.2-10.

9.3.4.1.5 Seal Water Injection

The CVCS is able to continuously supply filtered water to each reactor coolant pump seal, as required by the reactor coolant pump design. In situations where the charging pumps are not available, the seals can be supplied by the Alternate Seal Injection Pump.

9.3.4.1.6 Emergency Core Cooling

The centrifugal charging pumps in the CVCS also serve as the high-head safety injection pumps in the Emergency Core Cooling System. Other than the centrifugal charging pumps and associated piping and valves, the CVCS is not required to function during a loss of coolant accident (LOCA). During a LOCA, the CVCS is isolated except for the centrifugal charging pumps and the piping in the safety injection path and the reactor coolant pump seal injection path. Also, at strategically identified local high points, the CVCS is provided with indicating air-traps to ensure that the ECCS portions of the CVCS remain void free (reference NRC GL 2008-01).

9.3.4.2 System Description

The CVCS is shown in Figure 9.3-16 (Sheets 1 through 5) with system design parameters listed in Table 9.3-4. The CVCS consists of several subsystems: the charging, letdown and seal water system; the reactor coolant purification and chemistry control system; the reactor makeup control system; and the boron thermal regeneration system.

9.3.4.2.1 Charging, Letdown and Seal Water System

The charging and letdown functions of the CVCS are employed to maintain a programmed water level in the RCS pressurizer, thus maintaining proper reactor coolant inventory during plant operation. This is achieved by means of continuous feed and bleed process during which the feed rate is automatically controlled based on pressurizer water level. The bleed rate can be chosen to suit various plant operational requirements by selecting the proper combination of letdown orifices in the letdown flow path. Normal letdown flow consists of the flow from a single 60 gpm letdown orifice or any combination of two orifices aligned in parallel.

Reactor coolant is discharged to the CVCS from a reactor coolant loop crossover leg; it then flows through the shell side of the regenerative heat exchanger where its temperature is reduced by heat transfer to the charging flow passing through the tubes. The coolant then experiences a large pressure reduction as it passes through the letdown orifice(s) and flows through the tube side of the letdown heat exchanger where its temperature is further reduced. Downstream of the letdown heat exchanger a second pressure reduction occurs. This second pressure reduction is performed by the low pressure letdown valve, the function of which is to maintain upstream pressure thus preventing flashing downstream of the letdown orifices.

The coolant then flows through one of the mixed bed demineralizers. The flow may then pass through the cation bed demineralizer which is used intermittently when additional purification of the reactor coolant is required.

The letdown flow leaving the demineralizers may be directed to the Boron Thermal Regeneration System. The coolant then flows through the reactor coolant filter and into the volume control tank through a spray nozzle in the top of the tank. Hydrogen (from the gaseous waste processing system) is continuously supplied to the volume control tank where it mixes with fission gases which are stripped from the reactor coolant into the tank gas space. The contaminated hydrogen is vented back to the Gaseous Waste Processing System. The partial pressure of hydrogen in the volume control tank determines the concentration of hydrogen dissolved in the reactor coolant for control of oxygen produced by radiolysis of water in the core.

Three (3) centrifugal charging pumps are provided to take suction from the volume control tank and return the cooled, purified reactor coolant to the RCS. Normal charging flow is handled by 1 of the 3 charging pumps. This charging flow splits into 2 paths. The bulk of the charging flow is pumped back to the RCS through the tube side of the regenerative heat exchanger. The letdown flow in the shell side of the regenerative heat exchanger raises the charging flow to a temperature approaching the reactor coolant temperature. The flow is then injected into a cold leg of the RCS. Two (2) charging paths are provided from a point downstream of the regenerative heat exchanger. A flow path is also provided from the regenerative heat exchanger outlet to the pressurizer spray line. An air operated valve in the spray line is employed to provide auxiliary spray to the vapor space of the pressurizer during plant cooldown. This provides a means of cooling the pressurizer near the end of plant cooldown, when the reactor coolant pumps, which normally provide the driving head for the pressurizer spray, are not operating.

A portion of the charging flow is directed to the reactor coolant pumps (nominally 8 gpm per pump) through a seal water injection filter. It is directed down to a point between the pump shaft bearing and the thermal barrier cooling coil. Here the flow splits and a portion (nominally 5.5 gpm per pump) enters the RCS through the labyrinth seals and thermal barrier. The remainder of the flow is directed up the pump shaft, cooling the lower bearing, and to the RCP seal. The seal controlled bleed-off flow discharges to a common manifold, exits from the containment, and then passes through the seal water return filter and the seal water heat exchanger to the suction side of the charging pumps, or by alternate path to the volume control tank. A very small portion of the seal flow leaks through the seal faces. A number 3 seal provides a final barrier to leakage of reactor coolant to the Reactor Building atmosphere. The number 3 leakoff flow is discharged to the reactor coolant drain tank in the liquid waste processing system. In situations where the charging pumps are not available, the seals can be supplied by the positive-displacement Alternate Seal Injection (ASI) Pump, which provides a total of 20 gpm (approximately 7 gpm per RCP seal) directly from the RWST. The ASI pump is powered by a dedicated NNS diesel generator and is designed to operate continuously for no less than 24 hours following a station black-out event (SBO). The ASI system is a sub-system of CVCS (Figure 9.3-16, Sheet 3) and is designed as an ASME III, Code Class 2 system (safety-related for pressure boundary integrity). The Alternate Seal Injection pump was conservatively designed and procured as an active pump, although it is not credited in station analysis which would require its function to be active.

The excess letdown path is provided as an alternate letdown path from the RCS in the event that the normal letdown path is inoperable. Reactor coolant can be discharged from a crossover leg to flow through the tube side of the excess letdown heat exchanger where it is cooled by component cooling water. Downstream of the heat exchanger a remote-manual control valve controls the

letdown flow. The flow normally joins the RCP seal controlled bleed-off discharge manifold and passes through the seal water return filter and heat exchanger to the suction side of the charging pumps. The excess letdown flow can also be directed to the reactor coolant drain tank or directly into the volume control tank via a spray nozzle. When the normal letdown line is not available, the normal purification path is also not in operation. Therefore, this alternate condition would allow continued power operation for a limited period of time, dependent on RCS chemistry and activity. The excess letdown flow path is also used to provide additional letdown capability during the final stages of plant heatup. This path removes some of the excess reactor coolant due to expansion of the system as a result of the RCS temperature increase.

Surges in RCS inventory due to load changes are accommodated for the most part in the pressurizer. The volume control tank provides surge capacity for reactor coolant expansion not accommodated by the pressurizer. If the water level in the volume control tank exceeds the normal operating range, a proportional controller modulates a three-way valve downstream of the reactor coolant filter to divert a portion of the letdown to the Boron Recycle System. If the high-level limit in the volume control tank is reached, an alarm is actuated in the control room and the letdown flow is completely diverted to the Boron Recycle System.

The Boron Recycle System (Section 9.3.6) receives and processes reactor coolant effluent prior to discharge to the environment or alternatively for reuse in the plant. The system decontaminates the effluent by means of demineralization and gas stripping.

Low level in the volume control tank initiates makeup from the reactor makeup control system. If the reactor makeup control system does not supply sufficient makeup to keep the volume control tank level from falling to a lower level, a low alarm is actuated. Manual action may correct the situation or, if the level continues to decrease, an emergency low level signal from both level channels causes the suction of the charging pumps to be transferred to the refueling water storage tank.

9.3.4.2.2 Reactor Coolant Purification and Chemistry Control System

9.3.4.2.2.1 pH Control

The pH control chemical employed is lithium hydroxide. This chemical is chosen for its compatibility with the materials and water chemistry of borated water/stainless steel/zirconium/inconel systems. In addition, Lithium-7 is produced in the core region due to irradiation of the dissolved boron in the coolant.

The concentration of Lithium-7 in the RCS is coordinated with boron concentration for RCS pH control (Table 5.2-10). If the concentration is too high, as it may be during the early stages of a core cycle, the cation bed demineralizer may be employed in the letdown line in series operation with a mixed bed demineralizer. Lithium may also be removed via a mixed bed demineralizer which has not had its cation resin converted to the lithium form. If the concentration of Lithium-7 is too low, lithium hydroxide can be introduced into the RCS via the charging flow. The solution is prepared in the laboratory and poured into the chemical mixing tank. Reactor makeup water is then used to flush the solution to the suction manifold of the charging pumps.

9.3.4.2.2.2 Oxygen Control

During reactor startup from the cold condition, hydrazine is employed as an oxygen scavenging agent. The hydrazine solution is introduced into the RCS in the same manner as described above for the pH control agent. Hydrazine is not employed at any time other than startup from the cold shutdown state.

Dissolved hydrogen is employed to control and scavenge oxygen produced due to radiolysis of water in the core region. Sufficient partial pressure of hydrogen is maintained in the volume control tank such that the specified equilibrium concentration of hydrogen is maintained in the reactor coolant. A pressure control valve maintains a minimum pressure in the vapor space of the volume control tank. This valve can be adjusted to provide the correct equilibrium hydrogen concentration (25 to 50 cc hydrogen at STP per kilogram of water). Hydrogen is supplied from the hydrogen manifold in the gaseous processing system.

9.3.4.2.2.3 Reactor Coolant Purification

Mixed bed demineralizers are provided in the letdown line to provide cleanup of the letdown flow. The demineralizers remove ionic corrosion products and certain fission products. One demineralizer is in continuous service and can be supplemented intermittently by the cation bed demineralizer, if necessary, for additional purification. The cation resin removes principally cesium and lithium isotopes from the purification flow. The second mixed bed demineralizer serves as a standby unit for use if the operating demineralizer becomes exhausted during operation.

A further cleanup feature is provided for use during residual heat removal. A remote operated valve admits a bypass flow from the Residual Heat Removal System (RHRS) into the letdown line upstream of the letdown heat exchanger. In addition, all 3 letdown orifice isolation valves may be opened at this time. The flow passes through the heat exchanger, through a mixed bed demineralizer and the reactor coolant filter to the volume control tank. The fluid is then returned to the RCS via the normal charging route.

Filters are provided at various locations to ensure filtration of particulate and resin fines and to protect the seals on the reactor coolant pumps.

Fission gases are removed from the reactor coolant by continuous purging of the volume control tank to the gaseous waste processing system.

9.3.4.2.3 Reactor Makeup Control System

The soluble neutron absorber (boric acid) concentration is controlled by the Boron Thermal Regeneration System and by the reactor makeup control system. The reactor makeup control system is also used to maintain proper reactor coolant inventory. In addition, for emergency boration and makeup, the capability exists to provide refueling water or 4 weight percent boric acid directly to the suction of the charging pump.

The reactor makeup control system provides a manually preselected makeup composition to the charging pump suction header or to the volume control tank. The makeup control functions are those of maintaining desired operating fluid inventory in the volume control tank and adjusting reactor coolant boron concentration for reactivity control. Reactor makeup water and boric acid solution (4 weight percent) are blended together at the reactor coolant boron concentration for use as makeup to maintain volume control tank inventory or they can be used separately to change the reactor coolant boron concentration.

The boric acid is stored in two boric acid tanks. Two (2) boric acid transfer pumps are provided with 1 pump normally aligned to provide boric acid to the suction header of the charging pumps, and the second pump in reserve. On a demand signal by the reactor makeup controller, the pump starts and delivers boric acid to the suction header of the charging pumps. The pump can also be used to recirculate the boric acid tank fluid.

All portions of the CVCS which normally contain concentrated boric acid solution (4 weight percent boric acid) are located within a heated area in order to maintain solution temperature at ≥ 65°F. If a portion of the system which normally contains concentrated boric acid solution is not located in a heated area, it is provided with some other means (e.g., heat tracing) to maintain solution temperature at ≥ 65°F.

The reactor makeup water pumps, taking suction from the reactor makeup water storage tank, are employed for various makeup and flushing operations throughout the systems. One of these pumps also starts on demand from the reactor makeup controller and provides flow to the suction header of the charging pumps or the volume control tank through the letdown line or spray nozzle, respectively.

During reactor operation, changes are made in the reactor coolant boron concentration for the following conditions:

1. Reactor startup - boron concentration must be decreased from shutdown concentration to achieve criticality.
2. Load follow - boron concentration must be either increased or decreased to compensate for the xenon transient following a change in load.
3. Fuel burnup - boron concentration must be decreased to compensate for fuel burnup and the buildup of fission products in the fuel.
4. Cold shutdown - boron concentration must be increased to the cold shutdown concentration.

The Boron Thermal Regeneration System can be used in conjunction with dilution operations of the reactor makeup control system to reduce the amount of effluent to be processed by the Boron Recycle System.

The reactor makeup control system can be set up for the following modes of operation:

1. Automatic Makeup

The "automatic makeup" mode of operation of the reactor makeup control system provides blended boric acid solution, preset to match the boron concentration in the RCS. Automatic makeup compensates for minor leakage of reactor coolant without causing significant changes in the reactor coolant boron concentration.

Under normal plant operating conditions, the mode selector switch is set in the "automatic makeup" position. This switch position establishes a preset control signal to the total makeup flow controller and establishes positions for the makeup stop valves for automatic makeup. The boric acid flow controller is set to blend to the same concentration of borated water as is contained in the RCS. A preset low level signal from the volume control tank level controller causes the automatic makeup control action to start a reactor makeup water pump, start a boric acid transfer pump, open the makeup stop valve to the charging pump suction, and position the boric acid flow control valve and the reactor makeup water flow control valve. The flow controllers then blend the makeup stream according to the preset concentration. Makeup addition to the charging pump suction header causes the water level in the volume control tank to rise. At a preset high level point, the makeup is stopped. This operation may be terminated manually at any time.

If the automatic makeup fails or is not aligned for operation and the tank level continues to decrease, a low level alarm is actuated. Manual action may correct the situation or, if the level continues to decrease, an emergency low level signal opens the stop valves in the refueling water supply line to the charging pumps, and closes the stop valves in the volume control tank outlet line.

2. Dilution

The "dilute" mode of operation permits the addition of a preselected quantity of reactor makeup water at a preselected flowrate to the RCS. The operator sets the mode selector switch to "dilute," the total makeup flow controller setpoint to the desired flowrate, the total makeup batch integrator to the desired quantity and initiates system start. This opens the reactor makeup water flow control valve, opens the makeup stop valve to the volume control tank inlet, and starts a reactor makeup water pump. Excessive rise of the volume control tank water level is prevented by automatic actuation (by the tank level controller) of a three-way diversion valve which routes the reactor coolant letdown flow to the boron recycle system. When the present quantity of water has been added, the batch integrator causes makeup to stop. Also, the operation may be terminated manually at any time.

Dilution can also be accomplished by operating the boron thermal regeneration system in the boron storage mode.

3. Alternate Dilution

   The "alternate dilute" mode of operation is similar to the dilute mode except a portion of the dilution water flows directly to the charging pump suction and a portion flows into the volume control tank via the spray nozzle and then flows to the charging pump suction. This decreases the delay in diluting the RCS caused by directing dilution water to the volume control tank.

4. Boration

   The "borate" mode of operation permits the addition of a preselected quantity of concentrated boric acid solution at a preselected flowrate to the RCS. The operator sets the mode selection switch to "borate," the concentrated boric acid flow controller setpoint to the desired flowrate, the concentrated boric acid batch integrator to the desired quantity, and initiates system start. This opens the makeup stop valve to the charging pumps suction, positions the boric acid flow control valve, and starts the selected boric acid transfer pump, which delivers a 4 weight percent boric acid solution to the charging pumps suction header. The total quantity added in most cases is so small that it has only a minor effect on the volume control tank level. When the preset quantity of concentrated boric acid solution is added, the batch integrator causes makeup to stop. Also, the operation may be terminated manually at any time.

5. Manual

   The "manual" mode of operation permits the addition of a preselected quantity and blend of boric acid solution to the refueling water storage tank, to the recycle holdup tanks in the Boron Recycle System, or to some other location via a temporary connection. While in the manual mode of operation, automatic makeup to the RCS is precluded. The discharge flow path must be prepared by opening manual valves in the desired path.

   The operator sets the mode selector switch to "manual," the boric acid and total makeup flow controllers to the desired flowrates, the boric acid and total makeup batch integrators to the desired quantities, and actuates the makeup start switch.

   The start switch actuates the boric acid flow control valve and the reactor makeup water flow control valve and starts the preselected reactor makeup water pump and boric acid transfer pump.

   When the preset quantities of boric acid and reactor makeup water have been added, the batch integrators cause makeup to stop. This operation may be stopped manually by actuating the makeup stop switch.

If either batch integrator is satisfied before the other has recorded its required total, the pump and valve associated with the integrator which has been satisfied will terminate flow. The flow controlled by the other integrator will continue until the integrator is satisfied. In the manual mode, the boric acid flow is terminated first to prevent piping systems from remaining filled with 4 weight percent boric acid solution.

The quantities of boric acid and reactor makeup water injected are totalized by the batch counters and the flowrates are recorded on recorders. Deviation alarms sound for both boric acid and reactor makeup water if flowrates deviate from setpoints.

9.3.4.2.4 Boron Thermal Regeneration System

Downstream of the mixed bed demineralizers, the letdown flow can be diverted to the Boron Thermal Regeneration System (BTRS) for processing when boron concentration reductions are desired. The BRTS can process any letdown flow rate up to the maximum design flow rate of 120 gpm. Part or all of the letdown flow can be directed through the thermal regeneration demineralizers for processing. After processing, the flow is returned to a point upstream of the reactor coolant filter.

Storage of boron is determined by the temperature of fluid entering the thermal regeneration demineralizers. A chiller unit and a group of heat exchangers are employed to provide the desired fluid temperatures at the demineralizer inlets.

During boron storage, the letdown stream enters the moderating heat exchanger and from there it passes through the letdown chiller heat exchanger. These two heat exchangers cool the letdown stream prior to its entering the demineralizers. The letdown reheat heat exchanger is permanently piped out of service on the tube side and performs no function. The temperatures of the letdown stream at the point of entry to the demineralizers is controlled automatically by the temperature control valve which controls the shell side flow to the letdown chiller heat exchanger. After passing through the demineralizers, the letdown enters the moderating heat exchanger shell side, where it is heated by the incoming letdown stream before going to the volume control tank.

Therefore, for boron storage, a decrease in the boric acid concentration in the reactor coolant is accomplished by sending the letdown flow at relatively low temperatures to the thermal regeneration demineralizers. Reactor coolant with a decreased concentration of boric acid leaves the demineralizers and is directed to the RCS via the charging system.

As an additional function, a thermal regeneration demineralizer can be used as a deborating demineralizer, which would be used to dilute the RCS down to very low boron concentrations towards the end of a core cycle. To make such a bed effective, the effluent concentration from the bed must be kept very low, close to zero ppm boron. This low effluent concentration can be achieved by using fresh resin. Use of fresh resin can be coupled with the normal replacement cycle of the resin; one resin bed being replaced during each core cycle.

9.3.4.2.5 Component Description

A summary of principal component design parameters is given in Table 9.3-5, and safety classifications and design codes are given in Section 3.2.

In addition, portions of the system that are required to carry ECCS fluid outside containment during the recirculation phase of ECCS operation are designed to minimize leakage to the atmosphere as described in Section 6.3.2.11.3.

9.3.4.2.5.1 Piping

CVCS piping that handles radioactive liquid is austenitic stainless steel. Piping joints and connections are welded, except where flanged connections are required to facilitate equipment removal for maintenance and hydrostatic testing.

9.3.4.2.5.2 Charging Pumps

Three (3) charging pumps of the single speed, horizontal, centrifugal type are supplied to inject coolant into the RCS. One (1) pump is normally running, 1 is a non running pump and the third is a spare with its breaker(s) normally racked out. The third pump can be used as a replacement if 1 of the other pumps is out of service. Parts in contact with the reactor coolant are fabricated of austenitic stainless steel or other material of adequate corrosion resistance. There is a minimum flow recirculation line to protect the centrifugal charging pumps from a closed discharge valve condition. The component cooling water cooling flow to the charging pump lube oil system is established through the air operated component cooling water valves which open when the charging pumps start.

Charging flowrate is determined from a pressurizer level signal. When operating a centrifugal charging pump, charging flow control is accomplished by a modulating valve on the discharge side of the centrifugal pumps. The centrifugal charging pumps also serve as high-head safety injection pumps in the Emergency Core Cooling System.

9.3.4.2.5.3 Boric Acid Transfer Pumps

Two (2) canned motor pumps are supplied. One (1) pump is normally aligned to supply boric acid to the suction header of the charging pumps while the second serves as a standby. Manual or automatic initiation of the reactor coolant makeup system will start the aligned pump to provide normal makeup of boric acid solution to the suction header of the charging pumps. Miniflow from this pump flows back to the associated boric acid tank and helps maintain thermal equilibrium. The standby pump can be used intermittently to circulate boric acid solution through the other tank to maintain thermal equilibrium in this part of the system. Emergency boration, supplying 4 weight percent boric acid solution directly to the suction of the charging pumps, can be accomplished by manually starting either or both pumps. The transfer pumps also function to transfer boric acid solution from the batching tank to the boric acid tanks.

The pumps are located in a heated area to prevent crystallization of the boric acid solutions. Parts in contact with the solution are of austenitic stainless steel.

9.3.4.2.5.4 BTRS Chiller Pumps

These centrifugal pumps circulate the water through the chilled water loop in the Boron Thermal Regeneration System. One (1) pump is normally operated, with the second serving as a standby.

9.3.4.2.5.5 Regenerative Heat Exchanger

The regenerative heat exchanger is designed to recover heat from the letdown flow by reheating the charging flow, which reduces thermal effects on the charging penetrations into the reactor coolant loop piping.

The letdown stream flows through the shell of the regenerative heat exchanger and the charging stream flow through the tubes. The unit is constructed of austenitic stainless steel, and is of all welded construction.

The temperatures of both outlet streams from the heat exchanger are monitored with indication given in the control room. A high temperature alarm is actuated on the main control board if the temperature of the letdown stream exceeds desired limits.

9.3.4.2.5.6 Letdown Heat Exchanger

The letdown heat exchanger cools the letdown stream to the operating temperature of the mixed bed demineralizers. Reactor coolant flows through the tube side of the exchanger while component cooling water flows through the shell side. Surfaces in contact with the reactor coolant are austenitic stainless steel, and the shell is carbon steel.

The low pressure letdown valve, located downstream of the heat exchanger, maintains the pressure of the letdown flow upstream of the heat exchanger in a range sufficiently high to prevent two phase flow. Pressure indication and high pressure alarm are provided on the main control board.

The letdown temperature control indicates and controls the temperature of the letdown flow exiting from the letdown heat exchanger. A temperature sensor, which is part of the CVCS, provides input to the controller in the Component Cooling Water System. The exit temperature of the letdown stream is thus controlled by regulating the component cooling water flow through the letdown heat exchanger. Temperature indication is provided on the main control board. If the outlet temperature from the heat exchanger is excessive, a high temperature alarm is actuated and a temperature controlled valve diverts the letdown directly to the volume control tank.

9.3.4.2.5.7 Excess Let Down Heat Exchanger

The excess letdown heat exchanger cools reactor coolant letdown flow at a rate which is equivalent to the portion of the nominal seal injection flow which flows into the RCS through the reactor coolant pump labyrinth seals.

The excess letdown heat exchanger can be employed either when normal letdown is temporarily out of service to maintain inventory control in the RCS or it can be used to supplement maximum letdown during heatup. The letdown flows through the tube side of the unit and component cooling water is circulated through the shell. Surfaces in contact with reactor coolant are austenitic stainless steel and the shell is carbon steel. Tube joints are welded. A temperature detector measures the temperature of the excess letdown flow downstream of the excess letdown heat exchanger. Temperature indication and high temperature alarm are provided on the main control board.

A pressure sensor indicates the pressure of the excess letdown flow downstream of the excess letdown heat exchanger and excess letdown control valve. Pressure indication is provided on the main control board.

9.3.4.2.5.8 Seal Water Heat Exchanger

The seal water heat exchanger is designed to cool fluid from 3 sources: reactor coolant pump controlled bleed-off flow, reactor coolant discharged from the excess letdown heat exchanger, and miniflow from a centrifugal charging pump. Reactor coolant flows through the tube side of the heat exchanger and component cooling water is circulated through the shell. The seal water heat exchanger is sized for a design basis case, for which the flowrate through the tube side is equal to maximum design reactor coolant pump seal leakage and miniflow from two centrifugal charging pumps. The heat exchanger is also sized for an alternate case, for which the flowrate through the tube side is equal to the sum of the nominal excess letdown flow, maximum design reactor coolant pump seal leakage, and miniflow from one centrifugal charging pump. The unit is designed to cool the above flows to the temperature normally maintained in the volume control tank. Surfaces in contact with reactor coolant are austenitic stainless steel and the shell is carbon steel.

9.3.4.2.5.9 Moderating Heat Exchanger

The moderating heat exchanger operates as a regenerative heat exchanger between incoming and outgoing streams to and from the thermal regeneration demineralizers.

The incoming flow enters the tube side of the moderating heat exchanger. The shell side fluid, which comes directly from the demineralizers, enters at low temperature during boron storage. The unit is constructed of austenitic stainless steel.

9.3.4.2.5.10 Letdown Chiller Heat Exchanger

During the boron storage operation, the process stream enters the tube side of the letdown chiller heat exchanger after leaving the tube side of the moderating heat exchanger. The letdown chiller

heat exchanger cools the process stream to allow the thermal regeneration demineralizers to remove boron from the coolant. The desired cooling capacity is adjusted by controlling the chilled water flowrate passed through the shell side of the heat exchanger.

The letdown chiller heat exchanger surfaces in contact with reactor coolant are austenitic stainless steel and the shell is carbon steel.

9.3.4.2.5.11 Letdown Reheat Heat Exchanger

The letdown reheat heat exchanger is no longer used.

9.3.4.2.5.12 Volume Control Tank

The volume control tank provides surge capacity for part of the reactor coolant expansion volume not accommodated by the pressurizer. When the level in the tank reaches the high level setpoint, the remainder of the expansion volume is accommodated by diversion of the letdown stream to the Boron Recycle System. The tank also provides a means for introducing hydrogen into the coolant to maintain the required equilibrium concentration and is used for degassing the reactor coolant. It also serves as a head tank for the charging pumps.

A spray nozzle located inside the tank on the letdown line provides liquid to gas contact between the incoming fluid and the hydrogen atmosphere in the tank.

The tank is constructed of austenitic stainless steel.

Hydrogen (from the hydrogen manifold in the gaseous waste processing system) is continuously supplied to the volume control tank while a remotely operated vent valve, discharging to the gaseous waste processing system, permits continuous removal of gaseous fission products which are stripped from the reactor coolant and collected in this tank. Relief protection, gas space sampling, and nitrogen purge connections are also provided. The tank also accepts the seal water return flow from the reactor coolant pumps; this flow can be routed directly to the suction of the charging pumps.

Volume control tank pressure is monitored with indication given in the control room. Alarm is actuated in the control room for high and low pressure conditions.

Two (2) level channels govern the water inventory in the volume control tank. Level indication with high and low alarms is provided on the main control board for one channel and local level indication is provided for the other channel.

If the volume control tank level rises above the normal operating range, 1 level channel provides an analog signal to the proportional controller which modulates the three-way valve downstream of the reactor coolant filter to maintain the volume control tank level within the normal operating band. The three-way valve can split letdown flow so that a portion goes to the Boron Recycle System and a portion to the volume control tank. The controller would operate in this fashion

during a dilution operation when reactor makeup water is being fed to the volume control tank from the reactor makeup control system.

If the modulating function of the channel fails and the volume control tank level continues to rise, the high level alarm will alert the operator to the malfunction and the full letdown flow will be automatically diverted by the backup level channel.

During normal power operation, a low level in the volume control tank initiates auto makeup which injects a preselected blend of boric acid solution and reactor makeup water into the charging pump suction header. When the volume control tank level is restored to normal, auto makeup stops.

If the automatic makeup fails and the tank level continues to decrease, a low level alarm is actuated. Manual action may correct the situation or, if the level continues to decrease, a low-low signal from both level channels opens the stop valves in the refueling water supply line, and closes the stop valves in the volume control tank outlet line.

9.3.4.2.5.13 Boric Acid Tanks

The combined boric acid tank capacity is sized to store sufficient boric acid solution for refueling plus enough for a cold shutdown from full power operation immediately following refueling with the most reactive control rod not inserted.

The concentration of boric acid solution in storage is maintained between 7000 and 7700 ppm. Periodic manual sampling and corrective action, if necessary, assure that these limits are maintained. As a consequence, measured amounts of boric acid solution can be delivered to the reactor coolant to control the boron concentration.

A temperature sensor provides temperature measurement of each tank’s contents. Temperature indication as well as high and low temperature alarms are provided locally.

Three (3) level detectors indicate the level in each boric acid tank. Redundant level indication with high, low, low-low and empty level alarms is provided on the main control board for each tank. The high alarm indicates that the tank may soon overflow. The low alarm warns the operator to start makeup to the tank. The low-low alarm is set to indicate the minimum level of boric acid in the tank to ensure sufficient boric acid is available for a cold shutdown with one stuck rod. The empty level alarm is set to give warning of loss of pump suction.

9.3.4.2.5.14 Batching Tank

The batching tank is used for mixing a makeup supply of boric acid solution for transfer to the boric acid tanks.

A local sampling point is provided for verifying the solution concentration prior to transferring it out of the tank. The tank is provided with an agitator to improve mixing during batching operations and a steam jacket for heating the boric acid solution.

9.3.4.2.5.15 Chemical Mixing Tank

The primary use of the chemical mixing tank is in the preparation of caustic solutions for pH control and hydrazine solution for oxygen scavenging.

9.3.4.2.5.16 BTRS Chiller Surge Tank

The BTRS chiller surge tank handles the thermal expansion and contraction of the water in the chiller loop. The surge volume in the tank also acts as a thermal buffer for the chiller. The fluid level in the tank is monitored with level indication and high and low level alarms provided on the main control board.

9.3.4.2.5.17 Mixed Bed Demineralizers

Two (2) flushable mixed bed demineralizers assist in maintaining reactor coolant purity. A hydrogen-form cation resin and a hydroxyl-form anion resin are charged into the demineralizers. The cation resin is converted to lithium-form and the anion resin is converted to the borate form in operation. Both types of resin remove fission and corrosion products. The resin bed is designed to reduce the concentration of ionic isotopes in the purification stream, except for cesium, yttrium and molybdenum, by a minimum factor of 10.

Each demineralizer has more than sufficient capacity for 1 core cycle with 1% of the rated core thermal power being generated by failed fuel. One (1) demineralizer is normally in service with the other in standby.

A temperature sensor monitors the temperature of the letdown flow downstream of the letdown heat exchanger and if the letdown temperature exceeds the maximum allowable resin operating temperature (approximately 140°F), a three-way valve is automatically actuated to bypass the flow around the demineralizers. Temperature indication and high alarm are provided on the main control board. The air operated three-way valve failure mode directs flow to the volume control tank.

9.3.4.2.5.18 Cation Bed Demineralizer

A flushable demineralizer with cation resin in the hydrogen form is located downstream of the mixed bed demineralizers and is used intermittently to control the concentration of Li^7 which builds up in the coolant from the B^{10} (n, α) Li^7 reaction. The demineralizer also has sufficient capacity to maintain the Cesium-137 concentration in the coolant below the value listed in Table 11.1-2. The resin bed is designed to reduce the concentration of ionic isotopes, particularly cesium, yttrium, and molybdenum by a minimum factor of 10. The demineralizer is sized to accommodate a letdown flow rate of 60 gpm when in service, which is more than adequate to control Li^7 or cesium in the RCS. Any letdown flow in excess of 60 gpm is diverted through the bypass line around the cation bed demineralizer.

The demineralizer has more than sufficient capacity for 1 core cycle with 1% of the rated core thermal power being generated by failed fuel.

9.3.4.2.5.19 Thermal Regeneration Demineralizers

The function of the thermal regeneration demineralizers was to store the total amount of boron that must be removed from the RCS to accomplish the required dilution during a load cycle in order to compensate for xenon buildup resulting from a decreased power level. Furthermore, the demineralizers were able to release the previously stored boron to accomplish the required boration of the reactor coolant during the load cycle in order to compensate for a decrease in xenon concentration resulting from an increased power level. The load following capabilities of the thermal regeneration demineralizers was removed by plant modification MRF 21511. The resins continue to be used to store boron. However, the boron release feature of the system has been disabled.

The thermal regeneration demineralizer resin capacity is directly proportional to the solution boron concentration and inversely proportional to the temperature. Further, the differences in capacity as a function of both boron concentration and temperature are reversible.

Temperature instrumentation is provided upstream of the thermal regeneration demineralizers to control the temperature of the process flow. During boron storage operations, it controls the flow through the shell side of the letdown chiller heat exchanger to maintain the process flow at 50°F as it enters the demineralizers. Temperature indication and a high temperature alarm are provided on the main control board.

An additional temperature instrument is provided to protect the demineralizer resins from a high temperature condition. On reaching the high temperature setpoint, an alarm is sounded on the main control board and the letdown flow is diverted to the volume control tank from a point upstream of the mixed bed demineralizers.

Failure of the temperature controls resulting in hot water flow to the demineralizers would result in a release of boron stored on the resin with a resulting increase in reactor coolant boron concentration and increased margin for shutdown. If the temperature of the resin rises significantly above 140°F, the number of ion storage sites will gradually decrease, thus reducing the capability of the resin to remove boron from the process stream. Degradation of ion removal capability will occur for temperatures of approximately 160°F and above. The extent of the degradation and rate at which it will occur depend upon the temperature experienced by the resin and the length of time that the resin experiences this elevated temperature.

Failure of the temperature control system resulting in cold water flow to the demineralizers would result in storage of boron on the resin and reduction of the reactor coolant boron concentration. The amount of reduction in reactor coolant boron concentration is limited by the capacity of the resin to remove boron from the water. As the boron concentration is reduced, the control rods would be driven into the core to maintain power level. If the rods were to reach the shutdown limit setpoint, an alarm would be actuated informing the operator that emergency boration of the RCS is necessary in order to maintain capability of shutting the reactor down with control rods alone.

9.3.4.2.5.20 Reactor Coolant Filter

The reactor coolant filter is located in the letdown line upstream of the volume control tank. The filter collects resin fines and particulates from the letdown stream. The flow capacity of the filter is designed to accept the maximum purification flowrate.

Two (2) local pressure indicators are provided to show the pressures upstream and downstream of the reactor coolant filter and thus provide filter differential pressure.

9.3.4.2.5.21 Seal Water Injection Filters

Two (2) seal water injection filters are located in parallel in a common line to the reactor coolant pump seals; they collect particulate matter that could be harmful to the seal faces. Each filter is sized to accept flow in excess of the normal seal water flow requirements.

A differential pressure indicator monitors the pressure drop across each seal water injection filter and gives local indication with high differential pressure alarm on the main control board.

9.3.4.2.5.22 Seal Water Return Filter

This filter collects particulates from the reactor coolant pump seal water return and from the excess letdown flow. The filter is designed to pass the sum of the excess letdown flow and the maximum design seal leakage from all reactor coolant pumps.

Two (2) local pressure indicators are provided to show the pressures upstream and downstream of the filter and thus provide differential pressure across the filter.

9.3.4.2.5.23 Boric Acid Filter

The boric acid filter collects particulates from the boric acid solution being pumped from the boric acid tanks by the boric acid transfer pumps. The filter is designed to pass the design flow of 2 boric acid transfer pumps operating simultaneously.

Local pressure indicators indicate the pressure upstream and downstream of the boric acid filter and thus provide filter differential pressure.

9.3.4.2.5.24 Letdown Orifices

Three (3) letdown orifices are provided to reduce the letdown pressure from reactor conditions and to control the flow of reactor coolant leaving the RCS. The orifices are placed into or out of service by remote operation of their respective isolation valves. Normal letdown ranges from 60 to 120 gpm and is obtained by placing one 60 gpm orifice or any combination of two orifices aligned in parallel. All 3 orifices may be used in parallel for either flow control when the RCS pressure is less than normal or greater letdown flow during maximum purification or heatup. Each orifice consists of an assembly which provides for permanent pressure loss without recovery, and is made of austenitic stainless steel or other adequate corrosion resistant material.

A flow monitor provides indication in the control room of the letdown flowrate, and a high alarm to indicate unusually high flow.

A low pressure letdown controller located downstream of the letdown heat exchanger controls the pressure upstream of the letdown heat exchanger to prevent flashing of the letdown liquid. Pressure indication and high pressure alarm are provided on the main control board.

9.3.4.2.5.25 Number 1 Seal Bypass Orifices

Number 1 Seal bypass flow was necessary for Westinghouse RCP seal to ensure adequate flow for cooling of the pump's lower radial bearing and to limit the temperature rise of the water cooling the number 1 seal during startup or shutdown when the RCS pressure was low. The number 1 seal bypass orifice is constructed of austenitic stainless steel and designed to pass adequate flow for the differential pressure existing at the lowest allowable RCS pressure for reactor coolant pump operation. The Westinghouse RCP seals were replaced with N-9000 seals which have sufficient cooling flow at low RCS pressure. Therefore the bypass flow is no longer required. The number 1 seal bypass orifices remain in the piping system but the downstream piping is capped.

9.3.4.2.5.26 Boric Acid Blender

The boric acid blender, made of austenitic stainless steel, is provided to ensure thorough mixing of the 4 weight percent solution of boric acid and reactor makeup water when required. The blender is designed to pass the maximum letdown flow.

9.3.4.2.5.27 DELETED.

9.3.4.2.5.28 BTRS Chiller

The BTRS chiller is located in a chilled water loop containing a surge tank, chiller pumps, the letdown chiller heat exchanger, piping, valves and controls.

The purpose of the chiller is to cool down the process stream during storage of boron on the resin.

9.3.4.2.5.29 Valves

Where pressure and temperature conditions permit, diaphragm type valves are used to essentially eliminate leakage to the atmosphere. Packed valves which are larger than 2 inches and which are designated for radioactive services are provided with a stuffing box and lantern leakoff connections. Design requirements for zero-leakage valves and dual vent and drain isolation, described in Section 6.3.2.11.3 apply to valves 2 inches and smaller located in portions of the system designed to carry ECCS fluid outside containment during post-LOCA recirculation. Control (modulating) and three-way valves are either provided with stuffing box and leakoff connections or are totally enclosed. Leakage to the atmosphere is essentially 0 for these valves. Basic material of construction is stainless steel for valves which handle radioactive liquid or boric acid solutions.

Relief valves are provided for lines and components that might be pressurized above design pressure by improper operation or component malfunction.

1. Charging Line Downstream of Regenerative Heat Exchanger

   If the charging side of the regenerative heat exchanger is isolated while the hot letdown flow continues at its maximum rate, the volumetric expansion of coolant on the charging side of the heat exchanger is relieved to the RCS through a spring loaded check valve.

2. Letdown Line Downstream of Letdown Orifices

   The pressure relief valve downstream of the letdown orifices protects the low pressure piping and the letdown heat exchanger from overpressure when the low pressure piping is isolated. The capacity of the relief valve is equal to the maximum flowrate through all letdown orifices. The valve set pressure is equal to the design pressure of the letdown heat exchanger tube side.

3. Letdown Line Downstream of Low Pressure Letdown Valve

   The pressure relief valve downstream of the low pressure letdown valve protects the low pressure piping and equipment from overpressure when this section of the system is isolated. The overpressure may result from leakage through the low pressure letdown valve. The capacity of the relief valve exceeds the maximum flowrate through all letdown orifices. The valve set pressure is equal to the design pressure of the demineralizers.

4. Volume Control Tank

   The relief valve on the volume control tank permits the tank to be designed for a lower pressure than the upstream equipment. This valve has a capacity equal to the summation of the following items: maximum letdown, normal seal water return, excess letdown and nominal flow from one reactor makeup water pump. The valve set pressure equals the design pressure of the volume control tank.

5. Charging Pump Suction

   A relief valve on the charging pump suction header relieves pressure that may build up if the suction line isolation valves are closed or if the system is overpressurized. The valve set pressure is equal to the design pressure of the associated piping and equipment.

6. Seal Water Return Line (Inside Reactor Building)

   This relief valve is designed to relieve overpressurization in the seal water return piping inside the Reactor Building if the motor operated isolation valve is closed. The valve is designed to relieve the total controlled bleed-off flow of the reactor coolant pump seals plus the design excess letdown flow. The valve is set to relieve at the design pressure of the piping.

7. Seal Water Return Line (Charging Pumps Bypass Flow)

   This relief valve protects the seal water heat exchanger and its associated piping from overpressurization. If either of the isolation valves for the heat exchanger are closed and if the bypass line is closed, the piping would be overpressurized by the miniflow from the centrifugal charging pumps. The valve is sized to handle the design basis flowrate of the Excess Letdown Heat Exchanger, the fluid from the reactor coolant pump seals returning to the volume control tank, and the miniflow from two operating centrifugal charging pumps, which bounds that of the Seal Water Heat Exchanger. The valve is set to relieve at the design pressure of the heat exchanger.

8. Letdown Reheat Heat Exchanger

   The relief valve is located on the piping leading from the shell side of the heat exchanger. If the shell side were filled with cold water and isolated, overpressurization could occur when the water warms to room temperature. The valve is set to relieve at the design pressure of the heat exchanger shell side.

9. Letdown Chiller Heat Exchanger

   The relief valve is located on the piping leading from the shell side of the heat exchanger. If the shell side were isolated while flow was maintained in the tube side, overpressurization could occur. The valve is set to relieve at the design pressure of the heat exchanger shell side.

10. Steam Line to Batching Tank

    The relief valve on the steam line to the batching tank protects the low pressure piping and batching tank heating jacket from overpressure when the condensate return line is isolated. The capacity of the relief valve equals the maximum expected steam inlet flow. The set pressure equals the design pressure of the heating jacket.

9.3.4.2.6 System Operation

9.3.4.2.6.1 Reactor Startup

Reactor startup is defined as the operations which bring the reactor from cold shutdown to normal operating temperature and pressure.

It is assumed that:

1. Normal residual heat removal is in progress.
2. RCS boron concentration is at the cold shutdown concentration.
3. Reactor makeup control system is set to provide makeup at the cold shutdown concentration.
4. RCS is either water solid or drained to minimum level for the purpose of refueling or maintenance. If the RCS is water solid, system pressure is maintained by operation of a

charging pump and controlled by the low pressure letdown valve in the letdown line (letdown is achieved via the low pressure letdown connection from the residual heat removal system, as well as one or more letdown orifices).

5. The charging and letdown lines of the CVCS are filled with coolant at the cold shutdown boron concentration. The letdown orifice isolation valves are closed.

If the RCS requires filling and venting, the procedure is as follows:

1. One (1) charging pump is started, which provides blended flow from the reactor makeup control system at the cold shutdown boron concentration.
2. The vents on the head of the reactor vessel and pressurizer are opened.
3. The RCS is filled and the vents closed.

The system pressure is raised by using the charging pump and controlled by the low pressure letdown valve. When the system pressure is adequate for operation of the reactor coolant pumps, seal water flow to the pumps is established and the pumps are operated and vented sequentially until all gases are cleared from the system. Final venting takes place at the pressurizer.

After the filling and venting operations are completed, charging and letdown flows are established. All pressurizer heaters are energized and the reactor coolant pumps are employed to heatup the system. After the reactor coolant pumps are started, the residual heat removal pumps are stopped but pressure control via the Residual Heat Removal System (RHRS) and the low pressure letdown line is continued as the pressurizer steam bubble is formed. At this point, steam formation in the pressurizer is accomplished by manual control of the charging flow and low pressure letdown valve with all letdown orifices open. When the pressurizer water level reaches the no-load programmed setpoint, the pressurizer level control is shifted to control the charging flow to maintain programmed level. The RHRS is then isolated from the RCS and the normal letdown path is established. The pressurizer heaters are used to increase RCS pressure.

The reactor coolant boron concentration is now reduced by operating the reactor makeup control system in the "dilute" mode. The reactor coolant boron concentration is corrected to the point where the control rods may be withdrawn and criticality achieved. Nuclear heatup may then proceed with corresponding manual adjustment of the reactor coolant boron concentration to balance the temperature coefficient effects and maintain the control rods within their operating range. During heatup, the appropriate combination of letdown orifices is used to provide necessary letdown flow.

Prior to or during the heating process, the CVCS is employed to obtain the correct chemical properties in the RCS. The reactor makeup control system is operated on a continuing basis to ensure correct control rod position. Chemicals are added through the chemical mixing tank as required to control reactor coolant chemistry such as pH and dissolved oxygen content. Hydrogen overpressure is established in the volume control tank to assure the appropriate hydrogen concentration in the reactor coolant.

9.3.4.2.6.2 Power Generation and Hot Standby Operation

1. Base Load

   At a constant power level, the rates of charging and letdown are dictated by the requirements for seal water to the reactor coolant pumps and the normal purification of the RCS. One (1) charging pump is employed and charging flow is controlled automatically from pressurizer level. The only adjustments in boron concentration necessary are those to compensate for core burnup. These adjustments are made at infrequent intervals to maintain the control groups within their allowable limits. Rapid variations in power demand are accommodated automatically by control rod movement. If variations in power level occur, and the new power level is sustained for long periods, some adjustment in boron concentration may be necessary to maintain the control groups within their maneuvering band.

   During normal operation, normal letdown flow (60 to 120 gpm) is maintained and 1 mixed bed demineralizer is in service. Reactor coolant samples are taken periodically to check boron concentration, water quality, pH and activity level. The charging flow to the RCS is controlled automatically by the pressurizer level control signal through the discharge header flow control valve.

2. Load Follow

   A power reduction will initially cause a xenon buildup followed by xenon decay to a new, lower equilibrium value. The reverse occurs if the power level increases; initially, the xenon level decreases and then it increases to a new and higher equilibrium value associated with the amount of the power level change.

   The reactor makeup control system is used to vary the boron concentration in the reactor coolant to compensate for xenon transients occurring when reactor power is changed.

   The most important intelligence available to the plant operator, enabling him to determine whether dilution or boration of the RCS is necessary, is the position of the control rods. For example, if the control rods are below their desired position, the operator must borate the reactor coolant to bring the rods outward. If, on the other hand, the control rods are above their desired position, the operator must dilute the reactor coolant to bring the rods inward.

   During periods of plant loading, the reactor coolant expands as its temperature rises. The pressurizer absorbs this expansion as the level controller raises the level setpoint to the increased level associated with the new power level. The excess coolant due to RCS expansion is letdown and stored in the volume control tank. During this period, the flow through the letdown orifice remains constant and the charging flow is reduced by the pressurizer level control signal, resulting in an increased temperature at the regenerative heat exchanger outlet. The temperature controller downstream from the letdown heat exchanger increases the component cooling water flow to maintain the desired letdown temperature.

During periods of plant unloading, the charging flow is increased to make up for the coolant contraction not accommodated by the programmed reduction in pressurizer level.

3. Hot Standby

   If required, for periods of maintenance, or following spurious reactor trips, the reactor can be held subcritical, but with the capability to return to full power within the period of time it takes to withdraw control rods. During this hot standby period, temperature is maintained at no-load T_{avg} by initially dumping steam to remove core residual heat, or at later stages, by running reactor coolant pumps to maintain system temperature.

   Following shutdown, xenon buildup occurs and increases the degree of shutdown; i.e., initially, with initial xenon concentration and all control rods inserted, the core is maintained at a minimum of 1% $\Delta k/k$ subcritical. The effect of xenon buildup is to increase this value to a maximum of about 3% $\Delta k/k$ at about 8 hours following shutdown from equilibrium full power conditions. If hot standby is maintained past this point, xenon decay results in a decrease in degree of shutdown. Since the value of the initial xenon concentration is about 3% $\Delta k/k$ (assuming that an equilibrium concentration had been reached during operation), boration of the reactor coolant is necessary to counteract the xenon decay and maintain shutdown.

   If a rapid recovery is required, dilution of the system may be performed to counteract this xenon buildup. However, after the xenon concentration reaches a peak, boration must be performed to maintain the reactor subcritical as the xenon decays out.

4. Cold Shutdown

   Cold shutdown is the operation which takes the reactor from hot shutdown conditions to cold shutdown conditions (reactor is subcritical by at least 1% $\Delta k/k$ and $T_{avg} \leq 200$ °F

   Before initiating a cold shutdown, the RCS hydrogen concentration is lowered by reducing the volume control tank overpressure, by replacing the volume control tank hydrogen atmosphere with nitrogen, and by continuous purging to the gaseous waste processing system.

   Before cooldown and depressurization of the reactor plant is initiated, the reactor coolant boron concentration is increased to the cold shutdown value. After the boration is completed and reactor coolant samples verify that the concentration is correct, the operator resets the reactor makeup control system for leakage makeup and system contraction at the shutdown reactor coolant boron concentration.

   Contraction of the coolant during cooldown of the RCS results in actuation of the pressurizer level control to maintain normal pressurizer water level. The charging flow is increased, relative to letdown flow, and results in a decreasing volume control tank level. The volume control tank level controller automatically initiates makeup to maintain the inventory.

After the RHRS is placed in service and the reactor coolant pumps are shutdown, further cooling of the pressurizer liquid is accomplished by charging through the auxiliary spray line. Coincident with plant cooldown, a portion of the reactor coolant flow is diverted from the RHRS to the CVCS for cleanup. Demineralization of ionic radioactive impurities and stripping of fission gases reduce the reactor coolant activity level sufficiently to permit personnel access for refueling or maintenance operations.

9.3.4.3 Safety Evaluation

9.3.4.3.1 Reactivity Control

Any time that the plant is at power, the quantity of boric acid retained and ready for injection always exceeds that quantity required for the normal cold shutdown assuming that the control assembly of greatest worth is in its fully withdrawn position. This quantity always exceeds the quantity of boric acid required to bring the reactor to hot shutdown and to compensate for subsequent xenon decay. An adequate quantity of boric acid is also available in the refueling water storage tank to achieve cold shutdown.

When the reactor is subcritical; i.e., during cold or hot shutdown, refueling and approach to criticality, the neutron source multiplication is continuously monitored and indicated. Any appreciable increase in the neutron source multiplication, including that caused by the maximum physical boron dilution rate, is slow enough to give ample time to start a corrective action to prevent the core from becoming critical. The rate of boration, with a single boric acid transfer pump operating, is sufficient to take the reactor from full power operation to 1% shutdown in the hot condition, with no rods inserted, in less than 90 minutes. In less than 90 additional minutes, enough boric acid can be injected to compensate for xenon decay, although xenon decay below the equilibrium operating level will not begin until approximately 25 hours after shutdown. Additional boric acid is employed if it is desired to bring the reactor to cold shutdown conditions.

Two (2) separate and independent flow paths are available for reactor coolant boration; i.e., the charging line and the reactor coolant pump seal injection line. Solution temperature requirements are maintained. A single failure does not result in the inability to borate the RCS. Two (2) separate high head safety injection flow paths are also available.

If the normal charging line is not available, charging to the RCS is continued via reactor coolant pump seal injection at the rate of approximately 5 gpm per pump. At the charging rate of 15 gpm (5 gpm per reactor coolant pump), approximately 6 hours are required to add enough boric acid solution from the Boric Acid Tank to counteract xenon decay, although xenon decay below the full power equilibrium operating level will not begin until approximately 25 hours after the reactor is shutdown.

As backup to the normal boric acid supply, the operator can align the refueling water storage tank outlet to the suction of the charging pumps.

Since inoperability of a single component does not impair ability to meet boron injection requirements, plant operating procedures allow components to be temporarily out of service for

repairs. However, with an inoperable component, the ability to tolerate additional component failure is limited. Therefore, operating procedures require immediate action to effect repairs of an inoperable component, restrict permissible repair time, and require demonstration of the operability of the redundant component.

9.3.4.3.2 Reactor Coolant Purification

The CVCS is capable of reducing the concentration of ionic isotopes in the purification stream as required in the design basis. This is accomplished by passing the letdown flow through 1 of the mixed bed demineralizers which removes ionic isotopes, except those of cesium, molybdenum and yttrium, with a minimum decontamination factor of 10. Through occasional use of the cation bed demineralizer the concentration of cesium can be maintained below the Cs-137 value listed in Table 11.1-2.

The maximum temperature that will be allowed for the mixed bed and cation bed demineralizers is approximately 140°F. If the temperature of the letdown stream approaches this level, the flow will be automatically diverted so as to bypass the demineralizers. If the letdown is not diverted, the only consequence would be a decrease in ion removal capability. Ion removal capability starts to decrease when the temperature of the resin goes above approximately 160°F for anion resin or above approximately 250°F for cation resin. The resins do not lose their exchange capability immediately. Ion exchange still takes place (at a faster rate) when temperature is increased. However, with increasing temperature, the resin loses some of its ion exchange sites along with the ions that are held at the lost sites. The ions lost from the sites may be re-exchanged farther down the bed. The number of sites lost is a function of the temperature reached in the bed and of the time the bed remains at the high temperature. Capability for ion exchange will not be lost until a significant portion of the exchange sites are lost from the resin.

There would be no safety problem associated with over-heating of the demineralizer resins. The only effect on reactor operating conditions would be the possibility of an increase in the reactor coolant activity level. If the activity level in the reactor coolant were to exceed the limit given in the Technical Specifications, reactor operation would be restricted as required by the Technical Specifications.

9.3.4.3.3 Seal Water Injection

Flow to the reactor coolant pumps' seals is assured by the fact that there are 3 charging pumps, any 1 of which is capable of supplying the normal charging line flow plus the nominal seal water flow.

9.3.4.3.4 Leakage Provisions

CVCS components, valves, and piping which see radioactive service are designed to limit leakage to the atmosphere. Leakage to the atmosphere is limited through:

1. Welding of all piping joints and connections except where flanged connections are provided to facilitate maintenance and hydrostatic testing,

2. Extensive use of leakoffs to collect leakage, and
3. Use of diaphragm valves where conditions permit.

The volume control tank in the CVCS provides an inferential measurement of leakage from the CVCS as well as the RCS. Low level in the volume control tank actuates makeup at the prevailing reactor coolant boron concentration. The amount of leakage can be inferred from the amount of makeup added by the reactor makeup control system.

9.3.4.3.5 Ability to Meet the Engineered Safety Features Function

A failure analysis of the portion of the CVCS which is safety-related (used as part of the emergency core cooling system) is included as part of the emergency core cooling system failure analysis resented in Tables 6.3-6 and 6.3-7.

9.3.4.4 Tests and Inspections

As part of plant operation, periodic tests, surveillance inspections and instrument calibrations are made to monitor equipment condition and performance. Most components are in use regularly; therefore, assurance of the availability and performance of the systems and equipment is provided by control room and/or local indication.

9.3.4.5 Instrumentation Application

Process control instrumentation is provided to acquire data concerning key parameters about the CVCS. The location of the instrumentation is shown on Figure 9.3-16. The instrumentation furnishes input signals for monitoring and/or alarming purposes. Indications and/or alarms are provided for the following parameters:

1. Temperature.
2. Pressure.
3. Flow.
4. Water level.

The instrumentation also supplies input signals for control purposes. Some specific control functions are:

1. Letdown flow is diverted to the volume control tank upon high temperature indication upstream of the mixed bed demineralizers.
2. Pressure upstream of the letdown heat exchanger is controlled to prevent flashing of the letdown liquid.
3. Charging flowrate is controlled during charging pump operation.
4. Water level is controlled in the volume control tank.

5. Temperature of the boric acid solution in the batching tank is maintained.
6. Reactor makeup is controlled.
7. Temperature of letdown flow to the Boron Thermal Regeneration System is controlled.
8. Temperature of the chilled water flow to the letdown chiller heat exchanger is controlled.
9. Temperature of letdown flow return from the boron thermal regeneration demineralizers is controlled.

9.3.5 Failed Fuel Detection System

The Virgil C. Summer Nuclear Station does not employ a specific failed fuel detection system. However, provision is made for detection of failed fuel by utilization of the process sampling system and the Radiation Monitoring System, discussed in Sections 9.3.2 and 11.4, respectively. In addition, the refueling machine mast is equipped with hardware to support in-mast sipping - a failed fuel detection process that can be used during refueling.

Radiation monitor, RM-L1, provides indication of the gross gamma activity in the reactor coolant. Alarms are provided in the control room to alert the operator to an excessive increase in reactor coolant activity. Laboratory analysis of a reactor coolant sample is used to establish that fission products are present and, if so, the concentration. In this manner information for the determination of fuel failure is obtained.

9.3.6 Boron Recycle System

This section describes the design and operating features of the Boron Recycle System (BRS) which includes the Reactor Grade Water System (RGWS) demineralizers.

9.3.6.1 Design Bases

9.3.6.2 Collection Requirements

The BRS primarily collects and processes water from the recycle holdup tank. Provisions are made to sample and analyze fluids before they are discharged. Based on the laboratory analysis, these wastes are either released under controlled conditions via the penstocks of the Fairfield Pumped Storage Facility or retained for further processing. Permanent records of liquid releases are provided by analyses of known volumes of waste. Alternatively, the liquid may be reused in the plant. For the most part, this effluent is the deaerated, tritiated, borated, and radioactive water from the letdown and drains.

The BRS is designed to collect, via the letdown line in the Chemical and Volume Control System (CVCS), the excess reactor coolant that results from the following plant operations during 1 core cycle:

1. Dilution for core burnup from approximately 1800 ppm boron at the beginning of an 18 month core cycle to approximately 10 ppm near the end of the core cycle.

2. Hot shutdowns and startups. Four (4) hot shutdowns are assumed to take place during an 18 month core cycle.
3. Cold shutdowns and startups. Three (3) cold shutdowns are assumed to take place during an 18 month core cycle.
4. Refueling shutdown and startup.

The BRS also collects water from the following sources:

1. Reactor coolant drain tank (liquid waste processing system) - collects leakoff type drains from equipment inside the containment.
2. Volume control tank and charging pump suction pressure reliefs (CVCS) and residual heat removal pumps pressure reliefs (Emergency Core Cooling System).
3. Boric acid blender (CVCS) - provides storage of boric acid if a boric acid tank must be emptied for maintenance. The boric acid solution is stored in a recycle holdup tank after first being diluted with reactor makeup water by the blender to ensure against precipitation of the boric acid in the unheated recycle holdup tank.
4. Spent fuel pool pumps (Spent Fuel Cooling System) - provides a means of storing the fuel transfer canal water in case maintenance is required on the transfer equipment.
5. Valve leakoffs and equipment drains.

9.3.6.2.1 Capacity Requirement

The BRS is designed to process the total volume of water collected during a core cycle as well as short term surges. The design surge is that produced by a cold shutdown and subsequent startup during the latter part of a core cycle or by a refueling shutdown and startup.

9.3.6.2.2 Purification Requirement

The water collected by the BRS contains dissolved gases, boric acid, and suspended solids. Based on reactor operations with 1% of the rated core thermal power being generated by failed fuel, the BRS is designed to provide sufficient cleanup of the water to allow discharge to the environment within regulatory limits.

The maximum radioactivity concentration buildup in the BRS components is based on operation of the reactor at its engineered safeguards design rating with failed fuel generating 1% of the rated core thermal power. For each component, the shielding design considers the maximum buildup on an isotopic basis including only those isotopes which are present in significant amounts. Filtration and demineralization are the means by which the activity concentrations are controlled.

9.3.6.3 System Description

The BRS is shown in Figure 9.3-18 (piping and instrumentation diagram). When water is directed to the BRS, the flow passes first through the recycle evaporator feed demineralizers and filters and then into the recycle holdup tanks.

The recycle evaporator feed pumps can be used to transfer liquid from one recycle holdup tank to the other if desired. When sufficient water is accumulated to warrant cleanup operation, the recycle evaporator feed pumps take suction from the selected recycle holdup tank. The fluid then flows through the RGWS demineralizers after which it normally is transferred to one of the waste monitor tanks for eventual release from the plant. Alternatively, the water may be sent back to the other monitor tank or to the excess liquid waste system for further processing.

9.3.6.3.1 Component Description

A summary of principal component data is given in Table 9.3-6 and the code requirements are given in Section 3.2.

9.3.6.3.1.1 Recycle Evaporator Feed Pumps

Two (2) centrifugal, canned pumps supply feed to the RGWS demineralizers from the recycle holdup tanks. The pumps can also be used to recirculate water from the recycle holdup tanks through the recycle evaporator feed demineralizers for cleanup if desired. An auxiliary discharge connection is provided to return water to the transfer canal from the recycle holdup tanks, if those tanks were used for storage of transfer canal water during refueling equipment maintenance. Another auxiliary discharge connection is provided to supply water to the suction of the charging pumps (CVCS) for refilling the RCS after loop or system drain.

9.3.6.3.1.2 Recycle Holdup Tanks

Two (2) recycle holdup tanks provide storage of radioactive fluid which is discharged from the RCS during startup, shutdown, load changes and boron dilution. The sizing criteria for the tanks is based on the design surge cold shutdown and startup. The tanks are constructed of austenitic stainless steel.

Each tank has a diaphragm which prevents air from dissolving in the water and prevents the hydrogen and fission gases in the water from mixing with the air. The volume in the tank above the diaphragm is continuously ventilated with building supply air, and the volume of gas below the diaphragm is vented to the gaseous waste processing system.

In addition to the collection of effluent the recycle holdup tanks provide the following functions:

1. Serve as a head tank for the recycle evaporator feed pumps.
2. Provide holdup for draining the RCS to the centerline of the reactor vessel nozzles, including the pressurizer and steam generators.

3. Provide storage for refueling transfer canal water during refueling equipment maintenance.
4. Collect discharge from the relief valve which bypasses the recycle evaporator feed demineralizers.

9.3.6.3.1.3 Recycle Evaporator Feed Demineralizers

Two (2) sluiceable demineralizers remove fission products from the fluid directed to the recycle holdup tanks. The demineralizers also provide a means of cleaning the recycle holdup tank contents via recirculation.

9.3.6.3.1.4 Recycle Evaporator Condensate Demineralizer

A flushable demineralizer is provided as a polishing demineralizer and provides a means of cleanup of the reactor makeup water storage tank contents.

9.3.6.3.1.5 Recycle Evaporator Feed Filter

This filter collects resin fines and particulates from the fluid entering the recycle holdup tanks.

9.3.6.3.1.6 Recycle Evaporator Condensate Filter

This filter collects resin fines and particulate and may be used in conjunction with the recycle evaporator condensate demineralizer.

9.3.6.3.1.7 Recycle Evaporator Concentrates Filter

This filter removes particulates and may be used during certain fluid transfer operations.

9.3.6.3.1.8 Reactor Grade Water System Demineralizers

The Reactor Grade Water System demineralizers are provided to process radioactive waste prior to release to the environment. The demineralizers are located on the 447’ elevation of the Auxiliary Building.

The liquid waste stream enters the demineralizers through a booster pump, a mechanical filter, and an Influent Control Leg which monitors waste stream parameters and provides attachments for service air and water. From the Influent Control Leg, the waste may enter one of the three pressure vessels that contain media for cleanup of the liquid waste. The media normally include:

- Cation resin to remove metals and transition metals.
- Mixed bed resin that reduces undesired positive and negative ions.
- Charcoal media for cleanup as a prefilter providing mechanical filtration capability to protect the other demineralizer beds.

A typical lineup for the three Duratek demineralizers in series could be charcoal, cation and mixed bed with cation.

The actual required vessel lineup during normal plant operation is determined prior to processing by sampling the recycle holdup tank to be processed and determining the parameter(s) that are out of specification. Selection of the appropriate vessels is made by a quick-disconnect logic arrangement. After processing, decontaminated effluent passes through an Effluent Control Leg which records waste volume.

9.3.6.3.1.9 Recycle Holdup Tank Vent Ejector

The ejector is designed to pull gases from under the diaphragm in a recycle holdup tank and deliver them to the gaseous waste processing system. Nitrogen, provided by the standby waste gas compressor, provides the motive force.

9.3.6.3.1.10 Valves

The basic material of construction for most valves is stainless steel. All valves are welded to the piping except the three-way and relief valves, which are flanged. All three-way valves are provided with a stuffing box and lantern leakoff connections. The relief valve upstream of the recycle evaporator feed demineralizers protects the piping which feeds these demineralizers.

9.3.6.3.1.11 Piping

Piping that handles radioactive liquid is austenitic stainless steel. All piping joints and connections are welded, except where flanged connections are required to facilitate equipment removal for maintenance and hydrostatic testing. Stainless steel flex hose is used in a portion of the system.

9.3.6.3.2 System Operation

The BRS is manually operated with the exception of a few automatic protection functions. These automatic functions protect the recycle evaporator feed demineralizers from a high inlet temperature and a high differential pressure, prevent a high vacuum from being drawn on the recycle holdup tank diaphragm and protect the recycle evaporator feed pumps from low net positive suction head. The BRS has sufficient instrumentation readouts and alarms to provide the operator information to assure proper system operation.

9.3.6.3.2.1 Demineralization

Water is accumulated in the recycle holdup tank until sufficient quantity exists to warrant processing through the Reactor Grade Demineralizer System demineralizers. Prior to cleanup operation the contents of the recycle holdup tank are analyzed and if required the demineralizer sequence or resin mix adjusted. Following processing by the demineralizers the flow is sent to the waste monitor tank for discharge to the environment. When the water has been sufficiently processed, it is discharged via the waste monitor tank into the penstocks of the Fairfield Pumped Storage Facility at a rate so as not to exceed a small fraction of the 10 CFR 20 limits. Water leaving this system is monitored for radiation. This radiation monitor, RM-L5, is described in

Section 11.4. Should the radiation monitor close the discharge valve, it must be reset/bypassed before the valve can be reopened.

9.3.6.3.2.2 Recycle Holdup Tank Venting

Because hydrogen is dissolved in the reactor coolant at approximately 1 atmosphere overpressure, a portion of the hydrogen along with fission gases will come out of solution in the recycle holdup tank under the diaphragm. The hydrogen and fission gases are vented to the gaseous waste processing system as required. The total integrated flow from the letdown line and the reactor coolant drain tank to the recycle holdup tanks is monitored. An alarm indicates when a sufficient amount of water has passed to the recycle holdup tanks to require venting of the accumulated gases. A recycle holdup tank should also be vented before and after a RCS loop drain or a drain from the spent fuel pool (or fuel transfer canal).

When venting of either recycle holdup tank is required, the following steps are observed:

1. All inlets to the recycle holdup tank are closed.
2. The recycle holdup tank is lowered to less than or equal to 15%.
3. Both waste gas compressors are lined up to the recycle holdup tank vent ejector.
4. The compressors are started up and the vent from the holdup tank is opened. The vent flow is throttled to approximately 1.2 scfm. At this time, a sample of the vent gases can be taken to check the composition.
5. When the gases have been vented from the recycle holdup tank, the pressure in the vent line decreases, which automatically trips the recycle holdup tank vent isolation valve closed.
6. After the vent isolation valve closes, the manual vent valve is closed, the gas compressor is shut down, and the recycle holdup tank inlets and outlets are lined up for normal use.

9.3.6.3.2.3 Maintenance Drains

When large amounts of water must be drained from the RCS or the spent fuel pool (or fuel transfer canal) to the BRS, a recycle holdup tank is drained of water and vented to the gaseous waste processing system. The water can then be stored in this tank until maintenance is completed and, after checking the chemistry, returned. After returning the water, the recycle holdup tank is again vented to the gaseous waste processing system where it is directed to a shutdown gas decay tank to prevent accumulation of air (i.e., nitrogen) in the high activity gas decay tanks during the venting.

9.3.6.3.2.4 Reactor Makeup Water Cleanup

If the reactor makeup water requires purification, it can be recirculated through the recycle evaporator condensate demineralizer until its chemistry is within specifications. If further processing is necessary, water from the reactor makeup water storage tank can be directed through the recycle evaporator condensate demineralizer and into the recycle holdup tanks for processing via the RGWS demineralizers.

9.3.6.4 Safety Evaluation

Malfunctions in the BRS do not affect the safety of station operations. The BRS is designed to tolerate equipment faults with critical functions being met by the use of 2 pieces of equipment so that the failure of 1 will, at most, reduce the capacity of the BRS but not completely shut it down. Because of the large surge capacity of the BRS, the nonavailability of the RGWS demineralizers can be tolerated for periods of time.

9.3.6.5 Tests and Inspections

The BRS is in intermittent use throughout normal reactor operation. Periodic visual inspection and preventive maintenance are conducted using normal industry practice.

9.3.6.6 Instrumentation Application

The instrumentation available for the BRS is discussed below. Alarms are provided as noted. There is also a common alarm on the main control board which indicates any alarms on the BRS panel.

9.3.6.6.1 Temperature at Inlet to the Recycle Evaporator Feed Demineralizer

Instrumentation is provided to measure the temperature of the inlet flow to the recycle evaporator feed demineralizers and to control a three-way bypass valve. If the inlet temperature becomes too high, the instrumentation aligns the valve to bypass the demineralizers. Local temperature indication and a high temperature alarm on the BRS panel are provided by this instrumentation.

9.3.6.6.2 Pressure

1. Pressure Differential Across the Recycle Evaporator Feed Demineralizers

   Instrumentation is provided to measure the pressure differential across the recycle evaporator feed demineralizers and to control the same three-way valve as discussed above (but independently of the temperature control). If the pressure drop through the demineralizers is too high, this instrumentation aligns the valve to divert flow directly to the recycle evaporator feed filters. Local pressure differential indication and a high alarm on the BRS panel are provided by this instrumentation.

2. Pressure at Inlet and Outlet of Filters

   Instrumentation is provided to measure the pressure differential across each recycle evaporator feed filter, the recycle evaporator concentrates filter, and the recycle evaporator condensate filter. Local indication of the pressure in each inlet and outlet line is provided.

3. Pressure at Discharge of Recycle Evaporator Feed Pump

Instrumentation is provided to measure and give local indication of the discharge pressure of each recycle evaporator feed pump.

4. Pressure in Vent Line from the Recycle Holdup Tanks

   Instrumentation is provided to measure the pressure in the recycle holdup tank vent line and to control a shutoff valve in the vent line. This instrumentation is used during holdup tank venting operations. When the pressure in this line becomes too low, the valve will be automatically closed to protect the holdup tank diaphragm from an excessive differential pressure across it. Local pressure indication and low pressure alarm on the BRS panel are provided.

9.3.6.6.3 Flow

1. Boron Recycle System Flow Totalizer

   Instrumentation is provided to monitor the total integrated flow received by the BRS from the letdown line (CVCS) and the reactor coolant drain tank (waste processing system). Indication of integrated flow and high alarm are given on the BRS panel. Actuation of the high alarm indicates that the integrated flow has reached a value at which the volume of gases (hydrogen and fission gases) which have come out of solution should be vented from the recycle holdup tanks.

2. Flow in Vent Line from Recycle Holdup Tanks

   Instrumentation is provided which gives local indication of the recycle holdup tank vent purge flow.

3. Flow in Feed Line to the RGWS Demineralizers

   Instrumentation is provided which gives local indication of RGWS demineralizers feed flow.

9.3.6.6.4 Level in the Recycle Holdup Tanks

Instrumentation is provided to give an indication of the water level of each recycle holdup tank. Both high level and low level alarms are provided by this instrumentation at the BRS panel. If, after reaching the low level alarm setpoint, the recycle evaporator feed pumps are not stopped, the holdup tank level will continue to decrease until a second low level point is reached and a level actuated control circuit stops the pumps.

9.4 AIR CONDITIONING, HEATING, COOLING, AND VENTILATION SYSTEMS

9.4.1 Control Building Area Ventilation System

Air conditioning, heating, cooling and ventilating systems are provided for the control room and other Control Building areas to satisfy the following general requirements:

1. To maintain ambient air temperatures in all areas as required for the comfort andsafety of personnel.
2. To satisfy environmental requirements of equipment.
3. To meet the radiation control requirements of 10 CFR 20.
4. To satisfy the design requirements of General Design Criterion 19, relative to the control room.

9.4.1.1 Design Bases

The systems for the Control Building areas are designed in accordance with the following:

1. The general requirements indicated in Section 9.4.1 are satisfied.
2. Equipment, motors and controls in Safety Class 2b systems are supplied from Class 1E power sources and are separated and redundant to meet the single failure criteria.
3. Instrumentation and control is provided to detect abnormal conditions, such as smoke, high temperature or high radiation levels which require operation in a recirculation mode, emergency filtration mode or outside air purging mode.
4. Operation, monitoring and control of these systems, except for the NNS cooling for office space, in the control room is provided.

9.4.1.2 System Description

The system diagrams for the various Control Building area systems are provided by the following figures:

1. Figure 9.4-1, Control Room System.
2. Figure 9.4-2, Relay Room System and Computer Room System.
3. Figure 9.4-3, Controlled Access Area Supply System and Miscellaneous Room Systems.
4. Figure 9.4-4, Controlled Access Area Exhaust System.
5. Figure 9.4-5, Computer Rooms and SAS Room Cooling System.

Design and performance data are indicated on these figures.

9.4.1.2.1 Control Room System

The main components of this system include:

1. Two (2) 100% capacity air handling units, each with roughing filters (80% efficiency on National Bureau of Standards (NBS) dust), chilled water cooling coil, face and bypass damper section and fan section.
2. Electric reheat coils in the supply ducts.
3. Redundant supply, return, relief and outside air ducts, including necessary fire dampers.
4. Two (2) 100% capacity emergency filter systems, each with filter plenum fan, filter train consisting of roughing filters (80% efficiency on NBS dust), HEPA filters (99.97% efficiency on 0.3 micron particles), charcoal filters (95% efficiency on methyl iodide at 70% relative humidity, 77°F) and final HEPA filters (same efficiency as previous HEPA filter). Each filter plenum also includes a water deluge system.

   The control room emergency filter plenums have been nominally sized for a capacity of 20,000 cfm (21,270 cfm as built) each. The individual filter banks of each plenum have been sized as follows:

   a. Roughing filters: 15 units at 2000 cfm each. Total capacity 30,000 cfm.
   b. HEPA filters: 15 units at 1500 cfm each. Total capacity 22,500 cfm.
   c. Charcoal filters: 11 vertical beds at 2000 cfm each. Total capacity 22,000 cfm.
5. Air operated, spring opposed dampers to isolate the emergency filter systems when not in use; in the face and bypass damper sections of the air handling units; and in the relief air ducts. Air operated butterfly valves with the safety related air accumulators are located in outside air ducts.
6. Instrumentation and control devices to perform the following functions:
   a. Measure pressure drop across normal and emergency filter banks (local indication only).
   b. Cause an alarm in the control room upon detection of high concentration of smoke in the air handling unit return duct or in the emergency filter return duct.
   c. Cause an alarm in the control room upon detection of high temperature in the discharge duct or in the emergency filter charcoal bed.
   d. Indicate, in the control room, the air flow rate in the outside air duct.
   e. Indicate, in the control room, the position of the outside air valves, relief dampers and the emergency filter system isolation dampers.
   f. Provide means for automatically placing the system in the emergency mode and starting the emergency filter system upon receipt of safety injection or high radiation signal from the gaseous activity channel of RM-A1. Provide means to automatically start the normal air handling units and emergency filter fans following loss of offsite power.

g. Provide means, in the control room, for manually initiating system damper positioning for the emergency modes of operation and starting the emergency filter system.

h. Provide means, in the control room, for manually overriding the emergency mode of system operation and to indicate, in the control room, that system override is in effect.

i. Maintain positive control room pressure by adjusting outside air valves. Control room pressure in excess of system setpoints causes an alarm in the control room.

j. Automatically maintain control room temperature by modulating face and bypass damper position and an electric reheat coil in the supply duct.

k. Automatically maintain control room humidity by controlling a humidifier.

l. Indicate, in the control room, air handling unit or emergency filter fan operation.

The system continuously supplies filtered, cooled or heated air to the control room, the technical support center and the cable spreading area under the control room, during normal conditions. Filtered and cooled air is provided during post accident and loss of offsite power conditions. By operation of either one of the two supply air trains, and control of the proper dampers and valves, the system admits small amounts of outside make-up air to the control room to maintain positive pressure during normal and emergency operation, or admits 100% outside air during purge mode. The system maintains space temperature by automatically varying the volume of air passing through the cooling coil and by energizing circuits in the electric reheat coil. The cooling coil is supplied with chilled water from the safety class Chilled Water System (see Section 9.4.7.2.4).

Upon receipt of a safety injection or high radiation signal from the gaseous activity channel of RM-A1, the system automatically places the dampers in the emergency mode and starts the normal air handling unit and emergency filter fan. A loss of offsite power causes the air handling units and emergency filter fans to start automatically. In the event of loss of offsite power, the system can be manually reset for normal operation. Operation of the emergency filter fans passes control room return air through the emergency filter system. Normal operation of the system is accomplished using manual switches in the control room.

The mechanical components, control devices and supply and return ductwork are redundant and separated to ensure system availability. Each system component requiring electrical power is supplied from the Class 1E electrical system. Both systems are supplied with required instrument air from the non-nuclear safety class instrument air system. Since instrument air is not safety-related, system design is such that failure of instrument air will not inhibit system operation in the safety related mode.

During normal operation control room air is recirculated through the control room toilets and kitchen, via an exhaust fan and carbon filter, and is discharged into the return ductwork.

9.4.1.2.2 Relay Room System

The main components of this system include:

1. Two (2) 100% capacity air handling units, each with roughing filters (80% efficiency on NBS dust), face and bypass section, chilled water cooling coil and fan section.
2. Electric reheat coils in the supply duct.
3. Redundant supply, return, relief and outside air ducts.
4. Air operated, spring opposed dampers in the face and bypass damper sections of the air handling units and in the return and relief air ducts.
5. Instrumentation and control devices in each system to perform the following functions:
   a. Measure the pressure drop across the air handling unit filter bank (local indication only).
   b. Cause an alarm in the control room upon detection of high air temperature in the discharge duct and upon detection of high or low temperature in the relay room.
   c. Indicate, in the control room, damper position for the outside air dampers and relief air dampers.
   d. Provide means for automatically placing the system in the emergency recirculation mode (close outside air and relief dampers and open return dampers) and starting the air handling units upon receipt of a safety injection signal or high radiation signal from the gaseous activity channel of RM-A1. Loss of offsite power starts the air handling units but does not cause dampers to be positioned for operation in the recirculation mode.
   e. Provide means for manually initiating system damper positioning for the emergency recirculation mode of operation.
   f. Provide means for manual control of outside, return, and relief damper position.
   g. Automatically maintain relay room temperature by modulating face and bypass damper position and an electric reheat coil in the supply duct.
   h. Indicate, in the control room, air handling unit operation.

The system continuously supplies filtered, cooled, or heated air to the relay room under normal conditions. Filtered and cooled air is provided under post accident and loss of offsite power conditions. By operation of either 1 of the 2 supply air trains and by automatic control of the proper dampers, the system admits fixed amounts of outside ventilation air, no outside air (i.e., recirculation mode), or 100% outside air (i.e., purge mode). The system maintains space temperature by automatically varying the volume of air passing through the cooling coil and by energizing circuits in the electric reheat coil. The cooling coil is supplied by the safety class Chilled Water System (see Section 9.4.7.2.4). Upon receipt of a safety injection or high radiation signal from the gaseous activity channel of RM-A1, the system automatically positions the outside air dampers for the recirculation mode. Receipt of an ESFLS signal starts the fans in both air handling units. The units are normally operated from the control room. Mechanical components, controls, duct system redundancy, separation, power supply, and equipment location are the same as for the control room system, discussed in Section 9.4.1.2.1.

9.4.1.2.3 Computer Room System

The main components of this system include:

1. Two (2) 100% capacity air handling units, each with roughing filters (80% efficiency on NBS dust), face and bypass section, chilled water cooling coil and fan section. Chilled water is provided by the Non-nuclear Safety Related Chilled Water System. See Section 9.4.7.2.12.
2. Electric reheat coils in the supply duct.
3. Redundant supply, return, relief, and outside air ducts.
4. Air operated, spring opposed dampers in the face and bypass damper sections of the air handling units and in the outside, return, and relief air ducts.
5. Instrumentation and control devices to perform the following functions:
   a. Measure the pressure drop across the air handling unit filter bank (local indication only).
   b. Cause an alarm in the control room upon detection of high air temperature in the discharge duct and upon detection of high or low temperature in the computer room.
   c. Indicate, in the control room, damper position for the outside air dampers and relief air dampers.
   d. Provide means for manually initiating system damper positioning for recirculation mode of operation.
   e. Provide means for manual control of outside, return, and relief damper position.
   f. Automatically maintain computer room temperature by modulating face and bypass damper position, and an electric reheat coil in the supply duct.
   g. Indicate, in the control room, air handling unit operation.
   h. Provide means for automatically placing system dampers in the emergency recirculation mode positions (close outside air and relief dampers) upon receipt of a safety injection signal or high radiation signal from the gaseous activity channel of RM-A1.
   i. Automatically maintain constant computer room relative humidity by controlling a humidifier.

The system continuously supplies filtered, cooled, or heated air to the computer room under normal and post accident conditions if offsite power is available. By operation of either 1 of the 2 supply air trains and by automatic control of the proper dampers, the system admits fixed amounts of outside ventilation air, no outside air (i.e., recirculation mode), or admits 100% outside air (i.e., purge mode). The system maintains space temperature by automatically varying the volume of air passing through the cooling coils and by energizing circuits in the electric reheat coil. The cooling coil is supplied by the non-nuclear safety related Chilled Water System. Upon receipt of a safety injection or high radiation signal, the system dampers are automatically placed in the recirculation mode position, and the system continues to operate if normal power is available. Upon receipt of an ESF signal, the system dampers are automatically placed in the recirculation mode position

with the fan motors blocked from operation until manually reset. The units are connected to Class 1E power buses. The units are normally operated from the control room.

9.4.1.2.4 Controlled Access Area Supply System

The main components of this system include:

1. A 100% capacity air handling unit including roughing filters (80% efficiency on NBS dust), electric preheating coil, fan section, coil section with chilled water coil and electric heating coil, and a hot and cold deck zoning damper section. Chilled water is provided by the Non-nuclear Safety Related Chilled Water System. See Section 9.4.7.2.12.
2. A 100% capacity sample room and radiochemical laboratory hood supply fan.
3. Outside air, zone supply and hood supply ducts.
4. Air operated, spring opposed dampers to isolate the controlled access air handling unit and laboratory hood supply fan when not in use; in the air handling unit zoning damper section; and in the outside air intake duct.
5. Fire dampers in the zone supply ducts.
6. Instrumentation and control devices in each system to perform the following functions:
   a. Measure the pressure drop across the filter bank (local indication only).
   b. Cause an alarm in the control room upon detection of high temperature in the hood fan discharge duct or in the air handling unit supply duct to Zone II.
   c. Cause an alarm in the control room upon detection of high concentration of smoke in the laboratory hood supply fan discharge, or in the air handling unit supply duct to Zone II.
   d. Indicate, in the control room, the operating status of the laboratory hood supply fan and position of the isolation dampers.
   e. Interlock the position of the dampers with supply fan operation.
   f. Provide permissive interlocks so that controlled access air handling unit and the laboratory hood supply fan cannot operate unless control access filter exhaust fans are operating.
   g. Provide interlocks so that the outside air isolation dampers close on receipt of safety injection signal.
   h. Automatically maintain space temperature in each of four zones by modulating zoning dampers in the hot and cold decks of the air handling unit and by controlling the electric heating coil in the hot deck.
   i. Automatically maintain space temperature downstream of the preheat coil by energizing circuits of this coil as required by the temperature controller.
   j. Indicate, in the control room, the operating status of the air handling unit and the position of associated outside air dampers.

k. Measure and indicate locally, the differential pressure between the controlled access area and the outside and alarm in the control room upon detection of a high or low differential.

The system continuously supplies filtered, cooled or heated air to 4 zones of the controlled access area under normal and post accident conditions if offsite power is available. The system is connected to Class 1E buses. The air handling unit supplies a mixture of makeup and outside air. The laboratory hood supply fan furnishes air from the Turbine Building. The controlled access area ambient pressure and temperatures are controlled, and the various system motors are interlocked as indicated in the listing of instrumentation and control devices above. The cooling coils are each supplied from the NNS Chilled Water System. The air handling unit is located in the Control Building equipment area. The laboratory hood supply fan is located in the Turbine Building. The air handling unit and the laboratory hood supply fan is manually operated from the control room.

9.4.1.2.5 Controlled Access Area Exhaust System

The main components of the system include:

1. A 100% capacity controlled access area filter plenum, including roughing filters (80% efficiency on NBS dust), HEPA filters (99.97% efficiency on 0.3 micron particles), charcoal filters (95% efficiency on methyl iodide at 85% relative humidity and 70°F), and final HEPA filters (same efficiency as previous HEPA filters). The filter plenum also includes a water deluge system.
2. Two (2) 100% capacity controlled access area filter exhaust fans.
3. Exhaust ducts from controlled access areas to the filter plenum, exhaust fans, and plant vent.
4. Air operated, spring opposed dampers to isolate the exhaust fans when not in use.
5. Fire dampers in zone exhaust ducts.
6. Instrumentation and control devices for each component to perform the following functions:
   a. Measure the pressure drop across each filter bank (local indication only).
   b. Cause an alarm in the control room upon detection of high concentration of smoke at the filter inlet.
   c. Cause an alarm in the control room upon detection of high air temperature in the filter fan discharge ducts.
   d. Cause an alarm in the control room upon detection of high temperature of the plenum discharge air or in the filter charcoal bed.
   e. Indicate, in the control room, the position of the filter exhaust fan isolation dampers and interlock damper position with exhaust fan operation.
   f. Indicate, in the control room, exhaust fan operation.

The system operates continuously under normal conditions and emergency conditions if power is available. Power for the controlled access area exhaust and the laboratory hood exhaust fans is

normally supplied from the Class 1E bus. The system exhausts and filters air from normal and hot toilet, shower and locker areas, laundry areas, laboratory hood areas, count room, medical room, and storage areas of the controlled access area. After being filtered, the exhaust air is directed by either of the operating exhaust fans to the main plant vent. The controlled access area filter plenum and exhaust fans are in a shielded location in the Control Building. The exhaust fans are manually operated from the control room.

9.4.1.2.6 SAS/CPU Computer Rooms Cooling System

The main components of this system include:

1. A 32% capacity air handling unit (XAH-18-AH), including roughing filters (80% efficiency on NBS dust), coil face, bypass dampers, coil section with chilled water coil, and fan section. Chilled water is provided by the Non-nuclear Safety Related Chilled Water System. See Section 9.4.7.2.12.
2. A 68% capacity air handling unit (XAH-51-AH), including filters, coil section with R-22 refrigerant coil, and fan section.
3. Electric reheat coils in the supply duct.
4. Supply, return, relief, and outside air ducts.
5. Air operated, spring opposed dampers in the outside air, relief air, and return air ducts.
6. Instrumentation and control devices to perform the following functions:
   a. Measure the pressure drop across the air handling unit XAH-18-AH filter bank (local indication only).
   b. Cause an alarm in the control room upon detection of high air temperature in the air handling unit XAH-18-AH discharge.
   c. Cause an alarm in the control room upon detection of high or low SAS/CPU computer rooms space temperature.
   d. Indicate, in the control room, damper position for the outside air, return air, and the relief air dampers.
   e. Provide means for manual control from the control room of the outside, return, and relief damper positions.
   f. Provide means for automatically placing the system in the emergency recirculation mode (close outside air and relief dampers and open return dampers) upon receipt of a safety injection signal or high radiation signal (RM-A1).
   g. Automatically maintain SAS/CPU computer rooms temperature by modulating coil face and bypass damper position and an electric reheat coil in the supply duct.
   h. Interlock the reheat coil so it is inoperative when its corresponding air handling unit fan is not energized.
   i. Indicate, in the control room, air handling unit operation (XAH-18-AH only).

j. Automatically shut down air handling unit XAH-18-AH and XAH-51-AH upon halon release to either computer room or the SAS room.

The system continuously supplies filtered, cooled or heated air to the SAS/CPU computer rooms when normal power is available. Outside air flow is manually controlled from the control room. The room temperature is maintained and system dampers are operated as indicated by the listing of instrumentation and control devices, above. The cooling coil in XAH-18-AH is supplied from the non-nuclear safety related Chilled Water System. The XAH-18-AH air handling unit is located in the Control Building equipment area. The units XAH-18-AH and XAH-51-AH, and the outside, return and relief dampers are manually operated from the control room. The cooling coil in XAH-51-AH is supplied from condensing unit XRC-24-AH. The XAH-51-AH air handling unit is located in the Control Building on elevation 436’-0”.

9.4.1.2.7 Microwave Relay Room System

The major components of the microwave relay room system include the following:

1. A 100% capacity air conditioning unit, including refrigeration system, electric heating coil, and fan.
2. Supply and return air ducts.
3. Filter-grille with roughing filter (30% efficiency on NBS dust).
4. Instrumentation and control devices to perform the following functions:
   a. Cause an alarm in the control room upon detection of high or low microwave relay room space temperature.
   b. Automatically maintain microwave relay room temperature by cycling the refrigeration system and the electric heating coil in the air conditioning unit.

The system continuously supplies filtered, cooled or heated air to the microwave relay room when normal power is available. This is a total recirculation system with no outside/exhaust air. Room temperature is maintained by the instrumentation and control devices noted above. The refrigeration system is self-contained and is air cooled. The air conditioning unit is located on the Control Building roof.

9.4.1.2.8 Microwave Battery Room System

Major components of the microwave battery room system include the following:

1. A 100% capacity exhaust fan.
2. A 100% capacity outside air intake head.
3. Supply and exhaust air ducts.
4. Filter-grille with roughing filter (30% efficiency on NBS duct).
5. Instrumentation and control devices to perform the following functions:

a. Cause an alarm in the control room upon detection of high or low microwave battery room space temperature.

b. Automatically maintain minimum microwave battery room temperature by cycling the electric unit heater.

c. Provide means to shift exhaust fan from low speed to high speed when outside air temperature exceeds the setpoint temperature.

The system continuously exhausts air from the microwave battery room to the atmosphere when normal power is available. Makeup air enters the space through louvers in the battery room door adjoining the corridor space. Outside air is drawn into the corridor space through an intake head and filter-grille in the corridor roof. An electric unit heater, located in the corridor heats the air as necessary to maintain the desired minimum microwave battery room space temperature. Equipment is located on the microwave battery room roof.

9.4.1.2.9 Control Building Office Space System

The major components of the Control Building office space cooling system include the following:

1. A 100% capacity air handling unit with roughing filter and refrigerant coil.
2. A 100% capacity remotely mounted condensing unit, including refrigerant compressor and controls.
3. Ductwork between the air handling unit and the office space for supply and return. The function of this system is to provide cooling for personnel comfort.
4. A 100% capacity electric unit heater.

9.4.1.2.10 Control Building Elevator Machine Room System

Major components of the Control Building elevator machine room system include the following:

1. A 100% capacity exhaust fan.
2. Fixed, wall inlet louvers.
3. A 100% capacity electric unit heater.
4. Instrumentation and control devices to perform the following functions:
   a. Automatically limit maximum elevator machine room temperature by cycling the exhaust fan.
   b. Automatically limit minimum elevator machine room temperature by cycling the electric unit heater.

The system cyclically exhausts air from the elevator machine room to the atmosphere in response to a room thermostat when normal power is available. Makeup air enters the room through wall

louvers. A built-in thermostat cycles the electric unit heater to maintain minimum room temperature. Equipment is located in the Control Building elevator machine room.

9.4.1.3 Safety Evaluation

The control room and relay room systems are designed, protected and arranged with sufficient redundancy to ensure system cooling and filtering operation after a LOCA, assuming a single failure. Loss of the nonredundant instrument air results in decreased space temperatures which do not adversely affect installed equipment. The control room and relay room areas are independent of each other. Each area is served by 2, separated, independent HVAC and filtering subsystems supplied from separate Class 1E electric power supplies. Each system is served by separate instrumentation for control and monitoring. This equipment is Seismic Category 1, located in a Seismic Category 1 structure, and is not subject to floods, weather, external missiles, jet impingement or pipe whip.

The equipment areas are separated by fire walls. Ducts from equipment areas to the control room and relay room are protected by fire dampers. Thus, fire in either equipment area is isolated to that area and operation of the standby system is not affected.

The gaseous activity channel of RM-A1 automatically closes the outside air dampers of the relay room places both systems in the recirculation or emergency mode upon detection of high activity in the air supplied to the control room. High temperature in the supply ducts to the control room and to the relay room or in the discharge duct from the emergency filter system causes an alarm to be actuated in the control room. Smoke in the return duct from the control room to the normal and emergency filter air handling systems causes an alarm to be actuated in the control room. Air flow rates in the outside air ducts to the control room and to the relay room are indicated in the control room.

During normal and emergency operation, the control room is pressurized through the introduction of a fixed amount of outside air. The flow of outside air to the relay room is fixed but is manually adjustable. In the emergency mode control room air is filtered through roughing, HEPA and charcoal filters. Recirculated relay room air is not filtered.

For smoke removal, system dampers for both control and relay room systems can be positioned manually to purge with outside air at rates up to 100%. Prior to purging the control room, the chlorine bottles in the chlorine shed, if installed, must have their cylinder valves closed, then the relief damper blanking plates and outside air duct blanking plates must be removed in conjunction with closing the system return air damper. Degradation of equipment performance as a result of excess temperature and humidity is not anticipated since the control and relay room systems are designed in accordance with the criteria specified above.

9.4.1.4 Inspection and Testing Requirements

The Control Building area systems are subjected to preoperational testing in accordance with written procedures to verify proper wiring and control hookup, filter and duct system in place

integrity and leak tightness, proper function of system components and control devices and to establish system design water and air flow rates.

To ensure a continued state of readiness of the Control Building area systems after completion of the preoperational tests, the following inspection, maintenance and test procedures are performed.

1. Control Room System
   a. Record filter pressure drops.
   b. Verify function of dampers, valves and control devices necessary for monitoring or component isolation or changeover from normal to emergency mode.
   c. Bearing lubrication.
   d. Switch components that normally operate from standby to operating mode
   e. Laboratory test of charcoal filter test canisters for decontamination efficiency.
   f. Inplace leak test of the HEPA and charcoal filters.
2. Relay Room System

   Relay room system inspection, maintenance and test requirements are the same as control room system requirements a. through d.

3. Computer Room System

   Computer room system inspection, maintenance and test requirements are the same as control room system requirements a. through d.

4. Controlled Access Area Supply System

   Controlled access area supply system inspection, maintenance and test requirements are the same as control room system requirements a. through d.

5. Controlled Access Area Exhaust System

   Controlled access area exhaust system inspection, maintenance and test requirements are the same as control room system requirements a. through f.

6. SAS/CPU Computer Room Cooling System

   SAS/CPU Computer room cooling system inspection, maintenance and test requirements are the same as control room system requirements a. and c.

7. Microwave Relay Room System

Microwave relay room system inspection, maintenance and test requirements are the same as control room system requirement c.

8. Microwave Battery Room System

   Microwave battery room system inspection, maintenance and test requirements are the same as control room system requirement c.

9. Control Building Elevator Machine Room System

   Control Building elevator machine room system inspection, maintenance and test requirements are the same as control room system requirement c.

9.4.2 Auxiliary and Radwaste Area Ventilation System

Heating, cooling, ventilation, exhaust and filtering are provided throughout various Auxiliary Building, radwaste and hot machine shop areas to satisfy the following general requirements:

1. Maintain ambient air temperatures in all areas between minimum and maximum levels suitable for personnel and equipment.
2. Minimize the release of radioactive airborne particulates and gaseous activity to the atmosphere.
3. Provide for filtration of the refueling water storage tank vent discharge.

9.4.2.1 Design Bases

The systems for the Auxiliary Building and radwaste areas are designed in accordance with the following:

1. The general requirements indicated in Section 9.4.2 are satisfied.
2. Equipment, motors and controls in the Safety Class 2b portions of these systems are supplied from Class 1E electric power sources and have sufficient separation and redundancy to satisfy the single failure criteria.
3. Provision is made for monitoring and actuating alarms in the control room upon detection of: high temperature in ducts, HEPA/charcoal plenums, or pump cubicles; high smoke concentration in ducts; high vibration at fan motors; and motor trip. Provisions are also made for monitoring the following in the control room: damper positions, main plant vent flow rate, and radiation levels in the main plant vent (RM-A3) and waste gas decay tank vent (RM-A10).
4. Manual control of these systems as indicated is provided in the control room. Pump room units operate automatically when the respective pump operates.

5. Continuous, controlled air flow is maintained from areas of low to progressively higher radiation levels. Maintenance of a negative Auxiliary Building pressure ensures that exfiltration from the Auxiliary Building does not occur.
6. Exhaust air flows through roughing and HEPA filters or through roughing, HEPA, charcoal and HEPA filters, depending upon the potential radioactivity of the areas exhausted.

9.4.2.2 System Description

The system diagrams for the various auxiliary building and radwaste area systems are as follows:

1. Figure 9.4-6, Auxiliary Building Main Supply System.
2. Figure 9.4-7, Auxiliary Building HEPA Exhaust System.
3. Figure 9.4-8, Auxiliary Building Charcoal Exhaust System.
4. Figure 9.4-9, Auxiliary Building Main Exhaust System.
5. Figure 9.4-10, Auxiliary Building Pump Room and Motor Control Center Cooling Systems
6. Figure 9.4-10a, Hot Machine Shop Ventilation System.
7. Figure 9.4-11, Fuel Handling Building Charcoal Exhaust System and Air Supply Distribution

9.4.2.2.1 Auxiliary Building Main Supply System

The main components of this system include:

1. A 100% capacity supply fan directing ventilation air to various areas of the Auxiliary Building, radwaste areas and to the Fuel Handling Building.
2. Two (2) 50% capacity supply air filter plenums, each consisting of roughing filters (80% efficiency on NBS dust) and electric preheat coils.
3. Electric reheat coils in the zone supply ducts.
4. Air operated, spring opposed dampers to isolate the supply fan when not in use and to close or control the outside air supply.
5. Ductwork from the outside air connection to the filtering and preheating plenums, to the supply fan and to the various Auxiliary Building and radwaste areas.
6. Instrumentation and control devices to perform the following functions:
   a. Measure the pressure drop across the roughing filter banks (local indication only).
   b. Cause an alarm in the control room upon detection of high concentration of smoke in the supply main to the various Auxiliary Building areas.
   c. Cause an alarm in the control room upon detection of high temperature in the supply main to the various Auxiliary Building areas.
   d. Indicate, in the control room, supply fan isolation damper and outside air damper position.

e. Cause an alarm in the control room upon detection of excessive vibration of the supply fan.

f. Cause an alarm in the control room upon detection of high or low Auxiliary Building ambient air pressure.

g. Provide means for manual operation, from the control room, of the supply fan interlocked with its isolation dampers and with the main exhaust fan.

h. Automatically maintain minimum supply air temperature by controlling the supply system preheat coils and provide interlocks to prevent preheat coil operation unless supply fans are operating.

i. Automatically maintain fixed zone supply air temperature by controlling the zone reheat coils.

j. Maintain negative ambient static pressure within the Auxiliary Building by the setting of manual balancing dampers.

k. Indicate, in the control room, supply air fan operation.

l. Cause an alarm in the control room upon detection of supply air fan motor trip.

The Auxiliary Building main supply system continuously supplies outside air that is drawn through the Auxiliary Building supply air plenums where it is filtered and heated as required. The supply air is then ducted to various corridors, demineralizer tank areas, gas decay tank and holdup tank areas, valve areas, and stand-by air compressor area at elevations 485', 463', 436', 412', 397', 388', and 374'. This supply air is then drawn by various exhaust systems through equipment areas and through equipment cubicles. The supply air distribution is arranged so that the resultant exhaust air flow is toward progressively greater levels of activity. The Auxiliary Building supply air fan is manually controlled from the control room and operates continuously if normal power is available. The supply fan is electrically interlocked so that it cannot operate unless one of the Auxiliary Building main exhaust fans is operating, thereby ensuring that the Auxiliary Building ambient pressure does not become positive. The components for this system are located as follows:

1. Supply fan in the Auxiliary Building.
2. Filtering and heating plenums in the Auxiliary Building.

Outside air is drawn into the system through stormproof louvers in a mechanical equipment room roof penthouse.

9.4.2.2.2 Auxiliary Building HEPA Exhaust System

The main components of this system include:

1. Two (2) 100% capacity exhaust fans which exhaust air through the HEPA filter plenum.

2. A 100% capacity filter plenum with roughing filters (80% efficiency on NBS dust) and HEPA filters (99.97% efficiency on 0.3 micron particles).
3. Air operated, spring opposed dampers to isolate the exhaust fans when not in use.
4. Ductwork to direct the exhaust air from various Auxiliary Building areas to the HEPA filter plenum, the exhaust fans and, finally, to the plant vent.
5. Instrumentation and control devices to perform the following functions:
   a. Measure the pressure drop across the roughing/HEPA filter banks (local indication only).
   b. Cause an alarm in the control room upon detection of high concentration of smoke at the inlet of the exhaust filter plenum.
   c. Cause an alarm in the control room upon detection of high temperature in the discharge of either exhaust fan.
   d. Indicate, in the control room, fan isolation damper position.
   e. Cause an alarm in the control room upon detection of excessive vibration of the exhaust fans.
   f. Provide means for manual operation, from the control room, of the exhaust fans interlocked with their respective isolation dampers and with the Auxiliary Building charcoal exhaust fans.
   g. Indicate, in the control room, exhaust fan operation.
   h. Cause an alarm in the control room upon detection of exhaust fan motor trip.

The Auxiliary Building exhaust system continuously exhausts the air furnished by the supply system described in Section 9.4.2.2.1. The exhaust air is drawn from auxiliary building areas with minimum potential for contamination at elevations 485', 463', 436', 412', 388', and 374'. The supply and exhaust ducts are arranged so that air flow is always in the direction of progressively greater potential radioactivity. The exhaust air from these areas is continuously drawn through the roughing/HEPA filter plenum prior to ducting to the main exhaust fans and the main plant vent. There is no bypass around this filter plenum. The exhaust fans for this system are manually controlled from the control room and operate continuously if normal power is available. The HEPA exhaust fans are electrically interlocked so that they cannot be operated unless the Auxiliary Building charcoal exhaust fans are in operation. Thus, exhaust flow is always toward the potentially more radioactive areas. The components for this system are located as follows:

1. Exhaust fans, in the Auxiliary Building.
2. Filter plenum, in the Auxiliary Building.

9.4.2.2.3 Auxiliary Building Charcoal Exhaust System

The Auxiliary Building charcoal exhaust system consists of 2 subsystems, one which serves the north portion of the building and the other which serves the south portion of the building. Each subsystem provides approximately 50% of the total building filtration.

The main components of this system include:

1. Two (2) 100% capacity exhaust fans for each subsystem which exhaust air through the HEPA/charcoal plenum.
2. One (1) 100% capacity filter plenum for each subsystem, which corresponds to 50% capacity relative to the entire Auxiliary Building, each with roughing filters (80% efficiency on NBS dust), HEPA filters (99.97% efficiency on 0.3 micron particles), charcoal filters (95% efficiency on methyl iodide at 85% relative humidity and 70°F) and final HEPA filter (same efficiency as previous HEPA filter bank). The filter plenum also includes a water deluge system.
3. Air operated, spring opposed dampers to isolate the exhaust fans not in use.
4. Ductwork to direct the exhaust air from various Auxiliary Building areas of potentially moderate contamination to the HEPA/charcoal plenum, the exhaust fans and, finally, to the main plant vent.
5. Instrumentation and control devices to perform the following functions:
   a. Measure the pressure drop across the roughing/HEPA/charcoal filter banks (local indication only).
   b. Cause an alarm in the control room upon detection of high concentration of smoke in the inlet of each filter plenum.
   c. Cause an alarm in the control room upon detection of high temperature in the discharge of any exhaust fan or in either charcoal filter plenum.
   d. Indicate, in the control room, fan isolation damper position.
   e. Cause an alarm in the control room upon detection of excessive vibration of the exhaust fans.
   f. Provide means for manual operation, from the control room, of the exhaust fans interlocked with their respective isolation dampers.
   g. Indicate, in the control room, exhaust fan operation.
   h. Cause an alarm in the control room upon detection of exhaust fan motor trip.
   i. Cause an alarm in the control room upon detection of high radiation in the gas decay vent discharge (RM-A10).

The Auxiliary Building charcoal exhaust system continuously exhausts the air furnished by the supply system described in Section 9.4.2.2.1. The exhaust air is drawn from Auxiliary Building areas with moderate potential for radioactive contamination (demineralizers, storage tanks, gas decay tanks, evaporators, pump rooms, etc.) at elevations 463’, 436’, 412’, 397’, 388’, and 374’. The vent from the refueling water storage tank also discharges into this exhaust system. The supply and exhaust ducts are arranged so that air flow is always in the direction of progressively greater potential radioactivity. Exhaust air from these areas is drawn through the roughing/HEPA/charcoal filter plenums continuously and is ducted to the main exhaust fans and the main plant vent. There is no bypass around this filter plenum. The exhaust fans for this system are manually

controlled from the control room and operate continuously if power is available. The fans stop upon loss of Class 1E bus voltage but may be restarted after Class 1E electric power is regained.

Components of this system are located as follows:

1. Exhaust fans, in the Auxiliary Building.
2. Filter plenum, in the Auxiliary Building.

9.4.2.2.4 Auxiliary Building Main Exhaust System

The main components of this system include:

1. Two (2) 100% capacity main exhaust fans which exhaust air from various Auxiliary and Fuel Handling Building areas to the main plant vent.
2. Two (2) 100% capacity exhaust fan bypass dampers.
3. Air operated, spring opposed dampers to isolate the exhaust fans when not in use.
4. Ductwork to direct the exhaust air from the various systems through the main plant vent.
5. Instrumentation and control devices to perform the following functions:
   a. Cause an alarm in the control room upon detection of high concentrations of smoke in the discharge of either exhaust fan.
   b. Cause an alarm in the control room upon detection of high temperature in the discharge of either exhaust fan.
   c. Cause an alarm in the control room upon detection of excessive vibration of the exhaust fans.
   d. Indicate, in the control room, fan isolation damper position.
   e. Provide means for manual operation, from the control room, of the main exhaust fans. Fan isolation dampers operate in conjunction with associated fans. The Auxiliary Building HEPA exhaust fans must be operating prior to starting one of the main exhaust fans.
   f. Provide means for automatically opening the bypass dampers when neither of the main exhaust fans is operating.
   g. Indicate, in the control room, the main plant vent flow rate.
   h. Indicate, in the control room, exhaust fan operation.
   i. Cause an alarm in the control room upon detection of exhaust fan motor trip.
   j. Cause an alarm in the control room upon detection of a high radiation level in the main plant vent (RM-A3).

The Auxiliary Building main exhaust system operates continuously to direct all air from the Fuel Handling Building exhaust system, the Auxiliary Building HEPA exhaust system and the Auxiliary Building charcoal exhaust system to the main plant vent. Interlocking of the various

systems prevents operation of the Auxiliary or Fuel Handling Building supply fans unless the exhaust system is operating. Similar interlocking prevents operation of the Auxiliary Building HEPA exhaust fans unless the Auxiliary Building charcoal exhaust fans are operating. Thus, the Auxiliary Building and Fuel Handling Building ambient pressure does not become positive and the exhaust flow paths toward increasing potential radioactivity are not violated. The main exhaust fans are manually controlled from the control room and use non-Class 1E power.

9.4.2.2.5 Auxiliary Building Pump Room Cooling Systems

The main components of these systems include:

1. For each charging pump room and each residual heat removal/Reactor Building spray pump room, a 100% capacity air handling unit consisting of fan section, chilled water coil and roughing filter.
2. Ductwork supply and return from each air handling unit to its respective room.
3. Instrumentation and control devices for each system to perform the following functions:
   a. Measure the pressure drop across the roughing filter (local indication only).
   b. Cause an alarm in the control room upon detection of high concentration of smoke at the inlet of the charging pump room fans or at the discharge of the residual heat removal/Reactor Building spray pump room fans.
   c. Cause an alarm in the control room upon detection of high temperature in the discharge of the fan.
   d. Indicate, in the control room, fan operation.
   e. Cause an alarm in the control room upon detection of fan motor trip.
   f. Cause an alarm in the control room upon detection of high pump room temperature.
   g. Provide the means for manual control of pump room air handling units from the control room and for automatic operation of the units interlocked with pumps.

The air handling units are mounted in locations shielded from the pump rooms, accessible for maintenance, supplied with safety class chilled water and operate either manually or automatically when the pumps are energized. The units are powered from the Class 1E electric system.

9.4.2.2.6 Hot Machine Shop Ventilation System

A. Auxiliary Building Hot Machine Shop

The main components of this system include:

1. A 100% capacity supply fan directing ventilation air to the hot machine shop.
2. A 100% capacity, two-speed exhaust fan exhausting air from various hot machine shop areas.

3. Ductwork to the supply fan from an outside air inlet connection with roughing filters and electric heating coil. Ductwork from various hot machine shop areas to the fuel handling building exhaust filter plenums.
4. Three (3) electric unit heaters along the perimeter walls of the hot machine shop.
5. Instrumentation and control devices to perform the following functions:
   a. Modulate return and outside air dampers in the system ductwork in accordance with a differential pressure controller. The differential pressure controller maintains a negative differential pressure between the hot machine shop and the outside.
   b. Control the electric duct heater with a room thermostat.
   c. Control the electric unit heaters with integral thermostats.

When normal power is available, the hot machine shop supply and exhaust fans are operated so as to maintain air supply to and exhaust from the hot machine shop when required. The supply and exhaust fans are controlled from location stations and are supplied from non-Class 1E power sources.

B. Radiological Maintenance Building Hot Machine Shop

The main components of this system include:

1. Two (2) air handling units, each comprised of a roughing filter, electric heating coil, a direct expansion cooling coil, and fan section continuously operate. Each air handling unit is rated at 50% of the required supply air flow.
2. Each air handling unit has an associated air cooled condensing unit.
3. A centrifugal exhaust fan rated at 100% of the required exhaust air flow.
4. A filter plenum containing a roughing and HEPA filter bank. The filter is rated at 100% of the exhaust air flow.
5. Four (4) electric unit heaters provide perimeter heating. Two (2) electric unit heaters are installed at the outside roll-up door.
6. Ductwork between the air handling units and points of distribution, between exhaust registers and HEPA filter plenum, between HEPA filter plenum and exhaust fan, and between exhaust fan and the plant vent.
7. Instrumentation and control devices to perform the following functions:
   a. Each air handling unit, condensing unit, and exhaust fan is energized from a local disconnect switch.
   b. Air handling unit fans are interlocked with the exhaust fan.
   c. Room thermostats set at 104°F control the operation of the condensing units and cycle them as necessary.

d. A smoke detector in the discharge duct of each air handling unit de-energizes the associated fan if smoke is present in the duct.

e. Each electric unit heater is controlled by a built-in thermostat.

9.4.2.2.7 Hot Machine Shop Decontamination Area Ventilation System

The main components of this system include:

1. An air handling unit comprised of a roughing filter section, an electric heating coil section and a fan section. The unit is rated at 100% of the required supply air flow.
2. An exhaust fan rated at 100% of the required exhaust air flow.
3. A filter plenum containing a roughing and a HEPA filter bank. The filter is rated at 100% of the exhaust air flow.
4. Ductwork between the air handling unit and the points of distribution, between the wall hoods and the filter, between the filter and the exhaust fan, and between the exhaust fan and the plant vent. The ductwork contains an automatic isolation damper for each fan which closes when the respective fan is off and vice versa.
5. Instrumentation and control devices to perform the following functions:
   a. To sense and correct the air handling unit supply air temperature by energizing the electric heating coil.
   b. To sense and alarm locally in the event of high temperature air in both the supply and exhaust ducts.
   c. To indicate locally the pressure differential air on each exhaust filter bank.

All components of this system are non-nuclear safety. When normal power is available, both fans operate continuously to supply air to and exhaust air from the wall hoods when required. The fans are controlled from local stations and are supplied from non-Class 1E power sources.

9.4.2.2.8 Auxiliary Building Motor Control Center and Switchgear Areas Cooling Systems

The main components of these systems include:

1. Three (3) 100% capacity air handling units and 2 non-nuclear safety class supplemental air handling units for the safety class switching gear areas on elevation 412’ and 463’. Each of these air handling units serves 1 of the 3 motor control center and switchgear areas. The safety class air handling units serving motor control center and switchgear areas at elevations 412’ and 463’ each include a fan section, chilled water coil supplied with safety class chilled water (see Section 9.4.7.2.4) and roughing filter. The non-safety class air handling units serving the motor control center and switchgear areas includes a fan section, direct expansion type cooling coil and roughing filter. Also a part of the non-safety class systems are a remotely mounted condensing unit, including refrigerant compressor, condensing section, piping and controls.

2. Ductwork from the various air handling units to the areas requiring cooling.
3. Instrumentation and control devices for each system to perform the following functions:
   a. Measure the pressure drop across the roughing filter (local indication only), except the non-safety class units.
   b. Cause an alarm in the control room upon detection of high concentration of smoke in the electrical equipment room.
   c. Cause an alarm in the control room upon detection of high temperature in the discharge of the air handling unit or in the electrical equipment room.
   d. Indicate, in the control room, fan operation (safety related fans only).
   e. Cause an alarm in the control room upon detection of fan motor trip (safety related fans only).
   f. Automatically cycle the selected air handling unit in response to a room thermostat (safety related fans only).

The air handling units in each of the two safety related systems recirculate and cool while cycling on/off in response to a room thermostat. Under emergency conditions, the thermostat control of the safety related air handling unit is bypassed and the units start and operate continuously following receipt of a safety injection or loss of offsite power signal. Power is supplied to the safety related units at elevations 412’ and 463’ from separated, independent Class 1E power sources. Power is supplied to the non-safety related system from a non-Class 1E source. The air handling unit at elevation 436’ operates continuously when started at the local control station. The non-safety class cooling systems for the switchgear areas at elevation 412’ and 463’ are controlled by temperature switches in the rooms. A room thermostat controls the refrigerant solenoid valves. The safety related air handling units can be manually started or stopped from the control room.

9.4.2.2.9 Hot Instrument Repair Shop Ventilation System

The main components of this system are contained in a single, factory-assembled, through the wall, air conditioner with built-in electric heating coil. All controls are self-contained. No ductwork is employed with this system which is classed as non-nuclear safety.

This system operates continuously. The unit compressor and electric heating coil cycle as required to maintain the room temperature controlled by the self-contained thermostat.

9.4.2.2.10 Auxiliary Building Elevator Machine Room Exhaust System

The main components of this system are an exhaust fan with back-draft damper, a gravity-operated air louver and electric unit heater. A room thermostat cycles the fan. A self-contained thermostat cycles the unit heater. No ductwork is employed. The system is non-nuclear safety class.

9.4.2.2.11 HP Calibration Lab and Repair Shop HVAC System

The main components of this system include:

1. A self-contained, air-cooled heat pump containing a compressor motor, an indoor fan motor, an outdoor fan motor and an electric heating coil.
2. Ductwork to and from the lab and shop including manual balancing dampers in the return and outside air ducts, a splitter damper in the supply duct, supply air diffusers, return registers and a roughing filter.
3. Controls include a compressor crankcase heater, automatic defrost package, room thermostat and switchbase, emergency heat relay and outdoor thermostat package. All motors have thermal-and-current- sensitive overload devices.

This system is classed as non-nuclear safety.

The heat pump is started by a remote manual switch which causes its indoor fan to operate continuously to provide air circulation and ventilation. The compressor and electric heating coil cycle automatically under thermostatic control to maintain the space temperature.

9.4.2.3 Safety Evaluation

The auxiliary and radwaste area systems, excluding the pump room units, and motor control center and switchgear cooling units at elevations 412’ and 463’, are not safety class systems. However, redundant fans are provided for the main exhaust, the charcoal exhaust and the HEPA exhaust systems. Charcoal exhaust fans and plenums are physically separated, housed in shielded concrete enclosures and the fans receive power from the Class 1E electric system. All charcoal and HEPA filter plenums are constructed in accordance with Seismic Category 1 requirements. Additionally, provision is made for suitable maintenance and change-out space and adequate instrumentation and lighting, all of which reduce personnel exposure.

The pump room systems and the motor control center and switchgear cooling units are not redundant but are arranged as single units for each pump room. Loss of a pump room, motor control center or switchgear cooling unit requires use of redundant equipment and its cooling unit. The cooling units are separated, located in an accessible, shielded location and are not subject to floods, weather, external missiles, jet impingement or pipe whip. The pump room units are powered from separated Class 1E power supplies.

Where indicated, units are administratively controlled from the control room during normal operating or refueling periods. This control is subject to protective electric interlocking so that negative auxiliary building pressure and design air flow paths are maintained. Operation of the pump room units is automatic. These units operate when the associated pump operates.

Where indicated, units are monitored from and alarms are provided in the control room. The charcoal plenums have manually actuated water deluge systems for fire protection.

Radiation levels in the charcoal filters, the exhaust from the gas decay vent and the main plant vent exhaust are monitored from, and alarms are provided in, the control room. Exhaust filter plenums provide a minimum of 95% removal efficiency for both organic and elemental forms of iodine.

9.4.2.4 Inspection and Testing Requirements

The auxiliary and radwaste area ventilation systems are subjected to preoperational test procedures to verify proper wiring and control hookup, system inplace integrity and leak tightness, proper function of system components and control devices and to establish system design air flows.

To ensure a continued state of readiness of the auxiliary and radwaste area ventilation systems after completion of the preoperational tests, the following inspection, maintenance and test procedures are performed:

1. Auxiliary Building Charcoal Exhaust System
   a. Record filter pressure drops.
   b. Verify function of dampers or control devices necessary for monitoring, component isolation or changeover from normal to emergency mode.
   c. Bearing lubrication.
   d. Switch components that normally operate from standby to operating mode.
   e. Laboratory test of charcoal filter test canisters for decontamination efficiency.
   f. Inplace leak test of HEPA and charcoal filters.
2. Auxiliary Building HEPA Exhaust System

   Auxiliary Building HEPA exhaust system inspection, maintenance and testing requirements are the same as Auxiliary Building charcoal exhaust system requirements a. through d. and inplace leak test of HEPA filters.

3. Auxiliary Building Main Exhaust System

   Auxiliary Building main exhaust system inspection, maintenance and testing requirements are the same as Auxiliary Building charcoal exhaust system requirements b. through d.

4. Auxiliary Building Main Supply System

   Auxiliary Building main supply system inspection, maintenance and testing requirements are the same as Auxiliary Building charcoal exhaust system requirements a., c., and d.

5. Auxiliary Building Pump Room Cooling System

Auxiliary Building pump room cooling system inspection, maintenance and testing requirements are the same as Auxiliary Building charcoal exhaust system requirements a. through d.

6. Hot Machine Shop Ventilation System

   Hot machine shop ventilation system inspection, maintenance and testing requirements are the same as the Auxiliary Building charcoal exhaust system requirements a. through d.

7. Hot Machine Shop Decontamination Ventilation System

   Hot machine shop decontamination ventilation system inspection, maintenance and testing requirements are the same as the Auxiliary Building charcoal exhaust requirements a. through d., plus inplace leak test of HEPA filters.

8. Auxiliary Building Motor Control Center and Switchgear Areas Cooling System

   Auxiliary Building motor control center and switchgear areas cooling system inspection, maintenance and testing requirements are the same as the Auxiliary Building charcoal exhaust system requirements a. through d.

9. Hot Instrument Repair Shop Ventilation System

   Hot instrument repair shop package HVAC system inspection, maintenance and testing requirements are the same as the Auxiliary Building charcoal exhaust system requirement d.

10. Auxiliary Building Elevator Machine Room Exhaust System

    Auxiliary Building elevator machine room exhaust system inspection, maintenance and testing requirements are the same as the Auxiliary Building charcoal exhaust system requirement d.

11. HP Calibration Lab and Repair Shop HVAC System

    Calibration lab and repair shop air conditioning system inspection, maintenance and testing requirements are the same as the Auxiliary Building charcoal exhaust system requirements b. and d.

9.4.3 Fuel Handling Building Ventilation

Continuous ventilation and exhaust of the spent fuel pool area and the Fuel Handling Building results in an environment suitable for personnel and equipment. Additionally condensation from the fuel pool area and the release of airborne radioactivity to the atmosphere is minimized.

9.4.3.1 Design Bases

The system for the spent fuel pool area are designed in accordance with the following:

1. Equipment motors and controls in the safety class portions of the systems are supplied from Class 1E electric power sources and have sufficient redundancy to satisfy the single failure criteria.
2. Provision is made for monitoring and manual control of the safety class portions of the systems from the control room. Operation of exhaust system fans and dampers is initiated automatically by a loss of offsite power signal.
3. The supply and exhaust systems provide continuous flow across the spent fuel pool water surface and provide controlled ventilation air flow in other Fuel Handling Building spaces. Ventilation air flow is from areas of low to progressively higher radiation levels.
4. Ventilation air is supplied to the Fuel Handling Building from the Auxiliary Building by two non-safety related fans. These fans are not automatically tripped during accident or high radiation situations and will usually operate during normal and emergency conditions. One of two safety related exhaust fans is operated during normal and emergency conditions. Supply and exhaust air flow are balanced so that a negative pressure with respect to the outside of at least 1/8 inch water gage is maintained in the Fuel Handling Building with both supply fans and one exhaust fan operating. Postulated failures of the non-safety related supply fans would result in a negative pressure of more than 1/8 inch which would provide additional assurance in preventing the outflow of unfiltered air.
5. Ventilation air flow is directed through a roughing, HEPA and charcoal filter assembly to minimize the radioactivity being released to the plant vent.
6. Provision is made to maintain a minimum ventilating supply air temperature to the Fuel Handling Building of 65°F.
7. Provision is made to monitor normal and abnormal radiation levels in the area.

9.4.3.2 System Description

The system diagrams for the various spent fuel pool area systems are as follows:

1. Figure 9.4-11, Fuel Handling Building Charcoal Exhaust System and Air Supply Distribution.
2. Figure 9.4-6, Auxiliary Building Main Supply System.

Design and performance data are indicated on these figures.

9.4.3.2.1 Fuel Handling Building Supply and Charcoal Exhaust System

The main components of this system include:

1. Two (2) 100% capacity fuel handling building exhaust fans which draw air through the HEPA/charcoal filter plenums.
2. Three (3) 50% capacity filter plenums, each consisting of roughing filters (80% efficiency on NBS dust), HEPA filters (99.97% efficiency on 0.3 micron particles), charcoal filters (95% efficiency on methyl iodide at 95% relative humidity and 86o F, and final HEPA filters (same efficiency as previous HEPA filter). The filter plenum also includes a water deluge system.
3. A 100% capacity supply fan which directs outside air across the spent fuel pool surface.
4. Air operated, spring opposed dampers to isolate the supply and exhaust fans when not in use.
5. One electric reheat coil in each supply duct.
6. Ductwork which directs the supply air to the spent fuel pool surface, and various areas of the building, exhausts this air from the spent fuel pool surface and exhausts air from various Fuel Handling Building areas through the charcoal/HEPA filter plenum to the exhaust fans and the plant vent.
7. Instrumentation and control devices to perform the following functions:
   a. Measure the pressure drop across the HEPA/charcoal filter banks (local indication only).
   b. Cause an alarm in the control room upon detection of high concentration of smoke in the inlet of the exhaust plenum.
   c. Cause an alarm in the control room upon detection of high temperature in any one of the charcoal filter plenums, in the discharge of either exhaust fan or in the discharge of the supply fan.
   d. Indicate, in the control room, supply and exhaust fan isolation damper position.
   e. Cause an alarm in the control room upon detection of excessive vibration of the supply or exhaust fans.
   f. Provide means for manual operation of the following components from the control room:
      (1) Exhaust fans interlocked with associated isolation dampers.
      (2) Supply fan interlocked with associated dampers and the exhaust fans.
   g. Provide means for automatic operation of the exhaust fans upon receipt of a loss of offsite power signal.
   h. Automatically maintain minimum supply air temperature by controlling the supply system reheat coil.
   i. Indicate, in the control room, supply or exhaust fan operation.
   j. Cause an alarm in the control room upon detection of exhaust fan motor trip.
   k. Provide for radiation monitoring (RM-A6) and cause an alarm in the control room upon detection of radioactivity levels exceeding the setpoint in the Fuel Handling Building exhaust (see Section 12.2.4).

The system continuously supplies outside air that has been drawn through the Auxiliary Building supply air plenums where it is filtered and heated as required. The supply air is directed across the width of the spent fuel pool water surface so that gases or particles are entrained in the "push-pull" air flow above the water surface. The exhaust air is collected along the opposite side of the spent fuel pool. Supply air is also directed to various other parts of the building. Exhaust air is also drawn from various decontamination, holdup, filter and general areas of the Fuel Handling Building with air flow rates varying from 6 to 10 changes per hour. Ventilation air flow is directed from areas of low to progressively higher activity. Higher ventilation air flow rates occur in potentially high radioactive areas.

The total exhaust from the Fuel Handling Building is drawn through the HEPA/charcoal filters and ducted to the Auxiliary Building main exhaust fans and the main plant vent. Both Fuel Handling Building exhaust fans operate following a loss of offsite power. Continuing exhaust flow maintains Fuel Handling Building negative pressure under loss of offsite power conditions.

The supply system may be operated if normal power is available. The components for this system are located as follows:

1. Exhaust fans, in the Auxiliary Building.
2. Exhaust filters, in the Auxiliary Building.
3. Supply fan, in the Auxiliary Building.

A comparison of the spent fuel pool area charcoal filter plenums with Regulatory Guide 1.52 requirements is given in Table 6.5-1. General compliance with Regulatory Guide 1.52 is discussed in Appendix 3A.

9.4.3.3 Safety Evaluation

The Fuel Handling Building exhaust system fans and filters are arranged with sufficient redundant equipment to ensure that the system can sustain a single failure without impairing full functional capability of the standby system or component. The exhaust system fans and filters are separated, shielded and are served by separate Class 1E electric power supplies. Each is served by separate instrumentation, control and monitoring components. The fans and filters are Seismic Category 1, located in a Seismic Category 1 structure and are not subject to floods, weather, external missiles, jet impingement or pipe whip. Additionally, provision is made for suitable maintenance and change-out space and adequate instrumentation and lighting, all of which reduce personnel exposure.

The supply and exhaust system are administratively controlled during normal operating or refueling periods. However, the exhaust system starts automatically upon loss of offsite power, thus ensuring that a negative pressure is maintained in the Fuel Handling Building.

Exhaust air from the spent fuel area and from potentially radioactive areas of the Fuel Handling Building is monitored for particulate, iodine and gaseous activity (RM-A6). A control room alarm

is actuated upon detection of high radiation. The charcoal exhaust plenums have internal temperature sensing devices and water deluge systems for fire protection.

The spent fuel ventilation system filter trains provide a minimum of 99.95% removal efficiency for particulates and a minimum of 95% removal efficiency for methyl iodine at 95% relative humidity and 86°F.

9.4.3.4 Inspection and Testing Requirements

The spent fuel pool equipment is subjected to preoperational testing in accordance with written procedures to verify proper wiring and control hookup, system inplace integrity and leaktightness, proper function of system components and control devices and to establish system design air flow rates.

To ensure a continued state of readiness of the spent fuel pool area ventilation system after completion of the preoperation tests, the following inspection, maintenance and test procedures are performed:

1. Spent Fuel Pool Exhaust Fans and Filters
   a. Record filter pressure drops.
   b. Verify function of dampers or control devices necessary for monitoring, component isolation or changeover from normal to emergency mode.
   c. Bearing lubrication.
   d. Switch components that normally operate from standby to operating mode.
   e. Laboratory test of charcoal filter test canisters for decontamination efficiency.
   f. Inplace leak test of HEPA and charcoal filters.
2. Spent Fuel Pool Supply Fan

   Spent fuel pool supply fan inspection, maintenance and testing requirements are the same as spent fuel pool exhaust fan and filter requirements b and c.

9.4.4 Turbine Building

Ventilation and cooling of the Turbine Building areas are provided by the Turbine Building ventilation system and by the Turbine Building switchgear room cooling system.

9.4.4.1 Design Bases

1. Limit the maximum average turbine building temperature to 120°F by means of the Turbine Building exhaust system.

2. Limit the maximum average switchgear room temperature to 104°F and the minimum average temperature to 40°F by means of the Turbine Building switchgear room cooling system.

All components of the Turbine Building ventilation system and switchgear room cooling system are non-nuclear safety class and non-Seismic Category 1.

9.4.4.2 System Description

The system diagrams for the Turbine Building area ventilation system are as follows:

1. Figure 9.4-12, Turbine Building Ventilation System.
2. Figure 9.4-13, Turbine Building Switchgear Room Cooling System.

9.4.4.2.1 Turbine Building Ventilation System and Switchgear Room Cooling System

The main components of this system include:

1. Seven (7) 120 inch diameter roof exhaust fans with powered isolation dampers over the general Turbine Building roof.
2. Three (3) 48 inch diameter roof exhaust fans with powered isolation dampers over the heater bay roof.
3. Inlet wall louvers along the north and east walls of the heater bay and along the south wall of the general Turbine Building.
4. Two (2) "draw-through" type air handling units for the switchgear rooms, each with roughing filters, chilled water cooling coil, fan and motor section. Chilled water is provided by the Turbine Building switchgear rooms chilled water system. See Section 9.4.7.2.11.
5. Supply and return ductwork from the switchgear units to the turbine room switchgear areas at elevations 412’, 436’, and 463’.
6. Five (5) thermostatically controlled electric unit heaters for the switchgear rooms.
7. Instrumentation and control devices to perform the following functions:
   a. Measure the pressure drop across the switchgear room air handling unit roughing filter bank (local indication only).
   b. Cause an alarm in the control room upon detection of high temperature in the switchgear cooling system air handling unit supply duct or in the switchgear rooms.
   c. Cause an alarm in the control room upon detection of high concentration of smoke in the switchgear room cooling system air handling unit supply duct or at the Turbine Building exhaust fans.
   d. Provide interlocks so that the Turbine Building exhaust fans do not operate unless the exhaust dampers at the roof exhaust fans are open.

e. Provide means for manual operation and control of the roof exhaust fans from a local control station.

f. Provide for operation of switchgear room cooling system air handling units from a local station and automatic control of chilled water pumps by means of room thermostats.

g. Provide interlocks so that switchgear room cooling system air handling units do not operate unless isolation dampers are fully open.

h. Cause an alarm in the control room upon trip of the switchgear room cooling system air handling unit.

i. Provide interlocks so that Turbine Building exhaust fan dampers open upon detection of high temperature.

j. Automatically close the inlet wall louvers along the south wall of the Turbine Building upon receipt of a signal from the transformer area fire protection system.

9.4.4.3 Safety Evaluation

The Turbine Building ventilation system and the Turbine Building switchgear room cooling system serve no safety function. They maintain acceptable temperatures in the building during all seasons. Redundancy of equipment is provided to maintain Turbine Building switchgear room cooling. Failure of Turbine Building ventilation system or switchgear room cooling system components does not result in conditions affecting safe operation of the plant. There is no requirement to maintain any preferred air flow pattern or specific building pressure. The function and fire safety aspects of all units of these systems are monitored, and appropriate alarms are actuated upon the occurrence of abnormal conditions, in the control room.

9.4.4.4 Inspection and Testing Requirements

The Turbine Building ventilation system and the Turbine Building switchgear room cooling system are subjected to preoperational testing to verify proper wiring and functioning of system components and control devices. Turbine Building ventilation systems are maintained as necessary to provide adequate ventilation.

9.4.5 Engineered Safety Features Ventilation System

The engineered safety features ventilation system design bases, system description, safety evaluation and inspection and testing requirements are described in the following sections:

1. Reactor Building cooling units - Section 6.2.2.
2. Control room normal ventilation and emergency filter system - Section 9.4.1.2.1.
3. Relay room cooling system - Section 9.4.1.2.2.
4. Cooling units for residual heat removal/Reactor Building spray pump rooms - Section 9.4.2.2.5.
5. Cooling units for charging pump rooms - Section 9.4.2.2.5.

6. Engineered safety features switchgear rooms cooling systems - Section 9.4.6.2.2.
7. Battery rooms ventilation system - Section 9.4.6.2.3.
8. Service water booster pumps area cooling system - Section 9.4.6.2.5.
9. Cooling units for emergency feedwater pump rooms - Section 9.4.6.2.5.
10. Diesel Generator Building ventilation system - Section 9.4.7.2.1.
11. Service Water Pumphouse ventilation system - Section 9.4.7.2.2.

9.4.6 Intermediate Building Ventilation Systems

Heating, cooling, ventilating and exhaust are provided for various Intermediate Building systems to the extent indicated to maintain ambient air temperatures in all areas between minimum and maximum levels suitable for personnel and equipment.

9.4.6.1 Design Bases

1. Furnish continuous outside air ventilation for the battery room system.
2. Safety Class 2b systems are designed for adequate physical separation and are so located as not to be affected by floods, weather, external missiles, jet impingement or pipe whip.
3. Equipment, motors and controls in Safety Class 2b systems are supplied from Class 1E power sources and have sufficient redundancy to satisfy the single failure criterion.
4. Provide, in the control room, for monitoring of process conditions and equipment status necessary for operation of the systems.
5. Provide for operation and manual control of the Intermediate Building ventilation systems as described in Sections 9.4.6.2.1, 9.4.6.2.2, 9.4.6.2.3, 9.4.6.2.4, 9.4.6.2.5, and 9.4.6.2.6.
6. Provide steam propagation barriers / components (SPB) in the equipment and floor drainage system required to maintain area environmental conditions for equipment qualification (EQ) purposes. SPB components may include orifice plates, check valves, or loop seals designed to segregate EQ zones to ensure that the conditions for which the equipment qualification were based on are not exceeded. Plant procedures specify the technical criteria for design, procurement, installation /maintenance and inspection of these QR components.

9.4.6.2 System Description

The system diagrams for the various intermediate building systems are as follows:

1. Figure 9.4-14, CRDM Switchgear Room Cooling System and Chiller Area Ventilation System.
2. Figure 9.4-15, ESF Switchgear Rooms and Speed Switch Rooms Cooling Systems.
3. Figure 9.4-16, Battery Room System and BOP Charger Area System.

4. Figure 9.4-17, Intermediate Building and Intermediate Building Pump Room Cooling System.

9.4.6.2.1 CRDM Switchgear Room Cooling System

The main components of this system include:

1. Two (2) 100% capacity air handling units, each consisting of roughing filters (20% efficiency on NBS dust), chilled water cooling coil, fan and motor section. Chilled water is provided by the Non-nuclear Safety Related Chilled Water System. See 9.4.7.2.12.
2. Ductwork to direct air from each air handling unit to the CRDM switchgear room and return air from this room to the air handling unit.
3. Instrumentation and control devices to perform the following functions:
   a. Measure the pressure drop across the roughing filter banks (local indication only).
   b. Cause an alarm in the control room upon detection of high smoke concentration in the CRDM switchgear room.
   c. Cause an alarm in the control room upon detection of high temperature in the supply duct of either air handling unit or upon detection of high room temperature.
   d. Automatically cycle the selected air handling unit in response to a room thermostat.

The CRDM switchgear room cooling system operates continuously during all normal operating and shutdown periods unless normal power is not available. The cooling coils are normally provided by the NNS Chilled Water System. In the event this system is unavailable, a back-up source from the Turbine Building switchgear rooms Chilled Water System can be used. The air handling units are normally powered from non-Class 1E buses. The air handling units are controlled from a local control station, the unit selected for automatic operation cycles in response to a room thermostat.

9.4.6.2.2 ESF Switchgear Rooms and Speed Switch Rooms Cooling Systems

The main components of these systems include:

1. One (1) 100% capacity air handling unit for each ESF switchgear room, one (1) 100% capacity air handling unit for the A and C speed switch room and A evacuation panel room, and 1 similar unit for the B and C speed switch room and B evacuation panel room. Each air handling unit consists of roughing filters (20% efficiency on NBS dust), chilled water cooling coil, and a fan and motor section.

   Each ESF switchgear room air handling unit is also equipped with a standby direct expansion cooling coil. These non-safety related standby cooling coils provide ESF switchgear room cooling when the safety class chilled water train is not operating.

The standby cooling coil rejects heat to an air-cooled condensing unit located on the Intermediate Building roof.

2. Ductwork to direct air from each air handling unit to the ESF switchgear room and return air from this room to the air handling unit; ductwork to direct air from the A air handling unit to the A and C speed switch room and A evacuation panel room and return ductwork to the A air handling unit; similar ductwork to and from the B air handling unit and B and C speed switch room and B evacuation panel room.
3. Instrumentation and control devices to perform the following functions:
   a. Measure the pressure drop across the roughing filter banks (local indication only).
   b. Cause an alarm in the control room upon detection of high smoke concentration in the discharge ducts of any of the air handling units.
   c. Cause an alarm in the control room upon detection of high temperature in the discharge ducts of any of the air handling units and upon detection of high room temperature.
   d. Automatically cycle the selected air handling unit in response to a room thermostat.
   e. Automatically cycle the standby cooling coil system based on room temperature when the ESF switchgear is in a standby mode.
   f. Cause an alarm in the control room upon detection of air handling unit motor trip.

The air handling units cycle in response to a room thermostat under normal conditions to remove the heat generated by the ESF electrical equipment or by the speed switchgear. Under emergency conditions, the thermostatic control is bypassed and the air handling units start and operate continuously following receipt of a safety injection or loss of offsite power signal. Power is supplied to the air handling units from separated, independent Class 1E power sources. The air handling units can be manually started from the control room. The air handling units are located in separate equipment rooms in the Intermediate Building.

9.4.6.2.3 Battery Room Systems

The main components of these systems include:

1. Two (2) 100% capacity air handling units, each including roughing filter (20% efficiency on NBS dust), electric heating coil, face and bypass section, safety class chilled water cooling coil, fan, and motor section.
2. Two (2) 100% capacity exhaust air fans.
3. Air operated, spring opposed dampers to isolate the inactive battery room air handling unit and exhaust air fan.
4. One (1) 100% capacity air handling unit, including roughing filter (20% efficiency on NBS dust), chilled water cooling coil, fan, and motor section for the balance of plant charging space. Chilled water is provided by the Non-nuclear Safety Related Chilled Water System. See 9.4.7.2.12.

5. Instrumentation and control devices to perform the following functions:
   a. Measure the pressure drop across the roughing filter bank (local indication only).
   b. Cause an alarm in the control room upon detection of high smoke concentration in the discharge of either air handling unit or exhaust fan.
   c. Cause an alarm in the control room upon detection of high temperature in the discharge ducts from the air handling units or exhaust fans.
   d. Cause an alarm in the control room upon detection of high temperature in any of the battery or charger rooms.
   e. Indicate, in the control room, isolation damper position.
   f. Provide means for manually operating the air handling units and exhaust fans from the control room. The isolation dampers operate in conjunction with the fans. The battery air handling units start automatically at full cooling rate upon receipt of safety injection or loss of offsite power signals.
   g. Automatically maintain battery room and charger room air temperature during normal operation by controlling the battery air handling unit heating coil, face and bypass damper, and the battery room reheat coils. During safety injection or loss of offsite power, the face and bypass damper moves to the full cooling position, isolating the heating coil from the system flow path. Heating may still be accomplished through the reheat coils if power is available. If battery room temperature becomes too low, the room will be isolated by means of an isolation damper in the room supply.
   h. Indicate, in the control room, air handling unit fan operation.
   i. Cause an alarm in the control room upon detection of air handling unit fan motor trip for the safety-related battery rooms supply and exhaust fans.
   j. Indicate local temperature in each battery room.

The battery room system operates during all normal, shutdown, and emergency periods. Continuous system operation maintains suitable ambient temperatures and prevents the accumulation of battery gases in these areas. The battery room air handling units and exhaust fans are supplied by separated Class 1E power sources. The balance of plant charging space air handling unit is supplied from non-Class 1E power. The air handling units and exhaust air fans can be manually started and their operation monitored from the control room. The battery room air handling equipment is located in separated equipment rooms in the Intermediate Building.

9.4.6.2.4 Intermediate Building Ventilation System

The main components of this system include:

1. Two (2) 50% capacity supply fans for the Intermediate Building.
2. Two (2) 50% capacity exhaust fans for the Intermediate Building.

3. One (1) 100% capacity supply filter plenum for the Intermediate Building, including roughing filter (20% efficiency on NBS dust), and an electric heating coil.
4. Air operated, spring opposed dampers to isolate a supply or exhaust fan if it is deenergized and to regulate the quantities of outside, return, and relief air.
5. Ductwork from the supply fans to the Intermediate Building, back to the exhaust fans.
6. Instrumentation and control devices to perform the following functions:
   a. Measure the pressure drop across the roughing filter banks (local indication only).
   b. Cause an alarm in the control room upon detection of high smoke concentration in the fan discharges.
   c. Cause an alarm in the control room upon detection of high temperature in fan discharge ducts.
   d. Indicate, in the control room, fan isolation damper position.
   e. Provide means for manually operating the supply and exhaust fans from the control room. Supply fans are interlocked to prevent operation unless exhaust fans are operating. Isolation dampers are interlocked to operate with associated fans.
   f. Automatically maintain minimum supply air temperature by controlling the outside, return and relief dampers, and the Intermediate Building heating coil.
   g. Indicate, in the control room, supply and exhaust fan operation.
   h. Cause an alarm in the control room upon detection of fan motor trip.

The Intermediate Building ventilation system supply and exhaust fans operate continuously during all normal and shutdown periods. System operation maintains suitable ambient conditions and provides outside air ventilation. The units are supplied with normal power. The fans are operated from the control room.

9.4.6.2.5 Intermediate Building Pump Room Cooling Systems

The main components of these systems include:

1. Two (2) 100% capacity air handling units for each of the following locations: service water booster pump area and emergency feedwater pump area. Each air handling unit includes a roughing filter (20% efficiency on NBS dust), safety class chilled water cooling coil, fan, and motor section.
2. Ductwork from the pump room air handling units to the pump areas.
3. Instrumentation and control devices to perform the following functions:
   a. Measure the pressure drop across the roughing filter banks (local indication only).
   b. Cause an alarm in the control room upon detection of high smoke concentration in air handling unit discharges.

c. Cause an alarm in the control room upon detection of high temperature in air handling unit discharge ducts.

d. Cause an alarm in the control room upon detection of high temperature in the pump room areas.

e. Provide means for manually operating the air handling units from the control room.

f. Indicate, in the control room, air handling unit operation.

g. Cause an alarm in the control room upon detection of air handling unit motor trip.

h. Provide a means of tripping the air handling unit fans on detection of high ambient temperature in the pump room area.

The pump room air handling units start automatically, provided a high ambient temperature condition does not exist in the area, with their respective pump. The air handling units remove heat generated due to normal equipment operation in the area. Upon detection of high ambient temperature conditions in the area, which may be caused by an HELB in the IB-412' area, fan operation is prohibited until area temperatures return to design parameter operational levels. Air handling units are supplied by separated class 1E power sources and are located in separate equipment rooms in the Intermediate Building.

9.4.6.2.6 Water Chiller Area Ventilating System

The main components of this system include:

1. One (1) ventilating fan arranged to supply, relieve, and return outside ventilating air.
2. One (1) duct mounted heating coil.
3. Ductwork with control dampers and fire dampers arranged to supply, relieve, and return air as required.
4. Instrumentation and control devices to perform the following functions:
   a. Cause an alarm in the control room upon detection of high smoke concentration in the return air duct.
   b. Cause an alarm in the control room upon detection of high temperature in the fan discharge.
   c. Automatically control the outside and return dampers and the heating coil using a temperature controller which senses return air temperature.
   d. Indicate, locally, fan operation.
   e. Cause an alarm in the control room upon detection of fan motor trip.

The system operates continuously after manual start. System equipment is supplied from a non-Class 1E power source.

9.4.6.3 Safety Evaluation

Since the Intermediate Building ventilation systems are redundant, loss of 1 of the air handling units or fans does not prevent system function. For the ESF switchgear rooms cooling systems, 1 air handling unit serves the A channel ESF switchgear and a second, separate air handling unit serves the B channel ESF switchgear.

Safety Class 2b equipment is located in physically separated equipment rooms accessible for maintenance and not subject to floods, weather, external missiles, jet impingement or pipe whip. Safety Class 2b equipment is supplied by separated Class 1E power supplies. Units are administratively controlled from the control room. ESF switchgear rooms air handling units, speed switchgear rooms air handling units and CRDM switchgear room air handling units are cycled by room thermostats. Upon receipt of a safety injection or loss of offsite power signal, the ESF switchgear rooms air handling units and speed switchgear rooms air handling units are automatically started and operated continuously. Pump room air handling units are operated automatically with their respective pump. Operation of units is monitored from, and alarms indicating abnormal conditions are provided in, the control room. Assurance of system operation capability is further provided by preoperational and post operational test procedures.

9.4.6.4 Inspection and Testing Requirements

The Intermediate Building ventilation systems are subjected to preoperational test procedures to verify proper wiring and control hookup, system "in-place" integrity and leak tightness, proper function of system components and control devices, and to establish system design air flow rates. To ensure a continued state of readiness of the Intermediate Building ventilation systems after completion of the preoperational tests, the following inspection, maintenance, and test procedures are performed:

1. CRDM Switchgear Room Cooling System
   a. Record filter pressure drops.
   b. Verify function of dampers or control devices necessary for monitoring or component isolation or changeover.
   c. Bearing lubrication.
   d. Switch components from standby to operating mode.
2. ESF Switchgear Rooms Cooling Systems

   ESF switchgear rooms cooling systems inspection, maintenance and test requirements are the same as CRDM switchgear room cooling system requirements a. through c.

3. Battery Room System

   Battery room system inspection, maintenance and test requirements are the same as CRDM switchgear room cooling system requirements a. through d.

4. Intermediate Building Ventilation System

   Inspection, maintenance and test requirements for this system are the same as CRDM switchgear room cooling system requirements a. through c.

5. Intermediate Building Pump Cooling Systems

   Inspection, maintenance and test requirements for these systems are the same as CRDM switchgear room cooling system requirements a. through d.

6. Speed Switchgear Rooms Cooling Systems

   Inspection, maintenance and test requirements for these systems are the same as CRDM switchgear room cooling system requirements a. through d.

9.4.7 Miscellaneous Building Ventilation and Cooling Systems

Heating, cooling, ventilation, exhaust, heat rejection and generation of mechanically chilled water are provided by various systems to the extent indicated in the following sections to maintain ambient air temperatures in areas discussed between minimum and maximum levels suitable for personnel and equipment.

9.4.7.1 Design Bases

The miscellaneous building ventilation and cooling systems are designed in accordance with the following criteria, where applicable:

1. Equipment, motors, and controls in Safety Class 2b systems are supplied from Class 1E power sources and have redundancy as required to satisfy the single failure criterion of 10 CFR 50, Appendix A.
2. Instrumentation and controls are provided to monitor normal operation and detect abnormal conditions, such as high or low temperatures, low pressure, smoke, equipment vibration and motor trip.
3. Provide outside air ventilation to remove heat developed by motors and electrical equipment.
4. Provide a system to generate and distribute mechanically chilled water to safety and non-nuclear safety class equipment.
5. Provide a heat rejection system for the Reactor Building cooling system.
6. Provide a comfort cooling system for the Service Building.
7. Provide for operation and manual control of these systems from the control room. Also, provide for automatic starting of the Diesel Generator Building ventilation system when the diesel generator is started and for automatically starting the Service Water Pumphouse ventilation system.

9.4.7.2 System Description

The system diagrams for the miscellaneous building ventilation and cooling systems are as follows:

1. Figure 9.4-18, Diesel Generator Building Ventilation System.
2. Figure 9.4-19, Service Water Pumphouse Ventilation System.
3. Figures 9.4-20 and 9.4-21, Service Building Ventilation System.
4. Figures 9.4-22 through 9.4-24, Chilled Water System.
5. Figure 9.4-25, Industrial Cooling Water System.
6. Figure 9.4-26, Substation Relay House System.
7. Figure 9.4-26a, Penetration Room Ventilation System.
8. Figure 9.4-26b, Miscellaneous Pump Room Systems and Lube Oil Room System.
9. Figure 9.4-26c, Water Treating Area Laboratory Heating and Cooling System.
10. Figure 9.4-26d, Unit 1 Relay House HVAC.
11. Figure 9.4-32, CRDM Cooling Water System.
12. Figure 9.4-33, Chilled Water - Turbine Building Switchgear Rooms.
13. Figure 9.4-34, Non-Nuclear Safety Chilled Water System.
14. Figure 9.4-35, SH. 1, EB HVAC - Electrical and Battery Room
15. Figure 9.4-35, SH. 2, EB HVAC - Diesel Generator 1 Room
16. Figure 9.4-36, AEB HVAC - Diesel Generator 2 Room

Design and performance data are provided on these figures.

9.4.7.2.1 Diesel Generator Building Ventilation System

The main components of this system for each diesel room include:

1. Two (2) 50% capacity ventilation fans to supply outside air to the diesel generator room, the diesel generator electric equipment room, and the diesel generator cable-pipe-basement area.
2. Air operated, spring opposed dampers with damper position limit switches to isolate the ventilation supply fans when not in use.
3. Ductwork to connect the two supply fans and distribute supply air to the various diesel room areas.
4. Instrumentation and control devices to perform the following functions:
   a. Cause an alarm in the control room upon detection of high smoke concentration in the discharge of each fan.

b. Cause an alarm in the control room upon detection of high temperature in the discharge of each fan.

c. Provide means for manually operating the supply fans from the control room. The supply fans are interlocked with the damper limit switches to prevent fan operation if dampers are closed.

d. Provide means for automatically cycling the supply fans under control of room thermostats located in the diesel generator rooms, and diesel generator electric equipment rooms. Cycling in this manner maintains acceptable temperatures when diesel generators are not operating.

e. Provide means for automatically starting each supply fan if the associated diesel generator is started. Associated supply fans operate continuously while the diesel generator is in operation.

f. Indicate, in the control room, supply air fan operating status.

g. Cause an alarm in the control room upon detection of fan motor trip.

The fans in this system cycle and associated dampers open and close in response to room thermostats located in the diesel generator rooms, and diesel generator electric equipment rooms when the diesel generators are not operating. Both fans associated with a diesel room start automatically and operate continuously whenever the diesel generator in that room operates. Ventilation air is drawn through roof openings shielded from external tornado missiles and forced into the diesel room by the fans. The ventilation air is ducted to various areas of the diesel room, diesel generator electric equipment room and cable-pipe areas under the diesel generator. Ventilation air is relieved from the cable-pipe areas and electric equipment room to the diesel room and through the exhaust silencer space to the outside. The relief air is vented to the outside through roof openings which are also shielded from external tornado missiles. The fans are powered from separated Class 1E power sources. The fans are manually operated from the control room or operate automatically as previously noted. System operation is monitored from the control room. The fans are located on the west end of the Diesel Generator Building.

9.4.7.2.2 Service Water Pumphouse Ventilation System

The main components of this system include:

1. Two (2) 100% capacity ventilation supply fans to provide outside air to various areas of the Service Water Pumphouse.
2. Air operated, spring opposed dampers to isolate the return air path to the ventilation supply fans and to regulate the quantities of outside, return and relief air. Gravity dampers are provided at the discharge of each supply fan.
3. Fire dampers are located in the switchgear and pump rooms supply and return ducts.
4. Eight electric unit heaters are provided to maintain minimum ambient temperatures during shutdown periods.

5. Ductwork is provided for supply, return and relief of ventilation air in service water pump areas and related motor control center and electrical rooms.
6. Instrumentation and control devices to perform the following functions:
   a. Cause an alarm in the control room upon detection of high smoke concentration in the return duct to each fan.
   b. Cause an alarm in the control room upon detection of high temperature in the discharge duct of each ventilation supply fan.
   c. Indicate, in the control room, open and closed positions of ventilation supply fan isolation, outside, return and relief air dampers.
   d. Cause an alarm in the control room upon detection of excess vibration of the ventilation supply fans.
   e. Indicate, in the control room, the air flow rate in the outside air supply ducts to the ventilation supply fans.
   f. Automatically control outside, return and relief air damper position by means of a return air temperature controller.
   g. Provide means for manually operating the ventilation system fans from the control room. These fans are interlocked with the associated inlet isolation dampers.
   h. Provide an outside/return air manual control station in the control room.
   i. Provide means for automatically starting the ventilation air supply fans upon receipt of a safety injection or loss of offsite power signal and bypassing the discharge temperature controller upon receipt of a safety injection signal.
   j. Indicate, in the control room, high and low ambient temperatures in the pump/screen room and in the switchgear rooms.
   k. Indicate, in the control room, ventilation supply fan operation.
   l. Cause an alarm in the control room upon detection of ventilation supply fan motor trip.

Either of the 2 supply fans operates continuously during normal operating periods. Both fans start automatically following receipt of a safety injection or loss of offsite power signal. Outside, return and relief air damper positions are automatically controlled by a return air temperature controller. Alternatively, position of these dampers can be manually controlled by a hand control station in the control room. The fans are powered from separate Class 1E power sources. The fans are manually started from the control room or are automatically started as previously noted. The air handling equipment is located in a shielded fan room above the equipment areas. Ductwork in the equipment areas is fireproofed. Fireproofing is accomplished by "boxing-in" the duct. System operation is monitored from the control room.

9.4.7.2.3 Service Building Ventilation System

Air conditioning, heating, cooling, and ventilation systems are provided for the Service Building areas to satisfy the following general requirements:

1. To maintain ambient air temperatures in all areas as required for the comfort and safety of personnel.

9.4.7.2.4 Safety Class Chilled Water System

The main components of this system include:

1. Three (3) 100% capacity screw type, electric motor driven water chilling machines.
2. Three (3) 100% capacity chilled water pumps.
3. Chilled water cooling coils for the following areas:
   a. Charging pump rooms.
   b. Residual heat removal/Reactor Building spray pump rooms.
   c. Emergency feedwater pump areas.
   d. Service water booster pump rooms.
   e. ESF switchgear rooms.
   f. Control room/Technical Support Center.
   g. Relay room/Technical Support Equipment Room.
   h. Auxiliary Building motor control center cooling units.
   i. Battery Room.
   j. Speed Switch Room.
4. Piping supply and return mains with expansion tanks, chemical feed, systems and provisions for balancing, manual and automatic isolation of portions of the system.
5. Instrumentation and control devices to perform the following functions:
   a. Cause an alarm in the control room upon detection of low chilled water flow.
   b. Indicate, in the control room, which chiller and chilled water pump are energized.
   c. Cause an alarm in the control room upon detection of chilled water pump motor trip.
   d. Cause an alarm in the control room upon detection of low chilled water pressure in pipe mains.
   e. Indicate, in the control room, chilled water temperature in the supply pipe mains and cause an alarm in the control room upon detection of high or low chilled water temperature.
   f. Indicate, in the control room, chilled water temperature in the discharge of the chiller and cause an alarm in the control room upon detection of high chilled water temperature.
   g. Cause an alarm in the control room upon detection of loss of chiller condenser water flow.

h. Indicate water temperature locally in the pipe supply and return mains at the inlet and outlet of each cooling coil.

i. Provide thermal wells for local testing in the supply and return mains and in the discharge of the A and B chillers.

j. Indicate water pressure locally at the suction and discharge of each pump.

k. Cause an alarm in the control room upon detection of low Chilled Water System water level.

l. Provide interlocks requiring chilled water pump operation before the chiller can be started.

m. Provide means to automatically start chilled water pumps and chillers following receipt of a safety injection or loss of offsite power signal.

n. Cause an alarm in the control room upon chiller trip.

Continuous operation of 1 of the 3 chillers and chilled water pumps is required during normal and emergency periods to provide 45°F water to the chilled water coils listed in Section 9.4.7.2.4, item 3. Use of 3 chillers and 3 chilled water pumps permits one unit to undergo extended maintenance, 1 unit to operate, and the remaining unit to be a nonrunning chiller and pump set. If all 3 chiller and pump sets are available, 1 is designated as a spare and its breaker(s) is racked out. Continuous chilled water flow is maintained through chilled water coils in the operating loop during normal plant operation. The Chilled Water System is a closed system with redundant supply and return mains. Chiller condenser cooling water is supplied by the Service Water System. Equipment is supplied from separated Class 1E power sources. The chillers and chilled water pumps may be started from the control room. All chillers may also be started locally. Local control of the "B" and "C" aligned "B" chilled water pumps only is available. This allows the "B" train of the Chilled Water System to be available in the event of a postulated exposure fire where "B" train is the selected train for plant shutdown. The operation and status of Chilled Water System components are monitored and alarms are annunciated in the control room. The chillers and chilled water pumps are located in 3 separated, concrete shielded, equipment spaces in the Intermediate Building.

9.4.7.2.5 Industrial Cooling Water System

The Industrial Cooling Water System has the ability to reject heat to either of two heat sinks, the industrial coolers (Wet-surface Air Cooler) or the RB Chiller Loop (via the industrial cooling heat exchangers). The main components of this system include:

1. Two (2) 50% capacity industrial coolers, each consisting of closed loop, sectionalized cooling water coils, an external spray system and sump, sump heaters, makeup and bleed off devices, 4 spray pumps (2 normal-2 standby), and 8 fans.
2. Two (2) 100% capacity industrial cooling water pumps to circulate water in the closed cooling loop from the industrial cooler (or industrial cooling heat exchangers) to air dryers,

air compressors, thermal regenerative chiller condenser, and the Reactor Building cooling units and back to the industrial cooler (or industrial cooling heat exchangers).

3. Piping supply and return mains with connections to the coils and heat exchangers noted in item 2, above. An expansion tank, chemical feed tank, and provisions for fill, drain, balancing, and isolation of system components are supplied.
4. Instrumentation and control devices for the Industrial Cooling Water System and the industrial coolers perform the following functions:
   a. Cause an alarm in the control room upon detection of loss of industrial cooling water flow.
   b. Indicate industrial cooling water flow locally.
   c. Indicate, in the control room, which industrial cooling water pump is energized.
   d. Cause an alarm in the control room upon detection of industrial cooling water pump motor trip.
   e. Cause an alarm in the control room upon detection of high industrial cooling water temperature.
   f. Cause an alarm in the control room upon detection of low water level in the industrial cooler expansion tank.
   g. Provide means to automatically reset the required discharge water temperature in response to Reactor Building ambient temperature changes.
   h. Indicate, locally, water temperature entering and leaving all components served by the Industrial Cooling Water System and water temperature entering and leaving the industrial coolers.
   i. Indicate, in the control room, water temperature entering the Industrial Cooling System at the discharge of the industrial cooling water pumps.
   j. Locally indicate water pressure at the suction and discharge of the industrial cooler pumps and at the inlet and discharge of each industrial cooler.
   k. Input to the plant computer for Industrial Cooling Water Heat Exchanger inlet and outlet temperatures.
5. The RB chiller loop of the Industrial Cooling Water system contains:
   a. Two (2) 100% capacity, variable flow chiller loop water pumps to circulate water in the closed cooling loop from the RB chillers to the industrial cooling heat exchanger and back to the RB chillers.
   b. Piping supply and return mains with connections to the heat exchangers noted in item 5a, above. An expansion tank, chemical feed tank, and provisions for fill, drain and isolation of system components are supplied.
   c. An Industrial Cooling Pump House (ICPH) which houses the pumps with variable frequency drives, chemical feed tank and chiller control panel.
   d. Instrumentation and control devices to perform the following functions:

i. Cause a common trouble alarm in the control room upon detection of either out of range water temperatures and flows, expansion tank level high/low, chiller failure or chiller pump failure.

ii. Industrial cooling supply water temperature to the Reactor Building is automatically controlled by the RB chiller loop.

iii. Provide local indication of differential pressure across Industrial Cooling Heat Exchangers.

iv. Input to the plant computer for Industrial Cooling Heat Exchanger chiller water inlet and outlet temperatures.

v. Input to plant computer for chiller loop expansion reservoir level.

vi. Provide local indication of water pressure at the suction and discharge of the chiller loop pumps.

Operation of one industrial cooling water pump is required during all normal, shutdown and Reactor Building leak rate test periods to circulate water through the closed system. During operation, heat is absorbed in the various heat exchangers and rejected to the outside via industrial coolers or via plate heat exchanger(s) and air-cooled chillers. The water supply and return main flows to the Reactor Building cooling units are automatically diverted from the industrial cooler or industrial cooling heat exchanger(s) to the Service Water System upon receipt of a safety injection or loss of offsite power signal. The industrial cooler fans and spray pumps are automatically controlled to maintain discharge water temperature. The RB chillers and chiller loop pumps are automatically controlled by RB chilled water temperature determined by ITK09205. RB Chiller loop flow is automatically controlled with variable frequency drive pumps. The required discharge water temperature is manually set to maintain a constant Reactor Building ambient temperature. Makeup water to the industrial cooling loop and RB chiller loop is supplied from the filtered water and demineralized water respectively. Industrial cooling water circulation pumps are manually controlled from the control room. Equipment is supplied with normal power.

9.4.7.2.6 Substation Relay House and Unit 1 Relay House Cooling Systems

The main components of the Substation Relay House system include:

1. One (1) 100% capacity self-contained cooling unit consisting of casing, roughing filters, direct expansion cooling coils, fan and motor section and controls.
2. One (1) 100% capacity air cooled condensing unit consisting of refrigerant compressor, condensing coil, condenser fan and motor section and controls.
3. Ductwork system with outlets, balancing devices and electrically operated outside air dampers.
4. Refrigerant piping system between condensing unit and cooling unit.
5. Two (2) 50% capacity, wall mounted, battery room exhaust fans.
6. Five (5) electric unit heaters for the relay room and storage areas.

The substation relay house cooling unit operates continuously after local manual start and is subsequently controlled automatically by self-contained equipment controls. Equipment is supplied from normal power supplies. No provisions are made for power supplied from an emergency source. The air handling unit is located along the east end of the substation relay house. The condensing unit is pad mounted directly outside.

The main components of the Unit 1 Relay House Cooling system include:

1. Air conditioning units are four (4) 33% capacity units. Each unit is a self contained unit with air conditioning and heating equipment. Each unit has its own wall mounted thermostat. Units have built in economizer with exhaust damper. The units are 5 ton units with 6kW heater.
2. Each battery room has two (2) 100% exhaust fans. One fan is running while the other is in standby. Loss of flow to the primary fan automatically starts the standby fan.

   The Unit 1 relay house cooling unit operates continuously after local manual start and is subsequently controlled automatically by self-contained equipment controls. Three (3) of the four (4) air conditioning units run during normal operation. Equipment is supplied from normal power supplies. No provisions are made for power supplied from an emergency source.

9.4.7.2.7 Penetration Access Areas Ventilation System

The main components of this system include:

1. Two (2) 100% capacity exhaust fans.
2. Two (2) 50% capacity ventilation supply air fans for each of the following locations:
   a. Elevation 412’, east penetration area.
   b. Elevation 412’, west penetration area.
   c. Elevation 436’, east penetration area.
   d. Elevation 436’, west penetration area.
3. Supply ductwork with outlets, control dampers and outside air intake provisions. Exhaust ductwork with control dampers and make-up air intake provisions.
4. Instrumentation and control devices to perform the following functions:
   a. Alarm in the control room upon detection of high concentrations of smoke in each penetration area, upon a fan motor trip, upon excessive exhaust fan vibration, and upon low exhaust air flow.
   b. Manual operation of supply and exhaust fans from remote control stations. The fans are also interlocked with their respective isolation dampers which open when their respective fan runs and vice versa.
   c. Automatically control outside and return air dampers in response to a room thermostat.

d. Indicate fan operation at each switch.

e. Automatic/Manuel control of the exhaust fan make-up damper in response to a local flow monitor.

The fans operate continuously after manual start from the local control stations. The amount of outside air introduced is controlled automatically by a room thermostat. Exhaust air is discharged to outdoors through the plant vent. The fans are powered from a non-Class 1E power source.

9.4.7.2.8 Miscellaneous Pump Room Systems and Lube Oil Room System

The main components of these systems include:

1. Two (2) exhaust fans and 2 motorized inlet openings for the motor driven fire service pump room.
2. One (1) exhaust fan and motorized inlet opening for the diesel driven fire service pump room.
3. One (1) exhaust fan and motorized inlet opening for the screen wash pump room.
4. Two (2) wall mounted exhaust fans each equipped with a gravity operated backdraft damper and a temperature controlled fire damper and a common room inlet equipped with a temperature controlled fire damper. (For the Turbine Lube Oil Treatment Room.)
5. Electric unit heaters for the following locations:
   a. Motor driven fire service pump room, 2 units.
   b. Diesel driven fire service pump room, 1 unit.
   c. Screen wash pump room, 1 unit.
6. Instrumentation and control devices to perform the following functions:
   a. Provide local control of each fan.
   b. Provide thermostat control for each of the exhaust fans noted in items 1 through 4, above.
   c. Provide interlocks so that the fans do not operate unless the inlet louver and fan isolation dampers are open. (Pump room ventilation systems only.)
   d. Provide local indication of fan operation.
   e. Provide control room indication of fan motor trip in the turbine lube oil treatment room.
   f. Provide thermostat control of the electric unit heaters described in Section 5 above.

Roof ventilators and dampers in the pump room ventilation system operate automatically in response to thermostats after manual start. Unit heaters, as described in Section 5 above, operate in response to integral thermostats. Equipment is powered from non-Class 1E power sources.

9.4.7.2.9 Water Treating Area Laboratory Heating and Cooling System

The main components of this system include:

1. One (1) package type heating and cooling unit, including direct expansion type air handling unit with electric heating coil and roughing filter and refrigerant condensing unit.
2. Two (2) laboratory hood exhaust fans and a chemical storage area exhaust fan.
3. Twelve (12) electric unit heaters in the chemical storage and general floor areas.
4. Ductwork connecting the air handling unit with the sample room and the water treating laboratory and for supply and exhaust of the laboratory hoods.
5. Instrumentation and control devices to perform the following functions:
   a. Automatically operate the condensing unit and the air handling unit heating coil in response to a room thermostat.
   b. Automatically place the outside, return and relief dampers under control of theoutside and return mixture temperature controller or at a fixed minimum position in accordance with outside temperature.
   c. Automatically prevent or permit the condensing unit to operate in accordance with outside temperature.
   d. Control electric unit heaters with integral thermostats.
   e. Automatically close hood inlet dampers when the entering air is below a set temperature.

The air handling unit operates continuously. The laboratory hood and chemical storage area exhaust fans are operated as required from local control stations. System components are supplied from non-Class 1E power sources.

9.4.7.2.10 CRDM Cooling Water System

(System has been abandoned in place pending demolition by ECR 50917)

The main components of this system include:

1. One (1) CRDM cooler rack assembly which is an air to water heat exchanger.
2. One (1) CRDM cooling water industrial cooler, including 2 electric heaters, 8 forced convection fans, and 4 circulation pumps.
3. One (1) expansion tank to control thermally induced water volume changes.
4. Two (2) 100% circulating water pumps, including a bypass line with a chemical feed tank.

The system is designed to remove heat from the containment air used to cool the Control Rod Drive Mechanism (CRDM) and dissipate this heat to the atmosphere via the Industrial Cooler.

The system can operate continuously while the plant is in operation. System components are powered from non-Class 1E power sources.

9.4.7.2.11 Turbine Building Switchgear Rooms Chilled Water System

The main components of this system include:

1. One (1) air-cooled, electric motor drive, reciprocating water chiller.
2. One (1) primary water pump.
3. Two (2) 100% capacity secondary water pumps.
4. Chilled water piping system including a compression tank, an air separator, a chemical feed tank, and valves.
5. Chilled Water Coils - 1 coil bank consisting of two (2) sections in each of 2 redundant Turbine Building switchgear rooms air handling units. Each section has 2 connections.
6. Instrumentation and control devices to perform the following functions:
   a. Chiller is equipped with a unit mounted starter and microprocessor based control panel with local controls, status panel, and diagnostic capability. When temperature or pressure is reported out of range by local sensors, a diagnostic is sent to the unit control panel. Chiller is interlocked with the primary pump; therefore the energized chiller will not start unless the primary pump is running.
   b. The primary pump is started by a remote manual switch. The primary pump is interlocked with the main power for the chiller; therefore the pump will not turn on without power running to the chiller.
   c. The secondary pumps are redundant and each is wired to run only with its respective air handling unit. The active pump is controlled by 1 of 3 parallel-wired room thermostats.
   d. Indicate locally the level of water in the compression tank and alarm of low level in the control.
   e. Alarm in the control room of low water flow.
   f. Indicate locally the temperature of water entering and leaving the chiller and provide a computer high temperature alarm and CRT display in the control room of water leaving the chiller.
   g. Indicate locally the pressure of water entering and leaving each pump.

Under normal conditions, the primary pump continuously circulates water in the primary pipe loop. This water is maintained at 45°F by the chiller which loads/unloads and cycles automatically under its self contained controls. The secondary pump circulates water between the primary loop and the chilled water coils identified in Section 9.4.4.2.1, subitem 4. It cycles upon demand of room thermostats.

Additionally, this system can provide chilled water to the CRDM Switchgear Room cooling coils via a booster pump in the event that chilled water is unavailable to these coils. This system can be provided chilled water from the non-nuclear safety related Chilled Water System. The system is non-nuclear safety class.

9.4.7.2.12 Non-nuclear Safety Related Chilled Water System

The main components of this system include:

1. One (1) air-cooled, electric motor driven reciprocating water chiller.
2. Two (2) 100% capacity chilled water circulating pumps.
3. One (1) chilled water booster pump.
4. Chilled water piping system including an atmospheric expansion tank, provisions for chemical sample and feed, and provisions for balancing the system.
5. Chilled water cooling coils for the following areas:
   a. CRDM Switchgear Room.
   b. Controlled Access Area.
   c. SAS/Computer Room.
   d. Computer Room.
   e. BOP Charger Area.
6. Instrumentation and control devices to perform the following functions:
   a. Cause an alarm at a local panel and a common trouble alarm in the control room upon detection of either low chilled water flow, high chilled water temperature, or low expansion tank level.
   b. Provide local indication of system flow.
   c. Provide interlocks which shut the chiller down on low system flow.
   d. Indicate water temperature locally at the pipe supply and return headers and at the inlet and outlet of each cooling coil.
   e. Provide thermowells for local testing in the supply and return headers at the chiller.
   f. Indicate water pressure locally at the suction and discharge of each pump.
   g. Provide the means for determining pressure drop across each system cooling coil.
   h. Provide local indication of expansion tank level.
   i. Provide a remote means for filling the system.
   j. Provide a local panel at the fill station to indicate "Normal," "Low," and "Fill Complete" expansion tank level with status lights.

Under normal conditions, the system provides chilled water via redundant circulating pumps to the cooling coils listed in Section 9.4.1.2.3, 9.4.1.2.4, 9.4.1.2.6, 9.4.6.2.1, and 9.4.6.2.3. The chiller loads/unloads and cycles automatically to maintain chilled water temperature at 45°F. This system can be aligned to provide a backup source of chilled water to the Turbine Building Switchgear Rooms cooling coils. In the event that chilled water is unavailable to the CRDM Switchgear Room cooling coils, the booster pump can be aligned to the Turbine Building Switchgear Rooms Chilled Water System to provide a backup source of cooling to the CRDM Switchgear Room.

9.4.7.2.13 ISFSI Electrical Building (EB) HVAC System

The main components of the system include:

1. Three (3) 50% capacity wall mounted HVAC units.
2. Two (2) 100% capacity Battery Room wall mounted ventilation fans.
3. One (1) 100% capacity EB Diesel Generator Room wall mounted ventilation fan.
4. One (1) 100% EB Diesel Generator Room Cooling wall mounted supply fan.
5. One (1) 100% EB Diesel Generator Room Cooling wall mounted exhaust fan.
6. One (1) 100% EB Diesel Generator Radiator Cooling wall mounted supply fan.
7. One (1) 100% EB Diesel Generator Engine Driven Radiator Cooling exhaust fan.

The EB HVAC units condition the air in the Electrical Room and Battery Room in order to maintain the UPS batteries within the normal operating temperature range. Ventilation air is supplied through the lead HVAC unit into the Electrical Room, drawn through a fire damper in the Battery Room wall into the Battery Room and then exhausted through a wall mounted exhaust fan to remove any hydrogen generated by the batteries and cool or heat the battery room air. The primary ventilation fan operates at all times. If air flow is lost through the primary ventilation fan, an alarm is generated on the Main Control Board and local panels XPN5386 and XPN5387 and the secondary fan is started automatically.

Ventilation air is drawn in through a gravity operated supply damper in the exterior wall of the EB Diesel Generator Room and exhausted by the EB Diesel Generator Room Ventilation fan exhaust fan to remove any diesel fumes released into the room. If air flow is lost through the ventilation fan an alarm is generated on the Main Control Board and local panels XPN5386 and XPN5387 and the EB Diesel Generator Room Cooling supply and exhaust fans will be started automatically. The EB Diesel Generator Radiator Cooling Supply fan is started automatically when the EB Diesel Generator is started along with the EB Diesel Generator Engine Driven Radiator Cooling exhaust fan. If room temperatures continue to increase above 80°F the Diesel Generator Room Cooling supply and exhaust fans will start to provide additional room cooling. Reference FSAR Figures 9.4-35, Sheets 1 and 2.

9.4.7.2.14 ISFSI Auxiliary Electrical Building (AEB) HVAC System

The main components of the system include:

1. One (1) 100% capacity AEB Diesel Generator Room wall mounted ventilation fan.
2. Two (2) 50% capacity AEB Diesel Generator Room Cooling wall mounted supply fans.
3. Two (2) 50% capacity AEB Diesel Generator Radiator Cooling wall mounted supply fans.
4. One (1) 100% capacity AEB Diesel Generator Room Cooling wall mounted exhaust fan.
5. One (1) 100% AEB Diesel Generator Engine Driven Radiator Cooling exhaust fan.

Ventilation air is drawn in through a gravity operated supply damper in the exterior wall of the AEB Diesel Generator Room and exhausted by the AEB Diesel Generator Room Ventilation fan exhaust fan to remove any diesel fumes released into the room. If air flow is lost through the ventilation fan an alarm is generated on the Main Control Board and local panels XPN5386 and XPN5387 and the AEB Diesel Generator Room Cooling supply and exhaust fans will be started automatically. The Diesel Generator Radiator Cooling Supply fan is started automatically when the AEB Diesel Generator is started along with the AEB Diesel Generator Engine Driven Radiator Cooling exhaust fan. If room temperatures continue to increase above 80°F the AEB Diesel Generator Room Cooling supply and exhaust fans will start to provide additional room cooling. Reference FSAR Figure 9.4-36.

9.4.7.3 Safety Evaluation

The Service Building ventilation system, Industrial Cooling Water System, substation relay house and Unit 1 relay house cooling systems, penetration access areas ventilation system, miscellaneous pump room systems and lube oil room systems, water treating area laboratory heating and cooling system, and Turbine Building switchgear rooms chilled water system perform no safety function. They do provide acceptable temperature levels in the various buildings.

Additionally, the substation battery room exhaust fan in both the substation relay house and the Unit 1 relay house cooling system prevents the occurrence of any appreciable hydrogen concentration in the battery room.

The Diesel Generator Building ventilation system, Service Water Pumphouse ventilation system, and safety class Chilled Water System do perform safety functions since total loss of the heat removal capability of any one of these systems could produce conditions affecting the safety of the plant. These systems are designed with redundant equipment and piping systems and are so arranged, serviced, and maintained such that complete loss of system function or system cooling is highly unlikely. Each of the safety class systems is located in equipment rooms accessible for maintenance but not subject to floods, weather, external missiles, main steam line break effects, jet impingement, or pipe whip. Each is supplied by separated Class 1E power supplies. The safety class systems are administratively controlled from the control room. Operation of the Diesel Generator Building ventilation system is automatically initiated by diesel generation. Operation of the Service Water Pumphouse ventilation system and the Chilled Water System are

automatically initiated by receipt of a safety injection or loss of offsite power signal. Safety class systems are monitored and alarms are annunciated in the control room.

9.4.7.4 Inspection and Testing Requirements

The miscellaneous building ventilation and cooling systems are subjected to preoperational testing to verify proper wiring and control hookup, system "in-place" integrity and leak tightness, proper function of system components and control devices, and to establish system design air and water flow rates. To ensure a continued state of readiness of the miscellaneous building ventilation and cooling systems after completion of the preoperational tests, the following inspection, maintenance, and test procedures are performed:

a. Verify function of dampers or control devices necessary for monitoring or component isolation or changeover from normal to emergency mode.

b. Bearing lubrication.

c. Switch components from standby to operating mode.

9.4.8 Reactor Building Cooling and Filtering Systems

Under normal operating conditions, continuous circulation and cooling of the Reactor Building air is required to maintain the ambient air temperature at a suitable level for continuous operation of equipment within the building.

Under shutdown conditions, heating and cooling of the Reactor Building is provided by the ventilation system as required.

Cleanup of the Reactor Building atmosphere is required before purging to minimize the release of radioactivity to the environment. Purging may be utilized to maintain a suitable environment for personnel prior to entering the Reactor Building for maintenance or refueling operations.

During a post accident period, the Reactor Building cooling system assists other heat removal systems in their heat removal function.

9.4.8.1 Design Bases

The ventilating, cooling and filtering systems of the Reactor Building are designed to perform the following functions:

1. Satisfy the general requirements stated in Section 9.4.8.
2. Maintain an average Reactor Building air temperature below a maximum of 120°F during normal power operation as assumed in the accident analyses and below 100°F during refueling operations for personnel comfort and safety.
3. Maintain an average Reactor Building air temperature above 60°F during shutdown conditions for personnel comfort and safety.

4. Provide post accident heat removal capability to assist in depressurizing the Reactor Building following a LOCA or main steam line rupture. See Section 6.2.2 for a discussion of the engineered safety features functions of the Reactor Building cooling system.
5. Provide forced air cooling systems in areas of high local heat release within the Reactor Building. These systems limit temperatures of the adjacent concrete to a maximum of 150°F and provide a suitable ambient temperature for instrumentation and equipment. These areas include the annular spaces between the reactor vessel, reactor vessel nozzles and the shielding concrete, the concrete under the reactor vessel supports, the neutron detector wells, the reactor coolant pumps, the pressurizer and steam generator compartments, and the rod position indicator data cabinet area.
6. Provide forced air cooling in sufficient capacity to remove control rod drive mechanism (CRDM) heat and reject it to the general Reactor Building atmosphere.
7. Provide Reactor Building cleanup capacity to reduce airborne radioiodine levels prior to personnel entry and to minimize radioactivity released during Reactor Building purging. Cleanup capacity is based upon equilibrium I-131 concentrations and 16 hours of cleanup system operation. Cleanup capacity is sufficient to reduce airborne I-131 levels to below the limits specified in 10 CFR 20, Appendix B, Table I.
8. Provide outside air purge capacity to reduce airborne radioactivity levels prior to personnel entry. The purge system design assumes a flow rate that, when considered with the site meteorology, results in site boundary concentrations that do not exceed allowable limits.
9. Provide a push-pull ventilation system for the refueling canal and refueling cavity which nominally causes air flow to travel across the entire water surface.
10. Provide control room monitoring of process conditions and equipment status necessary for operation of the systems.
11. Provide for remote operation, from the control room, of all systems except the push-pull refueling canal ventilation system and the elevator machine room ventilation system which are locally controlled.
12. For engineered safety features systems, provide sufficient redundancy and separation in air handling equipment, duct systems, controls and power supplies to satisfy the single failure criteria.

9.4.8.2 System Description

The system diagrams for the various reactor building systems are as follows:

1. Figure 9.4-28, Reactor Building Purge Supply and Exhaust System.
2. Figure 6.2-58, Post Accident Hydrogen Removal and Alternate Reactor Building Purge System.
3. Figure 9.4-29, Reactor Building Charcoal Cleanup System, Reactor Compartment Cooling System and Secondary Compartment Cooling System.

4. Figure 9.4-30, Reactor Building Refueling Water Surface System, Rod Position Data Cabinet System, and Reactor Building Elevator Machine Room System.
5. Figure 9.4-31, Reactor Building CRDM Shroud Cooling System.

Design and performance data are indicated on these figures.

9.4.8.2.1 Reactor Building Cooling System

The main components of this system include:

1. Four (4) air handling units, each capable of providing 33-1/3% of normal system cooling capacity. Each air handling unit has moisture separators, HEPA filters, a filter bypass section, cooling coils, fan and dual motors.
2. Gravity dampers to isolate each air handling unit discharge from the distribution duct system when the unit is not operating.
3. Ductwork from the discharge connection of the units to various elevations of the Reactor Building.
4. Instrumentation and control devices to perform the functions detailed in Section 6.2.2.5.2.

Section 6.2.2.2 presents detailed descriptions of system equipment and functions.

9.4.8.2.2 Reactor Building Purge Supply and Exhaust System

The main components of this system include:

1. Two (2) 50% capacity supply fans directing filtered and tempered outside air into the Reactor Building.
2. Two (2) 50% capacity exhaust fans exhausting Reactor Building air to the purge exhaust vent.
3. Two (2) 50% capacity supply plenums, each with roughing filters (80% efficiency on NBS dust), and electric heating coils.
4. One (1) 100% capacity exhaust filter plenum with roughing filters (80% efficiency on NBS dust), HEPA filters (99.97% efficiency on 0.3 micron particles), a charcoal filter (95% efficiency on methyl iodide at 85% relative humidity and 70°F) and a second bank of HEPA filters (same efficiency as the initial bank).
5. Four (4) 100% capacity containment isolation butterfly valves. These valves are air opened, spring closed and fail in the closed position upon loss of power or instrument air.
6. Air operated, spring opposed dampers to isolate supply or exhaust fans and the outside air inlet duct.
7. Supply ductwork to direct outside air to the supply plenums, the supply fans and into the Reactor Building. Exhaust ductwork to direct Reactor Building exhaust air to the exhaust plenums, the exhaust fans and the purge exhaust vent.

8. Instrumentation and control devices to perform the following functions:
   a. Measure the pressure drop across the supply and exhaust filter banks by means of differential pressure gages (local indication only).
   b. Cause an alarm in the control room upon detection of high concentration of smoke in the discharge of each supply and exhaust fan.
   c. Cause an alarm in the control room upon detection of high temperature in the discharge of each supply and exhaust fan.
   d. Cause an alarm by means of a temperature scanner upon detection of high temperature in the charcoal filter plenum.
   e. Indicate fan isolation damper position by means of status lights in the control room.
   f. Indicate containment isolation butterfly valve position by means of status lights and ESF monitor lights in the control room.
   g. Provide means for manual operation of the following equipment from the control room.
      (1) Supply fans and associated isolation dampers. One (1) switch is provided for each fan. The isolation dampers operate in conjunction with the associated fan.
      (2) Exhaust fans and associated isolation dampers. One (1) switch for each fan is provided. Dampers operate in conjunction with the associated fans.
      (3) Containment isolation butterfly valves. One (1) switch is provided for each valve. Interlocks affecting valve operation are discussed in Section 9.4.8.3.2.
      (4) Outside air damper. One (1) switch is provided.
   h. Automatically maintain minimum supply air temperature by controlling the supply system heating coils by means of a pneumatic temperature controller.
   i. Indicate, in the control room, supply and exhaust fan motor status.
   j. Indicate and record, in the control room, Reactor Building purge exhaust flow rate.
   k. Cause an alarm in the control room upon detection of excessive fan vibration.
   l. Measure, record, and provide high radiation alarms and interlocks to close purge supply and exhaust isolation valves on the occurrence of high radiation levels in the Reactor Building cooling system duct (RM-A2) (see Section 12.2.4) and in the purge exhaust duct (RM-A4) (see Section 11.4).
   m. Measure, record, and provide high radiation alarms and interlocks to close purge supply and exhaust isolation valves on the occurrence of high radiation levels in the manipulator crane area of the Reactor Building (RM-G17A and RM-G17B) (see Section 12.1.4).
   n. Close the purge supply and exhaust isolation valves upon receipt of a containment isolation signal.

The 36 inch Reactor Building supply and exhaust system may be operated during cold shutdown and refueling to maintain suitable radiation levels inside the Reactor Building. This system is operated prior to personnel entering the Reactor Building to reduce radiation levels inside.

The 36 inch purge system supplies filtered and tempered outside air to the Reactor Building and exhausts air from the Reactor Building through HEPA and charcoal filters to the purge exhaust vent. The 36 inch purge system is powered from normal power sources, except for the solenoid valves and limit switches associated with the system containment isolation valves. These components are powered from Class 1E power sources. System equipment is operated and monitored from the control room. The 36 inch purge system supply and exhaust fans and plenums are located in the Auxiliary Building.

The 36 inch purge system and the 6 inch alternate purge system (see Section 9.4.8.2.3) use common outside air supply and exhaust vents, a common outside air intake damper and a common exhaust filter plenum. In other respects these 2 systems are separate.

9.4.8.2.3 Alternate Reactor Building Purge System

Major components of the alternate Reactor Building purge system include the following:

1. One (1) 100% capacity pressure blower to supply filtered outside air to the Reactor Building.
2. One (1) 100% capacity pressure blower to exhaust air from the Reactor Building to the purge exhaust vent.
3. One (1) 100% capacity supply filter plenum with roughing and medium efficiency (85-90% on NBS dust) filters.
4. One (1) 100% capacity exhaust filter plenum with roughing filters (80% efficiency on NBS dust), HEPA filters (99.97% efficiency on 0.3 micron particles), and a charcoal filter (95% efficiency on methyl iodine at 85% relative humidity and 70°F).
5. Four (4) containment isolation gate valves. These valves are spring return, air operated and fail in the closed position upon loss of power or instrument air.
6. Supply ductwork to direct air from the purge intake vent to the Reactor Building.
7. Exhaust ductwork to direct air from the Reactor Building to the purge exhaust vent on the Auxiliary Building roof.
8. Instrumentation and control devices to perform the following functions:
    a. Measure pressure drop across supply and exhaust filter banks by means of differential pressure gages (local indication only). (Part of Reactor Building purge supply and exhaust system.)
    b. Cause an alarm by means of a temperature scanner upon detection of high temperature in the charcoal filter plenum. (Part of Reactor Building purge supply and exhaust system.)
    c. Cause an alarm in the control room upon purge exhaust pressure blower motor trip.

d. Indicate containment isolation valve position by means of status lights in the control room.

e. Indicate purge exhaust pressure blower motor status by means of lights in the control room.

f. Indicate and record, in the control room, purge exhaust flow rate (recorder is part of Reactor Building purge supply and exhaust system).

g. Provide means for manual operation of the following equipment from the control room:

(1) Supply and exhaust pressure blowers.

(2) Containment isolation valves.

(3) Outside air intake damper.

h. Measure, record, and provide high radiation alarms and interlocks to close purge supply and exhaust isolation valves on occurrence of high radiation levels in the Reactor Building cooling system duct (RM-A2) and in the purge exhaust duct (RM-A4) (see Section 11.4).

i. Close the purge supply and exhaust isolation valves upon receipt of a containment isolation signal.

The 6 inch alternate Reactor Building purge system may be operated up to 1000 hours per year during modes 1 - 4 to maintain suitable moisture and radiation levels inside the Reactor Building. In addition to the ventilation functions described, the alternate Reactor Building purge system performs combustible gas control and pressure relief functions as discussed in Section 6.2.5.

9.4.8.2.4 Reactor Building Charcoal Cleanup System

The main components of this system include:

1. Two (2) 50% of system capacity fans to recirculate the general Reactor Building atmosphere through the Reactor Building charcoal cleanup filter plenums.
2. Two (2) 50% of system capacity Reactor Building charcoal cleanup filter plenums, each with roughing filters (80% efficiency on NBS dust), HEPA filters (99.97% efficiency on 0.3 micron particles), charcoal filters (95% efficiency on methyl iodide at 85% relative humidity and 70°F) and a second bank of HEPA filters (same efficiency as the initial bank).
3. Instrumentation and control devices to perform the following functions:
   a. Measure the pressure drop across the filter banks using differential pressure gages (local indication only).
   b. Cause an alarm in the control room upon detection of high concentration of smoke at the suction of each fan. Note that these duct detectors are maintained by the plant, but are not credited because other means exist to detect a fire in the Reactor Building. Their purpose is to aid plant operators in their decision making process.
   c. Cause an alarm in the control room upon detection of high temperature at the suction of each fan.

d. Cause an alarm in the control room upon detection of high temperature in the charcoal filter plenum.

e. Provide means to operate the fans from the control room. One (1) control switch is provided for each fan.

f. Cause an alarm in the control room upon detection of excessive fan and motor vibration.

g. Indicate, in the control room, fan motor status.

h. Cause an alarm in the control room upon fan motor trip.

The Reactor Building charcoal cleanup units are operated prior to Reactor Building access, during personnel access and during refueling operations to reduce iodine concentration to acceptable levels. One (1) or both units are manually operated and monitored from the control room. The units, when in operation, filter Reactor Building air and discharge it to the general Reactor Building atmosphere. The units are powered from normal power supplies.

The filter plenums and related fans are located on platforms along the perimeter of the Reactor Building above the operating floor.

9.4.8.2.5 Reactor Building Reactor Compartment Cooling System

The main components of this system include:

1. Two (2) 100% capacity supply fans to direct cooled Reactor Building air into the compartments surrounding the reactor vessel.
2. Gravity dampers to isolate the inactive fan.
3. Ductwork to direct cooled ambient air to the incore instrument chase from the discharge of the fans.
4. Instrumentation and control devices to perform the following functions:
   a. Cause an alarm in the control room upon detection of high concentration of smoke in the primary compartment incore instrument chase. Note that this detector is maintained by the plant, but is not credited because other means exist to detect a fire in the Reactor Building. Their purpose is to aid plant operators in their decision making process.
   b. Cause an alarm in the control room upon detection of high ambient temperature in the primary compartment incore instrument chase.
   c. Provide means to operate the fans from the control room. One (1) control switch is provided for each fan.
   d. Cause an alarm in the control room upon detection of excessive fan and motor vibration and trip the affected fan motor.
   e. Indicate, in the control room, fan motor status.
   f. Cause an alarm in the control room upon fan motor trip.

Either 1 of the 2 fans operates continuously during normal operation and, during shutdown so that heat losses from the reactor vessel and nozzles can be removed. In the unlikely event of the failure of both fans, full power operation can be supported by establishing natural circulation ventilation of the reactor cavity within 16 hours of the loss of forced ventilation. Natural circulation can be established by opening the door (RB-101) to the incore instrument chase. The fans are not required to operate during a post LOCA period. The fans when operating, direct air cooled by the Reactor Building cooling units into the reactor compartment from which it circulates around the reactor vessel, around neutron detector tubes, around the vessel supports and exits around the vessel nozzles and seal ring, thus removing heat from these items. The fans are supplied from normal power sources. The fans are operated and monitored from the control room. The fans are mounted in the wall enclosing the incore instrumentation tubes.

9.4.8.2.6 Reactor Building Secondary Compartment Cooling System

The main components of this system include:

1. Nine (9) supply fans to direct cooled Reactor Building air into the secondary compartments housing the reactor coolant pumps, steam generators and pressurizer. Six (6) of the 9 fans are normally required to operate.
2. Instrumentation and control devices to perform the following functions:
   a. Cause an alarm in the control room upon detection of high concentration of smoke in the discharge of each fan. Note that these detectors are maintained by the plant, but are not credited because other means exist to detect a fire in the Reactor Building. Their purpose is to aid plant operators in their decision making process
   b. Cause an alarm in the control room upon detection of high temperature in the discharge of each fan.
   c. Provide means to operate the fans from the control room. One control switch is provided for each fan.
   d. Cause an alarm in the control room upon detection of excessive fan and motor vibration and trip the affected fan motor.
   e. Indicate, in the control room, fan motor status.
   f. Cause an alarm in the control room upon fan motor trip.

Two (2) of the 3 fans for each of the 3 secondary compartments operate continuously during normal operation so that reactor coolant pump, steam generator, pressurizer and piping heat losses can be removed. The fans are not required to operate during a post LOCA period. The fans, when operating, direct air cooled by the Reactor Building cooling units into the secondary compartments where it absorbs the heat losses listed above. The heated air exits above the operating floor at an elevated temperature. The fans are supplied from normal power sources. The fans are operated and monitored from the control room. The fans are mounted in shielded wall openings in the secondary compartments.

9.4.8.2.7 Reactor Building Refueling Water Surface System and Rod Position Indication Cooling System

The main components of this system include:

1. Two (2) 50% capacity supply fans to direct Reactor Building ambient air to the refueling water surface duct system.
2. One (1) 100% capacity exhaust fan to direct exhaust air from the refueling water surface to the purge exhaust filter system.
3. Ductwork from 1 of the vertical ducts of the Reactor Building cooling system is provided to supply cooling air to the rod position indication data cabinet area. Flexible ducts provide air directly from a supply grille to each air inlet of the 2 cabinets. As a backup for cooling the cabinet area a 100% capacity air handling unit is provided to supply filtered and cooled air to the area.
4. Ductwork from the supply fans to the refueling water surface supply duct distribution system and from the exhaust side of this system to the exhaust fan and then to the purge exhaust duct. Ductwork to and from the rod position indication data cabinet area and the related air handling unit.
5. Instrumentation and control equipment, including a local control station and circuitry to interlock the operation of the supply and exhaust fans with Reactor Building purge exhaust fan operation.
6. Instrumentation to indicate, in the control room, excessive discharge temperature from the rod position indication cooling system. When the air handling unit cooling system is not operating, this instrumentation also indicates an excessive temperature in the cabinet area.

The Reactor Building refueling water surface system is not normally operated, but does operate continuously during refueling periods to reduce operator exposure due to the release of airborne radioactivity from the refueling canal and refueling cavity surface. The system is arranged to develop a moving air flow across the surface of the refueling canal and refueling cavity. The exhaust from this system is directed to the Reactor Building purge exhaust system. Each unit is supplied from normal power supplies. The fans are operated from a local control station. The supply and exhaust fans are mounted on the secondary compartment shield walls above the operating floor. The rod position indication air handling unit operates as a backup cooling system during normal operating periods to maintain the rod position indicator data cabinet at a suitable ambient temperature. The air handling unit is served by normal power supplies. The cooling coil is supplied from the industrial cooling water system. The air handling unit is located adjacent to the rod position data cabinet.

9.4.8.2.8 Integrated Head Assembly CRDM Cooling System

The Integrated Head Assembly CRDM Cooling System is contained within the Integrated Head Assembly (IHA). The IHA houses internal ducting that pulls RB area air into the IHA and draws the air downward past the CRDM coils, providing cooling. The air is then ducted upward to a

common air plenum which the fans draw from. Two (2) fans are normally operating which will exhaust the air from the plenum to the RB general area.

The main components of this system include:

1. Three (3) 50% capacity exhaust fans to draw general Reactor Building ambient air through the CRDM shroud for cooling.
2. Gravity dampers to isolate the inactive fans.
3. Ductwork connecting the exhaust ports of the CRDM shroud to the inlet connections of the exhaust fans, all within the Integrated Head Assembly (IHA).
4. Instrumentation and control devices to perform the following functions:
   a. Indicate, in the control room, the temperature of the air at the CRDM shroud plenum and cause an alarm in the control room upon detection of high air temperature.
   b. Cause an alarm in the control room upon detection of high temperature in the discharge of each fan.
   c. Provide means to operate the fans from the control room. One control switch is provided for each fan.
   d. Cause an alarm in the control room upon detection of excessive fan and motor vibration.
   e. Indicate, in the control room, fan motor status.
   f. Cause an alarm in the control room upon fan motor trip.

Each fan is normally supplied from a BOP power source. However, provision is made to manually connect 1 unit to a Class 1E bus. The fans are operated and monitored from the control room. The fans are located above the air plenum atop the IHA.

9.4.8.2.9 Reactor Building Elevator Machine Room System

Major components of the Reactor Building elevator machine room system include the following:

1. A 100% capacity exhaust fan.
2. Fixed, wall inlet louvers.
3. Instrumentation and control devices to automatically limit maximum elevator machine room temperature by cycling the exhaust fan.

The system cyclically exhausts air from the elevator machine room to the general open area of the Reactor Building in response to a room thermostat when normal power is available. Makeup air from the general open area of the Reactor Building enters the room through fixed, wall inlet louvers. Equipment is located in the Reactor Building elevator machine room wall.

9.4.8.3 Safety Evaluation

9.4.8.3.1 Reactor Building Cooling and Filtering System

A safety evaluation of this system is presented in Section 6.2.1.

9.4.8.3.2 Reactor Building Purge Supply and Exhaust System

Containment isolation is safeguarded through the use of redundant, fail closed, butterfly valves on both the purge supply and exhaust lines. For both the supply and the exhaust portions of this system, redundant fans are furnished so that equipment failure does not prevent purge but simply extends the required purge time period. Radiation monitoring of the purge exhaust vent is provided by radiation monitor RM-A4 (see Section 11.4). Electrical interlocks allow no more than 1 valve of a redundant pair of containment isolation valves to be open unless the exhaust system is operating (1 valve of the pair can be open for testing purposes). Automatic closure of the 4 containment isolation valves of this system occurs upon receipt of a containment isolation signal (see Section 7.3) or a high radiation signal (see Sections 11.4, 12.1.4, and 12.2.4). These measures, combined with administrative control of system operation, ensure that containment air is not released to the atmosphere through uncontrolled paths. The purge supply and exhaust system are not required to operate during a post accident period. The purge supply and exhaust isolation valves, as noted above, isolate the containment and are redundant safety class equipment.

9.4.8.3.3 Alternate Reactor Building Purge System

Containment isolation is assured through the use of redundant, fail closed, gate valves on both the alternate purge supply and exhaust lines. Automatic closure of the 4 containment isolation valves in the alternate Reactor Building purge system occurs upon receipt of a containment isolation signal (see Section 7.3) or a high radiation signal (see Sections 11.4 and 12.2.4). These measures, combined with administrative control of system operation, ensure that containment air is not released to the atmosphere through uncontrolled paths. Post accident operation of the alternate purge system is discussed in Section 6.2.5.

The alternate Reactor Building purge system containment isolation valves and accessories are safety class equipment. The remainder of the system is not safety related.

9.4.8.3.4 Reactor Building Charcoal Cleanup System

Redundancy of cleanup units provides iodine removal capability even if 1 of the units is not available. This condition extends the required cleanup time period prior to purging, but does not prevent eventual completion of system function. This system is not required to operate under accident conditions and is not supplied from emergency power sources. The system is not safety-related.

9.4.8.3.5 Reactor Building Reactor Compartment Cooling System, Secondary Compartment Cooling System and CRDM Shroud Cooling System

For each of the these 3 systems, adequate redundancy of system components is provided to ensure that sufficient cooling capacity is delivered under varying conditions of component availability. These systems are not required to operate under accident conditions and are not safety-related.

In the unlikely event that natural circulation is relied upon to cool the reactor cavity, the temperature of the concrete at the reactor vessel support anchorages, and the air temperature around the nuclear instrumentation will exceed the design basis values. These elevated temperatures have been acceptably evaluated to support full power operation until the next regularly scheduled outage.

9.4.8.3.6 Reactor Building Refueling Water Surface System

This system is operated only during refueling and has no post accident safety function.

9.4.8.3.7 Reactor Building Elevator Machine Room System

The Reactor Building elevator machine room system operates in response to the room thermostat. The system has no post accident safety function and is not safety related.

9.4.8.4 Inspection and Testing Requirements

The Reactor Building systems are subjected to preoperational test procedures to verify the following: proper wiring and control hookup, system "in-place" integrity and leak tightness, proper function of system components and control devices and to establish system design air flows.

To ensure a continued state of readiness of the Reactor Building systems after completion of the preoperational tests, the following inspection, maintenance and test procedures are performed:

1. Reactor Building Cooling System

   Inspection and testing of the Reactor Building cooling system are discussed in Sections 6.2.2.4.2 and 6.5.1.4.

2. Reactor Building Purge Supply and Exhaust System and Alternate Reactor Building Purge System.
   a. Record filter pressure drops.
   b. Verify function of dampers or control devices necessary for monitoring or component isolation or changeover from normal to emergency mode.
   c. Bearing lubrication.
   d. Laboratory test of charcoal filter test canisters for decontamination efficiency.

e. In place leak test of the HEPA and charcoal filters.

3. Reactor Building Charcoal Cleanup System

   Reactor Building charcoal cleanup system inspection, maintenance and testing requirements are the same as those for the Reactor Building purge supply and exhaust system.

4. Reactor Building Reactor Compartment Cooling System, Secondary Compartment Cooling System, CRDM Shroud Cooling System and Refueling Water Surface System.

   a. Bearing lubrication.

   b. Switch components that normally operate from standby to operating mode.

5. Reactor Building Elevator Machine Room System.

   a. Bearing lubrication.

9.5 OTHER AUXILIARY SYSTEMS

9.5.1 Fire Protection

The fire protection program is based on the NRC requirements and guidelines, Nuclear Electric Insurance Limited (NEIL) Property Loss Prevention Standards and related industry standards. With regard to NRC criteria, the fire protection program meets the requirements of 10 CFR 50.48(c), which endorses, with exceptions, the National Fire Protection Association's (NFPA) 805, "Performance-Based Standard for Fire Protection for Light Water Reactor Electric Generating Plants", 2001 Edition. V.C. Summer Nuclear Station (VCSNS) Unit 1 has further used the guidance of NEI 04-02, "Guidance for Implementing a Risk-Informed, Performance-Based Fire Protection Program under 10 CFR 50.48(c)" as endorsed by Regulatory Guide 1.205, "Risk-Informed, Performance Fire Protection for Existing Light-Water Nuclear Power Plants."

Adoption of NFPA 805, "Performance-Based Standard for Fire Protection for Light Water Reactor Electric Generating Plants", 2001 Edition in accordance with 10 CFR 50.48(c) serves as the method of satisfying 10 CFR 50.48(a) and General Design Criterion 3. Prior to adoption of NFPA 805, General Design Criterion 3, "Fire Protection" of Appendix A, "General Design Criteria for Nuclear Power Plants," to 10 CFR Part 50, "Licensing of Production and Utilization Facilities," was followed in the design of safety and non-safety related structures, systems, and components (SSC), as required by 10 CFR 50.48(a).

NFPA 805 does not supersede the requirements of GDC 3, 10 CFR 50.48(a), or 10 CFR 50.48(f). Those regulatory requirements continue to apply. However, under NFPA 805, the means by which GDC 3 or 10 CFR 50.48(a) requirements are met may be different than under 10 CFR 50.48(b). Specifically, whereas GDC 3 refers to SSCs important to safety, NFPA 805 identifies fire protection systems and features required to meet the Chapter 1 performance criteria through the methodology in Chapter 4 of NFPA 805. Also, under NFPA 805, the 10 CFR 50.48(a)(2)(iii) requirement to limit fire damage to SSCs important to safety so that the capability to safely shut down the plant is satisfied by meeting the performance criteria in Section 1.5.1 of NFPA 805.

A Safety Evaluation was issued on February 11, 2015 by the NRC, that transitioned the existing fire protection program to a risk-informed, performance-based program based on NFPA 805, in accordance with 10 CFR 50.48(c).

9.5.1.1 Design Basis Summary

9.5.1.1.1 Defense-in-Depth

The fire protection program is focused on protecting the safety of the public, the environment, and plant personnel from a plant fire and its potential effect on safe reactor operations. The fire protection program is based on the concept of defense-in-depth. Defense-in-depth shall be achieved when an adequate balance of each of the following elements is provided:

1. Preventing fires from starting,

2. Rapidly detecting fires and controlling and extinguishing promptly those fires that do occur, thereby limiting fire damage,
3. Providing an adequate level of fire protection for structures, systems, and components important to safety, so that a fire that is not promptly extinguished will not prevent essential plant safety functions from being performed.

9.5.1.1.2 NFPA 805 Performance Criteria

The design basis for the fire protection program is based on the following nuclear safety and radiological release performance criteria contained in Section 1.5 of NFPA 805:

1. Nuclear Safety Performance Criteria. Fire protection features shall be capable of providing reasonable assurance that, in the event of a fire, the plant is not placed in an unrecoverable condition. To demonstrate this, the following performance criteria shall be met:
   a. Reactivity Control. Reactivity control shall be capable of inserting negative reactivity to achieve and maintain subcritical conditions. Negative reactivity inserting shall occur rapidly enough such that fuel design limits are not exceeded.
   b. Inventory and Pressure Control. With fuel in the reactor vessel, head on and tensioned, inventory and pressure control shall be capable of controlling coolant level such that subcooling is maintained for a PWR and shall be capable of maintaining or rapidly restoring reactor water level above top of active fuel for a BWR such that fuel clad damage as a result of a fire is prevented.
   c. Decay Heat Removal. Decay heat removal shall be capable of removing sufficient heat from the reactor core or spent fuel such that fuel is maintained in a safe and stable condition.
   d. Vital Auxiliaries. Vital auxiliaries shall be capable of providing the necessary auxiliary support equipment and systems to assure that the systems required under (a), (b), (c), and (e) are capable of performing their required nuclear safety function.
   e. Process Monitoring. Process monitoring shall be capable of providing the necessary indication to assure the criteria addressed in (a) through (d) have been achieved and are being maintained.
2. Radioactive Release Performance Criteria. Radiation release to any unrestricted area due to the direct effects of fire suppression activities (but not involving fuel damage) shall be as low as reasonably achievable and shall not exceed applicable 10 CFR, Part 20, Limits.

Chapter 2 of NFPA 805 establishes the process for demonstrating compliance with NFPA 805.

Chapter 3 of NFPA 805 contains the fundamental elements of the fire protection program and specifies the minimum design requirements for fire protection systems and features.

Chapter 4 of NFPA 805 establishes the methodology to determine the fire protection systems and features required to achieve the nuclear safety performance criteria outlined above. The methodology shall be permitted to be either deterministic or performance-based. Deterministic

requirements shall be “deemed to satisfy” the performance criteria, defense-in-depth, and safety margin and require no further engineering analysis. Once a determination has been made that a fire protection system or feature is required to achieve the nuclear safety performance criteria of Section 1.5, its design and qualification shall meet the applicable requirement of Chapter 3.

9.5.1.1.3 Codes of Record

For specific applications and evaluations of plant fire protection system codes and standards, refer to the FP Design Basis Document (DBD), NFPA 805 Fire Protection. The codes and standards used for the design and installation of plant fire protection systems are as follows:

- NFPA 10, Installation of Portable Fire Extinguishers (1973)
- NFPA 12, Standard on Carbon Dioxide Extinguishing Systems (1973)

9.5.1.2 System Description

9.5.1.2.1 Required Systems

Nuclear Safety Capability Systems, Equipment, and Cables

Section 2.4.2 of NFPA 805 defines the methodology for performing the nuclear safety capability assessment. The systems equipment and cables required for the nuclear safety capability assessment are contained in the FP DBD.

Fire Protection Systems and Features

Chapter 3 of NFPA 805 contains the fundamental elements of the fire protection program and specifies the minimum design requirements for fire protection systems and features. Compliance with Chapter 3 is documented in the FP DBD.

Chapter 4 of NFPA 805 establishes the methodology and criteria to determine the fire protection systems and features required to achieve the nuclear safety performance criteria of Section 1.5 of NFPA 805. These fire protection systems and features shall meet the applicable requirements of NFPA 805 Chapter 3. These fire protection systems and features are documented in the FP DBD.

Radioactive Release

Structures, systems, and components relied upon to meet the radioactive release criteria are documented in the FP DBD.

9.5.1.2.2 Definition of “Power Block” Structures

Where used in NFPA 805 Chapter 3 the terms “Power Block” and “Plant” refer to structures that have equipment required for nuclear plant operations. For the purposes of establishing the structures included in the fire protection program in accordance with 10 CFR 50.48(c) and NFPA 805, the plant structures listed in Table 9.5-1 are considered to be part of the “Power Block”.

9.5.1.3 Safety Evaluation

The FP DBD documents the achievement of the nuclear safety and radioactive release performance criteria of NFPA 805 as required by 10 CFR 50.48(c). This document fulfills the requirements of Section 2.7.1.2 “Fire Protection Program Design Basis Document” of NFPA 805. The document contains the following:

1. Identification of significant fire hazards in the fire area. This is based on NFPA 805 approach to analyze the plant from an ignition source and fuel package perspective.
2. Summary of the Nuclear Safety Capability Assessment (at power and non-power) compliance strategies.
    a. Deterministic compliance strategies.

b. Performance-based compliance strategies (including defense-in-depth and safety margin.

3. Summary of the Non-Power Operations Modes compliance strategies.
4. Summary of the Radioactive Release compliance strategies.
5. Summary of the Fire Probablistic Risk Assessments.
6. Key analysis assumptions to be included in the NFPA 805 monitoring program.

9.5.1.4 Fire Protection Program Documentation, Configuration Control and Quality Assurance

In accordance with Chapter 3 of NFPA 805 a fire protection plan documented in Station Administrative Procedure SAP-131 defines the management policy and program direction and defines the responsibilities of those individuals responsible for the plan's implementation. SAP-131:

1. Designates the senior management position with immediate authority and responsibility for the fire protection program.
2. Designates a position responsible for the daily administration and coordination of the fire protection program and its implementation.
3. Defines the fire protection interfaces with other organizations and assigns responsibilities for the coordination of activities. In addition, SAP-131 identifies the various plant positions having the authority for implementing the various areas of the fire protection program.
4. Identifies the appropriate authority having jurisdiction for the various areas of the fire protection program.
5. Identifies the procedures established for the implementation of the fire protection program, including the post-transition change process and the fire protection monitoring program.
6. Identifies the qualifications required for various fire protection program personnel.
7. Identifies the quality requirements of Chapter 2 of NFPA 805.

Detailed compliance with the programmatic requirements of Chapters 2 and 3 of NFPA 805 are contained in the FP DBD.

9.5.2 Communication Systems

9.5.2.1 Design Bases

The communication systems are designed to provide reliable communications between all essential areas of the station, and to essential locations remote from the plant during normal operations or under emergency conditions. This capability is provided by diverse types of communication systems.

9.5.2.2 Description

9.5.2.2.1 Intra-Plant Communications

The intra-plant communications network consists of the following systems:

1. A page/party public address with evacuation alarms and a fire alarm.
2. A maintenance communications system.
3. A redundant paging system in selected areas.
4. A fuel handling communication system (tied with main system, item 1).
5. A private telephone system.
6. Emergency Communications Plant Digital Radio Repeater System.

Working stations that may require communication between plant personnel and the control room or control room evacuation panel during and/or after transients or accidents are identified in Table 7.4-1. Types of communication systems available at each working station are shown by Figures 9.5-1a through 9.5-1h.

9.5.2.2.1.1 Page/Party Public Address System

The page/party public address system is the main plant communications system. It provides facilities for voice communications at stations located in strategic operating areas. From each of these stations, information can be broadcast over system speakers located in every building and control area throughout the plant. Paging type communications equipment is capable of effective operation to 110 decibels.

Two-way conversations are possible between stations over telephone type receiver-transmitter handsets. The system is common-talking so that all stations may take part in any conversation.

The public address system, powered from an uninterruptible power supply system vital bus, is normally used in daily operations to communicate messages between individuals in the plant. In an emergency, the system may be used to alert all personnel on the site. The evacuation alarms and fire alarm are manually initiated from the control room. These alarms are sounded through the paging system to ensure audibility throughout the plant, with the exception of the control room where the speakers associated with the main page/party public address system are muted. Alarms override the paging system when actuated.

A switching arrangement at each handset station enables that handset to be switched from the paging circuit to the amplified, party line circuits. Three (3) separate party line circuits are provided. Individual party line circuits are selected by a three-position selector switch. Speakers do not carry party line conversation. The circuits are so arranged that when the party line feature is in use, a second conversation can take place simultaneously over the page circuit with no interference between the 2 circuits. Handsets perform satisfactorily without the use of acoustic protective enclosures or devices in areas where the noise level may be as high as 115 decibels.

There are 2 subsystems to the main page/party system:

1. The fuel handling paging/party system.
2. A system of paging/party line access jacks for use with portable handset units.

The fuel handling paging/party system consists of handsets and dual input speakers which can be switched to a separate communications system during refueling. A switch is provided on the designated handsets to isolate them from the main plant system and to tie them to the dual input speakers. These speakers carry both the main plant system and the fuel handling paging system.

The paging/party line access jack receptacles are placed at locations where communication is desirable on a limited basis. Each jack accepts the plug from a portable handset/speaker station. The portable station functions in the same manner as a standard handset station.

All handset stations are designed for maximum safety and isolation from live circuits under all operating conditions.

9.5.2.2.1.2 Maintenance Communications System

The maintenance communications system contains a network of plug-in jacks in selected areas of the plant. This system is completely isolated from all other communication systems.

Headsets, consisting of earphones and a microphone, are connected through the plug-in jacks to 4 two-wire nonshielded channels permitting direct communications between persons in different areas. The system obtains its power from the non-Class 1E power system bus. This system is normally used for maintenance of calibration and equipment. During an emergency, the system may be used as an alternate means to relay messages between different areas of the plant.

9.5.2.2.1.3 Redundant Paging System

The redundant paging system consists of handsets, speakers, amplifiers, and accessories similar to the main page/party system. This system is powered from a Class 1E source. This system is completely independent of all other communication systems and is limited to areas where communications are required under emergency operating conditions.

All equipment in the redundant paging system is painted red. This system operates only in the paging mode and only over redundant speakers.

9.5.2.2.1.4 Private Telephone System

A private telephone system using commercial type telephone handsets is installed throughout the station for local use and offsite communications. The telephone system has a reliable power supply with battery backup which maintains the system in an operational condition during a loss of normal station power.

The system consists of switchboard equipment, power supply and telephones. The switchboard is equipped for multiple private subscribers, 2 wire lines for local service and links for simultaneous talking paths.

Backup control systems are provided for critical switching and signaling equipment so that if 1 component fails, the entire system is not lost.

9.5.2.2.1.5 Emergency Communications Plant Digital Radio Repeater System

This is a new plant digital radio repeater system. This system is installed for use by plant Operations, Maintenance and Fire Brigade personnel to meet NFPA 805 Emergency Communications criteria. This system is designated as the primary NFPA 805 Emergency Communications system, and the existing Gai-Tronics plant paging system is considered as a back-up system. The system has a reliable power supply with battery back-up which maintains the system in an operational condition for up to 24 hours during a loss of normal station power.

The system consists of strategically located antennas located within different areas of the power block buildings for radio coverage. This will enable Plant Operations, etc. to communicate via hand held radios for normal and fire safe shutdown communication purposes.

The system is designed using redundant “A” and “B” antenna signal loops so that if one loop is compromised during a fire event, emergency communications from that area is still received by the antenna equipment in the other loop.

9.5.2.2.2 Plant to Offsite Communications

Plant to offsite communications operate through the private telephone system and in conjunction with the commercial telephone landline system, as well as through a fiber optics receiving and transmitting system. Both the landline and fiber optics systems operate through the private telephone system switchboard.

Commercial telephone landlines are provided between the station, and the control office of the Southern Bell Telephone and Telegraph in Columbia and Chapin, S. C.

The fiber optics system, owned and operated by SCE&G, consists of solid-state equipment designed and engineered for voice communication. The tones received via this channel have volume, fidelity and noise suppression comparable with the quality normally obtained on a commercial telephone. The master station is located at the main SCE&G office in Columbia, S. C.

Redundant paging system equipment is capable of effective operation to 110 decibels.

9.5.2.2.3 Safety Evaluation

A failure of 1 communication system does not affect the operation of the other types of communication systems since they are of diverse types and are not interdependent.

The operability of the onsite communications system is assured by installation of the redundant communications system (see Section 9.5.2.2.1.3). This redundant system has separate phone stations, power supply, line balance equipment and cable system. Phone stations of the redundant system consist of telephone type receiver-transmitters, a handset, amplifiers and speakers. The redundant system provides paging facilities only.

The plant to offsite communications systems are not subject to common mode failure due to loss of station power or failure of the interconnecting wireway. The redundant system is powered by a diesel backed bus. The normal plant paging system is supplied from a battery backed, 60 Hz static inverter. The telephone landlines are fed from offsite sources by the commercial telephone company.

9.5.2.3 Inspection and Testing Requirements

The design of the communications systems permits routine testing and inspection without disrupting normal communications. Since all systems are in daily use, any degradation is readily identified and corrected. The evacuation alarms and fire alarm systems are tested periodically in accordance with written and approved procedures.

Effective communication between the work stations identified in Table 7.4-1 and the control room is verified during plant startup and testing and is reverified periodically.

9.5.3 Lighting Systems

The lighting system throughout the plant, Service Building and outdoor areas is designed to provide good light distribution with adequate light intensities. The lighting system is divided into normal, essential, and emergency lighting.

9.5.3.1 Normal Lighting

Normal lighting is provided in attended areas and constitutes the majority of plant lighting. Illumination is from incandescent, fluorescent and high intensity discharge (HID) light sources supplied from buses other than engineered safety features (ESF) buses. Local lighting panels for 480 Y/277 volt, 3 phase, 4 wire and 208 Y/120 volt, 3 phase, 4 wire power supply the branch circuits.

Outdoor lighting consists of roadway, perimeter security, area lighting and switchyard lighting. Outdoor lighting is supplied by 480 volt, single phase power from the nearest available 480 volt load center. All poles and luminaires are effectively grounded.

9.5.3.2 Essential Lighting

Essential lighting operates in conjunction with and supplements the normal lighting where a more reliable source of illumination is required for the performance of critical tasks or for access or egress. Essential lighting is provided for access in the Turbine Building, Auxiliary Building, Diesel Generator Building, Water Treatment Building, Intermediate Building and Control

Building. Essential lighting is also provided, with emergency d-c backup, for continuation of critical activities in the control room, relay room, computer room, and critical electrical distribution areas of the Control Building, as well as the evacuation panel and ESF switchgear rooms, and the diesel generator rooms. Essential lighting, supplied from ESF buses, is divided into Channel A and Channel B, as determined by the channel of the power supply bus. Class 1E fuses located in separate panels are connected in series with the Class 1E circuit breakers at the ESF bus to provide isolation, thereby eliminating the requirements for separation criteria identification. Local lighting panels for 480Y/280 volt, 3 phase, 4 wire and 208Y/120 volt, 3 phase, 4 wire supply the branch circuits.

9.5.3.3 Emergency Lighting

The emergency lighting system provides adequate station lighting in the Diesel Generator Building, Reactor Building, control room, and control room evacuation panels for control and maintenance of safety-related equipment, as well as for access and egress from these areas and egress from the Reactor Building. The Diesel Generator Building and Reactor Building emergency lighting panels are connected to the BOP battery, and the control room and control room evacuation panel room emergency lighting panels are connected to the ESF batteries. Emergency lighting is provided in buildings to satisfy the South Carolina Building Code and the Illuminating Engineers Society Handbook, 5th Edition, and is supplied from the station 125 volt d-c system.

The d-c power is supplied from multi-purpose batteries equipped with battery chargers. This lighting, which is not a part of the normal or essential lighting supplying the areas, only becomes energized upon loss of power to Reactor Building normal lighting or upon loss of power to the Diesel Generator Building or control room essential lighting. The individual branch circuits are run in conduits different from the conduits for the normal lighting. Circuits feeding the panel boards are run in the cable trays applicable to the separation channel of the d-c power supply.

In addition to the 125 volt d-c system, self-contained battery packs are used in areas required for remote shutdown lighting for access and egress in buildings affected by loss of power.

9.5.3.4 Tests and Inspection

Everyday use of the normal and essential lighting systems is considered to be proof of system integrity. Periodic testing of the d-c emergency lighting system is accomplished by tripping the emergency panel sensing circuits.

9.5.4 Diesel Generator Fuel Oil Storage and Transfer System

9.5.4.1 Design Bases

The diesel generator fuel oil storage and transfer system is safety-related and is designed in accordance with the recommendations of ANSI N195 (Reference 4) and satisfies the requirements of the DEMA Standard (Reference 6). The system is designed to withstand the safe shutdown earthquake (SSE) without loss of function. The system is also protected against

missiles. The diesel generator fuel oil storage tanks, day tanks and transfer pumps are designed in accordance with the ASME Code, Section III, and are classified Safety Class 2b, Seismic Category 1.

No single active or passive failure prevents the supply of fuel oil to at least 1 diesel generator.

The onsite capacity of each redundant diesel generator fuel oil storage and transfer system is sized to provide fuel oil for a minimum of 7 days of continuous operation of a diesel generator under time dependent load conditions enveloped by Table 8.3-3 Parts A2 and B2 following a design basis accident and loss of offsite power, as required by ANSI N195 (Reference 4), except that the fuel inventory margin for modes 1-4 is 2% vs. the 10% recommended by ANSI N195.

9.5.4.2 System Description

Two (2) emergency diesel generator sets are provided. The diesel engines are fueled with No. 2 diesel fuel oil supplied by the diesel generator fuel oil storage and transfer system. Figure 9.5-2 presents the system diagram.

The system includes the following components:

1. Two (2) underground (buried) diesel generator fuel oil storage tanks are provided. The locations of these tanks are shown by Figure 9.5-2a. Each tank has a nominal capacity of approximately 52,000 gallons of No. 2 diesel fuel oil. This nominal tank capacity (52,000 gallons) is sufficient to hold the required fuel oil to sustain the operation of one diesel generator for 7 days under time dependent load conditions identified in Table 8.3-3. Each storage tank is vented to atmosphere and is protected from corrosion as necessary.
2. Four (4) full capacity, a-c, electric motor driven fuel oil transfer pumps, located in the basement of the Diesel Generator Building, are provided. These pumps are powered from the Class 1E electric system. Two (2) pumps are associated with each diesel generator fuel oil storage tank. The pumps take suction from the storage tank and supply fuel oil to the fuel oil day tank. Each pump is provided with a pressure relief recirculation line to the associated diesel generator fuel oil storage tank.
3. Two (2) diesel generator fuel oil day tanks are provided, 1 for each diesel engine. Each day tank is located near the associated diesel engine and is sized to store approximately 550 gallons of No. 2 diesel fuel oil. Each tank has sufficient fuel oil capacity to sustain full load operation for approximately 1.5 hours. The day tanks are located in accordance with the diesel generator manufacturer’s requirements to ensure drainage of the normal clean fuel leakage from the injection pumps on the engines. Each day tank is separately vented to atmosphere and is provided with corrosion protection as necessary. An overflow line from each day tank returns fuel oil to the associated fuel oil storage tank. Two (2) positive displacement diesel fuel oil pumps are mounted on the engine. One (1) of these pumps is engine driven; the other, d-c motor driven. The pumps are of the positive displacement type with suction lift capability to draw fuel from the daytank. The diesel engine is also equipped with an engine mounted fuel oil accumulator tank to provide a reservoir which keeps the engine fuel oil headers full during engine shutdown periods.

4. A truck hose connection, strainer, pump, filter, associated piping and instrumentation are provided for fuel oil unloading.

Redundant components, except for the diesel generator fuel oil storage tanks, are located in a Seismic Category 1 structure and are isolated from each other. The diesel generator fuel oil storage tanks are coated to afford protection against corrosion. Vents, located 3 feet above the site grade (elevation 436’), are equipped with flame arrestors.

9.5.4.3 Safety Evaluation

As a result of the redundancy incorporated in the system design, the diesel generator fuel oil storage and transfer system provides the minimum required safety functions under any one of the following conditions:

1. Loss of offsite power coincident with failure of 1 diesel generator.
2. Loss of offsite power coincident with maintenance outage or failure of 1 diesel generator fuel oil transfer pump associated with each diesel generator.
3. Loss of offsite power coincident with maintenance outage or failure of either diesel generator fuel oil storage tank.
4. A single failure analysis for the diesel generator fuel oil system is in accordance with Table 9.5-2.

Each fuel oil storage tank contains sufficient No. 2 diesel fuel oil for 7 days continuous operation of its associated diesel generator, with the time dependent loads identified in Table 8.3-3. A 10% fuel margin is maintained for Modes 5-6 in compliance with ANSI N195, and a 2% fuel margin is maintained in Modes 1-4; this reduced margin for Modes 1-4 was approved by the NRC per License Amendment 150. Fuel oil in large quantities is available within 7 days from commercial sources. Each diesel generator fuel oil day tank is sized to store approximately 550 gallons of No. 2 diesel fuel.

9.5.4.4 Test and Inspection Requirements

The diesel generator fuel oil supply piping is pressure tested during construction. Active system components: pumps, valves and controls; are functionally tested during startup and periodically thereafter. Diesel fuel oil analyses are performed periodically in accordance with Technical Specification, Section 4.

Surveillance testing of the diesel generator fuel oil, both upon initial delivery and periodic testing is based upon applicable ASTM standards. Since some of the ASTM standards used are applicable to other applications of petroleum fuel oils, some requirements in the standards will not be complied with. Specific examples of exceptions to requirements in the applicable standards include:

- The Sample containers used for sampling fuel oil using the ASTM D2276-88 (Determination of Particulate Contamination in Fuel Oil) method will not have a clean piece of plastic film rinsed with petroleum ether placed over the top of the bottle.
- Filtered petroleum ether of filtered 1,1,2-trichloro-1,1,2-trifluoroethene used in the ASTM D2276-88 method may be substituted with unfiltered 1,1,2-trichloro-1,1,2-trifluoroethene, n-7 hexane, or iso-octane.
- The viscometer bath temperature will be allowed a 0.05 degree C variation during the performance of Kinematic Viscosity, as described in ASTM D445 (Standard Test Method for Kinematic Viscosity of Transparent and Opaque Liquids).
- An alternate thermometer that meets the stated range and accuracy requirements of specified ASTM thermometers may be used during the analysis of diesel fuel oils.
- The determination of Flash Point in oil testing analysis results will not be corrected for barometric pressure.

The bases for these specific exceptions is documented in the Safety Evaluation for Amendment 164 to the facility Technical Specifications.

9.5.4.5 Instrumentation Application

Indication and monitoring of diesel fuel oil temperature is not required. The specified diesel fuel oil pour point range is 0°F to - 20°F. The diesel generator fuel oil storage tank and all fuel oil piping from the tank to the transfer pumps, located in the Diesel Generator Building, is buried below the frost line. The frost line was determined from National Fire Protection Association recommendations for depth of earth cover to avoid freezing of underground fire protection water mains.

Figure 9.5-2 shows pressure gages on the diesel fuel oil transfer pump discharge. Low fuel oil pressure in the diesel injector inlet header actuates an alarm on the main control board and the local diesel generator control panel. This low pressure alarm is not illustrated by Figure 9.5-2 because it is supplied by the diesel generator manufacturer.

9.5.5 Diesel Generator Cooling Water System

9.5.5.1 Design Bases

The diesel generator cooling water system is a self-contained, closed type system located in the Seismic Category 1 Diesel Generator Building. The water is cooled by thermostatically controlled heat exchangers wherein heat is rejected to the Service Water System (see Section 9.2.1). Cooling water is circulated by engine driven pumps through two subsystems. One, the intercooler system, provides cooling for the turbocharger air intercoolers and the alternator outboard bearing. The other, the jacket water system, cools the cylinder liners, cylinder heads and turbocharger cooling spaces. An expansion tank is provided and an electric heater and auxiliary, motor driven pump permit "keep warm" system operation under standby conditions.

The water in this closed system is treated with corrosion inhibitor in accordance with the manufacturer’s recommendations.

The diesel engine cooling system is classified Safety Class 2b, Seismic Category 1 and is designed and fabricated in accordance with the ASME Code, Section III, Class 3, except for certain components not commercially available as ASME Code, Section III, Class 3 items. In the case of such items, other established industry codes or standards are applied. The system is also designed in accordance with the DEMA Standard (Reference 6).

The expansion tank is non-nuclear safety class and is connected to a Safety Class 2b, ASME Code, Section lII, Class 3, standpipe by a non-nuclear safety class expansion joint. The 17 foot high standpipe is designed to provide sufficient static head to satisfy jacket water pump NPSH requirements and to provide adequate makeup to the system for 7 days of continuous operation of the diesel generator. The wall mounted expansion tank is seismically designed to preclude damage to safety related equipment during an earthquake.

9.5.5.2 System Description

The diesel generator cooling water system consists of 2 subsystems.

1. Intercooler System

   The turbocharger air intercoolers and alternator outboard bearing are cooled by the intercooler system. Circulation of treated cooling water is accomplished by an engine driven, centrifugal pump. Heat from the cooling water is rejected to the Service Water System through a thermostatically controlled heat exchanger. Also included is an expansion tank mounted on top of a standpipe which serves both the intercooler and jacket water systems. Figure 9.5-3 is a schematic of the system.

2. Jacket Water System

   The engine is cooled by the closed circuit jacket water system. Water, treated in accordance with the manufacturer’s recommendations, is circulated through the cylinder liners, cylinder heads and turbocharger cooling spaces by an engine driven, centrifugal pump. Heat from the cooling water is rejected to the Service Water System through a thermostatically controlled heat exchanger. Also included is an expansion tank mounted on top of a standpipe which serves both the jacket water and intercooler systems.

   An electric heater and auxiliary, motor driven centrifugal pump are furnished to permit "keep warm" operation under standby conditions. Figure 9.5-4 is a schematic of the system.

   Cooling water enters the engine from the external piping system through the lower headers at each side of the engine. It enters each cylinder at the lower end of the jacket through a duct in the frame opening (see Figure 9.5-5). The water circulates around the cylinder liner and then flows to the cylinder head through an external duct. The cylinder head cooling water also cools the exhaust valve guides. Cooling water also flows from the lower headers to the turbocharger.

After cooling, the water flows through the upper headers to the external piping and then to the heat exchanger.

Heat rejected and flow rates for both the intercooler system and jacket water system are summarized in Table 9.5-3, as are the design heat removal capacity and operating temperature differential.

9.5.5.3 Safety Evaluation

Each diesel generator unit is provided with a separate cooling water system. The use of engine driven pumps renders the cooling water systems immune to loss of offsite power. No single failure can compromise availability of emergency power since redundant diesel generators are provided.

Diesel generator protective trip signals, arising from malfunction of the diesel generator cooling water system, are bypassed under accident conditions.

9.5.5.4 Tests and Inspections

The diesel generator cooling water system is tested in conjunction with the testing of the diesel generator. No separate test of the cooling water system, except hydrostatic testing of certain portions, is performed. Those portions of the system upon which hydrostatic tests are performed by the manufacturer are indicated on notes of drawing 1MS-32-005. The diesel generator intercooler and jacket water systems, sheets 4 and 5 of drawing 1MS-32-005, are shown in simplified form in Figures 9.5-3 and 9.5-4.

9.5.5.5 Instrumentation Application

The diesel generator cooling water system is monitored and protected by pressure and temperature switches as shown in Figure 9.5-4. Local instrumentation is provided as shown by Figures 9.5-3 and 9.5-4.

The board mounted temperature indicator, with the high and low temperature alarm switches, senses temperature in the jacket water return line and indicates abnormal temperatures in the jacket water system. A low pressure alarm switch is also provided to indicate a system failure. These alarm switches are annunciated locally and by grouped alarms on the main control board. Excessive temperature or other maloperation of this intercooler system is indicated by board mounted temperature meters which sense air temperature in the engine air supply manifolds.

9.5.6 Diesel Generator Starting System

9.5.6.1 Design Bases

Each diesel generator is started by its own independent air starting system. These air starting systems cannot be cross connected in any manner. Each of the 2 air compressors for each diesel generator has sufficient capacity to recharge the air storage tanks from 0 to normal pressure in 110

minutes; the recharge time for each start with both compressors operating is approximately 5 minutes. The Diesel Generator procurement specification required the air storage tanks to have a sufficient capacity to permit 5 successive starts without recharge. Factory testing demonstrated the capacity for 10 consecutive starts, without recharge, using both air storage tanks. In these tests the engine was brought from rest to rated speed and voltage. These tests duplicate field starting conditions.

The air starting system is provided with a noncycling refrigerated air dryer. The air dryer provides air with a dew point of 35°F. Also, dirt and solid particles are filtered out during the drying process.

The diesel generator starting system is designed to remain operable during a total loss of offsite power.

The starting system was designed in accordance with the DEMA Standard (Reference 6) and is classified as Safety Class 2b, Seismic Category 1, with the exception of the air compressors and air dryer which are classified as non-safety related. The safety related position of the system is designed and fabricated in accordance with the ASME Code, Section III, and the DEMA Standard (Reference 6).

9.5.6.2 System Description

The starting system for one engine is shown by Figure 9.5-6, the simplified sketch of the manufacturer’s drawing, 1MS-32-005 Sht 6.

Each diesel generator is provided with 2 independent air starting systems, 1 for each bank of cylinders. Compressed air in the range of 375 to 415 psig is supplied by 2 separate a-c, motor driven air compressors and storage tank systems. Each bank of engine cylinders has its own engine driven air start distributor with a connection to each cylinder. The engine starts using either or both banks.

Starting air pressure is also used to operate the governor servo rack booster which opens the fuel injection pump racks to ensure adequate fuel at startup.

The air starting system features a moisture separator with trap and a refrigerated air dryer with trap to remove water, oil and foreign particles from the air supply to the storage tanks. These features preclude fouling of the air start valve by contaminants, such as oil or rust.

Each air storage tank is protected from overpressure by a safety valve. Each of these tanks is also equipped with a pressure gage.

The system is skid mounted and includes necessary pressure switches and control devices for automatic operation of the air compressors. A low air pressure alarm switch is provided on the diesel engine skid in each of the air supply lines to the diesel air start valves. Low air pressure actuates alarms on the local control panel and main control board. Figure 9.5-6 shows instrumentation.

9.5.6.3 Safety Evaluation

Each diesel generator is equipped with a separate and independent starting air system, thereby protecting against a single failure effecting both generators. Use of 2 air compressors and 2 air receivers within each starting air system and independent air start distributors for each bank of engine cylinders provides added assurance of engine start. The storage capacity of the system, sufficient for 10 successive engine starts without recharging, ensures starting in the event of a loss of offsite power.

Low air pressure alarms are provided to alert the operator should starting air pressure decay to an unsatisfactory level.

9.5.6.4 Tests and Inspections

The diesel generator air starting system is tested in conjunction with diesel generator during startup and periodically thereafter. Factory testing of the system included hydrostatic testing and functional testing for total number of starts without recharging, for recharging time, and for total starting time.

9.5.6.5 Instrumentation Application

The diesel generator starting system is monitored and protected by pressure and temperature instrumentation as shown in Figure 9.5-6.

Low pressure alarm switches are provided as a part of the engine mounted gauge board; this alarm is annunciated locally and in a separate alarm on the main control board. Pressure switches are also provided for compressor control and a temperature switch is provided to alarm on high exit temperature from the air compressor. In addition, local indicators are provided at the gauge board and on the air compressor --air storage tank skid.

9.5.7 Diesel Generator Lubrication System

9.5.7.1 Design Bases

The diesel generator lubrication system is integral with the engine and is positive in action. Three (3) subsystems are provided. The engine lube oil system supplies oil under pressure to all main bearings and, through a pressure reducing valve, to the camshaft bearings, cam followers, fuel injection pumps and valve push rods. This subsystem also provides oil to the crank pin journals and for piston cooling, as well as to accessory gearing. A separate rocker lube system supplies oil to each cylinder head rocker assembly. An auxiliary oil system permits continuous prelubrication of the engines at "keep warm" temperature during standby and continuous bypass filtration of the main oil supply during engine operation.

The diesel generator lubrication system was designed in accordance with the DEMA Standard (Reference 6) and is classified Safety Class 2b, Seismic Category 1. Also, the system is designed and fabricated in accordance with the ASME Code, Section III, Class 3, except for certain

components not commercially available as ASME Code, Section III, Class 3, items. In the case of such items, other established industry codes or standards are applied.

9.5.7.2 System Description

The diesel generator lubrication system is comprised of the following 3 subsystems:

1. Engine Lube Oil System

   In the engine lube oil system, an engine driven double rotor screw pump draws oil through a suction strainer from the engine sump and delivers it to a thermostatically controlled lube oil cooler and then through a 30 micron strainer to the main engine lube oil header. The header supplies lube oil under pressure to all main bearings and, through a pressure reducing valve, to the camshaft bearings, cam followers, fuel injection pumps and valve push rods. Branches from the main header supply lube oil to the camshaft and accessory drive gears.

   The main bearings are supplied through passages in the frame and bearings caps, feeding oil to the bearing groove. The oil flows through holes in the crank webs to the crank pin journals, providing bearing lubrication. Cooling oil then flows through the drilled connecting rod to furnish oil for piston cooling (see Figure 9.5-7).

   The lube oil cooler rejects a maximum of 1,395,000 Btu/hr to the Service Water System. Service water, at a maximum temperature of 95°F and flowing at 1000 gpm, is supplied to 3 series connected heat exchangers. The lube oil heat exchanger is the third in this series and receives service water nominally at 114°F and discharges the water nominally at 117°F, as designed by the diesel generator manufacturer.

2. Rocker Lube System

   To protect the crankcase oil from contamination by possible cooling water and fuel leaks at the cylinder head upper deck level, the valve rockers are lubricated and drained by a separate system. A gear type pump mounted at the free end of the engine is driven by the engine crankshaft. The pump draws oil from an engine mounted reservoir and discharges it under pressure through a duplex filter to a header. Pipes from the header supply each cylinder head rocker assembly. Drain pipes return the oil to a drain header which conveys the oil back to the reservoir. The system includes a small motor driven pump for prelubrication. This pump is run automatically once a week for 5 minutes. A backup timer is provided to shut down the pump and alarm on overrun. An alarm is also provided to indicate failure of the pump contactor to close. Figure 9.5-9 depicts oil flow through a valve rocker.

3. Auxiliary Oil System

   A motor driven gear pump, mounted on the diesel generator skid serves the following purposes:

a. It draws oil from the main sump through a suction strainer and discharges through an electric heater and a 5 micron filter into the engine lube oil system. During standby, this arrangement provides for continuous prelubrication at "keep warm" temperature.

b. During engine operation, this pump and associated components are used for continuous bypass filtration of the engine oil supply.

c. For initial engine startup, the pump is used to fill the external system and prelubricate the engine.

d. During maintenance, the pump is used to empty the engine sump.

9.5.7.3 Safety Evaluation

Each diesel generator is provided with a separate lubrication system, designed to operate under the same conditions as is the engine. The use of engine driven pumps for lube oil circulation renders the system immune to loss of offsite power and no single failure can compromise the availability of emergency power since redundant diesel generators are provided.

The diesel is provided with a crankcase cover installed with a pressure relief valve to mitigate the effects of a crankcase explosion. The diesel is also equipped with a high crankcase pressure alarm and trip (trip during test operating conditions only).

9.5.7.4 Tests and Inspections

The diesel generator lubrication system is tested in conjunction with the testing of the diesel generator.

To ensure diesel lube oil quality, periodic samples of oil are taken from the main and rocker lube oil systems. Lube oil is replaced when it no longer satisfies site standards.

In addition, the operation of the rocker arm prelube pump is verified weekly.

Visual inspection of the diesel lube oil system during periodic engine testing and the provision of the lube oil system pressure and level alarms facilitate detection of any system leakage.

9.5.7.5 Instrumentation Application

The diesel generator lubrication systems are monitored and protected by pressure and temperature switches as shown in Figure 9.5-7. Local instrumentation is also shown by Figure 9.5-7.

The diesel engine sump is provided with a low level alarm. The rocker arm lube system is not equipped with temperature alarms or temperature indicators since it is not designed to provide cooling.

The lube oil sump temperature switch provides a low temperature alarm in the event of failure of either the motor driven auxiliary lube oil system or the lube oil keep warm heater.

9.5.8 Diesel Generator Combustion Air Intake and Exhaust System

9.5.8.1 Design Bases

Design bases for the diesel generator combustion air intake and exhaust system include consideration of the following hazards and phenomena:

1. Wind loadings caused by tornadoes or hurricanes (see Section 3.3 for discussion of design basis wind and tornado).
2. Missile impact (see Section 3.5 for discussion of provisions for missile protection).
3. System capability to withstand single failure without loss of function of both diesel generators.

The elevation of the diesel generator combustion air intake and exhaust system is well above the maximum flood design water level (see Section 3.4). Contaminating substances in quantities sufficient to adversely affect diesel engine operation, if inducted with the combustion air, are not present at or near the site.

System components are classified as Seismic Category 1 and were designed in accordance with the DEMA Standard (Reference 6).

9.5.8.2 System Description

Two (2) separate and independent diesel generators are provided. For each diesel engine, the combustion air intake system consists of 2 filter/silencer units, mounted in a cubicle above the associated diesel generator, with connecting piping to the intake manifold of the engine. Each filter/silencer unit serves 1 engine cylinder bank. The exhaust system for each diesel engine consists of 1 muffler, mounted in a cubicle above the associated diesel generator, and connecting piping from the engine exhaust manifolds. A short exhaust stack extends from the muffler through the roof to the atmosphere.

The cubicles containing the filter/silencer units and the mufflers are Seismic Category 1 and are designed to protect the contained components from missile impact. Protection is accomplished by reinforced concrete construction and a labyrinth arrangement for admission of intake air to the filter/silencer units. See Section 3.5.1.4 for a discussion of missiles generated by natural phenomena.

The labyrinth arrangement also provides protection of the air intake system from atmospheric conditions. Louvers on the air intake opening and the labyrinth prevent wind circulation which could cause ice and snow buildup on the intake filter/silencer units.

The exhaust muffler is located within the Diesel Generator Building to provide protection from atmospheric conditions. The short, large diameter exhaust stack from the muffler is equipped with a weather protection cover. This cover precludes the possibility of clogging of the stack as a result

of atmospheric conditions, such as ice, freezing rain and snow, during standby or operation of the diesel generator.

Figures 1.2-11 through 1.2-14 illustrate the arrangement of the combustion intake and exhaust system. Figure 9.5-10 shows details of the combustion air intake labyrinth and exhaust piping arrangement.

9.5.8.3 Safety Evaluation

The functioning of the diesel generator combustion air intake and exhaust system is not adversely affected by any of the phenomena or events postulated to occur during plant life. Each of the 2 diesel generators which comprise the onsite emergency power source is provided with completely separate and independent combustion air intake and exhaust systems. These redundant systems are physically separated and are housed in Seismic Category 1, missile resistant structures.

Specific conditions considered in the design are as follows:

1. Recirculation of diesel engine combustion products to the air intake is prevented. The exhaust stacks are spatially separated from, and located at a higher elevation than the intake filter/silencer units. Thus, since hot exhaust gases rise and disperse, recirculation to the intake is prevented.
2. Gases that could adversely affect diesel generator operation are not stored in the vicinity of the Diesel Generator Building.
3. Restriction of intake air flow is prevented by housing air intake components in a missile resistant structure and providing labyrinth passages for air ingress. System piping is designed to withstand the SSE without significant deformation.
4. The intake of particulates is prevented by the filter/silencer units through which intake air is filtered.
5. Low barometric pressure does not affect engine operation since each diesel engine is equipped with turbochargers. The turbochargers compensate for varying barometric pressure by increasing or decreasing boost pressure as required.
6. No high energy piping systems are located within the diesel generator buildings. Thus, such systems do not pose a threat to the combustion air intake and exhaust system.

9.5.8.4 Inspection and Testing Requirements

Inspection requirements for the diesel generator combustion air intake and exhaust system include:

1. Periodic inspection and cleaning and/or replacement of the air intake filter in accordance with manufacturer's recommendations.
2. Periodic inspection of exhaust mufflers and exhaust piping for evidence of corrosion due to action of the exhaust gases.

No specific provisions for testing of the system are required since periodic testing of diesel generator operation verifies proper operation of the combustion air intake and exhaust system.

CHAPTER 10 - STEAM AND POWER CONVERSION SYSTEM

10.0 STEAM AND POWER CONVERSION SYSTEM

10.1 SUMMARY DESCRIPTION

The steam and power conversion system is shown schematically by Figure 10.1-1, Sheets 1 and 2. Principal design and performance characteristics are given in detail in Section 10.4. The heat balance guaranteed by the turbine manufacturer is shown by Figure 10.1-2. Figure 10.1-3 shows the maximum calculated turbine power (stretch power) heat balance.

The steam and power conversion system includes the following:

1. Main Steam System.
2. Turbine Generator.
3. Condensate System.
4. Condenser Air Removal System.
5. Feedwater System.
6. Turbine Bypass System.
7. Circulating Water System.
8. Steam Generator Blowdown System.
9. Emergency Feedwater System.

The thermal energy of steam generated by a 3 loop, Pressurized Water Reactor Nuclear Steam Supply System (NSSS) is converted to electrical energy through a tandem compound, 1800 rpm turbine generator.

Steam is produced in 3 steam generators where heat is transferred from the reactor coolant system to the feedwater. This steam flows from each steam generator to a distribution header. From this distribution header, 4 main steam lines convey the steam to a double flow, high pressure turbine. Steam exiting the high pressure turbine normally passes through 2 moisture separator reheaters prior to entering 2, double flow, low pressure turbines. Steam exits from the low pressure turbines to the main condenser. The high and low pressure turbines are equipped with a total of 6 extraction points which provide steam for feedwater heating. Moisture separator drains, steam reheater drains and high pressure heater drains are returned to a deaerating heater where they become part of the feedwater. Low pressure heater drains and steam packing condenser drains are cascaded to the main condenser.

Steam exhausted from the low pressure turbines is condensed and deaerated in a 2 shell surface condenser. Condensate is collected in a hotwell sized for a holding capacity of approximately 2 minutes at maximum condensate pump flow. Condensate is normally pumped from the hotwell by 2 of the 3 condensate pumps. The condensate passes through the steam packing condenser and 3

stages of low pressure heaters to the deaerating heater and deaerator storage tank. Each of the 3 stages of low pressure heaters is comprised of 2 parallel 50 percent capacity trains.

The feedwater booster pumps take suction from the deaerator storage tank and discharge to the feedwater pump suction. The feedwater pumps discharge to 2 trains of high pressure heaters. Feedwater exiting these heaters passes into a single header from which it is distributed to the feedwater flow control valves. The feedwater flows from the feedwater flow control valves through the containment isolation valves into the steam generators.

The Emergency Feedwater System provides an additional means for the supply of feedwater to the steam generators for use when the Feedwater System is not available. This permits continued transfer of reactor coolant thermal energy to feedwater in the steam generators. The Emergency Feedwater System consists of 2 electric motor driven and 1 turbine driven emergency feedwater pumps. These pumps, when required, provide feedwater to the steam generators from a reserve supply maintained in the condensate storage tank. A backup source of water is provided by connection to the Service Water System.

Noncondensible gases removed from the condenser by the Condenser Air Removal System are monitored for radioactivity. The condenser offgas is normally discharged to the Auxiliary Building Exhaust System charcoal filters. Provision is made for discharge of the noncondensibles to atmosphere.

Should a 100 percent loss of turbine load occur, reactor coolant thermal energy is dissipated through the formation of steam in the steam generators and subsequent bypassing of the steam to the condenser and/or the atmosphere through the Turbine Bypass System and through the power operated relief valves.

The following portions of the steam and power conversion system are safety-related:

1. Main Steam System piping inside the Reactor Building.
2. The portion of the Main Steam System which forms a part of the containment boundary, including main steam safety valves, power operated relief valves, and main and branch steam isolation valves.
3. The main steam piping to the emergency feedwater pump turbine.
4. The Emergency Feedwater System.
5. Feedwater System piping from the feedwater containment isolation valves to the steam generators.
6. Steam generator blowdown piping from the steam generator to and including the containment isolation valves.

10.2 TURBINE GENERATOR

10.2.1 Design Bases

The turbine generator is a General Electric Company (GE) TC4F-43" LSB, tandem compound, 4 flow exhaust unit with moisture separation and reheat between the high pressure (HP) and low pressure (LP) sections. The unit operates at 1800 rpm and is rated at a gross generator output of 1,017,000 kW with all feedwater heaters in service, at the nominal plant exhaust pressure of 2.13/2.92 inches Hg (absolute) and zero makeup.

Steam conditions at the turbine inlet are 980 psia and 1193.5 BTU/lb. Normal and upset conditions are tabulated on the system diagram, Figure 10.3-2.

The turbine generator design capacity is 1,039,489 kW (Ref. Figure 10.1-3). The turbine generator is expected to operate in the base load mode for the majority of its design life. Normal load swings are limited to 5% per minute which is the rate of change permitted by the Nuclear Steam Supply System (NSSS). A step load change of 10% of full power rating can be accommodated without use of the Turbine Bypass System.

10.2.2 Description

10.2.2.1 General

The turbine consists of 3 casings: a double flow HP section followed by 2 double flow LP casings. The last stage turbine wheels have 43 inch buckets. Mechanical moisture separation and reheat are provided between HP and LP sections.

The heat cycle provides for extraction at 6 pressure stages:

1. One (1) on the high pressure turbine casing (heater No. 1).
2. One (1) on the moisture separator (heater No. 2).
3. Four (4) on each of the 2 LP turbine casings (heaters No. 3 through 6).

The generator operates at 1800 rpm. It is a 3 phase, 60 Hz unit, rated 1,137,680 kVA at 22,000 volts, 0.905 pf and 60 psig hydrogen pressure. A shaft driven alternator exciter, rated at 2940 kVA @ 0.95 power factor (pf) provides the power necessary for field excitation. Section 10.2.2.4 presents a discussion of the Generator Gas System.

10.2.2.2 Turbine Generator Control

An Electrohydraulic Control System (EHC) (using electronic computing devices and high pressure, fire resistant fluid) actuates and controls the steam valves. This system is completely separated from the bearing oil supply.

The original EHC analog control cabinet and turbine-generator skid interfaces underwent a significant upgrade during RF-19 to replace obsolete equipment and to enhance overall system reliability. The upgrade consists of a “triple modular redundant” (TMR) digital control system, which utilizes three separate and independent controller processor modules and associated redundant input/output. EHC control logic algorithms utilize 2-of-3 (typical) “software implemented fault tolerance” (SIFT) voting techniques to optimize input/output signal data integrity and diagnostic trending. Primary <Q> controllers perform primary system control and trip protection functions (including primary overspeed protection). Emergency <P> controllers perform emergency (backup) overspeed protection function.

<Q> and <P> controller protection functions which result in a Turbine Trip condition (as described below and per Figure 7.2-1, Sheet 15) interface with downstream Trip Manifold Assembly (TMA) electromechanical and hydraulic devices, located in the Turbine front standard. The TMA is comprised of two independent trains of three sets of Electronic Trip Device (ETD) solenoids/pilot-actuated dump valves, of which 2-of-3 in either train must change position to trip the turbine. A trip condition results in pressure relief of the emergency trip system (ETS) header, which in turn causes turbine steam valves closure due to the loss of ETS hydraulic fluid pressure.

During normal operation, reactor power is controlled (using the Reactor Control System, as described in Section 7.7.1) to match turbine load as measured by turbine first stage pressure. The desired turbine steady-state load is established manually by the operator through inputs into EHC. EHC control logic algorithms establish/maintain the allowable turbine speed and turbine load conditions, ensure the required positioning of all turbine steam valves, and facilitate other loading/unloading evolutions (e.g., shell/chest warming, runbacks). These algorithms perform programmed control functions based upon comparison of: actual turbine-related operating parameters monitored by EHC (e.g., valve positions, system pressures); desired operator input settings; and pre-programmed system state point limits (e.g., control valve steam flow-to-valve lift position characterizations [per steam flow to turbine load demand correlations], runback conditions, overspeed regulation, other system limitations).

Table 10.2-0 provides a listing of signals that will shut down the turbine. Figure 7.2-1, Sheet 15 functionally shows EHC and turbine system interfaces which perform turbine trip-related functions. Receipt of 2-of-3 actuations via either <Q> Primary Trip Relays (PTRs) or <P> Emergency Trip Relays (ETRs), in either train of its <Q> or <P> controllers, will result in the corresponding change of state of its downstream TMA EHC interface devices (i.e., de-energized ETD solenoids and tripped-open ETD pilot-actuated dump valves associated with the actuated train). The outcome of either train’s 2-of-3 dump valve actuation is loss of ETS hydraulic fluid, closure of Turbine Stop and Control Valves, and a Turbine Trip condition. This 2-of-3 Turbine Trip actuation can also result from a complete loss of both non-safety related power supply feeders to the EHC control system cabinet (including the loss of a dedicated EHC battery-backed uninterruptible power supply, in the alternate feeder circuit).

10.2.2.3 Turbine Generator Overspeed Protection

The turbine’s rotational speed is sensed by a total of six passive magnetic-type probes used in conjunction with a multi-toothed wheel on the turbine shaft. Three of these speed probes (in the

<Q> controllers) provide input signals to speed control and primary trip protection algorithms. The remaining three speed probes (in the <P> controllers) provide input signals directly to emergency trip protection algorithms.

Steam valves associated with turbine generator overspeed protection are shown by Figure 10.3-2. Control details for the main stop valves (MSV) are shown by Figure 10.2-2. Control details for the control valves are shown by Figure 10.2-3a. Control details for the combined intermediate valves (CIV), which are the intermediate stop valve (ISV) and intercept valve (IV), are shown by Figure 10.2-3b. The ISV and IV are 2, independent, separately actuated valves in the same valve body, called the CIV.

Overspeed protection mechanisms and the hydraulic trip system are shown by Figure 10.2-4.

ETD components (as described in Section 10.2.2.2) receive high pressure (1600 psig nominal) hydraulic fluid from the EHC power unit, and regulate the ETS header pressure condition. ETS pressure is high when the hydraulic trip system is reset, and low (at drain pressure) when the system is tripped. The condition of the ETS header depends upon the state of 2-of-3 ETD solenoids/dump valves.

During a turbine generator overspeed occurrence, the EHC control system receives <Q> and/or <P> speed sensor input signals which exceed the pre-defined Primary and/or Emergency speed setpoint levels. Turbine trip logic actuation will occur when 2-of-3 <Q> speed signals or 2-of-3 <P> speed signals exceed their respective speed setpoint. (Note that turbine trip actuation will also occur in the event of postulated speed sensor failures, including the <Q> and <P> speed difference fault trip and zero speed mismatch trips functionally shown on Figure 8.3-8.) Overspeed-related turbine trip logic actuation will cause ETD solenoids to de-energize and ETD dump valves to de-pressurize the ETS hydraulic trip header (identical to other turbine trip conditions, as described in Section 10.2.2.2).

1. The disc dump valves of the MSV, CV, IV, and ISVs are opened causing rapid closure of the steam valves due to spring and steam force.
2. The ETS pressure transmitters maintain the tripped condition within the EHC control system.
3. The extraction relay dump valve isolates the air supply to and vents air from the air cylinders of the turbine extraction nonreturn valves. Spring assist on the air cylinder aids in positive closure of the nonreturn valves.

Frequent inservice testing of the overspeed trip mechanisms and steam valves ensures the reliability of the overspeed protection systems. All steam valves, except the nonreturn valves, located inside the condenser in the low pressure feedwater heater extraction piping, are capable of online testing.

This system is designed to be fail safe, i.e., a malfunction of the system will trip close all turbine steam source valves, limiting turbine overspeed. A high or moderate energy piping failure at the turbine, which would cause a loss of power (electric or hydraulic) to the overspeed protection

system due to severance of electrical cable or hydraulic lines, would cause all turbine steam source valves to close.

The turbine trip logic also includes fail safe features which limit turbine overspeed. The trip logic verifies that at least 1 of the 2 low pressure steam source valves (i.e., intermediate stop valve or intercept valve) in each line to the turbine has closed and that all high pressure main turbine stop valves have closed before load is disconnected from the main generator. In the event of a pipe rupture, with manual turbine trip, load would not be disconnected from the main generator unless all turbine steam source valves, excluding extraction valves, were closed. The extraction valves are nonreturn (check) valves and, therefore, do not require external signals to close.

The connection from the low pressure turbine to the condenser is under vacuum during operation. In the event of failure of this connection, air would initially be drawn into the condenser and backpressure on the turbine would increase to the point where the turbine would trip due to the high backpressure. Venting of air into the condenser is a method normally used to quickly slow a turbine following a trip. Some steam may be released while the turbine is being tripped.

A turbine trip will initiate a reactor trip. The reactor trip from turbine trip will be automatically blocked by P-9 (power level less than 50% rated thermal power) and on increasing power reinstated automatically by P-9.

Since the turbine overspeed protection system is of a fail safe design and no credit is taken for reactor trip due to turbine trip in any accident analysis, protection from pipe rupture is neither required nor provided.

A failure analysis of the turbine generator overspeed protection system is presented by Table 10.2-2.

10.2.2.4 Generator Gas System

The bulk hydrogen and carbon dioxide storage facilities are located in the yard area south of the Turbine Building (see Figure 1.2-1). The hydrogen and carbon dioxide storage and distribution systems are schematically illustrated by Figure 10.2-5.

The hydrogen storage facility consists of 6 storage tanks, each pressurized to a nominal pressure of 2300 psig. Hydrogen pressure is reduced to the generator manufacturer’s control panel supply pressure in 2 stages.

Liquid carbon dioxide is stored in a refrigerated storage tank and is vaporized in the Turbine Building as required for generator purging.

The Generator Gas System is equipped with an inservice gas analyzer. This analyzer actuates an alarm upon detection of low (<90%) hydrogen purity.

Safety features associated with the Generator Gas System include the following:

1. Remote, outdoor, bulk hydrogen storage and pressure reduction facilities are provided. Hydrogen supply piping from the storage facility to the Turbine Building is under low pressure and is also buried.
2. The inservice generator gas analyzer actuates an alarm to warn of low hydrogen purity in advance of formation of an explosive mixture. A generator differential fan pressure gage provides an independent check of hydrogen purity.
3. The Generator Gas System is operated by experienced personnel.
4. Generator gases are vented to atmosphere independent of other plant vents.
5. Operating procedures require complete purging of the generator before and after maintenance. Hydrogen is purged from the generator by carbon dioxide before it is opened. When maintenance is completed, the generator is again purged with carbon dioxide to remove the air prior to refilling with hydrogen.
6. The generator gas analyzer is periodically calibrated to assure accuracy.
7. System valves are periodically checked for indication of leakage to assure system leak tightness.
8. Physical separation of the Generator Gas System from safety related equipment required for safe plant shutdown provides additional safety.

10.2.3 Turbine Missiles

The LP turbine built up rotors consisting of wheels shrunk-on a central shaft have been replaced by single piece monoblock rotors in spring, 1996. The monoblock turbine rotor design eliminates the brittle fracture failure mode and the probability for a wheel burst and missile generation at normal operating speeds. Furthermore, the 2011 installation of the digital EHC control system provides significant redundancy and reliability enhancements over the original overspeed protection. The improvements to rotors and controls (relative to the original plant design) provide for a further reduction in the probability of turbine missile generation due to an overspeed protection system failure.

A compilation report (Reference 4) contains various missile probability and reliability analyses performed by the turbine manufacturer, which encompass the current system configuration details (of the monoblock rotors and the digital control system retrofit). These analyses document the following summary of pertinent results:

- The maximum attainable main turbine shaft speed is 214% - 217% of normal running speed at the worst possible operating conditions. At this point, the driving forces in the steam are counteracted by the drag forces and the rotor train can no longer accelerate.

- A complete failure of the Main Turbine Control System is required to achieve the maximum attainable overspeed. The annual probability of a complete control failure is in the range 10^{-8}.

- The LP monoblock overspeed capability based on material properties and rotor design is 221% for LPA and 222% for LPB.

1. Turbine Design

   The turbine assembly was designed to withstand normal conditions and anticipated transients, including those resulting in turbine trip, without loss of structural integrity. The design of the turbine assembly satisfied the following criteria:

   a. Turbine shaft bearings were designed to retain structural integrity under normal operating loads and anticipated transients, including those leading to turbine trips.

   b. The multitude of natural critical frequencies of the turbine shaft assemblies existing between zero speed and 20% overspeed were controlled in the design and operation so as to cause no distress to the unit during operation.

   c. The maximum tangential stress in rotors resulting from centrifugal forces, interference fit and thermal gradients does not exceed 0.75 of the yield strength of the materials at 115% of rated speed.

2. Inservice Inspection

   The inservice inspection program for the turbine assembly will include the following:

   a. Disassembly of the turbine at approximately 10 year intervals, during plant shutdown, and complete inspection of all normally inaccessible parts, such as couplings, coupling bolts, turbine shafts, low pressure turbine buckets, low pressure wheels, and high pressure rotors.

   b. Visual, surface, and volumetric examinations, as indicated below:

      (1) A thorough volumetric examination of all low pressure wheels and high pressure rotors, including areas immediately adjacent to keyways and bores, will be conducted. This examination is predicated on the development of suitable remote inspection equipment.

      (2) Visual examination of all accessible surfaces of rotors and wheels.

      (3) Visual and surface examination of all low pressure buckets.

      (4) Surface examination (100%) of couplings and coupling bolts.

   The inservice inspection of main steam and reheat valves will include the following:

   a. Dismantle at least 1 main steam stop valve, 1 main steam control valve, 1 reheat stop valve, and 1 reheat intercept valve at approximately 3-1/3 year intervals during refueling or maintenance shutdowns, and conduct a visual and surface examination of valve seats, discs, and stems. If unacceptable flaws or excessive corrosion are found in a valve, all valves of that type will be inspected. Valve bushings will be inspected and cleaned, and bore diameters will be checked for proper clearance.

b. Main steam stop and control, reheat stop and intercept valves will be exercised at least once during a 3 month operating interval, by closing each valve and observing, by the valve position indicator, that it moves smoothly to a fully closed position. This observation will be made by actually watching the valve motion.

10.2.4 Evaluation

Turbine rotor missiles will not be generated with the rotor burst capability exceeding the overspeed potential. Therefore, the possibility of missiles being generated by a wheel burst due to stress corrosion cracking and causing damage to critical plant components, is no longer present, and there no longer exists any wheel disc integrity concern.

Reference 4 provides a detailed safety evaluation of steam valve arrangement and trip devices, turbine extraction line overspeed trip protection, and operating and testing of overspeed protection systems.

Table 10.2-0

Turbine Shutdown Signals

1. Train A EHC external trips, from any one of the following conditions:
   - Train A Reactor Trip.
   - High-high steam generator level (2 of 3) or Train A Safety Injection.
   - Loss of 3-of-3 feedwater pumps.
   - Generator electrical fault.
   - LP Heater 5A, 5B, 6A, and/or 6B high-high levels (10 second time delay).
   - AMSAC actuation above C-20, due to low-low level in 2 of 3 steam generators.
2. Train B EHC external trips, from any one of the following conditions:
   - Train B Reactor Trip.
   - Hi-Hi steam generator level (2 of 3) or Train B Safety Injection.
   - AMSAC actuation above C-20, due to low-low level in 2 of 3 steam generators.
3. Manual turbine trip pushbuttons (2 of 2 at MCB, or 2 of 2 at Front Standard).
4. Main shaft oil pump discharge pressure low (2 of 3), and turbine speed greater than 1350 rpm.
5. Lube oil bearing header pressure low (2 of 3).
6. EHC hydraulic header pressure low (2 of 3).
7. Speed signal mismatch trips, in Primary (<Q>) and/or Emergency (<P>) controllers, from any one of the following conditions:
   - <Q> zero speed mismatch fault (2 of 3 Primary <Q> speed sensors indicate zero speed condition while <P> Emergency sensors indicate greater than 15% of rated speed).
   - <P> zero speed mismatch fault (2 of 3 Emergency <P> speed sensors indicate zero speed condition while <Q> Primary sensors indicate greater than 15% of rated speed).
   - <Q> and <P> speed difference fault (difference greater than 5%).
   - <Q> excessive acceleration or deceleration rate change (2 of 3 <Q> speed sensors).
   - <P> excessive acceleration or deceleration rate change (2 of 3 <P> speed sensors).
8. Primary (<Q> controllers) overspeed trip (109.5% of rated speed).
9. Emergency (<P> controllers) overspeed trip (110% of rated speed).
10. Exhaust vacuum (absolute) pressure high (2 of 3 in either [LP A or LP B] hood), and turbine speed greater than 150 rpm.
11. Exhaust hood high temperature (2 of 3 in either [LP A or LP B] hood).
12. Loss of stator cooling trip (due to failed runback).

TABLE 10.2-0 (Continued)
Turbine Shutdown Signals

13. Moisture separator reheater level high (15 second time delay) (2 of 3 in either A or B MSR).
14. Thrust bearing excessive wear detection (from 2 of 3 axial bearing position sensors).
15. Shaft bearing high vibration (10 second time delay); manual operator action required if automatic trip disabled.
16. Train A or Train B Off-line ETD Test tripped condition (2 of 3 electronic trip devices [ETDs] under test are de-energized [tripped]).

Table 10.2-1
Turbine Generator Overspeed Protection System

Overspeed Trip Mechanism	Set Speed	Action
Speed Governor (Normal)	1836 to 1872 RPM (102% to 104%)	Complete closure of intercept valves at 102% of rated speed; complete closure of control valves at 104% of rated speed. Loss of two speed signals actuates the hydraulic trip system.
Primary Overspeed Trip	1971 RPM (109.5%)	Actuates the hydraulic trip system.
Emergency Overspeed Trip	1980 RPM (110%)	Actuates the hydraulic trip system.

Table 10.2-2
Turbine Overspeed Protection System
Failure Analysis

Component	Malfunction	Comment
Steam Valve (MSV, CV, IV, ISV)	One valve fails to close on overspeed trip	Each steam line contains “paired” steam valves installed in series. Thus, failure of one valve (e.g., CV1) to close does not defeat its paired valve (e.g., MSV1). No impact to overspeed function exists.
Turbine Extraction Nonreturn Valve	One valve fails to close	The overspeed potential of the feedwater heating system is small. The total uncontrolled energy can contribute no more than 1.5% to the running speed of the turbine generator.
Primary <Q> Overspeed Trip Actuation Logic	One Train of <Q> protection logic fails to trip at Primary Overspeed setpoint	Two Trains of <Q> logic are installed. Thus, failure of one Train will not defeat the other Train. Furthermore, backup protection is provided by Emergency <P> Overspeed Trip Actuation Logic.
Emergency <P> Overspeed Trip Actuation Logic	One Train of <P> protection logic fails to trip at its Overspeed setpoint	Two Trains of <P> logic are installed. Thus, failure of one Train will not defeat the other Train.
Electronic Trip Device (ETD)	One Train of 2-of-3 ETD solenoid/dump valve components fail to trip	Trip manifold assembly consists of two trains of 2-of-3 ETD solenoid/dump valve components. Either ETD train will trip the turbine.

Table 10.2-2 (continued)
Turbine Overspeed Protection System
Failure Analysis

Component	Malfunction	Comment
Hydraulic Trip System Piping	Piping fails causing depressurization	All steam valves close as in overspeed trip.
Primary AC Power Supply Feeder	Loss of primary power supply (failure or other unavailability) to EHC control system	No impact to overspeed protection function exists. - Alternate AC feeder will maintain EHC control system power, to assure actuation logic function. - Complete loss of power will de-energize/dump ETD components.
Alternate AC Power Supply Feeder	Loss of alternate power supply (failure or other unavailability) to EHC control system	No impact to overspeed protection function exists. - If available, primary feeder available will maintain EHC control system power and actuation logic function. - If primary feeder is not available, a battery-backed UPS (in alternate feeder circuit) will permit timely manual turbine trip and post-trip monitoring. - Complete loss of power will de-energize/dump ETD components.

10.3 MAIN STEAM SUPPLY SYSTEM

The Main Steam Supply System conveys main steam from the steam generators to the turbine generator and, through branch lines, to the following: feedwater pump drive turbines, emergency feedwater pump drive turbine, moisture separator reheaters, auxiliary steam system, deaerating feedwater heater, and steam dumps to the condenser and atmosphere.

10.3.1 Design Bases

10.3.1.1 Codes and Standards

The Main Steam Supply System is designed in conformance with the following codes and standards:

1. Steam generator secondary sides, piping and valves, between the steam generators and main steam isolation valves, including the main steam isolation valves, main steam safety valves, and power relief valves, are classified as Safety Class 2a and are designed in accordance with the ASME Code, Section III, Class 2.
2. Steam piping and components in the lines to the emergency feedwater pump drive turbine are classified as Safety Class 2b and are designed in accordance with the ASME Code, Section III, Class 3.

   The emergency feedwater pump drive turbine exhaust piping is classified as safety class 2b and is designed in accordance with the ASME Code, Section III, Class 3 except for hydrotesting and code stamping.
3. Main steam piping in the Intermediate Building between the main steam isolation valves and the Turbine Building wall is non-nuclear safety class. However, this piping excluding branch lines, satisfies the requirements except for stamping, of the ASME Code, Section III, Code Class 2. This provides greater assurance of design and fabrication integrity, thus, reducing risk of postulated pipe rupture in this area. This piping is identified as “Note 1" piping on Figures 10.3-1 and 10.3-2.

   Originally the main and branch lines were designated as “Note 1" piping to reduce the number of postulated pipe rupture locations by the use of a code stress analysis to choose intermediate breaks. In the final pipe rupture analysis of the branch lines, stress analysis was not used and intermediate breaks were postulated at each fitting (see Section 3.6.2.5.1). Therefore, it was no longer necessary to provide code piping and the “Note 1" designation for these branch lines was deleted.
4. Piping other than that noted in 1, 2 and 3, above, is non-nuclear safety class and is designed in accordance with ANSI B31.1 (Reference 1).
5. Cast steel valves, except those noted in 1, 2 and 3, above, are non-nuclear safety class and are designed in accordance with ANSI B16.5 (Reference 2) 0.

6. Main Steam Supply System drains are designed using “Recommended Practices for the Protection of Water Damage to Steam Turbines Used for Electric Power Generation, Part II,” (Reference 3) as a guide.
7. The Main Steam Supply System is designed to permit inservice inspection as required by the ASME Code, Section XI.
8. The Main Steam Supply System is designed with the capability to dump steam to the condenser and/or the atmosphere as discussed in Section 10.4.4.

10.3.1.2 Heat Balance

The Main Steam Supply System is designed to deliver 11,734,149 lb/hr of steam to the turbine control valves and 1,123,964 lb/hr to the moisture separator reheater for a total of 12,858,113 lb/hr. (See GE Heat balance 170x595-21, Rev. 1).

10.3.1.3 Design Conditions

The system is designed to withstand the same conditions as are the steam generator secondary sides. Design pressure is 1185 psig; design temperature is 600°F. Design pressures and temperatures for piping, valves, and pressure retaining components are tabulated on Figures 10.3-1 through 10.3-4.

10.3.1.4 Environmental Conditions

Environmental conditions considered in the design of the Main Steam Supply System are presented in Table 10.3-1.

The emergency and faulted conditions are based on the Main Steam Line Break and Loss of Coolant Accidents. Components within the Reactor Building are also subjected to a spray of borated water and sodium hydroxide as described in Section 6.2.2.2.1.

10.3.2 Description

10.3.2.1 General

The Main Steam Supply System consists of 3 steam generators, 3 flow restrictors, 15 safety valves, 3 steam generator power relief valves, 3 main steam isolation valves, 8 steam dump valves to the condenser, 3 atmospheric steam dump valves and other required valves, steam traps, instrumentation, controls, and associated piping. See Figures 10.3-1 through 10.3-4.

The Main Steam Supply System conveys saturated steam from the 3 steam generators to the turbine generator.

One (1) line from each of the 3 steam generators conveys main steam to a header located in the Intermediate Building. From the header a total of 4 lines proceed to the turbine stop valves. Steam flow to the high pressure turbine is regulated by the turbine control valves.

Moisture separator reheater units are located immediately beside the turbine between the high pressure and low pressure elements. Heating tube bundles within each moisture separator reheater, supplied with steam from the Main Steam Supply System, superheat high pressure turbine exhaust steam approximately 136°F before it enters the low pressure turbine elements.

Main steam is also supplied to the following:

1. Feedwater pump drive turbines for startup and runout.
2. Auxiliary Steam System for the liquid waste evaporator as required during normal operation and during plant shutdown until the auxiliary boiler is operational.
3. Extraction Steam System for pegging and sparging the deaerator.
4. Emergency feedwater pump drive turbine during emergency and normal plant shutdown to supply minimum feedwater requirements.

The Main Steam Supply System was originally designed to follow a full load rejection, defined as a reduction from 100% of rated turbine generator load to plant auxiliary load, without reactor trip through actuation of the steam dump to the condenser and atmosphere. With the transition to longer fuel cycles and less negative moderator temperature coefficients at the beginning of the fuel cycle, a full load rejection can no longer be sustained without a reactor trip for all times in core life and all allowable values of full power, average coolant temperatures within the Reactor Coolant System.

Steam dump valves permit unit operation at turbine loads lower than the minimum power setting (15% reactor power) of the Nuclear Steam Supply System (NSSS) automatic control. In addition, the steam dump valves permit reduction of turbine generator load at a rate greater than the 5% per minute maximum rate of load reduction for the NSSS.

Steam generator power relief valves provide a means for plant cooldown by controlled steam discharge to the atmosphere should the condenser not be available. These valves pass a total of ¡«18.76% of the rated maximum steam flow (at full load pressure). One (1) valve is provided in each generator line, upstream of the main steam isolation valves.

10.3.2.2 Main Steam System Piping

Each line from the steam generators is 32 inch nominal OD, 1.15 inch minimum wall, carbon steel pipe. The piping inside the Reactor and Intermediate Buildings is routed and restrained to minimize the possibility of a single line failure affecting the other piping. In the area where the safety valves are located, the pipe OD is increased and the nominal wall thickness is 1.90 inches to provide extra strength. The 3 lines from the steam generators are manifolded into a 32 inch nominal OD, 1.15 inch minimum wall, carbon steel header.

From the header, steam flows through four(4) 30 inch nominal OD, 1.125 inch nominal wall, carbon steel lines to the turbine generator. Steam also flows from the header through a 24 inch OD, schedule 80, carbon steel pipe to the moisture separator reheater and feedwater pump drive turbines.

A 4 inch OD, schedule 80, carbon steel pipe supplies steam from each of 2 steam generator main steam lines to the emergency feedwater pump drive turbine. Steam from only one steam generator is needed for pump operation; 2 sources are provided for required redundancy.

Steam generators and flow restrictors are discussed in detail in Section 5.5.

10.3.2.3 Main Steam Isolation Valves

Each of the 3 main steam lines proceeding from the steam generators to the main steam header is equipped with a quick closing main steam isolation valve capable of tight closure, regardless of flow direction. The main steam isolation valves are of the articulated poppet, wye type design. These nominal 32 inch valves have a capacity of 4,277,315 lb/hr steam flow with an approximately 2.26 psi maximum calculated pressure drop across the fully open valve. These valves are designed for 1284 psig at 600°F. The valves are actuated by an air cylinder operator (air to open; spring to close). Closure time is adjustable. Maximum closure time is 7 seconds after receipt of a closure signal. Main steam isolation valve closure signals are as follows:

1. High containment pressure.
2. High steam flow with coincident lo-lo average primary coolant temperature.
3. Low steam pressure.
4. Manual.

These valves are located in the Intermediate Building downstream of the main safety valves.

The quick closing main steam isolation valves prevent reverse flow of steam. If a steam line rupture occurs between an isolation valve and a steam generator, the affected steam generator continues to blow down, while the isolation valves are automatically closed to prevent blowdown from the unaffected steam generators. Should an isolation valve not close, flow from the Main Steam System downstream of the main isolation valves is limited by either normally closed valves or by valves that are automatically closed by interlocks from the NSSS system or from the turbine generator system as tabulated in Table 10.3-2. This small steam flow does not impact the results of the main steam line break analysis in Section 15.4-2.

If a main steam line rupture occurs downstream of an isolation valve, all 3 isolation valves are automatically closed, stopping main steam flow. Closure of the isolation valves terminates the sudden large release of energy in the escaping steam, thereby preventing rapid cooldown of the Reactor Coolant System. Closure of the isolation valves also ensures a supply of steam for the 100% capacity, turbine driven emergency feedwater pump.

The maximum permissible main steam isolation valve leakage in the direction of normal flow is in accordance with the recommendations of MSS SP-61 (Reference 4). In the direction of reverse flow, leakage is less than 1% of normal steam flow through the main steam isolation valve.

10.3.2.4 Main Steam Safety Valves

Main steam safety valves are located in each main steam line outside the Reactor Building, upstream of the main steam isolation valves to protect the steam generators against overpressure. These valves are designed, fabricated and stamped in accordance with the ASME Code, Section III. The safety valve setpoints are given in Table 10.3-1a. The safety valves are sized to pass the steam flow resulting from complete load rejection or shutoff of main steam flow without reactor trip. The maximum steam flow through each individual valve is limited to 970,000 lb/hr at steam generator design conditions, in accordance with Nuclear Steam Supply System criteria. In the event that a single main steam safety valve sticks in the full open position, uncontrolled blowdown from the affected steam generator is restricted within limits compatible with maintenance of reactor fuel integrity and integrity of the reactor internals.

10.3.3 Evaluation

The Main Steam Supply System design limits the effects of a main steam line rupture. Seamless pipe is used inside the Reactor Building and for the spool piece of the penetration terminal end outside the Reactor Building. This minimizes the probability and consequences of postulated pipe rupture. Rupture of any main steam line, malfunction of any single isolation valve, or any consequential damage does not cause uncontrolled flow from more than 1 steam generator, nor does it result in containment pressure exceeding the design value.

The effects of pipe whip are considered in the layout of the system. Safety-related equipment is protected from the effects of pipe whip by restraints, physical separation, and/or barriers, if required. Pipe rupture is discussed in detail in Section 3.6, seismic design is discussed in Section 3.7.

10.3.4 Inspection and Testing Requirements

Inspection and testing requirements for the Main Steam Supply System can be divided into 2 parts: preoperational testing and inservice testing and inspection.

1. Preoperational Testing

   Preoperational testing of the Main Steam Supply System includes:

   a. Cold hydrostatic testing.
   b. Hot functional testing, including test of the functional capability of system valves.
   c. Preservice inspection to establish baseline data for subsequent inservice inspection, as required by the ASME Code, Section XI.

2. Inservice Testing and Inspection

   Inservice testing and inspection of the Main Steam Supply System includes:

a. Main steam isolation valve testing as follows:

(1) The main steam isolation valves are capable of being tested during normal plant operation to demonstrate their ability to respond to a “test close” signal. Upon receipt of a “test close” signal, the main steam isolation valve being tested moves to a 90 to 95% open (5 to 10% closed) position. Upon removal of the “test close” signal, the valve returns to the 100% open position. In the event that a close signal is received during this test, such a signal overrides the test signal and the isolation valve closes completely within the specified closing time. This testing is no longer performed based on NUREG 1482, “Guidelines for Inservice Testing at Nuclear Power Plants,” Section 4.2.4 recommendation.

(2) Testing for complete main steam isolation valve closure is performed under shutdown conditions and verifies the ability of the valves to fully close within the specified closure time.

b. Inservice inspection requirements, in accordance with the ASME Code, Section XI, apply to all Class 2 and Class 3 main steam piping from the steam generators to the point where the main steam piping enters the Turbine Building.

Weld examinations are performed in accordance with the ASME Code, Section XI. Inservice inspection of other Main Steam Supply System components within this boundary is discussed in Section 5.7. System components not within this boundary are not subject to inservice inspection.

10.3.5 Water Chemistry

Secondary side water chemistry “all volatile treatment” (AVT) for corrosion control consists of the following:

1. Addition of an amine or mixture of amines for pH control.
2. Addition of an oxygen scavenger to minimize dissolved oxygen concentration.
3. Continuous steam generator secondary side blowdown to limit concentrations of dissolved and suspended solids.
4. A Condensate Cleanup System, consisting of filter/demineralizers, operated during startup to approximately 50% flow and as required during condenser leakage and if needed, during shutdown.
5. Boric acid may be added to mitigate denting of steam generator tubes.
6. Ammonium Chloride may be added for molar ratio control.
7. Other chemicals may be added based on EPRI, NSSS supplier or SGOG guidelines and evaluation by SCE&G.

Secondary side water chemistry specifications are in accordance with the recommendations of EPRI. Recommendations of the NSSS supplier and/or the Steam Generator Owners Group (SGOG), may also be applied.

Samples of condensate, feedwater, steam, steam generator blowdown, and demineralized makeup water are available for use in monitoring and controlling secondary side water chemistry. Sampling equipment is located in the water treatment building and in the nuclear sampling room of the Control Building. Sampling equipment consists of pH, conductivity, cation conductivity, hydrazine, sodium, and dissolved oxygen analyzers for monitoring the appropriate samples at reduced temperature and pressure.

Steam generator blowdown samples are routed to the nuclear sampling room, as are other potentially radioactive samples (see Section 9.3.2). Samples from other secondary side sample points are routed to the sampling panel at the Water Treatment Building.

Grab samples are taken from secondary side sample points at regular intervals and are subjected to laboratory analyses to ensure that the analyzers are functioning properly and that secondary side water chemistry is within specification.

Steam generator water chemistry is controlled through sampling, steam generator secondary side blowdown, and chemical addition. During normal operation, amine injection for control of secondary side pH and oxygen scavenger for dissolved oxygen control may be regulated automatically or manually. Under transient conditions, amine and oxygen scavenger injections are manually regulated as required by grab sample analytical results. Amine and oxygen scavenger injection equipment is located in the Intermediate Building.

There are 3 possible mechanisms for hydrogen production in secondary side water. These mechanisms are as follows:

1. Corrosion.
2. Decomposition of hydrazine.
3. Leakage and/or diffusion from the primary side.

Hydrogen production rates will be inconsequential and any buildup in secondary side water will not be a safety hazard.

The secondary water chemistry control program will include a comprehensive monitoring program. The aim of this program is the minimization of overall system corrosion. Special emphasis will be placed on the inhibition of steam generator tube degradation. In general, the program will be based on recommendations and criteria supplied by EPRI. Recommendations from the NSSS vendor and/or the SGOG may also be incorporated. This program consists of procedures covering those items contained in Section 6.8 of the Technical Specifications.

10.3.6 Steam and Feedwater System Materials

10.3.6.1 Fracture Toughness

Where specified, test methods and acceptance criteria for fracture toughness are in compliance with the ASME Code, Section III, Article NC-2300. Charpy V-notch tests are specified for ferritic materials used in the following Class 2 components of the feedwater system:

1. Feedwater isolation valves.
2. Feedwater check valves.
3. Feedwater system Reactor Building penetration assemblies.
4. Feedwater piping.

Tests are specified for these feedwater system components because nominal pipe size exceeds 6 inches, material section thickness exceeds 5/8 inch and minimum service temperature can be as low as 50°F inside containment and 40°F outside containment.

Fracture toughness testing (impact testing) for ferritic materials used in the Main Steam System piping whose nominal pipe size exceeds 6 inches and material section thickness exceeds 5/8 inch was performed at a temperature of 120°F since minimum service temperature is approximately 327°F at 100 psia. This is the lowest temperature at which the steam generators are used to remove heat from the Reactor Coolant System. Testing was performed at 32°F on the main steam penetration process pipe. The Residual Heat Removal System is used at lower temperatures and pressures. The ASME Code, Section III does not specifically require impact testing of materials used in the Main Steam Supply System. The Code stipulates that the design specification must state whether or not impact testing is required. In consideration of the high minimum service temperature for the Main Steam Supply System, impact testing is not specified.

Fracture toughness testing (impact testing) is not required for ferritic Class 2 and Class 3 components of the Emergency Feedwater System, since pipe, fittings, pumps, and valves in this system have a nominal pipe size less than 6 inches. Articles NC-2311(b) and ND-2311(b) of the ASME Code, Section III exempt these materials from impact testing requirements.

10.3.6.2 Materials Selection and Fabrication

10.3.6.2.1 Materials Not Included in Appendix I to Section III of the ASME Code

Materials used are included in Appendix I to Section III of the ASME Code. Each line from the steam generators to the containment penetration assembly, inside the Reactor Building, is fabricated from SA-106, Grade C, seamless, carbon steel pipe material. The first straight piece of pipe attached to the containment penetration assembly outside the Reactor Building is also of this material. The main steam lines from this point to the Turbine Building wall, including piping in the penetration rooms and Intermediate Building, are fabricated from SA-155, KC-70, Class 1 welded, carbon steel pipe material.

Main steam piping within the Turbine Building is fabricated from A-155, KC-70, welded, carbon steel pipe material.

10.3.6.2.2 Austenitic Stainless Steel Components

No austenitic stainless steel components are used.

10.3.6.2.3 Cleaning and Handling of Class 2 and 3 Components

Cleaning and handling of components is performed in accordance with Regulatory Guide 1.37 (see Appendix 3A) and ANSI N45.2.1 (Reference 5).

10.3.6.2.4 Preheat Temperatures

Compliance with Regulatory Guide 1.50 is discussed in Appendix 3A.

10.3.6.2.5 Welding Procedures

Compliance with Regulatory Guide 1.71 is discussed in Appendix 3A.

10.4 OTHER FEATURES OF STEAM AND POWER CONVERSION SYSTEM

10.4.1 Main Condenser

The main condenser acts as a heat sink for the 2 low pressure turbine exhausts, limiting the back pressure and thus increasing the amount of available work from the turbines. The main condenser also serves as a collection point for main steam dump flow, low pressure heater drains, and other miscellaneous flows, as well as, being the makeup point for the secondary cycle. It deaerates and provides storage capacity for the condensate system.

The auxiliary condensers are heat sinks for their individual feed pump turbines. Condensate from these condensers is returned to the main condenser.

10.4.1.1 Design Bases

The main condenser is of the dual shell, dual pressure type (a high pressure shell and a low pressure shell). The high pressure shell is designed to operate at ~2.91 inches, HgA. The low pressure shell is designed to operate at ~2.13 inches, HgA with a design cooling water inlet temperature of 77 °F (circulating water temperature).

The low pressure shell features a false bottom plate which separates the low pressure condensing zone of the shell from a high pressure storage zone. The low pressure zone is connected to the high pressure zone by a downcomer. Condensate flows from the low pressure zone at a temperature of ~103.23°F to the high pressure zone by gravity. Condensate from the high pressure zone of the low pressure shell flows by gravity to the high pressure shell where it is reheated to 115.04 °F by mixing with high pressure shell hotwell condensate. The condensate is reheated to the saturation temperature of the high pressure shell at the design point. The condensate pumps take suction from the high pressure shell. The design temperature of condensate out of the high pressure shell is ~ 115.04 °F. Normal maximum operating pressure of the main condenser is limited to approximately 5 inches, HgA, and 175 °F at the turbine exhaust to any shell. Condenser design capacities are listed in Table 10.4-1. Radioactivity concentrations in the condenser are expected to be approximately equivalent to the concentrations given in Table 11.1-5 for steam. Radioiodine concentrations in the condenser should be slightly lower because of a main condenser/air ejector partition factor of 0.15 for volatile iodine species.

Noncondensable gases are removed by the vacuum pumps described in Section 10.4.2. Design air inleakage rates are 40 scfm for normal main condenser operation and 15 scfm, total, for normal auxiliary condenser operation.

The main condenser will receive approximately 6.93 x 10^6 lb/hr of main steam from the Turbine Bypass System. This flow is bypassed to the condenser as required following a large load rejection, turbine trip, or other similar occurrence.

Main steam pressure is reduced to approximately 100 psig by the turbine bypass system at the condenser main steam dump inlet header. The steam is then dispersed by the main condenser through an internal spray pipe which directs the steam flow to a stainless steel baffle. This internal

arrangement and the relatively low pressure (100 psig) protects the tubes and other components from impingement damage failure.

The condenser hotwell is capable of maintaining a normal water level corresponding to a retention time of at least 2 minutes (approximately 39,200 gallons).

Each condenser shell is provided with a compartmented hotwell and leak detection trays. A tray is located inside the hotwell adjacent to the tubesheet of each waterbox. The compartmented hotwells and leak detection trays are continuously sampled to provide early detection of tube leakage. Design of the compartmented hotwells and leak detection trays permits obtaining local samples to facilitate locating of tube leaks if necessary.

The combination of good quality (lake) cooling water and stainless steel tubes reduces corrosion and erosion of condenser tubes. An Amertap cleaning system is also provided for use in maintaining condenser tube cleanliness.

10.4.1.2 System Description

The main condenser is of the dual shell, dual pressure type with a rubber expansion joint in each neck. Circulating water is arranged to pass through the 2 sections in series. Condenser leakage is monitored by installed condensate monitoring instrumentation with an associated alarm in the control room. Heaters 5A and 6A are installed in the low pressure shell; heaters 5B and 6B are installed in the high pressure shell.

During normal operation the main condenser receives the following flows:

1. Main turbine exhaust steam.
2. Auxiliary condenser condensate and vents.
3. Low pressure heater drains.
4. Steam and water associated with the Turbine Gland Sealing System.
5. Condensate makeup.
6. Auxiliary condenser air removal (Low Pressure Condenser).

Possible additional flows during startup, shutdown or under transient conditions include:

1. Condensate pump and steam packing condenser minimum flow recirculation.
2. Startup vents.
3. Moisture separator/reheater drains.
4. Turbine bypass flow through the Main Steam Dump System.

10.4.1.3 Safety Evaluation

Disassociated hydrogen and other noncondensible gases are removed by the mechanical vacuum pumps to the atmosphere. These noncondensible gases may be routed to the Auxiliary Building Ventilation System charcoal filters if radiation levels in excess of established limits exist in the vacuum pump discharge. In the event 1 vacuum pump fails, another is available on standby. Thus, hydrogen buildup does not occur during operation of the condenser.

The influence of the main condenser on the Reactor Coolant System is reduced by the decoupling effect of the deaerator and steam generator water inventories. Therefore, control functions associated with the main condenser do not directly influence the operation of the Reactor Coolant System.

If the condenser pressure should start to rise, exhaust hood sprays are activated by a turbine exhaust hood temperature signal. Normal operation of the main condenser and its associated control functions do not affect the Reactor Coolant System. The only main condenser control function indirectly affecting the Reactor Coolant System is the loss of condenser vacuum which results in turbine trip. A turbine trip due to loss of condenser vacuum results in programmed steam dump to the atmosphere and reactor shutdown.

Provisions for protection of safety-related equipment from flooding as a result of condenser failure are discussed in Section 7.6.

10.4.1.4 Tests and Inspections

The condenser is subjected to a shell side hydrostatic test in the field. The pressure is limited to the static head of water at the turbine flange.

Condenser tubes are subjected to eddy current testing to ensure leak tight operation. The tubes are also subjected to periodic hydro cleaning to remove any scale, silt, or biological material which may inhibit heat transfer.

10.4.1.5 Instrumentation

The high pressure and low pressure condenser shells are equipped with level controllers for sensing of condenser water level. These level controllers provide signals to control valves which control the supply of condensate to the condensate storage tank and normal or emergency condensate flow to the condensate system. At low-low hotwell level, these level controllers open the demineralized water makeup valve to the low pressure hotwell. Monitoring of condenser water level is accomplished through level transmitters which provide signals to level indicators on the main control board in the control room. Each condenser shell has 1 pressure switch and 1 pressure transmitter to provide tripping and interlock functions upon loss of vacuum. If either of the pressure switches sense loss of vacuum, the turbine generator is tripped. The pressure transmitters operate bistables which interlock the turbine bypass system to prevent steam dump to the condenser upon loss of vacuum (see Section 10.4.4). Condenser vacuum is indicated and low vacuum is alarmed in the control room.

Condenser instrumentation is shown schematically on Figures 10.4-8 and 10.4-9.

10.4.2 Condenser Air Removal System

The Condenser Air Removal System maintains main and auxiliary condenser vacuum by removing noncondensible gases, including dissociated hydrogen and oxygen from the main and auxiliary condensers.

10.4.2.1 Design Bases

The non-nuclear safety class Condenser Air Removal System is designed to establish main and auxiliary condenser vacuum during plant startup and to maintain vacuum during normal operation. Mechanical vacuum pumps remove noncondensible gases from the main condensers and the auxiliary condensers via the main condensers. Under normal conditions, discharge is through the Auxiliary Building Ventilation System charcoal filters. Provision is made for discharge of the noncondensibles to atmosphere.

Mechanical vacuum pumps are designed for the capacities listed in Table 10.4-1 in accordance with Heat Exchange Institute Standards (Reference 4). Piping and valves are designed in accordance with ANSI B31.1 (Reference 1) and B16.5 (Reference 2), respectively.

10.4.2.2 System Description

Two (2) subsystems comprise the condenser air removal system: the main condenser air removal subsystem and the Auxiliary Condenser Air Removal Subsystem. Figure 10.4-1 provides the system diagram.

Each of the 2 main condenser shells is evacuated by an individual, 100% capacity, mechanical vacuum pump. A third pump is provided for backup. These pumps are used both to establish vacuum during plant startup (hogging) and to maintain vacuum during operation (holding).

The auxiliary condensers are piped to and normally aligned to the LP main condenser shell to maintain vacuum. Additionally, there are 2 mechanical vacuum pumps provided as back up for the auxiliary condensers. One (1) mechanical vacuum pump can be used to maintain vacuum in the three auxiliary condensers. A second pump is provided for backup.

All vacuum pumps can be operated during startup to speed the hogging operation.

Cooling water for the mechanical vacuum pumps is supplied from the Turbine Building Closed Cycle Cooling System. Seal water is provided by the condensate system.

Both subsystems discharge through the Auxiliary Building Ventilation System charcoal filters through a common line under normal conditions. Condenser discharge radiation monitor, RM-A9, is set to provide an alarm at approximately twice normal operating background. The high alarm is also normally set at approximately 2 times background. Provision is made for obtaining local samples for analysis and evaluation.

10.4.2.3 Safety Evaluation

The Condenser Air Removal System is not required to operate under emergency conditions nor is it necessary to achieve safe plant shutdown. Each subsystem is provided with a backup mechanical vacuum pump. Thus failure of an operating pump is not detrimental to continued plant operation.

Under normal conditions, the Condenser Air Removal System has no effect upon the Reactor Coolant System and radioactive leakage is negligible. However, should primary to secondary reactor coolant leakage occur, the flowpath through the Auxiliary Building charcoal filters limits the release of radioactivity to the environment. Anticipated release rates during normal operation are presented in Section 11.3.6.

10.4.2.4 Tests and Inspections

The Condenser Air Removal System is operated continuously during normal plant operation. Therefore, periodic testing is not required. System operation is verified prior to initial plant startup by preoperational and startup testing. During subsequent plant startups, system operation is verified by observation during hogging operations. System components are readily accessible for visual inspection under normal plant conditions.

10.4.2.5 Instrumentation

1. Main Condenser Air Removal

   Local pressure and air flow indication is provided to monitor vacuum pump performance. Lube oil pressure and discharge air temperature switches are provided for startup and shutdown interlocks. Alarms are sounded in the control room to alert the operator to vacuum pump trip, vacuum pump lube oil pump trip, low oil pressure, high off gas air temperature, and high off gas radiation.

2. Auxiliary Condenser Air Removal

   Local pressure and air flow indication is provided to monitor vacuum pump performance. Lube oil pressure and discharge air temperature switches are provided for startup and shutdown interlocks. Alarms are sounded in the Control Room to alert the operator to vacuum pump trip and high lube oil temperature.

10.4.3 Turbine Gland Sealing System

10.4.3.1 Design Bases

Main turbine and feedwater pump turbine shaft seals are of the injection/labyrinth/leakoff type. These seals are designed to prevent air leakage into and/or steam leakage out of the turbine casings.

The Turbine Gland Sealing System is not safety-related. Piping and valves associated with the system are designed in accordance with ANSI B.31.1 (Reference 1) and ANSI B16.5 (Reference 2), respectively.

10.4.3.2 System Description

Sealing steam is normally supplied to the Turbine Gland Sealing System from the Main Steam Supply System under all load conditions. Steam for turbine gland sealing may be provided by the auxiliary boiler through the Auxiliary Steam System. The sealing steam passes inward through the seals toward the turbines to a leakoff which is piped to the condenser. Gland sealing steam also passes though the seal toward the outside where it enters the vent annulus. The vent annulus is maintained at a slight vacuum by the steam packing condenser.

A small amount of air is drawn into the vent annulus and this air, together with the sealing steam, goes to the steam packing condenser. In the steam packing exhauster, the steam is condensed and the remaining saturated air is discharged to the atmosphere by a motor driven blower.

The turbine gland seal exhaust blower is part of the steam packing exhauster which is located in the Turbine Building at elevation 439’. Saturated air from this blower is discharged through a 12 inch pipe to the turbine building roof near the Intermediate Building wall. The saturated air is discharged to atmosphere approximately 8 feet above the roof (elevation 522’).

This discharge is not monitored for radiation. Radiation monitor RM-A9, which monitors the Main Condenser Air Removal System discharge, actuates an alarm in the event of primary to secondary leakage.

The LP turbine seals operate against vacuum at all times.

Pressure in the steam seal header is automatically controlled by steam seal regulating valves.

10.4.3.3 Safety Evaluation

As long as a steam generator tube leak does not occur, the steam supplied to the Turbine Gland Sealing System is nonradioactive. A steam generator tube leak may result in small amounts of radioactive process steam leakage from the steam packing condenser. Such steam generator tube leakage would be detected by the Steam Generator Blowdown System radiation monitor (RM-L3) or the condenser exhaust radiation monitor (RM-A9). See Sections 10.4.8 and 11.4.

Suitable manual regulator bypass valves are provided for use under emergency conditions. Relief valves are included to protect the system from over pressurization.

10.4.3.4 Tests and Inspections

No special tests or inspections are required.

10.4.3.5 Instrumentation

Steam seal header pressure is automatically controlled by a steam seal feed valve and a steam packing unloading valve. Controls for system operation, such as pressure indicators, switches, transmitters, and controllers are mounted on a local panel and the main control board. Additionally, a local level alarm switch and temperature indicator are provided.

10.4.4 Turbine Bypass System

10.4.4.1 Design Bases

The Turbine Bypass System is capable of bypassing main steam to the main condenser and/or to the atmosphere. This provides an artificial steam load for the steam generators so that differences between reactor output and turbine generator load can be absorbed without imposing undesirable transients upon the nuclear steam supply system.

System design permits the accommodation of large load reductions without reactor trip during most times in core life. The system also permits a gradual, orderly cooldown of the reactor to the point where the Residual Heat Removal System can assume the cooling function. The Turbine Bypass System is designed to operate in conjunction with the turbine generator, when available, or without the turbine generator if required. When including the power relief valves, it has sufficient capacity to pass ~ 93.6% of main steam flow at full load temperature and pressure. Capacities of individual valves in the Turbine Bypass System are presented in Section 10.4.4.2. The capacity of any 1 valve in the system does not exceed 970,000 lb/hr at 1,200 psia when fully open.

The Turbine Bypass System was originally designed to accommodate a full load rejection, defined as a reduction from 100% of rated turbine generator load to plant auxiliary load without a reactor trip. The transition to 18 months cycles, to less negative moderator temperature coefficients at the beginning of the fuel cycle, and to a full power T_{avg} operating window of 572 °F to 587.4 °F has, however, reduced this capability. Best estimate analyses indicated that a full load rejection is possible at all times in core life when operating with a full power T_{avg} of 587.4 °F. However, at a full power T_{avg} of 572 °F, full load rejection capability is feasible only for times in core burnup when the full power moderator temperature coefficient that is more negative than -18pcm/ °F. Therefore, full load rejection capability cannot be guaranteed for all values of full power T_{avg} and for all time in core life. Generally, margin to trip improves with core burnup due to the more negative moderator temperature coefficient.

Step load changes of up to 10% can be accommodated by the reactor control system in automatic mode without a reactor trip or actuation of the turbine bypass system.

System valves, piping and related equipment are designed and fabricated to satisfy the requirements of the following codes and standards and are non-nuclear safety class, non-Seismic Category 1, except as noted below:

1. Power relief valves are designed and fabricated to satisfy the ASME Code, Section III, Class 2 (Reference 5), and are classified Safety Class 2a, Seismic Category 1.
2. Atmospheric and condenser dump valves are designed and fabricated to satisfy ANSI B16.5 (Reference 2).
3. Vent diffusers are designed and fabricated to satisfy the ASME Code, Section VIII (Reference 6).
4. Inline diffusers are designed and fabricated to satisfy ANSI B31.1 (Reference 1).
5. Piping is designed and fabricated to satisfy ANSI B31.1 (Reference 1) and associated standards for fittings, flanges, etc.

Additionally, the Turbine Bypass System is designed to satisfy Occupational Safety and Health Act (OSHA) requirements concerning noise levels during operation.

10.4.4.2 System Description

The Turbine Bypass System is shown schematically by Figure 10.3-1. The system is comprised of the following components:

1. Condenser Dump Valve/Diffuser Combinations

   Eight condenser dump valved/diffuser combinations are provided and described in Table 10.3-2. The valve/diffuser combinations have an average rated/calculated capacity of ~ 6.74% of the main steam flow at full load pressure and temperature, thereby providing a bypass capacity to the condenser of ~ 53.95% of rated main steam flow. Each valve is provided with an inline diffuser mounted downstream of the valve. This combination produces reduced noise levels compared to levels generated by a valve without the diffusers. The system configuration separates the valve and diffuser, permitting location of the valve to allow easy access for maintenance. The diffusers are mounted in pairs in large, straight headers leading directly to the main condenser. Thus, problems associated with routing large diameter, hot piping are minimized.

2. Atmospheric Dump Valve/Diffuser Combinations

   Three atmospheric dump valve/diffuser combinations are provided and described in Table 10.3-2. The valve/diffuser combinations have an average rated/calculated capacity of ~ 6.95% of the main steam flow at full load pressure and temperature, thereby providing a bypass capacity to the atmosphere of ~ 20.85% of rated main steam flow. Each valve is provided with a diffuser mounted downstream of the valve. The system configuration separates the valve and diffuser, permitting location of the valve to allow easy access for maintenance. The diffusers are mounted on the intermediate building roof and discharge directly to the atmosphere.

3. Power Relief Valve/Diffuser Combinations

   Three power relief valve/diffuser combinations are provided. The power relief valves are similar to the atmospheric dump valves previously described, except for the design codes applied. The valve/diffuser combinations have an average rated capacity of ~ 6.25% of the main steam flow at full load pressure and temperature, thereby providing a bypass capacity to the atmosphere of ~ 18.76% of rated main steam flow. These valves serve a dual purpose. They operate in conjunction with the atmospheric dump valves to provide additional steam dump capacity to the atmosphere and they also serve as power operated relief valves for the steam generator secondary side.

   The power relief valves are Safety Class 2a and are located outside the Reactor Building, upstream of the main steam isolation valves in Safety Class 2a main steam piping. Piping downstream of the power relief valves, between the valves and diffusers is non-nuclear safety class.

   Operability testing of the valves was performed in accordance with the recommendations of Regulatory Guide 1.48 (Reference 11) as discussed in Appendix 3A. Electrical components (solenoid valves and position indicator limit switches) mounted on the valves are qualified to satisfy IEEE-382-1972. (Reference 10)

4. Piping and Other Valves

   System piping is provided to convey the steam to the condenser and to the Intermediate Building roof, where it may be discharged to the atmosphere. Manual isolation valves are provided for all control valves in the system to permit maintenance without shutting down.

   Turbine Bypass System control functions and control interactions with other plant controls and systems are discussed in detail in Section 7.7.1. A detailed analysis of system design adequacy is presented in Section 7.7.2.

10.4.4.3 Safety Evaluation

The Turbine Bypass System is not required for plant control following an accident and is not a safety related system. Failure of any single control valve to a wide open position results in uncontrolled secondary side blowdown that is within limits compatible with maintenance of reactor fuel integrity and integrity of the reactor internals.

The capacity of the power relief valves is in addition to that required by the ASME Code, Section III (Reference 5) for overpressure protection of the steam generators. Steam generator overpressure protection is provided by the main steam safety valves, discussed in Section 10.3.

Failure of the Turbine Bypass System to operate does not preclude operation of any essential systems since this system does not interface with any essential systems. Postulated failure of Turbine Bypass System high energy piping will not adversely affect or preclude operation of any safety- related systems or components located close to the Turbine Bypass System. Postulated

pipe rupture of high energy lines in the Turbine Bypass System is analyzed as discussed in Section 3.6.

10.4.4.4 Tests and Inspections

The Turbine Bypass System is tested prior to commercial operation. Proper system response to simulated temperature and pressure inputs is verified during preoperational testing. During hot functional testing, each valve is stroked open and closed to verify operation. After entering service, periodic testing is performed to assure availability. The power relief valves, which are Safety Class 2a, are tested and inspected in accordance with the applicable ASME Code, prescribed under 10CFR50.55a. This includes preservice and inservice inspection and test. Section 5.7 discusses a comprehensive program of compliance with the ASME Code, Section XI relative to inservice inspection.

10.4.4.5 Instrumentation Applications

Instrumentation and controls specifically related to the Turbine Bypass System are shown by Figures 10.3-1, and 10.4-3 through 10.4-4b. Setpoints are listed in Table 10.4-2. They are provided to permit monitoring of system performance and to permit manual valve operation if required.

10.4.5 Circulating Water System

The Circulating Water System removes thermal energy from the main and auxiliary condensers and dissipates this energy to Monticello Reservoir.

10.4.5.1 Design Bases

The principal performance requirement for the Circulating Water System is that it provide cooling water to the main and auxiliary condensers. The system is capable of pumping ~5.34 x 10^5 gpm of circulating water through the plant. This provides a heat transfer capability to the environment of 6.675 x 10^9 BTU/hr, with a nominal system temperature rise of 25 °F. This capability is adequate to satisfy system requirements for all normal and upset plant conditions, including turbine trip from full load. The system is not required to function under plant emergency or faulted conditions.

The following equipment is cooled by the Circulating Water System:

1. Main condenser - 2 shells.
2. Auxiliary condensers - 3 shells.
3. Circulating water motor bearing coolers are supplied only as backup cooling, (Normal Cooling Water Supply is from the Filtered Water System).

Circulating water is also used to wash the traveling screens and as a backup for circulating water pump motor bearings and jockey pump bearing lubrication.

Design parameters for major system components are presented in Table 10.4-3. The design pressure and temperature requirements for piping, valves, and pressure retaining parts are tabulated in the lower left margin of Figure 10.4-5. The upset condition tabulated is the shutoff head of the circulating water pumps. This condition occurs less than 1% of the time.

Circulating Water System piping and valves are designed in accordance with applicable industry codes and standards.

Condensers are designed in accordance with Heat Exchange Institute Standards. (Reference 4)

Pumps are designed in accordance with Hydraulic Institute Standards. (Reference 9)

10.4.5.2 System Description

Circulating Water System water requirements are supplied by three 33-1/3% capacity vertical wet pit pumps, located in the circulating water intake structure. The discharges from these pumps are headered into a main supply line to the plant. Two (2) or three (3) pumps are used during normal operation at reduced or full load.

The circulating water pumps can be controlled from the main control room or locally. Six (6) traveling water screens and two 100% capacity screen wash pumps with a strainer provide screened water to the pumps.

A circulating water jockey pump is included in the system to fill the circulating water system during startup.

The main condensers are supplied with cooling water through branches from the main circulating supply line. These branches are equipped with motor operated butterfly valves and expansion joints at the condenser waterbox inlet and discharge.

The auxiliary condensers, also supplied directly from the main circulating water line, are three (3) ~ 50% capacity units equipped with motor operated butterfly valves at the inlet and with manual butterfly valves at the discharge. Expansion joints are provided at the inlet and discharge.

The main and auxiliary condenser piping is equipped with automatic tube cleaning equipment of the sponge ball type.

10.4.5.3 Safety Evaluation

The Circulating Water System is independent of the emergency cooling facilities. It is not essential for safe operation and shutdown of the Nuclear Steam Supply System nor is it required to operate under accident conditions. Therefore, the system is non-nuclear safety class, non-Seismic Category 1.

A failure in the circulating water transport system inside the Turbine Building would be detected by a high water level alarm in the main condenser cleaning pit. As a result of effluent radiation

monitor response capabilities the sump pumps located in this pit are limited to a combined maximum capacity of 2000 gpm. A leak exceeding the capacity of these pumps would activate an alarm when the water level in the main condenser cleaning pit approached elevation 390'. The main condenser cleaning pit is located within the Amertap strainer pit.

A continued rise of water into the Amertap strainer pit to elevation 400' actuates 2 groups of 3 level switches. The actuation of any 2 switches within either group trips the circulating water pumps and initiates pump discharge valve and high pressure condenser discharge valve closure. Another alarm signals tripping of the pumps and closure of the pump and condenser discharge valves.

The lowest design pressure for any component in the Main Circulating Water System is 50 psig. Design data and system data are shown on Figure 10.4-5. To reduce the possibility of water hammer, slow closing, motor operated butterfly valves are used for condenser isolation.

A postulated complete failure of the condenser inlet expansion joint, which would result in an estimated flow rate of 780 ft3 /sec, would actuate the condenser cleaning pit alarm in less than 5 seconds. The rise of water to elevation 400' and resultant actuation of the alarm and pump trip would require approximately 46 seconds.

At initiation of pump trip, the pump discharge valves and high pressure condenser discharge valves begin to close. These valves require approximately 120 seconds and 90 seconds, respectively, to reach the fully closed position.

Pump coastdown time is extremely short and, for all practical purposes, is considered to be negligible.

The total time required to stop circulating water flow from the instant of failure would be approximately 2 min - 50 sec. Water levels versus time for a postulated expansion joint failure are presented in Table 10.4-3a.

A completely failed expansion joint would cause flooding of the Turbine Building basement (see Figure 1.2-16) up to elevation 413.5'. No essential systems or components are located in the Turbine Building. The lowest penetration of the Control Building or Intermediate Building walls, that could cause flooding from the Turbine Building, is at elevation 427', considerably above the flood elevation of 413.5'.

The system may be operated with less than 3 circulating water pumps in operation.

10.4.5.4 Tests and Inspection

Testing of the Circulating Water System is limited to that normally provided for non-safety related systems and includes:

1. Hot functional testing.

2. Normal, operational checking, and routine maintenance of the system.

10.4.5.5 Instrumentation

System instrumentation is shown schematically on Figure 10.4-5. The following instrumentation is provided to permit operator evaluation of major equipment performance and to provide a performance record:

1. Pressure indicators, switches, and test connections.
2. Level switches.
3. Temperature indicators and test connections.

10.4.6 Condensate Cleanup System

The Condensate Cleanup System is provided to aid in maintaining feedwater and steam generator water chemistry within specifications during all modes of plant operation and as required during condenser leakage. Figure 10.4-7a schematically illustrates the system.

10.4.6.1 Design Bases

1. The system is not safety related. Failure or malfunction of any system component will not affect the ability of the plant to achieve or maintain shutdown conditions.
2. The system is designed for cleaning up to approximately half of the maximum condensate flow.
3. System effluent purity will be within the limits provided in the Condensate System Design Basis Document as follows:

Total suspended solids, max. ppb	10
Sodium, max., ppb	1
Chloride. max., ppb	1

4. The system will be used when condensate polishing is required to maintain chemistry specifications.
5. Wastes from the system will be sent to the backwash receiving tank. Disposal from the tank will be dependent upon results of grab sample analysis.

10.4.6.2 System Description

The purpose of the Condensate Polishing System (CPS) is to minimize the time for plant startup. During plant operation, the Steam Generator Blowdown System is in service for system cleanup. However, the CPS will be used (assuming no SG leaks) to better maintain prescribed chemistry parameters in the condensate and feedwater cycle.

The CPS consists of 3 vessels in the condensate cycle. Two (2) vessels will be in service at a time with the third as a spare. The total flow through them will be a maximum of 8822 gpm (4411 each vessel). This is approximately 1/2 of the total condensate flow needed for full load capability of the V. C. Summer Nuclear Station, Unit 1.

The condensate polishers will be placed in service during plant startup for chemical cleaning of the condensate and feedwater cycles. There is a recirculation mode that will be used as a prestart cleanup of a major portion of the condensate and feedwater systems. This prestart cleanup will recirculate water using the condensate and feedwater booster pumps to the closed feed water isolation valves and back to the hotwell.

On unit startup, the polishers can be on line via the condensate pumps until the plant attains approximately 50% full load capacity.

During shutdown of the unit, the CPS could be placed in service when the plant load is approximately 50% if system chemistry indicates a need for cleanup.

If the condenser develops a leak, which will be detected by the Condenser Leak Detection System, the leak location will be determined and that half of the condenser will be taken out of service for repairs. At this time, the unit will be at a load of about 50% and the condensate polishers can be placed in service to assist in removing chemical impurities introduced by the detected leak.

If a primary to secondary leak occurs, it will be detected by the steam generator leak detection system and the CPS will be isolated. It is not intended to operate the CPS if a SG leak occurs. In the event that the condensate polishers are used in the presence of a steam generator tube leak, all applicable Health Physics measures and precautions will be observed.

Depleted resins are backflushed to a backwash receiving tank from which samples will be taken and analyzed prior to release. The results of gamma isotopic analyses are then utilized via established station procedures and administrative controls to determine if a release is possible. If a release is acceptable, the normally disconnected spool piece is installed and the depleted resins are discharged to the settling pond through RML-11. RML-11 will alarm on the local control panel and stop the backwash transfer pumps to prevent a release if its setpoint is exceeded.

If a release is not acceptable and the resin must be handled as solid radwaste, the contents of the backwash receiving tank are discharged to a DOT approved low level radwaste container. Using a preinstalled filter arrangement and the dewatering equipment shown in Figure 10.4-7a, excess water is removed from the powdex resin according to the Process Control Program for the packaging of low level radioactive waste. The resin may be dewatered to DOT requirements and shipped to a licensed low level radwaste burial facility. The dewatered resin may also be transported around to the Auxiliary Building truck bay entrance and solidified using the inplant solidification equipment.

The anticipated operational information is as follows:

1.	Flow rate each vessel:	condensate flow rate = 4411 gpm backwash flow = 375 gpm
2.	Backwash frequency:	3 backwashes per 24 hr startup
3.	Backwash holdup tank:	12,000 gallon capacity
4.	Average backwash rate:	18 backwashes per year
5.	Provisions exist for sampling condensate and resin backwash.	

10.4.6.3 Safety Evaluation

The Condensate Cleanup System is not safety related and is not required to ensure any of the following:

1. The integrity of the reactor coolant pressure boundary.
2. The capability to shut down the reactor and maintain it in a safety shutdown condition.
3. The ability to prevent or mitigate the consequences of accidents which could result in potential offsite exposures in excess of established limits.

Dissolved and suspended solid impurities within the condensate and feedwater circuits are not expected to contribute to plant activity levels. Any radioactive contamination that might occur in the Main Steam/Condensate System is actually reduced during the condensate cleanup process.

Scheduled, infrequent operation of the condensate polishers minimizes the possibility of producing potentially radioactive waste.

10.4.6.4 Tests and Inspections

Prior to system startup, the service vessels are hydrostatically pressure tested and flushed clean. All components and instruments are checked for operational status. During plant operation, instruments are routinely calibrated with known standards for accurate monitoring of pH, dissolved oxygen, sodium and conductivity. Continual surveillance and prescribed inspections of system components are standard operating procedures.

To assure protection of plant personnel and the environment during suspected primary to secondary steam generator leakage the following precautions should be taken:

1. Increased radiation survey frequency in the condenser polisher area.
2. Grab sample analysis prior to backwash receiving tank discharge will be extended to include tritium and isotopic ß-y analysis.

10.4.6.5 Instrumentation Application

Manually initiated, automatic backwash sequence controls are provided for use in replacing exhausted powdered resins. Resin trap strainers in the effluent stream have differential pressure switches to actuate alarms upon detection of high pressure drop.

An automatic bypass valve around the demineralizer system opens upon detection of excessive differential pressure. Instrumentation also indicates high differential pressure across a demineralizer vessel. The demineralizer is then manually removed from service and replaced by the standby vessel. Instrumentation is also provided to monitor effluent for sodium, pH, dissolved oxygen, and conductivity.

10.4.7 Condensate and Feedwater Systems

10.4.7.1 Condensate System

The Condensate System pumps condensed turbine exhaust steam from the main condenser hotwell through the low pressure feedwater heaters to maintain deaerator storage tank level for anticipated operating conditions. It also serves as a source of cooling water for the steam packing condenser and the steam generator blowdown heat exchanger, and provides sealing water for various vacuum valves and the feedwater pump seals.

10.4.7.1.1 Design Bases

Design conditions for system piping, valves, and pressure retaining parts are tabulated in the lower left margin of Figures 10.4-8 and 10.4-9. At the discharge of the condensate pumps, the upset condition bounds the discharge pressure of the condensate pumps under minimum recirculation. This condition is expected to occur less than 1% of the time.

Condensate pumps are designed in accordance with the requirements of the Hydraulic Institute Standards. (Reference 9) The original pump design point was selected to satisfy the requirements of the turbine thermal cycle (at pre-uprate conditions) at the “valve wide open” condition, plus a wear margin.

For post-uprate operation, the design of the pumps was evaluated against predicted required flow plus an allowance for transients.

Low pressure feedwater heaters, deaerator, and deaerator storage tank are designed, fabricated, inspected, tested, and stamped in accordance with the ASME Code, Section VIII, Division 1. (Reference 6) Thermal performance is governed by the Heat Exchange Institute Standards (Reference 7).

The Condensate System, except for the condensate storage tank, is non-nuclear safety class. The condensate storage tank is Safety Class 2b, Seismic Category 1, since it is the primary inventory source for the Emergency Feedwater System.

The condensate storage tank is designed, fabricated, inspected, tested and stamped in accordance with the ASME Code, Section III. (Reference 5) During normal operation the condensate storage tank water level is not permitted to fall below a level corresponding to a usable volume of 160,054 gallons (see section 9.2.6.1). Makeup to the condensate storage tank is demineralized water, admitted through the condenser and condensate storage subsystem. See Section 9.2.6 for a description of condensate storage facilities.

Under transient conditions, the deaerator storage tank serves as an additional source of water for the Feedwater System, providing adequate net positive suction head (NPSH) for the feedwater booster pumps.

System piping and valves are designed in accordance with ANSI B31.1 (Reference 1) and ANSI B16.5 (Reference 2), respectively.

Design parameters of major components in the Condensate System are listed on Table 10.4-4.

10.4.7.1.2 System Description

The Condensate System contains three (3) 50% capacity motor driven condensate pumps, a 50% capacity powdered resin filter/demineralizer cleanup system (see Section 10.4.6), 3 stages of closed low pressure feedwater heaters, associated piping, valves, and instrumentation. The 2 lowest stages of feedwater heaters are located in the condenser neck.

Equipment interfacing with, but not part of, the Condensate System includes the steam packing condenser and steam generator blowdown heat exchangers.

Condensate is pumped from the hotwell storage area, located below the main high pressure condenser, by 2 normally operating condensate pumps through the steam packing condenser. The condenser then passes through two 50% capacity, parallel strings of low pressure heaters to the deaerator and deaerator storage tank.

Condensate pumps are of the 4 stage, vertical can, centrifugal type, and are electric motor-driven. Condensate flow is controlled by the deaerator level control valve which follows the difference between feedwater and condensate flow, trimmed by deaerator level. The pumps are protected from a low flow condition by individual recirculation valves back to the main condenser.

The steam packing condenser is a shell and U-tube type heat exchanger. Condensate passes through the tube side. A manual bypass is provided for maintenance.

Low pressure feedwater heaters are shell and U-tube heat exchangers with 2 heating zones: A condensing zone and an integral drain cooling zone. The three (3) 50% capacity feedwater heaters in each string are bypassed and isolated as a group when necessary. A bypass line is provided for use when 1 heater string is out of service. Turbine load must be adjusted according to the manufacturers instructions when a feedwater heater string is isolated.

The deaerator is of the horizontal, direct contact, tray type. The preheated condensate drops onto the stainless steel trays where it is scrubbed by rising steam. Condensate then passes from the trays to the deaerator storage tank which has a capacity of 75,000 gallons.

Condensate is also supplied to the suction of the exhaust hood spray pumps. These pumps provide hood spray, gland sealing for various valves in vacuum service and seal water for vacuum pumps and feedwater pump seals. A small amount of condensate is used as the coolant for the steam generator blowdown heat exchangers.

10.4.7.1.3 Safety Evaluation

Three (3) 50% capacity condensate pumps are provided. Two (2) of these pumps are normally operated. The third is in standby. Upon the trip of an operating pump, which is annunciated in the control room, the standby pump is started by the operator. No detrimental effect upon the Reactor Coolant System is realized.

System makeup is provided directly from the condensate storage tank to the low pressure condenser shell. Makeup to the condensate storage tank is accomplished by injection of demineralized water to the low pressure condenser shell and thence through the Condensate System to the condensate storage tank.

Sentinel type, tube side relief valves are provided for all closed feedwater heaters. A feedwater heater tube rupture causes high level alarms in the Control Room and initiates automatic valve operation where appropriate. A high-high level alarm on condenser neck heaters initiates turbine trip if the condition exists more than 10 seconds.

Pressure, temperature, or flow deviations due to a malfunction in the Condensate System is not immediately felt by the Reactor Coolant System due to the capacity of the deaerator storage tank and the Feedwater System. The deaerator storage tank allows corrective action, an orderly runback to a compatible load, or shutdown.

10.4.7.1.4 Tests and Inspections

Tests of the Condensate System are limited to that normally provided for non-safety related systems and includes:

1. Hot functional testing. (Historical)
2. Normal, operational checking and routine maintenance of the system.

The closed, low pressure feedwater heaters were subjected to both shell and tube side hydrostatic tests at 150% of the respective design pressures. The shell sides were also tested for vacuum. Alterations to the shells to obtain higher maximum allowable working pressures call for leak tests at system operating conditions.

10.4.7.1.5 Instrumentation Applications

Instrumentation provided for the Condensate System is shown on Figures 10.4-8 and 10.4-11. This instrumentation is provided to permit operator evaluation of major equipment performance and to provide a record of equipment performance. Instrumentation includes the following:

1. Pressure indicators, switches, and test connections.
2. Flow indicators, recorders, switches and test connections.
3. Level indicators, recorders, controllers and switches.
4. Temperature indicators, controllers, switches and test connections.

10.4.7.2 Feedwater System

The Feedwater System is designed to pump feedwater from the deaerator storage tank through 2 stages of high pressure heaters to the steam generators. Thus, heated, deaerated water required to maintain steam generator water level is provided during normal operation, after startup, and before shutdown.

10.4.7.2.1 Design Bases

Design conditions for system piping, valves, and pressure retaining parts are tabulated in the lower left margin of Figures 10.4-10 through 10.4-12.

Feedwater System piping and valve components from and including the feedwater check valves to the steam generators are Safety Class 2a, Seismic Category 1 and are in accordance with ASME Code, Section III (Reference 5), Class 2 requirements. System components upstream of the feedwater check valves in the Intermediate Building, excluding branch lines 2 inches and less, are Quality Related safety class (QR), Seismic Category 1 and satisfy ASME Code, Section III (Reference 5), Code Class 2 requirements; however, are not code stamped. This piping is identified as “Note 1” piping on Figure 10.4-12. Feedwater piping in the Turbine Building is designed in accordance with ANSI B31.1 (Reference 1); valves conform to ANSI B16.5. (Reference 2)

The feedwater booster pumps and feedwater pumps are designed in accordance with the requirements of the Hydraulic Institute Standards. (Reference 9) Original design points for these pumps were selected to satisfy the requirements of the turbine thermal cycle. At the “valve wide open” condition (pre-uprate power), plus a wear margin.

High pressure feedwater heaters are designed, fabricated, inspected, tested, and stamped in accordance with the ASME Code, Section VIII, Division 1. (Reference 6) Thermal performance of these feedwater heaters is governed by Heat Exchange Institute Standards. (Reference 7)

At less than approximately 3% plant load, the Emergency Feedwater System (see Section 10.4.9) is used to maintain steam generator water level. The Main Feedwater System is designed to

overlap the Emergency Feedwater System down to the no load conditions but the Emergency Feedwater System is normally used for conditions such as startup and shutdown.

10.4.7.2.2 System Description

The Feedwater System is divided into nuclear safety class and non-nuclear safety class portions. The nuclear safety class portion, downstream of and including the containment isolation valves, is schematically shown on Figure 10.4-12. Feedwater System parameters are listed on Table 10.4-5.

The non-nuclear safety class portion of the Feedwater System includes four 33-1/3% capacity, constant speed, motor driven, feedwater booster pumps; three 50% capacity, variable speed, turbine driven, feedwater pumps; 2 stages of high pressure heaters; valves, instrumentation, controls; and associated piping. The feedwater booster pumps take suction from the deaerator storage tank and discharge to the feedwater pump suction. The feedwater pumps discharge through 2 strings of high pressure heaters into a single 30 inch diameter header which distributes the feedwater to 3 feedwater flow control valves and/or 3 feedwater bypass control valves. A recirculation line runs from the termination of the 30 inch diameter header near the feedwater flow control valves to the deaerator. This line is equipped with block valves and a pressure breakdown orifice and is used during startup to permit warming of the Feedwater system to and including the 30 inch diameter header.

Feedwater flows from the feedwater flow control valves through individual lines and the feedwater isolation valves to the three steam generators.

The feedwater booster pumps are horizontal, split case, single stage and centrifugal pumps. They are motor driven at a constant speed of 1780 rpm. Minimum recirculation flow is bypassed to the deaerator storage tank, as required. Normally, 2 feedwater booster pumps operate at low load; three or four at intermediate or full load. Feedwater booster pumps provide the necessary flow and suction pressure for the feedwater pumps.

Steam is supplied to the deaerator storage tank through a sparger during initial stages of Feedwater System warmup. This is followed by admission of pegging steam to the deaerator to complete Feedwater System warmup.

The feedwater pumps are horizontal, split case, single stage, double suction, and diffuser pumps. The speed of the variable speed turbine drive is varied and the feedwater flow control valves adjusted to maintain water levels in each steam generator. In general, 2 feedwater pumps are operated at low or intermediate loads. Three (3) feedwater pumps are operated at full load. Feedwater pumps are protected by minimum flow, recirculation lines to the deaerator storage tank.

High pressure feedwater heaters are shell and U-tube type heat exchangers with 2 heating zones: a condensing zone and an integral drain cooling zone. The two 50% capacity feedwater heaters in each string are manually bypassed and isolated as a group to remove the string from service if necessary. Turbine load must be adjusted according to the manufacturer’s instructions when a feedwater heater string is isolated.

10.4.7.2.3 Safety Evaluation

1. General

If it becomes necessary to remove a feedwater booster pump or feedwater pump from service due to malfunction or failure or for maintenance, plant loads are reduced in accordance with a predetermined operating scheme. When the normal operating schemes are followed, the Feedwater System provides satisfactory service under plant operating conditions.

Reactor runback is minimized and reactor trip is avoided following loss of any 1 feedwater or feedwater booster pump from the normal operating scheme. It is possible to operate the Feedwater System beyond the normal operating scheme for short periods of time. Following the loss of any 1 operating feedwater booster pump or feedwater pumps, a power reduction may be necessary to prevent reactor trip due to low water level in the steam generators. Reactor trip is prevented when maximum pumping scheme capability satisfies or exceeds feedwater flow requirements at the time a pump is lost from service. The feedwater pumps and drive turbines may be operated at runout capacity temporarily, but extended off-design point operating results in drive turbine efficiency loss. The feedwater booster pumps may be operated up to their horsepower limits for extended periods of time without detrimental effects.

If a feedwater piping break should occur in the Intermediate Building, alarm and control devices act to prevent flooding of safety-related equipment on the floors. Section 7.6 outlines the details of provisions for leak detection. Pipe break is discussed in Sections 3.6 and 15.4.2. As noted in Section 10.4.7.2.1, feedwater piping in the Intermediate Building, excluding branch lines, satisfies the requirements, except for stamping, of the ASME Code, Section III (Reference 5), Code Class 2, to provide greater assurance of piping system integrity and to minimize the potential for postulated pipe rupture.

The feedwater isolation valves are designed to close within 5 seconds after receipt of a closure signal to provide containment isolation in the event of a feedwater line break either inside or outside the Reactor Building. These valves have relief valves installed to prevent pressure locking due to thermal expansion of fluid trapped between the double-disc gate following closure. These valves are designed with safety related air accumulators and fail as is upon loss of control air and to close upon loss of channel A electric power. Valve status is indicated by lights on the main control board and is monitored by the plant computer. Any of the following signals initiate closure:

a. Feedwater isolation signal (channel A only, see Table 6.2-54 signal D for initiating conditions).
b. High-high Intermediate Building sump level switches energized (see Section 7.6 for initiating conditions, channel A only).
c. Intentionally left blank by RN 00-082 in Amendment 02-01.
d. Intentionally left blank by Amendment 96-03.

e. Intentionally left blank by RN 00-082 in Amendment 02-01.

f. Manual switch train A in the control room.

The recommendations of the NSSS vendor are followed in routing of feedwater piping to minimize flow instabilities in the Feedwater System.

Standard industry safety precautions are observed in the handling of feedwater chemicals.

Table 10.4-6 presents a Feedwater System failure analysis.

10.4.7.2.4 Tests and Inspections

1. Operability Test for Containment Isolation Valves

   The containment isolation valves are subjected to periodic operability tests in accordance with the applicable ASME Code, prescribed under 10CFR50.55a.

   There are 3 containment isolation valves in this system: three (3) on the main feedwater line. These valves are tested for operability by complete closure and opening during plant shutdown.

2. System Tests

   Major equipment is periodically inspected to ensure proper conditions and operation. Additional testing includes:

   a. Hydrostatic testing of safety class system piping and equipment following construction and prior to placing the system in service.

   b. Hot functional testing subsequent to cold hydrostatic testing.

   c. Normal, operational checking, and routine maintenance of the system.

Inservice inspection of safety class portions of the system is performed in accordance with the ASME Code, Section XI (Reference 8), requirements.

10.4.7.2.5 Instrumentation Applications

Instrumentation for the Feedwater System is shown schematically by Figures 10.4-10 through 10.4-12. The following instrumentation is supplied for the non-nuclear safety class portion of the system to permit operator evaluation of major equipment performance and to provide a performance record:

1. Pressure indicators, switches, and test connections.
2. Flow indicators, controllers, and test connections.
3. Level switches.

4. Temperature indicators and test connections.

In the nuclear safety class portion of the system, instrumentation to permit monitoring of the temperature of feedwater entering the steam generators is provided. Instrumentation associated with the development of control signals for the containment isolation valves is provided in Section 7.3 and Table 6.2-54.

10.4.8 Steam Generator Blowdown System

10.4.8.1 Design Bases

10.4.8.1.1 General

The Steam Generator Blowdown System continuously purges the steam generators of concentrated impurities, thereby maintaining secondary side steam generator water chemistry. The Nuclear Blowdown Processing System is used to process cooled steam generator blowdown fluid and return decontaminated water to the secondary cycle. The steam generator wet layup system skid provides forced circulation of the steam generator secondary side water inventory during cold shutdown conditions.

Steam generator blowdown fluid can be directed to any 1 of the following:

1. Nuclear Blowdown Processing System.
2. Circulating water discharge.
3. Alum sludge lagoon.

Steam generator blowdown fluid is normally directed to the Nuclear Blowdown Processing System or the circulating water discharge. During plant startup, steam generator blowdown fluid may be directed to the alum sludge lagoon for reduction of suspended solids content prior to discharge. Radiation monitoring controls divert steam generator blowdown fluid to the Nuclear Blowdown Processing System upon detection of radioactivity in the fluid, thus limiting release of radioactivity to the environment.

The ATWS (Anticipated Transient Without Scram) Mitigation System Actuation Circuitry (AMSAC) isolates steam generator blowdown when 2 of 3 steam generators are at low-low level.

During cold shutdown and refueling, the steam generator wet layup system skid may be attached between the blowdown and Emergency Feedwater Systems. The skid circulates water through the steam generators to provide improved mixing and less severe concentration gradients to mitigate steam generator fouling and corrosion.

10.4.8.1.2 Thermal

Blowdown fluid from each steam generator is directed to a separate heat exchanger for heat recovery. A portion of the condensate flow serves as the cooling fluid in these heat exchangers. The heat exchangers are designed to cool the steam generator blowdown fluid to 120°F.

10.4.8.1.3 Secondary Side Contaminants

Impurities associated with the secondary cycle include:

1. Dissolved amines and an oxygen scavenger, introduced for control of feedwater pH and oxygen.
2. Ammonium chloride for molar ration control if required.
3. Boric acid for mitigation of steam generator tube denting if required.
4. Impurities associated with condenser leakage.
5. Ingress from the demineralized water system and/or the water treatment plant.

10.4.8.1.4 Primary Side Contaminants

Impurities associated with the Reactor Coolant System may enter the steam generator secondary side should steam generator tube leakage occur. Such impurities include radioactive and nonradioactive particulate and dissolved material.

10.4.8.1.5 Operating Parameters

1. Total Blowdown Flow
   a. Minimum flow - 30 gpm.
   b. Normal flow - as required to maintain secondary side water chemistry.
   c. Design flow - 1.0% of main steam flow (nominally 250 gpm).
   d. Cold shutdown on steam generator wet layup system - 100 gpm (nominal flow).
2. Water Chemistry of Steam Generator Blowdown Fluid

   Blowdown flow from each steam generator aids in maintaining secondary side water chemistry specifications. The controlling parameters include pH, cation conductivity, sodium, chloride and sulfate.

3. Steam Generator Tube Leakage

   For purposes of radioactive release determinations, a primary to secondary leakage rate of 100 lb/day and 0.12% failed fuel is used. The leakage rate is derived from NUREG-0017 (Reference 3).

For the design of equipment, a primary to secondary leakage rate of 0.1 gpm (1195 lb/day) under standard conditions is assumed. Major contaminants considered include boron and lithium with primary coolant concentrations of 1000 ppm and 2 ppm, respectively.

10.4.8.1.6 Codes and Standards

The Steam Generator Blowdown System is non-nuclear safety class and quality related class, except for that portion inside the Reactor Building and up to the containment isolation valve which is Safety Class 2a, Seismic Category 1. Safety class and quality related class piping is designed in accordance with the ASME Code, Section III (Reference 5), Class 2. Non-nuclear safety class piping is designed in accordance with ANSI B31.1 (Reference 1). Equipment classification is presented in Table 3.2-1.

10.4.8.2 System Description

The Steam Generator Blowdown System is illustrated by Figure 10.4-13. Individually regulated blowdown from each steam generator is cooled and reduced in pressure prior to combination with other blowdown streams. The total blowdown is then processed through the Nuclear Blowdown Processing System or is routed into the circulating water discharge and thence to Monticello Reservoir.

The Nuclear Blowdown Processing System is illustrated by Figures 10.4-14 and 10.4-15. Should blowdown activity exceed preset levels, the blowdown flow is automatically diverted to the nuclear blowdown holdup tank. One (1) of 2 nuclear blowdown holdup tank pumps then takes suction from the holdup tank and delivers the fluid through a filter, 2 demineralizers in series, and a post filter from which it returns to the secondary cycle through the main condenser (an alternate path being to the penstocks of the Fairfield Pumped Storage Facility [see Figure 10.4-17] during operation of that facility in the generation mode).

The Nuclear Blowdown Processing System includes a sluicing pump and spent resin storage tank for transfer and storage of exhausted demineralizer resin. Processing of solid waste is accomplished by the Solid Waste Disposal System (see Section 11.5).

10.4.8.2.1 Component Description

The general arrangement of system equipment is shown by Figures 1.2-5 and 1.2-6. Design parameters for major components are presented in Table 10.4-7. Major components of the Steam Generator Blowdown System include:

1. Radiation Monitors

   Radiation monitoring equipment is located to sample continuously the total Steam Generator Blowdown and Nuclear Blowdown Processing System demineralizer effluent. Section 11.4 describes radiation monitoring equipment in detail.

2. Steam Generator Blowdown System Heat Exchangers

Each of the 3 Steam Generator Blowdown System heat exchangers consist of 2 shell and tube vessels in series, designed to cool the steam generator blowdown fluid with condensate.

3. Nuclear Blowdown Holdup Tank

   The nuclear blowdown holdup tank retains potentially radioactive steam generator blowdown fluid for processing.

4. Nuclear Blowdown Monitor Tank

   The nuclear blowdown monitor tank is similar in design to the nuclear blowdown holdup tank. This tank provides additional holdup capacity, if required, as well as the capability for periodic effluent sampling.

5. Nuclear Blowdown Holdup Tank Pumps

   Two (2) 100% capacity, centrifugal, nuclear blowdown holdup tank pumps are provided. These pumps take suction from the nuclear blowdown holdup tank and discharge through the filter, demineralizers, and post filter.

6. Nuclear Blowdown Monitor Tank Pump

   A single, canned motor pump is provided. This pump takes suction from the nuclear blowdown monitor tank and discharges to the nuclear blowdown holdup tank or recirculates the monitor tank contents through the post filter.

7. Nuclear Blowdown Demineralizer Inlet Filter

   This inlet filter removes particulate matter from the holdup tank fluid upstream of the demineralizers, thus protecting against resin fouling and premature capacity loss. The filter is a disposable cartridge type. Pressure drop indication and an alarm are provided to alert the operator that filter media replacement is required. Since the filter is potentially radioactive, shielding is provided for personnel protection. Radiological controls to reduce personnel exposure are implemented during spent filter cartridge removal and transportation to the drumming station.

8. Nuclear Blowdown Demineralizer Discharge Filter

   This post filter traps and retains degraded or crushed resin particles which may pass through the demineralizers during normal operation. Design of this filter and radiation protection considerations are similar to those for the nuclear blowdown inlet filter.

9. Nuclear Blowdown Sluice Filter

   The sluice filter is located on the discharge side of the resin sluice pump. Its function is similar to that described for the nuclear blowdown demineralizer discharge filter.

10. Nuclear Blowdown Demineralizers

    Four (4) ion exchange vessels, arranged for 2 step demineralization with 100% standby capacity, are provided. This arrangement assures the capability for continuous removal of radionuclides as well as high effluent purity. Operation of each demineralizer is on a nonregenerable basis. Resin is removed and replaced as dictated by chemical analysis or radioactivity measurements.

11. Nuclear Blowdown Spent Resin Storage Tank

    The nuclear blowdown spent resin storage tank is provided to permit recycling of resin sluice water, storage of spent demineralizer resin, and transfer of spent resin to the drumming station.

12. Nuclear Blowdown Resin Sluice Pump

    The nuclear blowdown resin sluice pump is used to loosen resin in and transfer resin from nuclear blowdown demineralizers.

13. Steam Generator Wet Layup System Skid

    The Steam Generator Wet Layup System Skid consists of a pump, two 100% filters in parallel, valves, connectors, flexible hoses, and a skid-mounted motor control center. When used, during cold shutdown conditions, the pump suction is connected by flexible hose to the blowdown system and the discharge is similarly connected to the Emergency Feedwater System.

10.4.8.2.2 System Operation

System operations are divided into three categories, as follows:

1. Normal Operation

   During normal plant operation, steam generator blowdown is continuous to maintain secondary side steam generator water chemistry within the limits recommended by the Nuclear Steam Supply System (NSSS) vendor. Blowdown is normally directed to the Nuclear Blowdown Processing System or to the circulating water discharge after passing through the steam generator blowdown heat exchangers.

   The combined blowdown from the 3 steam generators is continuously sampled and analyzed for radioactivity. Should the activity level reach a pre-established setpoint, the discharge paths are automatically isolated and the total blowdown flow is automatically diverted to the nuclear blowdown holdup tank.

Low specific activity effluent resulting predominately from continuous steam generator blowdown sampling may be processed from the nuclear blowdown holdup tank to the main condenser or Turbine Building sump. When high radiation setpoint is reached for RM-L3 or RM-L10 and steam generator blowdown has been diverted to the holdup tank, the process pathway to the Turbine Building sump is terminated. The contents of the nuclear blowdown holdup tank are periodically analyzed for radioactivity and chemical contamination.

2. Special or Infrequent Operation

   As discussed in 1, above, blowdown radioactivity levels in excess of a

   pre-established setpoint (as sensed by RM-L3 and RM-L10) result in automatic diversion of blowdown flow to the nuclear blowdown holdup tank. Under such conditions, samples from each steam generator blowdown stream are analyzed to determine the source of the radioactivity. Once the source has been determined, the blowdown from the affected steam generator may be processed separately while blowdown from the remaining steam generators may continue to be discharged. If the faulty steam generator cannot be satisfactorily isolated, total blowdown flow continues to be directed to the nuclear blowdown holdup tank.

   A nuclear blowdown holdup tank pump starts at a preset holdup tank level to deliver tank contents to the inlet filter, demineralizers, post filter and thence to the main condenser. Detection of abnormally high activity by RM-L7 downstream of the post filter results in automatic termination of flow to the condenser or through the alternate path to the penstocks of the Fairfield Pump Storage Facility. This flow is then directed to the nuclear blowdown monitor tank.

3. Startup

   During plant startup and subsequent restarts, steam generator blowdown, up to the design flow rate, is used for removal of accumulated deposits from the steam generators and to bring steam generator water chemistry within recommended limits. The cooled steam generator blowdown fluid may be discharged through the circulating water discharge to Monticello Reservoir.

   During these operations, however, the steam generator blowdown fluid may contain high concentrations of corrosion products in the form of iron oxides. Should the concentrations of these impurities exceed acceptable limits, the blowdown fluid is routed to the alum sludge lagoon through the clarifier blowdown sump for reduction of suspended solids content prior to discharge.

4. Cold Shutdown and Refueling

   During cold shutdown and refueling the steam generator wet layup system skid may be attached, by flexible hoses, between the blowdown system and the Emergency Feedwater System. The skid takes suction from blowdown and returns water to the steam generators via the turbine-driven emergency feedwater pump header.

The Steam Generator Wet Layup System may be used only during modes 5 and 6. It must be isolated and disconnected before entering mode 4.

The blowdown and Emergency Feedwater System valves may be used to direct wet layup recirculation to any of the three steam generators, allowing one or more to be maintained in layup with one or more others open for maintenance.

Operation of the steam generator wet layup skid equipment is local and manual.

10.4.8.2.3 Radiological Considerations

Annual release quantities and expected doses to individuals at or beyond the site boundary are discussed in Section 11.2. Since heat exchangers are installed in the system to provide for cooling the blowdown fluid and to prevent flashing, negligible gaseous release is expected to result from this system. Process and effluent monitoring and sampling are discussed in Section 11.4.

10.4.8.3 Safety Evaluation

Steam generator blowdown flow is automatically terminated under the following conditions:

1. Receipt of a containment isolation signal.
2. Activation of the Emergency Feedwater System.

For 1, above, a containment isolation signal (S signal) is received which closes the steam generator blowdown containment isolation valves. For 2, above, a signal indicating emergency feedwater pump start is received resulting in closure of the steam generator blowdown containment isolation valves. The closure of valves resulting from 2, above, may be manually overridden, provided that plant and personnel safety requirements have been satisfied.

The Steam Generator Blowdown System is non-nuclear safety class and quality related class, except for that portion of the system inside the Reactor Building and up to the containment isolation valve, and is not required to function under accident conditions. Termination of steam generator blowdown may be accomplished manually. If the Nuclear Blowdown Processing System is operating at the time steam generator blowdown is terminated, the nuclear blowdown holdup tank level controller stops the pump when holdup tank level reaches the low level setpoint. Thus, the system is isolated.

Section 10.3.5 provides more detail concerning secondary side water chemistry.

Safety considerations directly associated with the steam generators are discussed in Section 5.5.2.

Since radioactive materials are concentrated in filters and demineralizers, radiation shielding is provided to protect personnel from these potential hazards.

10.4.8.4 Tests and Inspections

Steam generator tests and inspections are discussed in Section 5.5.2. No special maintenance is required for Steam Generator Blowdown System components. Equipment and piping is periodically subjected to visual examination for evidence of leakage, corrosion, proper support bolting, wear points, and electrical arcing or burning. Active components, including manual valves and controls are operated periodically to ensure availability when required.

10.4.8.5 Instrumentation Applications

The following instrumentation is shown schematically on Figures 10.4-13 through 10.4-15 and is provided to permit the operator to evaluate major equipment performance and to provide a performance record:

1. Pressure indicators, transmitters, and switches.
2. Flow indicators, controllers, recorders, switches, and transmitters.
3. Level indicators, transmitters, controllers, and switches.
4. Temperature indicators, controllers, and switches.
5. Conductivity analyzers, indicators, and switches.
6. Analyzers, indicators, and switches for pH.
7. Engineered safety features monitor lights, located on the main control board, for the containment isolation valves (see Section 7.5 for detailed description).
8. Radiation monitors.

10.4.8.5.1 Temperature Control

Steam generator blowdown temperature reduction is controlled by regulating the cooling water flow through the heat exchangers. The blowdown temperature is controlled below saturation to preclude flashing.

Temperature protection is provided for the demineralizers by a temperature switch located on the discharge header of the blowdown holdup tank transfer pumps. At high temperature, an alarm is actuated and the demineralizer inlet valves are automatically closed.

Additional temperature switches actuate alarms upon detection of high blowdown heat exchanger effluent temperature.

10.4.8.5.2 Flow Control

The hydraulic design of the blowdown piping provides for minimal pressure drop up to the blowdown control valves, downstream of the respective heat exchangers. Each blowdown control valve is designed to regulate blowdown flow and thus maintains a relatively constant downstream pressure of approximately 40 psig.

Flow indicating transmitters provide electronic inputs for high and low blowdown flow and blowdown flow control valve closure upon detection of high flow and to a controller to regulate blowdown pressure control valves: Electronic hand controllers are provided to permit adjustment of individual blowdown flows through the respective flow control valves.

10.4.8.5.3 Level Control

The blowdown holdup tank level transmitter provides an electronic input for high and low level alarms, dual level pump actuation and low level pump trip.

The monitor tank level transmitter provides an electronic input for high and low level alarms, low level pump trip, and low level closure of the tank discharge valve.

The spent resin storage tank level transmitter provides an electronic input for high and low level alarms and low level pump trip.

10.4.9 Emergency Feedwater System

10.4.9.1 Design Bases

The Emergency Feedwater System is required to deliver sufficient feedwater to the steam generators for cooldown upon loss of the normal feedwater supply and during a ATWS (Anticipated Transient Without Scram) event. The Emergency Feedwater System is used, additionally, to supply feedwater to the steam generators during startup, shutdown, and layup operations. Emergency feedwater pump starting is automatic. The Emergency Feedwater System operates in conjunction with the Turbine Bypass System, if available, or the main steam power relief valves and safety valves, to remove thermal energy from the steam generators.

The system is designed to automatically deliver feedwater, at a minimum total flow of 380 gpm, to at least 2 steam generators pressurized to 1211 psig. There is sufficient redundancy to establish this flow while sustaining a single active failure in the system in the short term or a single active or passive failure in the long term. The Emergency Feedwater System operates until the Residual Heat Removal (RHR) System can be placed in operation. The RHR system is started when reactor coolant pressure and temperature are approximately 400 psig and less than 350°F, respectively. Corresponding steam generator shell side pressure is approximately 125 psia. This pressure and temperature condition represents the lower limit of Emergency Feedwater System functional requirements as long as the reactor coolant pumps are operating.

When forced circulation from the reactor coolant pumps is not available, Emergency Feedwater System operation is required down to a main steam pressure of 100 psia. This corresponds to a reactor coolant cold leg temperature of 325°F and a hot leg temperature of 350°F. The primary coolant temperature differential is required in order to maintain a density gradient to drive natural circulation of primary coolant, in the absence of reactor coolant pump operation.

Sufficient feedwater is available under emergency conditions to bring the plant to a safe shutdown condition. Assuming prior plant operation at engineered safety design rating (ESDR) of 2900

MWt in the core, the minimum required usable volume for the condensate storage tank is 158,570 gallons based on maintaining the plant at hot standby conditions for 11 hours. This volume also satisfies the minimum required volume to cool down the plant to hot shutdown conditions assuming the plant is maintained at hot standby for 2 hours and then cooled down to hot shutdown in 4 hours.

The condensate storage tank is a Safety Class 2b tank. The Service Water System provides an additional safety class backup source of emergency feedwater. Both service water loops can supply the Emergency Feedwater System if required.

System components are classified Safety Class 2a or 2b, except as noted on the system diagram, Figure 10.4-16. Pressure retaining components are designed, fabricated, tested and inspected in accordance with the ASME Code, Section III (Reference 5), Classes 2 and 3 as applicable. Normal operating and design conditions are tabulated on Figure 10.4-16. Design upset condition is considered to be the shutoff head of the pumps and is expected to occur less than 1% of the time.

Any two emergency feedwater pumps operating together are designed to deliver a total of 380 gpm of feedwater distributed between 2 steam intact generators at pressures of 1211 psig, while also feeding the faulted steam generator which has flow passively limited by the cavitating venturi in the faulted loop. Any one emergency feedwater pump is designed to deliver 400 gpm total to all three steam generators at a pressure of 1211 psig during the non-faulted event. Pump suction is from the Safety Class 2b condensate storage tank, or, if this source is not available, from the Service Water System. Although the condensate storage tank is used for normal plant makeup, a reserve is maintained for emergency feedwater purposes. (See Section 9.2.6.1).

This reserve is 160,054 gallons, based on the physical configuration of the tank from the bottom of the condensate to condenser nozzle to the top of the emergency feedwater suction nozzle. The actual usable amount of this reserve, however, is dependent on the instrument setpoints of the automatic switchover controls to the backup Service Water supply.

The design, with automatic switchover to Service Water occurring prior to full utilization of the dedicated inventory, satisfies safe shutdown requirements. It is considered that full utilization of the dedicated inventory of condensate quality water is highly desirable from a commercial risk viewpoint, but is not absolutely required for safe shutdown as long as a redundant safety class alternate source is available.

The Emergency Feedwater System is required for plant startup. Fill and maintenance of steam generator water level is accomplished by manual control of feedwater flow rates from the Control Room. The flow rate to each steam generator is individually adjusted as required in response to the Control Room steam generator water level indication. After normal steam generator water level is reached, flow rates are adjusted as required. A sampling connection is supplied on the electric motor driven emergency feedwater pump recirculation lines for oxygen level tests.

After reactor criticality is achieved, a limited amount of steam may be withdrawn from the steam generators for steam line warmup and other startup steam uses. The amount of steam that may be

withdrawn is limited to the ability of the emergency feedwater pumps to maintain steam generator water level. Electric motor driven emergency feedwater pump head/flow characteristics result in flow rates of up to approximately 255 gpm per steam generator at hot standby conditions. Based on a nominal steam generator blowdown rate of 50 gpm per steam generator, (equivalent cold volume) approximately 307,488 lb/hr of steam may be withdrawn from the steam generators with 2 motor driven pumps operating. This corresponds to a nominal 3% plant load condition. The Main Feedwater System must be operated at loads which exceed the capacity of the Emergency Feedwater System.

If a loss of steam generator water level incident occurs during startup, after the reactor becomes critical, Emergency Feedwater System controls operate automatically. This action enhances proper system operation for plant shutdown.

Seismic and quality group classifications for components in this system are discussed in detail in Section 3.2. Environmental conditions are discussed in Section 3.11.

10.4.9.2 System Description

The Emergency Feedwater System includes 2 electric motor driven emergency feedwater pumps, 1 turbine driven emergency feedwater pump, the condensate storage tank, necessary piping, valves, instrumentation, and controls. The Emergency Feedwater System is essential to safety. The system is designed such that no single failure prevents delivery of the minimum feedwater flow to at least 2 steam generators while passively limiting flow to a postulated secondary side line break by virtue of cavitating venturis installed in the piping to each of the three steam generators (one cavitating venturi per steam generator). Pump and turbine bearings are cooled by the pumped emergency feedwater, thereby making pump operation independent of plant cooling systems. The quick start, steam turbine driven emergency feedwater pump is supplied with steam from the Main Steam System and is designed to operate without air or electrical power. Both motor driven emergency feedwater pumps are provided with a mechanical-type, automatic recirculation control valves (ARC), which provides for pump protection for low flows and maximizes flow to the steam generators by automatically closing the recirculation line once the pumps' minimum flow requirement is met. Conversely, the turbine driven pump utilizes a fixed-restriction minimum-flow system, which provides for continuous recirculation and overall system diversity; this fixed recirculation flow design feature is made possible due to the performance margins inherent in the turbine driven pump.

Each pump motor is supplied from a separate, independent Class 1E electric system bus. Complete physical separation is followed throughout for control and instrumentation systems. The required instrumentation and control are powered from separate and independent vital buses.

The steam supply to the turbine driven emergency feedwater pump consists of connections to the safety class sections of 2 main steam lines upstream of the main steam isolation valves. Two (2) connections are provided to obtain redundancy of supply in the event of a main steam line break. Each connection is provided with a remote manual motor operated gate valve and a check valve for positive isolation in the event of a main steam break. In the common line to the pump turbine, a normally closed, fail open steam inlet valve is provided. This valve has slow opening

characteristics to minimize shock to the turbine during automatic startup. This line then connects to a turbine trip and throttle valve which is part of the turbine package. The turbine discharge steam exhausts to atmosphere through a roof vent. Vent piping is safety-related since, if it were blocked, pump turbine operation would be affected.

The emergency feedwater pumps take suction from the condensate storage tank. There is an outlet valve and an outlet bypass valve in parallel at the EFW suction outlet in the tank. These valves are 10 inch manual valves feeding the 10 inch header and are locked open to prevent undesired isolation of the EFW system from its primary supply of water. Each pump draws from a common header through a locked open isolation valve and a check valve. The redundant backup source of supply is the Service Water System. The A service water loop can supply the A electric motor drive emergency feedwater pump and the turbine driven emergency feedwater pump. The B service water loop can also supply the turbine drive emergency feedwater pump and the B electric motor driven emergency feedwater pump. Suction lines to each pump from each service water loop have normally closed remote manual, motor operated isolation valves. These valves are automatically opened on low pressure in the emergency feedwater pump suction header from the condensate storage tank. The plant can operate indefinitely, if required, without normal feedwater. The Emergency Feedwater System can take suction from the Service Water System for an indefinite period of time.

There are 2 emergency feedwater headers supplying each steam generator, 1 header from the electric motor driven emergency feedwater pumps and one header from the turbine driven emergency feedwater pump. These headers join downstream of the flow control valves into one line for each steam generator. Each of the three parallel lines proceed through, a flow-limiting cavitating venturi, a containment isolation valve and a containment penetration to its respective steam generator. The containment isolation valve for each line is an air-piston assisted, hinged check valve that allows forward passage of emergency feedwater flow but closes to prevent reverse flow.

Each emergency feedwater pump discharge is provided with a check valve and locally operated isolation valve. These valves prevent backflow through an emergency feedwater pump and permit maintenance of a pump and/or check valve. Two (2) sets of normally open isolation valves and normally open, pneumatically operated, flow control valves, designed to fail open upon loss of control signal or air, are provided on each line to each steam generator. One (1) set control flow from the electric motor driven emergency feedwater pumps; the other, flow from the turbine driven emergency feedwater pump. Remote manual control of the flow control valves from the control room and CREP is provided, as well as provision for local manual operation. Safety class air accumulators are provided for the pneumatically operated valves. These accumulators have sufficient capacity to permit remote valve closure for isolation of a secondary system break. The air operated nonreturn valve functions as a containment isolation valve to prevent back flow in the event of a pipe break on the pump side of the valve.

A connection is provided for steam generator wet layup during cold shutdown conditions, using the steam generator wet layup skid of the blowdown system. (Section 10.4.8)

The EF system also has an automatic detection and isolation system in the event of an EF system pipe break between the automatic isolation valves and the cativating venturis.

10.4.9.3 Safety Evaluation

Normal Emergency Feedwater System conditions encompass the automatic, startup, operating, shutdown and testing modes. During the automatic mode, the system is aligned and set for automatic startup upon receipt of a signal. During the other modes 1 or 2 emergency feedwater pumps may be operating.

During normal plant operation the Emergency Feedwater System is idle. Controls for the system are set for automatic operation to allow for quick system start if necessary. The electric motor driven emergency feedwater pumps start automatically upon receipt of any of the following signals:

1. Two (2) out of 3 low-low steam generator level signals from any 1 of the 3 steam generators.
2. Trip of all 3 main feedwater pumps.
3. Engineered safety features loading sequence (under voltage on 1E bus and/or safety injection signal).
4. The ATWS (Anticipated Transient Without Scram) Mitigation System Actuation Circuitry (AMSAC) starts the motor driven pumps on low-low level in 2 out of 3 steam generators.

The turbine driven emergency feedwater pump starts automatically upon receipt of any of the following signals:

1. Two (2) out of 3 low-low steam generator level signals from any 2 steam generators.
2. Under voltage on diesel buses.
3. The ATWS (Anticipated Transient Without Scram) Mitigation System Actuation Circuitry (AMSAC) starts the turbine driven pump on low-low level in 2 out of 3 steam generators.

The turbine driven emergency feedwater pump and the parts of the system necessary for its operation are designed to operate under loss of electrical power and loss of compressed air conditions. Flow control valves fail in the open position and are normally open. Root valves in the main steam branch lines to the emergency feedwater pump drive turbine are left open during normal plant operations. When either root valve is closed, it is annunciated in the control room.

The essential controls, valve operators, and other supporting systems associated with the turbine driven emergency feedwater pump are independent from a-c power. The lube oil cooler receives cooling water from the pump discharge.

Subsequent to a start signal, the Emergency Feedwater System, automatically delivers no less than a total flow of 380 gpm to both intact steam generators assuming a secondary line break. For non-faulted conditions no less than a total of 400 gpm to all three steam generators can be supplied. In the event that a secondary break results in a depressurized steam generator, the

Emergency Feedwater System automatically (passively) limits the flow to the affected steam generator via cavitating venturis, thus resulting in more flow to the intact steam generators and less to the faulted steam generator. Also, since flow is immediately limited to the faulted steam generator, less mass and energy will be produced by the faulted steam generator before operator action is required to manually isolate the faulted steam generator. Thus, the cavitating venturis ensure sufficient flow is directed to the intact steam generators and limits flow to the faulted steam generator to ensure the design pressure of containment is not exceeded. Following an automatic startup signal, the operator adjusts flow rates to maintain steam generator water level while the plant is shut down or held at the hot standby condition.

The following operator actions are required to limit generation of mass and energy from the faulted steam generator following a secondary side break:

After 10 minutes:

1. Determine which steam generator is faulted.
2. Manually terminate emergency feedwater flow on the line associated with the break from the control room if possible by closing both parallel flow-control valves leading to the faulted steam generator.
3. Adjust flow rates to maintain intact steam generator water levels.
4. Monitor condensate storage tank water level and provide makeup, if available, or shift alignment to the service water supply before the condensate storage tank inventory is expended.

Within the next 20 minutes:

1. Close any flow control valve supplying a faulted steam generator if it failed to close after the first 10 minutes, from the control room or locally.
2. Close at least one additional isolation valve in series with each of the two, closed, parallel flow-control valves leading to the faulted steam generator to reduce the possibility of emergency feedwater leak-by.

During the 30 minute period, flow to the affected steam generator is limited by the cavitating venturi, if one or both isolation valves failed to close from the control room.

It is important to note that to ensure acceptable results from the feedwater line break event (FSAR Section 15.4.2.2), the manual actions described above are not required; the above described actions are only concerned with containment pressure-and temperature analysis and for determination of environmental conditions due to steam line breaks outside of containment.

The operator in the Control Room is provided with position indication for the six emergency feedwater isolation valves. In addition, isolation valve status is included in the ESF monitoring equipment on the main control board.

A summary failure analysis of the Emergency Feedwater System is presented by Table 10.4-8 for a secondary pipe break with a simultaneous loss of non-class 1E electrical power. A more detailed failure analysis, covering deterministic and probabilistic considerations, is documented in design calculations maintained by the PRA group.

Failure to automatically isolate emergency feedwater to the affected SG is an important consideration within two secondary pipe break analyses. For secondary side pipe breaks inside containment (FSAR Section 6.2), operator action at 30 minutes is credited to isolate emergency feedwater to the affected SG. Local or remote operator action within 30 minutes is required to prevent overpressurizing the containment. Secondly, for secondary side pipe breaks outside containment (FSAR Section 3.11.2.2.2.2), credit is taken for operator action at 10 minutes to isolate emergency feedwater to the affected SG. Since the harsh environment will limit local manual actions, operator action from the control room is required for secondary pipe breaks outside containment to preserve environment conditions for equipment qualification.

Operator action is required within 24 hours after the secondary side line break to visually inspect Emergency Feedwater System piping for passive failure.

If a pipe break should occur in the Intermediate Building, alarm and control devices act to prevent flooding at safety-related equipment on the floors. Section 7.6.5.1.2 outlines the details of the provisions for leak detection.

The Emergency Feedwater System is used to bring the plant to a sufficiently cold condition to permit Residual Heat Removal (RHR) System operation. The plant can operate indefinitely, if required, without normal feedwater. The Emergency Feedwater System can take suction from the Service Water System for an indefinite period.

Table 10.4-8 presents an Emergency Feedwater System failure analysis which addresses the consequences of various single active failures within the system in conjunction with a secondary side pipe break and a simultaneous loss of non-Class 1E electrical power. These conditions are considered to establish the limiting conditions for Emergency Feedwater System design. In addition, the emergency feedwater piping has been laid out to minimize water hammer occurrences induced by the piping system.

10.4.9.4 Inspection and Testing Requirements

Inservice functional testing is performed by manual startup of the emergency feedwater pumps. Pumps and valves may be tested while the plant is in operation.

The actuation circuitry of the service water-to-emergency feedwater cross connect valves is periodically tested during normal power operations. Stroke testing of these motor-operated valves is performed during cold shutdown to preclude contamination of the steam generators.

To avoid injection of cold water into the steam generators during normal plant operation, the flow control valves associated with the pump under test (motor driven or turbine driven) are closed during the test.

Periodic system and component checks and inspections are performed as specified by the applicable ASME Code, prescribed under 10CFR50.55a.

10.4.9.5 Instrumentation Requirements

Emergency Feedwater System instrumentation provides the necessary inputs for control, operation, and performance/status monitoring of the system.

Those devices (indicators, switches, alarms, computer monitoring, etc.) available to the operator in the Control Room are shown schematically on Figure 10.4-16. In addition, indicators and/or controls are also located on the control room evacuation panel, local panels, and near the components.

10.4.9.5.1 Pressure Measurement

1. Pressure Transmitters

   Pressure transmitters are provided in the common feed line to each steam generator for control room indication.

   In addition to the above pressure transmitters, 4 pressure transmitters are provided in the emergency feedwater pump suction header from the condensate storage tank. The output from these transmitters is arranged in a 2 out of 4 logic to automatically open the cross connect valves to the Service Water System (XVG-1037A-EF, XVG-1037B-EF, XVG-1001A-EF, XVG-1001B-EF, XVG-1002-EF, XVG-1008-EF) on low emergency feedwater pump suction header pressure.

2. Pressure Switches

   Pressure switches located in the suction line to each pump provide contacts for a low pressure alarm.

3. Pressure Indicators

   Pressure indicators are provided to monitor the availability of a water supply for each pump and to meet the inservice testing requirements for the pumps.

10.4.9.5.2 Level Measurement

Level Transmitters

Redundant level transmitters located on the condensate storage tank provide signals for low level alarms, computer inputs, and Control Room indicators (for post accident monitoring). In addition, the transmitters provide nonredundant signals for level indication at the panel supplied with the cycle makeup treatment plant and the control room evacuation panel.

10.4.9.5.3 Flow Measurement

Flow transmitters provide signals for alarms and redundant safety grade flow indication in the Control Room. Flow transmitters also provide signals for computer input, and for interlocks which automatically close the emergency feedwater flow control valves in case of a break in the emergency feedwater system between the flow control valves and the cavitating venturis. The emergency feedwater control valves are manually controlled from the Control Room or the control room evacuation panel for startup, shutdown and testing modes. Whenever an emergency feedwater control valve is in manual control and receives a signal indicative of an accident condition, the valve is automatically tripped open. During normal power operation, the emergency feedwater control valves are in the open position ready for automatic start of the emergency feedwater pumps. The control valves will remain open until throttled or closed by the operator or automatically closed by a high flow signal indicative of a break in the emergency feedwater system between the flow control valves and the cavitating venturis. Closure of the 2 emergency feedwater control valves terminates emergency feedwater flow only into the faulted steam generator loop. Due to the passive flow limitation of the cavitating venturis, the emergency feedwater control valves will not automatically close due to a faulted steam generator and will rely on operator action to isolate the faulted loop within 10 minutes.

For each emergency feedwater control valve (FV-3531, FV-3541, FV-3551, FV-3536, FV-3546, FV-3556), position indicating design provisions include the following:

1. Visual indication in the main control room by means of an ESF monitor light that will be “bright” when the valve is not open. Section 7.5.4 provides a more detailed explanation of the operation of the ESF monitor lights. An alarm will be annunciated via a common monitor light alarm if an emergency feedwater control valve is not open. This grouping highlights a valve not properly lined up. This light is energized from an ESF monitor light supply different from the valve control power and actuated by a valve limit switch. In addition to this visual position information, there are also red (open) and green (closed) position indicating lights at the control switch for each valve. These lights are actuated by valve limit switches and are powered by valve control power.
2. Audible and visual alarm annunciator points will be activated whenever an emergency feedwater control valve control switch is not in the auto position. The alarm activated by the control switch will be recycled by a timer at approximately 60 minute intervals to remind the operator of the improper valve line up. Both the alarm reflash annunciator point and the timer will be energized separately from the valve control power.

10.4.9.5.4 Speed Measurement

A speed transducer, supplied with the turbine driven emergency feedwater pump turbine, provides signals for Control Room indication.

10.4.9.5.5 Special Instrumentation

The main control board ESF monitor lights (see Section 7.5 for a more detailed explanation) provide an easily recognizable indication of the status of essential components and equipment. Included among the monitor lights for this system are status (position) indication of the flow control valves, the motor driven pumps, and the valve that admits steam to the turbine driven emergency feedwater pump.

An alarm is actuated if either control switch for the valve that admits steam to the turbine driven emergency feedwater pump is in the close position. The alarms ensure proper control switch alignment for normal operations. Switch covers are provided for these switches to prevent inadvertent operator action.

The emergency feedwater flow to each steam generator and condensate storage tank level are part of the post accident monitoring instrumentation (see Section 7.5 for a more detailed explanation).

10.4.9.5.6 Qualifications

Sections 3.10, 3.11, and 7.1 outline the qualifications and diversity of the instrumentation utilized in this system.

10.4.10 Turbine Building Closed Cycle Cooling Water System

The Turbine Building Closed Cycle Cooling Water System provides cooling water to components associated with the steam and power conversion system. The energy is dissipated to the atmosphere by a wet surface industrial cooling water.

10.4.10.1 Design Bases

The Turbine Building Closed Cycle Cooling Water System supplies non-nuclear safety class cooling water to the following components:

1. Turbine oil coolers
2. Hydrogen coolers
3. Exciter air cooler
4. Stator coolers
5. Main condenser vacuum pump coolers
6. Auxiliary condenser vacuum pump coolers
7. Instrument/service air compressors
8. Non-nuclear sample coolers
9. Non-nuclear sample chiller
10. Feedwater pump and turbine oil coolers

11. Feedwater booster pump mechanical seals and oil coolers
12. EHC oil coolers
13. Isophase bus duct coolers
14. Condensate pump seal coolers
15. Condensate demineralizer system air compressor

Major design parameters for the cooling water system pumps and the cooling tower are presented in Table 10.4-9.

System piping and valves are designed in accordance with the applicable ANSI industry standards B31.1 (Reference 1) and B16.5 (Reference 2) respectively. Hydrogen coolers, stator coolers, exciter air cooler, and turbine oil coolers are designed in accordance with the ASME Code, Section VIII (Reference 6), Division 1. Pumps are designed in accordance with Hydraulic Institute Standards. (Reference 9) The system is sized to ensure adequate heat removal based on 95° F nominal cooling tower water outlet temperature.

10.4.10.2 System Description

The Turbine Building Closed Cycle Cooling Water System components include a wet surface industrial cooling tower, two 100% capacity tower spray pumps, 4 cooling tower fans, two 100% capacity closed cycle cooling pumps, two 100% capacity closed cycle cooling booster pumps, various equipment coolers, and a head tank. Chemical injection and blowdown are provided to maintain the quality of the spray water.

Under normal operation, 1 of the 2 cooling water pumps circulates treated water through the cooling tower coils transferring the heat removed from the various components to the spray water and then to the atmosphere by evaporation of the spray water in the air stream produced by cooling tower fans. The dispersant and anti-fouling chemicals added to the cooling tower raw water are sufficiently diluted to ensure negligible effect on the environment. Cooling tower effluents, including salt drift and chemical discharges, will have negligible effect on plant structures and systems.

In the event of loss of the operating closed cycle pump while a-c power is available, the non-operating closed cycle pump starts automatically on detection of a pressure drop in the pump header.

The head tank located at the highest point in the system provides makeup and storage for thermal volume changes.

10.4.10.3 Safety Evaluation

The Turbine Building Closed Cycle Cooling Water System is independent of the plant emergency cooling facilities. This system is not required for reactor protection nor for safe shutdown of the nuclear portion of the plant and is therefore classified as non-nuclear safety class, non-Seismic

Category 1. Failure or malfunction of any system component will not affect the ability of the plant to achieve or maintain shutdown conditions.

A postulated failure in the Turbine Building Closed Cycle Cooling Water System inside the Turbine Building is bounded by the postulated failure of an expansion joint in the Circulating Water System piping as discussed in Section 10.4.5.3. Failure of the Turbine Building Closed Cycle Cooling Water System, having a limited volume of water which could be released into the turbine building, results in a lower flood level than the postulated event where circulating water is released through an expansion joint failure until the pump isolation valve closed.

The case of postulated missiles resulting from a broken cooling tower fiberglass fan blade is enveloped by the tornado missile spectrum applicable to the design of Seismic Category 1 structures.

10.4.10.4 Tests and Inspection

Testing of the Turbine Building Closed Cycle Cooling Water System is limited to that normally provided for non-safety related systems and includes:

1. Hot functional testing.
2. Normal, operational checking and routine maintenance of the system.

10.4.10.5 Instrumentation

System instrumentation to permit operator evaluation of equipment performance and to provide a performance record includes:

1. Pressure indicators, switches and test connections.
2. Flow indicators.
3. Level switches.
4. Temperature indicators and test connections.
5. Distributed Control System (DCS) for controlling and monitoring including operator interface.

Table 10.4-6
Feedwater System Failure Analysis

Component	Malfunction	Comment
Feedwater Booster Pump	1. Trip of one operating pump from normal operating scheme.	No effect.
	2. Trip of one operating pump from beyond normal operating scheme.	Limited power reduction in accordance with operating procedures.
Feedwater Pump	1. Trip of one operating pump from normal operating scheme.	Remaining feedwater pump(s) run out, no effect on NSSS.
	2.Trip of one operating pump from beyond normal operating scheme.	Reactor trip or runback in accordance with operating procedures.
Feedwater Flow Control Valve	Valve fails closed.	Reactor trip.
Feedwater Isolation Valve	Valve fails closed.	Reactor trip.
Feedwater Piping	Postulated pipe rupture.	See Section 10.4.7.2.3.

Quantity	1	
Type	Canned motor, centrifugal	
Capacity, gpm	150	
Total Developed Head, ft	230	
Material	Wetted parts - type 304 stainless steel	

Table 10.4-8
Emergency Feedwater System Failure Analysis for
Secondary Side Break With Los of Non-1E Electrical Power

Component	Malfunction	Comment
Any Emergency Feedwater Pump	Fails to start	The two remaining emergency feedwater pumps feed all three steam generators with the two unaffected steam generators receiving required flow. Flow is passively limited to the faulted SG steam generator by the cavitating venturi for 10 minutes (until operator action is credited). [1,2]
Motor Driven Pump ARC Valve	Fails to automatically isolate pump recirculation path	All three emergency feedwater pumps feed all three steam generators with the two unaffected steam generators receiving required flow. Flow is passively limited to the faulted SG steam generator by the cavitating venturi for 10 minutes (until operator action is credited). [1,2]
Electrical Channel A (instrumentation and power)	Failure (total loss)	Channel B motor driven emergency feedwater pumps and the Turbine Driven pump feed all three steam generators with the two unaffected steam generators receiving required flow. Flow is passively limited to the faulted SG steam generator by the cavitating venturi for 10 minutes (until operator action is credited). [1,2]

Table 10.4-8 (continued)
Emergency Feedwater System Failure Analysis for
Secondary Side Break With Los of Non-1E Electrical Power

Component	Malfunction	Comment
Electrical Channel B (instrumentation and power)	Failure (total loss)	Channel A motor driven emergency feedwater pump and the Turbine Driven pump feed all three steam generators with the two unaffected steam generators receiving required flow. Flow is passively limited to the faulted SG steam generator by the cavitating venturi for 10 minutes (until operator action is credited). [1,2]

(1) The pressure and temperature analyses for secondary side pipe breaks inside containment credit operator action at 30 minutes to isolate emergency feedwater to the affected SG and thus allow for operator action outside of the control room. Action is required to prevent overpressurizing the containment.
(2) The pressure and temperature analyses for secondary side pipe breaks outside containment credit operator action at 10 minutes to isolate emergency feedwater to the affected SG since the harsh environment will limit local manual actions. Action is required to prevent environment conditions for equipment qualifications.

V.C. Summer Nuclear Station
Safety Analysis Report

Radioactive Waste Management

Chapter 11

Revision 26--06/25/26

This Revision summary replaces the List of Effective pages of the VC Summer FSAR, effective June 30, 2021. It will appear in Chapter 00 of the VC Summer FSAR and is the best history available of all the changes made to the original VC Summer FSAR.

CHAPTER 11 - RADIOACTIVE WASTE MANAGEMENT

11.1 Source Terms

The fission product inventory in the reactor core and the diffusion to the fuel pellet/cladding gap are presented in Chapter 15. Source terms and models used in the evaluation of radwaste treatment systems and effluent releases are based on operating plant data where available (Reference 1).

Two source terms are presented. The first is a conservative model which utilizes a conventional fuel clad defect model. This conservative model serves as a basis for calculations of the maximum offsite doses resulting from postulated accidents.

The second source term is a realistic model used to predict expected long term average concentrations of radionuclides and expected releases. This realistic model is based on ANSI/ANS-18.1-1984.

11.1.1 Radioactivities in Systems and Components, Conservative Model

11.1.1.1 Reactor Coolant Activity

The parameters used in the calculation of the reactor coolant fission product inventories, together with the pertinent information concerning the expected coolant cleanup flowrate and demineralizer effectiveness, are summarized in Table 11.1-1. Calculated reactor coolant radionuclide concentrations, based on the assumptions of Table 11.1-1, are presented in Table 11.1-2. In these calculations, the defective fuel rods are assumed to be present at the initial core loading and to be uniformly distributed throughout the core; thus, the fission product escape rate coefficients are based upon average fuel temperature.

For fuel failure and burnup experience, see Chapter 4.

The fission product activities in the reactor coolant during operation with small cladding defects (fuel rods containing pinholes or fine cracks) are computed using the following differential equations:

For parent nuclides in the coolant:

$$\frac{dN_{C_i}}{dt} = \frac{R_i N_{F_i}}{M_C} - \left[\lambda_i + D_i + \frac{Q_L}{M_C}\left(\frac{\psi_i + DF_i - 1}{DF_i}\right)\right] N_{C_i} \qquad (11.1\text{-}1)$$

For daughter nuclides in the coolant:

$$\frac{dN_{C_j}}{dt} = \frac{R_j N_{F_j}}{M_C} + f_i \lambda_i N_{C_i} - \left[\lambda_j + D_j + \frac{Q_L}{M_C}\left(\frac{\psi_j + DF_j - 1}{DF_j}\right)\right] N_{C_j} \qquad (11.1\text{-}2)$$

where:

N_c = Concentration of nuclide in the reactor coolant (atoms/gram)
NF = Inventory of nuclide in the fuel (atoms)
t = Operating time (seconds)
R = Nuclide release coefficient (1/sec) = F v
F = Fraction of fuel rods with defective cladding
v = Fission product escape rate coefficient (1/sec)
M_c = Mass of reactor coolant (grams)
λ = Nuclide decay constant (1/sec)
DF = Nuclide demineralizer decontamination factor
Q_L = Purification or letdown mass flow rate (grams/sec)
ψ = Nuclide volume control tank stripping fraction
f = Fraction of parent nuclide decay events that result in the formation of the daughter nuclide
D = Dilution coefficient for feed and bleed (1/sec) =

$$\frac{\beta}{B_o - \beta t} * \frac{1}{DF}$$

B_o = Initial boron concentration (ppm)
β = Boron concentration reduction rate (ppm/sec)

and where:

subscript i refers to the parent nuclide.
subscript j refers to the daughter nuclide.

The above equations are based on the assumption that there is no activity reduction due to pressurizer operation and that the nuclide concentration in the volume control tank can be approximated by:

$$N_{VL} = \frac{1-\psi}{DF} * N_c$$

where:

N_{VL} = Concentration of nuclide in the volume control tank (atoms/gram)

The corrosion product activities in the Reactor Coolant System are based on measurements at operating reactors (Reference 1). The reactor coolant inventories of corrosion products (which are independent of fuel defect level) are given in Table 11.1-2.

Another potential source of primary coolant activity is activation products from the silver-indium-cadmium control rods. The presence of Ag-110m has been noted in the primary coolant or plant discharges at a few of the operating plants. Several mechanisms can contribute to the presence of

this isotope; namely, fission product decay of the mass 109 chain followed by activation to Ag-110m, surface contamination of the control rods with absorber material, or escape of activation products from the control rods. The control rods are designed to contain products formed in the absorber material and are not expected to contribute to the coolant activity. Current information, however, is insufficient to determine the source of the silver, and thus no model is available for predicting coolant activity levels due to the above sources. Investigations of this will be continued as more data become available.

11.1.1.2 Gaseous Waste Processing System Activity

The stripping fractions used in determining the amount of fission gases removed from the reactor coolant in the volume control tank and collected by the Gaseous Waste Processing System (GWPS) are calculated as follows:

$$\psi = 1 - \left[\frac{KQ}{KQ + \lambda(KL + V) + P}\right] \quad (11.1\text{-}3)$$

where:

- ψ = Nuclide volume control tank stripping fraction
- K = RT / MH
- R = Gas constant = 45.59 atm/cc per gram-mole /°R
- T = Nominal volume control tank temperature (°R)
- M = Molecular weight of water = 18.0 grams/gram-mole
- H = Henry's Law constant
- Q = Letdown or purification flow rate (grams/sec)
- λ = Nuclide decay constant (1/sec)
- L = Volume control tank liquid mass (grams)
- V = Volume control tank vapor volume (cc)
- P = Volume control tank purge rate to the gaseous waste processing system (cc/sec at volume control tank conditions)

An activity balance is performed on the Reactor Coolant System and volume control tank to obtain the Reactor Coolant System activity, volume control tank activity, and stripping fraction. Stripping fractions are shown in Table 11.1-1. Gaseous waste source terms are discussed in Section 11.3.

11.1.1.3 Volume Control Tank Activity

Table 11.1-3 lists the maximum activities in the volume control tank using the assumptions summarized in Table 11.1-1. The liquid activity is assumed to be the same as the letdown coolant activity for the halogen and particulate activity.

11.1.1.4 Pressurizer Activity

The specific activities for major nuclides in the pressurizer are discussed below.

- Pressurizer Liquid Phase Source Strengths - The pressurizer liquid specific activity is assumed to be the same as that of the reactor coolant. Table 11.1-4 lists only those nuclides that are the major contributors to total source strength.

- Pressurizer Steam Phase - Pressurizer steam phase radiogas concentrations (Table 11.1-4) are based on the stripping of radiogases from the continuous 2-gpm pressurizer spray and the subsequent buildup of these radiogases in the steam space. The buildup time is assumed to be 480 days. Decay credit has been taken during spray line transit. The radiogases are assumed to be completely stripped from the spray, except for Kr-85 and Xe-133, which are in Henry's Law Equilibrium with the liquid in the pressurizer.

  Pressurizer steam phase iodine concentrations are obtained from the liquid phase nuclide activities and measured values of the partition coefficient for I-131. A large partition coefficient was chosen to maximize the activities. It was assumed to apply to all radioiodines.

The activities in the pressurizer are separated between the liquid and the steam phase and the results obtained are given in Table 11.1-4 using the above assumptions and those summarized in Table 11.1-1.

11.1.1.5 Liquid Waste Processing System Activity

Liquid waste source terms are discussed in Section 11.2.

11.1.1.6 Solid Waste

Solid waste source terms are discussed in Section 11.5.

11.1.2 Leakage Rates

As a necessary part of the effort to reduce effluent of radioactive liquid wastes, Westinghouse has been surveying various Pressurized Water Reactor (PWR) facilities which are in operation, to identify design and operating problems influencing reactor coolant and non-reactor grade leakage and hence the load on the LWPS.

Leakage sources have been identified in connection with pump shaft seals and valve stem leakage. Where packed glands are provided, a leakage problem may be anticipated, while mechanical shaft seals provide essentially zero leakage. Valve stem leakage was experienced where the originally specified packing was used. A combination of a graphite filament yarn packing sandwiched with asbestos sheet packing is used with improved results in several plants. A bellows seal is being utilized in later plants which eliminates all stem leakage.

In addition, seat leakage was experienced on some pressurized power operated relief valves. However, this was found to be due to a manufacturing error and has been corrected.

11.1.3 Radioactivities in the Fluid Systems, Realistic Model

The parameters used to describe the Virgil C. Summer Nuclear Station reactor are given in Table 11.1-6.

Specific activities in the primary coolant, steam generator water, and steam generator steam are based on the parameters of Table 11.1-6 and are given in Table 11.1-5.

11.1.4 Tritium

The release of tritium to the environment from operating Westinghouse PWRs has always been well below 10 CFR 20 limits. This section discusses the reduced tritium production in the plant as a result of employing Zircaloy clad fuel and silver-indium-cadmium control rods.

11.1.4.1 System Sources

There are two principal contributors to tritium production within the PWR system: the ternary fission source, and the dissolved boron in the reactor coolant. Additional contributions are made by Li6, Li7, and deuterium in the reactor water. Tritium production from various sources is shown in Table 11.1-7.

11.1.4.1.1 Fission Source

This tritium is formed within the fuel material and may:

1. Remain in the fuel rod uranium matrix,
2. Diffuse into the cladding and become hydrided and fixed there,
3. Diffuse through the clad for release into the primary coolant,
4. Release to the coolant through macroscopic cracks or failures in the fuel cladding.

Previous Westinghouse designs conservatively assumed that the ratio of fission tritium released into the coolant to the total fission tritium formed was approximately 0.30 for Zircaloy clad fuel. The operating experience at the Robert Emmett Ginna Station of the Rochester Gas and Electric Corporation, and at other operating reactors using Zircaloy clad fuel, has shown that the tritium release through the Zircaloy fuel cladding is less than the earlier estimates. Consequently, a tritium release rate into the primary coolant of 0.001 curies per megawatt-day or less can be anticipated.

11.1.4.1.2 Control Rod Source

The full length rods for the Virgil C. Summer Nuclear Station are silver-indium-cadmium. There are no reactions in these absorber materials which would produce tritium, thus eliminating any

contribution from this source. Activation products from control rods are discussed in Section 11.1.1.1.

11.1.4.1.3 Boric Acid Source

A direct contribution to the reactor coolant tritium concentration is made by neutron reaction with the boron in solution. The concentration of boric acid varies with core life and load follow so that this is a steadily decreasing source during core life. The principal boron reactions are the B^{10} (n, 2α) H^3 and B^{10} (n, α) Li^7 (n, nα) H^3 reactions. The Li^7 reaction is controlled by limiting the overall lithium concentration to approximately 2 ppm during operation. Li^6 is essentially excluded from the system by utilizing 99.9% Li^7.

11.1.4.1.4 Burnable Shim Rod Source

These rods are in the core only during the first operating cycle and their potential tritium contribution occurs only during this period.

11.1.4.1.5 Lithium and Deuterium

Lithium and deuterium reactions contribute only minor quantities to the tritium inventory as shown in Table 11.1-7. These sources are due to the activation of the lithium and deuterium in the Reactor Coolant System as they pass through the reactor.

11.1.4.2 Design Bases

The design intent is to reduce the tritium sources in the Reactor Coolant System to a practical minimum to permit longer retention of the reactor coolant within the plant without compromising operator exposures. Reduction of source terms is provided by utilizing silver-indium-cadmium control rods and the determination that the quantity of tritium released from the fuel rods with Zircaloy cladding is less than originally expected.

11.1.4.3 Design Evaluation

Table 11.1-7 lists the present expected release of tritium to the reactor coolant. It will be noted that there are two principal contributors to the tritium production: ternary fission source and the dissolved boron in the reactor coolant.

For a leakage from the Reactor Coolant System into the Reactor Building atmosphere of 50 pounds per day with an assumed tritium concentration of 3.5 μCi/gm, the tritium concentration in the Reactor Building atmosphere would be low enough to permit access with no Reactor Building purge and without protective equipment by plant maintenance personnel for an average of 2 hours per week.

During refueling operations, a refueling water concentration activity of 2.5 μCi/gm is expected to result in Reactor Building air concentrations at or below the 10 CFR 20 occupational Maximum

Permissible Concentration (MPC) value. This concentration would permit 40 hours per week access to the Reactor Building.

Although the actual relationship between reactor coolant activities and Reactor Building air concentrations will be determined by the particular operating conditions inside the Reactor Building (temperature, relative humidity, ventilation purge rate, etc.), field measurements indicate that the design objective of 3.5 μCi/gm in the reactor coolant and 2.5 μCi/gm in the refueling water are reasonable values.

Note: Power level = 2958 MWt
IFBA B-10 mass = 1730 gm
Initial cycle reactor coolant boron concentration = 1200 ppm
Equilibrium cycle reactor coolant boron concentration = 2100 ppm
Lithium concentration (99.9 atom percent Li^7) = 2.2 ppm

11.2 Liquid Waste Systems

This section describes the design and operating features of the Liquid Waste Processing System (LWPS). In addition the total plant liquid releases from all sources are estimated and summarized in Section 11.2.6. Section 11.2.2 describes an upper limit system capacity which can be maintained for an indefinite period of time.

11.2.1 Design Objectives

The LWPS is designed to receive, control, segregate, process, reuse, and discharge liquid wastes. The system design considers potential personnel exposure and assures that quantities of radioactive releases to the environment are in accordance with 10 CFR 50, Appendix I.

Under normal plant operation, the activity from radionuclides leaving the penstock of the Fairfield Pumped Storage Facility, due to releases from the LWPS, is a small fraction of the effluent concentration limits (ECLs) as defined in Appendix B of 10 CFR 20.

Section 11.2.6 establishes that the LWPS adequately meets the above listed design objectives.

11.2.2 Systems Descriptions

The LWPS primarily collects and processes potentially radioactive wastes for release to the environment. Provisions are made to sample and analyze fluids before they are discharged. Based on the laboratory analysis, these wastes are either released under controlled conditions via the penstocks of the Fairfield Pumped Storage Facility or retained for further processing. Permanent records of liquid releases are provided by analyses of known volumes of waste. Alternatively, the liquid waste may be reused in the plant.

The bulk of the radioactive liquids discharged from the Reactor Coolant System is processed by the Reactor Grade Demineralizer System discussed in Section 9.3.6. This limits input to the LWPS and results in processing of relatively small quantities of generally low activity level wastes.

The LWPS consists of five collection systems which are provided by the waste holdup tank, floor drain tank, the laundry and hot shower tank, the Excess Liquid Waste Processing System (ELWS) (the excess waste holdup tank and the decon pit collection tank), and the laboratory drain system. Capability for handling and storage of spent demineralizer resins is also provided.

The LWPS does not include provisions for processing secondary system wastes. The Nuclear Blowdown Processing System (NBS) is discussed in Section 10.4.8. The segregation of primary and secondary side wastes is maintained since ammonia from the secondary side could result in the loss of LWPS demineralizer efficiency, and condenser inleakage could lead to undesirable chemical inclusion in the LWPS. Additionally, the mixing of low activity wastes (secondary side) with those of higher activity (primary side) should be avoided since a large volume of contaminated water is produced. The present design, which segregates primary and secondary

wastes, minimizes the amount of water which must be processed by discharging low activity wastes directly, where permissible, with no treatment.

In the event of equipment faults of moderate frequency (Section 11.2.4.2), the LWPS is capable of processing up to 1 gpm of primary coolant leakage with no change in system operation.

As a practical upper limit of system operation, the LWPS can process 25 gpm not including laundry type effluents which are normally discharged without processing. This liquid may be collected in either the floor drain tank or waste holdup tank or in both tanks.

Instrumentation and controls necessary for the operation of the LWPS are located on a control board in the Auxiliary Building. Any alarm on this control board is relayed to the main control board in the Control Room.

11.2.2.1 Waste Holdup Tank

The waste holdup tank is provided to collect both reactor and non-reactor grade water which enters the LWPS via equipment leaks and drains, valve leakoffs, pump seal leakoffs, tank overflows, Reactor Building sump flows, and other tritiated and aerated water sources.

Deaerated tritiated water inside the Reactor Building from sources such as valve leakoffs, which is collected in the reactor coolant drain tank, need not enter the waste holdup tank. These may be routed directly to the recycle holdup tanks for processing.

The basic composition of the liquid collected in the waste holdup tank is normally boric acid and water with some radioactivity. Liquid collected in this tank is normally processed through the Waste Water System (Duratek demineralizers) and released to the environment under controlled conditions.

Liquid wastes are released from the waste monitor tanks through the penstocks of the Fairfield Pumped Storage Facility. The discharge valve is interlocked with a process radiation monitor and closes automatically when the radioactivity concentration in the liquid discharge exceeds a preset limit. The waste monitor tanks act as a reservoir for storing waste which is to be released from the LWPS to the Fairfield Pumped Storage Facility. Prior to entering these tanks, the liquid may pass through a waste monitor tank demineralizer and a waste monitor tank filter, if required for additional cleanup.

Normally, the waste monitor tank demineralizer and filter are bypassed. A sample is taken and, after analysis, the results are logged and the liquid is discharged. This radiation monitor, RM-L5, is described in Section 11.4. Liquid waste discharge flow and volume are recorded.

11.2.2.2 Floor Drain Tank

The floor drain tank is provided to collect non-reactor grade (non-recyclable) liquid wastes. These include floor drains, equipment drains containing non-reactor grade water, and other non-reactor grade sources. Normally, only non-radioactive water is collected in the floor drain tank which can

then be sent directly to the waste monitor tank without processing and subsequently discharged. If there is activity in the floor drain tank liquid and is such that the discharge limits cannot be met without cleanup, the liquid may be processed through the Waste Water System (Duratek demineralizers) and released under controlled conditions via the penstocks of the Fairfield Pumped Storage Facility.

Non-recyclable reactor coolant leakage normally enters the floor drain tank from system leaks in the Auxiliary Building via the floor drains. This liquid is not reused because it is diluted and contaminated by non- reactor grade water entering the floor drain tank from other sources. Sources of water include fan cooler leaks, secondary side steam and feedwater leaks, component cooling water leaks, and decontamination water.

11.2.2.3 Laundry and Hot Shower Tank

Laundry and hot shower drains normally need no treatment for removal of radioactivity. This water is transferred to waste monitor tank number 2 via the laundry and hot shower filter. A sample is taken and, after analysis, the results are logged and the water is discharged if the activity level is below acceptable limits.

11.2.2.4 Excess Liquid Waste Processing System (ELWS)

The ELWS consists of two storage tanks, the excess waste holdup tank and the decon pit collection tank.

The excess waste holdup tank is used to accept excess liquid waste from the floor drain tank, laundry and hot shower tank, and waste holdup tank when these tanks are filled to capacity. The liquid from this tank can be recycled back to these tanks, released directly to the environment via the waste monitor tank, or processed through the Duratek demineralizers prior to release from the plant.

The decon pit collection tank collects liquid from the Fuel Handling Building sumps, the Radiological Maintenance Building drains, excess waste holdup tank sump, excess waste holdup area sump, and decon pit drains. If the activity in this tank liquid is such that the discharge limits cannot be met without cleanup, the liquid is processed through the Duratek demineralizers and released under controlled conditions via the penstocks of the Fairfield Pumped Storage Facility.

This system also normally receives liquid waste from the Normal and Post Accident Sampling System waste pump. In addition, the Turbine Building Floor Drain System discharge will be directed to the ELWS when excessive radioactive discharge is detected by radiation monitor number RM-L8.

11.2.2.5 Laboratory Drain System

The laboratory drain system consists of three sinks in the radiochemical laboratory and two sinks in the sample room.

In the radiochemical laboratory spent reactor coolant samples, equipment rinse water and other non-reactor grade fluids are disposed of in the two sinks that drain to the floor drain tank. No liquids or wastes are intentionally disposed of in the sink that drains to the chemical drain tank.

In the sample room, excess sample purges of reactor grade water and excess reactor coolant samples are drained from one sink to the waste holdup tank for processing. The other sink is used for draining non-reactor grade fluids to the nuclear blowdown holdup tank.

11.2.2.6 Waste From Spent Resin

The spent resin sluice portion of the LWPS consists of a spent resin storage tank, a spent resin sluice pump, and a spent resin sluice filter. The equipment is arranged such that the resin sluice water after entering a demineralizer vessel returns to the spent resin storage tank for reuse. The purpose of this system is to transport spent resin to the spent resin storage tank without generating large volumes of waste liquid. This is accomplished by reusing the sluice water for subsequent resin sluicing operations.

11.2.3 System Design

11.2.3.1 Component Design

Principal design parameters for the LWPS equipment are given in Table 11.2-2. Parts or components in contact with borated water are fabricated from or clad with austenitic stainless steel except for the Royal Flex hose provided by the vendor as an integral part of the Duratek demineralizers. The Royal Flex hose is a reinforced Thermoplastic Vinyl Nitrile hose. Pumps are provided with vent and drain connections.

Component safety classes and the corresponding code and code class are shown in Table 3.2-1. Except for flanged joints and quick disconnect couplings, all-welded construction is used.

Table 11.2-3 lists the isotopic inventory of each major component, using the following assumptions:

1. Concentrations based on an equivalent fuel defect level of 1 percent. Values given in the table indicate liquid activity only.
2. For tanks upstream of the Duratek system (floor drain tank, waste holdup tank), the tanks were assumed 80 percent full of primary coolant.
3. The tanks downstream of the Duratek system were assumed 80 percent full of processed primary coolant.
4. The Duratek system components for a typical lineup are shown in Figure 11.2-5.
5. The laundry and hot shower tank was assumed 80 percent full of laundry waste water.

These activities are the recommended source terms for the analysis of consequences of a postulated failure of the LWPS components.

11.2.3.1.1 Pumps

11.2.3.1.1.1 Reactor Coolant Drain Tank Pumps

Two pumps are provided. One reactor coolant drain tank pump provides sufficient flow for normal tank operation with one pump for standby.

11.2.3.1.1.2 Waste Evaporator Feed Pump

One pump of standard design is used. The waste evaporator feed pump is used to transfer liquid from the waste holdup tank. The pump trips off in auto.

11.2.3.1.1.3 Waste Evaporator Condensate Pump

The waste evaporator condensate pump is a transfer pump. One pump of standard design is used to transfer the contents of the waste evaporator condensate tank to the waste monitor tank.

11.2.3.1.1.4 Chemical Drain Tank Pump

The chemical drain tank pump is of standard design and is used to transfer the liquid from the chemical drain tank.

11.2.3.1.1.5 Spent Resin Sluice Pump

This pump is identical to the reactor coolant drain tank pumps. Its delivery flow is based on the required velocity to sluice resin.

11.2.3.1.1.6 Laundry and Hot Shower Tank Pump

The laundry and hot shower tank pump is of standard design and is used to transfer the water to the waste monitor tank.

11.2.3.1.1.7 Floor Drain Tank Pump

The floor drain tank pump is of standard design and is used to normally transfer water to the waste monitor tank.

11.2.3.1.1.8 Waste Monitor Tank Pumps

A waste monitor tank pump is of standard design and is used for each tank to discharge water from the LWPS or for recycle if further processing is required. The pump may also be used for circulating the water in the waste monitor tank in order to obtain uniform tank contents and hence a representative sample before discharge. The pump can be throttled to achieve the desired discharge rate.

11.2.3.1.1.9 Excess Liquid Waste Pumps

The two excess liquid waste pumps are used to transport the waste fluid from the excess waste holdup tanks through the processing portion of the ELWS and to return waste to the LWPS. These pumps also circulate the waste in the tank to obtain proper mixing prior to sampling tank contents.

11.2.3.1.2 Reactor Coolant Drain Tank Heat Exchanger

The reactor coolant drain tank heat exchanger is a U-tube type with one shell pass and four tube passes. Although the heat exchanger is normally used in conjunction with the reactor coolant drain tank, it can also cool the pressurizer relief tank contents from 200 to 120°F in less than 8 hours.

11.2.3.1.3 Tanks

11.2.3.1.3.1 Reactor Coolant Drain Tank

One tank is provided. The purpose of the reactor coolant drain tank is to collect leakoff type drains inside the Reactor Building at a central collection point for further disposition through a single penetration via the reactor coolant drain tank pumps. The tank provides surge and net positive suction head requirements to the pumps.

Only water which can be directed to the recycle holdup tanks enters the reactor coolant drain tank. The water must be compatible with reactor coolant and it must not contain dissolved air.

Sources of water entering the reactor coolant drain tank include the reactor vessel flange leakoff, valve leakoffs, number 3 seal leakoffs from the reactor coolant pumps, and the excess letdown heat exchanger flow. No continuous leakage is expected from the reactor vessel flange during operation.

A constant level is maintained in the tank to minimize the amount of gas sent to the gaseous waste processing system and also to minimize the amount of hydrogen required. The level is maintained by running one pump continuously and using a proportional control valve in the discharge line. This valve operates on a signal from a level controller to limit the flow out of the system. The remainder of the flow is recirculated to the tank.

11.2.3.1.3.2 Waste Holdup Tank

One atmospheric pressure tank is provided outside the Reactor Building to collect equipment drains, valve and pump seal leakoffs, recycle holdup tank overflows, Reactor Building sump fluid, and other water from tritiated aerated sources.

11.2.3.1.3.3 Waste Evaporator Condensate Tank

One tank with a diaphragm to exclude air is provided to collect low level liquid waste prior to sending it to the waste monitor tank.

11.2.3.1.3.4 Chemical Drain Tank

One tank is available to collect chemically contaminated tritiated water from the laboratories; however, this tank is normally not used.

11.2.3.1.3.5 Spent Resin Storage Tank

The purpose of the spent resin storage tank is to provide a collection point for spent resin to allow for decay of short lived radionuclides before disposal. The tank serves also as a head tank for the spent resin sluice pump.

The tank is designed so that sufficient pressure can be applied in the gas space of the tank to push resin out and to the solid waste disposal unit, which is at a higher elevation than the spent resin storage tank.

The spent resin storage tank is shielded to limit the dose to personnel.

11.2.3.1.3.6 Laundry and Hot Shower Tank

One atmospheric pressure tank is used to collect laundry and hot shower drains.

11.2.3.1.3.7 Floor Drain Tank

One atmospheric pressure tank is used to collect floor drains from the reactor plant.

11.2.3.1.3.8 Waste Monitor Tanks

The two atmospheric waste monitor tanks are provided for monitoring liquid discharges from the plant site. Each tank is sized to hold a volume large enough such that sampling requirements are minimized, thus minimizing further laboratory effluent.

11.2.3.1.3.9 Excess Waste Holdup Tank

The excess waste holdup tank normally receives liquid waste from the floor drain tank, laundry and hot shower tank, and waste holdup tank when these tanks are filled to capacity.

This system also normally receives liquid waste from the Normal and Post Accident Sampling System waste pump. In addition, the Turbine Building Floor Drain System discharge will be directed to this tank when excessive radioactive discharge is detected by radiation monitor number RM-L8.

11.2.3.1.3.10 Decontamination Pit Collection Tank

The decontamination pit collection tank receives drainage from the Fuel Handling Building sumps, the Radiological Maintenance Building drains, excess waste holdup tank sump, excess waste holdup area sump, and decon pit drains.

11.2.3.1.4 Demineralizers

As part of a continuous PWR operating plant following, Westinghouse has obtained operational data on demineralizer decontamination factors for selected isotopes. The measured range of decontamination factors for these isotopes is given in Table 11.2-4.

These values were observed across mixed bed demineralizers containing cation resin in the lithium-7 form and anion resin in the borated form.

The minimum values in Table 11.2-4 were generally observed just prior to resin flushing and recharging, while during the operating life of the demineralizer, decontamination factors were consistently closer to the maximum values.

Although specific operating decontamination factors have not as yet been measured for other isotopes, their behavior in a similar purification media may be inferred from this data. One would anticipate, for example, bromine to have a decontamination factor similar to that given above for the iodine and fluorine.

11.2.3.1.4.1 Waste Water System (Duratek Demineralizers)

The Waste Water System (Duratek demineralizers) is provided to process radioactive waste prior to release to the environment. The Duratek demineralizers are located on the 447’ elevation of the Auxiliary Building. Prior to entering the mixed bed and cation Duratek demineralizers, the liquid waste stream is normally processed through a charcoal vessel. The charcoal media acts as a prefilter providing mechanical filtration capability prior to the Duratek demineralizers. The charcoal filtration provides for cleanup of oil and grease (organics), cobalt 58 and 60, initial iodines, cesium, and other suspended solids.

The liquid waste stream enters the Duratek demineralizers through a booster pump, a mechanical filter, and an Influent Control Leg which monitors waste stream parameters and provides attachments for service air and water. From the Influent Control Leg, the waste may enter one of the five pressure vessels that contain media for cleanup of the liquid waste. The media normally include:

- Cation resin to remove metals and transition metals.
- Mixed bed resin that reduces undesired positive and negative ions.
- Charcoal media for cleanup of oil and grease (organics), cobalt 58 and 60, initial iodines, and cesium and for service as a prefilter to protect the other demineralizer beds.

A typical lineup for the five Duratek demineralizers in series would be charcoal, cation, charcoal, cation, mixed bed with cation.

The actual required vessel lineup during normal plant operation is determined prior to processing by sampling the tank to be processed and determining the parameter(s) that are out of specification. Selection of the appropriate vessels is made by a quick-disconnect logic

arrangement. After processing, decontaminated effluent passes through an Effluent Control Leg which records waste volume, and may flow through a combined resin polisher.

Polyelectrolytes may be added upstream of the second charcoal vessel to help remove colloidal cobalt. This is mainly used during an outage post reactor coolant system cleanup.

11.2.3.1.4.2 Waste Evaporator Condensate Demineralizer

One demineralizer vessel is provided which is used during primary demineralizer resin (CVCS) transfer and provides a means to tie the resin supply and return headers together during resin transfer to prevent resin excursions throughout the solid waste system. The demineralizer vessel is empty (no contained resin beds) and is not used for waste decontamination.

11.2.3.1.4.3 Waste Monitor Tank Demineralizer

One demineralizer is provided upstream of the waste monitor tanks.

11.2.3.1.4.4 Excess Liquid Waste Demineralizers

Two redundant demineralizers are provided in the ELWS process train. Liquid wastes may be passed through one demineralizer prior to being discharged to a waste monitor tank.

11.2.3.1.5 Filters and Strainers

11.2.3.1.5.1 Filters

The filters provided are of a wound cartridge or spun cartridge type construction which relies on a tortuous path to filter particles with an absolute rating.

The methods employed to change filters and screens are dependent on activity levels. Filters are valved out of service with a pressure indicator between the isolation valves to assure the valves are not leaking and the filter is not at system pressure. The filter is drained to the appropriate tank and vented locally. If the radiation level of the filter is low enough, it is changed manually. If activity levels do not permit manual change, the spent cartridge is removed remotely with temporary shielding to protect personnel. The spent cartridge is placed in a shielded pig for removal to the solid waste disposal area. A new cartridge is installed, the housing is reassembled, vent and drain valves are closed, and the filter is valved into service. Filters are normally changed because of high ΔP rather than high radiation levels.

The excess liquid waste filters are back flushable and have cylindrical woven screen cartridges. One of the two excess liquid waste filters removes suspended solids from the waste water upstream of the demineralizers. The second filter traps resin fines downstream of the demineralizer.

11.2.3.1.5.2 Strainers

The strainers provided are basket type which are of a mesh or screen construction. The nominal rating of the strainers is given in Table 11.2-2.

The basket type laundry and hot shower strainer is not replaced after use, but is cleaned and put back in service. Because this screen traps only large particles, it contains only negligible activity and provides no hazard to personnel. It is cleaned regularly.

The decontamination pit collection tank strainer is a duplex basket strainer that removes large suspended particles from the wastes entering the decontamination pit collection tank. This strainer is also cleaned and put back into service.

11.2.3.2 Instrumentation Design

The system instrumentation is described in Table 11.2-5. The instrumentation readout is located mainly on the Waste Processing System (WPS) panel in the Auxiliary Building and excess liquid waste panel (ELWP) in the Fuel Handling Building. Some instruments are read where the equipment is located. Alarms are shown on the WPS panel or ELWP and further relayed to one common WPS annunciator on the main control board in the Control Room.

Pumps are protected against loss of suction pressure by a control setpoint on the level instrumentation for the respective vessels feeding the pumps. The reactor coolant drain tank pumps and the spent resin sluice pump are in addition interlocked with flowrate instrumentation and stop operating when the delivery flows reach minimum setpoints.

Pressure indicators upstream and downstream of filters, strainers, and demineralizers provide local indications of pressure drops across each component.

All releases to the environment are monitored for radioactivity.

11.2.3.3 Tank Overflow Protection

All tanks in the Chemical and Volume Control System (CVCS), Boron Recycle System (BRS), NBS, and WPS that could potentially contain radioactive liquids are designed to provide adequate warning of potential overflow conditions. A summary of the overflow protection features is given in Table 11.2-6. These tanks are provided with level indication instrumentation which has an alarm function on high liquid level in the tank. Alarm annunciation is provided separately on the local system control panel and further relayed to a common annunciator on the main control board in the Control Room for each system. A description of the level instrumentation provided for these systems is given in Sections 9.3.4.5, 9.3.6.5, 10.4.8.2, and 11.2.3.2 for the CVCS, BRS, NBS, and LWPS, respectively.

In addition to tank level monitoring and warning of potential overflow conditions, provisions are made in the systems design to collect and process overflows from tanks containing potentially radioactive liquids. The collection and processing provisions are delineated in Table 11.2-6.

Table 11.2-6a presents a comparison of tanks with Branch Technical Position ETSB 11-1 (Rev. 1), Paragraph B.1.b, Items (1) through (4).

11.2.4 Operating Procedures

The LWPS is manually operated except for some functions of the reactor coolant drain tank circuit. The system includes adequate control equipment to protect the system components and adequate instrumentation and alarm functions to provide operator information to ensure proper system operation.

11.2.4.1 Normal Operation

Operation of the LWPS is essentially the same during all phases of normal and defined off-normal reactor plant operation; the only differences are in the loads on the system. The following sections discuss the operation of the system in performing its various functions. In this discussion, the term “normal operation” should be taken to mean all phases of operation except operation under emergency or accident conditions. The LWPS is not regarded as an Engineered Safety Feature System.

11.2.4.1.1 Waste Holdup Tank

Water is accumulated in the waste holdup tank until sufficient quantity exists to warrant processing through the Waste Water System (Duratek demineralizers).

When this water has been sufficiently processed, it is discharged into the penstocks of the Fairfield Pumped Storage Facility at a rate so as not to exceed a small fraction of the 10 CFR 20 limits. Water leaving this system is discharged to the penstocks of the Fairfield Pumped Storage Facility and is monitored for radiation. This radiation monitor, RM-L5, is described in Section 11.4. Should the radiation monitor close the discharge valve, it must be reset/bypassed before the valve can be reopened. The monitor element can be cleared by flushing it with demineralized water from the temporary connection back to the waste monitor tank. During refueling, the load on the waste portion of the LWPS is increased but there is no change in operation.

During normal operation, the reactor coolant drain tank level regulation and pressure control are automatic and require no operator action.

Operation of the recycle portion of the LWPS during refueling is the same as for power operation, although the load on the system may be increased when refueling is complete. The water remaining in the fuel transfer canal following normal drain down is pumped to the suction of the refueling water purification pump by the reactor coolant drain tank pumps. When the pumps lose suction, the remainder is drained to the RB sump and pumped to the waste holdup tank for processing.

11.2.4.1.2 Floor Drain Tank

The water in the floor drain tank is sampled to determine the degree of processing required. Normally the water collected in the floor drain tank is not radioactive and can be sent directly to the waste monitor tanks. If required, it can be processed through the Waste Water System. When this water has been sufficiently processed, it is discharged into the penstocks of the Fairfield Pumped Storage Facility at a rate so as not to exceed a small fraction of the 10 CFR 20 limits. Water leaving this system is discharged to the penstocks of the Fairfield Pumped Storage Facility and is monitored for radiation. This radiation monitor, RM-L5, is described in Section 11.4. Should the radiation monitor close the discharge valve, it must be reset/bypassed before the valve can be reopened. The monitor element can be cleared by flushing it with demineralized water from the temporary connection back to the waste monitor tank. During refueling, the load on the waste portion of the LWPS is increased but there is no change in operation.

11.2.4.1.3 Laundry and Hot Shower Tank

Laundry and hot shower water enters the laundry and hot shower tank for holdup. There it is sampled, filtered, and transferred to the waste monitor tank for discharge.

11.2.4.1.4 Excess Liquid Waste Processing System (ELWS)

The excess waste holdup tank is normally only used to collect excess flow from the floor drain tank, laundry and hot shower tank, and waste holdup tank when these tanks are filled to capacity. The decontamination pit collection tank receives drainage from the Fuel Handling Building sumps, the Radiological Maintenance Building drains, excess waste holdup tank sump, excess waste holdup area sump, and decon pit drains. The contents of these tanks are sampled to determine the degree of processing required. The liquid from this tank can be released directly to the environment via the waste monitor tank or, if required, processed through the Duratek demineralizers prior to release from the plant.

When this water has been sufficiently processed, it is discharged into the penstocks of the Fairfield Pumped Storage Facility at a rate so as not to exceed a small fraction of the 10 CFR 20 limits. Water leaving this system is discharged to the penstocks of the Fairfield Pumped Storage Facility and is monitored for radiation. This radiation monitor, RM-L5, is described in Section 11.4. Should the radiation monitor close the discharge valve, it must be reset/bypassed before the valve can be reopened. The monitor element can be cleared by flushing it with demineralized water from the temporary connection back to the waste monitor tank. During refueling the load on the waste portion of the LWPS is increased but there is no change in operation.

11.2.4.1.5 Laboratory Drain Portion

The laboratory drain system consists of three sinks in the radiochemical laboratory and two sinks in the sample room.

In the radiochemical laboratory spent reactor coolant samples, equipment rinse water and other non-reactor grade fluids are disposed of in the two sinks that drain to the floor drain tank. No liquids or wastes are intentionally disposed of in the sink that drains to the chemical drain tank.

In the sample room, excess sample purges of reactor grade water and excess reactor coolant samples are drained from one sink to the waste holdup tank for processing. The other sink is used for draining non-reactor grade fluids to the nuclear blowdown holdup tank.

11.2.4.1.6 Spent Resin Handling Portion

This portion of the system sluices resin from the demineralizers, transports resin from the spent resin storage tank to the solid waste disposal unit.

11.2.4.1.6.1 Resin Sluicing

Before resin sluicing begins, the demineralizer is valved out of service and the flowpath is aligned from the spent resin sluice pump through the process line of the demineralizer, through the screen at the top of the demineralizer, and back to the spent resin storage tank. The spent resin sluice pump provides flush water for loosening the bed for sluicing. After about 15 minutes of back flushing, the valves in the back flush circuit are closed and the sluice line is opened. The resin then flows to the spent resin storage tank. After the spent resin sluice pump is shut off, the fresh resin is added via the resin fill line and the valve is then closed. The flowpath is now aligned the same as for resin flushing, e.g., through the process line, through the screen at the top of the demineralizer, and back to the spent resin storage tank. The pump is then started to remove resin fines, should any remain. The valves are then realigned for normal process operation. Resins are never sluiced through the spent resin sluice pump

11.2.4.1.6.2 Resin Drumming

No resin drumming is performed on site.

11.2.4.1.7 Analysis of System Operation

In order to evaluate the expected operation of the LWPS, an analysis has been performed presenting average operating parameters and expected isotopic concentrations throughout the system. The analysis is based on normal operation, including anticipated operational occurrences, of the plant and the LWPS and a realistic estimation of the potential input sources based on plant operating experience. Hence, the results are representative of the anticipated operation of the LWPS of the Virgil C. Summer Nuclear Station. The input sources assumed in the study are summarized in Table 11.2-7, and the isotopic concentrations are based on reactor coolant inventories as given in Table 11.1-5. The resulting isotopic concentrations at key locations in the LWPS are given in Table 11.2-1. The study is not indicative of maximum system capacity as the maximum processing capability is considerably greater than the values given in Table 11.2-7. The analysis is not used as a basis for the plant release evaluation, which is based on the GALE Code (see Section 11.2.6).

11.2.4.2 Faults of Moderate Frequency

The system is designed to handle the occurrence of equipment faults of moderate frequency such as:

1. Malfunction in the LWPS

   Malfunction in this system could include pump, valve, or demineralizer failure. Because of pump standardization throughout the system, a spare pump can be used to replace most pumps in the system. There is sufficient surge capacity in the system to accommodate waste until the failure can be fixed and normal plant operation resumed.

2. Excessive Leakage in Reactor Coolant System Equipment

   The system is designed to handle a 1 gpm reactor coolant leak in addition to the expected leakage during normal operation.

   Operation of the system is almost the same as for normal operation except the load on the system is increased. A 1 gpm leak into the reactor coolant drain tank is handled automatically.

   If the 1 gpm leak enters the waste holdup tank, operation is the same as normal except for the increased load on the demineralizers. Abnormal reactor coolant leakage can also be accommodated by the floor drain tank and processed.

   As discussed in Section 11.2.2, a practical upper limit to the Duratek demineralizer processing capacity is 25 gpm. Depending on the source of the liquid, the 25 gpm may be collected in either the floor drain tank or waste holdup tank or both tanks. Normally the potentially radioactive fluids are only collected in the waste holdup tank since the floor drain tank is typically used to collect non-radioactive leakage. If the flow is collected in both tanks, the effluent should be discharged after processing. It is possible to operate in this condition for an indefinite time.

3. Excessive Leakage in Auxiliary System Equipment

   Leakage of this type could include water from fan cooler leaks inside the Reactor Building which is collected in the Reactor Building sump and sent to the waste holdup tank. Other sources could be Component Cooling water leaks, Service Water Leaks, and steam and secondary side leaks. This water enters the floor drain tank and is processed and discharged as during normal operation.

NOTE 11.2.5

Section 11.2.5 is being retained for historical purposes only.

11.2.5 Performance Tests

Initial performance tests are performed to verify the operability of the components, instrumentation and control equipment, and applicable alarms and control setpoints.

The specific objectives are to demonstrate the following:

1. Pumps are capable of producing the flowrate and head as required.
2. Waste filters are capable of passing the required flowrate.
3. Waste evaporator is operable to specifications.
4. Instrumentation, controllers, and alarms operate satisfactorily to maintain process parameters, indicate, record, and alarm as required.
5. All sampling points are available for sampling.

During reactor operation, the system is used at all times and hence is under continuous surveillance.

11.2.6 Estimated Releases

Liquid releases from the Virgil C. Summer Nuclear Station are calculated using the PWR-GALE Code[1] as specified by Regulatory Guide 1.112 (see Appendix 3A). The input parameters used to calculate liquid releases are listed in Table 11.2-8 and are discussed in more detail below. Releases calculated using the parameters listed in Table 11.2-8 are presented in Tables 11.2-12 and 11.2-13. A comparison of effluent concentrations with 10 CFR 20, Appendix B, Table II, Column 2 values is presented in Section 11.2.8.

11.2.6.1 Reactor Grade Demineralizers

A conservatively estimated 300 gpd of reactor grade wastes are collected by the reactor coolant drain tank (equipment drain wastes).

The equipment drain wastes are processed via the reactor grade demineralizers prior to entering a waste monitor tank for monitoring and discharge. The release calculations use an assumed discharge fraction of 1.0.

Radioactive decay during collection of the equipment drains is conservatively calculated using a collection time of 2.08 days. Radioactive decay during processing is calculated using a process time of 0.11 days. No credit is taken for radioactive decay during discharge since the waste monitor tank may be discharged prior to complete processing.

The minimum expected decontamination factors for radionuclide removal with the Duratek system are 1,000 for iodine, 200 for cesium and rubidium, and 10,000 for other nuclides. These values are based upon the decontamination factors for two mixed bed and one cation demineralizer in series. In calculating the effluent releases, the above values are conservatively reduced by a factor 10.

The isotopic distribution of this release is given in Table 11.2-12.

11.2.6.2 Liquid Waste Processing System

11.2.6.2.1 Waste Holdup Tank

Wastes from reactor grade sample drains, valve and pump leakoffs, and equipment drains outside the Reactor Building (clean wastes) are collected in the 10,000 gallon waste holdup tank and processed through the Waste Water System. The processed wastes are pumped to a waste monitor tank for monitoring and discharge or additional processing, if required. Based upon the information in (Reference 1) for liquid waste volumes and activities and on expected volumes and activities for liquid wastes not included in (Reference 1), the total flow is conservatively estimated to be 200 gpd at primary coolant activity (PCA). The release calculations conservatively use a discharge fraction of 1.0.

Radioactive decay during collection in the waste holdup tank is calculated using a collection time of 2.08 days. This value is based upon filling the waste holdup tank to 40 percent of capacity. Radioactive decay during processing is calculated using a process time of 0.11 days. This value is based upon processing 80 percent of the waste holdup tank capacity at the design flow rate of 25 gpm. No credit is taken for radioactive decay during discharge since the waste monitor tank may be discharged before the waste holdup tank is completely processed.

The minimum expected decontamination factors for radionuclide removal with the Waste Water System are 1,000 for iodine, 200 for cesium and rubidium, and 10,000 for other nuclides. These values are based upon the decontamination factors for two mixed bed and one cation demineralizer in series. In calculating the effluent releases, the above values are conservatively reduced by a factor of 10.

The isotopic distribution of this release is given in Table 11.2-12.

11.2.6.2.2 Floor Drain Tank

Wastes from floor drains, laboratory drains, and miscellaneous sources are collected in a 10,000 gallon floor drain tank, sampled to determine the degree of processing required and processed as necessary through the Waste Water System. The processed wastes are then pumped to a waste monitor tank for monitoring and discharge. Based upon the information in Reference 1 for liquid waste volumes and activities, the waste flow is estimated to be 1340 gpd at 0.05 PCA. Since all of the processed wastes are normally discharged, a discharge fraction of 1.0 is used in the release calculations.

Radioactive decay during collection in the floor drain tank is calculated using a collection time of 2.97 days. This value is based upon filling the floor drain tank to 40 percent of capacity. Radioactive decay during processing is calculated using process time of 0.11 day. This value is based upon processing 80 percent of the floor drain tank capacity at the design flow rate of 25 gpm. No credit is taken for radioactive decay during discharge since the waste monitor tank may be discharged before the floor drain tank is completely processed.

The minimum expected decontamination factors for radionuclide removal with the Waste Water System are 1,000 for iodine, 200 for cesium and rubidium, and 10,000 for other nuclides. These values are based upon the decontamination factors given in Reference 1 for two mixed bed and one cation demineralizer in series. In calculating the effluent releases, the above values are conservatively reduced by a factor 10.

The isotopic distribution of this release is given in Table 11.2-12.

11.2.6.3 Detergent Wastes

The plant typically ships all protective clothing off site for cleaning. There is a washer and dryer located in the HP area that is periodically used to clean personal garments. The potential release from this mechanism is considered negligible. Therefore, since there are no full scale onsite laundry facilities, consistent with the assumptions in the PWR-GALE Code (Reference 1), there are no releases assumed from this pathway.

11.2.6.4 Secondary System

11.2.6.4.1 Turbine Building Floor Drains

The discharge from the Turbine Building Floor Drain System is monitored by a flow meter and a radiation monitor since wastes collected by the Turbine Building Floor Drain System may contain small quantities of radioactive materials resulting from secondary system leakage. These wastes are not treated prior to discharge. The isotopic distribution of this release is given in Table 11.2-12.

The discharge flow is monitored by radiation monitor number RM-L8. If radiation discharge limits are exceeded, the sump pumps are automatically tripped and the flow path may be aligned to discharge to the Excess Liquid Waste System per plant procedure HPP-710.

11.2.6.4.2 Condensate Cleanup System

The Condensate Cleanup System is used during startup and as required during condenser leakage. Scheduled, infrequent operation minimizes the possibility of producing potentially radioactive waste. Based upon PWR-GALE Code (Reference 1) criteria and infrequent operation, polishers will have no impact on release calculations.

11.2.6.4.3 Steam Generator Blowdown

Blowdown from the steam generators is processed as required through the NBS and returned to the condenser. There are also provisions for the discharge of treated or untreated blowdown. If the blowdown contains any significant quantity of radioactivity, radiation-monitor-controlled valves automatically divert the blowdown flow to the NBS.

With the 100 lbs/day primary-to-secondary leakage used in the PWR-GALE Code (Reference 1), blowdown flow would always be diverted to the NBS. Consequently, release calculations were performed on this basis.

Blowdown that is to be processed through the NBS is routed to a 14,000 gallon holdup tank and is processed through one of two demineralizer trains, each containing a mixed bed primary demineralizer and a mixed bed polishing demineralizer. Release calculations are based upon processing 45,000 lbs/hr of blowdown through one of the demineralizer trains and discharging 100 percent of the treated blowdown.

Radioactive decay during collection in the holdup tank is calculated using a collection time of 0.01 day. This value is based upon filling the holdup tank to 40 percent capacity. No credit is taken for radioactive decay during processing or discharge.

The decontamination factors used in calculating radionuclide removal are 1,000 for iodine, 100 for cesium and rubidium, and 1,000 for other nuclides. These values are based upon the decontamination factors given in Reference 1 for two steam generator blowdown mixed bed demineralizers in series.

The isotopic distribution of this release is given in Table 11.2-12.

11.2.6.5 Adjustments to Liquid Radwaste Source Term for Anticipated Operational Occurrences

The PWR-GALE Code (Reference 1) increases the calculated source term by 0.15 Ci/yr per reactor using the same isotopic distribution as the calculated source term to account for anticipated operational occurrences. This adjustment, plus the calculated tritium release, results in the releases given in Table 11.2-12.

11.2.6.6 Criteria for Reuse, Discharge, and Recycle

Processed liquids are normally discharged under the following conditions:

1. The processed water does not satisfy plant operating requirements for water quality and tritium buildup.
2. The effluent concentrations are within the limits specified by 10 CFR 20, Appendix B, Table II, Column 2.
3. The discharge does not cause the limits of 10 CFR 50, Appendix I to be exceeded.

Processed liquids could be reused within the plant if desired, provided that the following criteria are satisfied:

1. The plant water inventory requires makeup.
2. The water to be reused satisfies system water quality requirements.
3. Tritium buildup is less than plant operating requirements.

11.2.7 Release Points

Flow diagrams for the systems which have the potential to release radioactive materials in liquid effluents are shown by Figures 9.3-14, 9.3-18, 10.4-7a, 10.4-13, 10.4-14, 10.4-17. The locations of the release points for three systems are as follows:

Releases from the LWPS (Figure 11.2-1) and Reactor Grade System (Figure 9.3-18) are made through waste monitor tank 1 or 2 in the LWPS. Releases of detergent wastes are made through waste monitor tank 2 in the LWPS. Releases from the waste monitor tanks are piped to the penstocks of the Fairfield Pumped Storage Facility where they are diluted by the water released to the Broad River during the generating portion of the pumped hydro cycle. Planned liquid releases are made only during the generating portion of the cycle. Figure 11.2-3 shows the location of this release point relative to the plant site. Figure 11.2-4 is a close-up of the facility.

If processed steam generator blowdown (see Figure 10.4-14) is released to the environment, it is piped to the penstocks of the Fairfield Pumped Storage Facility where it is diluted by the water released through the dam during the generating portion of the cycle. If unprocessed steam generator blowdown (see Figure 10.4-13) is released to the environment, it is released through the circulating water discharge canal. During startup, blowdown may be routed to the alum sludge lagoon in the Industrial Waste System. Releases from this system are routed to the discharge canal by a 24 inch pipe which terminates at the circulating water discharge structure. The circulating water discharge canal is shown by Figure 2.4-1.

Liquid effluents from the Turbine Building floor drains (Figure 9.3-15) are released through a collecting sump in the Industrial Waste System which, when discharged, is routed to the circulating water discharge canal.

11.2.8 Dilution Factors

Concentrations of radioactive effluents in waters affected by operation of the plant were calculated according to the methods set forth in Regulatory Guide 1.113. The specific rationale utilized is as follows.

During the daily generating phase of the Fairfield Pumped Storage Facility, 29,000 acre-feet of water from Monticello Reservoir will flow into Parr Reservoir. A similar amount will later be pumped back into Monticello Reservoir during periods of off-peak power demand; this volume of water is equivalent to 14,620 cfs over a 24 hour period. In contrast, the average stream flow of the Broad River at Parr Dam is about 5,600 cfs, amounting to less than 40 percent of the daily volume

of water exchanged. Thus, mixing between the two reservoirs is expected to be relatively complete. This expectation has been confirmed by physical model studies conducted by Alden Research Laboratories (Reference 2) which indicate that effluents present in the plant discharge achieve nearly equal steady-state concentrations throughout the Parr-Monticello system. Therefore, it is preferable to consider the system as a single reservoir unit for the purposes of aquatic modeling. Several analytical models suitable for use in simulation of reservoirs and cooling ponds are described in Appendix A, Section 5, of Regulatory Guide 1.113. For the Parr-Monticello system, the pond blowdown rate, Q_b, is equivalent to the flow rate of the Broad River. A flow rate of 5,600 cfs, equal to the average stream flow of the Broad River at Parr Dam, was used. The plant pumping rate, Q_p, is the plant condenser water recirculation rate. A flow rate of 480,000 gpm, or 1,069 cfs, was utilized as an appropriate value under average conditions. The resulting recirculation factor, R, is determined by the ratio Q_b/Q_p and has a value of 5.24. Review of Figure 12 from Regulatory Guide 1.113 shows that, with the above determined values of 5.24 for R and a flushing time, Vt/Q_b, of 36.2 days, the partially mixed flow model approaches the plug flow model for relatively long lived isotopes. Conservatively ignoring credit for radiological decay and use of the plug flow model is conservative for short lived isotopes.

Therefore, conservatively ignoring radiological decay, the dilution factor simply relates to the final flow or 5,600 cfs, equal to the average stream flow of the Broad River at Parr Dam (FSAR Table 2.4-3).

In addition to the limits for each isotope, the requirements of 10 CFR 20 state that, for a mixture of radionuclide, the following relationship must hold:

$$\sum_{i=1}^{N} \frac{C_i}{ECiL} \leq 1$$

where:

C_i = concentration of radionuclide I.
EC_iL = effluent concentration limit (ECL) of radionuclide i from 10 CFR 20, Appendix B, Table II, Column 2.
N = number of radionuclides in the mixture.

The sum of the ratios of expected radionuclide concentrations to their ECL values for the mixture defined by the second column of Table 11.2-13 is 6.8×10^{-4}, which is less than unity, as required.

11.2.9 Estimated Doses

Potential pathways of exposure of man to radioactive materials in liquid effluents from the Virgil C. Summer Nuclear Station are identified and discussed in Section 11.6.2. Doses to individuals in the environs of the plant from each of the potentially significant pathways were calculated; methodology for and results of the calculations are discussed in the following paragraphs.

All results presented in these sections were obtained using the calculational techniques prescribed in Regulatory Guide 1.109. Except where noted in discussion of doses for specific pathways, all usage and consumption values, transport times, bioaccumulation factors, dose conversion factors, and other constants utilized were those suggested in Regulatory Guide 1.109.

Dilution factors for liquid pathways were calculated according to the methods of Regulatory Guide 1.113, as discussed in Section 11.2.8.

Doses to individuals were calculated for drinking water, fish consumption, and recreational activity (swimming, boating, shoreline activity) pathways. Assumptions, including point of exposure, are described for each pathway in the following paragraphs; the calculated liquid pathway doses are summarized in Table 11.2-14. Each dose was calculated at the location of the highest dose offsite at which the pathway could be assumed to exist.

The nearest downstream point of withdrawal of drinking water for human use is at Columbia, S. C., where the city of Columbia water supply system utilizes water from the Broad River. The dose to an individual obtaining his entire annual water requirement from this system was calculated. The maximum calculated dose to a single organ from this pathway was 1.4×10^{-1} mrem/yr to an infant's liver; maximum whole body dose was 4.6×10^{-2} mrem/yr to an adult.

Radionuclides released from the plant were assumed to be immediately available for uptake by fish. For purposes of determining the annual dose to man from the fish consumption pathway, a transport time of 0 hours was used. The maximum predicted dose to a single organ from the fish consumption pathway was 3.3 mrem/yr to a teen's liver. Maximum total body dose was 1.35 mrem/yr to a teen.

Exposure to an adult swimming or boating on the reservoir or engaging in recreational activity on the shore was evaluated by assuming that the individual receiving the maximum dose spends 100, 500, and 500 hours per year, respectively, in the three activities. Doses from these pathways were evaluated based on the average radionuclide concentrations in the Parr-Monticello system. The doses from recreational exposure are summarized in Table 11.2-15. Maximum predicted total dose to a single organ from recreational pathways was 0.15 mrem/yr to the skin. Maximum calculated total body dose was 0.12 mrem/yr.

Maximum individual doses calculated as described above were used to evaluate the status of conformance of predicted liquid effluents from the Virgil C. Summer Nuclear Station with the requirements of Appendix I to 10 CFR 50. The assumptions and results of this evaluation are summarized in Table 11.2-15. It will be noted that the calculated doses indicate that liquid effluents from the plant will conform to the "as low as reasonably achievable" criteria established in Appendix I.

(4) System modeled with first three components in Duratek processing system (Charcoal processing, mixed bed resin demineralizer, and cation demineralizer). No credit taken for additional removal prior to waste monitor tank.
(5) Activity values based on 50% waste holdup tank processing and 50% floor drain tank processing.

Usable volume, gallons	10,000
Type	Vertical
Design pressure, psig	Atmosphere
Design temperature, °F	200
Material	Stainless Steel
Diaphragm	No
DEMINERALIZERS	
1. Waste Evaporator Condensate Demineralizer	
Number	1
Type	Flushable
Design pressure, psig	150
Design temperature, °F	200
Design flow, gpm	35
Resin volume, ft^3	NA
Material	Stainless Steel
Purification media	None
Design process decontamination factor	NA
2. Waste Monitor Tank Demineralizer	
Number	1
Type	Flushable
Design pressure, psig	150
Design temperature, °F	200
Design flow, gpm	35
Resin volume, ft^3	30
Material	Stainless Steel
Purification media	Anion and/or cation exchange resins as required
Design process decontamination factor	10
3. Excess Liquid Waste Demineralizers	
Number	2
Type	Flushable
Design pressure, psig	150
Design temperature, °F	200
Design flow, gpm	35
Resin volume, ft^3	30
Material	Stainless Steel
Purification media	Anion and/or cation exchange resins as required

Table 11.2-2 (continued)
Equipment Principal Design Parameters

Component	
4. Duratek Demineralizer Vessels	
Number	5
Type	Flushable
Design pressure, psig	150
Design temperature, °F	200
Design flow, gpm	25
Resin volume, ft^3	19.5 to 45
Material	Stainless Steel
Purification media	Charcoal Bed, Mixed Bed, and/or cation exchange resins as required
5. Polishing Vessel	
Number	1
Type	Flushable
Design pressure, psig	150
Design temperature, °F	200
Design flow, gpm	25
Resin volume, ft^3	30
Material	Stainless Steel
Purification media	Mixed Bed and Cation
FILTERS	
1. Waste Evaporator Condensate Filter	
Number	1
Design pressure, psig	150
Design temperature, °F	200
Design flow, gpm	35
ΔP at design flow, psi	≈5
Size of particles, 98% ret., microns (nominal)	≤25
Materials	
Housing	Stainless Steel
Filter element	EICF (5)

Table 11.2-2 (continued)
Equipment Principal Design Parameters

	Component	
2.	Spent Resin Sluice Filter	
	Number	1
	Design pressure, psig	150
	Design temperature, °F	200
	Design flow, gpm	250
	ΔP at design flow, psi	≈5
	Size of particles, 98% ret., microns (nominal)	≤25
	Surface radiation level, R/hr	100
	Materials	
	Housing	Stainless Steel
	Filter element	EICF (5)
3.	Laundry and Hot Shower Tank Filter	
	Number	1
	Design pressure, psig	150
	Design temperature, °F	200
	Design flow, gpm	35
	ΔP at design flow, psi	≈5
	Size of particles, 98% ret., microns (nominal)	≤25
	Surface radiation level, R/hr	100
	Materials	
	Housing	Stainless Steel
	Filter element	EICF (5)
4.	Floor Drain Tank Filter	
	Number	1
	Design pressure, psig	150
	Design temperature, °F	200
	Design flow, gpm	35
	ΔP at design flow, psi	≈5
	Size of particles, 98% ret., microns (nominal)	≤25
	Surface radiation level, R/hr	100
	Materials	
	Housing	Stainless Steel
	Filter element	EICF

Table 11.2-2 (continued)
Equipment Principal Design Parameters

Component	
5. Waste Monitor Tank Filter	
Number	1
Design pressure, psig	150
Design temperature, °F	200
Design flow, gpm	35
ΔP at design flow, psi	≈5
Size of particles, 98% ret., microns (nominal)	≤25
Surface radiation level, R/hr	90
Materials	
Housing	Stainless Steel
Filter element	EICF
6. Excess Liquid Waste Filters	
Number	2
Design pressure, psig	150
Design temperature, °F	200
Design flow, gpm	35
ΔP at design flow, psi	<5
Size of particles, 98% ret., microns (nominal)	20
Surface radiation level, mR/hr	<100
Materials	
Housing	Stainless Steel
Filter element	Stainless Steel
STRAINERS	
1. Laundry and Hot Shower Tank Strainer	
Number	1
Type	Basket
Design pressure, psig	150
Design temperature, °F	200
Design flow, gpm	35
ΔP at design flow, psi	0.2 (Estimated)
Nominal rating, inch	0.0625
Surface radiation level	Negligible
Materials	Stainless Steel

Table 11.2-2 (continued)
Equipment Principal Design Parameters

	Component	
2.	Floor Drain Tank Strainer	
	Number	1
	Type	Basket
	Design pressure, psig	150
	Design temperature, °F	200
	Design flow, gpm	35
	ΔP at design flow, psi	0.2 (Estimated)
	Nominal rating, inch	0.0625
	Surface radiation level	Negligible
	Materials	Stainless Steel
3.	Decontamination Pit Collection Tank Strainer	
	Number	1
	Type	Duplex Basket
	Design pressure, psig	150
	Design temperature, °F	200
	Design flow, gpm	350
	Nominal rating, inch	0.015
	Materials	Stainless Steel
EVAPORATORS		
1.	Waste Evaporator **(No Longer in Service)**	
	Number	1
	Design flow, gpm	15
	Feed conc., ppm boron	10 - 2500
	Bottoms conc., ppm boron	7000 - 21,000
	Design process decontamination factor	1000
	Steam design pressure, psig	50

(1) Also serves as spent resin sluice pump.
(2) Also serves as reactor coolant drain tank pump.
(3) External design pressure - 60 psig.
(4) Total for resin and liquid.
(5) Epoxy Impregnated Cellulose Fiber or glass fiber.

* Normal discharge path for Laundry and Hot Shower Tank - No significant activity.
** Not calculated.
*** Excess Waste Holdup is not normally used. If used, the estimated inventories would be similar to the Waste Holdup Tank.
**** Estimated inventories would be similar to the Floor Drain Tank.

Table 11.2-4
Range of Measured Demineralizer Decontamination Factors for Selected Isotopes

Isotope	Minimum	Maximum
I-131	$1.1.x\ 10^{1}$	1.6×10^{4}
I-133	1.1×10^{1}	1.8×10^{4}
I-135	1.4×10^{1}	2.0×10^{4}
Cs-137	2.4	1.3×10^{3}
F-18	1.73×10^{1}	1.5×10^{3}
Co-58	3.2×10^{1}	8.2×10^{3}
Mn-54	$> 2.5 \times 10^{1}$	$> 1.3 \times 10^{2}$

Note: Mixed bed demineralizers cation resin in lithium^{-7} form, anion resin in borated form.

Notes:

(1) Location
AB - Auxiliary Building
FB - Fuel Handling Building
YD - Yard; refueling water storage and reactor makeup water tanks are in an outdoor extension of the Auxiliary Building
(2) C - Conforms to ETSB 11-1 (Rev. 1)
NC - Does not conform to ETSB 11-1 (Rev. 1)

Table 11.2-7
Parameters Used in the Calculation of Estimated
Activity in Liquid Wastes(1)

Collector Tank With Sources	Volume of Liquid Waste	Collection Period Assumed Before Processing	Comments
Reactor Coolant Drain Tank Waste Holdup Tank (1)			
1. Shim Bleeds	500 gal/day		
2. Equipment drains	100 gal/day		
3. WHT inputs	75 gal/day		
Total	675 gal/day	6.0 days	Discharged
Floor Drain Tank (1)			
1. FDT inputs	450 gal/day	8.8 days	Discharged
Total	410,100 gal/yr		

(1) This table does not represent system capacity. The estimated waste processing system capacity based on indefinite operation for liquids collected in the floor drain tank and waste holdup tank is 25 gpm or approximately 12,500,000 gal/yr.

Table 11.2-8
(Sheet 1)

PWR-GALE Code Input Parameters Used in Calculating Releases
of Radioactive Materials in Liquid Effluents

Reactor Power Level, MWt	2900
Primary System	
Mass of Primary Coolant, thousand lbs	377.9
Average Letdown Rate, gpm	105
Average Letdown Cation Demineralizer Flow Rate, gpm	10.5
Secondary System	
Steam Flow Rate, million lbs/hr	12.85
Mass of Steam/Steam Generator, thousand lbs	7.407
Mass of Liquid/Steam Generator, thousand lbs	109
Mass of Secondary Coolant, thousand lbs	2220
Steam Generator Blowdown Rate, thousand lbs/hr	45
Steam Generator Blowdown Treatment Option	See Section 11.2.6.4.3

Table 11.2-8 (continued)
(Sheet 2)

PWR-GALE Code Input Parameters Used in Calculating Releases
of Radioactive Materials in Liquid Effluents

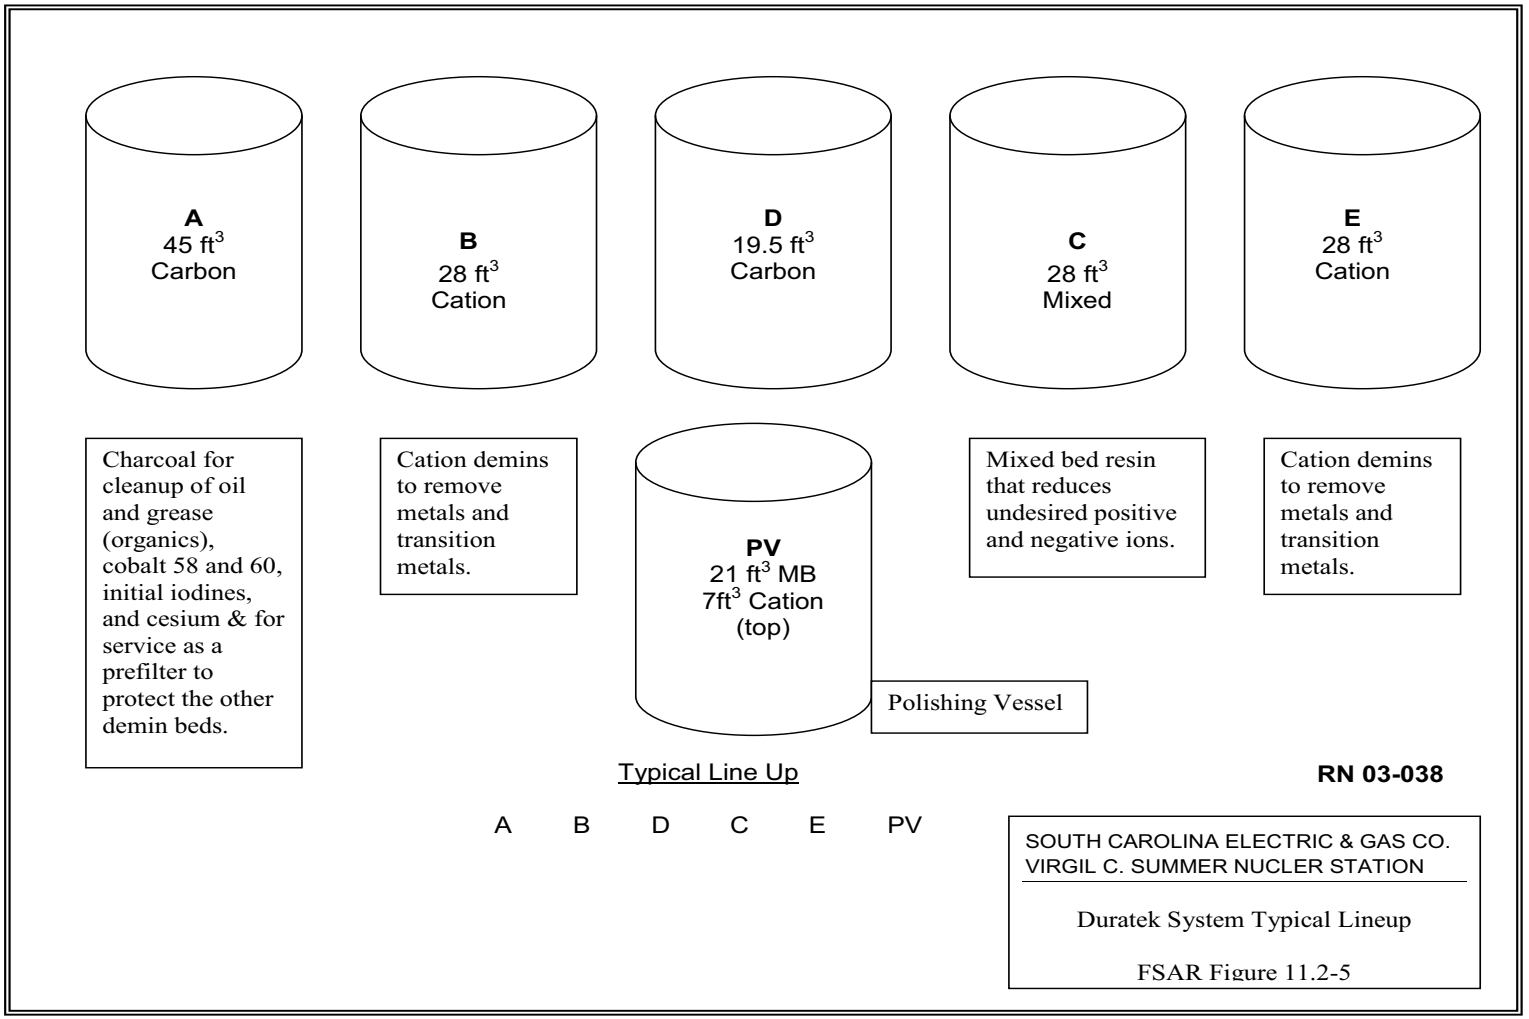
DURATEK SYSTEM TYPICAL LINEUP



11.3 Gaseous Waste System

11.3.1 Design Objectives

The Gaseous Waste Processing System (GWPS) is designed to remove fission product gases from the reactor coolant in the volume control tank. The system is also designed to collect gases from the boron recycle and waste evaporators, reactor coolant drain tank, recycle holdup tanks, and reactor vessel. The system has the capacity for long term storage.

Under normal operation, the annual releases due to leakage and routine releases from the GWPS will be sufficiently low such that site boundary doses will be a small fraction of regulation requirements.

The system is capable of operating under conditions of fuel defects in combination with equipment faults of moderate frequency.

The system is designed to preclude the possibility of an internal explosion. However, the system volume is distributed so that the dose in the unlikely event of an explosion is approximately the same as the dose due to a gas decay tank rupture as analyzed in Section 15.3.5.

11.3.2 System Description

The GWPS consists mainly of a closed loop comprised of two waste gas compressors, two catalytic hydrogen recombiners, and gas decay tanks to accumulate the fission product gases. The routing of piping containing radioactive gases is either through shielded cubicles or behind shield slabs.

NOTE:

The following paragraph is being retained for historical purposes only.

Components of a similar design to those used in the GWPS have been operating for several years with excellent performance. Systems constructed from carbon steel have been in service for more than three years and no failure due to corrosion damage has been reported.

The major input to the GWPS during normal operation is taken from the gas space in the volume control tank.

Table 11.3-1, based on the Reactor Coolant System activities given in Table 11.1-2, shows the maximum fission product inventory in the GWPS over the 40 year plant life. Table 11.3-2, based on the Reactor Coolant System activities given in Table 11.1-5, shows the expected fission product inventory in the GWPS over the 40 year life.

Figure 11.3-1, based on the reactor coolant activities given in Table 11.1-2, shows that for a given power rating with 1% fuel defects, the quantity of fission gas activity accumulated after 40 years continuous operation is about twice the activity accumulated after short term operation.
Figure 11.3-2, based on realistic reactor coolant activities given in Table 11.1-5, shows that the

quantity of fission gas activity accumulated after 40 years continuous operation is essentially Krypton-85 with the short lived isotopes contributing approximately 12% of the total. This is because the accumulated activity other than Krypton-85 arises from short lived isotopes which reach equilibrium after a short operating period.

This accumulation of Krypton-85 is not a hazard to the plant operator because:

1. Radiation background levels in the plant are not noticeably affected by the accumulation of Krypton-85 which is a beta emitter, for which the tanks themselves provide adequate shielding.
2. The system activity inventory is distributed in several tanks so that the maximum permissible inventory in any single tank is actually less than that of earlier GWPS designs.

Since this system permits fission gas removal from the reactor coolant during normal operation, it is expected to reduce plant activity levels caused by a leakage of reactor coolant. With operation of this system, it is possible to collect virtually all of the Krypton-85 released to the reactor coolant and to achieve a reduction in the fission product gas inventory in the Reactor Coolant System as shown in Table 11.3-3. Table 11.3-3 is based on the Reactor Coolant System activities given in Table 11.1-1. Provisions are made to collect any residual gases stripped out of solution by the boron recycle and waste evaporators, gases from the reactor coolant drain tank, gases from the recycle holdup tanks, and gases from the reactor vessel.

Process flow diagrams and piping and instrumentation diagrams are shown on Figures 11.3-3 and 11.3-4, respectively. Table 11.3-4 gives process parameters for key locations in the system, with reference to locations on Figure 11.3-3 and based on the Reactor Coolant System activities given in Table 11.1-5.

The process parameters are derived assuming the system to operate as described in Section 11.3.4. The stripping efficiency used in the analysis is 0.4, and the volume control tank purge rate is 0.7 scfm of hydrogen.

11.3.3 System Design

11.3.3.1 Component Design

Gaseous waste processing equipment parameters are given in Table 11.3-5. Component safety classes and the corresponding code and code class are shown in Table 3.2-1. All materials used for pressure retaining components are allowed by Section III of the ASME Code, and no malleable wrought or cast iron or plastic pipe is used.

Quality assurance requirements of Westinghouse Administrative Specifications for the Procurement of Nuclear Steam Supply System Components, Revision 5, March 1975 are applied to all NNS components within Westinghouse scope. Hence, all components within Westinghouse scope meet the design guidance as outlined in Branch Technical Position ETSB 11-1.

11.3.3.1.1 Waste Gas Compressor Packages

Two waste gas compressor packages are provided to circulate gases around the system loop. One unit is normally used with the other on a standby basis.

The units are water-sealed centrifugal displacement machines which are skid-mounted in a self-contained package. Construction is primarily of carbon steel. Mechanical seals are provided to minimize the out-leakage of seal water.

11.3.3.1.2 Catalytic Hydrogen Recombiner Packages

Two catalytic hydrogen recombiners are provided. One of the two recombiners is normally used to remove hydrogen from the hydrogen-nitrogen-fission gas mixtures by oxidation to water vapor, which is removed by condensation. The other recombiner is available on a standby basis. Both units are self-contained and designed for continuous operation. The recombiner is located in the system where the hydrogen concentration and pressure are optimum with respect to hydrogen removal.

11.3.3.1.3 Waste Gas Decay Tanks

Waste gas decay tanks are provided as described in Table 11.3-5. The tanks are of vertical-cylindrical type and are constructed of carbon steel. There are eight waste gas decay tanks, six are used during normal operation while the remaining two are used for shutdown and startup.

11.3.3.1.4 Valves

Each valve in the recombiner system is designed to meet the temperature, pressure, and code requirements for the specific application in which it is used. The recombiner circuits contain manual valves provided with a metal diaphragm to prevent stem leakage and control valves with gaseous leakoffs returned to the GWPS. Other parts of the GWPS use control valves with bellows seal. Relief valves have soft seats and operate at pressures which are normally less than 2/3 of the relief valve set pressure. The relief valves of the major components discharge to the shutdown tanks. This permits decay and controlled disposal of all discharges less than about 3000 scf. It also provides a means for containing and detecting seat leakage across the relief valves.

11.3.3.2 Instrumentation and Control Design

The main system instrumentation is described in Table 11.3-6 and shown on the piping and instrumentation diagrams, Figure 11.3-4.

The instrumentation readout is located mainly on the Waste Processing System (WPS) panel in the Auxiliary Building. Some instruments are read near the equipment location.

All alarms are shown separately on the WPS panel and further relayed to one common WPS annunciator on the main control board.

Where suitable, instrument lines are provided with diaphragm seals to prevent fission gas outleakage through the instrument.

Figure 11.3-5 shows the location of the instruments on the compressor package.

The compressors are interlocked with the seal water inventory in the moisture separators and trip off on either a high or a low moisture separator level. During normal operation, the proper seal water inventory is maintained automatically.

Figure 11.3-6 indicates the location of the instruments on the recombiner installation.

The catalytic hydrogen recombiner packages are designed for automatic operation with a minimum of operator attention. Each package includes four online gas analyzers, one each to measure hydrogen in, oxygen in, hydrogen out, and oxygen out, which are the primary means of recombiner control. A multipoint temperature recorder monitors temperatures at several locations in the packages.

Process gas flowrate is measured by an orifice located upstream of the recombiner preheater. Local pressure gauges indicate pressure at the recombiner inlet and the oxygen supply pressure.

The following controls and alarms are incorporated to maintain the gas composition outside the range of flammable and explosive mixtures:

1. A high flow alarm actuates when the volume control tank purge flow exceeds a predetermined value. This high flow alarm is set below the flow which corresponds to the maximum inlet concentration (6% hydrogen by volume) the recombiner can process in one pass.
2. If the hydrogen concentration in the recombiner feed exceeds 4% by volume, a high hydrogen and high-high hydrogen/oxygen shutdown alarm sounds, the oxygen feed is terminated through TCV01114, and the volume control tank hydrogen purge flow is terminated. The control and alarm setpoints were lowered to a identical setpoint of 4% by volume to limit the possible accumulation of hydrogen in the system to 4% by volume for compliance with Technical Specifications.
3. If the oxygen concentration in the recombiner feed reaches 2% by volume, a high oxygen and high-high oxygen/shutdown alarm sounds, oxygen feed flow is limited through HCV01118, and the oxygen feed is terminated through TCV01114. The control and alarm setpoints were lowered to a identical setpoint of 2% by volume which is below the flammable limit for hydrogen-oxygen mixtures for Technical Specifications compliance.
4. If hydrogen in the recombiner discharge exceeds 0.15% by volume, an alarm sounds. This alarm warns of high hydrogen feed, possible hydrogen-oxygen catalytic reactor malfunction, or loss of oxygen feed.
5. If oxygen in the recombiner discharge exceeds 60 ppm, an alarm sounds and oxygen feed is terminated. This control prevents any accumulation of oxygen in the system in case of catalytic reactor malfunction.

6. On low flow through the recombiner, oxygen feed is terminated. This control prevents an accumulation of oxygen following system malfunction.
7. High discharge temperature from the cooler-condenser (downstream from the catalytic reactor) will terminate oxygen feed. This protects against loss of cooling water flow in the cooler-condenser.
8. High temperature indication by any one of six thermocouples in the catalyst bed will limit oxygen feed so that no further increase is possible.
9. High temperature indication at the recombiner catalytic reactor discharge will terminate oxygen feed to the recombiner.

11.3.4 Operating Procedures

11.3.4.1 General Description

The GWPS is a closed loop comprised of two waste gas compressors, two catalytic hydrogen recombiners, six gas decay tanks for normal power service, two gas decay tanks for service at shutdown and startup, one gas decay tank drain pump, one waste gas drain filter, and four gas traps. All of the equipment is located in the Auxiliary Building.

11.3.4.2 Startup Operation

Startup commences with the system flushed free of air by purging with nitrogen which is discharged to the atmosphere. One compressor, one recombiner, and one shutdown decay tank are in service. The reactor is at cold shutdown and the volume control tank contains nitrogen in the gas space. Reactor coolant contains neither hydrogen nor fission gases, but it may be saturated with air.

When the reactor startup procedure requires that a hydrogen blanket be established in the volume control tank gas space, fresh hydrogen is charged into the tank. The hydrogen-nitrogen mixture vented from the tank enters the circulating nitrogen stream at the compressor suction. Since the pressure downstream remains constant by use of a pressure regulating valve, nitrogen added to the loop will accumulate in the shutdown decay tank causing the tank pressure to rise.

Initially, the volume control tank vent gas will be very lean in hydrogen, and almost all the influent gas will accumulate in the tank. As the operation continues, however, the vent gas hydrogen content will gradually increase until it is almost totally hydrogen at the point when all of the nitrogen has been removed from the coolant. At that time, hydrogen gas is entering the volume control tank at 0.7 scfm and mixing with the 40 scfm circulating nitrogen stream to give a 1.8 volume% mixture of hydrogen in nitrogen at the recombiner inlet. Approximately 0.35 scfm of oxygen is added in the recombiner and reacted with the hydrogen to yield a discharge stream of 0.1 volume% hydrogen in nitrogen after water vapor is condensed.

When the reactor coolant nitrogen concentration is within operating specifications, the shutdown tank is isolated and flow is routed to one of the decay tanks provided for normal power service.

Gas accumulated in the shutdown tank will be retained for use during operations to strip hydrogen from the reactor coolant when the plant is shut down.

11.3.4.3 Normal Operations

During normal power operation, nitrogen gas is continuously circulated around the loop by one of the two compressors. Fresh hydrogen gas is charged to the volume control tank where it is mixed with fission gases which are stripped from the reactor coolant into the tank gas space. The contaminated hydrogen gas is then vented from the tank into the circulating nitrogen stream to transport the fission gases into the GWPS. The resulting mixture of nitrogen-hydrogen-fission gas is pumped by the compressor to the recombiner where enough oxygen is added to reduce the hydrogen to a low residual level by oxidation to water vapor on a catalytic surface. After the water vapor is removed, the resulting gas stream is circulated to the waste gas decay tanks and back to the compressor suction to complete the loop circuit.

Each waste gas decay tank is capable of being isolated and the number of tanks valved into operation at any time is restricted to diminish the amount of radioactive gases which could be released as a consequence of any single failure, such as the rupture of any single tank or connected piping. By alternating use of these tanks, the accumulated activity is distributed among the tanks.

11.3.4.4 Shutdown

When the hydrogen contained in the reactor coolant must be removed in preparation for a cold shutdown, the normal gas decay tanks are valved out of service and one of the two shutdown tanks is placed in service. Additional nitrogen may have to be added to raise the shutdown tank to an acceptable pressure for this operation. In addition, the flow of hydrogen to the volume control tank is stopped, and the tank pressure is maintained with nitrogen. The volume control tank level may be raised and lowered to aid in hydrogen removal. Once the hydrogen concentration has been lowered to acceptable levels, the volume control tank purge to the waste gas system may be secured.

11.3.5 Performance Tests

NOTE:

The following paragraph is being retained for historical purposes only.

Compressor and recombiner packages are subjected to helium leak test after assembly. Initial performance tests are performed to verify the operability of the components, instrumentation, and control equipment.

During reactor operation, the system is in use and hence is under continuous surveillance. The system design permits the use of industry standard leak detection methods for leak testing and subsequent elimination of leaks.

11.3.6 Estimated Releases

Gaseous releases from the Virgil C. Summer Nuclear Station were calculated using the PWR-GALE Code[1] as specified in Regulatory Guide 1.112 (see Appendix 3A). The input parameters used to calculate gaseous releases are listed in Table 11.3-7 and are discussed in more detail in Sections 11.3.6.2 through 11.3.6.4. Calculated releases using the parameters listed in Table 11.3-7 are presented in Table 11.3-8. A comparison of effluent concentrations with 10 CFR 20, Appendix B, Table 2, Column 1 is presented in Section 11.3.8.

11.3.6.1 Gaseous Waste Processing System

The GWPS collects and stores gases stripped from the primary coolant in a continuously recirculating loop which includes pressurized storage tanks. Release calculations for the GWPS are based upon the options allowed by the PWR-GALE Code[1] for such a system (continuous purging of Volume Control Tank, 90 days decay time in storage tanks, zero day fill time). Using these options and the input parameters given in Table 11.3-7, the GWPS releases are calculated to be 214 Ci/yr of noble gases, 4×10^{-4} Ci/yr of airborne particulates, and 7 Ci/yr of Carbon-14. The isotopic distribution of these releases is given in Table 11.3-8.

11.3.6.2 Reactor Building Purge

Radioactive gases are released inside the Reactor Building when primary system components are opened or if leakage from the primary system occurs. The gaseous activity inside the Reactor Building may be purged up to 1000 hours per year in Modes 1-4 by the 6 inch low volume purge system. The low volume purge rate is 600 cfm. Activity is also released periodically when the 36 inch Reactor Building Purge System is used during Modes 5-6. The Reactor Building Charcoal Cleanup System is operated intermittently to reduce airborne iodine concentrations prior to Reactor Building access or purge system operation. The Reactor Building 36 inch and 6 inch purge flow is exhausted to the atmosphere through HEPA filters and charcoal adsorbers. Release calculations are based upon the PWR-GALE Code (Reference 1) parameters for leakage rate (1%/day of primary coolant noble gas inventory, 0.001%/day of primary coolant iodine inventory), recirculation cleanup time (16 hours), mixing efficiency (70%), decontamination factors (100 for HEPA filters, 10 for charcoal adsorbers) and number of high volume purges (36 inch during cold shutdown) per year (4) and a conservatively assumed continuous low volume purge (6 inch) rate of 1000 cfm. Using these parameters and the input parameters given in Table 11.3-7, the Reactor Building purge releases are calculated to be 2638 Ci/yr of noble gases, 2.5×10^{-2} Ci/yr of iodine, 1.9×10^{-3} Ci/yr of airborne particulates, and 1 Ci/yr of Carbon-14. The isotopic distribution of these releases is given in Table 11.3-8.

11.3.6.3 Auxiliary Building Ventilation

The Auxiliary Building Charcoal Exhaust System continuously exhausts air drawn from Auxiliary Building areas with moderate potential for radioactive contamination (demineralizers, storage tanks, gas decay tanks, evaporators, pump rooms, etc.). The supply and exhaust ducts are arranged so that air flow is always in the direction of progressively greater potential contamination. Exhaust air from these areas is drawn through the roughing/HEPA/charcoal filter

plenums continuously and is ducted to the main exhaust fans and the main plant vent. There is no bypass around this filter plenum.

The release calculations are based upon the assumption that reactor coolant leakage in the Auxiliary Building occurs primarily in the areas exhausted by the charcoal exhaust system. PWR-GALE Code (Reference 1) parameters for Auxiliary Building leakage (160 lbs/day), iodine partition factor (0.0075), and decontamination factors (100 for HEPA filters, 10 for charcoal adsorbers) have been used in the calculations. Using these parameters and the input parameters given in Table 11.3-7, the Auxiliary Building ventilation release is calculated to be 128 Ci/yr of noble gases, 1.1×10^{-2} Ci/yr of iodine, and 1.6×10^{-3} Ci/yr of airborne particulates. The isotopic distribution of this release is given in Table 11.3-8.

11.3.6.4 Secondary System

11.3.6.4.1 Turbine Building Vents

Turbine Building steam leakage may release radioactive gas to the Turbine Building atmosphere if primary to secondary leakage occurs. Turbine Building Ventilation System exhausts are not treated prior to release. Release calculations were based on the PWR-GALE Code (Reference 1) parameters for steam leakage (1700 lbs/hr), primary to secondary leakage (100 lbs/day), and fraction of iodine that remains airborne (Reference 1). Using these parameters and the input parameters given in Table 11.3-7, the Turbine Building vent release is calculated to be 2.4×10^{-3} Ci/yr of iodine. The isotopic distribution of this release is given in Table 11.3-8.

11.3.6.4.2 Condenser Air Removal System

Offgas from the Condenser Air Removal System may contain radioactive gases, if primary to secondary leakage occurs. When condenser offgas contains any significant amount of radioactivity, it is exhausted through HEPA filters and charcoal adsorbers in the Auxiliary Building Charcoal Exhaust System from particulate and iodine removal. Release calculations are based upon taking credit for the charcoal adsorbers and the PWR-GALE Code (Reference 1) parameters for primary to secondary leakage (100 lbs/day), steam generator partition factors (0.01 for iodine and 0.001 for nonvolatiles), and Main Condenser/Condenser Air Removal System partition factors (0.15 for volatile iodine species and zero for nonvolatile species). Using these parameters and the input parameters given in Table 11.3-7, the Condenser Air Removal System release is calculated to be 81 Ci/year of noble gases and 6.9×10^{-3} Ci/yr of iodine. The isotopic distribution of this release is given in Table 11.3-8.

11.3.6.4.3 Steam Generator Blowdown

The Steam Generator Blowdown Processing System provides for cooling the blowdown in heat exchangers to prevent flashing. Consequently, no gaseous release is expected to result from steam generator blowdown.

11.3.6.5 Release Criteria

It is the intent of the Applicant to operate this system by periodically discharging gases stored by the GWPS. This method of operation minimizes disposal of the accumulated inventory at the end of plant life and reduces plant personnel exposure. Planned discharges during periods of favorable meteorology are made after a sample of decayed gaseous effluent is analyzed and are continuously monitored during release. Radiation monitor (RM-A10) automatically terminates the discharge upon detection of high activity by closing the appropriate tank outlet valve. This method of operation provides both operational flexibility and assures that the release of radioactive material in gaseous effluents is within the limits of 10 CFR 20, Appendix B, Table 2, Column 1 and the limits of Appendix I to 10 CFR 50.

11.3.7 Release Points

Release points for potentially radioactive gaseous wastes are shown schematically by Figure 11.3-7. Figure 11.3-8 shows the physical locations of these, and other nonradioactive exhausts. Table 11.3-9 presents data for the numbered vents shown by Figure 11.3-8. The data include base and exit elevations of the stacks, cross section dimensions, volumetric flow rate, exit velocity, and comments. Table 11.3-9 compares exhaust system equipment to Branch Technical Position ETSB 11-2.

11.3.8 Dilution Factors

Dilution factors (χ/Qs) utilized in evaluating the releases of gaseous effluents were calculated according to the methods set forth in Regulatory Guide 1.111, based on one year of onsite meteorological data. A detailed discussion of the applicable methodology appears in Section 2.3.5.2; the results of the calculation of annual average (χ/Q's) values are listed in Table 2.3-133. Examination of Table 2.3-133 reveals that the highest concentration of gaseous effluents at the exclusion zone boundary is expected to occur in the southeastern sector, where relative concentration of 5.3×10^{-6} sec/m^3 was calculated.

Expected annual gaseous release rates presented in Table 11.3-8 were used in conjunction with a (χ/Qs) value of 5.3×10^{-6} sec/m^3 to estimate maximum expected radioisotope concentrations in air outside the restricted area. The release rates, the expected concentrations, and the effluent concentration limits from 10 CFR 20, Appendix B, Table 2, are listed in Table 11.3-10. As prescribed in 10 CFR 20, these concentrations are those expected as an average at the exclusion zone boundary over a one-year period. It can be seen that the expected concentration level of each isotope is well below the individual limit specified. In addition to the limits for each isotope, the requirements of 10 CFR 20, Appendix B state that, for a mixture of radionuclides, the following relationship must hold:

$$\sum_{i=1}^{N} \frac{C_i}{ECL_i} \leq 1$$

where:

C_i= concentration of radionuclide i.
ECL_i=effluent concentration limit of radionuclide i from 10 CFR 20, Appendix B, Table 2, Column 1.
N= number of radionuclides in the mixture.

The sum of the ratios of expected radionuclide concentrations to their effluent concentration limits for the mixture defined by the second column of Table 11.3-10 is 3.5×10^{-3}, which is less than unity, as required.

11.3.9 Estimated Doses (2)

Potential pathways of exposure (1) of man to radioactive materials in gaseous effluents from the Virgil C. Summer Nuclear Station are identified and discussed in Section 11.6.2. Doses to individuals in the environs of the plant from each of the potentially significant pathways were calculated; methodology for the results of the calculations is discussed in the following paragraphs.

Dilution factors and relative deposition were calculated according to the methods of Regulatory Guide 1.111, as discussed in Section 2.3.

All results presented in these sections were obtained using the calculational techniques prescribed in Regulatory Guide 1.109. Except where noted in discussion of doses for specific pathways, all usage and consumption values, transport times, bioaccumulation factors, dose conversion factors, and other constants utilized were those suggested in Regulatory Guide 1.109.

Maximum doses to individuals were calculated for cloud submersion, ground plane contamination, inhalation, and vegetable, milk, and meat ingestion pathways. Assumptions, including point of exposure, are described for each pathway in the following paragraphs; the calculated gaseous pathway doses are summarized in Table 11.3-11. All estimates were based on the predicted gaseous releases given in Table 11.3-8. Each dose was calculated at the location of the highest dose offsite at which the pathway could be assumed to exist.

Exposure to an individual from submersion in a cloud containing radioactive effluents was evaluated at the nearest residence, located 1.1 miles to the east-southeast of the plant. The total body dose was calculated to be 6.4×10^{-2} mrem/yr, while the skin dose was 1.8×10^{-1} mrem/yr.

External irradiation from activity deposited on the ground surfaces was also evaluated at the nearest residence. These analyses indicate that a dose of 5.0×10^{-3} mrem/yr to the skin and 4.3×10^{-3} mrem/yr to the total body can be expected from this pathway.

---

(1) The term “exposure” as used in this Section refers only to the disposition of radioactive materials in the environment in such a way that persons could receive a dose from them.
(2) Current values are being maintained in the ODCM.

In addition, the nearest residence is the location for estimating the maximum individual dose to be received from the air inhalation pathway. The maximum dose to an organ of an individual at this location inhaling radioiodine and radioparticulates in the plant effluent was calculated to be 6.9×10^{-2} mrem/yr to an adult's thyroid.

The predicted dose to an individual obtaining 100% of his vegetable consumption from a garden adjacent to the nearest residence was also determined. Maximum calculated exposure from this pathway was 7.7×10^{-1} mrem/yr to a child's thyroid. Maximum total body dose was 7.1 x 10-^{1} mrem/yr to a child.

Predicted doses from ingestion of milk from animals grazing year-round on land contaminated by radioparticulates deposited from the effluent plume were evaluated at the location of the nearest cow, in the west-southwest sector at 1.5 miles from the plant. Although the cow at this location is not currently being milked, the suitability of the location for raising dairy cattle and the increasing popularity of dairying in the region were considered sufficient reasons to assume that the pathway could reasonably be expected to exist at this location during the life of the plant. The maximum organ dose from ingestion of milk from a cow grazing year-round at this location was 1.1 x 100 mrem/yr to an infant's thyroid. The infant is also expected to receive the maximum total body dose of 3.2×10^{-1} mrem/yr.

Exposure from consumption of meat was evaluated at the same location as that for cow milk. The maximum organ dose to an individual from ingestion of meat from a cow grazing year-round at this location was 1.4×10^{-1} mrem/yr to the bones of an adult. The maximum total body dose from the meat ingestion pathway was 4.6×10^{-2} mrem/yr to a child.

Maximum individual doses calculated as described above were used to evaluate the status of conformance of predicted gaseous effluents from the Virgil C. Summer Nuclear Station with the requirements of Appendix I to 10 CFR 50.

The assumptions and results of this evaluation are summarized in Table 11.3-12. Beta and gamma doses in air were calculated according to the methods of Regulatory Guide 1.109. It will be noted that the calculated doses indicate the plant design conforms to the "as low as reasonably achievable" criteria established in Appendix I. Conformance with 10 CFR 50, Appendix I was demonstrated using meteorological data observed during 1975 and preoperational land use census data. During plant operation, conformance with Appendix I will be demonstrated in the USNRC Regulatory Guide 1.21 Annual Radioactive Effluent Release Report. Meteorological data used in preparation of the annual effluent report may consist of meteorological data averaged over multiple years to provide a better estimate of dispersion values. The maximum exposed individual location used for gaseous release dose calculation will be based on current census data.

Stack Release Information

NOTES

(1) See Figure 11.3-8 for location.

(2) Condensate return unit vent volume flow rate is maximum theoretically possible.

(3) Location of intermediate building air exhaust relative to air intakes has not been finalized.

(4) Condenser exhaust flow is continuous.

(5) Main steam dump and power relief estimated occurrences are as follows:

a. Actual, 22 times per year for 10 minutes each time.
b. Test, 12 times per year for 1 minute each time.

(6) Main steam dump and power relief exit velocities are not available. Each vent incorporates a valve and exit diffuser of a proprietary design which diffuses and disperses the flow in a horizontal pattern, 360 degrees around the vent vertical axis. The volume flow rate is the flow through the vent stack prior to diffuser release.

(7) Main steam safety and relief estimated occurrences are as follows:

a. Actual, 2 times per year for 2 minutes each time.
b. Test, 3 times per year for less than 1 minute each time.

(8) Not expected to occur during life of plant. Test monthly for 10 minutes each time.

Gaseous Effluents

(1) Design objectives as specified in the Commission's Appendix I Conformance Option, 40 FR 40816, September 4, 1975.
(2) Evaluated at a location that is anticipated to be occupied during plant lifetime or evaluated with respect to such potential land and water usage and food pathways as could actually exist during the term of plant operation.
(3) Calculated only for noble gases.
(4) Evaluated at a location that could be occupied during the term of plant operation.
(5) Doses due to carbon-14 and tritium intake from terrestrial food chains are included in this category.
(6) Evaluated at a location where an exposure pathway actually exists at time of licensing. However, if the applicant determines design objectives with respect to radioactive iodine on the basis of existing conditions and if potential changes in land and water usage and food pathways could result in exposures in excess of the guideline values given above, the applicant should provide reasonable assurance that a monitoring and surveillance program will be performed to determine: (1) the quantities of radioactive iodine actually released to the atmosphere and deposited relative to those estimated in the determination of design objectives; (2) whether changes in land and water usage and food pathways which would result in individual exposures greater than originally estimated have occurred; and (3) the content of radioactive iodine and foods involved in the changes, if and when they occur.
(7) Cows are not currently milked at this location. Doses evaluated were based on the assumption that pathways could reasonably be expected to exist during plant life.
(8) Dose to an infant thyroid from air inhalation and cow milk ingestion.
(9) Points given correspond to points of dose evaluation under Appendix I heading.

11.4 Process and Effluent Radiological Monitoring Systems

Radiation monitors and analysis of samples are used to monitor process and effluent streams in order to record and control releases of radioactive materials generated as a result of normal operations, including anticipated operational occurrences, and during postulated accidents. The general description and approximate ranges of radiation monitors that measure, indicate, and record the activity of process and effluent streams in the plant are tabulated in Table 11.4-1. Additional radiation monitors are discussed in Sections 12.1.4 and 12.2.4. More detailed information on instrument ranges may be found in Health Physics procedures.

11.4.1 Design Objectives

Major and potentially significant effluent discharge paths for release of radioactive material during normal reactor operation, including anticipated operational occurrences, are monitored as required by General Design Criterion 64. These effluent discharge paths are as follows:

1. Major Effluent Discharge Paths
    a. Reactor Building purge exhaust
    b. Plant vent exhaust (including the gaseous waste discharge)
    c. Liquid waste discharge
2. Potentially Significant Effluent Discharge Paths
    a. Condenser exhaust
    b. Nuclear Blowdown waste effluent
    c. Steam Generator Blowdown
    d. Turbine room sump
    e. Condensate Polish Backwash Tank effluent

Additionally, samples of these effluents are required for laboratory analysis to allow evaluation of the measured releases and compliance with the reporting requirements of Regulatory Guide 1.21 (see Appendix 3A). Monitoring and analysis of samples provide information useful in complying with the objectives of Appendix I to 10 CFR 50.

Process systems which do not discharge to the environment are monitored to permit identification of possible system or equipment malfunction through detection of activity levels in the system. The systems monitored are the following:

1. Component Cooling Water
2. Primary Coolant Letdown
3. Spent Fuel Cooling Water

The Radiation Monitoring System continuously monitors the normal plant effluent discharge paths under steady-state, transient, or accident condition. After an accident, the system provides information to aid in determining the magnitude of the accident. Locations where permanently mounted monitors are not provided are monitored periodically with portable instruments. Radiation monitoring, effluent flow measurements, and meteorological instrumentation provide data which, under emergency procedures, determine the direction and rate of movement of radioactive effluents.

The monitors located in the normal plant effluent discharge paths, area gamma monitors, and manual sampling provide information on the rate and location of releases.

Radiation monitoring, analysis of samples, and Health Physics surveillance provide data used for assuring compliance with the requirements of 10 CFR 20.

Utilization of off-line process monitors provides improved access for maintenance and inspection. Remotely actuated check sources for the radiation monitor detectors facilitate routine functional verification. Detector assemblies are removable in the event that extensive maintenance is required. Decontamination of process monitors is facilitated by use of appropriate taps or valving to allow flushing or cleaning.

Expected process flow, composition, and contamination are a function of the specific process system being monitored and are discussed in the section where the system is discussed.

11.4.2 Continuous Monitoring

Measurement data from the effluent radiation monitors and the analysis of samples by laboratory equipment (see Section 11.4.3) provide information used to comply with Regulatory Guide 1.21 (see Appendix 3A) and for evaluation of the releases to the environment.

Measured activity levels are indicated and recorded on the Radiation Monitoring control panel located in the Control Room (except RM-L8 and RM-L11). Local indication at or near the detector location is provided for each channel. The turbine room sump radiation monitor, RM-L8, is equipped for local indication, recording, and high level alarm and also actuates an alarm in the Control Room. If radiation discharge limits are exceeded, the sump pumps are automatically tripped and the flow path may be aligned to discharge to the Excess Liquid Waste System.

The condensate polish backwash effluent radiation monitor RM-L11 is equipped for local indication, recording, and high level alarm. Alarm is also provided through the local control panel for the condensate polishing system. A high radiation alarm will trip the backwash tank discharge pumps.

Detectors have remotely actuated check sources to provide functional verification. In addition, the monitoring channels are routinely calibrated by exposure to a calibrated test source for verification against initial calibration curves. Radiation monitor detection range is based upon the type of fluid being monitored for activity, the capability of commercial instrumentation, and the function of the monitor. Each rate meter is equipped with two adjustable alarm levels (alert and

high) and a channel failure/loss of power alarm. These alarms, except for movable monitors, are annunciated on the Radiation Monitoring System control panel in the Control Room. Channels which have an interlock function with other systems (see Figure 11.4-1) are provided with a bypass switch for use during maintenance or testing. Use of the bypass switch is annunciated. Reliable power for the fixed, process, and effluent radiation monitoring instrumentation is obtained from the diesel backed, 120 volt instrument bus. Associated sample pumps obtain power from the 480 volt diesel backed bus. Radiation monitors RM-L8 and RM-L11 are powered by local 120 volt a-c power.

Individual ratemeter power supplies are independent of each other. The reliable a-c power source is divided between two trains (see Table 11.4-1) to provide a high degree of availability.

Specific instrumentation channels used for process and effluent monitoring are as follows:

1. Primary Coolant Letdown Monitor, Channel RM-L1

   A sample of the primary coolant letdown from the Nuclear Sampling System is monitored by this channel utilizing an off-line monitor located outside the Reactor Building (see Figure 9.3-4). The sample is delayed to allow decay of N16 activity. Two detectors, overlapping in ranges, as shown by Table 11.4-1, are used to obtain a wide measuring range, from approximately 1 x 10^{-3} μCi/cc to 10^{3} μCi/cc, based upon Cs-137.

   The reactor coolant gross gamma activity resulting from instantaneous mixing of fission products from a small fraction of one fuel rod at equilibrium causes a net signal increase approximately equal to the signal produced by one percent failed fuel within four minutes. The contribution to gross gamma activity from corrosion products and tramp uranium is minor compared to that from one percent failed fuel.

   The alarm setpoint is established at a level such that any sudden increase above the normal or expected operational reactor coolant activity is suspected as being due to gross fuel failure. Analyses of a manual sample provide verification of compliance with Technical Specifications and indicate any action to be taken.

   No automatic interlock functions are served by this channel. If the detector is not available, the sampling frequency is increased. Loss of sample flow is annunciated in the Control Room.

   Use of two detectors, scintillation and Geiger-Mueller (G-M), and two alarm modules provides a high level of availability.

2. Component Cooling Water Monitors, Channels RM-L2A and RM-L2B

   Each of the two Component Cooling Water loops (see Figure 9.2-4) is equipped with an off-line, shielded sampler having a gamma sensitive scintillation detector for measurement of gross gamma activity in a sample of the cooling water. These monitors detect leakage of radioactivity into the Component Cooling Water and cause an alarm to sound upon detection

of excessive activity levels. Sensitivity and range of these monitors is approximately 2 x 10^{-6} to 2 x 10^{-2} μCi/cc, Cs-137.

High activity, approximately one decade above normal background, causes an alarm and initiates closure of the Component Cooling Water surge tank vent valve. Laboratory analysis of a Component Cooling Water sample is used to verify the cause of an alarm and the extent of leakage into the Component Cooling Water loop.

3. Steam Generator Blowdown Monitor, Channel RM-L3

   A fluid sample from the combined Steam Generator Blowdown (see Figure 10.4-13) is passed through a shielded, off-line sampler having a gamma sensitive scintillation detector for measurement of gross gamma activity. This monitor is used to detect primary to secondary leakage and sound an alarm upon detection. Design, sensitivity and range are similar to RM-L2A.

   High activity causes an alarm and initiates valve operations to divert blowdown flow to the Nuclear Blowdown holdup tank. Laboratory analysis of Steam Generator Blowdown samples is used to verify the alarm condition.

4. Spent Fuel Cooling Water, Channel RM-L4

   A sample of Spent Fuel Cooling Water (see Figure 9.1-3) is monitored by a shielded, off-line sampler using a gamma sensitive scintillation detector for measurement of gross gamma activity. Alarms are sounded upon detection of excessive activity. Design, sensitivity, and range are similar to RM-L2A.

   The monitor alarms alert the operator to an increase of activity. Such an increase is then verified by laboratory analysis of a manual grab sample.

5. Liquid Waste Effluent Monitor, Channel RM-L5

   An off-line monitor is used to sample the Liquid Waste effluent. A lead shielded sampler with a gamma sensitive scintillation detector is located upstream of the discharge dilution point for measurement of effluent gross gamma activity (see Figure 11.2-2, Sheet 4). Sensitivity and range are similar to RM-L2A.

   High effluent activity causes an alarm and initiates closure of the waste processing discharge valve. The activity level at which this interlock is actuated is adjustable based upon the activity level of an analyzed sample of the waste batch and/or dilution flow available. The activity and dilution flow are evaluated prior to discharge. A high level alarm is also provided at the local Liquid Waste System control panel.

6. Boron Recycle System Monitor, Channel RM-L6 --**NO LONGER IN SERVICE**--

   A sample of the discharge (see Figure 9.3-18) from the Boron Recycle System recycle evaporator condensate filter to the reactor makeup storage tank is monitored by an off-line, shielded sampler. This sampler uses a gamma scintillation detector to measure gross gamma activity. Sensitivity and range are similar to RM-L2A.

   High activity in the recycle evaporator condensate filter discharge to the reactor makeup storage tank causes an alarm and initiates diversion of the discharge flow from the reactor makeup storage tank to the recycle evaporator. Laboratory analysis of a sample is used to verify the alarm condition.

7. Nuclear Blowdown Waste Effluent Monitor, Channel RM-L7

   A sample of the discharge (see Figure 10.4-14) from the Nuclear Blowdown Processing System is monitored for gross gamma activity by a shielded, gamma sensitive detector. This off-line monitor is used to detect excessive activity releases from the Nuclear Blowdown Processing System. Alarms are sounded upon detection of such releases. Design, sensitivity, and range are similar to RM-L2A.

   High activity causes alarms and initiates valve operations to terminate discharge and divert the flow to the Nuclear Blowdown Processing System monitor tank. Laboratory analysis of the process discharge fluid is used to verify alarm conditions. The alarm setpoint is based upon the maximum release activity and dilution of the discharge stream.

8. Turbine Room Sump Monitor, Channel RM-L8

   A sample of the turbine room sump discharge is monitored by a shielded gamma scintillation detector to provide local measurement, indication, and alarm of gross gamma activity. The monitor sample valve is opened and the 120 volt a-c sample pump is started when the turbine room sump pumps are operated. A high activity alarm annunciated in the control room stops the sump pumps.

9. Main Plant Vent Exhaust Monitor, Channel RM-A3

   This channel monitors particulate, iodine, and gaseous activity released through the main plant vent from the Auxiliary Building. The particulate detector, a beta scintillator, has a sensitivity and range of approximately 10^{-11} to 10^{-7} µCi/cc, Cs-137. The iodine detector, a gamma scintillator, has a sensitivity and range of approximately 2×10^{-11} to 10^{-7} µCi/cc, I-131. The gas detector, a beta scintillator, has a sensitivity and range of approximately 2.6×10^{-6} to 2×10^{-2} µCi/cc, Kr-85.

   A particulate collection filter with an efficiency of 90 percent for particles 0.3 microns or larger is provided and is removable for laboratory analysis. A charcoal filter cartridge, removable for laboratory analysis and having an efficiency of 95 percent for elemental iodine, is also provided.

The plant vent discharge sample is taken downstream of the filtering units by a nozzle located near the point of discharge to the environment (see Figure 9.4-9). Sample nozzle flow is adjusted to be isokinetic at a nominal discharge flow rate (227,588 cfm) from the vent stack.

The pumping station and the three shielded detection channels are located on the floor below the sampling point to minimize sample line losses. This pumping station is equipped with two pumps to permit continued operation when pump maintenance is required.

Should the gaseous activity released through the main plant vent reach or exceed the Hi-Rad setpoint, the gaseous activity detection channel initiates closure of the Waste Gas decay tank discharge valve.

The RM-A3 setpoints are estimated by plant procedures to ensure that the site boundary dose limits specified in the ODCM are not exceeded.

Radiation monitor RM-A3 utilizes detectors which are 4-Pi shielded with 3 inches of lead to minimize the effect of the background radiation in normal operation in an environment as listed in Table 3.11-3.

10. Reactor Building Purge Exhaust Monitor, RM-A4

This monitor measures particulate, iodine, and gaseous activity in the discharge of the Reactor Building Purge Exhaust System during purging operations. This monitor is similar to RM-A3 with respect to its description, range, and sensitivity.

The monitored sample is obtained through an isokinetic nozzle located in the purge exhaust duct upstream of the discharge point (see Figure 9.4-28). The monitor is located on the floor below the duct to minimize sample line loses. The monitor obtains its sample from either of two sample probes in the discharge duct. One probe is isokinetic at the design discharge flow rate (20,000 cfm), the other probe is isokinetic at the design low flow rate. The duct flow rate is measured and indicated in the Control Room. Under operating conditions where this flow is more than 10 percent below design conditions, the data collected by RM-A4 will be corrected for an isokinetic sampling in accordance with ANSI 13.1 1969 Appendix C. Appendix C implies that an isokinetic correction for particle sizes less than 4 microns does not need to be considered. Particles penetrating the containment HEPA filters are normally less than 0.3 microns.

Should an unplanned gaseous activity release rate of approximately 4×10^{1} µCi/sec, Kr-85, be exceeded, this monitor initiates closure of the Reactor Building purge valves. This activity release rate is based upon a flow rate of 20,000 cfm through the Reactor Building purge vent and a gaseous activity level setpoint of approximately two times the expected background at the monitor location. Such a setpoint provides for rapid detection of any unplanned release.

The alarm setpoints for particulate and iodine activity are estimated by plant procedures to ensure that the site boundary dose limits specified in the ODCM are not exceeded.

Alarm setpoints may be readjusted prior to commencement of Reactor Building purging based upon existing activity levels within the Reactor Building.

Radiation monitor RM-A4 utilizes detectors which are 4-Pi shielded with 3 inches of lead to minimize the effect of the background radiation in normal operation in an environment as listed in Table 3.11-3.

The gamma dose rate from the charcoal cartridge located inside the atmospheric monitor (RM-A4) shield assembly at a distance of one foot is approximately 2.8 mr/hr, assuming a sample activity of 102 μCi/cc, sample flow of 1 cfm, 95 percent collection efficiency, average E of 0.5 Mev, and 30 minutes collection time.

11. Condenser Exhaust Monitor, RM-A9

This monitor is a shielded, off-line unit with a gamma scintillation detector which monitors gaseous samples taken from the condenser exhaust discharge line (see Figure 10.4-1). Its purpose is detection of primary to secondary system leakage. Range of this monitor is approximately 2×10^{-6} to 2×10^{-2} μCi/cc, Xe-133. This range combined with a design discharge flow rate of 40 cfm permits monitoring of an activity discharge rate of 7.5×10^{-2} to 7.5×10^{2} μCi/sec.

12. Waste Gas Discharge Monitor, Channel RM-A10

This monitor is a shielded beta scintillation detector which monitors and controls the gaseous activity released from the Waste Gas decay tanks. Sensitivity and range of this monitor are approximately 2×10^{-4} to 2 μCi/cc, Xe-133.

Detection of high gaseous activity initiates closure of the Waste Gas decay tank discharge valve. Prior to a planned Waste Gas decay tank release, the alarm setpoint may be readjusted according to analyzed activity level existing in the Waste Gas decay tanks.

13. Main Plant Vent Exhaust High Range Gas Discharge Monitor, Channel RM-A13

This monitor (see Figure 11.4-2) provides extended range backup to channel RM-A3. The monitor utilizes an ion chamber gamma sensitive detector with a sensitivity and range of approximately 10^{-2} to 10^{+5} μCi/cc, XE-133. Detection of high activity provides an alarm, indication, and a record of excessive gas activity released through the main plant vent exhaust. The energy dependence is ± 10 percent from 80 KeV to 3 MeV. Background correction is achieved by a 2-inch lead shield which reduces background and provides collimation of the detector to respond to the gamma radiation from the exhaust duct.

Graphs will be available to operating personnel to reflect the readout of RM-A13 versus the curie concentration for a given release and an assumed isotopic mixture of the effluent.

14. Liquid Waste Effluent Monitor, Channel RM-L9

    An off-line monitor is used to sample the Liquid Waste effluent to the penstocks. A lead shielded sampler with a gamma sensitive scintillation detector is located downstream of radiation monitor RM-L5 to monitor the discharge from the Liquid Waste Processing System or the discharge from the Nuclear Blowdown Processing System. Sensitivity and range of this monitor are similar to RM-L2A.

    High effluent activity actuates an alarm and initiates closure of the waste discharge valve, thus terminating flow to the penstocks. The activity level at which this interlock is actuated is adjusted to limit the maximum permitted activity of the discharge to the penstocks and to provide backup for radiation monitors RM-L5 and RM-L7.

15. Steam Generator Blowdown Discharge Monitor, Channel RM-L10

    A fluid sample from the Steam Generator Blowdown discharge to the Circulating Water System is passed through a shielded, off-line sampler having a gamma sensitive scintillation detector for measurement of gross gamma activity. This monitor is used to terminate the discharge flow to the Circulating Water System in the event of primary to secondary leakage in the steam generators. Design, sensitivity, and range of this monitor are similar to RM-L2A.

    High activity actuates an alarm and initiates valve closure to terminate Steam Generator Blowdown flow to the Circulating Water System. This monitor backs up radiation monitor RM-L3. Laboratory analysis of Steam Generator Blowdown samples is used to verify the alarm condition.

16. Purge Exhaust Effluent High Range Radiation Monitor, Channel RM-A14

    This monitor (see Figure 11.4-2) provides extended range backup to channel RM-A4. The monitor utilizes an ion chamber gamma sensitive detector with a sensitivity and range of approximately 10^{-2} to 10^{+5} μCi/cc, Xe-133. Detection of high activity provides an alarm, indication, and a record of excessive gas activity released through the purge vent exhaust. The energy dependence is ± 10 percent from 80 KeV to 3 MeV. Background correction is achieved by a 2-inch lead shield which reduces background and provides collimation of the detector to respond to the gamma radiation from the exhaust duct.

    Graphs will be available to operating personnel to reflect the readout of RM-A14 versus the curie concentration for a given release and an assumed isotopic mixture of the effluent.

17. Steam Line High Range Monitors, Channels RM-G19A, B, and C

    Each Main Steam line header upstream of the relief valves (2806-MS) is provided with a high range gamma sensitive monitor to provide indication of the steam activity in the event of a release equivalent to 2 curies/sec/MW_{th} of Xe-133.

These monitors are responsive to 0.1 mr/hr up to 10^7 mr/hr gamma with a flat response of ± 10 percent from 80 KeV to 3 MeV. The anticipated dose response, calculated for the detector due to an equivalent concentration of Xe-133 in the discharge effluent from the steam line, is 6.1×10^{-1} mr/hr/μCi/cc. Background correction for each monitor is achieved by 2-inch lead shielding to reduce background and provide collimation of the detector to respond to the gamma radiation from the steam line.

18. Condensate Polish Backwash Effluent Monitor, Channel RM-L11

A sample of the recirculated or batch discharge fluid from the Condensate Polish System backwash receiver tank is monitored for gross gamma activity by an off-line liquid radiation monitor, RM-L11 (see Figure 10.4-7a). Sensitivity is approximately 1×10^{-6} μCi/cc referenced to Cs-137. Indication, alarms, and recording are provided locally.

Interlocks are provided to trip the backwash pumps upon a high activity alarm. The activity of the fluid is evaluated prior to discharge. Alarm is also provided at the local Condensate Polish System control panel.

As agreed with the NRC Staff, this monitor is required to be installed prior to startup after the first refueling.

11.4.3 Sampling

The requirements of General Design Criterion 64 are satisfied with respect to effluent discharge paths as stated below.

Radiation monitoring is accomplished using the Radiation Monitoring System and laboratory analysis of samples in accordance with Regulatory Guide 1.21 (see Appendix 3A).

Table 11.4-2 presents normal and potential discharge paths from the plant and lists the monitoring and analyses performed. The frequency of sampling is increased should abnormal levels of activity be detected.

Effluent monitors RM-L5, RM-L11, and RM-A10 provide backup control of the administrative release of liquid and gaseous waste. These batch releases are analyzed and evaluated prior to discharge. Main plant vent exhaust monitor RM-A3 provides additional backup to the Waste Gas discharge monitor RM-A10.

Ventilation discharge effluent monitors RM-A3 (main plant vent exhaust) and RM-A4 (Reactor Building purge exhaust) provide removable particulate filters and charcoal cartridges for laboratory analyses which allow evaluation of normal and/or abnormal releases.

Continuous effluent discharge radiation monitor (RM-A3, RM-A9, and RM-L7) readings of gas or liquid activity would be affected by abnormal background directly following a LOCA and would, at that time, indicate a higher gas or liquid activity than was actually being discharged. This would result only in the possibility of premature actuation of interlocks or alarms. Use of

portable instrumentation, sample analysis, and appropriate emergency procedures, as well as the radiation monitors, permits evaluation of the plant discharge to the environment under accident conditions.

Liquid effluent monitor RM-L7 (Nuclear Blowdown waste) diverts the process discharge upon detection of excessive gross gamma activity. A manual sample of the diverted discharge fluid is analyzed in the laboratory for evaluation of the isotopic content.

Primary to secondary leakage is detected by the condenser exhaust monitor, RM-A9. Additional backup information is provided by the steam generator liquid blowdown monitor, RM-L3. Subsequent analysis of liquid samples in the laboratory provides verification.

In the event of simultaneous primary to secondary and turbine leaks, the Turbine Building Ventilation System and Floor Drain System become potential discharge points. Portable monitors and manual samples are used to determine the rate of release.

Liquid radiation monitor, RM-L8, monitors turbine room sump discharge and stops the sump pumps upon occurrence of a high radiation alarm.

The ventilation exhaust from the Intermediate Building is not considered a potential discharge point due to a lack of potential sources within this building. Routine Health Physics surveillance with portable monitors and analysis of particulate portable sampler filters are used for verification.

General Design Criterion 60 is satisfied by use of interlock circuits which are illustrated by Figure 11.4-1. In addition, alarms resulting from detection of high activity alert the operator to the need for appropriate action.

Requirements of General Design Criterion 63, with respect to the monitoring of radiation levels in radioactive waste process systems, are satisfied by use of the effluent and process radiation monitoring instrumentation, area gamma monitoring, Health Physics surveillance with portable instruments, and laboratory analysis of process samples.

11.4.4 Inservice Inspection, Calibration, and Maintenance

The analyses of radioactive effluents are performed in accordance with requirements set forth in Regulatory Guide 1.21 (see Appendix 3A). Inplant laboratory facilities for these analyses include a separate sample room, radiochemistry laboratory, and count room located in the Control Building. Appropriate equipment for the safe handling of samples and standards is provided. Count room equipment includes the following:

1. Germanium detectors
2. Liquid scintillation counter
3. Gross alpha counter
4. Appropriate shielding for detection devices

5. Multichannel analyzers
6. Data reduction and storage system

Detailed written analytical laboratory procedures are provided to assure compliance with sensitivity, accuracy, and reproducibility requirements within the capabilities of commercially available equipment.

The schedule for routine calibration of laboratory equipment used for effluent sample analysis is detailed in such a manner as to assure the continuing accuracy of measurements. Calibration performance for the various equipment is closely monitored to determine if malfunction due to procedural difficulties or minimal equipment failure has occurred and, where applicable, whether equipment maintenance is required. Functional checks of equipment performance are performed on a more frequent basis than is calibration in accordance with written laboratory procedures. These checks use materials with the accuracy, stability, and range (though not necessarily traceable to the National Institute of Standards and Technology) necessary to assure a timely indication of equipment operational status. Maintenance or readjustment of the laboratory counting equipment is followed by appropriate recalibration.

Laboratory counting systems used in the analysis of effluent samples are calibrated using specific standards consistent with the particular effluent sample geometry.

The radioactive material in these standards is either certified by the National Institute of Standards and Technology or has been calibrated against standard reference material certified by the National Institute of Standards and Technology. Calibration standards have the accuracy, stability, and range required for the intended use. Detailed written procedures for calibration of laboratory counting equipment and preparation of standards are provided to assure the continuing adequacy of effluent sample measurements. Intercomparison and interlaboratory spiked samples and analyses of such samples provide further assurance of system measurement accuracy. Equipment ancillary to qualification and quantification of effluent samples is also calibrated using detailed written procedures such as those called for in Regulatory Guides 1.21 and 1.23 (see Appendix 3A) to assure analytical accuracy.

Maintenance of laboratory equipment used in the analysis of effluent samples is performed in accordance with procedures recommended by the equipment manufacturers. Laboratory equipment availability is maximized as follows:

1. The incorporation of modular designs where appropriate
2. Provision of spare parts
3. Interchangeability of certain components within different laboratory counting systems when consistent with design considerations.

The process sampling system is described in Section 9.3.2.

11.5 SOLID WASTE SYSTEM

11.5.1 Design Objectives

The Solid Waste System is designed to package and/or solidify radioactive wastes for shipment to an approved offsite burial facility in accordance with applicable Department of Transportation (DOT), NRC, and State regulations. The system conforms to 10 CFR 20 and 10 CFR 50 requirements by providing shielding so that radiation exposure of operating personnel and the public is within acceptable limits. Solid waste packaging is accomplished in an area located on the ground floor (elevation 436') of the Auxiliary Building, a Seismic Category 1 structure.

Design, fabrication, and testing of Solid Waste System components and piping is in accordance with ANSI B31.1 and other accepted standards referenced by ANSI B31.1. Additional onsite system tests will be performed using nonradioactive materials prior to commercial operation. Packaging and shipping conform to 49 CFR 171 through 49 CFR 178.

Individual container shields and casks are used, when required, to maintain radiation levels within applicable radioactive materials regulations.

11.5.2 System Inputs

Radioactive waste packaged includes:

1. Spent resins.
2. Used filter cartridges.
3. Radioactive hardware.
4. Compacted waste such as rags, paper, clothing, etc.

Secondary side condensate polisher resin may also be handled by the Solid Waste System (refer to 10.4.6).

Design quantities and activity levels of the various wastes are listed in Tables 11.5-1 through 11.5-4.

11.5.3 Equipment Description

11.5.3.1 Processing

The input to the Solid Waste System consists of the contents of several radioactive waste storage tanks containing primary spent resins, reactor grade demineralizer spent resins, non-reactor grade demineralizer spent resins, and nuclear blowdown spent resins and the associated valves, piping, and pumps. These components are located at elevation 412' and 447' in the Auxiliary Building.

Radwaste solidification when required is accomplished using approved equipment and process control program. Liquid waste contained in the reactor grade and non-reactor grade demineralizer

is recirculated using their respective pumps and a sample is taken. This sample is used in the Process Control Program to determine pH adjustment, waste/binder ratio, and for the purpose of test solidification. Liquid waste is transferred to the fill head and into the liner located in the solidification area.

Primary and secondary spent resins are transferred from their respective holdup tanks to either a disposable liner in the solidification area or a liner in the truck bay. A process shield or a DOT cask may be used when activity or exposure dictates. The resins may then be either solidified or dewatered for shipment. Dewater return is routed to the Excess Liquid Waste Hold up Tank, the Decon Pit Collection Tank, or the Floor Drain Tank.

Each waste transfer is immediately followed by a flush operation of the waste transfer piping and the internals of the fill head when used.

Labyrinth shield walls separate the drumming station control room, the piping process skid cubicle, and the container fill area from one another. Equipment is described in more detail in Section 11.5.3.2.

11.5.3.2 Equipment

The equipment comprising the Solid Waste System is described in Sections 11.5.3.2.1 through 11.5.3.2.6. Table 11.5-5 provides equipment design parameters.

Table 11.5-7 shows how the utility equipment, components, structures, and services that interface with the vendor-supplied solidification system comply with the applicable criteria of Regulatory Guide 1.143, Rev. 1, October 1979, “Design Guidance for Radioactive Waste Management Systems, Structures and Components Installed in Light-Water-Cooled Nuclear Power Plants” and Branch Technical Position ETSB 11-3, Rev. 2, July 1981, “Design Guidance for Solid Radioactive Waste Management Systems Installed in Light-Water-Cooled Nuclear Power Plants.”

11.5.3.2.1 Waste Storage Tanks and Pumps

Tanks containing radioactive waste and wetted parts of pumps are fabricated from stainless steel, type 304, except as noted. The primary spent resin storage tank and pump are described in Section 11.2. Other radwaste tanks and pumps are the Nuclear Blowdown spent resin storage tank and Nuclear Blowdown spent resin storage tank pump.

The spent resin storage tank and the associated pump are located in the Auxiliary Building at floor elevation 412’. The waste holdup tank and the associated pump are located at floor elevation 374’.

The resin transfer lines are sloped to avoid low points in the piping. Also, 5 diameter pipe bends are used from the resin tanks to the solidification area. These long sweeping bends are necessary to avoid plugging that could occur in the inner wall of a bend. Instrument lines are kept to a minimum to avoid dead legs. All lines will be flushed with makeup water prior to any

maintenance activities. The reactor grade and non-reactor grade demineralizers located on elevation 447’ are flushed directly to liners in the truck bay at elevation 436’.

The resin and waste transfer lines are 2" nominal diameter. This size is sufficient for the desired flow rates without causing excessively large pressure drops that could result in line plugging.

11.5.3.2.2 Instrumentation and Controls

The system uses temperature, flow, pressure, and level instruments to monitor and/or control the process located throughout the system.

1. Inplant Control Panel

   The inplant control panel is a standard enclosure of NEMA 12 construction. The inplant control panel provides full operational control for resin and liquid waste transfer operations to the waste processing equipment. It is also used to interface with equipment for dewater return and for flushing operations. This panel contains switches and lights for valves and pumps which facilitate these operations.

2. Power Panel

   The power panel provides power for the operation of the various pump motors and valve motors in the system.

3. Radiation Monitoring

   Radiation monitoring is provided by portable instrumentation and/or semi-permanent radiation monitoring equipment.

11.5.3.2.3 Waste Containers and Shielding

All wastes are packaged in containers which meet DOT/NRC requirements. The containers used for solidification and resin dewatering provide appropriate connections for processing.

Higher activity wastes will be processed with the liner already in a cask located in the truck bay access. A double lid cask top will be used to limit exposure in this area. The main part of the lid shields the entire top of the cask except the immediate area required for the fill head. After the process is complete, the fill head is removed and the secondary cask lid is installed.

Final closure of all radwaste liners may be accomplished by remote handling equipment, if required. High integrity containers are remotely sealed by a hand manipulated device which screws the closure cap into the liner.

11.5.3.2.4 Contamination Control Facilities

An adjacent decontamination area is provided for cleanup of contaminated containers. Exposed surfaces of filled containers or casks are surveyed by the Health Physics Group to identify the presence of removable radioactive contamination prior to transfer to storage or shipment. Containers are decontaminated in the adjacent decontamination area, if required.

11.5.3.2.5 Handling Equipment

Equipment used for handling waste containers and equipment within the radwaste area and for truck loading includes the following:

1. One ton jib crane.
2. Three ton jib crane.
3. Twenty ton hoist and monorail.
4. Three ton bridge crane.
5. Ten ton bridge crane.

The one ton jib crane is located on a wall above the truck access floor at elevation 455’. It is used for hoisting chemicals and equipment from the truck access area to the mezzanine floor. It has a lift of 23 feet at a speed of 22 ft/min.

The three ton jib crane is located on a wall above the solidification area. It is used to handle the vendor’s fill head and other equipment. It has a 23 foot lift at a speed of 11 ft/min.

The 20 ton hoist and monorail is used to load the containers on a truck for transport to a burial site. It has a lift of 27 feet at a speed of 10 ft/min.

The three ton bridge crane is located over the radioactive filter area at floor elevation 463’. It is used in conjunction with a 3-1/2 inch thick lead filter transfer cask to remove spent radioactive filter cartridges from the filter housings located in concrete cubicles on the floor below at elevation 452’-6”. The trolley has a transfer mechanism which permits the hoist and the cask to engage a monorail which extends over the radwaste fill area. A hatch at floor elevation 463’ is removed and the hoist lowers the cask to the radwaste area at floor elevation 436’. It has a lift of 52 feet at a speed of 22 ft/min and a trolley speed of 65 ft/min.

The ten ton bridge crane is located in the hot machine shop. It is chiefly used to service the machine shop. However, a portion of the floor area in the machine shop is partitioned from the rest of the shop for storage of unused containers, 55 gallon drums, pallets, etc. The storage area is also serviced by this crane. The hoist has a lift of 24 feet at either 7 or 20 ft/min. The trolley has a speed of either 32-1/2 or 65 ft/min.

11.5.3.2.6 Waste Compactors

One waste compactor is available for use and is capable of handling 90 cubic feet of waste in one compaction.

11.5.3.2.6.1 Normal Use Compactor

An electromechanical compactor with a compressive force capacity of 100,500 lbs. is used to compact dry wastes into a 90 cubic foot container. During compaction, the container is completely enclosed. A self-contained HEPA filter and blower system filters the air released in the compaction process before any air is discharged to the Fuel Handling Building Charcoal Exhaust System. An electrical interlock prevents the operation of the compactor if the door which encloses the container is not completely closed. This prevents injury to the operator and unfiltered air from escaping to the Hot Machine Shop atmosphere.

11.5.3.2.6.2 Standby Compactor -**No Longer In Service**-

11.5.3.2.7 Truck Loading Features

A wall penetration is provided between the fill and truck access area to fill directly to containers on a truck. This penetration is located in the shielded cubicle of the solidification area such that exposure in the truck access is limited.

11.5.4 Expected Volumes

The expected annual volume of solid radioactive wastes together with the associated Curie content of principal nuclides to be processed are described in Sections 11.5.4.1 through 11.5.4.4.

11.5.4.1 Activity Levels

The activity level of the wastes generated directly from operation of the Nuclear Steam Supply System is based upon reactor plant operation at a base load factor of 80 percent power with reactor coolant activity levels determined on the basis of fission product diffusion through cladding defects in 0.12 percent of the fuel rods. The system is conservatively designed to accommodate solid wastes generated by plant operations with up to one percent fuel defects. Source term data used for system design are presented in Section 11.1.

Table 11.5-1 lists the demineralizer resin volumes and expected volumes replaced on an average yearly basis. Table 11.5-2 presents a summary of the anticipated total solid radioactive waste generated per year. The expected activity of the solid waste at time of shipment is dependent upon the decay storage time. An isotopic breakdown of spent resin activities is presented in Table 11.5-3. The maximum activity of expended filter cartridges is given in Table 11.5-4. The associated Curie content and volume of waste shipped from a number of Westinghouse designed operating reactors is given in Table 11.5-6 for each year from 1971 through 1974.

11.5.4.2 Processed Wastes

In the case of primary spent resins, the Curie content totals approximately 1390 Ci/yr. Nuclear Blowdown System spent resins are estimated, for design purposes, to account for approximately 4.0 Curies per year.

11.5.4.3 Filter Cartridges

The volume of expended filter cartridges processed for disposal by the Solid Waste System is based upon the expected filter cartridge change frequency for potentially radioactive filters. The assumption is made that filters processing reactor coolant will require cartridge renewal due to excessive radiation levels or high ΔP.

The maximum expected activity of expended filter cartridges shipped from the site is conservatively based upon a shielding criteria of a maximum contact dose rate.

11.5.4.4 Miscellaneous Solid Wastes

The annual volume of miscellaneous solid wastes processed by the solid waste compactor is assumed to amount to 85 containers of 90 cubic feet of compacted refuse. The wastes consist of rags, coveralls, ventilation filter cartridges, and various other potentially contaminated refuse. This refuse is normally classified as low specific activity.

11.5.5 Packaging

11.5.5.1 Evaporator Bottoms and Chemical Samples -**No Longer In Service**-

11.5.5.2 Spent Resin

Resin in a demineralizer is considered spent when its decontamination factor falls below a permissible level. The spent resin, from demineralizers in the primary system, is stored in a 350 ft^3 storage tank. The spent resin from nuclear blowdown demineralizers in the secondary system is stored in a 600 ft^3 Nuclear Blowdown System storage tank. The resin stored in the primary system is normally allowed to decay for a period of up to several months.

The reactor grade water demineralizers normally contain 28 ft^3 of resin per demineralizer in each of the three demineralizers. The non-reactor grade water demineralizers contain 28 ft^3 of resin per demineralizer in each of the seven demineralizers. These ten demineralizers are located on elevation 447’ of the auxiliary building and are sluceable directly to an available liner in the truck bay. These demineralizers are flushed when the decontamination factor falls below a permissible level.

When a sufficient quantity of resin has accumulated and decayed, the resin is sampled, analyzed for isotopic constituents and activities, and packaged. Prior to packaging, nitrogen is sparged into the tank to form a slurry which is transferred to the liner by nitrogen cover gas pressure. Dewatering of the resin is accomplished using dewatering equipment with the water being

returned either to the Excess Liquid Waste Holdup Tank, the Decon Pit Collection Tank, or the Floor Drain Tank. Spent resin may also be solidified.

The radiation level of the primary resin is expected to require use of a 4 inch lead shield on some occasions. The radiation level of the Nuclear Blowdown System resin is expected to require not more than 1-1/2 inch lead shield.

The primary spent resin storage tank has a two inch discharge line located along the tank center line, protruding from its top and extending to within 3 inches above the dished bottom. In preparation for packaging, the discharge valve is opened and the center discharge tube cleared by backflush with a burst of flush water from the Reactor Makeup Water System. Pressure to 100 psig is available, if required. Flush water may continue to be added if needed to obtain a reasonable slurry. The discharge valve is then closed. Loosening of the resin is achieved by introducing nitrogen through seven spargers at the tank bottom. Resin sluice water can be recirculated through the spargers to loosen the resin if desired. When the nitrogen pressure increases to that required for resin transfer, the resin discharge valve is opened. Nitrogen continues to bubble through the resin bed to maintain a gas pressure for transfer of the resin until the liner reaches the full level. The liner vent during this operation is directed to the plant vent or to a portable ventilation unit. Similarly, the reactor grade and non-reactor grade demineralizers are flushed directly to a truck bay liner.

The Nuclear Blowdown System spent resin storage tank is discharged by use of a procedure similar to that used for the primary spent resin storage tank. The resin slurry is discharged through a 2 inch nozzle located at the tank bottom. Nitrogen gas is bubbled into the tank bottom connection to loosen and mix the resin and pressurize the tank. When the tank gas pressure increases to that required for resin transfer, the resin slurry discharge valve is opened. Operation of both tanks from this point is similar.

When the transfer is complete, the resin discharge and nitrogen supply valves are closed and a tank vent valve is opened to discharge the nitrogen cover gas from the storage tank. In addition, the flush water supply valve is opened to backflush and forward flush and decontaminate the resin transfer line. A flow diagram of the primary resin system is provided by Figure 11.2-2, Sheet 3. Figure 10.4-15 describes the nuclear blowdown resin storage.

A flow of approximately 40 gpm is required to transfer the resin slurry to the liner in the radwaste area. It is anticipated that approximately 1300 std ft^3 and 2200 std ft^3 of nitrogen gas will be the maximum required for each resin transfer operation from the 350 ft^3 primary resin storage tank and 600 ft^3 nuclear blowdown resin storage tank, respectively.

The Nitrogen System is set to supply nitrogen to the resin storage tanks at a pressure of 100 psig, if needed. The resin storage tanks are designed for 150 psig. Relief valves on the primary and nuclear blowdown resin storage tanks are set to relieve at 100 psig and 150 psig, respectively. The primary resin storage tank relieves to the waste holdup tank. The Nuclear Blowdown resin storage tank relieves to the Nuclear Blowdown System reservoir by way of an open drain.

11.5.5.3 Filter Disposal

Filters are of the disposable cartridge type contained in housings having hinged tops. They are replaced when surface dose rate or pressure drop exceeds established levels. Filters which are potentially radioactive are located in individual cubicles in an area close to the drumming station area. If the radiation level of the cartridge requires shielding during removal, a concrete plug in the floor above the housing is removed and another plug with a hole in it is placed in the stepped opening. A filter cask with 3 1/2" lead encased in stainless steel is placed over the hole. The filter housing is opened and the cartridge is drawn into the cask by the use of special tools having extension rods. Once the filter is in place, the cask bottom is closed and the tops installed. The cask is then transported by an overhead crane to a hatch at floor elevation 463' of the Auxiliary Building. This hatch is located above the drumming station area on the floor below. The cask is lowered into the drumming station area. Storage and disposal of all filters is within either high integrity containers or DOT approved containers depending on the specific activity of the filters. For filters requiring shielding, the container is stored in a shielded cask. The filter transfer cask is positioned over a small opening in the shield cask, the bottom slide is pulled open, and the filter is lowered into the shielded container. In this manner, the handling of highly contaminated filters is kept to a minimum.

11.5.5.4 Radioactive Hardware

Radioactive hardware can consist of damaged or used equipment or instruments which, due to geometry or materials of fabrication, cannot be readily decontaminated. Such material is disposed of in much the same way as are filter cartridges or as compacted waste, depending upon radiation levels.

11.5.5.5 Compacted Wastes

An electromechanical compactor provides 100,500 lbs. of compressive force for the compaction of compressible waste into 90 cubic foot containers. During compaction, the container and compacting mechanism are enclosed and the enclosure is vented to the Fuel Handling Building Charcoal Exhaust System through a HEPA filter by a blower. The blower and filter are contained within the compactor. The blower is automatically operated when the door is closed; however, a manual switch is provided so the blower may be operated without compactor operation. The compactor will not operate unless the door is closed, protecting the operator from injury and preventing escape of unfiltered air to the atmosphere.

11.5.6 Storage

Compactable waste, filled containers of compacted waste, and spent filter cartridges are stored in the shielded areas of the radwaste area or in a location determined by the Manager, Radiological Protection and Chemistry. Contaminated hardware and tools may also be stored in these rooms. Solidified waste, after solidification is complete, and dewatered resins, once dewatering is complete, may be shipped off-site for immediate burial at a licensed facility. Primary spent resins will normally have at least a one month decay period while being held in the spent resin storage tank. Secondary blowdown resins do not normally require a decay period.

If solidified waste and/or dewatered resins require storage for any reason, they will be stored in the radiation control area outside the truck access on the concrete pavement or in a location determined by the Manager, Radiological Protection and Chemistry. Waste stored in the storage area will be shielded as required by portable shields and/or casks used for shipment.

Storage areas for solidified waste, dewatered resins, and compacted waste are sufficient, based on the estimates presented in Section 11.5.4, to accommodate greater than 30 days waste generation.

11.5.7 Shipment

Shipment, in accordance with applicable regulations, is made as necessary--dependent upon operational considerations and storage area availability.

The primary activity determination method will be to sample the waste stream (resins and liquid waste) during transfer to a process container and analyze the sample using the appropriate counting instrumentation. An isotopic determination is made of the radionuclides present and the activity of each. Summation of the individual activities is used to calculate the Curie content of the processed container.

For cases where the primary method cannot be used, an alternate technique will be implemented. The alternate method entails using the dose rate of the packaged waste in order to calculate the Curie content. The calculation considers the waste characteristics, geometry of the waste package, characteristics of the container and solidification media (if applicable), and the average gamma energy. For spent cartridge filters, this alternate method will be used to determine the Curie content. The appropriate counting instrumentation is used to analyze samples taken from the process stream to identify radionuclides present and the average gamma energy.

11.5.8 Potential for Releases

11.5.8.1 Potential for Release during Container Filling

The filling operation may be terminated via visual inspection using a remote monitor/television camera. Termination is accomplished by closing valves MOV-2 and MOV-5.

There is no airborne release to the atmosphere in the fill areas. Air in the container and gas, if any, from the waste entering the container are vented to the building exhaust, through a local filter, or through a portable ventilation unit. Only one line feeds waste to the container. This is flushed with water as the final phase of the fill cycle.

If leaks of any kind or spills are observed, the operation in progress can be immediately terminated. Any spill which may occur will be contained by permanent curbing in the solidification area.

Except for the curb in the solidification area, there are no physical barriers in the immediate fill areas to contain spills. Spills from the shipping container would need to be drained to a specific location or container as determined by the type of material spilled.

The floor surfaces have a special nonporous finish to permit decontamination of the surface, if required.

11.5.8.2 Potential for Release from Storage Tanks

11.5.8.2.1 Waste Evaporator Concentrates Tank -**No Longer In Service**-

11.5.8.2.2 Chemical Drain Tank -**No Longer In Service**-

11.5.8.2.3 Primary Spent Resin Storage Tank

This tank contains only a negligible quantity of radioactive gases in the gas space. The gas is normally contained in the tank by a closed vent valve. This vent is ducted to the Auxiliary Building Exhaust System and is open only during transfer of resin from the demineralizers or at the conclusion of transferring resin from this tank to the radwaste packaging area.

Overflow is not anticipated since primary spent resin storage tank capacity is sufficient to accommodate at least 60 days waste generation under normal plant operating conditions. Overflow protection is provided by a high level alarm at the Solid Waste System control panel. Excess water can either be pumped or drained to the waste holdup tank. Overflow, if it occurs, is to the waste holdup tank through a relief valve.

The tank is enclosed within a concrete cubicle with entrance from an overhead shield slab. Any leakage is directed to the floor drain tank through a floor drain.

11.5.8.2.4 Nuclear Blowdown Spent Resin Storage Tank

This tank contains only trace amounts of radioactive gas. The gas is normally contained in the tank by a closed vent valve. The tank is vented to the cubicle, which is serviced by the building exhaust system, only during transfer of resin from the demineralizers or at the conclusion of resin transfer from this tank to the radwaste packaging area.

Overflow is not anticipated since the nuclear blowdown spent resin storage tank capacity is sufficient to accommodate at least 30 days waste generation under normal plant operating conditions.

Overflow protection is provided by a high level alarm at the Solid Waste System control panel. Excess water can either be pumped or drained to the Nuclear Blowdown System reservoir. Overflow, if it occurs, is to the Nuclear Blowdown System reservoir through a relief valve.

The tank is enclosed within a concrete cubicle with entrance from an overhead shield slab. Any leakage is directed to the Nuclear Blowdown System reservoir through a floor drain.

CHAPTER 12 - RADIATION PROTECTION

NOTE: Section 12.0 is being retained for historical purposes only.

12.0 RADIATION PROTECTION

Paragraph 20.1(c) of 10 CFR 20, states that licensees should, in addition to complying with the limits set forth in that part, make every reasonable effort to maintain radiation exposures as far below the limits as practicable. The as low as practicable philosophy was followed in designing the Virgil C. Summer Nuclear Station.

This philosophy is reflected in the design by layout recommendations for pipes carrying radioactive fluids, equipment design, handling, and maintenance features. For example, pipe runs carrying radioactive fluid are arranged to minimize potential crud traps. Lines which transport spent resin are arranged with five diameter bends and continuous sloping. Piping vent and drain locations are minimized to reduce possible leakage paths and crud traps. Where possible, vents and drains are consolidated so that one vent and one drain serve several lines. Components that may require periodic maintenance are shielded from components most likely to be high radiation sources. Shielding is provided for fixed sample vessels associated with equipment stream pumps. Canned pumps are used in the liquid waste processing system (LWPS) to minimize potential leakage of radioactive fluids. Pumps requiring local start-stop or jog switches are placed in shielded cubicles. Control switches for such pumps are located outside the cubicles. Filters have lifting bails located on the heads to facilitate cartridge assembly removal and disposable cartridges for ease of changing. Demineralizers in the LWPS are considered to be potentially radioactive and are located inside individually shielded cubicles. Tanks containing radioactive waste are located in watertight compartments to contain the tank contents in the event of leakage. Heat exchangers incorporate design features that minimize exposure time during maintenance. Valves are located so that operation and maintenance can be performed from standard service equipment. Valves which normally carry radioactive fluid have leakoffs.

Equipment and/or components that may require servicing are located or designed to be movable to the lowest practicable radiation field. Penetrations through shielding walls are designed to minimize exposure. Radiation sources and normally occupied areas are separated. Pipes or ducts containing potentially highly radioactive fluids either do not pass through occupied areas or are shielded by shield slabs. Provisions are made for flushing equipment prior to maintenance where practicable. Ventilation systems are designed for easy access and service to minimize doses during maintenance, decontamination, filter changes, etc. Remote handling equipment is provided wherever practicable. Movable shields and means for their utilization are available for use as practicable. Where practicable, shielding is provided between radiation sources and areas requiring normal or routine access. As a result of operating experience, permanent removable shielding has been incorporated to minimize radiation exposure for operations and maintenance personnel in local areas such as for parts of the Residual Heat Removal and Safety Injection piping.

General guidance on the radiation protection aspects of the balance of plant design (BOP) is provided to engineers and designers by the appropriate discipline project engineer. Specific guidelines concerning BOP design are provided to the individual engineers whose specialties are radiation protection. These guidelines are based upon accumulated indepth design experience available to the architect-engineer from previously completed nuclear projects, as well as the experience acquired from frequent visits to operating nuclear plants. In addition to the design experience of the architect-engineer, conceptual shielding design guidelines are also provided from References 3, 8, and 9 (see Section 12.1.7).

BOP design is reviewed by both the architect-engineer and SCE&G personnel who are competent in radiation protection.

The review by the architect-engineer is accomplished through internal circulation of drawings and other design documents. When these documents contain design information that affects the radiation exposures to which plant workers will be subjected, they are reviewed by a group of specialists competent in radiation protection. This review results in the elimination or mitigation, to the extent practicable, of design features that would result in unnecessary radiation exposure. The individuals who have performed such reviews for the Virgil C. Summer Nuclear Station have the following position titles: Supervising Engineer, Project Engineer, Nuclear Engineer, Staff Health Physicist. Their qualifications include either a B. S. or M. S. degree in nuclear engineering, health physics or a related science, and six to ten years of experience related to radiation protection.

Westinghouse is responsive to the ALARA requirements of Regulatory Guide 8.8 and has devoted considerable effort via design and technology to minimize occupational radiation exposures due to equipment/systems/components within Westinghouse scope. Although Westinghouse does not charge the design engineers whose expertise lies in fluid dynamics, thermodynamics, etc. with radiation protection functions, Westinghouse does employ system analysis engineers, competent in the area of health physics and radiation protection, to work with those engineers in their disciplines of component or system design. Together, these personnel participate in the design review process in a systematic manner.

Following the review of design by the architect-engineer, and NSSS vendor, the design documents are similarly reviewed through internal circulation by the Applicant’s Engineering and Operations groups. Comments or changes required as a result of these reviews are incorporated or resolved prior to the issuance of the documents for construction. This review is accomplished by various engineers cognizant of radiation protection considerations assigned to the Nuclear Engineering Group, by the Staff Health Physicist, and by Station Health Physics. Qualifications of these reviewing personnel include appropriate education/degrees and experience ranging from 5 to 10 years.

Specific examples of BOP areas reviewed during the design review process and changes made in the BOP as a result of the design review include:

1. Radiation Shielding

   a. A permali shield for the push-pull rod for the out-of-core detector at the 180° reactor vessel position was added to prevent neutron streaming to an area outside the secondary shield.

   b. The gap between the reactor building and the fuel handling building was shielded to prevent streaming when spent fuel elements are transferred from the reactor building to the fuel handling building.

   c. The wall separating the mixed bed demineralizers in the chemical and volume control system (CVCS) was increased in thickness to lower the potential dose from the adjacent demineralizer.

   d. The sample sink was relocated to make it possible to put the sample lines and the sample vessels in a shielded chase.

2. Facility and Equipment Design

   a. The original design of the solid radwaste area, which did not include provisions for separation of high and low level waste, was modified to provide separate storage areas.

   b. The decontamination area in the hot machine shop was increased and additional equipment (a turbolator and additional ultrasonic sinks) was added to provide more capability for equipment and tool decontamination.

   c. The design previously included a provision for processing blowdown with minimal radioactivity through the cycle makeup demineralizers. This provision was deleted to preclude the possibility of a significant radiation source occurring in an unlimited access area.

3. Location of Instrumentation

   Two (2) monitors were relocated to lower radiation areas. Radiation monitor RM-L1 was moved from a CVCS piping area to a lower radiation area. Radiation Monitor RM-L6 was moved from a valve gallery to an operator access corridor.

   Examples of design features developed by the NSSS vendor and other features in Westinghouse PWR’s that reduce occupational radiation exposure are given in WCAP-8872, “Design, Inspection, Operation and Maintenance Aspects of the Westinghouse NSSS to Maintain Occupational Exposures as Low as Reasonably Achievable, edited by R. J. Lutz, April, 1977."

   These radiation protection design considerations have resulted in satisfying 10 CFR 20. Thus, the basic intent of Regulatory Guide 8.8 concerning as low as reasonably achievable (ALARA) is satisfied. It is the policy of the management of SCE&G that future design and construction also be accomplished in such a manner as to maintain occupational radiation exposures ALARA.

12.1 RADIATION SHIELDING

Radiation protection of plant operating personnel is accomplished by the use of adequate shielding against radiation. This radiation shielding is provided principally by concrete walls, floors, and ceilings, the thickness of which was determined by the need for access to the area, the type of radiation sources present, and structural requirements. Therefore, where structural strength is the controlling criteria, the radiation shielding provided is in excess of requirements.

NOTE: Section 12.1.1 is being retained for historical purposes only.

12.1.1 Design Objectives

The primary objective of the radiation protection systems, shielding design, and administrative controls is protection of operating personnel and the general public from potential radiation sources in the reactor, radwaste systems, and other auxiliary systems, including associated equipment and piping.

During normal operation, including anticipated operational occurrences, the design objectives for the radiation shielding are as follows:

1. To restrict the quarterly and annual doses to plant operating personnel and visiting radiation workers to within the limits set forth in 10 CFR 20. These limits are given in Table 12.1-1. Maximum whole body exposure rates are generally less than 100 mrem/hr, except in the case of certain maintenance, inspection, and refueling functions. The maximum dose rate in each instance is determined by the 10 CFR 20 quarterly restriction, by the required exposure time and by the previous and anticipated subsequent doses during the quarter.
2. To limit onsite whole body doses to nonoccupational workers and site visitors to 500 mrem/yr, with a maximum whole body dose during any given seven consecutive day period of 100 mrem. These personnel are not permitted in areas where whole body exposure rates are greater than 2.0 mrem/hr.
3. To ensure that the integrated offsite dose is within the limits specified by 10 CFR 20.
4. To protect certain components from excessive radiation damage or activation.

In the unlikely event of an accident, the radiation shielding design objectives are as follows:

1. To satisfy the requirements of 10 CFR 50, Appendix A, Criterion 19, i.e., to provide adequate radiation protection for operating personnel following a reactor accident such that the accident may be terminated without excessive radiation exposure to the operators or the general public.
2. To limit offsite doses from both contained and released radioactivity to within the limitations set forth in 10 CFR 50.67.

The above shielding objectives served as an upper limit during design of the radiation shielding. The philosophy followed during design and construction of the plant has been to give extensive consideration to the shielding design to assure that radiation exposures to personnel are kept as low as is reasonably achievable (ALARA). This philosophy has resulted in a shielding design that results in occupational and general public exposures being well within the design objectives previously listed. During the operational phase of plant life, this policy of maintaining radiation exposures at a minimum will be continued.

12.1.2 Design Description

Scaled layouts and cross sections of the Reactor Building and surrounding shield buildings and of the Auxiliary, Control, and Fuel Handling Buildings are provided by Figures 12.1-1 through 12.1-20. While these figures do show specific layout of equipment, the purpose of presenting these figures is to show specific areas in the plant which have been zoned in accordance with maximum design radiation levels and occupancy requirements. These figures will be revised only when the boundaries or designations of the radiation zones change and will not be revised to show equipment relocations, deletions, additions, etc. Figure 1.2-1 shows the total plant layout within the site boundary, as well as identifying any outside storage areas and railroad spur or siding locations.

12.1.2.1 Plant Shielding Description

Specific areas in the plant have been zoned in accordance with maximum design radiation levels and occupancy requirements. The occupancy requirements have been based on the general access requirements (as defined by an analysis of the operation of the plant and from information obtained from operating facilities) and access requirements for other operations such as maintenance, refueling, instrument calibration, and similar reoccurring activities. An explanation of each of the five zones and the maximum dose rates anticipated are given below:

Zone	Occupancy	Dose Rate (mrem/hr)
I	Uncontrolled. No restrictions on occupancy expected.	< 1.0
II	Controlled, Unlimited access, 40 hrs./week	< 2.5
III	Controlled. Limited access, 6 to 40 hrs./week.	< 15.0
IV	Limited access for short periods, 1 to 6 hrs/week.	< 100.0
V	Controlled, high radiation area, occupancy averages less than one hr/week.	> 100.0

The radiation shielding is designed to attenuate direct and scattered radiation according to the dose limits required by this zoning.

The locations of these radiation zones throughout the plant are depicted in the layouts shown by Figures 12.1-1 through 12.1-20. An equipment list is presented as Figure 1.2-28a. Figures 12.1-1 through 12.1-9 show this radiation zoning for the plant during normal operation, while Figures

12.1-10 through 12.1-18 depict this zoning for zoning of the Control Building during normal operating and shutdown periods. The radiation sources used in determining these radiation levels are defined in Section 12.1.3 and were calculated assuming fuel cladding failures of one percent. The thickness of radiation shielding in various parts of the plant is presented in Table 12.1-1A.

Plant radiation shielding is divided into six categories: primary, secondary, Reactor Building, Control Room, fuel transfer, and Auxiliary Building shielding. Each of these categories is discussed below:

1. Primary Shield

   The primary shield is a concrete structure surrounding the reactor pressure vessel. It is of varied thickness and has inspection openings (above the reactor-to-coolant pipe nozzles) and penetration ports adjacent to the core for excore neutron detectors.

   The excore neutron detector push rods penetrate the primary shield at the height of the core. Where these penetrations are not inside the secondary shield, one foot thick permali (densified beechwood laminate) shield covers are provided to preclude any neutron streaming from these penetrations.

   The inspection openings above the reactor-to-coolant pipe nozzles remain open during operation. They are closed during shutdown for refueling. The design of the reactor cavity and control rod missile shield is such that a direct exposure to plant personnel from these inspection openings or from the annular gap between the reactor vessel and primary shield is not possible. However, the scattering of neutron and gamma radiation from the Reactor Building dome will result in dose rates that range from 1 mrem/hr to 100 mrem/hr at the operating floor level. Measured dose rates in operating plants support this conclusion. Exposure of workers to these dose rates will be minimized since access to the operating floor during power operation is under strict administrative control.

   The three basic paths by which neutron and gamma radiation may stream out of the primary shield are indicated by Figure 12.1-21, with the basic locations involved as follows:

   a. Primary piping penetrations.
   b. Excore neutron detector instrumentation push rods.
   c. Vertical streaming of neutrons along the pressure vessel wall.

   Primary piping penetrations do not contribute an appreciable amount to the dose rate in any accessible area since the penetrations are only open to the inside of the secondary compartments which are inaccessible at all times during power operation.

Neutron detector push rods penetrate the primary shield in an area which is not circumscribed by the secondary shield and neutrons of energy less than 1.0 MEV stream in iron; therefore, the COHORT-II Monte Carlo computer code with a mono-directional point source directed into the inner end of the push rod was utilized to calculate a neutron removal cross Section for this particular geometry. Neutron shield covers were designed to cover the areas where the push rods exit the primary shield. The neutron dose rate outside these shield covers is estimated to be less than 50 mrem/hr.

It is well known that neutrons emanating from the core scatter up and out of the gap between the pressure vessel and the concrete primary shield, whereupon they are free to scatter to the operating elevation inside containment. The magnitude of the neutron dose rate on the operating elevation from this neutron source is strongly dependent upon the size of the gap between the pressure vessel flange and the primary shield. The gap width between the pressure vessel flange and the primary shield is only 7.25 inches. Therefore, it may be anticipated that the neutron dose rate on the operating elevation will be rather low.

Additionally, Monte Carlo calculations have been performed utilizing the COHORT-II computer code. The main feature of the geometry of the pressure vessel, primary shield, gap, nozzles, reactor cavity, and containment were incorporated. The source was conservatively assumed to be isotropic and located in the gap on the surface of the pressure vessel over the core height. Neutrons were biased in direction (going up the gap) and in energy (toward the high energy end of the spectrum). Point fluxes and resultant dose rates were obtained on the operating level using this code. These calculation estimates indicate that the neutron dose rate will be less than 100 mrem/hr on the operating level.

Primary shielding includes the following:

a. The elements inside the reactor pressure vessel, including the core baffle, core barrel, thermal shield, and water annuli.

b. The reactor vessel wall.

c. The concrete structure surrounding the reactor vessel. This structure extends from below the floor at the 412’ elevation to an elevation of 437’-2-3/4" and, at a reduced thickness except across the refueling canal, from the 437’-2-3/4" elevation up to the operating floor (elevation 463’). The shield thickness in the lower region of the primary shield ranges in thickness from 8’-8-1/4" to 13’-8-1/4", while the upper, reduced thickness portion of the shield has a thickness of 4 feet. The upper part of the primary concrete shielding is completed by the walls of the refueling canal which also extend upward to the 463’ elevation. These walls have a minimum thickness of 3 feet.

   The primary shield as a whole or in part serves to:

   (1) Attenuate the neutron flux sufficiently to prevent excessive radiation damage to the reactor vessel.

(2) Reduce the heat flux from neutron and gamma radiation at the reactor vessel outer surface such that any cooling necessary to avoid high temperatures and possible dehydration in the surrounding concrete is an easier task.

(3) Attenuate neutron and gamma fluxes to prevent excessive radiation damage and activation of plant components and structures.

(4) Reduce, in conjunction with the secondary shield, the radiation escaping the reactor vessel sufficiently to allow limited access to certain areas of the Reactor Building during normal full power operation.

(5) Reduce the radiation escaping the reactor vessel sufficiently to permit access inside the secondary shield, at a reasonable time after shutdown, for routine maintenance and inspection.

1. Secondary Shield

   The secondary shield is a series of concrete structures which enclose the reactor coolant loops and pumps, the pressurizer and pressurizer relief tank, the steam generators, and portions of the primary shield. These structures extend from the floor at the 412’ elevation to varying elevations, the highest of which is elevation 513’-6". The secondary shield is 3’-8" thick.

   The main function of the secondary shield is to reduce the dose rates from the primary coolant loops such that most areas within the Reactor Building outside the secondary shield are classified as radiation Zone IV during normal full power operation and Zone III when the plant is shut down.

2. Reactor Building

   The Reactor Building is a steel reinforced concrete structure consisting of a 4 foot thick cylindrical wall and a 3 foot thick shallow dome roof. This structure encloses the Nuclear Steam Supply System (NSSS) and serves to attenuate any radiation escaping the primary-secondary shield complex such that the radiation level in occupied areas outside the Reactor Building permits unlimited occupancy. In addition, this structure shields operating personnel and the general public from radiation sources resulting from activity released to the Reactor Building from postulated accidents. The general shielding considerations employed in the arrangement of the Reactor Building penetrations are discussed in Section 12.1.2.2.

3. Control Room Shielding

   Shielding for the Control Room is designed to satisfy the requirements of General Design Criterion 19, i.e., adequate radiation shielding is provided to permit continuous occupancy of the Control Room under accident conditions described in Regulatory Guide 1.183 (see Appendix 3A) without personnel receiving radiation exposures in excess of 5 rem TEDE for the duration of the accident. The shielding that is provided for the control room is as follows:

a. Control Building walls - each 2 feet thick.

b. Control Building roof - 2 feet thick.

c. Control Room floor - 8 inches thick.

d. Control Room ceiling - 9 inches thick between column lines G and H and 2 feet thick between column lines H and H.6 (see Figure 1.2-19).

This shielding is of ordinary concrete and is adequate to attenuate radiation from external sources (e.g., activity inside the Reactor Building, airborne activity external to the Control Room, and activity in areas surrounding the Control Building) to a small fraction of the 5 rem TEDE limit in accordance with Regulatory Guide 1.183. A more significant portion of the radiation dose to Control Room personnel during a design basis accident is due to airborne activity within the Control Room. This subject is discussed in Chapter 15.

Figures 12.1-19 and 12.1-20 present a layout and section of the Control Room.

4. Fuel Transfer Shielding

During fuel transfer operations, the refueling canal and the region above the reactor vessel are filled with borated water to an elevation of 461.5’. The water level in the fuel transfer canal and spent fuel pool in the Fuel Handling Building is also at elevation 461.5’. This water, along with the surrounding concrete, serves as radiation shielding for the spent fuel as it is removed from the core, transferred through the refueling canal and transfer tubes, stored in the spent fuel pool, and, after a decay period, loaded into a shipping cask. This water and concrete also provide shielding from activated control rod clusters and reactor internals which are removed during refueling periods. The concentration of radioactivity in the refueling water is controlled by administrative procedures and a sufficient depth of water above the fuel assembly is maintained so that the direct exposure rate at the surface of the water does not normally exceed 2.5 mrem/hr. However, certain manipulations of fuel assemblies, rod clusters, or reactor internals may produce short term exposures in excess of 2.5 mrem/hr. The fuel transfer tube is shielded to limit doses due to radiation streaming through penetrations and gaps. Lead shielding is provided in the fuel transfer tube inspection accessway inside the Reactor Building, in the gap between the refueling cavity wall and the Reactor Building liner, and in the gap between the Reactor Building and Fuel Handling Building (see Figure 12.1-22). This shielding ensures that radiation doses do not exceed 100 mrem/hr in areas adjacent to the tube during transfer of fuel inside the Reactor Building.

Lead shielding was not provided on the underside of the 3 inch gap between the Reactor Building and the cantilevered top of the retaining wall adjacent to the Reactor Building. Access to this area will be limited during refueling operations by administrative control. Radiation levels are closely monitored during refueling operations to ensure that plant personnel doses are maintained well within the limits specified by 10 CFR 20.

5. Auxiliary Building Shielding

   Shielding in the Auxiliary Building is designed to protect plant personnel from radiation from components and piping of the following systems during normal operation, including anticipated operational occurrences:

   a. Chemical and Volume Control System.
   b. Waste Processing Systems.
   c. Solid Waste Disposal System.
   d. Residual Heat Removal System.
   e. Spent Fuel Cooling System.
   f. Boron Recycle System.
   g. Sampling Systems.
   h. Nuclear Blowdown Processing System.

   Auxiliary Building shielding includes concrete floors, walls, doors, covers and/or removable blocks, and local permanent shielding such as lead plates supported by steel framing. The shielding is designed to satisfy the radiation zoning requirements set forth previously.

   Where practical, shielding is also provided between components to permit plant personnel to enter the equipment compartments under controlled conditions and perform required maintenance without shutdown or decontamination of adjacent compartments.

   Additionally, shielding design considered the location of certain manways to components to provide optimum accessibility and the best possible work area to reduce exposure time during required maintenance.

   For example, in the case of the recycle holdup tanks, entrance to the cubicle is from the 412’ elevation (bottom of tank is at elevation 388’-6") since the compartment is watertight up to a level equivalent to the maximum volume of the tank. For normal maintenance, a platform is provided around the east side of the tank. For major maintenance, such as removal of the tank diaphragm or tank cleaning, the tank will be emptied and flushed prior to the commencement of maintenance. The manway, approximately three feet above the floor (elevation 388’), is located to maximize freedom of movement into and out of the tank. The minimal increase in exposure during major maintenance to a worker walking to the manway is more than offset by the provision of the best possible work area at the manway.

12.1.2.2 Plant Shielding Design Criteria

To ensure that doses to plant personnel are kept within the limits specified in Section 12.1.1, shield walls are erected around plant components and piping which are anticipated to contain potentially significant amounts of radioactive materials. These shield walls are constructed of

ordinary concrete (density of 145 lb/ft^3) and are sized such that radiation levels are reduced to satisfy the radiation zoning requirements defined in Section 12.1.2.1. The calculational methods used to determine the thickness and other dimensions of the shield walls are discussed in Section 12.1.2.4. In cases where access to equipment enclosures is through these shield walls, shielding effectiveness is maintained through the use of labyrinth entrances. Separation of shielded components and equipment compartments, where practicable, has been utilized in efforts to limit potential exposure during plant operation. The design criterion for piping penetrations, ducts, voids, and other irregularities in the shield walls is to situate them to minimize radiation streaming from a high radiation area to low radiation areas. If the penetrations, etc., cannot be so situated, compensatory shielding (e.g., steel or lead wool, steel plates, shadow shields, etc.) are provided. Examples of use of compensatory shielding are discussed below:

1. Most of the Reactor Building penetrations are in compartmentalized penetration access areas which provide further shielding for those areas of the plant more frequently occupied. Location of equipment anticipated to require frequent attention has been minimized in these access areas.
2. A concrete shadow shield for the Reactor Building equipment hatch above the 463’ elevation is provided.
3. A shadow shield is provided for the out of core neutron detector push rod penetrations of the primary shield.
4. Most of the Auxiliary Building shield wall penetrations are located close to the ceiling of the shielded penetration access areas.

When practical, piping containing radioactive material is routed through high radiation areas where accessibility is precluded. When this is not possible, such piping is routed through shielded pipe chases which serve to reduce radiation exposure rates to plant personnel when in the vicinity of this piping. Based on operating experience additional permanent, removable local shielding has been added to local areas such as around parts of the Residual Heat Removal and Safety Injection piping to reduce radiation exposure to operation and maintenance personnel.

Piping containing highly radioactive fluid is routed by engineering as stated in Section 12.0. Changes in the routing of such piping due to field conditions must be approved by engineering. In this manner, the same controls and considerations applied to the original pipe routing are applied to the field changes. If the changes are not acceptable from the standpoint of radiation exposure, other measures, such as additional shielding, etc., are employed.

Routing of very small piping is accomplished in the same manner as is the routing of large piping. Small, safety class piping is designed and routed by engineering, not by the field.

Equipment which contains or processes radioactive fluids is so located as to cause minimal occupational dose to plant personnel. Demineralized Water Nuclear Services supplies hose fittings located approximately every 50 feet along Reactor Building, Auxiliary Building, and Fuel Handling Building access ways for decontamination.

The components of the Excess Liquid Waste System, such as filters, demineralizers, tanks, and pumps, provide illustrative examples of equipment location. These components are located in individual shielded cubicles with labyrinthine entrances if personnel entry is required (see Figure 12.1-3).

Figures 12.1-3 through 12.1-20 illustrate the location of equipment associated with systems, such as Spent Fuel Cooling, Reactor Makeup Water, Sampling, and Solid Waste Disposal, and individual items, such as the miscellaneous waste drain tank. Color codes on these figures indicate expected dose rates in various areas and the length of time such areas may be occupied (on a weekly basis) by plant personnel.

Systems processing radioactive liquids are equipped with diaphragm type, leak proof valves to minimize spillage of radioactive materials.

Elevated door stops, concrete curbs, and floor drain systems which route a spill to the proper waste processing system are employed to minimize the spread of contamination. An effort has been made to locate instruments requiring inplace calibration in the lowest practicable radiation zones.

Provisions have been made to allow for flushing of systems that may become contaminated.

Remote handling equipment and portable shielding is available on site for use when needed.

12.1.2.3 Accident Shielding

The accident shielding objective is to attenuate radiation exposures due to activity in the Reactor Building to a small fraction of 10 CFR 100 limits and to a level at which required access to onsite locations can be achieved. The shielding design review performed for NUREG-0578 addresses the limitations imposed by the post-accident radiation fields on the timely recovery from an accident due to limited personnel access capability and/or safety equipment operation degradation. The results of the shielding review are presented in Appendix 12A.

12.1.2.4 Shielding Calculational Methods

The sizing of the radiation shielding required to reduce the exposure rates from the sources defined in Section 12.1.33 to satisfy the radiation zoning defined in Section 12.1.2.1 is done using the computer codes SDC (Reference 1) or QAD6G (Reference 2) and/or hand calculations. Both SDC and the hand calculations are utilized in performing basic shielding calculations involving relatively simple geometric source configurations, such as point, line, cylinder, sphere, slab, or disk. These methods employ many of the integrations and techniques found in Reference 3. QAD6G is a point kernel code utilized in performing shielding calculations with more generalized, complex geometric configurations.

Radiation dose rates in and around shielded labyrinth entranceways to cubicles were estimated using a simplified albedo hand calculation. The wall that is directly exposed to the radiation source was divided into scattering areas. Then, using the geometrical configuration to determine

the appropriate angles, the incident dose rates on each of the scattering areas and tabulated values of concrete gamma ray albedos, an estimate of radiation dose rates at areas in and around the labyrinths can be determined. This methodology has been checked using the G3 Code (Reference 10).

Source strengths and geometric models used for equipment during the performance of shielding calculations are presented in Tables 12.1-2 through 12.1-5.

12.1.3 Source Terms

The shielding design source items are based upon the three general plant conditions of normal full power operation, shutdown, and design basis events.

12.1.3.1 Sources for Normal Full Power Operation

Design consideration has been given to the reduction of activation product formation and buildup. For example, materials with low cobalt content are specified for primary coolant system alloys. However, the availability, durability, and economics of component materials must always be considered during material procurement. High cobalt, hard facing wear materials, such as Stellite, which come in contact with the primary coolant are used only where substitute materials cannot meet performance requirements.

The process of high flow rate/high temperature filtration is not a standard practice in Westinghouse NSSS and is not planned for Virgil C. Summer Nuclear Station.

These methods of cobalt reduction along with valve design and quantities of nickel alloys in the primary system are discussed in detail in WCAP-8872, “Design, Inspection, Operation and Maintenance Aspects of the Westinghouse NSSS to Maintain Occupational Radiation Exposures as Low as Reasonably Achievable.”

To minimize exposure levels associated with valve stem leakage, packless valves are provided for those systems that normally contain radioactive fluid. These valves are designed for zero stem leakage. A metal bellows seal is used in high pressure applications; an elastomer diaphragm, in low pressure applications. For safety related diaphragm valves, a new valve design is used. This design substantially reduces maintenance requirements since diaphragm life has been increased by a factor of five.

Several features are incorporated into the design of packed valves to reduce crud buildup and maintenance requirements. These features include positive backseats to permit inline replacement of packing, lantern ring seal leakoffs, and special, close tolerance graphoil packing in lieu of conventional packing.

The main sources of radiation during normal full power operation are the reactor core, the reactor coolant, and auxiliary systems associated with the processing or handling of reactor coolant.

12.1.3.1.1 Reactor Core

The neutron fluxes at the inside surface of the primary shield concrete at the core midplane are listed in Table 12.1-6. These fluxes represent average values on the core center plane and are based upon a core axial peaking factor of 1.30. Axial variation factors for off midplane variation of neutron flux in the primary shield concrete are also listed in Table 12.1-6.

The gamma fluxes at the inside surface of the primary shield concrete at the core midplane are listed in Table 12.1-7. Values of gamma fluxes above and below the core midplane can be obtained by applying the axial variation factors which are also presented in Table 12.1-7.

12.1.3.1.2 Reactor Coolant

The main sources of activity in the reactor coolant during normal full power operation are N_{16} from coolant activation processes, fission products from fuel clad defects, and corrosion and activation products. All shielding has as its design basis the maximum case of clad defects in fuel rods producing 1.0 percent of core thermal power. Activity concentrations in the reactor coolant are listed in Table 11.1-6. The activities in the pressurizer steam and liquid phases are given in Table 11.1-4 and the pressurizer deposited sources in Table 12.1-8. The N16 activity of the coolant is given in Table 12.1-9 as a function of transport time in a reactor coolant loop.

The N-16 sources in Table 12.1-9 include the effects of irradiation of the coolant both in the core and reflector regions outside the core. Transit times around a coolant loop and within the reactor vessel are based on design flow rates and active flow volumes at 100% power operation. The transit times are included in Table 12.1-9.

12.1.3.1.3 Sources for Auxiliary Systems

The auxiliary system equipment for which a determination of shielding sources is required consists of pumps, heat exchangers, demineralizers, filters, units of evaporator packages, liquid tanks, gas tanks, and pipes. Reactor coolant activities assumed in the development of all auxiliary system source terms are given in Table 11.1-2 and are based upon 1.0 percent failed fuel.

12.1.3.1.3.1 Chemical and Volume Control System Sources

The purpose of the Chemical and Volume Control System (CVCS) is to provide continuous purification and volume control of the reactor coolant water. The major equipment items include the regenerative and letdown heat exchangers, mixed bed and cation bed demineralizers, reactor coolant filter, volume control tank, and charging pumps. The Boron Thermal Regeneration (BTR) subsystem contains the three BTR heat exchangers and the BTR demineralizers. The Seal Water subsystem for the reactor coolant pumps includes the injection and return filters and the seal water heat exchanger. The spectral source strengths in the CVCS purification letdown flow are tabulated in Table 12.1-10. The sources assume sufficient delay time from the reactor coolant loop for decay of the N16 isotope.

The radiation sources in the ion exchangers of the CVCS system are listed in Table 12.1-2. The mixed bed retains the fission product activity, both cations and anions, and the corrosion product (crud) metals. The cation bed can be used intermittently to remove lithium for pH control and to supplement the mixed bed in removing yttrium, cesium, molybdenum, and the crud metals. The Boron Thermal Regeneration beds are used to regulate the boron concentration in the reactor coolant water. They are utilized during load following operations and for removal of boron from the coolant as the nuclear fuel is depleted. These demineralizers also collect radioactive anions, such as iodine, which may have passed through the mixed bed.

The sources in the volume control tank are listed in Table 12.1-3. These sources correspond to a nominal tank operating level of 125 ft^3 in the liquid phase and 175 ft^3 in the vapor phase.

Before transferring the contents of the evaporator batch tank to the boric acid tank, a sample is taken which should satisfy two criteria:

1. A boron content of ~ 7000 ppm
2. An activity concentration of < 0.01 μc/cc

If both criteria are not satisfied, the contents are recycled through the evaporator feed demineralizers. An activity concentration of < 0.01 μc/cc in the feed to the boric acid storage tanks is the basis for not shielding the tanks and associated piping.

For filters in the CVCS system, the design criteria for handling and shielding are primarily based upon operating experience and are as follows:

1. Capability should be provided for changing filters with radiation levels of 100 R/hr at contact with the filter housing. This criterion is applicable to the following filters: seal water injection and seal water return.
2. Capability should be provided for changing the reactor coolant filter with radiation levels of 500 R/hr at contact with the filter housing.
3. The total combined exposure to personnel changing any one of the above filters should not exceed 100 mr.

The exposure rates listed in Items 1 and 2, above, are considered to be maximums, with limits controlled by periodic monitoring.

The specific source strengths of the subject filters are included in Table 12.1-4. The sources for the reactor coolant filter correspond to an exposure rate of 500 R/hr at contact. The sources for the remaining filters correspond to an exposure rate of 100 R/hr at contact. The filters are assumed to be drained of process fluid and are considered to be homogeneous sources.

The radiation sources in the heat exchangers of the CVCS system are listed in Table 12.1-5. The regenerative and excess letdown heat exchangers are located in the Reactor Building. They provide the initial cooling for the reactor coolant letdown and their sources include N16 activity.

The remaining CVCS heat exchangers are located in the Auxiliary Building where N16 activity is not a significant factor. The letdown heat exchanger provides second stage cooling for the reactor coolant prior to entering the demineralizers. The seal water heat exchanger cools water from several sources, including the reactor coolant discharged from the excess letdown heat exchangers. The activity of these heat exchangers is identical to that listed in Table 12.1-10. The thermal regeneration heat exchangers include the moderating, chiller, and letdown reheat units. The radiation sources in this equipment are modified to account for activity removed by the demineralizers upstream of the units.

12.1.3.1.3.2 Boron Recycle System Sources

The major equipment items included in the Boron Recycle System (BRS) are the recycle holdup tank and the Reactor Water Grade System Demineralizers and associated equipment, i.e., feed demineralizers and filter, condensate demineralizers and filter, and concentrates filter. Radiation sources in the various pumps are assumed to be identical to the liquid sources in the tank from which the pump takes suction.

The radiation sources in the BRS ion exchangers are listed in Table 12.1-2. The evaporator feed demineralizers are located upstream of the holdup tanks and contain resins which remove nongaseous activity from the reactor coolant directed to the holdup tanks. A decontamination factor (DF) of 10 across those beds is taken for all particulate activity.

The recycle holdup tanks are each equipped with a diaphragm. Gases which flash from the reactor coolant letdown to the holdup tanks are retained under the diaphragm until approximately 500 ft^3 of gas has accumulated. The gases are then removed to the Waste Gas System. The radiation sources in the holdup tanks are based upon an assumed letdown rate of 120 gpm to a single holdup tank with 50 percent of the volatile activity flashing into the vapor phase. These sources are listed in Table 12.1-3.

The recycle evaporator feed filter and condensate filter are located downstream of their respective demineralizers and serve to retain particulates and any resin fines which may escape from the demineralizers. The maximum radiation sources in these filters are listed in Table 12.1-4. The sources for the feed filter correspond to a radiation level of 100 R/hr at contact. The condensate filter sources result in levels of less than 1 R/hr at contact. The radiation sources in the concentrates filter correspond to an exposure rate of approximately 10 R/hr.

12.1.3.1.3.3 Waste Processing System Sources

The radiation sources in the Waste Processing System (WPS) are tabulated in Tables 12.1-2 through 12.1-5 and 12.1-11. The major equipment items in the waste gas portion are the waste gas compressors, hydrogen recombiners, and gas decay tanks. The radiation sources in this equipment are based upon cold shutdown procedures during which the radioactive gases are stripped from the reactor coolant system. Since the gases are continuously recirculated, the radiation sources in the waste gas equipment are identical.

The Liquid Waste Processing System is considered as several subsystems, based upon intended use during normal operation.

Low activity, non-reactor grade water is directed to the Floor Drain Laundry and Hot shower, or Excess Waste/Decon Pit Collection (ELWS) tanks. Normally this water is analyzed, then discharged. If activity levels prevent this, the water can be processed by a demineralizer/filter. The equipment items included in the subsystems are the floor drain tank and filter, laundry and hot shower tank and filter, excess waste holdup tank demineralizer and filter, decon pit collection tank demineralizer and filter, waste monitor tank demineralizer and filter, and two waste monitor tanks. The floor drain, waste monitor, and excess waste tanks provide surge capacity for the waste holdup tank during periods when abnormal volumes of liquid waste are encountered. Hence, for shielding purposes, the radiation sources in these tanks are assumed to be the same, i.e., degassed reactor coolant. Similarly, the sources in the floor drain tank filter are based on degassed reactor coolant. The sources in the waste monitor tank demineralizer and filter are based upon circulating reactor coolant through these components.

Maximum radiation sources in demineralizers of the WPS and ELWS are presented in Table 12.1-2. Radioactive spent resins, discharged from the various demineralizers, are retained in the spent resin storage tank. Mixed bed demineralizers contain the most radioactive resin discharged to the spent resin storage tank. These sources determine the required tank shielding. The short lived activity is allowed to decay (approximately 30 days) and the resin is then directed to the drumming station for packaging. The associated equipment includes the spent resin storage tank and the resin sluice pump and filter. The resin sluice filter is shielded for radiation levels of 100 R/hr at contact.

The waste monitor tank demineralizer can be used to remove activity admitted to the waste monitor tanks.

The maximum radiation sources in the various filters of the WPS and ELWS are listed in Table 12.1-4. The waste monitor tank filter is located downstream of the demineralizer. The sources in the condensate filter result in radiation levels of approximately 1 R/hr at contact. The monitor tank filter sources produce approximately 85 R/hr at contact. The maximum radiation levels in the spent resin sluice and floor drain tank filters are 100 R/hr at contact.

Radiation sources in the various pumps of the WPS and ELWS are assumed to be identical to the liquid sources in the tank from which the pump takes suction.

Sources in the laundry and hot shower tank and filter and in the waste condensate tank are negligible. Therefore, these items do not require shielding.

Sources of solid waste for the drumming station are given in Table 12.1-11. A description of the solid waste system is given in Section 11.5.

12.1.3.1.3.4 Sources for Blowdown Systems

Radiation sources for equipment in the Steam Generator Blowdown and Nuclear Blowdown Processing Systems are presented in Tables 12.1-2 through 12.1-5.

The major equipment items in these systems are the steam generator blowdown heat exchangers, nuclear blowdown holdup and monitor tanks, blowdown filters, blowdown demineralizers, and the blowdown spent resin storage tank. Radiation sources are based upon one percent failed fuel and a maximum steam generator tube leakage rate of 0.1 gpm.

12.1.3.1.3.5 Sources for Spent Fuel Cooling Systems

The radiation sources in the spent fuel demineralizer and filter are listed in Tables 12.1-2 and 12.1-4, respectively. This equipment is used to maintain water clarity and remove activity released during refueling operations and the subsequent fuel cooling period. The filter sources correspond to an exposure rate of 100 R/hr at contact. The spent fuel pool skimmer is used only for cleaning the surface of the spent fuel pool water and does not require shielding.

12.1.3.2 Sources for Shutdown

12.1.3.2.1 Primary System Sources at Shutdown

The core gamma sources after shutdown are used to establish radiation shielding requirements during refueling operations and during shipment of spent fuel. The sources associated with the spent fuel are based upon an average power assembly with an irradiation time of 108 seconds (3.1 years). These source strengths per unit volume of homogenized core are listed in Table 12.1-12 for various times after shutdown.

The irradiated control rod sources are used in establishing radiation shielding requirements during refueling operations and during shipment of irradiated control rods. The absorber material used in the control rods is silver-indium-cadmium (Ag-In-Cd). The source strengths associated with the control rods are listed in Table 12.1-13 for various times after shutdown. The values are in terms of centimeter of height of a single control rod for an irradiation period of 100,000 hours.

The Ag-In-Cd control rod sources included in Table 12.1-13 are based on an irradiation period of 100,000 hours. This design basis leads to conservative source term values since it is not expected that any control rod will spend a majority of its design life (15 years) in the inserted position.

The incore detector drive wire sources are used in establishing the radiation shielding requirements for the wires when the detectors are not in use and during shipment when the detectors have failed.

The incore drive wire sources are based on the assumption that the drive wire has been lodged in the core for one full year. These sources are tabulated in Table 12.1-14 and are conservative in that the drive wires will normally be inserted in the core for short periods of time during flux mapping.

The activities of steam generator primary side surfaces are used in determining access limitations in and around the steam generators at plant shutdown.

Estimated corrosion product deposited sources are given in Table 12.1-8 and 12.1-15. The corrosion product sources are based on the methods and equations presented in the following reference:

S. Yerazunis, E. H. Alkire and R. L. Seidel, *Mechanisms of Reactor System Activatio*n, KAPL-M-SMS-98, May, 1959.

The transport and corrosion parameters used in the calculations are selected so that the results predicted by this method reflect operating plant data. The buildup of corrosion products deposits is treated as follows:

a. Transient crud layers are assumed to exist at a nominal thickness of 50 mg/dm^2.

b. Permanent crud films are assumed to build up to 90% of their maximum thickness (nominally assumed to be 50 mg/dm^2) early in the initial cycle of operation. The remaining 10% of the deposit is then assumed to build up linearly thereafter, over the operating period.

12.1.3.2.2 Auxiliary Cooling System Sources

The maximum specific source strengths in the Residual Heat Removal System are listed in Table 12.1-16. The Residual Heat Removal System is placed in operation approximately 4 hours after the start of reactor shutdown and reduces the reactor coolant temperature to approximately 120°F within about 20 hours after the start of shutdown. The sources are maximum values with credit taken for 4 hours of activity decay and purification. Accident sources in the Residual Heat Removal System are considered separately in Section 12.1.3.3.

12.1.3.3 Sources Under Accident Conditions

The sources for accident conditions are provided in Chapter 15.

12.1.4 Area Monitoring

12.1.4.1 Design Basis

The area radiation monitors are designed to detect, indicate, annunciate, and record the radiation levels monitored at selected locations inside the plant. These locations were selected on the basis of monitoring normally occupied zones critical to plant operation, monitoring occupied areas, access corridors and fuel handling areas with potential for airborne radioactivity, and having the capability to monitor the trend of Reactor Building activity following a loss of coolant accident. These monitors provide supporting data to the surveillance of plant radiation levels as recommended by ANSI N13.2 (Reference 5) and Regulatory Guide 8.2, and as required by 10

CFR 20. Area monitor instrumentation is provided to supply information and to aid in maintaining dose rates ALARA and is not considered safety-related.

Permanently installed area radiation monitors are not provided for the containment equipment access hatch area, low level waste storage area, or high level waste storage area because of the following considerations:

1. Portable radiation monitoring equipment will be used to survey these areas or any other potentially radioactive areas prior to access by personnel.
2. Access to these areas is required infrequently and will be permitted only under the supervision of health physics personnel after issuing a radiation work permit (RWP) as described in Section 12.3.2.3.7.
3. Although Figure 12.1-5 (sheet 2 of 2) indicates that the dose rates in the low and high level waste storage areas result in classification of these areas as Zone V, the dose rates will normally be reduced to a level less than required for Zone V classification by use, as required, of shielding.

12.1.4.2 System Description

The area radiation monitors consist of eighteen fixed and one movable channel, as identified in Table 12.1-19. The area radiation monitoring instruments provide indication of proper plant operation by measurement of the gamma dose rate levels in selected areas of the plant. Reliable power for the instrumentation is obtained from the diesel backed, 120 volt instrument buses. The local audible and visual alarm are powered from the 120 volt buses. The movable channel is powered from a 120 volt outlet.

Except for the movable unit, which is equipped for local recording and indication, the measured dose rate levels are indicated and recorded on the Area Radiation Monitoring System control panel located in the Control Room. Local indication is provided for each monitor except RM-G18. Each area radiation monitor is equipped with two adjustable alarm levels (alert and high) and a channel failure and/or loss of power alarm except RM-G7. Channel RM-G7 provides the following alarms: alert, high radiation, loss of power to the alarm module. These alarms (from the fixed monitors) are connected to an annunciator panel on the Radiation Monitoring System control panel in the control room. Each area radiation monitor, except for RM-G17A&B, RM-G7, and RM-G18, is provided with a local audible and visual alarm located near the detector or local readout. The manipulator crane area monitors RM-G17A&B, each have an audible alarm in the fuel handling area. The alarm setpoints are adjustable and are dependent upon the location of the individual monitors. In general, the alert setpoint is adjusted to a level below the high setpoint to provide warning of a change in normal plant operation conditions. The high setpoint is generally established by the zone limitations established for each area. The gamma dose rate resulting from a postulated loss of coolant accident (LOCA) is monitored by the high range Reactor Building monitors, RM-G7 and RM-G18. RM-G7 and RM-G18 are located inside the containment and are designed to meet IEEE-323-1974, IEEE-344-1975, ANSI N320-1978.

Channels RM-G7 and RM-G18 are composed of a Victoreen model 877-1 stainless steel ion chamber detector and a Victoreen model 876A-1, 7-decade ratemeter. Both of these channels of instrumentation meet seismic separation and 1E power source criteria and provide the appropriate display indication, record, and alarms in the Control Room. They also meet the IEEE-323 and LOCA environmental qualification requirements. Both channels have a clear view of the operating floor area of the containment as shown in Figure 1.2-6. The response of these channels to gamma (photon) radiation at 1 mev is approximately 100% and approximately 85% at 80 kev. Based on the average gamma energy anticipated after a LOCA as shown in report NUREG CR-1237, SAND 79-2143 (January 1980), RM-G7 and RM-G18 will respond to within +8%.

Radiation Monitors RM-G7 and RM-G18 were added to the Radiation Monitoring System to meet the requirements of NUREG-0578, NUREG-0737, and Regulatory Guide 1.97, Rev. 2. These provide a diverse means of measuring the containment for high level gamma radiation. The detectors are stainless steel gamma sensitive ion-chamber that are wall mounted inside the containment above the 463 foot floor elevation, reference Figure 1.2-6. Continuous 7 - decade analog readout is provided in the Control Room Radiation Monitoring System panel with an indication range of 1 to 10^7 R/h. The detector energy response is sensitive to 60 KEV, -15% at 80 KEV and within ± 10% from 100 KEV to 3 Mev.

The analog signals are recorded on multipoint recorders which are seismically mounted on the Radiation Monitoring System panel. High gamma dose rate or channel failure is annunciated in the Control Room.

1E instrument power is obtained from the A and B-train diesel backed 120 Vac. The detector and Control Room readout have been type tested for seismic qualification to meet the requirements of IEEE-323(1974). The detector and its interface cable-connector assembly have been type tested for LOCA environment to meet Regulatory Guide 1.89. Calibration of the high range containment gamma monitors is performed during refueling and consists of verification of the readouts by a calibrated current source and by a point source verification of response of the ion-chamber detectors in the low range (approximately 10R).

The gamma dose rate in the Reactor Building manipulator crane area, during refueling, is monitored by RM-G17A and RM-G17B. Either one, upon detection of high activity or loss of signal, interlock to close the purge discharge valves (Figure 11.4-1). These monitors are not required during normal operation.

Area radiation monitor electronics have a five decade logarithmic scale with a nominal measurement accuracy of ± 25 percent of the reading. The precision is ± 15 percent at all levels. Area radiation monitors are calibrated on a routine basis and after any maintenance work is performed on the detector by exposure to a standard radioactive source with its calibration traceable, directly or indirectly, to the National Bureau of Standards. Calibration of the high range area monitor, RM-G7 and RM-G18 uses a calibrated electrical current source to verify the performance of the readouts. Functional verification of all area radiation monitors, except RM-G7 and RM-G18 is achieved by use of remotely actuated check sources (isotopic or LED signal input). Functional verification of RM-G7 and RM-G18 is achieved through use of a built-in electronic test signal.

12.1.5 Operating Procedures

The Manager, Radiological Protection and Chemistry is responsible for developing the radiation protection training program, the radiation protection program and health physics procedures to ensure that exposures of all personnel are kept within the limits of 10 CFR 20 and ALARA. These procedures and programs are developed incorporating guidance contained in Regulatory Guides 8.2, 8.8, and 8.10. Plant personnel will receive radiation protection training, the depth of which will depend upon the work assignments, individual responsibilities, and the degree of radiation hazard anticipated.

Personnel whose duties entail entering controlled areas, or directing the activities of others who enter controlled areas, are required to have radiation protection training. This training qualifies personnel to implement plans and procedures, each in his area of responsibility, to maintain doses ALARA.

Administrative controls are established to assure that procedures and requirements relating to radiation protection are followed by plant personnel.

Radiation control procedures are established for systems that contain, collect, store, or transport radioactive liquids, gases, and solids. These procedures ensure that occupational radiation exposures are ALARA. The procedures that control radiation exposure are subject to review and approval as outlined in Section 13.5. The basic principles of time, distance, and shielding are applied during operation and maintenance to ensure that personnel exposure is within limits. The following techniques are employed:

1. During initial startup, neutron and gamma dose rate surveys are performed to verify the adequacy of shielding.
2. During normal operations dose rate, surface contamination, and airborne radioactivity surveys are performed periodically throughout the plant and areas are zoned accordingly. These surveys ensure that data is available for planning operation and maintenance activities.
3. Areas are conspicuously posted in accordance with 10 CFR 20.1902 as appropriate.
4. A radiation work permit (RWP) system is employed to ensure proper administrative control over work in restricted areas. The RWP is designed to ensure that the radiation conditions are defined and that appropriate measures are taken to minimize the dose received by personnel. Section 12.3.1.3 explains the use of the RWP.
5. Extension tools are used when practicable to increase the distance from the radiation source to the worker.
6. Equipment is moved to areas of lower radiation fields for maintenance when practicable.
7. Portable shielding in the form of lead bricks, lead sheets, lead shot, high density concrete block, or steel plates is used as practicable.
8. A personnel dosimetry program, as described in Section 12.3.3, is administered by the Health Physics group to ensure compliance with 10 CFR 20.

Experience gained from the operation and maintenance of several nuclear plants with whom SCE&G has contact is used to provide a basis for further evaluation.

12.1.6 Estimates of Exposure

The estimates of exposure presented in this Section address both the peak radiation exposure rates and expected annual doses. Personnel doses are based upon the radiation zone and the anticipated occupancy requirements for that area.

12.1.6.1 Dose Rates at Selected Inplant Locations

Figures 12.1-1 through 12.1-20 illustrate the location of the various zones throughout the plant. These zones have been established using design parameters and estimated occupancy requirements. Expected radiation levels should be only a fraction of the design values. Table 12.1-20 lists selected inplant locations and the associated design dose rate for each area.

12.1.6.2 Estimates of Personnel Occupancy Requirements

Occupancy requirements throughout the plant, based upon operating experience and estimated SCE&G personnel requirements, are considered in the establishment of radiation zones described in Section 12.1.2.1. To estimate occupancy requirements, plant personnel were categorized into five groups according to work function. Table 12.1-21 lists the estimated size of each group and the estimated occupancy requirements for each group in Zones I, II, and III. Estimates were not made for Zones IV and V since routine occupancy is not anticipated in these zones during normal operation or during anticipated operational occurrences.

12.1.6.3 Estimates of Annual Man-Rem Doses

Annual doses to plant personnel are estimated based upon the assumption of 2000 hours per year work time for each employee. For each zone, the lower and upper ends of the range have been evaluated in determining man-Rem doses. It is anticipated that the general radiation levels for each zone will be equal to or less than the lower values stated for the zone although isolated higher levels will exist in certain areas within the zone.

The estimated man-Rem doses for the various categories of plant personnel as discussed in Section 12.1.6.2 are listed in Table 12.1-21. The total annual dose for plant operation is conservatively estimated to range from 72 to 364 man-Rems. From the years 1969 to 1974, operational data indicate that for all light water reactors the average dose was approximately 404 man-Rem/unit/year (Reference 6). At Virgil C. Summer Nuclear Station the man-Rem doses are maintained ALARA by utilizing applicable operational data and guidance available in the industry and from the government in conjunction with the Health Physics ALARA oriented program (see Section 12.3).

Numerous dose assessment techniques are utilized in optimizing shielding design and in maintaining radiation doses ALARA. Regulatory guidance, such as that found in Regulatory

Guide 8.8, is followed in plant design and review. Some of the specific dose assessment techniques are as follows:

1. Utilization of operational data:
   a. Operational radiation levels.
   b. Trends in radiation levels associated with years of operation, plant type, plant size, power levels, plant design, etc.
   c. Radiation zones as described by occupancy requirements and actual radiation levels.
   d. Location of components with respect to plant operability.
   e. Reliability of components.
   f. Adequacy of plant layout in terms of traffic patterns; space allocation, such as around radioactive components requiring maintenance and inspection; pipe routing, etc.
   g. Number of plant employees associated with different tasks and the resulting man-Rem doses.
2. Review equipment and instrumentation and locate in zones I and II whenever possible to minimize occupancy requirements in higher radiation zones.
3. Review of the plant design by a competent professional in radiation protection and by the utility radiation protection manager.

As indicated by Table 12.1-22 no man-Rem estimates were made for Zones IV and V. It is anticipated that entry to these zones will be primarily during plant shutdown when special maintenance will be performed. Every effort will be made to decrease the radiation dose to the maintenance personnel by utilizing temporary shielding, component decontamination, or other acceptable techniques for assuring that radiation doses are ALARA. An analysis of operational data indicates that special maintenance has contributed approximately 20 percent to the annual plant dose (Reference 6 and Reference 7). Other operations have contributed to the annual plant man-Rem dose as follows (Reference 6):

1. Routine reactor operation and surveillance, 14 percent.
2. Routine maintenance, 45 percent.
3. Inservice inspection, 2.7 percent.
4. Waste processing, 2.5 percent.
5. Refueling, 14 percent.

A further estimate of the man-Rem doses has been made by identifying specific tasks anticipated to occur at the plant. Various data from operating plants and in current publications (see References 11 through 19) were used in identifying these tasks, manpower effort required to complete each task, and the radiation levels associated with doing the work. Tables 12.1-22A and 12.1-22B list the tasks anticipated for normal operation and those expected during an outage. Tables 12.1-22C and 12.1-22D provide a breakdown of personnel that will be involved with each

of the tasks and the extent of their involvement. Special maintenance tasks have been analyzed although it is anticipated that these tasks will occur infrequently. When these tasks, such as steam generator maintenance, are performed the man-Rem dose varies directly with the conditions surrounding the maintenance and the extent of the work to be performed at the time. Therefore, because of the variability of the man-Rem dose for special maintenance, special maintenance has been excluded from the yearly personnel dose commitment (see Table 12.1-22E).

Radiation doses associated with airborne radioactivity have not been analyzed in terms of tasks due to the lack of sufficient data. Conservative estimates were made using the occupancies given in Table 12.1-21. Table 12.1-22F presents the dose rates in various parts of the plant using calculated airborne contamination levels listed in Table 12.2-1. To determine the man-Rem dose commitment from airborne activity (see Table 12.1-22G), it was assumed that the airborne radiation levels to which plant personnel will be exposed are represented by those levels for the Turbine Building (Zone I), Auxiliary Building (Zone II) and the letdown heat exchangers (Zones III through V) listed in Table 12.1-22F. No man-Rem doses were calculated using the specific concentrations for the Reactor Building since routine occupancy of this area during normal operation is not anticipated.

12.1.6.4 Doses at the Radiation Controlled Area Boundary

The Radiation Controlled Area is located within the site boundary as defined in Figure 2.1-3. Additionally, except for unusual and unanticipated situations, the Radiation Controlled Area will not extend beyond the Protected Area fence. The only normal exceptions to this are: 1) the Radiography Vault which is operated under a separate license and 2) the storage of very low level materials such as exempt sources and other materials which present no significant radiological hazards. The Radiation Controlled Area consists of the Reactor Building, Auxiliary Building, Fuel Handling Building, the west penetration access areas, the east penetration access area (412’ elevation), portions of the Intermediate Building and tendon access area, radioactive waste areas, hot maintenance areas, hot warehouse, and other areas designated by Health Physics for the purposes of radiation protection. Areas may be removed from the Radiation Controlled Area at the direction of Health Physics when operating conditions and radiation levels are such that control is not necessary for the purposes of radiation protection. The area outside the Radiation Controlled Area has been zoned less than 1 mrem/hr. It is expected that, under normal operating conditions and during anticipated operational occurrences, the radiation level outside the above mentioned Radiation Controlled Area will be only a fraction of this design level.

Table 12.1-2 (continued)
Radiation Source Terms for Demineralizers

Source	Source Location	Source Geometry	Source Volume (Ft^3)	Activity (Mev/cc-sec) for Energy (Mev) of						
				0.40	0.80	1.30	1.70	2.20	2.50	3.50
Duratek Demineralizer (5)	AB (447')	Cylinder	(1)		(2)					

Source Location Legend

Location	Elevation
AB - Auxiliary Building	B - Basement
RB - Reactor Building	M - Mezzanine
FB - Fuel Handling Building	O - Operating Floor
Y - Yard	S - Sub-Basement

(1) For Source Volumes see Figure 11.2-5.

(2) Source Terms in Curies Provided in Table 11.2-1.

Table 12.1-3
Radiation Source Terms for Tanks

Source	Source Location	Source Geometry	Source Volume (Ft^3)	Activity (Mev/cc-sec) for Energy (Mev) of						
				0.40	0.80	1.30	1.70	2.20	2.50	3.50
Volume Control Tank (1) -VAPOR	AB-O	Cylinder	180.00	7.3×10^5	3.0×10^5	-	1.5×10^5	3.4×10^5	6.9×10^5	-
Volume Control Tank (1) -LIQUID	AB-0	Cylinder	120.00	9.3×10^4	7.5×10^4	2.3×10^4	2.7×10^4	4.2×10^4	8.7×10^4	2.0×10^3
Waste Holdup Tank (1)	AB-S	Cylinder	1,337.00	3.9×10^4	2.2×10^5	1.1×10^5	4.9×10^4	1.7×10^4	-	-
Floor Drain Tank (1)	AB-S	Cylinder	1,337.00	3.9×10^4	2.2×10^5	1.1×10^5	4.9×10^4	1.7×10^4	-	-
Waste Monitor Tank (2)	AB-0	Cylinder	668.00	3.9×10^4	2.2×10^5	1.1×10^5	4.9×10^4	1.7×10^4	-	-
Spent Resin Storage Tank (1)	AB-B	Cylinder	350.00	1.3×10^8	3.1×10^8	3.3×10^7	1.4×10^7	3.9×10^6	8.6×10^4	1.7×10^5
Catalytic Hydrogen Recombiner (2)	AB-S	Cylinder	2.02	3.6×10^5	9.1×10^4	-	7.1×10^4	1.3×10^5	3.1×10^5	-
Waste Gas Compressor (2)	AB-S	Cylinder	2.09	3.6×10^5	9.1×10^4	-	7.1×10^4	1.3×10^5	3.1×10^5	-
Gas Decay Tank (8)	AB-S	Cylinder	600.00	3.6×10^5	9.1×10^4	-	7.1×10^4	1.3×10^5	3.1×10^5	-
Recycle Holdup Tank (2) -VAPOR	AB-S	Sphere	494.00	2.8×10^5	7.8×10^4	-	5.7×10^4	1.2×10^5	2.7×10^5	-
Recycle Holdup Tank (2) -LIQUID	AB-S	Cylinder	5,120.00	4.7×10^5	5.7×10^4	1.7×10^3	3.2×10^4	1.2×10^5	1.7×10^5	-
Reactor Coolant Drain Tank (1)	RB-B	Cylinder	46.8	4.3×10^5	7.6×10^4	2.3×10^4	2.7×10^4	4.2×10^4	8.7×10^4	2.0×10^3
Nuclear Blowdown System Holdup Tank (1)	AB-M	Cylinder	1,740.00	8.4×10^1	2.9×10^2	1.0×10^2	1.7×10^1	5.2×10^1	-	-
Nuclear Blowdown System Monitor Tank (1)	AB-M	Cylinder	670.00	8.4×10^1	2.9×10^2	1.0×10^2	1.7×10^1	5.2×10^1	-	-

Table 12.1-3 (continued)
Radiation Source Terms for Tanks

Source	Source Location	Source Geometry	Source Volume (Ft^3)	Activity (Mev/cc-sec) for Energy (Mev) of 0.40	0.80	1.30	1.70	2.20	2.50	3.50
Nuclear Blowdown Spent Resin Storage Tank (1)	AB-B	Cylinder	600.00	1.3×10^8	3.1×10^8	3.3×10^7	1.4×10^7	3.9×10^6	-	-
Excess Waste Holdup Tank (1)	FB-B	Cylinder	1,340.00	3.9×10^4	2.2×10^5	1.1×10^5	4.9×10^4	1.7×10^4	-	-
Decontamination Pit Collection Tank (1)	FB-B	Cylinder	1,340.00	3.4×10^4	2.2×10^5	1.1×10^5	4.9×10^4	1.7×10^4	-	-
Pressurizer Relief Tank (1) (See Note 1)	RB-B	Cylinder	1,300.00	1.9×10^4	6.8×10^4	1.1×10^4	4.2×10^3	1.6×10^3	3.2×10^0	9.9×10^1

(1) In addition to the activity given in table, the other activities are 1.8 x 105 (mev/cc-sec) and 1.6 x 104 (mev/cc-sec) for 6.13 (mev) and 7.11 (mev), respectively.

Table 12.1-4
Radiation Source Terms for Filters

Source	Source Location	Source Geometry	Source Volume (Ft^3)	Activity (Mev/cc-sec) for Energy (Mev) of						
				0.40	0.80	1.30	1.70	2.20	2.50	3.50
Reactor Coolant Filter (1)	AB-M	Cylinder	0.40	-	5.7×10^7	1.5×10^7	-	-	-	-
Seal Water Return Filter (1)	AB-M	Cylinder	0.40	-	1.1×10^7	3.0×10^6	-	-	-	-
Seal Water Injection Filter (2)	AB-M	Cylinder	0.06	-	4.8×10^7	1.2×10^7	-	-	-	-
Recycle Evaporator Feed Filter (1)	AB-M	Cylinder	0.40	-	1.1×10^7	3.0×10^6	-	-	-	-
Recycle Evaporator Condensate Filter (1)	AB-M	Cylinder	0.04	1.6×10^5	8.0×10^4	3.3×10^4	-	-	-	-
Recycle Evaporator Concentrates Filter (2)	AB-M	Cylinder	0.04	-	1.2×10^6	-	-	-	-	-
Spent Fuel Purification Filter (2)	AB-M	Cylinder	0.40	-	5.7×10^7	1.5×10^7	-	-	-	-
Floor Drain Tank Filter (1)	AB-M	Cylinder	0.04	-	3.4×10^7	8.9×10^6	-	-	-	-
Spent Resin Sluice Filter (1)	AB-M	Cylinder	0.40	-	1.1×10^7	3.0×10^6	-	-	-	-
Waste Monitor Tank Filter (1)	AB-M	Cylinder	0.04	-	2.8×10^7	5.7×10^6	2.8×10^6	1.1×10^6	-	-
Waste Evaporator Condensate Filter (1)	AB-M	Cylinder	0.04	1.2×10^5	2.2×10^5	2.5×10^4	-	-	-	-
Laundry and Hot Shower Filter (1)	AB-S	Cylinder	0.04	-	1.1×10^7	3.0×10^6	-	-	-	-
Nuclear Blowdown Demineralizer Inlet Filter (1)	AB-M	Cylinder	0.50	3.3×10^4	1.2×10^5	1.5×10^4	2.4×10^3	6.7×10^2	-	-
Nuclear Blowdown Spent Resin Sluice Filter (1)	AB-M	Cylinder	0.50	3.3×10^4	1.2×10^5	1.5×10^4	2.4×10^3	6.7×10^2	-	-

Table 12.1-4 (continued)
Radiation Source Terms for Filters

Source	Source Location	Source Geometry	Source Volume (Ft^3)	Activity (Mev/cc-sec) for Energy (Mev) of						
				0.40	0.80	1.30	1.70	2.20	2.50	3.50
Nuclear Blowdown Demineralizer Outlet Filter (1)	AB-M	Cylinder	0.50	3.3×10^4	1.2×10^5	1.5×10^4	2.4×10^3	6.7×10^2	-	-
Waste Gas Drain Filter (1)	AB-M	Cylinder	0.04	1.9×10^6	3.6×10^5	9.1×10^4	7.1×10^4	1.3×10^5	1.3×10^5	-
Excess Liquid Waste Filter (1)	FB-B	Cylinder	0.24	-	3.4×10^7	8.9×10^6	-	-	-	-

Table 12.1-5
Radiation Source Terms for Heat Exchangers

Source	Source Location	Source Geometry	Source Volume (Ft^3)	Activity (Mev/cc-sec) for Energy (Mev) of						
				0.40	0.80	1.30	1.70	2.20	2.50	3.50
Regenerative Heat Exchanger (1)	RB-B	Cylinder	9.75	4.96×10^5	2.57×10^5	1.56×10^5	1.14×10^5	1.84×10^5	1.57×10^5	1.72×10^4
Letdown Heat Exchanger (1)	AB-B	Cylinder	48.05	1.48×10^5	8.42×10^4	5.23×10^4	3.77×10^4	6.39×10^4	4.94×10^4	5.81×10^3
Seal Water Heat Exchanger (1)	AB-B	Cylinder	27.3	1.72×10^5	9.78×10^4	6.07×10^4	4.38×10^4	7.08×10^4	5.73×10^4	6.74×10^3
Excess Letdown Heat Exchanger	RB-M	Cylinder	5.21	1.13×10^5	6.40×10^4	3.97×10^4	2.87×10^4	4.64×10^4	3.75×10^4	4.42×10^3
Moderating Heat Exchanger (1)	AB-B	Cylinder	30.90	4.80×10^5	1.10×10^5	2.30×10^4	4.10×10^4	1.30×10^5	1.70×10^5	2.00×10^3
Letdown Chiller Heat Exchanger (1)	AB-B	Cylinder	38.92	1.21×10^5	2.76×10^4	5.78×10^3	1.03×10^4	3.27×10^4	4.27×10^4	5.03×10^2
Reactor Coolant Drain Tank Heat Exchanger (1)	RB-B	Cylinder	9.97	1.66×10^5	9.45×10^4	5.87×10^4	4.24×10^4	7.17×10^4	5.54×10^4	6.52×10^3
Steam Generator Blowdown Heat Exchanger (3)	TB-B	Cylinder	75.3	1.42×10^1	5.26×10^1	2.93×10^1	6.55×10^0	1.73×10^1	6.89×10^{-1}	1.62×10^0
Letdown Reheat Heat Exchanger (1)	AB-B	Cylinder	1.92	4.80×10^5	1.10×10^5	2.30×10^4	4.10×10^4	1.30×10^5	1.70×10^5	2.0×10^3
Spent Fuel Pit Heat Exchanger (2)	AB-S	Cylinder	154.0	-	9.85×10^0	5.24×10^1	6.4×10^{-1}	-	-	-
Residual Heat Removal Heat Exchanger (2)	AB-B	Cylinder	208.3	1.32×10^5	4.90×10^4	1.66×10^4	1.09×10^4	9.42×10^3	1.58×10^4	-

Table 12.1-6
Neutron Source Term for Primary Concrete Shield

Neutron Fluxes on Inside Surface of Primary Concrete

Energy Group	Neutron Flux (Neutrons/cm2-sec)
ϕ1 (E > 1.0 Mev)	1.6×10^{9}
ϕ1 (5.53 kev < E ≤ 1.0 Mev)	2.2×10^{10}
ϕ3 (0.625 ev < E ≤ 5.53 Kev)	1.2×10^{10}
ϕ4 (E < 0.625 ev)	3.3×10^{9}

Axial Variation of Neutron Fluxes

Distance Above/Below Core Centerline (ft)	Variation Factor
0	1.0
1	1.0
2	0.99
3	0.93
4	0.76
5	0.51
6	0.30

Table 12.1-7
Gamma Source Term for Primary Concrete Shield

Gamma Fluxes on Inside Surface of Primary Concrete

Group	Flux (Mev/cm^2-sec)	Group Energy (Mev/Y)
1	6.9×10^9	7.5
2	6.2×10^9	4.0
3	3.2×10^9	2.5
4	2.0×10^9	0.8

Axial Variation of Gamma Fluxes

Distance Above/Below Core Centerline (ft)	F_a
0	1.0
1	1.0
2	0.99
3	0.93

5	0.51
6	0.30

Table 12.1-8
Pressurizer Deposited Activity

Isotope	Activity ($\mu ci/cm^2$)
Cr-51	9.8×10^{-2}
Mn-54	1.5×10^{-1}
Mn-56	2.2×10^{-2}
Co-58	3.8
Co-60	1.6×10^{-1}
Fe-59	1.4×10^{-1}

Table 12.1-9
Reactor Coolant N^{16} Activity

Position in Loop	Loop Transit Time (sec)	N^{16} Activity μCi/gram
Leaving core	0	132
Leaving reactor vessel	1.0	119
Entering steam generator	1.4	110
Leaving steam generator	6.6	74
Entering reactor coolant pump	7.2	70
Entering reactor vessel	7.9	65
Enter Core	10.4	52
Leaving core	11.3	132

Table 12.1-10
Radiation Source Term - Letdown Coolant

Gamma Energy (Mev/Y)	Specific Source Strength (Mev/gm-sec)
0.4	5.1×10^5
0.8	2.7×10^5
1.3	1.8×10^5
1.7	1.3×10^5
2.2	2.2×10^5
2.5	1.7×10^5
3.5	2.0×10^5

Table 12.1-11
Solid Waste Source for Drumming Station

Gamma Energy (Mev/Y)	Spent Resin Source Strength (Mev/cc-sec)
0.8	1.0×10^{8}
1.3	1.0×10^{7}

Table 12.1-12
Core Average Gamma Ray Source Strengths at
Various Times After Shutdown

Energy Group MeV / gamma	Source Strengths at Time After Shutdown (MeV / Watt-sec)								
	12 Hours	24 Hours	100 Hours	1 Week	1 Month	3 Months	6 Months	1 Year	5 Years
0.20 - 0.40	1.8e+09	1.5e+09	8.3e+08	5.9e+08	1.5e+08	5.2e+07	3.1e+07	1.8e+07	2.3e+06
0.40 - 0.90	1.1e+10	9.7e+09	6.6e+09	5.7e+09	3.6e+09	2.1e+09	1.2e+09	5.4e+08	1.5e+08
0.90 - 1.35	2.0e+09	1.4e+09	7.3e+08	5.6e+08	1.7e+08	4.8e+07	3.2e+07	2.4e+07	9.3e+06
1.35 - 1.80	3.7e+09	3.3e+09	2.7e+09	2.3e+09	6.5e+08	4.8e+07	2.0e+07	1.5e+07	2.8e+06
1.80 - 2.20	3.4e+08	2.6e+08	1.8e+08	1.5e+08	6.0e+07	2.0e+07	1.4e+07	8.6e+06	2.5e+05
2.20 - 2.60	2.4e+08	1.8e+08	1.5e+08	1.3e+08	3.9e+07	1.5e+06	1.1e+04	0	0
2.60 - 3.00	6.2e+06	3.2e+06	2.7e+06	2.3e+06	6.7e+05	2.6e+04	2.0e+02	0	0
3.00 - 4.00	4.3e+06	1.3e+06	1.1e+06	9.1e+05	2.6e+05	1.0e+04	0	0	0
Total	2.0e+10	1.6+10	1.1e+10	9.4e+09	4.7e+09	2.3e+09	1.2e+09	6.1e+08	1.7e+08

Table 12.1-13
Irradiated Ag-In-Cd Control Rod Source Strengths

Photon Energy (MeV / gamma)	Source Strength at Time After Shutdown (MeV / cm^3-sec)				
	1 Day	1 Week	1 Month	6 Months	1 Year
0.20 - 0.40	2.3e+08	2.3e+08	2.2e+08	1.4e+08	8.7e+07
0.40 - 0.90	1.1e+12	1.1e+12	1.0e+12	6.7e+11	4.1e+11
0.90 - 1.35	2.0e+11	1.9e+11	1.8e+11	1.2e+11	7.3e+10
1.35 - 1.80	3.8e+11	3.8e+11	3.5e+11	2.3e+11	1.4e+11

The absorber cross-sectional area is 0.589 square centimeters per rod.
The absorber material density is 10.17 grams per cubic centimeter.

Table 12.1-14
Irradiated Incore Detector Drive Cable Source Strengths

Energy Group MeV / gamma	Source Strength Time After Shutdown (MeV / cm^3-sec)						
	8 Hours	1 Day	1 Week	1 Month	6 Months	1 Year	5 Years
0.20 - 0.40	5.9e+08	5.8e+08	5.0e+08	2.9e+08	1.0e+07	2.9e+05	0
0.40 - 0.90	1.7e+10	1.2e+10	1.2e+10	1.1e+10	8.0e+09	5.1e+09	2.0e+08
0.90 - 1.35	1.6e+10	1.6e+10	1.5e+10	1.2e+10	5.7e+09	4.3e+09	2.6e+09
1.35 - 1.80	2.1e+07	1.1e+07	1.1e+07	8.7e+06	2.0e+06	3.4e+05	0
1.80 - 2.20	4.6e+09	6.2e+07	0	0	0	0	0
2.20 - 2.60	1.5e+08	2.0e+06	0	0	0	0	0
2.60 - 3.00	1.6e+08	2.1e+06	0	0	0	0	0
3.00 - 4.00	3.7e+07	5.1e+05	0	0	0	0	0

The drive cable effective cross-sectional area is 0.095 square centimeters.

Table 12.1-15
Deposited Corrosion Product Activity
On Steam Generator Surfaces ($\mu Ci/cm^2$)

	Operating Time (Months)				
Isotope	0	6	12	24	36
Mn-54	0.0	0.15	0.60	1.5	2.0
Mn-56	0.0	3.3	3.3	3.3	3.3
Co-58	0.0	4.5	10.2	11.0	11.0
Fe-59	0.0	1.4	3.0	3.0	3.0
Co-60	0.0	0.20	0.80	2.0	3.5

Residual Heat Removal Loop Shutdown Source

Gamma Energy (MeV/Y)	Specific Source Strength (Sec/gm-sec)
0.4	3.5×10^5
0.8	1.3×10^5
1.3	4.4×10^4
1.7	2.9×10^4
2.2	2.5×10^4
2.5	4.2×10^4

Table 12.1-19
Area Radiation Monitors

Monitor	Function	Sensitivity	Power Source
RM-G1 Control Room	Monitor control room operational area	10^{-1} to 10^{4} mR/hr	Bus A
RM-G2 Radiochemical Lab	Monitor radiochemical lab area	10^{-1} to 10^{4} mR/hr	Bus A
RM-G3 Sampling Room	Monitor sampling room near entrance	10^{-1} to 10^{4} mR/hr	Bus B
RM-G4 Hot Machine Shop	Monitor area in hot machine shop	10^{-1} to 10^{4} mR/hr	Bus B
RM-G5 Reactor Building Personnel Access	Monitor area inside containment near access, alarm inside & outside of access	10^{-1} to 10^{4} mR/hr	Bus A
RM-G6 Reactor Building Refueling Bridge	Monitor pool area and fuel handling	10^{-1} to 10^{4} mR/hr	Bus A
RM-G7 Reactor Building High Range	Provide indication of magnitude of LOCA	1.0 to 10^{7} R/hr	Bus B
RM-G8 Fuel Handling Building Fuel Handling Bridge	Monitor pool area and fuel handling	10^{-1} to 10^{4} mR/hr	Bus B
RM-G9 Auxiliary Building Demineralizer Area	Monitor access area near demineralizers	10^{-1} to 10^{4} mR/hr	Bus A

Table 12.1-19 (continued)
Area Radiation Monitors

Monitor	Function	Sensitivity	Power Source
RM-G10 Auxiliary Building Waste Gas Decay Tank Area	Monitor corridor near tank area	10^{-1} to 10^{4} mR/hr	Bus A
RM-G11 Auxiliary Building Drumming Area	Monitor operations area	10^{-1} to 10^{4} mR/hr	Bus B
RM-G12 Auxiliary Building Waste Holdup Tank Area	Monitor corridor near tank area	10^{-1} to 10^{4} mR/hr	Bus B

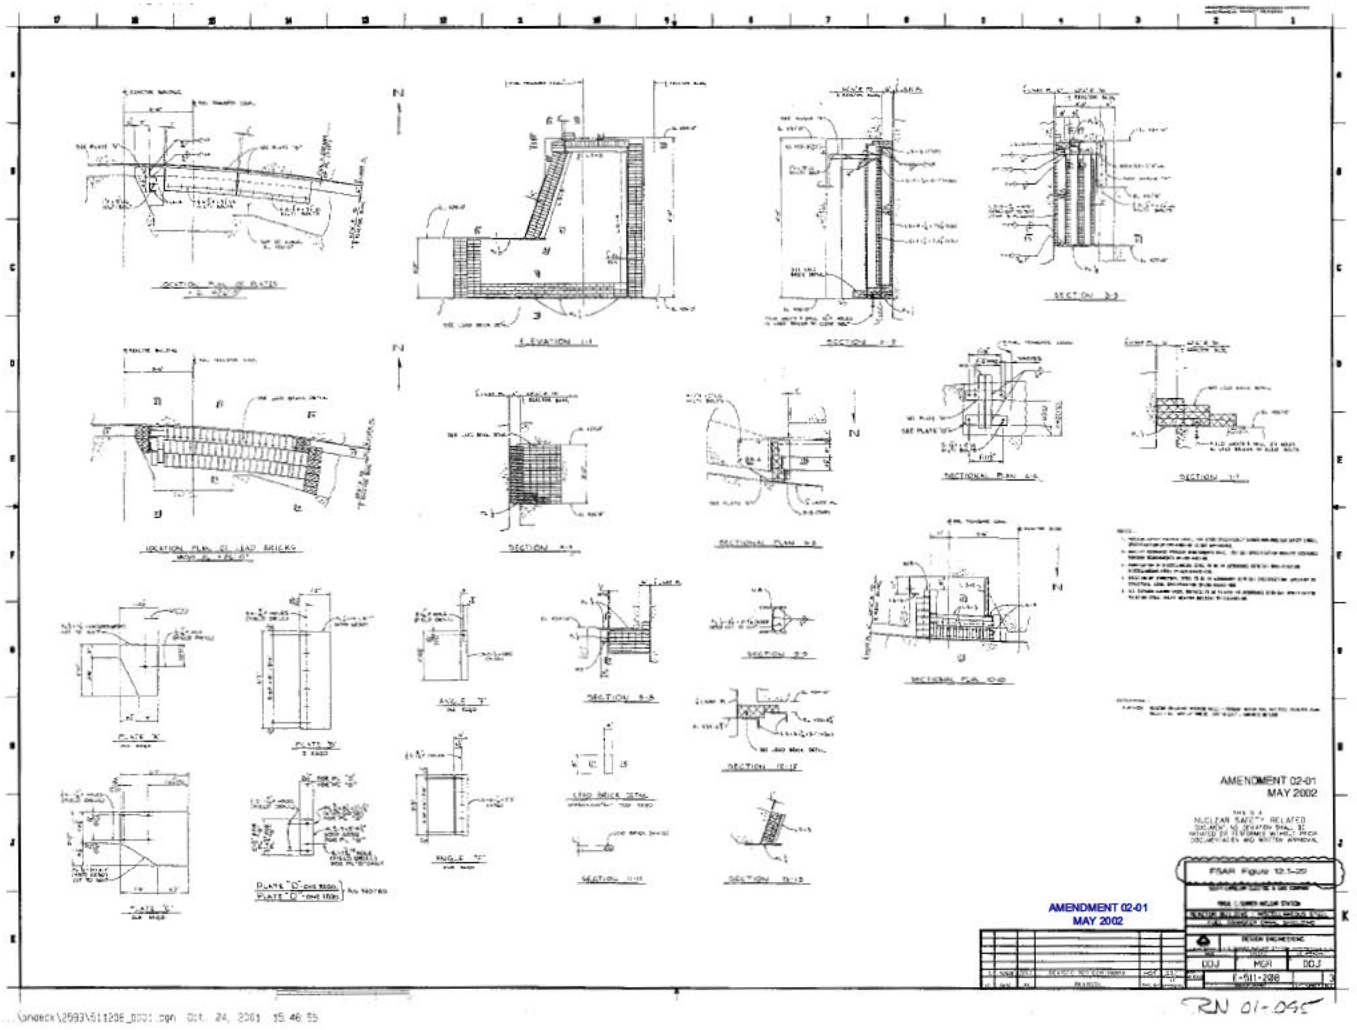
REACTOR BUILDING - MISCELLANEOUS STEEL
FUEL TRANSFER CANAL SHIELDING



12.2 VENTILATION

12.2.1 Design Objectives

The ventilation systems for various buildings and areas are designed to maintain ambient air temperatures suitable for personnel and equipment and to aid in minimizing radioactivity levels so that personnel are not exposed to airborne concentrations which exceed the limits of 10 CFR 20.

Calculated airborne radioactivity levels for various buildings during normal operation, including anticipated operational occurrences, are presented in Table 12.2-1, based upon the assumptions discussed in Sections 12.2.3 and 12.2.6. Calculated inhalation dose rates to personnel in various buildings are discussed in Sections 12.2.6.1.1, 12.2.6.1.2, and 12.2.6.1.3.

12.2.2 Design Description

Ventilation systems serving potentially radioactive areas and the Sections where detailed descriptions are presented are as follows:

1. Control Room Ventilation System, Section 9.4.1.2.1.
2. Controlled Access Area Exhaust System, Section 9.4.1.2.5.
3. Auxiliary and Radwaste Area Ventilation Systems, Section 9.4.2.
4. Spend Fuel Pool Area Ventilation System, Section 9.4.3.
5. Turbine Building Ventilation Systems, Section 9.4.4.
6. Reactor Building Charcoal Cleanup System, Section 9.4.8.2.4.

Air flow rates and approximate free volumes of buildings served by these ventilation systems are presented in Table 12.2-2.

The ventilation system protective features concerning airborne and effluent radioactivity and shielding are described in Sections 11.4, 12.1, 12.1.4, and 12.2.4.

Figures 1.2-15 and 12.2-1 indicate the arrangement of the control room emergency charcoal filter plenum components and available service space. Figure 12.2-1 is representative of all charcoal-HEPA filters in the plant. Test connections are provided in the duct system or housings after installation is completed.

Criteria for change of filters is dependent upon results of laboratory and field tests of filter system components. Test requirements are listed in Sections 6.5.1.4, 9.4.1.4, 9.4.2.4, 9.4.3.4, and 9.4.8.4.

Regulatory Guide 1.52 is discussed in Appendix 3A while design guidance contained in Regulatory Guide 8.8 is further described in Section 12.0.

12.2.3 Source Terms

The airborne radioactivity which workers might be exposed to during normal operations have been considered as follows:

The concentration of radioactive gases in the coolant prior to reactor vessel head removal is established based on DAC considerations and containment ventilation system capabilities of the plant. The major isotope of concern is Xe-133, since the other noble gas isotopes have either decayed away or been removed during the system degasification period. With conservative calculations, RCS activity which would result in the 10CFR20 occupational DAC in the containment atmosphere is approximately 0.1 μc/cc of Xe-133. However, operating plant experience has indicated that no problem with fission gas release to the containment atmosphere was incurred when the vessel head was removed, with the coolant Xe-133 concentration reduced to .05 μc/gm. Also, the exposure period is short so long as the containment purge is in operation during head removal.

The discharge of relief valves on lines which contain reactor coolant is piped to tanks, such as the pressurizer relief tank, volume control tank, recycle holdup tanks, reactor coolant drain tank, or waste holdup tank. Consequently, exposure of workers to airborne radioactivity from this source is precluded.

The gaseous activity released to the refueling water during the movement of spent fuel is expected to be insignificant. Fission product release from defective fuel cladding during refueling operations is a relatively slow process as compared to release during normal operation. Shutdown escape rate coefficients are several orders of magnitude below those during operation. Also, the noble gas activity inventories available for release from the defective fuel are reduced by radioactive decay during the fuel transfer operations.

Personnel entry into the Reactor Building at power will be limited to that absolutely necessary for essential operations. Appropriate radiological safety precautions will be implemented if entry into the reactor building at power is required.

The Reactor Building is normally purged prior to entry under shutdown conditions. If the shutdown is for maintenance, airborne activity is expected to be minimal. If the shutdown is for refueling, evaporation of tritiated water from the refueling cavity is expected to be the only source of airborne activity. As discussed in Section 11.1.4.3, airborne tritium concentrations during refueling will be low enough to allow 40 hour per week access to the reactor building if the tritium concentration in the refueling water is limited to 2.5 μCi/gm.

Airborne radioactivity is introduced into plant buildings when equipment processing or holding radioactive materials develops a leak. The assumed leakage rates into various buildings and the assumptions concerning the amount of radioactive material released from the leaked materials are presented in Sections 12.2.3.1 through 12.2.3.4. The values presented are based upon data presented in NUREG-0017 (Reference 1).

12.2.3.1 Assumptions Used in Determining Airborne Activity in the Reactor Building

1. Leakage to the Reactor Building is 1 percent per day of the primary coolant noble gas inventory and 0.001 percent per day of the primary coolant halogen inventory. It is conservatively assumed that the tritium leakage rate is equivalent to the noble gas leakage rate.
2. Primary coolant inventory is based upon values provided in Table 11.1-5.
3. A Reactor Building purge frequency of 24 per year is assumed.
4. Radioactive nuclides are removed between purges by radioactive decay only.

12.2.3.2 Assumptions Used in Determining Airborne Activity in the Auxiliary Building

1. Leakage to the Auxiliary Building is 160 lb/day at primary coolant activity.
2. Primary coolant inventory is based upon values provided in Table 11.1-5.
3. A partition factor of 1 is assumed for noble gases and 0.0075 for halogens.

12.2.3.3 Assumptions Used in Determining Airborne Activity in the Turbine Building

1. Leakage to the Turbine Building atmosphere is 1700 lb/hr of steam at main steam activity.
2. Main steam activity is based upon values provided in Table 11.1-5.
3. A partition factor of 1 is assumed for both noble gases and halogens.

12.2.3.4 Assumptions Used in Determining Airborne Activity in Other Buildings

All other buildings are expected to have negligible noble gas and halogen airborne activity.

12.2.4 Airborne Radioactivity Monitoring

12.2.4.1 Design Basis

The airborne radioactivity monitors are designed to detect, indicate, annunciate and record the radioactivity levels monitored at selected locations inside the plant. These monitors provide supporting data for the surveillance of plant radioactivity levels as recommended by ANSI N13.2 (Reference 2) and, Regulatory Guides 8.2 and 8.8, and as required by 10 CFR 20. Fixed continuous airborne radioactivity monitors taking particulate samples from ventilation ducts utilize isokinetic nozzles for air sampling designed according to ANSI N13.1-1969. Lengths of sample lines are minimized to reduce particulate sample loss. Sample point locations are selected to obtain an optimum mixed air sample. Areas not covered by airborne radioactivity monitors are periodically checked with movable air samplers. The Reactor Building and normally occupied areas which are considered sources of airborne activity such as the spent fuel area and the sampling room are monitored with equipment sensitive to DAC levels. Controlled access areas which contain sources of airborne activity require Health Physics air sampling prior to work in

these areas. Ventilation air flow design provides clean air for normal access corridors. These corridors are periodically monitored by portable air samplers. This monitoring instrumentation aids in maintaining airborne exposure as low as reasonably achievable (ALARA).

12.2.4.2 Airborne Radioactivity Monitors System Description

The airborne monitors consist of ten fixed and three movable channels. Some of these channels are used for effluent monitoring, as discussed in Section 11.4.

Ventilation ducts, local areas, and effluent paths are monitored in selected locations, as listed in Table 12.2-3, to provide assurance of proper plant operation.

Ventilation air flow in the Auxiliary Building is so arranged that the air flow path is in the direction of progressively greater potential contamination. This is accomplished by supplying clean air to the normally accessible areas, which are considered to be relatively free of airborne activity, and removing air from areas that could potentially have high levels of airborne activity. These areas are considered to be controlled areas, access to which is under strict administrative control. The air in the Auxiliary Building discharge path contains air from both clean and potentially contaminated areas. Thus, this air would not be representative of air breathed by personnel in the normally accessible areas regardless of whether samples are obtained upstream or downstream of the filters.

In the Fuel Handling Building, the spent fuel area could be considered as a source of airborne activity. Since this is a normally accessible area, the local air and the exhaust air prior to filtration are monitored for airborne activity as discussed in Sections 12.2.4.2.5 and 12.2.4.2.7.

In the control complex, the sampling room could be considered as a source of airborne activity. This air is monitored for airborne activity as discussed in Section 12.2.4.2.6.

Periodic surveillance of accessible areas, in accordance with Sections 12.1.5 and 12.3.2, will be performed.

Reliable power for the fixed instrumentation is obtained from the diesel backed, 120 volt instrument buses. Associated sample pumps obtain power from the 480 volt diesel backed buses. This assures continuity of operation in the event of a loss of offsite power. Measured activity levels are indicated and recorded (except RM-A11) on the Radiation Monitoring System control panel located in the control room. Local indication is provided for each channel. A differential pressure switch is provided on the particulate and iodine collection filter holders to cause an alarm on filter blockage. Another differential pressure switch is provided across the two filter holders (except on RMA-4) to cause an alarm on loss of flow. The loss of flow alarm for RMA-4 originates from the flow indication device (photohelic). The movable monitors have local indication, recording, and alarms. Detectors have remotely actuated check sources to provide functional verification. In addition, each channel is calibrated routinely by exposure to a calibrated source traceable either directly or indirectly to NIST for verification against its initial calibration. Calibration of the monitors is performed following any required maintenance of the detectors. Measurements have an accuracy of ± 25 percent of the true value. Precision is ± 15

percent at all levels. Each ratemeter is equipped with two adjustable alarm levels (alert and high) and a channel failure/or loss of power alarm. These alarms, associated with the fixed monitors, are annunciated on the Radiation Monitoring System control panel in the control room. Channels which have interlock functions with other systems (see Figure 11.4-1) are provided with a bypass switch for use during maintenance or testing. Use of this switch is annunciated.

12.2.4.2.1 Control Room Supply Air, Channel RM-A1

This channel monitors the particulate, iodine, and gaseous activity of air supplied to the control room. A sample of air is taken from the air supply duct through an isokinetic sampler nozzle and is drawn successively through a particulate sampler, an iodine sampler, and a gas sampler. The particulate sampler is equipped with a fixed filter which is continuously monitored by a lead shielded scintillator detector. The iodine sampler is similar to the particulate sampler except that an activated charcoal cartridge is used instead of a fixed filter. The fixed filter and the charcoal filter are designed to be removable for laboratory analysis. The sensitive volume of the gas sampler is shielded with lead and monitored by a scintillation detector. The approximate sensitivity and range of this channel are as follows:

1. Particulate, 4.7×10^{-11} to 10^{-7} μCi/cc based upon Cs-137.
2. Gas, 2×10^{-6} to 2×10^{-2} μCi/cc based upon Kr-85.
3. Iodine, 2×10^{-11} to 2×10^{-7} μCi/cc based upon I-131.

A high activity alarm from the gas channel automatically places the Control Room, Computer Room, Relay Room, and Instrument Repair Room Ventilation Systems in the recirculation mode, starts the Control Room Emergency Ventilation System, and closes the outside air dampers. The iodine and particulate channels provide high activity alarms to alert operating personnel. The high alarm setpoints are established on the basis of the requirements of the plant Technical Specifications and the sensitivity of the detection channels.

12.2.4.2.2 Reactor Building Air Sample Line, Channel RM-A2

This channel monitors the particulate, iodine, and gaseous activity level of the air inside the Reactor Building and is located inside the Auxiliary Building. Reactor Building air drawn from and returned through Reactor Building penetrations is monitored by RM-A2. The readout of the monitor is used to detect leaks in systems containing primary coolant. Channel ranges are similar to those of Channel RM-A1. To meet initial licensing requirements, the sensitivity of this monitor provides the capability to detect 10-MPC-hours of particulate and iodine radioactivity.

The monitor air sample and return lines are isolated (closed) upon occurrence of a containment isolation signal (Phase A). Post accident, this monitor can be used as a Reactor Building air sampling station, provided that Reactor Building pressure and temperature have been reduced sufficiently to allow opening of the sample line isolation valves. This monitor is also designed to withstand seismic conditions as recommended by Regulatory Guide 1.45.

The monitor design is similar to that of RM-A1, except that a moving particulate filter is used. An additional sample pump is also provided to allow operation when one pump is undergoing maintenance. The pumps and valves are located in a separate adjoining panel (XPN7321).

A high activity alarm from the gas channel initiates closure of the Reactor Building purge valves (see Figure 11.4-1).

High alarm setpoints are based upon plant operating requirements, sensitivity, and measured normal background.

A fixed alarm setpoint is not applicable to radiation monitoring for reactor coolant leak detection. The activity of the reactor coolant and background radiation must be taken into consideration.

The particulate and gas channels of radiation monitor RM-A2 will be operated with an initial setpoint of not less than twice background and may subsequently be readjusted based upon the changes in reactor coolant leakage and reactor building activity. Typically, the adjustments are made to provide the most sensitive response without causing an excessive number of spurious alarms. The maximum setpoint will be limited to no more than twice the operational equilibrium or operability limit defined in design calculations for the monitor, whichever is less.

12.2.4.2.3 Main Plant Vent Exhaust, Channel RM-A3

This channel is discussed in Section 11.4.2. It is used for detection of activity in the prefiltered discharge effluent from the Auxiliary Building main plant vent.

12.2.4.2.4 Reactor Building Purge Exhaust, Channel RM-A4

This channel is discussed in Section 11.4.2. It is used for detection of activity in the prefiltered purge discharge effluent from the Reactor Building.

12.2.4.2.5 Fuel Handling Building Exhaust, Channel RM-A6

This channel is used to monitor Fuel Handling Building exhaust air activity. Its function is to provide early detection of activity released. To meet initial licensing requirements, the sensitivity of this monitor provides for detection of 10-MPC-hours of particulate, iodine, and gaseous activity. A sample of the exhaust air is taken by an isokinetic nozzle located in the exhaust duct upstream of the exhaust filters. A local audible alarm is provided. The design, range, and sensitivity of this channel are similar to those of RM-A1. The high level alarm setpoints are based upon the sensitivity of the detectors and are set to alarm per the plant Technical Specifications.

12.2.4.2.6 Sampling Rooms, Channel RM-A7

Channel RM-A7 is a movable unit normally used to monitor a non-isokinetic sample of the sampling room air for particulate, iodine, and gaseous activity. Its design, range, and sensitivity are similar to those of RM-A1. The monitor may be used in other areas during refueling or as required by Health Physics personnel. The high level alarm setpoints are based upon the

sensitivity of the detectors and are normally set to provide a local high alarm upon the occurrence of activity in excess of 10 CFR 20 limitations.

12.2.4.2.7 Spent Fuel Area, Channel RM-A8

Channel RM-A8 is a movable unit similar to RM-A7. It is normally used for ambient air monitoring in the Fuel Handling Building for detection of particulate, iodine, and gaseous activity. The unit may be used in other areas at the discretion of Health Physics personnel. The alarm setpoints are based upon the sensitivity of the detectors and are normally set to provide a local high alarm upon occurrence of activity in excess of 10 CFR 20 limitations.

12.2.4.2.8 Condenser Air Removal, Channel RM-A9

This channel is discussed in Section 11.4.2. It is used for detection of activity in the effluent discharge of the Condenser Air Removal System and for detection of primary to secondary leakage.

12.2.4.2.9 Waste Gas Discharge, Channel RM-A10

This channel is discussed in Section 11.4.2. It is used to provide backup control of the batch release of waste gas from the waste gas decay tanks.

12.2.4.2.10 Auxiliary Building Ventilation Monitor, Channel RM-A11

Auxiliary Building ventilation duct air samples are monitored (see Figures 9.4-7 and 9.4-8) by a shielded scintillation detector for beta activity which is indicative of the presence of noble gases in the ventilation exhaust ducts. A pumping station is provided to sequentially obtain up to 12 different air samples from the Auxiliary Building ventilation ducts. Each of the 12 areas normally will be sequentially monitored at least once per hour. The activity of each sample is recorded locally. Indication and alarms are provided on the Radiation Monitoring System control panel in the control room. Should the sequential monitor alarm, operators in the control room can alert both individuals in the area and appropriate Health Physics personnel through the use of the Plant PA system. Should a high level alarm condition exist, appropriate Health Physics personnel can be dispatched to the specific area with portable sampling equipment. These samples will provide, on a timely basis, the information necessary to assess the airborne particulate and iodine radioactivity of the area. The approximate sensitivity and range of this channel are as follows: gas, 2×10^{-6} to 2×10^{-2} μCi/cc based upon Kr-85. Setpoints are adjusted as required by Health Physics personnel.

12.2.4.2.11 Movable Particulate Unit, Channel RM-A12

Channel RM-A12 is a movable, cart mounted unit provided to monitor and record particulate airborne activity in areas selected by Health Physics personnel. The unit provides a removable fixed particulate filter and a removable charcoal filter for laboratory analysis. The alarm setpoints

are set as required by Health Physics personnel for the zones being monitored. Sensitivity and range of the particulate monitor are approximately 10^{-11} to 10^{-7}, referenced to Cs-137.

12.2.4.3 Detection of DAC Levels of Airborne Radioiodine and Particulates

An analysis of the capability of the Airborne Radioactivity Monitoring System to detect DAC levels of airborne radioiodine and particulates in areas having potential for airborne contamination and which are normally accessed by personnel is presented in Sections 12.2.4.3.1 through 12.2.4.3.3.

The assumptions upon which this analysis is based are as follows:

1. DAC for airborne iodine is 2×10^{-8} μCi/cc.
2. DAC for airborne particulates (as cesium) is 6×10^{-8} μCi/cc.
3. Sensitivity of radiation monitor, RM-A7, is as follows:
   a. For Cs-137, 8 hour sampling, 4.7×10^{-11} μCi/cc.
   b. For I-131, 8 hour sampling, 2×10^{-11} μCi/cc.

12.2.4.3.1 Control Building

The sampling room is the area in the Control Building complex considered to have potential as a source of airborne activity. This room is sampled by a three channel radiation monitor, RM-A7, which measures airborne particulate, iodine, and gaseous activity.

It is assumed that if DAC levels of iodine and cesium activity are present in the sampling room air, the local radiation monitor, RM-A7, will detect this activity in a sampling time which is inversely proportional to the concentration:

$$\frac{\text{Monitor sensitivity}}{\text{Air concentration}} : \frac{\text{Sample time}}{8 \text{ hours}}$$

Therefore, the sample time to detect one DAC of cesium is determined as follows:

$$\text{Sample time} = \frac{4.7 \times 10^{-11} \mu\text{Ci/cc}}{6 \times 10^{-8} \mu\text{Ci/cc}} \times 8 \text{ hrs} \times \frac{60 \text{ min}}{1 \text{hr}}$$
$$= 0.38 \text{ min}$$

Assuming a high alarm setpoint at 3 times background, the time for response to one DAC of cesium would be approximately 1.1 minutes.

Similarly, the sample time to detect one DAC of iodine is determined as follows:

$$\text{Sample time} = \frac{2 \times 10^{-11} \mu\text{Ci/cc}}{2 \times 10^{-8} \mu\text{Ci/cc}} \times 8 \text{ hrs} \times \frac{60 \text{ min}}{1 \text{hr}}$$
$$= 0.48 \text{ min}$$

Assuming a high alarm setpoint at 3 times background, the time for response to one DAC of iodine would be approximately 1.4 minutes.

12.2.4.3.2 Fuel Handling Building

1. Spent Fuel Pool Floor Area

   Use of the local radiation monitor, RM-A8, would provide response times similar to the estimates used for the sampling room radiation monitor, RM-A7 (see Section 12.2.4.3.1):

Concentration	Detection Time (min)	Alarm at 3 Times Background (Min)
I-131, 2×10^{-8} μCi/cc	0.48	1.4
Cs-137, 6×10^{-8} μCi/cc	0.38	1.1

2. Fuel Handling Building Exhaust

   Use of radiation monitor, RM-A6, in the Fuel Handling Building exhaust would provide the following detection capability under the previously stated assumed conditions, based upon the discharge flow rates shown by Figure 12.2-2.

   The exhaust air flow from the Fuel Handling Building is approximately 27,000 cfm. This flow is monitored by RM-A6, a three channel monitor, which samples the air in the discharge duct upstream of the filter plenum through an isokinetic nozzle. By use of a dilution factor, based upon the ratio of sub-area exhaust air flow to total air flow, an estimate of detection times can be determined as follows:

$$\text{Detection time for one DAC in sub-area} = \frac{\text{Detection time for one DAC}}{\text{Dilution ratio}}$$

   Estimates of detection times for I-131 and Cs-137 obtained from the preceding expression are presented in Table 12.2-4.

12.2.4.3.3 Auxiliary Building

Normally accessible areas of the Auxiliary Building are supplied with clean air which then passes through such areas to restricted access areas with potentially high airborne activity levels. Use of a movable surveillance monitor, such as RM-A12, with an assumed sensitivity of 1.0×10^{-11} μCi/cc for cesium would provide the followingdetection capability:

$$\frac{1.0 \times 10^{-11}\ \mu Ci/cc}{6 \times 10^{-8}\ \mu Ci/cc} : \frac{x\ min}{480\ min}$$

Where:

6×10^{-8} µCi/cc is DAC for cesium

x is the time to detect one DAC, local activity (i.e., 0.1 min).

With the alarm set at 3 times background, the response to one DAC of Cs-137 in the area under surveillance would be approximately 0.3 minutes.

Periodic surveillance sampling by Health Physics personnel will provide samples for laboratory analysis of particulates and radioiodine to verify operational levels of airborne activity in the plant.

12.2.4.4 Reactor Coolant Leak Detection

Assumptions relative to reactor coolant leak detection are as follows:

1. Free containment volume, 1.8×10^{6} ft^3.
2. Continuous purge rate, approximately 1000 cfm.
3. Reactor Building Charcoal Cleanup System, not operating.
4. Reactor coolant activity, as listed below for the predominate isotopes.
5. Sensitivity of radiation monitor RM-A2, satisfies requirements of Regulatory Guide 1.45.

The major isotopes of interest and corresponding design basis activities for both the particulate and gas channels are as follows:

1. Cs-134, 2.6×10^{-2} µCi/gm.
2. Cs-137, 1.9×10^{-2} µCi/gm.
3. Co-58, 1.7×10^{-2} µCi/gm.
4. Co-60, 2.1×10^{-3} µCi/gm.
5. Rb-88, 2.3×10^{-1}µCi/gm.
6. Xe-133, 5.1 µCi/gm (gas).

Assuming a steady reactor coolant leak rate of 0.1 gpm, the equilibrium concentrations of particulate isotopes in the reactor building atmosphere are as follows:

1. Cs-134, 7.38×10^{-8} µCi/gm.
2. Cs-137, 5.40×10^{-8} µCi/gm.
3. Co-58, 4.77×10^{-8} µCi/gm.
4. Co-60, 5.96×10^{-9} µCi/gm.

5. Rb-88, 9.19 x 10^{-9}μCi/gm.

A step increase in leakage to 1 gpm for a period of 1 hour would increase total particulate activity by 75 percent which is readily detectable by the particulate channel of radiation monitor RM-A2.

Figure 12.2-3 shows the increase in the RB particulate concentration following a 1-gpm leak.

The major isotope of interest for gas channel detection is Xe-133. A reactor coolant leak of 0.1 gpm would result in an equilibrium Xe-133 concentration of 4.14 x 10^{-5} μCi/cc. A subsequent leak of 1 gpm over 1 hour would result in an increase of 1.55 x 10^{-5} μCi/cc. This is equivalent to a 37 percent increase which is detectable by the gas channel of radiation monitor RM-A2.

Figure 12.2-4 shows the increase in Xe-133 concentration.

12.2.5 Operating Procedures

The Health Physics group is responsible for developing procedures for evaluating potential airborne radioactivity concentrations and providing guidance for minimizing personnel exposures. Occupational exposure is minimized during operations and maintenance by using the following methods and procedures to determine and cope with potential hazards:

1. Monitoring

   High volume air samples of various flow rates are used to collect particulates on high efficiency filter media, at regularly scheduled intervals, for subsequent counting. For tritium sampling, freezeout methods, bubblers, or desiccants are used to obtain samples for counting by the use of liquid scintillation techniques. Assay of noble gases is performed on a regular schedule by drawing an air sample into an evacuated chamber for appropriate analysis.

2. Respiratory Protection

   It is the responsibility of the Health Physics group to monitor and post areas of airborne radioactivity, to establish the requirements for respiratory equipment, to control the use of respiratory equipment, and to control access to areas through the radiation work permit program. Training programs for respiratory protection are the responsibility of Health Physics Supervision.

   Experience gained during operation and maintenance of several nuclear plants with whom SCE&G has contact is used to provide one basis for further evaluation and development of respiratory protection programs. Guidance contained in Regulatory Guides 8.2, 8.8, and 8.10 is utilized in the development and review of these programs.

   In relation to TMI Action Plan Item II.F.1, “Additional Accident Monitoring Instrumentation,” station procedures will contain the following information for converting instrument readings to concentrations or/and release rates:

a. Graphs relating cpm readings to concentration (μCi/ml) for effluent radiation monitors based on the manufacturer's recommendation or measurements from onsite analyses.

b. Graph or formula for determining the release rate (Ci/sec) based on effluent radiation monitor readings and measured flow rates of the main vent.

c. Graph or formula for determining the volume of steam discharged after opening of main steam safety valves. A concentration based on the average reading of the radiation monitors can be used to quickly approximate the total amount of radioactivity released. Subsequent laboratory analysis more accurately determines the quantity and spectrum of radionuclides released.

Computer capabilities can also be used to assist with these calculations.

Also, as required by TMI Action Plan Item II.F.1, the Station Radiation Monitor Calibration Program is as follows:

Initial vendor calibration included the determination of response to various radioactive isotopes where they were calibrated to provide traceability to the National Bureau of Standards. The Liquid monitors were checked against Cs-137 and Mn-54; Particulate monitors were checked against Cs-137 and Ce-144; Iodine monitors were checked against Cs-137 and Ba-133; Gas monitors were checked against Kr-85 and Cs-137. The Condenser Offgas monitor was checked against Xe-133 and Cs-137. Area monitors were checked against Ra-226.

Inplant calibration will normally use calibrated sources for determination of monitor response. These sources will typically be Cs-137 or Co-60 for Area Gamma monitors; Cs-137 for Particulate monitors; Ba-133 for Iodine monitors; and Cs-137 for Liquid monitors. Frequency of periodic calibration is normally on a yearly basis except for those channels identified in the Technical Specification where frequency has been fixed. The High Range Gamma Area monitors require electronic verification as described in Section 12.1 as the use of high level isotopes is not practical.

12.2.6 Estimates of Inhalation Doses

The annual inhalation doses to plant personnel from airborne activity in the various plant buildings depend upon the occupancy of the various plant areas in which airborne activity can occur. The dose to plant personnel is controlled by limiting personnel occupancy in contaminated areas, using engineering controls when available, and by using respiratory protection equipment when warranted by TEDE-ALARA evaluation of the task being performed. The doses to plant personnel are therefore limited to the values specified in 10 CFR 20 for occupationally exposed individuals.

Sections 12.2.6.1.1 through 12.2.6.1.3 discuss peak airborne concentrations and inhalation dose rates for various plant buildings based upon the leak rates discussed in Section 12.2.3. The methods used to calculate concentrations and inhalation dose rates are discussed in Section 12.2.6.2.

12.2.6.1 Peak Airborne Concentrations and Inhalation Dose Rates

12.2.6.1.1 Reactor Building

Peak airborne concentrations for the Reactor Building during operation at power are presented in Table 12.2-1. The concentrations presented in Table 12.2-1 are those that would occur at the end of the interval between purges with the assumptions given in Section 12.2.3.1.

Exposure to the reactor building concentrations given in Table 12.2-1 would result in an upper limit inhalation dose rate of 21.9 mRem/hr to the thyroid. Exposure of workers to this dose rate is unlikely since operation of the Reactor Building Charcoal Cleanup System and/or partial purging of the Reactor Building normally occur prior to any lengthy access. Respiratory protection equipment is used for short term access when required by plant procedures.

12.2.6.1.2 Auxiliary Building

Average airborne concentrations for the Auxiliary Building were calculated using the assumptions given in Section 12.2.3.2 and the building volume and flow rate discussed in Section 12.2.2. These concentrations are given in Table 12.2-1. The corresponding inhalation dose rate to the thyroid is 1.8×10^{-2} mRem/hr.

As described in Section 9.4.2, the Auxiliary Building Ventilation System supplies clean air to areas expected to be relatively free of airborne activity and removes air from areas that could potentially have high levels of airborne radioactivity. Thus, airborne activity levels in normally occupied areas should be significantly lower than the calculated average concentrations presented in Table 12.2-1.

The peak airborne concentrations in the Auxiliary Building are expected to be in the individual rooms which house auxiliary reactor equipment, such as the letdown heat exchanger, volume control tank and connecting instrumentation, piping, and valves. These rooms are within controlled areas and access to these areas is maintained under strict administrative control. Respiratory protection equipment or other protective measures are used in accordance with plant procedures.

For calculational purposes in determining peak concentrations, it has been assumed that one half of the total leakage in the Auxiliary Building occurs around the letdown heat exchanger. The resultant calculated concentrations for the letdown heat exchanger are presented in Table 12.2-1. The corresponding inhalation dose rate to the thyroid is 2.5 mRem/hr.

12.2.6.1.3 Turbine Building

Average airborne concentrations for the Turbine Building were calculated using assumptions given in Section 12.2.3.3 and the building volume and flow rate discussed in Section 12.2.2. These concentrations are given in Table 12.2-1. The corresponding inhalation dose rate to the

thyroid is 2.8 x 10^{-5} mRem/hr. The Turbine Building concentrations and inhalation dose rate are sufficiently small to allow normal occupancy without the use of protective measures.

12.2.6.2 Methods Used to Estimate Airborne Concentrations and Inhalation Doses

The concentration of radionuclides in a given volume, V, with a steady-state leakage rate is determined from an activity balance. For the i^{th} isotope, the activity balance is as follows:

$$\frac{d}{dt}C_i(t) = \frac{S_i}{V} - \Lambda_i C_i(t) \qquad (12.2\text{-}1)$$

Where:

$C_i(t)$ = Concentration of i^{th} isotope at time t (μCi/cc).

S_i = Leakage rate of i^{th} isotope (μCi/sec).

Λ_i = Removal constant of i^{th} isotope (sec^{-1}).

In Equation (12.2-1), ingrowth from radioactive parent nuclides has been neglected and a homogeneous mixing model has been assumed. The solution is as follows:

$$C_i(t) = \frac{S_i(1 - e^{-\Lambda_i t})}{V\Lambda_i} + C_i(0)e - \Lambda_i t \qquad (12.2\text{-}2)$$

If the system is purged at a flow rate, R, then, for a volume, V, the removal constant is:

$$\Lambda = \lambda_i + \frac{R}{V} \qquad (12.2\text{-}3)$$

Where:

λ_i = The decay constant of the i^{th} isotope.

When an intermittent purging scheme is used, there is a period of buildup followed by a period of removal. During the building interval, the removal constant is:

$$\Lambda = \lambda_i \qquad (12.2\text{-}4)$$

Once the airborne concentrations have been determined, inhalation dose rates are calculated using the following formula:

Inhalation Dose Rate = $(C_i)(BR)(DCF_i)$

Where:

Ci = Equilibrium concentration of isotope i (μCi/cc).

BR = Breathing rate (cc/hr).

DCF_i = Dose conversion factor for isotope i (mRem/μCi).

12.3 HEALTH PHYSICS PROGRAM

12.3.1 Objectives and Organization

12.3.1.1 Program Objectives

12.3.1.1.1 As Low as Reasonably Achievable (ALARA): Policy Considerations

It is the policy of the management of South Carolina Electric and Gas Company (SCE&G) that the Virgil C. Summer Nuclear Station is operated in such a manner that occupational radiation exposures of plant personnel are as low as reasonably achievable (ALARA). This policy is implemented by the Manager, Radiological Protection and Chemistry, who is directly responsible for the ALARA aspects of plant operation, and who also has the authority to prevent operations which are not consistent with the ALARA policy. The Manager, Radiological Protection and Chemistry, is responsible to the Plant Manager, who has overall responsibility for the implementation of the ALARA policy. The ALARA program is subject to the review and audit process described in Section 13.4.2.

The Plant Manager, has familiarized plant personnel with the commitment to keep occupational exposures ALARA by providing appropriate instructions, policy statements, and training. The Plant Manager, determines if modifications to operating and maintenance procedures and to plant equipment and facilities should be made, where practicable to minimize exposures and where unresolved safety problems are not involved.

12.3.1.1.2 ALARA: Operational Considerations

Procedural guidance in exposure reduction has been established for all systems that contain, collect, store, or transport radioactive liquids, gases, and solids, for all operating conditions. The following are examples of specific exposure-reduction techniques for operations such as maintenance, inservice inspection, radwaste handling, and refueling:

1. During initial startup, neutron and gamma-ray dose rate surveys are performed to verify the adequacy of shielding.
2. During normal operations, dose rate, surface contamination, and airborne radioactivity surveys are performed periodically throughout the plant and areas are zoned accordingly. These surveys ensure that data is available for planning operation and maintenance activities in accordance with the ALARA objective of minimizing exposures.
3. Areas are conspicuously posted in accordance with 10 CFR 20, as appropriate.
4. A radiation work permit (RWP) system is employed to ensure proper administrative control over work in restricted areas. The RWP is designed to ensure that the radiological conditions are defined and that appropriate measures are taken to minimize the dose received by personnel. Section 12.3.2.3.7 explains the use of the RWP.
5. Extension tools are used when practicable to increase the distance between the radiation source and the worker.

6. Equipment is moved to areas with lower radiation fields for maintenance when practicable.
7. Portable shielding such as lead bricks, lead sheets, lead shot, high density concrete block, or steel plates are used as practicable for assuring ALARA doses.
8. A personnel dosimetry program as described in Section 12.3.3 is administered by the Health Physics group to ensure compliance with 10 CFR 20.

Administrative controls have been established to assure that all procedures and requirements relating to radiation protection are followed by all plant personnel. The procedures that control radiation exposure are subject to review and approval as outlined in Section 13.4.

In general, the plant procedures are designed to keep occupational radiation exposures ALARA and follow the recommendations of Regulatory Guides 8.8 and 8.10. These procedures are organized and revised by the Manager, Radiological Protection and Chemistry, in cooperation with the Maintenance or Operations Director, such that operations proceed within the framework of the ALARA policy.

Independent technical and quality oversight is provided by Quality Assurance. This organization, through audits, surveillances, and reviews as described in the Dominion Energy Nuclear Facility Quality Assurance Program Description (QAPD), provides input to the Management Safety Review Committee. Since Quality Assurance maintains a reporting chain independent of plant operations, continuing implementation of and adherence to the operational ALARA program is assured.

12.3.1.2 Program Organization

The Manager, Radiological Protection and Chemistry, has the authority for developing and implementing company policy for radiation protection and contamination control. The administration of the Health Physics program is also the responsibility of the Manager, Radiological Protection and Chemistry, whose minimum qualifications are as presented in Section 13.1.3. The Manager, Radiological Protection and Chemistry, reports directly to the Plant Manager, on radiological protection issues.

The Manager, Radiological Protection and Chemistry is responsible for keeping plant staff informed of radiation hazards and conditions related to potential exposure, contamination of plant equipment or contamination of site and environs (see Figure 12.3-1). As the administrator of the health physics program, the responsibilities of the Manager, Radiological Protection and Chemistry include:

1. Training and supervision of the Health Physics staff.
2. Planning and scheduling Health Physics activities.
3. Establishing and maintaining data on plant, environmental and laboratory radiation and contamination levels, personnel exposures, and work or effluent release restrictions.
4. Maintaining a current Health Physics manual which contains the standards and procedures to implement the ALARA policy for radiation exposures and effluent releases.

5. Ensuring that plant operations comply with applicable regulations pertaining to radiation and environmental radiological protection.
6. Assessing radiological conditions/issues for normal operations and emergencies and advising plant management or the emergency director.
7. Developing, implementing, directing, controlling, and supervising all aspects of the RWP, ALARA, Effluent Control, Radiological Environmental, Radwaste, Dosimetry, Radiological Respiratory Protection, Equipment CAL/Contamination Control, Surveillance, RCA Access, and Radiological Data Base Programs.
8. Controlling the receipt, shipment, and storage of all radioactive materials.
9. Providing radiological engineering expertise and assessing events, occurrences, program performance, and data while developing and implementing solutions and enhancements.
10. Reviewing radiation safety-related operating procedures.

The Manager, Radiological Protection and Chemistry is responsible for developing a radiation protection training program, a radiation surveillance program, and an effluent control program to ensure that radiation exposures of all personnel are kept as far below the limits of 10 CFR 20 as is reasonable achievable. He also develops policy and specific procedural guidance as necessary to implement the ALARA policy.

In order to carry out his responsibilities, the Manager, Radiological Protection and Chemistry is in charge of the Health Physics groups. These groups are made up of technicians, supervisors, and professional Health Physicists who meet the qualifications presented in Section 13.1.3.

The Health Physics groups are organized to provide the following services:

1. Establish and maintain a radiological surveillance program to routinely collect, post, and record data concerning radiation and contamination levels, both surface and airborne, throughout the plant.
2. Perform radiation monitoring for special plant operations and specific maintenance activities as required and maintain records of the surveys performed.
3. Establish and implement the ALARA and RWP/planning programs for RCA work/exposure control.
4. Provide for effective access control by establishing zones throughout the plant, based on radiation and contamination levels.
5. Provide, maintain, and instruct plant personnel in the proper use of protective clothing and respiratory equipment for plant operation and maintenance.
6. Provide procedures for dealing with radiation hazards in performing day to day operations and maintenance and verify the effectiveness of such procedures.
7. Develop and implement the personnel dosimetry and respiratory protection programs.

8. Assist in the plant personnel training and emergency preparedness programs by providing specialized training in radiation protection and expertise/manpower for emergency response and scenario development.
9. Make recommendations for performing equipment, area, and personnel decontamination.
10. Receive and ship radioactive materials, including special nuclear, source, and by-product material to ensure compliance with Federal and State regulations.
11. Calibrate and maintain Health Physics, laboratory, and dosimetry equipment and facilities.
12. Sample, analyze, and perform calculations necessary to ensure that radioactivity discharged to the environment in effluents is kept as far below established limits as is reasonably achievable.
13. Assess internal exposures and maintain official dose records.
14. Provide oversight and direction to the chosen dosimetry processor in processing Radiological Environmental and site personnel TLDs.
15. Develop, direct, and implement the Radwaste Process and Minimization program.
16. Develop and maintain the ODCM, serve as member of FSRC, and as Radiation Safety Officer for various DHEC rad material licenses.

The Health Physics section supervises the implementation of the procedures specified by the Manager, Radiological Protection and Chemistry, for personnel and environment exposure reduction during normal operations, maintenance, inservice inspection, radwaste handling, and refueling in accordance with ALARA policy.

12.3.2 Facilities, Equipment, and Procedures

12.3.2.1 Facilities

12.3.2.1.1 Health Physics Facilities

The Health Physics facilities consist of:

1. A Health Physics room and instrument storage area, sampling room, counting room, personnel decontamination area, locker room, and laundry area on the 412’ elevation of the Control Building.
2. Health Physics station(s), containing protection clothing, portable survey equipment, and other Health Physics materials at locations around the plant, as specified by the Manager, Radiological Protection and Chemistry to be of strategic importance for contamination and exposure control.
3. A Health Physics facility for Dosimetry, Whole Body Counting, and Radiological Respiratory Protection.

4. An offsite Radiological Support facility located at the Environmental Lab which provides laboratory and equipment resources necessary for the radiological, environmental, and emergency response programs.

The relevant areas of the Control Building at elevation 412’ are shown in Figures 12.1-19 and 12.1-20 to illustrate the layout of the access control area Health Physics facilities.

12.3.2.1.2 Instrument Storage, Calibration, and Maintenance Facilities

Portable instruments for routine Health Physics surveys are stored in the Health Physics areas around the CB412 HP Lab, RCA Access Control Point, and AB412 HP Instrument Calibration Facility. Other portable instruments are located at Health Physics stations around the plant (see Section 12.3.2.2.2) and at the Environmental Lab. Portable instruments for emergency use are stored at strategic locations around the plant, Environmental Lab, and other approved offsite locations.

Portable instruments and laboratory equipment are routinely maintained and calibrated by Health Physics personnel or by returning the instruments to the manufacturer for repair.

12.3.2.1.2.1 Personnel Contamination Control Facilities

The primary contamination control facility for personnel is the access control area, which is illustrated in Figure 12.1-19. Additional contamination control points are established in the immediate vicinity of known contaminated areas, as necessary, to prevent the spread of contamination. These points provide a controlled interface between the clean and contaminated areas. The personnel decontamination showers are shown in Figure 12.1-19. Additionally, emergency showers are located around the plant in areas with a high potential for personnel contamination. Personnel are checked for contamination with the equipment described in Table 12.3-1.

12.3.2.1.2.2 Equipment Contamination Control Facilities

An equipment decontamination area is located adjacent to the radwaste processing area of the Auxiliary Building. This facility contains installed and portable decontamination equipment. A decontamination area for spent fuel shipping casks is also provided, and is located in the Fuel Handling Building.

12.3.2.2 Equipment

12.3.2.2.1 Selection Criteria

The equipment and instrumentation used in the Health Physics program for the assessment of radioactivity and personnel exposures are selected according to the following criteria:

1. Ability to measure the quantity of interest to an acceptable degree of precision and accuracy.

2. Ease of operation, maintenance, and calibration.
3. Appropriate sensitivity and range for various operational situations, including normal operations, anticipated operational occurrences, and accident conditions, as determined by the requirements of applicable regulations pertaining to each measurement situation.

These criteria apply to portable instrumentation for radiation and contamination surveys, laboratory technical equipment, inplant airborne radioactivity monitoring and sampling equipment, area monitors, and personnel monitoring equipment.

12.3.2.2.2 Protective Clothing and Equipment

The following respiratory protection devices are made available at the plant:

1. Full face particulate filter masks.
2. Full face masks with air line respirator.
3. Hoods or suits with air line respirator.
4. Full-face masks with self contained breathing apparatus of the bottle air or chemox type.

Protective clothing is required in contaminated areas or in areas where the potential for radioactive material contamination exists. Protective clothing available at the plant includes the following:

1. Coveralls.
2. Laboratory coats.
3. Plastic suits.
4. Disposable caps.
5. Hoods.
6. Plastic and rubber shoe covers.
7. Plastic, rubber, and cotton gloves.
8. Disposable protective clothing.

This protective clothing and equipment is located in strategic locations around the plant, as specified by the Manager, Radiological Protection and Chemistry. The protective clothing and equipment is readily available at key location(s) throughout the plant, without the need to return to the protective clothing storage and issue area to obtain this equipment. Also, protective clothing and equipment is provided in the emergency kits located around, and outside, the plant.

12.3.2.2.3 Technical Equipment and Instrumentation

The equipment and instrumentation necessary to measure radioactivity, radiation fields, and exposures falls into two major categories:

1. Fixed or installed.
2. Portable.

The fixed equipment includes the Radiation Monitoring System, access-control contamination monitors, radiochemistry laboratory equipment, personnel dosimetry readout equipment, and the counting room radioactivity analysis instrumentation. The portable equipment includes radiation and contamination survey instruments, airborne radioactivity samplers, movable airborne radioactivity monitor, and personnel dosimeters.

The Radiation Monitoring System is described in Sections 11.4, 12.1.4, and 12.2.4. The access-control contamination monitors are described in Table 12.3-1. The sensitivity of these monitors is a function of the background level at the location of the monitor; the monitors are shielded to the extent practicable in order to increase their sensitivity. The radiochemistry laboratory equipment includes fume hoods, analytical balances, glassware, reagents, and other materials and equipment as required to perform analyses for personnel protection, radioactivity surveys, and related health physics functions. The counting room instrumentation is described in Table 12.3-2.

The portable Health Physics equipment is described in Table 12.3-3. These devices are calibrated at least annually and also after any major maintenance is performed on an instrument. These calibrations are performed using a source of the appropriate type directly or indirectly traceable to the National Institute of Standards and Technology.

12.3.2.2.4 Accident Radiation Monitoring

In-plant accident radiation monitoring combines the use of fixed radiation monitoring equipment and the use of portable monitoring instrumentation.

Area gamma radiation monitors and atmospheric radiation monitors are described in Sections 12.1.4 and 12.2.4. Portable monitoring instrumentation is tabulated in Table 12.3-3.

The fixed radiation monitors (area and airborne) are supplied with diesel backed power and are designed to operate in the normal and anticipated operational environment (see Tables 12.1-20 and 3.11-3), except that the area monitors in the Reactor Building are not required to withstand LOCA environment. This function is performed by area monitor, RM-G7, as described in Section 12.1.4.

In the event of an unplanned gas release involving high concentrations of noble gases, silver zeolite filter cartridges will be used for sampling atmospheres as conditions dictate. Silver zeolite cartridges do not significantly absorb noble gases, enabling a more accurate determination of the radioiodine collected. Fixed process radiation monitors, portable continuous air monitors, and grab samplers can utilize silver zeolite cartridges. Table 12.3-3 outlines the types and quantities of portable air samplers available. Table 11.4-1 lists the fixed process radiation monitors which detect radioiodine.

Normal laboratory instrumentation, i.e., Intrinsic Germanium detectors and a gas flow proportional counter, will be utilized to determine the quantity of radioiodine collected on a filter cartridge. Counting equipment is available at the Environmental Lab if normal laboratory instrumentation is inoperable.

Health Physics procedures include provisions for determining iodine concentrations in noble gas environments. Health Physics personnel are trained on action levels requiring the use of silver zeolite cartridges and the use of portable single channel analyzers and NaI detectors. This meets the requirements of NUREG-0578 Section 2.1.8.C.

12.3.2.3 Health Physics Program: Procedures

It is the intent of SCE&G that the Health Physics Procedures discussed in this section will conform with 10 CFR 20 and follow the recommendations contained in Regulatory Guides 8.7, 8.8, 8.9, and 8.10.

12.3.2.3.1 Radiation Surveys

12.3.2.3.1.1 Radiation Field Surveys

The Health Physics group conducts routine measurements of radiation field intensities around the plant, using portable instrumentation appropriate for the type(s) of radiation present, on a schedule which is determined by:

1. The level of radiation exposure rate.
2. The variability of radiation level.
3. The occupancy factor of the location.

Routine radiation field survey frequencies could increase or decrease due to plant conditions. Locations of strategic importance for ALARA (high exposure rate and occupancy) are routinely surveyed and the latest measured values are documented and available for review prior to work in these areas. Trending of specific areas, such as those containing RHR, and letdown system components is done on a routine basis to provide job planning information in such areas. Records are maintained of the results of these surveys as required by 10CFR20.

Prior to the initiation of any operation for which a RWP is required (see Section 12.3.2.3.7) a survey is made of the radiation field(s) in the vicinity where the operation is to be performed, using instrumentation appropriate for the type(s) of radiation present. The results of this survey are recorded electronically, on paper or in the RWP.

Further aspects of radiation-field surveys are discussed in Section 12.3.2.3.2, and the portable instruments are discussed in Section 12.3.2.2.3.

12.3.2.3.1.2 Surface Contamination Surveys

The Health Physics Services group conducts routine surface contamination surveys at locations around the plant, including the access control areas, administrative area, lunchrooms, control room, and main entrance security gate. All locations of importance for controlling the potential spread of contamination are surveyed at least weekly, using the “smear” technique, or an appropriate portable instrument, and the remaining locations are surveyed at least monthly. These survey frequencies could increase or decrease due to plant conditions. The results of these surveys are recorded and tabulated by locations so that trends in the data may be readily observed.

Contamination surveys are also made on personnel, equipment, and materials from time to time as necessary to ensure complete control over the levels and spread of removable contamination. Further aspects of contamination control are discussed in Sections 12.3.2.3.3 and 12.3.2.1.

12.3.2.3.1.3 Airborne Radioactivity Surveys

Levels of airborne radioactivity are assessed on a routine basis to ensure compliance with 10 CFR 20. These assessments are performed using equipment and techniques appropriate for the type(s) of radioactivity present at the sampling locations.

Any operation requiring respiratory protection will have the results of airborne radioactivity in µci/cc placed on the radiation work permit for that operation. The airborne radioactivity may be assessed prior to the operation but must be assessed during the operation.

The results of routine airborne radioactivity surveys are recorded by location so that trends in the radioactivity level can be readily identified. Air sampling surveys are performed at least daily in areas with both high occupancy factor and a high potential for the existence of airborne radioactivity. Other locations are surveyed weekly or monthly, as a function of the significance of the location as a source of occupational radiation exposure (ORE) from airborne radioactivity. These survey frequencies could increase or decrease due to the plant conditions.
Section 12.3.2.3.4 contains further discussion of airborne radioactivity surveys.

12.3.2.3.2 Radiation Area Access Control

All areas of the plant are subject to access control restrictions to an extent proportional to the potential for ORE in each area. The particular access control requirements for each area are specified by the Manager, Radiological Protection and Chemistry.

Specifically, any area of the plant in which the radiation level is at least 100 mrem/hr at 12 inches (30 cm) from a radiation source or from any surface that the radiation penetrates will be declared a “high radiation area”, and access to such areas is restricted. These areas are posted and secured in accordance with 10 CFR 20. Physical barriers to control access to high radiation areas include: locked and/or annunciated doors or gates, fences, or rope barriers. These barriers are arranged in such a manner as to allow exit from the area without a key or other special device.

Administrative measures for access control to high radiation areas include the use of an RWP for operations taking place in such areas. The estimated exposure for individuals entering such areas is based on radiation surveys made prior to, or at the start of work, and the nature of the operation to be performed. Again, depending upon the operation, a health physics technician may be assigned to supervise stay times and make appropriate surveys while the operation is in progress.

12.3.2.3.3 Contamination Control

Surveys for contamination control are performed by the Health Physics Services group on a routine basis at various locations around the plant (see Section 12.3.2.3.1.2). Nonroutine surveys are also made whenever there is a possibility of the spread of contamination by personnel, equipment, or materials.

Since the complete removal of surface contamination from parts of the plant is a practical impossibility, certain plant areas may be designated as “contamination areas”. The level of contamination and the number of these areas are reduced to the minimum practicable level, and control points are established to prevent the spread of contamination to other plant areas. Entrance to such an area requires compliance with the protective clothing and equipment requirements specified by Health Physics. These areas are conspicuously posted and roped off from normal traffic. Such areas are under the supervision of the Health Physics Services group.

Personnel shall be checked for contamination immediately after exiting a contaminated area at the nearest personnel monitor, or by standing on a “hand-and-foot” or “portal” monitor for a predetermined length of time or by portable Health Physics instrumentation. Permanent personnel contamination monitors are located so that an intercom station is close enough that help can be summoned if necessary.

Any equipment or materials leaving a potentially contaminated area, and all equipment or materials leaving the plant radiation controlled area, will be surveyed for surface contamination and nonremovable radioactivity using smears and/or portable instruments of appropriate sensitivity. Items of appropriate size may also be placed in the Tool and Equipment Monitor (TEM) for release from the plant radiation controlled area.

12.3.2.3.4 Airborne Radioactivity Assessment and Control

Airborne radioactivity is routinely assessed using local sampling, moveable air monitors, and the installed Radiation Monitoring System. Airborne radioactive materials (particulates, noble gases, halogens, tritium) are sampled and analyzed using appropriate techniques. Since local sampling will provide better estimates of airborne contamination levels existing in a work area than will a monitor reading, such special air sampling is used in the RWP program to keep ORE due to airborne radioactivity ALARA. Moveable air monitors and the installed airborne radioactivity monitors are used to provide alarm indications and additional information which is used with local sampling for the assessment of airborne radioactivity.

Airborne radioactivity is controlled by minimizing to the extent practical the sources of this radioactivity, such as surface contamination and leaking valves; and confining unavoidable or accidental releases of airborne radioactivity in plant areas through the use of the ventilation system.

12.3.2.3.5 Respiratory Protection

The respiratory protection equipment available at the plant is listed in Section 12.3.2.2.2. The issuance of this equipment is specified, when necessary, as part of the RWP program, on the basis of special air sampling conducted in areas where work is being performed. This equipment is selected and maintained by the Health Physics group. The fitting and training programs for respiratory protection equipment is the responsibility of the Manager, Radiological Protection and Chemistry. Training is required prior to the use of respiratory protection equipment. Depending on the type of respirator, a fit test and medical evaluation are required.

12.3.2.3.6 Radioactive Materials Handling

Radioactive materials, sealed or unsealed, are handled and stored in such a manner that ORE will be kept ALARA.

Examples of specific methods of handling and storage of radioactive materials to meet this objective include:

1. Minimizing the distance that radioactive samples are transported by personnel.
2. Use of shielded sample transporters as appropriate.
3. Storage of calibration sources in appropriately shielded, labeled, and secured containers.
4. Use of remote actuators or similar devices to maximize the distance of personnel from high level sources.
5. Maintenance of accurate source activity inventories on all calibration sources.

Procedures are written and implemented by the Manager, Radiological Protection and Chemistry for the handling of radioactive materials, including procedures for the safe recovery from radioactive spills or source leakage.

12.3.2.3.7 Radiation Work Permit Program

A RWP program is established as an integral part of the ALARA policy implementation, and is the responsibility of the Manager, Radiological Protection and Chemistry. A RWP may, at the discretion of the Manager, Radiological Protection and Chemistry, be required for any operation (including maintenance, adjustments, calibrations, inspections, or normal operations) which:

1. Takes place in a radiation, high radiation, or airborne radiation area, as defined in 10 CFR 20 or in a contaminated area as specified in the plant administrative procedures.
2. Involves maintenance or other adjustments to any system or component which contains, stores, transports, or collects radioactive materials.
3. In the judgment of the Manager, Radiological Protection and Chemistry warrants the issuance of a RWP prior to initiating the operations.

The primary objectives of the RWP program are:

1. To ensure that the radiological conditions associated with operations involving radioactive materials, directly or indirectly, are known as accurately as possible.
2. To ensure that appropriate and adequate protective measures are taken against these conditions.
3. To ensure that the personnel involved in these operations are aware of the radiological conditions and required protective measures associated with the operation.
4. To ensure that the Manager, Radiological Protection and Chemistry, Health Physicist, Field Operations, or the HP Shift Leader are aware of such operations, and approves of the required protective measures. This approval will be indicated by the signature of any of the previously mentioned individuals on the RWP form.
5. Provides a means for tracking radiation dose by group, job, location, and component.

The assessment of the radiological conditions associated with operations requiring the issuance of a RWP is performed by the Health Physics Services group. The protective measures taken to mitigate these conditions will be subject to the approval of the Manager, Radiological Protection and Chemistry.

Examples of such measures include:

1. Requiring the use of personnel protective clothing and equipment, as appropriate, for the conditions involved.
2. Limitation of stay time in radiation/radioactivity areas.
3. The use of temporary shielding, temporary containments, remote handling devices, or other techniques to minimize the conditions in the operation area.

The RWP form is used to record the total estimated exposure received as derived from the personnel dosimetry readings in order to acquire a total estimated man-rem figure. The actual stay time and estimated exposure of each individual in the RWP-controlled area is recorded electronically via computer or on a dose card. At the discretion of a Health Physicist, Health Physics group personnel may be assigned to supervise the implementation of RWP's and/or to make special surveys during the course of the operation. Personnel involved in the operation acknowledge (by their signature on the RWP form or other appropriate documents) their commitment to the ALARA policy and their obligation to abide by the radiological protection decisions of the Health Physics group personnel.

12.3.2.3.8 Radiation Protection Program Review

The Manager, Radiological Protection and Chemistry is responsible for conducting an ongoing review of the plant radiation protection program, with the primary objective of finding means to reduce ORE as far below the limits of 10 CFR 20 as reasonably achievable. This review includes an analysis of the following aspects of the program:

1. Personnel exposures, as indicated by RWP data and periodic dosimetry readings, to identify trends and identify groups or individuals that are receiving large doses.
2. Radiation survey data, to identify trends in exposure or contamination levels for various locations around the plant.
3. Methods and procedures, to determine means of further reducing ORE's, when practical.
4. Equipment and facilities, to determine where improvements are practical.

In addition to these reviews, management provides independent audit functions as described in Section 12.3.1.1.1.

12.3.2.3.9 Radiation Protection Training

Plant personnel, both permanently assigned and temporary, receive training in the principles of radiation protection commensurate with the degree of hazard associated with their respective work assignments. Such training encompass at least the following topics:

1. Properties of radiation and radioactivity.
2. Biological effects of radiation on humans.
3. Measurement of radiation and radioactivity.
4. Principles and techniques of radiation protection.
5. General regulatory and specific facility license radiation protection requirements.
6. Specific procedures appropriate for particular work assignments.
7. ALARA concept and management commitment thereto.

Personnel who are reassigned to positions involving a greater degree of radiation hazard are retrained and tested at the higher level of radiation protection proficiency required for that assignment. The Manager, Radiological Protection and Chemistry approves the content of the radiation protection training program.

12.3.3 Personnel Dosimetry

12.3.3.1 External Radiation Exposure

Plant employees, visitors, and support personnel who enter the radiation controlled area are required to wear personnel dosimetry. The type of dosimetry issued is based upon expected radiological conditions. Neutron exposure is tracked using staytime and exposure rate calculations and/or is measured (for record) using neutron sensitive dosimetry or calculations, as appropriate. Beta and gamma exposure is tracked/controlled using pocket dosimeters, electronic dosimeters, calculations, or secondary thermoluminescent dosimeters (TLDs) as appropriate. Beta and gamma exposure is measured (for record) by TLD or by calculation/investigation in unusual circumstances. TLDs are processed periodically, not to exceed annually, by a NVLAP accredited processor. TLDs may be processed more frequently during outages, refueling, or when an

individual’s exposure status is in question. Records of exposure are kept for each individual in accordance with the recommendations of Regulatory Guide 8.7. The results of the personnel dosimetry measurements are periodically analyzed to find trends in exposures, identify groups or individuals whose exposures are consistently high, and to find methods of reducing these exposures.

12.3.3.2 Internal Radiation Exposure

Internal radiation exposure is assessed using whole body counting and bioassay techniques and estimated where appropriate by calculational methods. The concepts, models, equations, and assumptions used for the assessment of internal radiation exposure follow the recommendations of Regulatory Guide 8.9 or those regulations/regulatory guides in effect at the time. All personnel who regularly enter areas where the potential exists for inhalation, ingestion, or absorption of radioactive materials are routinely assessed for internal contamination. Nonroutine internal radioactivity assessments are made whenever there is reasonable chance that personnel have inhaled, ingested, or absorbed radioactive materials.

Table 12.3-1
Contamination Control Monitors

Instrument Type	Remarks
Portal Monitor	Alarm sounds on high activity or insufficient length of count. Controls egress from potentially contaminated areas.
“Frisker”	“Pancake” type detector for quick contamination checks of personnel or equipment.

Table 12.3-2
Fixed Laboratory Instrumentation

Instrument	Detector	Sensitivity (1)	Number	Location	Remarks
Low Background Gas Flow Proportional Counter	Proportional Counter	200 dpm	2	412' CB	Used for counting alpha/beta smears, residue from evaporated water and radiochemistry samples; equipped with automatic sample chamber.
Spectroscopy System	Intrinsic Germanium	As per the Technical Specifications	2	412' CB	Spectroscopy system with low-level shield; used primarily for effluent sample analysis.
Liquid Scintillation	--	As per the Technical Specifications	1	412' CB	Used for tritium determination in water, air (freeze out or gel), and urine.
Shielded GM Counting System	GM	200 dpm	2	412' CB	High-level sample counting; backup for low background system.

Table 12.3-2 (continued)
Fixed Laboratory Instrumentation

Instrument	Detector	Sensitivity (1)	Number	Location	Remarks
Laboratory Monitor	GM	N/A	1	412' CB	Check potentially high-level samples before placing in low-level system; monitor background in counting room, warn of changes.
Self-Reading Pocket Dosimeter Chargers	N/A	N/A	2	Various	Used for charging and/or zeroing pocket chamber-type dosimeters.
Electronic Dosimeter Readers	N/A	N/A	2	412’ CB	Used for programming and turning electronic dosimeters on/off.

(1) Instruments will be calibrated as part of the counting laboratory quality control program, using NBS-traceable sources appropriate for each counting system.

Table 12.3-3
Portable Health Physics Instruments

Instrument	Radiation Detected	Range	Accuracy	Number (1)	Location	Remarks
GM Survey Meter	beta gamma	0-200 mr/hr	± 10% full Scale	6	Refer to Section 12.3.2.1.2	Equipped with end window, side window, or pancake probe.
GM Survey Meter	gamma	0-1000 R/hr	± 10%	14	Refer to Section 12.3.2.1.2	Fishing pole type with extendable probe; 20 in to 13 ft.
GM Survey Meter-Friskers	beta gamma	0-50,000 cpm	± 10%	50	Refer to Section 12.3.2.1.2	Primarily personnel monitoring usage.
GM Survey Meter-Remote Monitoring Gamma	gamma	0-1000 mr/hr	± 10% full scale	13	Refer to Section 12.3.2.1.2	Provide remote area monitoring capability.
Ionization Survey Meter	beta gamma	0-5000 mr/hr	± 10% full Scale	33	Refer to Section 12.3.2.1.2	Air ionization chamber.
High Range Survey Meter	beta gamma	0.1-≥500 R/hr	± 10% full Scale	1	Refer to Section 12.3.2.1.2	Air ionization chamber.
Neutron Rem Counter	thermal through fast neutrons	0-5 Rem/hr	± 10% full Scale	3	Refer to Section 12.3.2.1.2	A BF_3, helium or equivalent tube inside a moderator for detection of neutrons up to 10 MeV.
Scintillation Counter	alpha	0-1M cpm	± 10% full Scale	1	Refer to Section 12.3.2.1.2	An alpha scintillation crystal covered with a thin mylar window.
Pocket Dosimeter	gamma x-ray	0-500 mr	± 10%	360	Various	
Pocket Dosimeter	gamma x-ray	1500 mr	± 10%	120	Various	

Table 12.3-3 (continued)
Portable Health Physics Instruments

Instrument	Radiation Detected	Range	Accuracy	Number (1)	Location	Remarks
Electronic Dosimeters	gamma	-	± 5%	400	Various	Used for personnel exposure tracking. They are rate and integrating. Number is based on having sufficient in stock to support operational and E-kit needs.
Thermoluminescent Dosimeters	gamma, beta, neutron	-	± 20%	variable	Vendor Supplied	Used personnel exposure monitoring as dose of legal record. Integrating.
Job Site Air Samplers	-	-	-	14	Various	Particulate and iodine sampler; may have extendable sample head (tygon); normally used at job sites for longer or continuous sampling.
Hand Held Air "Grab" Samplers	-	-	-	17	Various	Particulate and iodine sampler; normally used for quick grab samples or short duration jobs.
Tritium Samplers	-	-	-	2	Various	
Noble-Gas Samplers	-	-	-	5	Various	

(1) The number of instruments is based on the minimum number that should be in inventory (not necessarily in calibration or in service) to support normal operational needs and in some cases, emergency kits; exceptions are noted in the remarks.

Intentionally Blank

12A DESIGN REVIEW OF PLANT SHIELDING AND ENVIRONMENTAL QUALIFICATION OF EQUIPMENT FOR SPACES/SYSTEMS WHICH MAY BE USED IN POST ACCIDENT OPERATIONS OUTSIDE THE REACTOR BUILDING AT THE VIRGIL C. SUMMER NUCLEAR STATION

12A.1 INTRODUCTION

This report has been prepared in response to the September 13, 1979, letter from Darrel G. Eisenhut of the NRC to all operating nuclear power plants. This letter presented an implementation schedule for the recommendations presented in "TMI-2 Lessons Learned Task Force Status Report and Short-Term Recommendations" (NUREG-0578). The requirements defined in the September 13th letter were subsequently clarified in a letter from Harold R. Denton to all operating nuclear power plants dated October 30, 1979.

Among the requirements defined in the two NRC letters is a review to determine whether post-accident radiation fields unduly limit personnel access to areas necessary for mitigation of or recovery from an accident or unduly degrade the proper operation of safety equipment. Corrective actions for problems identified as a result of the review are also to be determined. This report presents the results of such a review for the Virgil C. Summer Nuclear Station.

The review was based on the following guidelines:

a. The post-accident dose rate in areas requiring continuous occupancy should not exceed 15 mr/hr.

b. The post-accident dose rate in areas which do not require continuous occupancy should be such that the dose to an individual during a required access period is less than 5 Rem whole body or its equivalent, in order to maintain compliance with General Design Criterion 19.

c. The integrated dose to safety equipment as a result of the accident should be less than the dose for which the equipment has been qualified to ensure that the capability of the equipment to perform its safety function has not been degraded, in order to maintain compliance with General Design Criterion 4.

d. The minimum radioactive source term used in the evaluation should be equivalent to the source terms recommended in Regulatory Guides 1.3 and 1.4 (Reference 4).

12A.2 SUMMARY

This report provides a review of the Virgil C. Summer Nuclear Power Plant to determine whether post-accident radiation fields unduly limit personnel access to areas necessary for mitigation of or recovery from an accident, or unduly degrade the proper operation of safety

equipment. This review was accomplished using the recommendations and guidelines of NUREG-0578 and subsequent clarifications as provided by the NRC.

A detailed discussion of the evaluation of plant vital areas and equipment qualification for post-accident conditions is presented in Sections 4.0 and 5.0. Results indicated that certain areas of the plant required additional radiation shielding to reduce the post-accident radiation fields. These areas and the shielding modifications utilized are described in the following paragraphs.

Area “A” is the location of the residual heat removal (RHR) pumps, reactor building spray pumps, and the pump room cooling units. The RHR/Spray piping is adequately shielded and does not restrict post-accident access to this area. However, a significant potential source of exposure to plant personnel can result from the RHR/Spray pump room sump line. This line was unshielded and located in the hallway between pump room B and the waste holdup tank, and resulted in a potentially high radiation area during both normal and accident operating conditions. The resultant dose levels in the subject area have been reduced to acceptable values by the re-routing and venting of the line to permit the line to drain during sump pump shutdown periods, and the placement of lead shielding to prevent streaming to the operating floor 374’-0". The new pipe configuration and radiation shielding allows personnel access in accordance with the occupancy requirements of Table 12A.4-2, and the resultant integrated dose meets the dose requirements of 10CFR50, Appendix A, General Design Criterion 19 as outlined in NUREG-0737.

Following an accident, personnel access to the Auxiliary Building is controlled at the 412’-0" elevation from the Control Building. As a result, the use of the stairway and elevator located in cubicle 12-09 as an access route to vital areas above and below the 412’-0" elevation is important. A 10-inch RHR line penetrates the south and east shield walls of cubicle 12-09 at elevation 429’-6" resulting in significant doses to workers in this area. Shortly after the accident, the integrated dose to a worker transversing this area would be of the order of 1 rem. The resultant dose levels in the subject area have been reduced to acceptable values by the addition of lead shielding. The new configuration allows personnel access in accordance with the occupancy requirements of Table 12A.4-2, and the resultant integrated dose meets the dose requirements of 10CFR50, Appendix A, General Design Criterion 19 as outlined in NUREG-0737.

Area “I” is the location of the charging/safety injection pump room cooling units. This area was found to contain high radiation levels due to unshielded CVCS piping located at several places within the area. In order to permit the required occupancy time in the area for manual valve alignment or maintenance, the resultant dose levels in the area have been reduced to acceptable values by the addition of lead and concrete shielding. The new configuration allows personnel access in accordance with the occupancy requirements of Table 12A.4-2, and the resultant integrated dose meets the dose requirements of 10CFR50, Appendix A, General Design Criterion 19 as outlined in NUREG-0737.

In the area of the Intermediate Building between the east and west penetration access areas there were several RHR, safety injection, and CVCS lines which were routed above the sides of an open pipe chase at elevation 422’-3". This permitted direct streaming from the piping to reach the floor area of Intermediate Building floor elevation 412’-0" which contains safety related equipment. The resultant dose levels in this area of the Intermediate Building have been reduced to acceptable values by the modification of the pipe chase as follows: (1) extension of the pipe chase side above the 12" RHR line, (2) addition of 6" concrete shielding to the existing 1 foot concrete shielding, (3) re-location of an access ladder to prevent streaming through a concrete cutout. The new configuration allows personnel access in accordance with the occupancy requirements of Table 12A.4-2, and the resultant integrated dose meets the dose requirements of 10CFR50, Appendix A, General Design Criterion 19 as outlined in NUREG-0737.

12A.3 SOURCE TERMS AND CALCULATIONAL METHODOLOGY

12A.3.1 Source Terms

12A.3.1.1 Basis for the Source Terms

The activity releases assumed in this review are based on the assumptions and regulatory positions contained in the Regulatory Guides 1.4 (Reference 4) and 1.7 (Reference 5). The activity assumed for liquid source term calculation is based on 100 percent of the noble gas inventory, 50 percent of the halogen core inventory, and 1 percent of all other nuclides in the core inventory. The activity assumed for gaseous source term calculation is based on 100 percent of the noble gas core inventory and 25 percent of the halogen core inventory.

12A.3.1.2 Liquid Source Terms

Two liquid sources are considered in the design review: (1) the undiluted fluid as found within the reactor coolant system, and (2) the diluted fluid as found within the reactor building recirculation sump. The first source term, undiluted reactor coolant, is required in the examination of those systems whose flow originates from either the Reactor Coolant System or an auxiliary system containing the undiluted primary fluid. The source terms are based on the dilution of the liquid activity inventory discussed in the first paragraph with the fluid volume of the Reactor Coolant System. This source is used for the examination of the reactor coolant fluid sampling section of the Nuclear Sampling System, and those portions of the Chemical and Volume System associated with the degasification of the reactor coolant fluid.

In the second liquid source term, consideration is given for the dilution of the liquid activity inventory discussed in the first paragraph with the fluid volume contained in the reactor building recirculation sump. The minimum fluid volume expected in the sump, and the individual contributors to that volume, are given in Table 12A.3-1. These source terms are utilized in the examination of those systems which receive their fluid supply from the reactor building recirculation sump. Those systems which are considered in the review are:

Residual Heat Removal System

Reactor Building Spray System

Safety Injection System

Nuclear Sampling System (RHR process fluid sample)

12A.3.1.3 **Gas Source Terms**

The gaseous source terms were determined for containment and the waste gas system using the activity releases described in Section 12A.3.1.1.

The containment airborne source term was based on the dilution of the gaseous activity inventory by the containment free volume atmosphere.

Although not designed for reactor coolant degasification under post-accident conditions, the waste gas system was evaluated for the exposures emitted and received under the post-accident conditions. The waste gas system is designed to remove the fission product gases from the reactor coolant contained in the Volume Control Tank (VCT). The amount of fission gases removed from the reactor coolant in the VCT and collected by the waste gas system can be related to the amount entering the VCT as follows:

(1) Stripping Efficiency (SE):

$$SE = \frac{C_R - C_L}{C_R - C_{L_{eq}}}$$

2) Stripping Fraction (SF):

$$SF = \frac{C_R - C_L}{C_R}$$

where C_R = the gas concentration in the reactor coolant liquid entering the Volume Control Tank,

C_L = the gas concentration in the reactor coolant liquid leaving the Volume Control Tank,

$C_{L_{eq}}$ = the gas concentration in the reactor coolant liquid leaving the Volume Control Tank, assuming the ratio of the gas concentration in the liquid and gas phases in the Volume Control Tank follows Henry's Law.

The waste gas system source terms were determined for the degasification of the reactor coolant liquid by calculation of the quantity of activity entering the Volume Control Tank via the normal letdown path. For the sake of conservatism, the stripping efficiency of this process is assumed to be 100 percent. Therefore, in the previous equation of the stripping fraction, $C_L = C_{L_{eq}}$, and the stripping fraction is:

$$SF = \frac{C_R - C_{L_{eq}}}{C_R}$$

Thus, the separation of the fission gases from the reactor coolant liquid in the VCT will follow Henry's Law. This results in the maximum theoretical gas concentration in the vapor phase of the VCT and, hence, the maximum quantity of gas enters the waste gas system.

12A.3.2 Methodology

12A.3.2.1 Calculation of Dose Rates

Dose rates for the areas of interest in this review were calculated by determining the potential contributing sources at a representative location and using the appropriate source term from Table 12A.3-2 adjusted for decay as required. The dose rate at the representative location was used as the general area dose rate for the area. The SDC computer code (Reference 1) was used in performing the dose rate calculations. Energy groups required as input to the computer code were determined using the gamma ray energy and intensity data in References. 2 and 3 for the nuclides in Table 12A.3-2.

MicroShield (Reference 7) was used to determine gamma energy, intensities, and dose rates for the waste gas sources and the containment sump sources.

12A.3.2.2 Calculation of Doses to Personnel During Post Accident Access to Vital Areas

Personnel doses received in performing a specific task in a given vital area are calculated as the sum of the doses received during travel to and from the vital area and the dose received while performing the given operation in the vital area.

The doses received during travel are determined by calculating dose rates at selected locations (or at a single location if the dose rate along the travel route is relatively uniform) along the travel route using the methodology discussed in Section 12A.3.2.1 and multiplying the dose rates by the appropriate travel time for each selected location along the travel route.

Doses received while performing a given operation are determined by multiplying the dose rate for the given area by the time required to perform the operation. Dose rates for the given vital area are determined using the methodology discussed in Section 12A.3.2.1.

12A.3.2.3 Calculation of Integrated Doses to Safety Equipment

The integrated dose to a given item of safety equipment is determined by integrating the dose rate appropriate for the given item over the time period that it is required to be available to perform its safety function. Dose rates are calculated using the methodology discussed in Section 12A.3.2.1.

Table 12A.3-1
CONTAINMENT SUMP MINIMUM LIQUID INVENTORY

Liquid Source	Liquid Volume (ft^3)
Refueling Water Storage Tank	44,483 [(a)]
Safety Injection Accumulators	3,052 [(b)]
Sodium Hydroxide Storage Tank	406 [(c)]
Reactor Coolant System	6,623
Containment Sump Extension [(d)]	1,159
Minimum Containment Sump Volume =	55,723 ft^3

a. Refueling Water Storage Tank at minimum operating water level at start of drawdown of the tank. The tank drawdown will be terminated at LO-LO level upon the automatic initiation of recirculation via the RHR system.
b. The total volume attributed to the accumulators includes the minimum tank volumes plus the volume of the injection lines.
c. The minimum usable volume of liquid in the Sodium Hydroxide Storage Tank.
d. Containment Sump Extension refers to the fluid volume contained in systems that recirculate sump fluid during the recirculation phase of LOCA.

12A.4 REVIEW OF AREAS REQUIRING ACCESS FOR POST ACCIDENT OPERATIONS

A vital area is defined as any area which will or may require occupancy to permit an operator to aid in the mitigation of or recover from an accident. Vital areas for the Virgil C. Summer Nuclear Station are shown in Figures Figure 12A.4-1 through Figure 12A.4-7. Calculated exposure rates as a function of time after the accident are given in Table 12A.4-1. Vital area occupancy and access dose are summarized in Table 12A.4-2. Access routes to the vital areas are described in Table 12A.4-3.

12A.4.1 Area A: RHR/Spray Pump Rooms and Cooling Units

Area “A” as identified on Figure 12A.4-1 is the location of the residual heat removal (RHR) pumps, reactor building spray pumps and the common pump room cooling units. Failure of an RHR or Spray pump following an accident will result in a minimum safeguard condition and access to this area may be required to ensure that more than one pump is available for long term cooling of the reactor core. Under these circumstances, plant personnel may require access to this area for operations such as pump seal replacement or minor maintenance. Tasks such as these require that three individuals spend approximately 4 hours in the pump rooms or at the cooling units.

Sources of exposure in this area are the RHR and spray system piping in the system train that is operating. This piping is located in the adjacent pump room and in the valve and piping area located above at elevation 397’- 0". Piping in the train requiring maintenance or repair is assumed to be flushed and drained. Access to this area is not required immediately since only long term operation need be considered. One day after the accident, the exposure rate is 383 mr/hr in the pump rooms and 614 mr/hr at the cooling units. The calculated dose to an individual for 4 hours of occupancy is 1.41 rem and 2.25 rem, respectively. Table 12A.4-2 shows that 4 hours occupancy in this area is possible prior to one day following the accident.

The access route to area “A” is route “1” described in Table 12A.4-3. This access route will add a total of 0.024 rem to the worker dose if the task is started one day after the accident.

12A.4.2 Area B: Charging/SI Pump Rooms

Area “B” is the location of the charging/safety injection (SI) pumps and is identified on Figure 12A.4-2. Failure of one of these pumps following an accident will result in a minimum safeguards condition and access to this area may be required to ensure that all pumps are available for long term cooling of the reactor core. Under these circumstances, plant personnel may require access to this area for operations such as pump seal replacement or minor maintenance. Tasks such as these require that three individuals spend approximately 4 hours in the pump rooms.

Sources of exposure in this area are from the charging/SI pump piping for the pumps that are operational and are located in the adjacent pump rooms. Piping in the pump room where

maintenance or repair is required is assumed to be flushed and drained. Access to this area is not required immediately since only long term operation need be considered. Two days after the accident, the exposure rate is 630 mr/hr. The calculated dose of occupancy is 2.39 rem. Table 12A.4-2 shows that 4 hours occupancy in this area is possible prior to two days following the accident.

The access routes to area “B” are routes “3” and “8” and are described in Table 12A.4-3. These access routes will add 0.02 rem and 0.05 rem to the dose if the task is started two days after the accident.

12A.4.3 Area C: Charging/SI Pump C Auxiliaries Local Control Panel

Area “C” as identified on Figure 12A.4-2 is the location of charging/safety injection pump C auxiliaries local control panel. Failure of one of the charging/SI pumps will result in minimum safeguards condition and access to this area may be required for manual switching of the charging/SI pumps. This task would require that two workers spend approximately 2 minutes at the control panels.

The major source of exposure in this area is a 3 inch safety injection line located inside the shield labyrinth at the entrance to cubicles 88-23 and 88-24. A direct line of sight is possible from this source to the immediate vicinity of the pump C transfer switch. This line will not become a source of exposure until recirculation of containment sump liquid is initiated. Additional exposure in this area results from charging/SI piping in pump room 88-23.

Access to this area could be required immediately after the accident. Access at 30 minutes is assumed in order to evaluate the worst case of containment sump liquid in the 3 inch safety injection line at the start of recirculation. Assuming that the workers are in a direct line of sight with the unshielded safety injection line, the exposure rate in the area is 82.6 rem/hr which results in an occupancy dose of 2.75 rem for the 2 minute time period.

The access route to area “C” is route “7” described in Table 12A.4-3. This access route will add a total of 1.40 rem to the worker dose if the task is started 30 minutes after the accident.

12A.4.4 Area D: Spent Fuel Pit Heat Exchanger

Area “D” is the location of the spent fuel pit heat exchangers (see Figure 12A.4-2). Access to this area is not required to aid in the mitigation of or recovery from an accident, but should conditions dictate, access may be needed to service the heat exchanger to maintain cooling of the spent fuel. Under these circumstances, post-accident operations in this area require only long-term periodic surveillance.

The exposure rate in this area following an accident is negligible since there are no post-accident sources of activity in the vicinity of the heat exchangers. This permits unlimited access (40 hours/week) in this area.

The access route to area “D” is route “9” described in Table 12A.4-3. This access route will add a total of 0.02 rem to the worker dose if the task is started one day after the accident.

12A.4.5 Area E: Radwaste Gas Handling Control Panels

Area “E” as identified in Figure 12A.4-2 is the location of the radwaste gas recombiner analyzer and control panels. Access to this area is not required following an accident since it is not planned to start-up the radwaste gas handling system. If degassing of the primary coolant system becomes necessary following an accident, the operation will be accomplished by utilizing the reactor head vent system.

12A.4.6 Area F: Spent Fuel Pit Cooling Pumps and Local Control Panels

Area “F” as identified on Figure 12A.4-3 is the location of the spent fuel pit cooling pumps and local control panels. Access to this area is not required to aid in the mitigation of or recovery from an accident, but should conditions dictate, access to this area may be needed in order to maintain cooling of the spent fuel. Under these circumstances, plant personnel may require access to this area for operations such as pump seal replacement or minor maintenance. Tasks such as these require that three individuals spend approximately 4 hours at the pumps.

Dose contributors in this area are the containment building and a 3 inch safety injection line located approximately 20 feet away above the shield slab at elev. 426’-6". The time at which access to this area is required is based on the minimum time it takes to reach maximum spent fuel pool temperature with loss of both cooling pumps. This time is 12.5 hours. Eight hours after the accident, the exposure rate is 1.16 rem/hr. The calculated dose to an individual for 4 hours of occupancy is 3.03 rem.

The access route to area “F” is route “6” described in Table 12A.4-3. This access route will add a total of 0.11 rem to the worker dose if the task is started 8 hours after the accident.

12A.4.7 Area G: Engineered Safety Feature Motor Control Center

Area “G” is the location of the Engineered Safety Feature (ESF) Motor Control Center 1DA2Y and is identified on Figure 12A.4-3. It is not expected that access to this area would be required since all ESF control functions are performed from the control room. However, access may be required in the unlikely event that a safety-related component loses remote control power. Should such a component lose remote control power and fail in the unsafe position, in conjunction with a simultaneous failure of its redundant counterpart, it may be deemed necessary to gain

access to this area for manual control of the component. This task would require that two workers spend approximately 2 to 5 minutes in this area.

Dose contributors to this area are spray system, safety injection system, and chemical and volume control system piping located below and adjacent to this area. Access to this area could be required immediately after the accident. Access at 30 minutes is assumed in order to evaluate the worst case which is the initiation of the recirculation of containment sump liquid in the spray and safety injection systems. The exposure rate in this area is 24.1 rem/hr resulting in estimated exposures to an individual of 0.80 rem and 2.01 rem for occupancy times of 2 minutes and 5 minutes, respectively.

The access route to area “G” is route “4” described in Table 12A.4-3. This access route will add a total of 0.28 rem to the worker dose if access is required 30 minutes after the accident.

12A.4.8 Area H: Waste Processing System Control Panel

Area “H” is the location of the waste processing system panel (see Figure 12A.4-3). The waste gas system is not intended to be used for degassing the primary coolant system in post-accident conditions. Access to this area may be needed since the waste gas compressor are controlled from this panel. This task will require two persons to occupy this area for one minute.

Sources of exposure in this area are the containment building, and a 2 inch CVCS line located approximately 10 feet away and above the 2 foot thick concrete shield slab at elevation 426’-0". Immediately after the accident, the dose rate from these sources in area “H” is 3.74 rem/hr. The calculated dose for the one minute occupancy time is 0.06 rem.

The access route to area “H” is route “5” described in Table 12A.4-3. This route will add a total of 0.98 rem to the worker dose in this area for access immediately after the accident.

12A.4.9 Area I: Charging/safety Injection Pump Cooling Units

Area “I” is the location of the charging/safety injection pump room cooling units and is identified on Figure 12A.4-4. Although not a vital access area required for the mitigation of or recovery from an accident, the access may be established so as to ensure that more than one of the charging/safety injection pumps are available for the long term cooling of the reactor core. By this action, undesirable minimum safeguards condition that would result upon failure of one of these cooling units can be avoided. Under these circumstances, plant personnel may require access to one of the areas for operations such as manual switchover, maintenance, or repair. Tasks such as these require that two persons spend five minutes at the cooling units for manual switchover, or three persons spend four hours for the maintenance or repair of a cooling unit.

The major sources of exposure in this area are the charging/safety injection pump cubicle piping, the piping area immediately west of the cooling units on elevation 400’-0", and a 3-inch

chemical and volume control system (CVCS) pipe located inside the room containing cooling units 1 and 2.

The access route to Area "I" is route "10" described in Table 12A.4-3. For the manual valve switchover procedure, the access route will add a total of 1.03 rem to the worker dose at the time of the accident (i.e., 0 hr.). For the maintenance and repair activities after the accident, the access route will contribute 0.02 rem one day after the accident to the worker dose, and becomes negligible five days after the accident.

The resultant dose levels in this area have been reduced to the acceptable values shown in Table 12A.4-2 by the addition of concrete and lead shielding around the charging/safety injection and CVCS piping located within the charging/safety injection pump cooling unit cubicle. The new configuration allows personnel access in accordance with the occupancy requirements of Table 12A.4-2 and the occupancy guidelines for vital access areas requiring infrequent occupancy as contained in NUREG-0737.

12A.4.10 Area J: Engineered Safety Feature Substation Bus and Motor Control Center

Area "J" is the location of the engineered safety feature 480 volt unit substation bus 1DB1 and motor control center, 1DB2Y (see Figure 12A.4-6). Occupancy in this area following an accident will be the same as explained for area "G".

Dose contributors to this area are the volume control tank (cubicle 63-02), and valve gallery located in cubicle 63-03.

Access to this area could be required immediately after the accident. With the assumption that zero hour entry occurs, the exposure rate in this area will result in calculated exposures of 3.85 and 9.62 rem to an individual for the occupancy periods of 2 and 5 minutes, respectively. However, the resultant dose levels in this area are reduced to acceptable levels quickly as shown in Table 12A.4-2, and the resultant integrated doses meet the dose requirements of 10CFR50, Appendix A, General Design Criteria 19 as outlined in NUREG-0737.

The access route to area "J" is route "14" described in Table 12A.4-3. This access route will add 2.80 rem to a worker's dose immediately after the accident.

12A.4.11 Area K: Hydrogen Recombiner Control and Power Supply Panels

Area "K" as identified on Figure 12A.4-6 is the general location of the hydrogen recombiner control and power supply panels. Post-accident hydrogen formation in the Reactor Building may require operation of the hydrogen recombiner system. The system is started and controlled by operator action at the recombiner control panel. This task requires that two workers spend 10 minutes in this area per hour over a 3 hour period.

Dose contributors in this area are the personnel access hatch and a 3 inch chemical and volume control system pipe located below at elevation 450’6". Access to the control panels could be required shortly after an accident. The exposure rate 2 hours after the accident in this area is 16 rem/hr. The calculated dose to an individual in this area for 10 minutes of occupancy is 2.67 rem. If occupancy is required at one day after the accident, the exposure rate is calculated to be 1.14 rem/hr which results in a 10 minute dose of 0.19 rem.

The access route to area “K” is route “13” described in Table 12A.4-3. The calculated dose to an individual traveling this route is 0.92 rem 2 hours after the accident and 0.03 rem 1 day after the accident.

12A.4.12 Area L: Hydrogen Recombiner Control and Power Supply Panels

Area “L”, as identified on Figure 12A.4-6, is the general location of the hydrogen recombiner control and power supply panels. Occupancy in this area following an accident will be the same as explained for area “K”.

Dose contributors in this area are the Reactor Building located approximately 40 feet away and a 10 inch spray line located below the 2 ft. concrete floor at elevation 436’-0". Access to the control panels could be required shortly after an accident. The exposure rate 2 hours after the accident in this area is 0.74 rem/hr. The calculated dose to an individual in this area for 10 minutes of occupancy is 0.12 rem. If occupancy is required at one day after the accident, the exposure rate is calculated to be 16.0 mrem/hr which results in a 10 minutes dose of 0.003 rem.

The access route to area “L” is route “11” described in Table 12A.4-3. This access route will add a total of 0.52 rem to the worker dose 2 hours after the accident and 0.02 rem 1 day after the accident.A

12A.4.13-1 Area M1: Reactor Building Atmosphere Sample Collection Point and Hydrogen Gas Analyzer

Area “M1” as identified in Figure 12A.4-6 is the location where a reactor building air sample will be collected following an accident. It is also the location of the reactor building atmosphere hydrogen analyzer. The hydrogen analyzers are designed to continuously monitor the reactor building atmosphere following an accident. Access to the analyzer is not required since they are redundant (the other analyzer is located at elevation 463’-0" of the Auxiliary Building in cubicle 63-17) and all necessary functions are controlled remotely from the Control Room. However, access to this area is required to collect a reactor building air sample. The time required to collect the air sample has been estimated to be 10 minutes.

Dose contributors to this area are the Reactor Building located approximately 10 ft away, 3/8” gas sample lines for the sample cylinder and the hydrogen analyzer, and the gas sample cylinder itself. Access to this area could be required shortly after the accident. Access at 30

minutes is assumed. The exposure rate in this area 30 minutes after the accident is 12.9 rem/hr. This results in a calculated dose of 2.15 rem for 10 minutes of occupancy.

The access route to area “M” is route “12” described in Table 12A.4-3. This access route will add a total of 1.14 rem to the worker dose for access to and from this area 30 minutes after the accident.

12A.4.13-2 **Area M2: Reactor Building Atmosphere Sample Collection Point and Hydrogen Gas Analyzer**

Area “M2” as identified in Figure 12A.4-6 is the location where a reactor building air sample will be collected following an accident. It is also the location of the reactor building atmosphere hydrogen analyzer. The hydrogen analyzers are designed to continuously monitor the reactor building atmosphere following an accident. Access to the analyzer is not required since they are redundant (the other analyzer is located at elevation 463’-0” of the Fuel Handling Building) and all necessary functions are controlled remotely from the Control Room. However, access to this area is required to collect a reactor building air sample. The time required to collect the air sample has been estimated to be 10 minutes.

Dose contributors to this area are the Reactor Building located approximately 30 ft. away, 3/8-inch gas sample lines for the sample cylinder and the hydrogen analyzer, and the gas sample itself. Access to this area could be required shortly after the accident. Access at 30 minutes is assumed. The exposure rate in this area 30 minutes after the accident is 13.0 rem/hr. This results in a calculated dose of 2.17 rem for 10 minutes of occupancy.

The access route to area “M2” is route “13” described in Table 12A.4-3. This access route will add a total of 1.96 rem to the worker dose for access to and from this area 30 minutes after the accident.

12A.4.14 Area N: Technical Support Center

Area “N” as identified in Figure 12A.4-7 is the location of the technical support center. The technical support center is located adjacent to the control room on elevation 463’-0" of the Control Building. Continuous occupancy is required in this area following an accident.

A complete analysis of post-accident radiation doses in the control room and technical support center is presented in Section 15.4.1.

12A.4.15 Area O: Control Room

Area “O” as identified in Figure 12A.4-7 is the location of the control room. Continuous occupancy is required in this area following an accident.

A complete analysis of post-accident radiation doses in the control room is presented in Section 15.4.1.

12A.4.16 Area P: Sample Room

Area “P” as identified in Figure 12A.4-7 is the location of the sample room. Access to this area is required to place a primary system liquid sample on recirculation using the nuclear sampling system following an accident for assessing the extent of fuel damage using the measured recirculation radiation dose rate. The sample shall consist of fluid taken from the primary coolant hot leg, the pressurizer liquid, or residual heat removal loop.

The nuclear sampling system provides the means for the collection of post-accident samples in the sample room. The system has been designed to reduce the activity concentration of the samples to a level that will result in dose rates within the range of values normally associated with the 1% failed fuel design criteria.

In addition to the use of minimum activity concentrations, the resultant dose levels in this area have been reduced by the addition of 4-inch lead shielding between the sample rack in the chase area and the sink area of the sample room.

The access route to area “P” is route “15” described in Table 12A.4-3.

12A.4.17 Area Q: Radiochemistry Lab

Area “Q” as identified in Figure 12A.4-7 is the location of the radiochemistry laboratory. Access to this area provides for the radiological and chemical analyses of the post-accident samples following their transfer to this location.

Since the existing radiation shield design and sample analysis procedures in this area were designed for 1% failed fuel sources, the nuclear sampling system has been designed to reduce the activity concentration of the samples to a level that will result in dose rates in the radiochemistry lab within the range of values normally associated with the 1% failed fuel design criteria (< 2.5 mrem/hr).

The access route to area “Q” is route “15” as described in Table 12A.4-3.

12A.4.18 Area R: Count Room

Area “R” as identified in Figure 12A.4-7 is the location of the count room. Access to this area provides for the radiological analysis of the post-accident samples prepared in the radiochemistry laboratory.

The nuclear sampling system design criteria to provide post-accident sources with a radioisotope activity level comparable to that of the 1% failed fuel design criteria results in insignificant increases in personnel exposure above those received in the count room under normal operating conditions (<1 mrem/hr). The need for additional shielding has been reduced to make provisions for the availability of temporary personnel.

The access route to area “R” is route “15” as described in Table 12A.4-3.

12A.4.19 Intermediate Building

The Intermediate Building was reviewed to identify post-accident radiation sources, access requirements, and the location of safety related equipment. It was found that the only area of the Intermediate Building where exposure to post-accident radiation sources is possible is at the 412’-0" elevation adjacent to the east and west penetration access areas as shown in Figure 12A.4-8. At this elevation, residual heat removal (RHR), safety injection (SI), and chemical and volume control system (CVCS) piping containing post-accident sources is located in the east and west penetration access areas. The areas adjacent to the penetration access areas contain component cooling pumps, motor driven emergency feedwater pumps, and miscellaneous safety related valves and instrumentation which may require access. All other areas of the Intermediate Building are not exposed to post-accident sources and receive a negligible increase in dose.

The Intermediate Building at elevation 412’-0" is shielded from the radioactive piping located in the penetration access areas by a 2 foot concrete wall. This shield wall reduces the dose rates in this general area of the Intermediate Building to a level which permits limited access approximately 15 minutes immediately after the accident, 3 hours of access 8 hours following the accident, and 20 hours of access 1 day after the accident.

In the area between the east and west penetration access areas, several pipes containing post-accident sources were found to be located above the sides of a pipe chase located at elevation 422’-3". This allowed direct streaming of a 12-inch RHR pipe to the Intermediate Building floor elevation 412’-0". The resultant dose levels in this area of the Intermediate Building have been reduced to acceptable values by the modification of the pipe chase as follows: (1) extension of the pipe chase side above the 12" RHR line, (2) addition of 6" concrete shielding to the existing 1 foot concrete shielding, (3) relocation of access ladder to prevent streaming through concrete cutout. The new configuration allows personnel access in accordance with the occupancy requirements of Table 12A.4-2, and the resultant integrated doses meet the dose requirements of 10CFR50, Appendix A, General Design Criteria 19 as outlined in NUREG-0737.

12A.4.20 Emergency Operations Facility

The EOF is located beyond the 10-mile EPZ. Therefore there are no regulatory shielding requirements or ventilation isolation/HEPA filter requirements for the facility. The EOF is required to be “well engineered for design life of the plant” per NUREG-0696. The EOF is designed to the standards of the International Building Code, and as such resists the applicable loadings (wind, snow, earthquake, etc.) defined in ASCE 7, Minimum Design Loads for Buildings and Other Structures.

Table 12A.4-1
EXPOSURE RATES FOR VITAL AREAS AS A FUNCTION OF
TIME EXPOSURE RATE (MR/HR)

		Time after Accident									
	Vital Area	0	30 minutes	1 hour	8 hours	1 day	5 days	10 days	30 days	90 days	6 months

ACCESS ROUTES TO VITAL AREAS

Access Routes	Description
1.	From Control Building (C.B.), 463’ elev., down either stairway to 412’ elev. through 412’ elev. to north corridor. From C.B., 412’ elevation, enter Auxiliary Building (A.B.) at stairway tower 1, down stairway to 374’ elev., through hallways 74-01 and 74-09 W (formerly 74-09) to rooms 74-16 and 74-17. For cooling units, ladder up from hallway 74-09 to 385’ elev. to rooms 85-01 and 85-02.
2.	From C.B., 463’ elev., down either stairway to 412’ elev., through 412’ elev. to north corridor. From C.B., 412’ elev. enter A.B. at hallway 12-11, through hallways 12-11 and 12-09 to stairway tower 2, down stairway to 397’ elev. and through room 97-01 to stairs at column lines M and 9.5. Down stairs to 388’ elev. to room 88-13 S.
3.	Same as “2” but through room 88-13S to room 88-25.
4.	From C.B., 463’ elev., down either stairway to 412’ elev., through 412’ elev. to north corridor. From C.B., 412’ elev., enter A.B. at hallway 12-11, north through hallway 12-11 to room 12-28.
5.	Same as “4” but continues through hallway 12-11 to room 12-15.
6.	Same as “4” but north through hallway 12-11 and east through hallway 12-11 N to room 12-18.
7.	From C.B., 463’ elev., down either stairway to 412’ elev., through 412’ elev. to north corridor. From C.B., 412’ elev., enter A.B. at hallway 12-11, north through hallway 12-11 and east through hallway 12-11 N to stairway tower 3. Down stairway to 388’ elev. to room 88-13 NE.
8.	Same as “7” but through room 88-13 NE to rooms 88-23 and 88-24
9.	Same as “7” but through room 88-13 NE to room 88-13 N.
10	Same as “7” but continues through room 88-13 NE to room 88-13 N. Ladder up to 400’ elev.
11.	From C.B., 463’ elev., down either stairway to 412’ elev., through 412’ elev. to north corridor. From C.B., 412’ elev., enter A.B. at hallway 12-11, north through hallway 12-11 and east through hallway 12-11 N to stairway tower 3. Up stairway to 463’ elev. to room 63-09 at column line 7.7.
12.	Same as “11” but from room 63-09 enter Fuel Building (F.B.) 463’ elev., through room 63-01 S to column lines P.4-P.9 and 3.3-4.0.

CHAPTER 13 - CONDUCT OF OPERATIONS

13.1 Organizational Structure of South Carolina Electric and Gas Company

NOTE 13.1.1
Section 13.1.1 is being retained for historical purposes only.

13.1.1 Corporate Organization

This section describes the structure and qualifications of the South Carolina Electric and Gas Company (SCE&G) corporate organization and the corporate organizations of the principal contractors: Gilbert/Commonwealth (Gilbert), Westinghouse Electric Corporation (Westinghouse), and Daniel International Corporation (Daniel).

13.1.1.1 Corporate Functions, Responsibilities and Authorities

SCE&G owns and operates an integrated electric generation, transmission, and distribution system which serves approximately 304,000 customers in a 12,000 square mile service area. This area, stretching from the central region to the coastal plains, includes Columbia, the State capitol, and Charleston, South Carolina's principal seaport. SCE&G's transmission system is part of the interconnected grid extending over a large part of the central and eastern portion of the nation.

SCE&G's net generating capacity as of August 1983 was in excess of 3,950,000 kW. The South Carolina Public Service Authority (SCPSA), by joint ownership of the Virgil C. Summer Nuclear Station, owns one-third interest (300 MW) in the facility.

SCE&G, acting as its own general contractor, has constructed generating facilities which provide most of their present generating capacity. For the construction of the Virgil C. Summer Nuclear Station, SCE&G has engaged qualified contractors to construct the facility. SCE&G acted as construction manager.

SCE&G is a partner with Carolina Power and Light Company, Duke Power Company, and Virginia Electric and Power Company in Carolinas Virginia Nuclear Power Associates, Inc. (CVNPA). CVNPA was formed in 1956 to build and operate a 17,000 kWe nuclear steam generating plant at Parr, S. C., for research, operating, and engineering experience. The Carolinas Virginia Tube Reactor (CVTR) was constructed and operated under license granted by the Atomic Energy Commission. The CVTR was decommissioned in 1967 after completion of a successful operating and research program. SCE&G actively participated in the CVTR project at the planning, management, training, research, technical, and operational levels.

SCE&G has maintained active participation in the fast breeder programs of both Westinghouse and Atomics International. SCE&G also participated in the Savannah River Nuclear Study Group which examined the feasibility of developing power from a production reactor.

SCE&G was the sole applicant for the construction permit and operating license for the Virgil C. Summer Nuclear Station. As Applicant, SCE&G was responsible for the design, construction, quality assurance, and operation of this station. Figures 13.1-1 and 13.1-2 together show the SCE&G corporate organizational structure from the Board of Directors to the managerial level at the plant site. Figure 13.1-2 includes the organizational interfaces with the outside consultants and contractors; Gilbert, Westinghouse, and Daniel. Figure 13.1-3, exclusive of outside constraints, shows the SCE&G post commercial organizational operation.

Gilbert was retained by SCE&G as architect engineer for the entire project, including plant layouts and system arrangements, and design of balance of plant equipment. Engineering efforts by Gilbert were coordinated with construction by the SCE&G Nuclear Engineering Department.

SCE&G has contracted with Westinghouse for the design and manufacture of the complete nuclear steam supply system (NSSS). In addition, Westinghouse provided technical consultation in areas such as construction, initial fuel loading, testing, and initial startup. Westinghouse was also involved in the training of SCE&G operating personnel.

Daniel was under contract by SCE&G to act as general constructor for the Virgil C. Summer Nuclear Station construction activities.

13.1.1.2 In-House Pre-Commercial Organization

This section, which is historical in nature, describes the pre-commercial SCE&G corporate management, including technical support staffing and in-house organizational relationships, established for design, procurement, construction, and quality assurance functions. The responsibilities and authorities of in-house personnel are included. In addition, specific responsibilities and activities are included in order to show the accomplishments and plans for work in certain areas.

13.1.1.2.1 Corporate Management

The SCE&G corporate organization was responsible for handling all matters pertaining to the Virgil C. Summer Nuclear Station, including design, procurement, construction, quality assurance, testing, training, and operation, is shown in Figure 13.1-2. The departments primarily involved with plant activities and their relationships are described below.

The Vice President and Group Executive, Engineering and Construction, was responsible for the construction of power facilities. The Construction Department was separated into the Production Engineering Department and the Construction and Quality Control Department, each headed by a Group Manager. The Group Manager, Production Engineering and the Group Manager, Construction and Quality Control reported directly to the Senior Vice President, and Group Executive, Engineering and Construction.

The Vice President, Nuclear Operations, was responsible for the quality assurance, engineering, licensing, training, and operation of SCE&G nuclear power generating facility.

The General Manager, Nuclear Plant Operations, was responsible for station operations including start-up and test, power ascension, commercial power operation, nuclear security, and emergency planning. He was assisted in accomplishing his responsibilities by the Manager of Nuclear Protection Services, the Emergency Planning Coordinator, and the Manager, Virgil C. Summer Nuclear Station.

The Group Manager, Nuclear Engineering and Licensing, had the responsibility for plant and equipment design; plant licensing; and corporate health physics and environmental programs, geologic and hydrologic studies relating to plant sitting, design, construction and support to plant operations. This department was divided into four functional areas; Nuclear Engineering, Nuclear Licensing, the Independent Safety Engineering Group, and Corporate Health Physics and Environmental Programs. The Group Manager, Nuclear Engineering and Licensing, reported directly to the Vice President, Nuclear Operations.

The Group Manager, Nuclear Services, was responsible for the areas of Nuclear Fuel Management, incore technical support fuel cycle requirements, and quality assurance relating to design, construction and operation, and nuclear quality control relating to the operation and modification of the Virgil C. Summer Nuclear Station. Details of the quality assurance and nuclear quality control programs are found in Chapter 17.

The Group Manager, Nuclear Education and Training, was responsible for the development, implementation, and evaluation of operating and technical training programs for the Nuclear Operations Department in coordination with or upon recommendation of the General Manager, Nuclear Plant Operations; the Group Manager, Nuclear Engineering and Licensing; or the Group Manager, Nuclear Services. The Group Manager, Nuclear Education and Training, reported directly to the Vice President, Nuclear Operations.

The General Manager, Purchasing, had the company-wide responsibility for procurement of equipment and materials. This included procurement of safety-related items during design, construction, and operations of SCE&G power facilities. Purchase requisitions for the Virgil C. Summer Nuclear Station were initiated by personnel of the plant staff, nuclear engineering, or purchasing. Additional information pertaining to procurement is found in Chapter 17.

13.1.1.2.2 Specific Responsibilities and Activities

Specific responsibilities and activities in which SCE&G was engaged included:

1. Design and Construction Activities (Project Phase)

   The SCE&G Nuclear Engineering function within the Nuclear Engineering and Licensing Department had the responsibility for the design and engineering of the Virgil C. Summer Nuclear Station during the design and construction phase of the project. The Nuclear Engineering Group was responsible for coordinating and approving plant design and engineering, and geological, hydrological, and seismological studies related to the plant design and environmental effects.

Westinghouse was responsible to SCE&G for the design, engineering, procurement, and fabrication, including quality assurance, of the NSSS.

Gilbert had the responsibility for the overall design and engineering of the balance of the plant systems (nuclear and non-nuclear not within the NSSS scope of supply) and the coordination of all plant design and engineering activities. Gilbert design documents were submitted to the SCE&G Nuclear Engineering Department for review and approval. Westinghouse engineering drawings, specifications, and related design and engineering documents were submitted to Gilbert and SCE&G for review, comment, and interface information.

The final decision for procurement of materials and equipment, except those under the Westinghouse NSSS scope of supply, was made by the SCE&G purchasing committee. The vendor proposals were received by Gilbert and SCE&G and were evaluated for compliance by engineering, quality assurance, and purchasing for acceptable responses to the specification requirements in accordance with approved Gilbert and SCE&G evaluation and purchasing procedures. The SCE&G quality assurance group had to concur with the purchasing committee's decision of the selected vendor for safety-related purchases.

Site layout with respect to environmental effects and development of Safety Analysis Reports was done by Gilbert through coordination of the efforts of Westinghouse, Dames and Moore, and SCE&G.

Security during construction was the direct responsibility of the SCE&G Construction Department. Gilbert provided planning for the inclusion of security requirements in the design of the Virgil C. Summer Nuclear Station for the operations phase. The latter security planning and design documents were subject to the review and approval of the SCE&G Nuclear Engineering Department, but were reviewed by all affected SCE&G organizations.

Construction management was the responsibility of the SCE&G Construction Department under the direction of the Nuclear Site Manager who reported to the Group Manager, Construction and Control. Daniel was the constructor. Construction activities were directed by the Daniel Project Manager who reported to the SCE&G Nuclear Site Manager. Project Managers for other site contractors, performing safety-related construction activities, reported to the SCE&G Nuclear Site Manager administratively and to the Daniel Project Manager for scheduling and coordination of work activities.

Quality control activities were the direct responsibility of the SCE&G Quality Control Manager who reported to the SCE&G Group Manager, Construction and Quality Control. Site quality control activities were performed by, or under the direction of, the SCE&G Quality Control Manager, except for those contractors which had quality control responsibility. SCE&G had quality control responsibility for the Daniel scope of construction except for the ASME Boiler and Pressure Vessel Code related activities.

The SCE&G quality assurance section had the primary responsibility for surveillance and audit of site construction activities; however, Daniel had quality assurance responsibility for

the scope of work under its ASME Boiler and Pressure Vessel Code Certificates of Authorization. Several other contractors also performed surveillance and audit of their work onsite. The SCE&G quality assurance group performed surveillance and audit of all site activities including those for which contractors had quality assurance within their scope of activities. Further detail can be found in Section 17.1.

2. Preoperational Activities

The preoperational activities at the Virgil C. Summer Nuclear Station which were being accomplished included the following:

a. Development of human engineering design objectives and design phase review of proposed control room layouts

A coordinated effort had been placed on the design of the control room to best meet the needs of the plant operator during normal operation and emergency situations.

A practical review of the physical dimensions of the control board to suit the operator and the types and arrangement of controls, instrumentation, displays, and alarms required for safe operation and shutdown was performed by the plant staff. Consideration was given to the fact that certain systems normally require more attention from the operator and the controls for these systems were grouped accordingly.

Computers were used to provide supplementary information to the operator and are designed to be an effective tool in the operation of the plant. The design included adequate instrumentation to provide the operator with sufficient information for proper and safe system operation, irrespective of the availability of the computer system. The computer system obtained data by scanning analog and digital sensors. It logged data on typewriters, sequentially logged trip and post trip data, and alarmed various off-normal and abnormal conditions. Monitoring programs were also included for surveillance of reactor control and protection system operations, and for nuclear process calculations.

The computer readout and plant operator’s console are located in the control room. The control room was designed to ensure habitability under anticipated operational transients (see Section 9.4 for a discussion of control room ventilation systems).

b. Development and implementation of staff recruiting and training programs

SCE&G had developed a "Plan for Staffing the Virgil C. Summer Nuclear Station," designed for staff selection, training, and recruiting. This plan referenced ANSI N18.1-1971, "Selection and Training of Nuclear Power Plant Personnel," as the basis for determining the minimum experience and education requirements for plant personnel. The recommendations of the NRC in WASH-1130, "Utility Staffing and Training for Nuclear Power Plants," were also used in developing this plan. Details pertaining to experience and education requirements are found in Section 13.1.3 and training details are found in Section 13.2 although both are now based on the requirements of ANS 3.1-1981.

c. Development of plans for initial testing

The plans for the preoperational and startup testing of the Virgil C. Summer Nuclear Station were developed by the plant staff. Outside consulting services were used for guidance in establishing these plans. The Manager, Virgil C. Summer Station had the overall responsibility for the development and implementation of this program. Additional details regarding plans for preoperational and startup testing are found in Chapter 14.

d. Development of plant maintenance programs

The plant maintenance program was designed to implement good practices in preventative and corrective maintenance. Such practices assured that the plant would function reliably during its lifetime. This program was designed to control maintenance of equipment and associated controls in an orderly fashion by use of approved procedures.

3. Technical Support for Operations

This section describes the technical services and backup support for operations in the following areas:

a. Nuclear, mechanical, structural, electrical, thermal-hydraulic, plant chemistry, health physics, metallurgy and materials, and instrumentation and controls

The Manager, Virgil C. Summer Nuclear Station had available to him the plant Technical Staff and the offsite Nuclear Engineering Group to support engineering activities of the station. The plant could contact offsite suppliers and consultants to secure information or guidance as required. If offsite engineering was needed to provide support services, the Manager, Nuclear Engineering, determined whether the required work would be performed by the SCE&G nuclear engineering staff, or contracted to a qualified outside organization. A coordinator in the nuclear engineering group was to follow progress and coordinate work.

b. Fueling and refueling operations support

The Manager, Virgil C. Summer Nuclear Station had the option of selecting the qualified personnel for directing fueling and refueling operations.

These personnel could come from the plant staff, other company personnel (especially from nearby SCE&G power facilities), and qualified outside contractors.

c. Maintenance support

The Manager, Virgil C. Summer Nuclear Station had the option to utilize the plant maintenance staff, other company personnel (especially from nearby SCE&G power facilities, company wide maintenance personnel, and construction support), or outside contractors for special support in maintaining the plant.

13.1.1.3 Interrelationships with Contractors

SCE&G Nuclear Engineering Department was responsible for the overall coordination and final approval of plant design and engineering activities during the design and construction phases of the project. During the operating phase, the Nuclear Engineering Department in conjunction with the onsite technical support group was to be responsible for providing technical support services to the Station. The interface between these two Departments was further described in Chapter 17. The SCE&G Nuclear Engineering Department's technical staff and the onsite technical support group were described in Sections 13.1.1.4 and 13.1.2.2, respectively.

Westinghouse design documents which would have an effect on that portion of the plant (BOP) designed by either Gilbert or SCE&G were forwarded to Gilbert or SCE&G for their respective review and comment. Likewise, SCE&G and Gilbert design documents which had an effect on the Westinghouse or other suppliers' scopes of supply were forwarded to these other organizations for their review and comment as appropriate. Specified Gilbert design documents were reviewed and approved by SCE&G Nuclear Engineering. Final acceptance by the SCE&G Nuclear Engineering Department of design concepts, documents, and equipment suppliers was based on recommendations from the responsible Gilbert engineers along with recommendations from within SCE&G Construction, Purchasing, Quality Assurance, and power supply organizations, as appropriate.

Interrelationships and interfaces among various organizations during preoperational and startup testing were described in Section 14.2.2. These relationships for the plant operational phase were described in Chapter 14.

The responsibility for ensuring that equipment suppliers and contractors conform to the approved engineering specifications was the responsibility of Gilbert and/or SCE&G even though equipment was procured by SCE&G Purchasing Department.

Conformance with the approved specifications was verified through implementation of the quality assurance program, and was described in Chapter 17.

13.1.1.3.1 Gilbert Associates, Inc.

The professional qualifications and the organizational structure of Gilbert Associates were presented in Section 1.4.2 and in Chapter 17. During the design and construction phases of the project, the Gilbert Project Manager had the responsibility of coordinating the plant design activities of Gilbert under the overall supervision and direction of the SCE&G Manager, Nuclear Engineering. Upon completion of the plant, Gilbert was to continue to perform engineering services as needed. During the operational phase, the same basic organization which was used during design and construction was to continue with qualifications and structure. (The current organization is shown in Section 1.4.2 and Chapter 17.)

The Gilbert Technical Support Group, working in direct support of the Virgil C. Summer Nuclear Station, would be smaller in size than that required to design the plant. The Project Manager and principal engineers in this continuing engineering services group were to be physically located in

a project island configuration which was designed to enhance a more effective internal interface with the Gilbert organization. The individuals assigned to the continuing services group would, for the most part, be the same personnel who were involved in the original design of the Summer Station. Changes of the Project Manager or principal engineers assigned to this group had to receive approval of the SCE&G Manager, Nuclear Engineering.

The Gilbert project island was to keep and maintain the following records and documents:

1. Project correspondence
2. Project design documents, e.g., layouts, system diagrams, system design descriptions
3. As-built drawings (Gilbert and vendor)
4. Purchase orders
5. Updated FSAR and ER
6. Equipment, valve, instrument, and electrical feeder lists
7. Design calculations
8. Other documents deemed necessary for proper technical support.

A direct telephone line was installed between the Gilbert project office and SCE&G engineering offices. Telecopiers were also available in each location. Home telephone numbers of the principal Gilbert personnel assigned to the project office were available to the SCE&G Nuclear Engineering Department on a continuous and updated basis.

In addition to the personnel assigned to the Gilbert Technical Support Group, Gilbert management was committed to provide its corporate resources as needed.

The Project Manager and principal engineers assigned to the Gilbert continuing services group visited the plant site at least annually for refamiliarization and update on the engineering status and condition of the plant.

13.1.1.3.2 Westinghouse Electric Corporation

The qualifications and structure of Westinghouse were presented in Section 1.4.3 and in Chapter 17. The Westinghouse Project Manager, Pressurized Water Reactors Division, coordinated the design and manufacturing information supplied by Westinghouse with the SCE&G Manager, Nuclear Engineering during the design and construction phase. Upon completion of construction, a Westinghouse Project Manager from the Nuclear Service Division was assigned to the Virgil C. Summer Nuclear Station and was to report to the SCE&G Site Manager, as shown in Figure 13.1-2.

13.1.1.3.3 Daniel International Corporation

The qualifications and structure of Daniel are presented in Section 1.4.4 and Chapter 17. The Daniel Project Manager reported to the SCE&G Site Manager as shown on Figure 13.1-2. This arrangement gave SCE&G the managerial control of all construction activity at the plant site.

13.1.1.3.4 Interrelationshps

The present working interrelationships among the contractor organizations mentioned above are described as follows:

SCE&G Engineering Services is responsible for coordinating and approving plant engineering and design.

Westinghouse design documents that have an effect on that part of the plant design performed by Gilbert and SCE&G are forwarded to Gilbert and SCE&G for review and comment. SCE&G and Gilbert design documents which have an effect on the Westinghouse or other suppliers scope of supply are, likewise, sent to Westinghouse and other suppliers for their review and comment. All Gilbert design documents must be reviewed and approved by SCE&G.

Final acceptance by SCE&G Engineering Services of design concepts, documents, and equipment suppliers was based on recommendations from the responsible designers and consultation with SCE&G organizations as appropriate.

The interrelationships and interfaces among various organizations during preoperational and startup testing are described in Section 14.2.2.

The responsibility for ensuring that equipment suppliers and contractors conform to approved specifications is the responsibility of SCE&G. Conformance is verified through implementation of the quality assurance program described in Chapter 17.

13.1.1.4 South Carolina Electric & Gas Company Corporate Technical Staff

The SCE&G corporate technical staff supporting the Virgil C. Summer Nuclear Station was composed of experienced engineers in the Technical Services and Nuclear Regulatory and Developmental Support Services organizations as shown on Figure 13.1-3. This organizational structure functioned until early 1988 wherein the present Nuclear Operations Division was re-organized with all supporting staff located at the Virgil C. Summer Nuclear Station as shown on Figure 13.1-4.

13.1.2 Operating Organization

The nuclear organization and key individuals’ responsibilities are described in the Quality Assurance Program Description (QAPD) referred to in FSAR Chapter 17.2. Additionally, station personnel will meet the qualification requirements as specified in the station Technical Specifications and the QAPD.

13.2 TRAINING PROGRAM

13.2.1 INPO Accredited Training Programs

Virgil C. Summer Nuclear Station training programs are INPO accredited. They have been developed using the INPO Principles of Training System Development guidance and are supported by a plant-specific Job and Task Analysis. The programs that are INPO accredited consist of:

1. Non-Licensed Operator Training Program
2. Reactor Operator Training Program
3. Senior Reactor Operator Training Program
4. Licensed Operator Requalification Training Program
5. Shift Technical Advisor Training Program
6. Shift Manager
7. Chemistry Specialist Personnel Training Program
8. Health Physics Technician Personnel Training Program
9. Mechanical Maintenance Personnel Training Program
10. Electrical Maintenance Personnel Training Program
11. Instrument and Control Personnel Training Program
12. Engineering Support Personnel

NOTE 13.2.2

Section 13.2.2 is being retained for historical purposes only (per RN 00-064).

13.2.2 Training Program for Specialists and Nonlicensed Personnel

13.2.2.1 General

Specialized training programs for Virgil C. Summer Nuclear Station personnel are described below. Several technical staff personnel were involved in Senior Reactor Operator's training who were not required to hold a license; however, this training was beneficial in the safe and efficient performance of their assigned duties. SCE&G took advantage of the following specialized training programs offered by Westinghouse.

13.2.2.2 PWR Station Nuclear Engineering

This is a 13 week program conducted by Westinghouse in the Pittsburgh area. Instructors in this program are Westinghouse engineering personnel knowledgeable in the areas in which they instruct. The classes will contain lecture series and problem solving sessions. A topical outline of

the program includes responsibilities and duties of the station nuclear engineer, responsibilities and relationships to federal and state regulatory agencies, plant licensing and reference documentation, basic PWR design considerations, plant testing program, reactor physics testing, plant instrumentation and control, plant computer reactivity considerations, system reliability checks, station fuel management, and emergency situations.

13.2.2.3 Additional Training

1. Mitigating Core Damage Training was taught to the Plant Manager, the Assistant Plant Manager, I&C, Health Physics, and Chemistry personnel also participated in applicable portions of this training program.
2. Any additional training deemed necessary to meet the intent and training requirements described in Quality Assurance Program Description section 2.5 was handled in conjunction with vendors or through local universities and/or other technical schools to ensure trained personnel operate the Virgil C. Summer Nuclear Station.

13.2.3 General Employee Training

13.2.3.1 Station Orientation Training

All personnel granted unescorted access onto the Virgil C. Summer Nuclear Station will be required to attend applicable portions of the station orientation training program. The subjects covered in this training program are listed below and are required on a biennial basis. Portions of the program may be waived based on exemption exams and/or waivers as justified and approved by applicable supervisory personnel.

Station Familiarization

Station Radiation Emergency Plan and Related Procedures

Industrial Safety

Station Security

Quality Assurance

Basic and Station Specific Health Physics - Principles and Practices

13.2.3.2 Temporary Personnel Training

Personnel without unescorted access will be classified as visitor personnel and shall be escorted while within the boundaries of the protected area. Visitor personnel will be trained in emergency plan procedures as appropriate to ensure the safe execution of their duties.

13.2.4 Training Program Administration

Overall responsibility for training of personnel within the Virgil C. Summer Nuclear Station rests with the Chief Nuclear Officer and President Nuclear Operations through the Site Vice President, and the Director, Plant Support. Training is implemented under the direction of the Manager, Nuclear Training.

13.2.5 Records

Records of plant personnel qualification and training are maintained in a computerized data base system with sufficient hard copy records to support the validity of the data base such as class attendance and exam results.

Summary records of plant personnel qualifications and training may be maintained for each member of the plant staff in a qualification and training folder. This folder will contain a resume of the person's qualifications and general records of training programs and courses completed. Those staff members holding an NRC Nuclear Operator's License will be enrolled in a requalification program that is required to maintain their license. For this type of training, the records maintained will be much more extensive and detailed. These records will contain such items as copies of written examinations administered and the answers given by the licensee, retraining examinations, lecture attendance, trainee's evaluations, and results of retraining in areas in which personnel have exhibited deficiencies. This will assure that records are maintained to comply with 10 CFR 55.59(c)(5).

After initial criticality, the training program effectiveness of each employee shall be evaluated by the individual scores on tests given on the lecture material presented to each employee.

This Page Intentionally Left Blank

13.3 EMERGENCY PLANNING

The Virgil C. Summer Nuclear Station Radiation Emergency Plan (REP) contains the precautionary planning, delegation of authority and responsibility, and plans of action to protect the public, plant personnel, and equipment in case of an emergency. As specified in 10 CFR 50, Appendix E, this plan is for use at the local level for the control of emergencies such as fire, personal injury, tornadoes and high winds, and incidents that could result in the release of significant amounts of radioactivity. The actual Virgil C. Summer Nuclear Station REP is provided in Appendix 13A.

13.4 REVIEW AND AUDIT

A program of inplant and independent reviews and audits has been developed by SCE&G to provide a system to ensure that plant startup and operation are consistent with company policies, approved procedures, and license provisions. The review and audit program also assures that abnormal occurrences are promptly investigated and corrected in a manner which reduces the probability of recurrence of such events, and detects trends which may not be apparent to a day to day observer. Guidance provided by ANSI N18.7, "Administrative Controls and Quality Assurance for the Operating Phase of Nuclear Power Plants," (Reference 1) has been used in establishing the SCE&G review and audit program for the Virgil C. Summer Nuclear Station.

NOTE 13.4.1
Section 13.4.1 is being retained for historical purposes only.

13.4.1 Review and Audit - Construction

Review and audit during the design and construction phase of the Virgil C. Summer Nuclear Station are a part of the SCE&G quality assurance program. The review function is performed primarily by the exchange of information between SCE&G, the principal contractors, and other contractors and suppliers. Audits are conducted internally and externally in accordance with the approved quality assurance plan to ensure that design and construction are in accordance with the requirements of 10 CFR 50, Appendix B (see Chapter 17).

13.4.2 Review and Audit - Operations

Specific review and audit requirements are assigned to various committees in addition to the review and audit requirements assigned to the Virgil C. Summer quality assurance staff by the quality assurance program for station operations (see Chapter 17). The committees charged with specific review and audit functions are delineated in Dominion’s Nuclear Facility QAPD.

The Facility Safety Review Committee is charged with first-level review of station operations. The membership of the committee, committee responsibilities and authority, and quorum and meeting requirements are delineated in the QAPD. The members of this committee who are station supervisory personnel meet or exceed the qualification requirements of the QAPD.

Independent review of the safety of nuclear unit operation is performed by the Management Safety Review Committee. The organization and responsibilities of the Management Safety Review Committee are described in the QAPD.

Maintenance and modification of safety-related equipment are controlled and documented in accordance with the requirements of a formal quality control program for station operation and other administrative controls formulated by written procedures. Audits of quality control programs are periodically conducted as delineated in the operational quality assurance program. The quality assurance and quality control programs pertinent to station operation are discussed in the QAPD.

13.4.3 References

1. ANSI N18.7, "Administrative Controls and Quality Assurance for the Operating Phase of Nuclear Power Plants," February 1976.

13.5 PLANT PROCEDURES

Actions concerning structures, systems, and components of the Virgil C. Summer Nuclear Station that are safety-related are conducted in accordance with approved written procedures. Safety-related structures, systems, and components are those that prevent or mitigate the consequences of postulated accidents that could cause undue risk to the health and safety of the public and such structures, systems, or components that are essential for the safe shutdown of the plant.

These procedures are written in sufficient detail that a qualified individual can perform the required function without direct supervision. Some procedural steps such as immediate action steps for emergency procedures are required to be committed to memory. Routine actions are performed in accordance with approved written procedures. Plant procedures will cover the following categories:

1. Administrative Procedures
2. Control Room Operating Procedures
3. Maintenance and Modification Procedures
4. Emergency Plan Procedures
5. Chemical-Radiochemical Control Procedures
6. Plant Radiation Protection Procedures
7. Plant Security Procedures
8. Surveillance Test Procedures
9. Fire Protection Procedures

Procedures contain the following significant aspects wherever they apply to the intent of each particular procedure.

1. Title

   A concise descriptive statement describing the activity covered in the procedure.

2. Purpose

   A concise descriptive statement describing the purpose and scope of the procedure.

3. References

   Material which contains information related to the procedure, such as other plant procedures, instructions, drawings, technical manuals, reports, the FSAR, or other applicable documents.

4. Glossary

   Abbreviations and definitions used in the procedure.

5. Prerequisites

   Independent actions or procedures which shall be completed and plant conditions which shall exist prior to use of the procedures.

6. Precautions

   Actions which if not taken or events which if not avoided when performing the procedure could result in hazardous personnel conditions or damage to plant equipment. Precautions also appear in the main body of the procedure where applicable.

7. Check Off Lists

   Lists included in complex procedures requiring the person either performing or supervising the activity being performed to signify by his initials when important procedural steps have been completed.

8. Limitations

   Statements specifying limits on the parameters being controlled such as limiting safety settings and limiting conditions for operation as specified in Technical Specifications.

9. Main Body

   Statements specifying detailed steps for performing the procedure, presented in a degree of detail necessary for performing the required functions, should be identified.

10. Symptoms

    Emergency procedure symptoms shall be included to aid in the identification of the emergency. They should include significant alarms, operating conditions, and, where possible, probable magnitudes of parameter changes.

11. Automatic Actions

    The automatic actions that occur as a result of an emergency should be identified.

12. Immediate Operator Actions

    For emergencies, steps should be specified for operation of controls or confirmation of automatic actions that are required to stop the degradation of conditions and to mitigate their consequences.

13. Probable Cause

    The probable cause for alarms should be specified.

14. Acceptance Criteria

    The qualitative or quantitative criteria against which an evaluation of acceptability may be made.

15. Attachments

    Additional information that may be attached to a procedure for clarification or ease of understanding.

The Virgil C. Summer Nuclear Station Unit 1 conforms to NQA-1-1994 through Virgil C. Summer's QAPD. Operating procedures were prepared using ANSI N18.7, Revision 1, February 19, 1976 as a guide. The Plant Manager or his designated alternate has final approval before procedures are implemented.

13.5.1 Administrative Procedures

The administrative procedures as described in the administrative manual provide a clear understanding of operating philosophy and management policies to ensure safe operation of the plant within the limits set by the operating license and Technical Specifications. They provide that plant activities are conducted in a manner that will protect the general public, plant personnel, and equipment. A list of administrative procedure categories is provided in Table 13.5-1. A description of these procedure categories is as follows:

13.5.1.1 Plant Organization and Responsibility Procedures

These procedures describe the plant organization and give the responsibility of the individuals by position and authority to operate the plant in a safe and efficient manner.

13.5.1.2 Development, Review, Approval, and Control of Safety-Related Plant Procedures

These procedures describe the method by which plant procedures are written, the control process for review and approval, and the system utilized to revise the procedures where needed. Administrative procedures, security plan implementing procedures, and emergency plan implementing procedures receive final approval by the Plant Manager or his designated alternate. They are reviewed under the direction of a supervisor from a group other than the originating group before final approval by the Plant Manager.

13.5.1.3 Conduct of Plant Operations Procedures

These procedures describe the rules and instructions issued by the Plant Manager pertaining to personnel conduct and control. These rules and instructions provide a clear understanding of

operating philosophy and management policies. They delineate the authority and responsibility of the Reactor Operators and Senior Reactor Operators for the safe operation of the reactor as required by 10 CFR 50.54 (i), (j), (k), (l), and (m). They establish the rules for procedure use and the designation of the persons responsible to authorize a temporary change to an approved procedure. Additional procedures establish standard operating orders which deal with such matters as job turnover and relief, designation of the confines of the Control Room including a diagram of the Control Room that indicates the area designated as at the controls (Figure 13.5-1), transmittal of operating data, limitations on access to equipment, and other such matters. Provisions are made for periodic review and updating of standing orders. Instructions which have short time applicability such as housekeeping, publications and their distribution, and personnel actions are issued as special orders.

As required by NUREG 0578, Section 2.2.1.c, procedures define the procedural steps for relief of shift personnel. Checklists are provided for the oncoming and offgoing Control Room Supervisor and the oncoming Shift Manager to complete and sign. These checklists provide assurance that actual plant parameters are within allowable limits and that required systems are available and are in proper alignment for the prevention and mitigation of operational transients. Systems and components that are in a degraded mode of operation permitted by Technical Specifications shall be listed and time in degraded mode is compared with Technical Specification action statements. Auxiliary Operator checklists include any equipment under maintenance or test that could degrade a system or initiate an operational transient and shall include criteria for acceptable status. The Operations Supervisor will make unannounced audits of shift relief to evaluate the effectiveness of shift relief and turnover.

Also as required by NUREG 0578, Section 2.2.2.a, procedures establish the authority and responsibility of the person in charge of the Control Room to limit access.

As required by NUREG 0737, item I.A.1.3, administrative procedures establish actual work time limitations for plant shift personnel who maintain or operate any structures, systems, or components important to safety.

13.5.1.3.1 Shift Manager’s Responsibility

As required by NUREG 0578, Section 2.2.1.a, upper level management shall issue a directive that establishes the management responsibility for the Shift Manager under all plant conditions. It shall contain clear delineation of management chain of authority as to who can, and when the Shift Manager is relieved of the responsibility for direct control of the plant.

An administrative procedure is provided that gives the authority and responsibilities of the Shift Manager, Control Room Supervisor, Control Room Operator, and other shift personnel.

Both on the job training and classes emphasize responsibility for safe operation and management functions as given in the administrative procedure.

A review of administrative duties of the Shift Manager has been conducted by senior plant and corporate management. Additional administrative personnel have been added to the operating

group that relieve the Shift Manager of routine duties that distract from the management responsibility for assuring the safe operation of the plant.

NOTE 13.5.1.3.2
Section 13.5.1.3.2 is being retained for historical purposes only.

13.5.1.3.2 Westinghouse Review of Procedures

As required by NUREG 0737, item I.C.7, Westinghouse (NSSS Supplier) reviews station emergency operating procedures, power ascension procedures, and low power physics tests. Additional information on this subject has been submitted to the NRC under separate cover letter dated December 2, 1980.

13.5.1.3.3 NRC Review of Procedures

As required by NUREG 0737, item I.C.8, selected station emergency operating procedures have been demonstrated for the NRC on the Westinghouse Zion Simulator. Also, a walkthrough on the Virgil C. Summer Nuclear Station Control Board was performed as required. NRC comments on these procedures have been resolved.

13.5.1.3.4 Reporting Safety and Relief Valve Failures

Any failure of a pressurizer PORV or safety valve to close will be reported to the NRC promptly. Challenges to these valves will be documented in the annual report.

13.5.1.4 Control of Plant Documents Procedures

These procedures describe the preparation and retention of plant records. Retention periods are established to assure the ability to reconstruct significant events and satisfy statutory requirements.

13.5.1.5 Corrective Action Reporting Procedures

These procedures assure that conditions adverse to plant safety such as equipment and material malfunction, abnormal occurrences, and nonconformances are promptly identified and corrected. They ensure that the cause of the conditions is determined and reported to the appropriate level of management for corrective action.

13.5.1.6 Equipment Control Procedures

These procedures describe the control measures and actions such as locking, tagging, notification, removal of tags, and identification of equipment. They provide for control of equipment to maintain reactor and personnel safety and to avoid unauthorized operation of equipment. As required by NUREG 0737, items I.C.6 and II.K.1 (sub items 5 and 10), administrative procedures

provide instructions for verifying correct performance of operating activities. This item has been specifically addressed under separate cover letter to the NRC dated December 11, 1980.

13.5.1.7 Design Modification Control Procedures

These procedures ensure that plant modifications satisfy, at a minimum, the same design requirements as the original equipment. Regulatory Guide 1.64 was used as a guide for the preparation of these procedures.

13.5.1.8 Procurement and Materials Control Procedures

These procedures provide for the control of purchased material, equipment, and services. They provide for proper identification, quality level requirements, control, handling, storage, and shipping of materials, parts, and components. These procedures also provide for the proper documentation to ensure quality of safety-related systems, equipment, and structures after maintenance or repair.

13.5.1.9 Control and Calibration of Test Equipment and Instrumentation Procedures

These procedures ensure that testing and measuring devices are of the proper range and type and are controlled, calibrated, adjusted, and maintained at specified intervals or prior to use to assure the necessary accuracy of calibrated devices. Records are made and equipment suitably marked to indicate calibration status.

13.5.1.10 Control of Special Processes During Operations Procedures

These procedures assure that special processes are accomplished under controlled conditions in accordance with applicable codes, standards, specifications, criteria, and other special requirements using qualified personnel and procedures.

13.5.1.11 Non-Conformance Control/Deficiency Reporting Procedures

These procedures provide for control of items, services, or activities which do not conform to requirements. These procedures include instructions for identification, documentation, segregation, notification of affected organizations, and method of disposition of such items, services, or activities.

13.5.1.12 Test Control Procedures

These procedures assure that testing required to demonstrate that an item will perform satisfactorily in service is accomplished properly. Test procedures incorporate or reference the requirements and acceptance limits contained in applicable design documents. These test procedures may include preoperational tests, initial operational phase tests, surveillance tests, and tests during design, fabrication, and construction activities associated with plant maintenance and modification.

13.5.1.13 Feedback of Operating Experience

In accordance with NUREG 0737, item I.C.5, a program will be established for evaluating operating plant experience and providing the results of the evaluations, as necessary, to pertinent plant personnel. The services of “Industry Groups" such as INPO will be utilized to the extent possible in the performance of this function.

13.5.1.14 ECCS Outages

In accordance with NUREG-0737, item II.K.3.17, a program has been established using existing plant procedures for data collection including ECCS outage times, duration and cause of the outage, components involved in the outage, and corrective action taken. A plant procedure for removal and restoration of station equipment provides measures for data collection. The ECCS data taken by this procedure will be reviewed by appropriate plant personnel to determine if improvements to availability of ECCS are needed.

13.5.2 Control Room Operating Procedures

Control Room operating procedures are those procedures that are performed by the licensed Control Room Operator or under his direction and control. They are a preplanned method for the conduct of operations to minimize reliance on memory. These procedures include anticipated operating conditions, the normal method of control, means for and limits on operation of the plant, or plant systems that affect the safety of the plant and the public. These procedures address the areas discussed in Sections 13.5.2.1 through 13.5.2.6. As stated in NUREG-0660, item I.C. the applicant will incorporate changes into station operating procedures resulting from "Owners Group participation" as deemed necessary. A list of these procedure categories can be found in Table 13.5-2.

13.5.2.1 General Operating Procedures

General Operating Procedures (GOP) provide for the integrated operation of the plant. These procedures provide the sequence of plant operations to take the plant from a given initial condition to a final expected condition. Associated system operating procedures are referenced as applicable. Necessary precautions are inserted at critical points.

13.5.2.2 Emergency Operating Procedures

Emergency Operating Procedures (EOP) are written so that a trained operator and crew will be able to identify an emergency from the symptoms available to them and take immediate action on the expected course of events to place the plant in a known safe condition and to mitigate the consequence of a serious condition should it occur. Since emergencies may not follow anticipated patterns, these procedures provide sufficient flexibility to accommodate variations. Those sections of the procedure that require immediate response action from the operating crew are committed to memory. Considerable judgment on the part of competent personnel is exercised before departure from these procedures.

13.5.2.3 System Operating Procedures

System Operating Procedures (SOP) provide instructions for energizing, starting up, shutting down, changing modes of operation, and other instructions for operations of systems related to the safety of the plant.

These procedures are concerned with systems only and include valve and switch lineups, control operations, and instrumentation within the system boundaries. They are subdivided into normal operations, infrequent operations, and off normal conditions in the main body.

13.5.2.4 Annunciator Response Procedures

Annunciator Response Procedures (ARP) are written to instruct the operator on the proper action to be taken in response to annunciators on the Main Control Board. They contain annunciator identification, inputs into the annunciator, and logical operator responses to be taken to ensure proper corrective action. The ARPs are identified by panel number. An illustration in the beginning of the ARP depicts the annunciator panel. In the case of computer alarms, each alarm's unique identifier is listed.

When use of the ARP is required, the operator selects the proper tab by an alarm panel number.

13.5.2.5 Fuel Handling Procedures

Fuel Handling Procedures (FHP) are written to specify actions and philosophy for core alterations and partial or complete refueling operations. They include requirements for continuous monitoring of neutron flux throughout core loading and audible annunciation of abnormal flux increases. The duties of personnel assigned to refueling, such as periodic data taking, response actions to alarms during refueling, and criteria for stopping the refueling are specified. Also, instructions for proper sequence of events, verification, and frequency of sampling to ensure shutdown margin, communications between the control room and the fuel loading station, documentation of final fuel component serial numbers and location, containment integrity requirements, and rules for periods when refueling is interrupted are included. System operating procedures are referenced as required.

13.5.2.6 Special Procedures

Special procedures are written and issued to direct operations during testing, refueling, maintenance, and modifications. These procedures provide guidance in unusual situations not covered by existing procedures. They ensure orderly and uniform operations for short periods when the plant, a system, or a component is not performing in a normal manner and an existing procedure does not apply. Special procedures designate the period of time during which they may be used and are subject to the same review and approval process as other operating procedures.

13.5.3 Maintenance and Modification Procedures

Maintenance and modification procedures define the policies and practices by which structures, systems, and components are kept in a condition of good repair so that they are capable of reliably performing their intended functions. This includes those activities performed by maintenance or contractor personnel to maintain, repair, or modify safety-related equipment. Additional related activities covered are those by operating personnel to ensure that a planned maintenance activity can be safely accomplished, that proper plant operating conditions exist, to authorize the release of equipment to be maintained using equipment control procedures, and to assure that the equipment has been returned to normal operating status at the completion of maintenance work, as well as verification of functional acceptability. Procedures are written to assure measurement accuracies are adequate to keep safety parameters and controls within safety and operational limits. This instrumentation includes interlocks, alarm devices, sensors, readout instruments, transmitters, signal conditioners, laboratory equipment, key recorders, and protective logic circuits. Calibration, testing, and checking of instrumentation channels are performed at the frequency specified in Technical Specifications. A list of the areas covered by maintenance procedures is given in Table 13.5-3.

13.5.4 Emergency Plan Procedures

These procedures are written in sufficient detail that a qualified individual can perform the required actions without supervision. They provide a step by step order and logical sequence in a concise manner but are flexible enough to give latitude to the user for the exercise of judgment in implementing specific actions or parts of the procedure. These instructions specify the individual or organization having authority and responsibility for performing critical tasks. The actions to be performed by support agencies and the coordination with other elements of the emergency organization are also specified. Guidelines for initiating recovery after the emergency alert is over to restore the plant to the pre-emergency conditions are given. A list of the procedure categories is given in Table 13.5-4.

13.5.5 Chemical-Radiochemical Control Procedures

These procedures provide instructions for maintaining reactor coolant, condensate, and feedwater within prescribed quality limits and include the nature and frequency of sampling and analysis. They also include laboratory instructions and instructions for calibration of laboratory equipment. Limitations on concentrations of agents that could cause corrosive attack, foul heat transfer surfaces, or become sources of radiation hazards due to activation are given. A list of the procedure categories is given in Table 13.5-5.

13.5.6 Plant Radiation Protection Procedures

These procedures cover plant personnel, other SCE&G personnel temporarily assigned, contractor and vendor personnel, and visitor protection to maintain occupational dose rate to as low as reasonably achievable. They provide coverage for all normal operations and anticipated operational occurrences. This includes refueling, purging, fuel handling and storage, also radioactive material handling, processing, use, and storage. Other areas covered are maintenance,

routine operational surveillance, inservice inspection, and calibration. A list of the areas covered by the radiation protection procedure categories is included in Table 13.5-6.

13.5.7 Plant Security Procedures

These procedures are written to supplement physical barriers and features designed to control access to the plant and as appropriate to sensitive areas and equipment within the plant. Information concerning design features and administrative provisions is protected and distribution is limited. Plans for physical protection of the Virgil C. Summer Nuclear Station are described in a separate part of the application for license, withheld from public disclosure pursuant to 10 CFR 2, Paragraph 2.790 (d) (refer to Section 13.7). A list of the areas covered by these procedures is included in Table 13.5-7.

13.5.8 Surveillance Test Procedures

These tests and inspections are performed in accordance with the Technical Specifications to ensure that the required reliability of safety systems is maintained. These surveillance test procedures contain a description of the test objectives, the acceptance criteria used to evaluate the test results, and the prerequisites for performing the test. They include any special conditions to be used to simulate normal or abnormal operating conditions, limiting conditions, the test procedure, and any special test equipment or calibrations required to conduct the test. A master surveillance schedule reflecting the status of surveillance testing is also maintained. Additional control procedures ensure timely conduct of surveillance testing, appropriate documentation, reporting, and evaluation of test results. Significant deficiencies identified by the tests are reported to management. The deficiencies will be evaluated and the condition corrected in a timely manner. A list of surveillance test procedure categories is included in Table 13.5-8.

13.5.9 Fire Protection Procedures

These associated procedures provide the necessary planning and instructions to ensure adequate fire protection for the Virgil C. Summer Nuclear Station. Included, but not limited to, are the provisions made in the Fire Protection (FP) DBD and SAP-131. The responsibilities for preparation of schedules and procedures required by the Operations, Maintenance, and Technical Groups are stated in this report and are detailed in administrative procedures.

Amendment 00-01
December 2000

13.6 PLANT RECORDS

Records documenting the quality of the design, construction, testing, operation, maintenance, and modification of the Virgil C. Summer Nuclear Station will be maintained to meet the requirements of Basic Requirement 17 and Supplement 17S-1 of ASME NQA-1-1994 and Regulatory Guide 1.28, Revision 3 (see Appendix 3A). The records maintained comply with the requirements of Criterion XVII of Appendix B of 10 CFR 50 and Basic Requirement 17 and Supplement 17S-1 of ASME NQA-1-1994 and Regulatory Guide 1.28, Revision 3 (see Appendix 3A).

Records are normally stored and maintained in the permanent records storage facility which provides facilities to preserve the records in a manner to preclude deterioration. Records that are not maintained in the permanent record storage facility will be duplicated and stored in a separate remote location. Electronic records will be maintained as described in Part II, Section 17.2 of the Virgil C. Summer QAPD.

Records will not normally be removed from the permanent records storage facility as specified in implementing procedures. However, under unusual circumstances, the Nuclear Records Supervisor, designee, or the Director, Plant Support may authorize temporary removal of records from the permanent records storage facility. The SCE&G quality assurance organization is responsible for auditing these quality records as described in Part II, Section 18 of the Virgil C. Summer Nuclear Station Unit 1’s QAPD.

13.6.1 Plant History

Upon completion of the plant design, construction, and construction testing, the engineering and construction departments transferred or disclosed the location of all quality documentation to the plant staff and operations quality services group. The engineering and construction departments will state that the record types necessary to document quality have been identified and that the list is complete and accurate. Records not maintained at the plant site are kept at the material suppliers due to code and standard requirements or at Parsons Power, LTD (formerly Gilbert Associates, Inc.) offices, the architect-engineer for the Virgil C. Summer Nuclear Station.

This documentation, together with the records generated during the testing program, operation, maintenance, inspection, modification, and events of the Virgil C. Summer Nuclear Station, as described in Sections 13.6.2 and 13.6.3, serves as a recorded history of plant activities.

13.6.2 Operating Records

Preoperational and startup test records generated during the testing program are kept at the plant site along with appropriate operating records. These operating records include chemistry records; manuals and procedures; operating, maintenance, and testing records; special nuclear materials records; records and reports required by regulatory agencies; and administrative records.

Operations records and logs that are kept at the plant are considered as nonpermanent and are maintained for a predetermined time as shown on the SCE&G records accumulation and retention

chart, unless a longer period is required by applicable regulations. The following are examples of these type records:

1. Startup problems and resolutions.
2. Records of normal plant operation, including power levels and period of operation at each level.
3. Records of principal safety-related maintenance activities, including inspection, repair, substitution, or replacement of principal items of equipment.
4. Records of abnormal occurrences and unusual events.
5. Records of shipment of radioactive material.

Operations records that are considered to be of a significant value in demonstrating safe operation capability, in maintaining, replacing, or repairing an item, in determining the cause of an accident or malfunction of an item, or in providing baseline data for inservice inspection are maintained for the life of the plant. The following are examples of these type records:

1. Applicable plant procedures and drawings.
2. Records of inservice inspections.
3. Records of radiation exposure of plant personnel and others, who enter radiation control areas.
4. Records of new and spent fuel inventory and assembly histories.
5. Records and drawing changes made to the plant as described in the FSAR.
6. Reactor water chemistry data.

13.6.3 Event Records

Records of occurrences such as radioactive releases and environmental surveys are maintained at the plant site. These records are considered to be of a significant value in demonstrating the safe operation capability of the plant and are therefore kept for the life of the plant. The following are examples of these type records:

1. Records of plant radiation and contamination surveys.
2. Gaseous and liquid release data.

13.7 INDUSTRIAL SECURITY

The security plans for the Virgil C. Summer Nuclear Station are submitted under separate cover pursuant to paragraph 2.790 (d), 10 CFR Part 2, "Rules of Practice."

CHAPTER 14 - INITIAL TESTS AND OPERATION

NOTE 14.0

Chapter 14, in its entirety, is being retained for historical purposes only.

An extensive test program is conducted by SCE&G to verify that the systems, components, and structures which make up Virgil C. Summer Nuclear Station will perform as they were designed. The overall test objective is to assure that the operation of Virgil C. Summer Nuclear Station will not endanger the health and safety of the public. The ultimate responsibility for the initial tests and operation belongs to SCE&G.

14.1 TEST PROGRAM

The initial test program of Virgil C. Summer Nuclear Station is in three phases; Phase I, component or construction tests; Phase II, acceptance and preoperational tests; and Phase III, core loading and initial startup tests.

Component or construction tests are performed to ensure that components and subsystems meet their functional requirements. The Phase I test program consists of hydrostatic test, flushing, electrical checks, initial operation of equipment, and other specific tests on individual items of equipment.

Acceptance and preoperational tests demonstrate that systems and structures can perform their intended functions. These tests start with system or subsystem turnovers from construction and continue through core loading.

Core loading and initial startup tests begin only after the plant operating license has been issued. It begins with core loading and continues through initial criticality, ascension to power, and is complete when the plant is fully licensed for commercial operation. The results of these tests show that the plant follows its predicted nuclear parameters and can be operated at rated capacity without endangering the health or safety of the public.

Some of the tests described in Regulatory Guide 1.68 are considered preoperational tests but, because of their requirements, are performed during startup testing. An example is scram performance of control rods. This can only be done after the core is loaded and the vessel head is on although this test appears in the preoperational section of the guide.

To assure quality control, procedures used in testing are written and approved in accordance with Section 14.1.1. Changes made to approved procedures are in accordance with Section 14.1.2. The use of plant procedures is discussed in Section 14.1.5. Compliance with regulatory guides is discussed in Appendix 3A.

The Manager Virgil C. Summer Nuclear Station is responsible for the development, administration, and conduct of the test program. The test program is conducted by a startup group which is organized specifically for performing the initial tests and startup of the plant. After

commercial operation, this group will be disbanded. The startup group is described in more detail in Section 14.1.1.4.

The initial test program schedule is presented as Table 14.1-81.

14.1.1 Administrative Procedures (Testing)

14.1.1.1 Development of Procedures

The preparation of Phase I, II, and III test procedures is the responsibility of the Plant Manager or his designee (qualification described in Section 13.1.3). The Startup Supervisor may assume these duties for Phase I, II, and III while the startup group is active. Procedures which are contracted to other organizations are written in accordance with the terms of the contract but are reviewed as if written by SCE&G Nuclear Operations. Phase II and III test procedures as described in this Chapter are approved by the Manager Virgil C. Summer Nuclear Station. Acceptance criteria and performance requirements are determined by SCE&G Nuclear Operations by evaluating data furnished by Westinghouse, Gilbert, other vendors, and contractors. Information received from other departments of SCE&G is given close evaluation in the determination of acceptance criteria and performance requirements.

The preparation of Phase I Test Instructions is the responsibility of the Startup Supervisor, who will designate this responsibility to the Test Supervisors. The Test Supervisor will prepare the original test instruction following the guidelines and test methods set forth in generic instructions. If more guidelines are considered necessary, the Test Supervisor will follow specified formats depending on the type of instruction being written (Hydro, Electrical, I&C, Flush). During preparation of the Phase I Test Instruction, the Test Supervisor will use the following references as applicable: Virgil C. Summer Nuclear Station, FSAR, Westinghouse System Descriptions, Gilbert Design Descriptions, Westinghouse NSSS Startup Manuals, applicable vendor Instruction Manuals, and other sources as necessary. After preparation of the test instruction is completed, the Test Supervisor will submit the instruction to the Lead Systems Supervisor, who will review and approve the test instruction.

The preparation of Phase II test procedures as described in Section 14.1.3.2 is the responsibility of the Startup Supervisor who will designate this responsibility to the Test Supervisors. The Test Supervisor(s) prepares the assigned procedure in the prescribed format and submits the procedure for distribution. Copies will be sent to the Westinghouse Startup Representative, the Gilbert Associates Startup Representative, the Startup Supervisor, and the Manager, Virgil C. Summer Nuclear Station, or their designated alternates, each having at least the qualifications of a Lead Systems Supervisor as described in Section 14.1.1.4, for review. The Startup Supervisor may also send the procedure to designated groups or persons for review. These designated groups or persons may include Nuclear Engineering personnel, Quality Assurance personnel, the Assistant Managers Operations, Maintenance Services, and/or Technical Support. Minimum qualifications for Nuclear Engineering and plant personnel assigned to review Phase II test procedures are provided in Section 13.1.

The reviewers examine the procedure for correctness and comment as necessary. The procedure with comments is then returned to the originator for resolution/incorporation of comments. When comments are resolved/incorporated, the procedure is forwarded to the Startup Supervisor. The Startup Supervisor or his designee signs the procedure recommending approval. The procedure is transmitted to the Plant Manager or his designee for his approval.

The preparation of Phase III test procedures will be the responsibility of the Assistant Manager Technical Support or his designated alternate, who will assign the responsibility for the preparation of individual test procedures to plant or support personnel. The originator(s) prepares the assigned procedure in the prescribed format and submits the procedure for distribution. The procedure(s) will be reviewed and approved as per Plant Administrative Procedures (FSAR Chapter 13 and Technical Specifications Section 6).

Test procedures are available to NRC inspection personnel 30 days prior to the scheduled performance of the activity, but not less than 90 days prior to the scheduled core loading date. NRC possession of procedures shall not impede revision, review, or refinement of the procedures.

The format for Phase II and III test procedures is as follows:

TITLE PAGE

The title page contains the station name, procedure title and number, revision number, and signature and date for approval.

1.0 PURPOSE

This section contains the general purpose and objectives of the test.

2.0 REFERENCES

This section contains the references used to develop the test procedure such as FSAR, system descriptions, operating procedures, applicable standards and codes, drawings, manufacturer’s literature, etc. Where possible, revision numbers and dates are shown.

3.0 PREREQUISITES

This section contains title and number of pertinent tests or portions of tests which must be completed prior to conducting this test and/or tests which must be carried out concurrently with this test.

This section also contains the plant status required to conduct the tests such as pressure, temperature, levels, etc. and outline of system status, such as special valve lineups, test equipment installation, temporary equipment installation, temporary equipment, and identification of any equipment that should or should not be operating for equipment or personnel safety.

4.0 SPECIAL TEST EQUIPMENT

This section lists special equipment, other than normal system equipment and instrumentation, required to conduct the test.

5.0 LIMITATIONS AND PRECAUTIONS

This section contains design and safety limits for equipment and any special limitations and precautions needed for safety of personnel or equipment needed to assure that the required results are obtained during the test.

6.0 TEST METHOD

The test method consists of one or more sections containing step-by-step instructions to accomplish the purpose of the test.

Appropriate inspection points are established to record the accomplishment of the test objectives and test requirements.

Test method ensures that the system or plant is placed in a safe condition after a test has been completed and that nonstandard arrangements are restored to their standard condition and that proper verification and records are maintained.

7.0 DATA REQUIREMENTS

This section consists of the necessary instructions to assure that the required data are obtained by outlining requirements that can clearly be associated with steps of the test method.

Preplanned data sheets are used as much as possible with provisions for name of the person responsible for recording data, type of observation performed, and acknowledgment of the acceptability of the data. The data are compared with the acceptance criteria for the test to determine acceptability.

8.0 ACCEPTANCE CRITERIA

This section lists those qualitative or quantitative requirements or limits contained in the design documents against which test results are evaluated.

14.1.1.2 Execution of Test Procedures

Prior to the start of the initial testing program, the Virgil C. Summer Nuclear Station Operations Department arranges itself into a startup group which is more suited for the initial testing program. This organization is headed by the Manager Virgil C. Summer Nuclear Station. A Startup Supervisor who reports to the Manager Virgil C. Summer Nuclear Station organizes and directs the startup program. The Startup Supervisor appoints a Test Supervisor for each test. More

than one Test Supervisor may be appointed. The Test Supervisor ensures that the test is conducted according to the test procedure. Qualified test personnel are assigned by the Startup Supervisor to perform the tests. The personnel perform the test work under the supervision of the Test Supervisor.

Prior to fuel loading, all Phase I (component and construction) tests and Phase II (preoperational and acceptance) tests are scheduled to be conducted and the results reviewed and approved in accordance with approved administrative procedures.

A limited number of test deficiencies may exist at the scheduled core loading date. These test deficiencies will be evaluated and categorized.

Appropriate hold points in the Phase III (initial startup) test program will be identified. The applicable deficiencies will be resolved prior to proceeding with the Phase III test program.

During the power ascension phase of testing, certain data are analyzed by the Test Supervisor and the results are reviewed by the Plant Manager or his designee before power is increased to the next higher plateau. Analysis of data includes checking radial flux for symmetry, verifying that axial flux is within predicted values, checking effluent radioactivity, monitoring system operation, and checking power level and nuclear instrumentation by using a heat balance. Before power is increased to a higher plateau, the high flux trip is reset to a value no greater than 20 percent beyond the next power level. Approval of the Plant Manager or his designated alternate must be obtained before increasing power to the next plateau. Approval of the completed procedure documentation is not required for continuation of the startup program or power increases.

When conducting the test, the Test Supervisor ensures that the full intent of the procedure is met. If the Test Supervisor determines the need for either a procedure or plant change, it is accomplished as outlined in Section 14.1.2. The Test Supervisor shall notify the Startup Supervisor when the test has been completed.

14.1.1.3 Review, Evaluation, and Approval of Test Results

After a Phase I test is completed and the data are compiled, the Test Supervisor will review the test results and compare them to the applicable acceptance criteria. If he is satisfied that the test results are satisfactory, he will submit the test to the Lead Systems Supervisor. The Lead Systems Supervisor will be responsible for reviewing the test results and comparing them to the applicable acceptance criteria. If he is satisfied that the test results are acceptable, he will approve the test data. If the test results are not satisfactory, the Lead Systems Supervisor will recommend to the Startup Supervisor what actions are necessary.

After a Phase II test is completed and the data are compiled, the Startup Supervisor will assign the Westinghouse Startup Representative, the Gilbert Associates Startup Representative, or their designated alternates, each having qualifications of a Lead Systems Supervisor as described in Section 14.1.1.4, to review the test results. The assigned personnel will review the test results and compare them to the applicable acceptance criteria specified in the procedure, and forward the test results to the Startup Supervisor. The Startup Supervisor or designated alternate will then review

the test results and, if acceptable, sign the test results recommending approval to the Manager Virgil C. Summer Nuclear Station. The test results are then sent to the Manager Virgil C. Summer Nuclear Station for his review and approval. If test results are not acceptable, the personnel assigned to review the data recommends to the Startup Supervisor what actions are necessary. These actions are outlined in more detail in Section 14.1.2.1.

After a Phase III test is completed and the data are compiled, the Lead Phase III Test Supervisor will place the review of the completed test procedure on the agenda of the Plant Safety Review Committee Meeting for consideration for approval of the test results. If the review of the test results during the Plant Safety Review Committee Meeting shows that the test results are acceptable, the Plant Safety Review Committee Chairman signs a procedure recommending approval, the procedure is transmitted to the Plant Manager or his designated alternate for his approval.

14.1.1.4 Personnel Responsibilities and Qualifications

Personnel who will manage, supervise, or execute any of the Phase II or III tests of the initial test program are incorporated into the Virgil C. Summer Nuclear Station startup group. This group consists of the Manager, Virgil C. Summer Nuclear Station, a Startup Supervisor, Lead Systems Supervisor, Test Supervisors, and test personnel. To the extent practical, these individuals come from the plant operating, technical, and maintenance personnel. This allows the utilization of the knowledge these persons have acquired from their training and practical experiences. Utilization of plant personnel during testing further enhances their knowledge of the plant and aids in their training.

SCE&G also utilizes qualified startup personnel from other organizations as members of the startup group. These people constitute a temporary addition to the plant staff which provides the extra people needed during startup to handle the increased work load. These additional people may be obtained from contractors for the specific purpose of starting up the Virgil C. Summer Nuclear Station.

In addition to the startup group, SCE&G may utilize vendor service personnel to provide expert advice and assistance in check out, startup, and testing of their equipment. Technical services are available from Westinghouse, Gilbert, and Daniel.

The Manager Virgil C. Summer Nuclear Station, in addition to his other duties outlined in Section 13.1.2.2, has overall responsibility for Phase II and Phase III of the initial test program. He is responsible for the development of the test procedures, the administration and conduct of the test, and the review and actions taken on the test results. The qualifications of the Plant Manager are outlined in Section 13.1.3.

The Startup Supervisor is under the supervision of the Manager Virgil C. Summer Nuclear Station and ensures effective administrative control and implementation of the test program. The Startup Supervisor meets one of the following qualifications.

1. A graduate of a four-year engineering or science college or university plus five years of experience in operation, testing, or inspection of power plant, nuclear plant, heavy industrial, or other similar equipment or facilities. At least two years of this experience should be associated with nuclear facilities; or if not, the individual shall have training sufficient to acquaint him thoroughly with the safety aspects of a nuclear facility.
2. A high school graduate or equivalent, plus 10 years of experience in operation, testing, or inspection of power plant, nuclear plant, heavy industrial, or other similar equipment or facilities. At least two years of this experience should be associated with nuclear facilities; or if not, the individual shall have training sufficient to acquaint him thoroughly with the safety aspects of a nuclear facility.

See Appendix 3A for details of compliance with Regulatory Guide 1.58.

The Startup Supervisor's duties and responsibilities include, but are not limited to the following:

1. Supervision and coordination of the activities of the startup group.
2. Responsibility for the master startup schedule.
3. Assignment for review responsibilities for individual test results of members of the startup group.
4. Review of test data and test procedure modification in accordance with established administrative procedures.
5. Recommendations to Nuclear Engineering on any request for construction or engineering changes or modifications determined to be necessary by results of a test.
6. Liaison with contractors and vendors and coordination of any activities relative to the test program.
7. The preparation and maintenance of the startup manual.
8. The review of Phase II procedures and test results.

A Lead Systems Supervisor has the responsibility of coordinating test personnel assigned to work for him. He supervises any training needed for the personnel assigned. A Lead Systems Supervisor may be assigned to be the Test Supervisor on an individual test or any number of tests. Lead Systems Supervisors shall meet the qualifications of the Startup Supervisor. Lead Systems Supervisors shall receive indoctrination on startup administrative procedures prior to beginning work.

The Lead Systems Supervisor responsibilities include, but are not limited to, the following:

1. Establish system work loads and responsibility for Test Supervisors with the Startup Organization.
2. Attend meetings with other groups (i.e., construction) as needed.
3. Coordinate turned over system work schedules.

4. Review system turnover packages for completeness of documentation.
5. Review turnover packages for closure and completeness to ensure that the system is ready for testing.
6. Coordinate activities of suppliers/contractors (when applicable) onsite.
7. Coordinate all flushing and cleaning efforts on his assigned systems.
8. Assure that all system deficiencies (design or test) are properly documented, reported, and corrected as expeditiously as possible through the Startup Supervisor.
9. Provide technical guidance for designed systems of testing and operation as required.
10. Assure that the necessary test equipment supplies are available.
11. He is responsible for coordination of the activities of the Startup Test Supervisors assigned to his group. He will assist the Startup Supervisor in scheduling tests and work completion.
12. The review of Phase II procedures and test results.
13. Assign Test Supervisors to the preparation of test procedures.

A Test Supervisor has the responsibility of coordinating the test personnel assigned to work for him. He supervises any training needed for the specific test assigned. A Test Supervisor may be assigned to be the Test Supervisor on an individual test or any number of tests. He is assigned a copy of the test procedure on which all data and acknowledgments are recorded.

Test Supervisors shall meet one of the following qualifications:

1. A graduate of a four-year engineering or science college or university, plus two years of experience in operations, testing, or inspection of power plant, nuclear plant, heavy industrial, or other similar equipment or facilities. (For Phase III, at least one of the two years of experience must be applicable nuclear power plant experience.)
2. A high school graduate or equivalent, plus four years of experience in operations, testing, or inspection of power plant, nuclear plant, heavy industrial, or other similar equipment or facilities. (For Phase III, five years of experience, at least two of which must be applicable nuclear power plant experience.) Test Supervisors shall receive indoctrination on startup administrative procedures prior to beginning work.

See Appendix 3A for details of compliance with Regulatory Guide 1.58.

A Test Supervisor’s duties and responsibilities include, but are not limited to, the following:

1. Coordinate with construction to have the necessary temporary piping installed to facilitate flushing activities and other temporary arrangements to facilitate startup.
2. Carry out system inspection and participate in walkdowns.
3. Assure that the necessary electrical, mechanical, and instrument checkouts have been completed and documented.

4. In the initial operation (if applicable), obtain and record the necessary data. Report, record, and correct deficiencies as required.
5. Present test reports and system data files to the Lead System Supervisor for inclusion in the startup files.
6. Document all deficiencies noted, corrections made, and verifications performed during testing activities.
7. Document all print changes, etc. to ensure final prints are correct and data file is complete.
8. Ensure that approved flushing procedures are implemented and allowed.
9. Calculate the approximate quantities of water required to minimize the use of water and coordinate the use of pumps and the availability of Electrical Power.
10. Walkdown the system with the cognizant personnel using the flushing P & IDs to check valve line up prior to flushing. Supervise the flushing operation.
11. Check for and document, by signing off the steps of the procedure, such as metering devices, orifice plates, valve internals, temporary strainers, blind flanges, piping, and the isolation of sensitive instruments that are removed from the system to facilitate flushing.
12. Verify that the mechanical items are being flushed in accordance with the limits and precautions specified by the procedure so that contaminants and/or flow velocities will not adversely affect subsequent operation or damage the equipment.
13. In conjunction with SCE&G Chemistry Department, verify that the proper chemicals at the designated concentration and temperature are being used in the system layup condition.

14.1.1.5 Test Records

After a test is completed and the results are approved, the master test copy and other permanent information relative to the test will be filed as part of the plant's permanent file in the permanent records room as appropriate. This gives plant personnel access to information on systems, components, etc., from plant startup to serve as a baseline for evaluating performance at any future time in the plant's life.

14.1.2 Administrative Procedures (Modifications)

When the need arises for changes in plant systems or components or in test procedures, administrative procedures are followed.

14.1.2.1 Test Initiated Changes for Systems and Components

A minor change in a system, component, or control is one which does not involve design intent of the system. If, during a test, there arises a need for a minor change in the field, the change, authorized by the Test Supervisor, is made by qualified personnel. Minor changes are indicated with the test data. These minor changes must be approved by the Lead Systems Supervisor before

the test results may be approved. The Test Supervisor initiates changes in documents which the minor change affects and notifies appropriate design organization for review.

A major change in a system, component, or control is one which could alter design intent of the system. When personnel designated to review test results, the Test Supervisor or the Startup Supervisor, indicate the necessity of major changes, the Startup Supervisor assigns qualified personnel to review the data at hand and make recommendations to SCE&G Production Engineering for resolution and approval. The Production Engineering personnel studying the necessity of a major change may seek the assistance of vendor, contractor, or others. Before resulting modifications are started, they must have the written approval of the Manager Virgil C. Summer Nuclear Station or his designee. Additional tests or retests shall be rescheduled by the Startup Supervisor. These retests shall be conducted using approved procedures. Modifications or maintenance initiated by test results and the reason they were initiated are noted by the Startup Supervisor.

The Manager Virgil C. Summer Nuclear Station is notified when test results are not acceptable. Vendors, contractors, and others as necessary are notified of any developments and followup activities concerning unacceptable test results.

14.1.2.2 Test Procedure Change and Modifications

Modifications to approved Phase II test procedures are designated either minor or major modifications. A minor modification does not involve changes in scope, intent, or acceptance limits. Minor modification may be effected with approval of the Test Supervisor. The modification must be noted on the test procedure.

Other Phase II procedure modifications are designated as major modifications. These modifications are incorporated into the test procedure by an individual designated by the Startup Supervisor. (If the startup group is not in effect, the Technical Support Engineering Supervisor assumes his duties.) The revised procedure goes through the review and approval steps of an original procedure.

Phase III procedures will be changed and modified in accordance with Technical Specifications.

14.1.3 Test Objectives and Procedures

14.1.3.1 Phase I (Construction, Component, and Subsystem Functional Tests)

NOTE: Phase I tests are generic in nature and are written to demonstrate individual components or subsystems meet their functional requirements. The test abstracts furnished below describe the general objectives, test method, and acceptance criteria for each type of component or subsystem being tested utilizing a Phase I test procedure to demonstrate that the component or subsystem meets its functional requirements.

1. Generic Flush Procedure (see Table 14.1-82).
2. Generic Hydrostatic/Pneumatic Test Procedure (see Table 14.1-83).
3. Instrument Control Procedure (see Table 14.1-84).
4. Generic Functional Test Procedure (see Table 14.1-85).

14.1.3.2 Phase II (Preoperational Tests)

1. Fire Protection System (see Table 14.1-1).
2. Containment Isolation Valves Leakage Rate Test (see Table 14.1-2).
3. Containment Penetrations Leakage Rate Test (see Table 14.1-3).
4. Containment Air Locks Leakage Rate Test (see Table 14.1-4).
5. Reactor Building Structural Acceptance Test (see Table 14.1-5).
6. Containment Integrated Leakage Rate Test (see Table 14.1-6).
7. Unit Auxiliary, Emergency Auxiliary, and Engineered Safety Features Transformers (see Table 14.1-7).
8. 7200 Volt Electrical System (see Table 14.1-8).
9. 480 Volt Buses (see Table 14.1-9).
10. 480 Volt Motor Control Centers (see Table 14.1-10).
11. 120 Volt AC (see Table 14.1-11).
12. DC System (see Table 14.1-12).
13. Plant Paging and Communication System (see Table 14.1-13).
14. Diesel Fuel Oil Transfer and Storage System (see Table 14.1-14).
15. Emergency Diesel Generators (see Table 14.1-15).
16. Response to Loss of Instrument Air (see Table 14.1-16).
17. Auxiliary Building Ventilation System (Radioactive Portion) (see Table 14.1-17).
18. Fuel Handling Building Ventilation System (Radioactive Portion) (see Table 14.1-18).
19. Process and Area Radiation Monitoring System (see Table 14.1-19).
20. Component Cooling Water System (see Table 14.1-20).
21. Service Water System (see Table 14.1-21).
22. Boric Acid Batching and Transfer System (see Table 14.1-22).
23. Heat Tracing for Boron Injection Tank and Associated Piping (see Table 14.1-23).
24. Reactor Building Ventilation Systems (see Table 14.1-24).

25. Chemical and Volume Control System (see Table 14.1-25).
26. Pressurizer Relief Tank (see Table 14.1-26).
27. Reactor Coolant System Heatup for Hot Functional Testing (see Table 14.1-27).
28. Systems Thermal Expansion (see Table 14.1-28).
29. Hot Functional Testing (see Table 14.1-29).
30. Emergency Feedwater System (see Table 14.1-30).
31. Engineered Safety Features Circuitry (see Table 14.1-31).
32. Nuclear Sampling System (see Table 14.1-32).
33. Reactor Coolant System Cooldown From Hot Functional Testing (see Table 14.1-33).
34. Residual Heat Removal System (see Table 14.1-34).
35. Nuclear Instrumentation System (see Table 14.1-35).
36. Control Building Ventilation System (see Table 14.1-36).
37. Deleted.
38. Reactor Components and Fuel Handling Tools and Fixtures (see Table 14.1-38).
39. Fuel Transfer System (see Table 14.1-39).
40. Safety Injection Pumps Operational Test (see Table 14.1-40).
41. Safety Injection Accumulator Blowdown (see Table 14.1-41).
42. Spent Fuel Cooling System (see Table 14.1-42).
43. Containment Isolation System (see Table 14.1-43).
44. Reactor Protection Operational Check (see Table 14.1-44).
45. Engineered Safety Features System Operational Check (see Table 14.1-45).
46. Integrated Engineered Safety Features Test (see Table 14.1-46).
47. Reactor Building Spray System (see Table 14.1-47).
48. Leak Detection Monitoring System (see Table 14.1-48).
49. Post Accident Hydrogen Removal System (see Table 14.1-49).
50. Radioactive Waste Disposal System (see Table 14.1-50).
51. Boron Thermal Regeneration System (see Table 14.1-51).
52. Reactor Protection System Time Response Measurement (see Table 14.1-52).
53. Emergency Lighting (see Table 14.1-79a).
54. Heat Tracing for Safety Related Outdoor Piping (see Table 14.1-79b).
55. Pressure Boundary Integrity Test (see Table 14.1-79c).

56. Seismic Instrumentation (see Table 14.1-79d).
57. Steam Generator Power Operated Relief Valve (see Table 14.1-86).
58. Condensate System (see Table 14.1-87).
59. Main Condenser Dump Valves (see Table 14.1-89).
60. Circulating Water System (see Table 14.1-90).
61. Chemical Feed System (see Table 14.1-91).
62. Nuclear Blowdown Processing System (see Table 14.1-92).
63. Control Rod Drive (see Table 14.1-93).
64. Miscellaneous Plant Drains (see Table 14.1-94).
65. Fuel Handling Building Pool Liner Leak Test (see Table 14.1-95).
66. Reactor Building Ventilation Post Accident Operation (see Table 14.1-96).
67. ESF Equipment Rooms Cooling Systems (see Table 14.1-97).
68. S. I. Accumulator Discharge Valve Functional Test (see Table 14.1-98).
69. ECCS Check Valve Leak Testing System Operational Test (see Table 14.1-99).
70. S. I. Accumulator Check Valve Hot Operational Test (see Table 14.1-100).
71. Instrument Air System (see Table 14.1-101).
72. Pressurizer Pressure and Level Control (see Table 14.1-102).
73. Process Computer (see Table 14.1-70).

14.1.3.3 Phase III (Fuel Loading and Pre-Critical Test)

These tests are listed in the order in which they are most likely to be performed:

1. Core Loading Instrumentation (see Table 14.1-37).
2. Initial Fuel Loading (see Table 14.1-53).
3. Incore Movable Detectors (see Table 14.1-54).
4. Rod Drop Time Measurement (see Table 14.1-55).
5. Rod Drive Mechanism Timing (see Table 14.1-56).
6. Rod Position Indication (see Table 14.1-57).
7. Reactor Coolant System Flow Measurement (see Table 14.1-58).
8. Reactor Coolant System Flow Coastdown (see Table 14.1-59).
9. Resistance Temperature Detector Bypass Loop Flow Verification (see Table 14.1-60).
10. Reactor Vessel O-Ring Leak Test (see Table 14.1-61).

11. Pressurizer Spray and Heater Capability and Setting Continuous Spray Flow (see Table 14.1-62).
12. Water Quality Test (see Table 14.1-63).

14.1.3.4 Phase III (Power Ascension Test)

These tests are listed in the order in which they are most likely to be performed.

1. Initial Criticality (see Table 14.1-64).
2. Low Power Test (see Table 14.1-65).
   a. Augmented Low Power Test (see Table 14.1-65a).
3. Incore Movable Detector and Thermocouple Mapping at Power (see Table 14.1-66).
4. Power Coefficient and Power Defect Measurement (see Table 14.1-67).
5. Effluent Radiation Monitor Test (see Table 14.1-68).
6. Radiation Shielding Survey (see Table 14.1-69).
7. Thermal Power Measurements and Instrument Calibration (see Table 14.1-71).
8. Automatic Control Systems Checkout (see Table 14.1-72).
9. Feedwater System (see Table 14.1-88).
10. Plant Response to Step Load Changes (see Table 14.1-73).
11. Pseudo Rod Ejection Test (see Table 14.1-74).
12. Rod Drop Test (see Table 14.1-75).
13. Below-Bank Rod Test (see Table 14.1-76).
14. Plant Loss of Electrical Load (see Table 14.1-77).
15. Loss of Offsite Power (see Table 14.1-78).
16. Shutdown from Outside the Control Room (see Table 14.1-79).

Table 14.1-80 indicates power levels at which the above tests are performed.

14.1.4 Core Loading and Initial Operation

Core loading begins when all prerequisite system tests and operations are satisfactorily completed and the NRC operating license received. Upon completion of core loading, the reactor upper internals and pressure vessel head are installed and additional mechanical and electrical tests are performed. The reactor is then ready for its initial criticality. After the initial criticality, low power tests, and power ascension test will commence. The purpose of these tests is to establish the operational characteristics of the unit and core, to acquire data for the proper calibration of setpoints, and to ensure that operation conforms to the license requirements.

14.1.4.1 Core Loading

Before starting core loading, the precore loading tests must be complete, the plant shall have a NRC operating license, and there must be an appropriately licensed operating staff. The Plant Manager is responsible for the conduct of core loading and all core loading personnel. Technical assistance will be provided by Westinghouse during the initial core loading operation. During this time, containment integrity and security must be maintained through the use of established procedures. The overall process of initial core loading is, in general, directed from the operating floor of the Reactor Building.

The as-loaded core configuration is specified as part of the core design studies conducted well in advance of plant startup and as such is not subject to change at startup. In the event that mechanical damage is sustained during core loading operations by a fuel assembly of a type for which no spare is available onsite, an alternate core scheme whose characteristics closely approximate those of the initially prescribed pattern will be determined.

The core is assembled in the reactor vessel, submerged in water containing enough dissolved boric acid to maintain a calculated core effective multiplication constant of 0.95 or lower. The refueling cavity is dry during initial core loading. Core moderator chemistry conditions (particularly boron concentration) are prescribed in the core loading procedure document and are verified periodically by chemical analysis of moderator samples taken prior to and during core loading operation.

Core loading instrumentation consists of two permanently installed source range (pulse type) nuclear channels and two temporary incore source range channels plus a third temporary channel which can be used as a spare. The permanent channels, when responding, are monitored in the Control Room by licensed plant operators; the temporary channels are installed in the containment structure and are monitored by fuel loading personnel. At least one permanent channel is equipped with an audible count rate indicator heard in the Reactor Building and the Control Room. Both plant channels have the capability of displaying the neutron flux level on strip chart recorders. The temporary channels indicate on rate meters with a minimum of one channel recorded on a strip chart recorder. Minimum count rates of 1/2 counts per second, attributable to core neutrons, are required on at least two (i.e., temporary and/or permanent source range detectors) available nuclear source channels at all times following installation of the initial nucleus of eight fuel assemblies. A response check of nuclear instruments to a neutron source shall be performed within 12 hours prior to loading of the core, or resumption of loading if delay is for more than 12 hours.

At least two neutron sources are introduced into the core loading program to ensure a neutron population of a minimum of 1/2 counts/sec for adequate monitoring of the core.

Fuel assemblies together with inserted components (control rod assemblies, burnable poison inserts, source spider, or thimble plugging devices) are placed in the reactor vessel one at a time according to a previously established and approved sequence which was developed to provide reliable core monitoring with minimum possibility of core mechanical damage. The core loading procedure documents include a detailed tabular check sheet which prescribes and verifies the

successive movements of each fuel assembly and its specified inserts from its initial position in the fuel racks to its final position in the core. Multiple checks are made of component serial numbers and types at successive transfer points to guard against possible inadvertent exchanges or substitution of components and fuel assembly status boards are maintained throughout the core loading operations.

An initial nucleus of eight fuel assemblies, the first of which contains a neutron source, is the minimum source-fuel nucleus which permits subsequent meaningful inverse count rate monitoring. This initial nucleus is determined by calculation and previous experience to be markedly subcritical ($K_{eff} \leq 0.95$) under the required conditions of loading.

Subsequent fuel additions are accompanied by detailed neutron count rate monitoring to determine that the count rate does not increase excessively and that the extrapolated inverse count rate ratio is not decreasing for unexplained reasons. The results of each loading step are evaluated by SCE&G and technical advisors before the next prescribed step is started.

Criteria for safe loading require that loading operations stop immediately if:

1. An unanticipated increase in the neutron count rates by a factor of two occurs on all responding nuclear channels during any single loading step after the initial nucleus of eight fuel assemblies is loaded (excluding anticipated change due to detector and/or source movement).
2. The neutron count rate on any individual nuclear channel increases by a factor of five during any single loading step after the initial nucleus of eight fuel assemblies is loaded (excluding anticipated changes due to detector and/or source movements).
3. A decrease in boron concentration greater than 20 ppm is determined from two successive samples of Reactor Coolant System water until the decrease is explained.

An alarm in the Reactor Building and Control Room is coupled to the source range channels with a setpoint at five times the current count rate. This alarm automatically alerts the fuel loading personnel to an indication of high count rate and requires an immediate stop of all operations until the situation is evaluated by SCE&G and technical advisors.

Core loading procedures specify alignment of fluid systems to prevent inadvertent dilution of the reactor coolant, restrict the movement of fuel to preclude the possibility of mechanical damage, prescribe the conditions under which loading can proceed, identify chains of responsibility and authority, and provide for continuous and complete fuel and core component accountability.

14.1.4.2 Postloading Tests

Upon completion of core loading, the reactor upper internals and pressure vessel head are installed and additional mechanical and electrical tests are performed prior to initial criticality. The final pressure tests are conducted after filling and venting is completed.

Mechanical and electrical tests are performed on the control rod drive mechanisms. These tests include a complete operational checkout of the mechanisms. Checks are made to ensure that the control rod assembly position indicator coil stacks are connected to rod drive mechanism coils.

Tests are performed on the reactor trip circuits to test manual trip operation and actual control rod assembly drop times are measured for each control rod assembly. By use of dummy signals, the Reactor Control and Protection System is made to produce trip signals for the various plant abnormalities that require tripping.

At all times that the control rod drive mechanisms are being tested, the boron concentration in the coolant-moderator is large enough such that the shutdown margin requirements specified in the Technical Specifications are met. During individual RCCA or RCC bank motion, source range instrumentation is monitored for unexpected changes in core reactivity.

A complete functional electrical and mechanical check is made of the incore nuclear flux mapping system at operating temperature and pressure.

14.1.4.3 Initial Criticality

Initial criticality is established by sequentially withdrawing the shutdown and control groups of control rod assemblies from the core, leaving the last withdrawn control group inserted far enough in the core to provide effective control when criticality is achieved, and then continuously diluting the heavily borated reactor coolant until the chain reaction is self-sustaining. Successive stages of control rod assembly group withdrawal and of boron concentration reduction are monitored by observing changes in neutron count rate as indicated by the regular source range nuclear instrumentation as functions of group position during rod motion and, subsequently, of reactor coolant boron concentration and primary water addition to the Reactor Coolant System during dilution. Throughout this period, samples of the primary coolant are obtained and analyzed for boron concentration.

Primary safety reliance is based on inverse count rate ratio monitoring as an indication of the nearness and rate of approach to criticality of the core during control rod assembly group withdrawal and during reactor coolant boron dilution. The rate of approach is reduced as the reactor approaches extrapolated criticality to ensure that effective control is maintained at all times.

Written procedures specify alignment of fluid systems to allow controlled starting, stopping, and adjustment of the rate of the approach to criticality. These procedures also identify chains of responsibility and authority during initial criticality.

14.1.4.4 Low Power Testing

A prescribed program of reactor physics measurements is undertaken to verify that the basic static and kinetic characteristics of the core are as expected and that the values of the kinetic coefficients assumed in the safeguards analysis are indeed conservative.

The measurements are made at low power and primarily at or near operating temperature and pressure. Measurements, to include verification of calculated values of control rod assembly group reactivity worths, of moderator temperature coefficient under various core conditions, of differential boron concentration reactivity worth, and of critical boron concentrations as functions of control rod assembly group configuration, are made. In addition, measurements of the relative power distributions are made. Concurrent tests are conducted on the instrumentation including the source and intermediate range nuclear channels.

In accordance with NUREG 0737, item I.G.1, a discussion of the special low power testing to be performed at the Virgil C. Summer Station has been submitted to the NRC under separate cover letters dated 10/31/80, 12/2/80, and 12/22/80.

Detailed procedures are prepared to specify the sequence of tests and measurements to be conducted and the conditions under which each is to be performed to ensure both safety of operation and the relevancy and consistency of the results obtained. If significant deviations from design predictions exist, unacceptable behavior is revealed, or apparent anomalies develop, a review by qualified personnel will be performed. The Plant Manager may determine that a review by the Plant Safety Review Committee is appropriate prior to increasing power to the next testing plateau.

14.1.4.5 Power Ascension

When the operating characteristics of the reactor and plant are verified by low power testing, a program of power level escalation in successive stages brings the plant to its full rated power level. Prior to starting to the next higher power plateau, as defined by the startup test program, management approval shall be obtained; also, the high flux trip shall be reset to a value no greater than 20 percent beyond the next power level. During the power escalation, a predetermined test program is followed to verify that the reactor and plant are performing as expected. The minimum test requirements for each successive stage of power escalation are specified.

Measurements are made to determine the relative power distribution in the core as functions of power level and control assembly group position.

Secondary system heat balances ensure that the several indications of power level are consistent and provide bases for calibration of the power range nuclear channels. The ability of the Reactor Control System to respond effectively to signals from primary and secondary instrumentation under a variety of conditions encountered in normal operations is verified.

At prescribed power levels, the dynamic response characteristics of the Reactor Coolant and Steam Systems are evaluated. These responses are evaluated for step load changes of 10 percent and a plant loss of electrical load from 100 percent power.

Adequacy of radiation shielding is verified by gamma and neutron radiation surveys inside the containment and throughout the station site. Periodic sampling is performed to verify coolant chemistry and activity.

The sequence of tests, measurements, and intervening operations is described in the power escalation procedure with specific details relating to the conduct of the several tests and measurements.

14.1.5 Administrative Procedures (System Operation)

Whenever the test allows, the plant operating procedures for Virgil C. Summer Nuclear Station will be incorporated into the test procedures. This will help in evaluating plant operating procedures. If during a test it is found that the operating procedure is not adequate, the test procedure will be changed in the manner described in Section 14.1.2.2; and the operating procedure shall be changed in accordance with Chapter 13. Any operating procedure, or part of one, which is referenced in a test procedure must be approved.

Table 14.1-1
Fire Protection System

1.0 Objective

Demonstrate that the Fire Protection System is capable of providing adequate fire protection under all conditions, including loss of power to the motor driven pump.

2.0 Prerequisites

Fire Protection System installation and component checks completed.

3.0 Test Methods

3.1 Align the subsystems for operation and establish normal flow paths for water systems.

3.2 Check operation of water systems and CO_2 system.

3.3 Verify pump heads and flow rates under both normal and emergency power conditions of the water systems.

3.4 Verify operation and response of detector systems.

4.0 Acceptance Criteria

4.1 Alarms, interlocks, and detection devices function as per design requirements.

4.2 System is capable of providing protection in accordance with applicable fire protection codes.

4.3 Where appropriate, flows, pressures, and spray patterns are as per design requirements.

Table 14.1-2
Containment Isolation Valves Leakage Rate Test

1.0 Objective

Demonstrate that the leakage from containment isolation valves and gasketed blind flanges required to be tested by 10 CFR 50, Appendix J is within allowable limits.

2.0 Prerequisites

2.1 Portions of the systems containing isolation valves and/or gasketed blind flanges have been successfully pressure tested.

2.2 Motor operated and air operated containment isolation valves have been functionally tested.

2.3 Portions of the systems containing isolation valves and/or gasketed blind flanges have been properly drained and vented.

2.4 Containment isolation valves have been closed using their normal mode of operation.

3.0 Test Methods

3.1 A pressure of not less than P_a is applied against the isolation valve or gasketed blind flange.

3.2 Measurement of valve leakage is made using a rotameter array or other equivalent instrumentation.

4.0 Acceptance Criteria

4.1 Containment isolation valve and gasketed blind flange leakage rates are within allowable design limits.

Table 14.1-3
Containment Penetrations Leakage Rate Test

1.0 Objective

Demonstrate that the leakage from containment penetrations required to be tested by 10 CFR 50, Appendix J is within allowable limits.

2.0 Prerequisites

2.1 Penetrations have been properly installed.

3.0 Test Methods

3.1 A pressure of not less than P_a is applied to the penetration.

3.2 Measurement of penetration leakage is made using a rotameter array or other equivalent instrumentation.

4.0 Acceptance Criteria

4.1 Containment penetration leakage rates are within allowable design limits.

Table 14.1-4
Containment Air Locks Leakage Rate Test

1.0 Objective

Demonstrate that leakage from the containment personnel air locks and equipment hatch is within allowable limits.

2.0 Prerequisites

2.1 Containment personnel air locks and equipment hatch have been properly installed.

3.0 Test Methods

3.1 A pressure of not less than P_a is applied to the seals of the containment personnel air lock and equipment hatch.

3.2 Measurement of seal leakage is made using a rotameter array or other equivalent instrumentation.

4.0 Acceptance Criteria

4.1 Containment personnel air lock and equipment hatch leakage is within allowable design limits.

Table 14.1-5
Reactor Building Structural Acceptance Test

1.0 Objective

Verify the structural integrity of the Reactor Building.

2.0 Prerequisites

2.1 Reactor Building penetrations installed and penetration leak tests (Type B test) completed.

2.2 Isolation valve leak test (Type C test) completed.

2.3 Reactor Building Ventilation Systems operable to extent required to control Reactor Building internal temperature.

3.0 Test Methods

3.1 Prior to initial fuel loading, the Reactor Building will be subjected to a pressure equivalent to 115 percent of the Reactor Building designed pressure. This test demonstrates that the Reactor Building is capable of resisting the postulated accident pressure. In addition, by measuring the structural response and comparing the results with analytical predictions, the test verifies that the structure does behave as anticipated.

3.2 Instrumentation, measuring systems, pressurization procedure, deformation, strain and temperature measurements, crack pattern mapping, and data acquisition schedules for the preoperational structural acceptance test will be in accordance with the approved test procedure.

4.0 Acceptance Criteria

The Reactor Building meets structural integrity design requirements.

Table 14.1-6
Containment Integrated Leakage Rate Test

1.0 Objective

Demonstrate that the containment leakage rate following a postulated loss of coolant accident (LOCA) is within allowable limits.

2.0 Prerequisites

2.1 Reactor Building structural acceptance test completed.

2.2 Affected systems lined up in their post accident mode.

3.0 Test Methods

3.1 The containment is pressurized at a rate of 5 psi per hour or less to P_a as defined in the approved test procedure.

3.2 Containment temperature is held essentially constant for 24 hours while the internal temperature, pressure, and dewpoint are closely monitored.

3.3 Using the perfect gas law, the change in the containment air mass is computed.

3.4 The leakage rate in percent/day is computed from the changes in containment air mass.

3.5 A known leak is superimposed on the containment to verify instrumentation accuracy.

4.0 Acceptance Criteria

4.1 Integrated leakage rate is within allowable design limits.

4.2 Instrumentation accuracy is verified to be within allowable design limits.

Table 14.1-7

Unit Auxiliary, Emergency Auxiliary, and Engineered Safety Features Transformers

1.0 Objective

1.1 Demonstrate the capability of the unit auxiliary, emergency auxiliary, and engineered safety features transformers to supply electrical power to the 7200 volt buses.

1.2 Verify operation of protection devices and functional operation of controls and interlocks.

2.0 Prerequisites

2.1 230 kV substation operational and energized.

2.2 Meters, relays, and protective devices calibrated and tested.

2.3 125 volt DC available.

2.4 Erection work on transformers and switchgear completed.

2.5 Transformer oil and fan systems tested and in service.

2.6 Isolated phase bus tested and ready for service.

2.7 Breaker controls and transfer scheme verified.

2.8 PT and CT circuits checked for polarity and continuity.

2.9 7200 volt breakers racked out.

2.10 115 kV supply line energized.

3.0 Test Methods

3.1 Simulate signals to temperature controls and verify operation of transformer oil pumps and fans.

3.2 Simulate signals to verify annunciators for transformer protective devices.

3.3 Energize transformers and verify phase rotation.

4.0 Acceptance Criteria

Transformers provide reliable source of electrical power to 7200 volt buses in accordance with design requirements and Section 8.3.

Table 14.1-8
7200 Volt Electrical System

1.0 Objective

1.1 Verify that 7200 volt buses can be energized from their respective normal and alternate sources.

1.2 Verify that electrical and mechanical interlocks function properly.

2.0 Prerequisites

2.1 Breakers in the 7200 volt buses are racked out and tagged.

2.2 Meters, relays, and protective devices calibrated and tested.

2.3 125 volt DC available.

2.4 Phase rotation checked on 7200 volt buses.

2.5 Unit auxiliary, emergency auxiliary, and ESF transformers energized.

3.0 Test Methods

3.1 Rack in and close 7200 volt breakers to energize associated 7200 volt buses.

3.2 Record voltage and verify phase relationship.

3.3 Shift buses to alternate power sources as applicable and verify phase relationship.

3.4 Verify 7200 Volt BOP buses will transfer from normal source to alternate source if a fault occurs on normal supply.

3.5 Verify 7200 Volt ESF buses will transfer from normal source to emergency diesel generator if voltage is lost on normal supply.

4.0 Acceptance Criteria

4.1 The 7200 volt buses are capable of being energized from their normal and alternate sources and that proper phase relationship is exhibited.

4.2 System interlocks and alarms function properly.

4.3 BOP buses transfer from normal source to alternate source if a fault occurs on normal supply.

Table 14.1-8 (continued)
7200 Volt Electrical System

4.4 ESF uses will transfer from normal source to emergency diesel generator if voltage is lost on normal supply,

Table 14.1-9
480 Volt Buses

1.0 Objective

1.1 Verify that 480 volt buses can be energized from their normal and alternate sources.

1.2 Verify that electrical and mechanical interlocks function properly.

2.0 Prerequisites

2.1 Breakers in the 480 volt buses are racked out and tagged.

2.2 Meters, relays, and protective devices calibrated and tested.

2.3 125 volt DC and 7.2 kV buses energized.

2.4 Phase rotation checked on 480 volt buses.

3.0 Test Methods

3.1 Close 7.2 kV breakers to energize load center transformers and buses.

3.2 Measure voltage and verify phase relationship.

3.3 Shift buses to alternate power sources as applicable and verify phase relationship.

3.4 Simulate loss of power.

4.0 Acceptance Criteria

4.1 480 volt buses are capable of being energized from their normal and alternate sources, and proper phase relationship is exhibited.

4.2 The 480 volt buses respond correctly to a loss of power.

4.3 Interlocks and alarms function properly.

Table 14.1-10
480 Volt Motor Control Centers

1.0 Objective

1.1 Verify that 480 volt motor control centers can be energized from their normal sources.

1.2 Verify that electrical and mechanical interlocks function properly.

2.0 Prerequisites

2.1 All breakers in 480 volt motor control centers are racked out and tagged.

2.2 Meters, relays, and protective devices calibrated and tested.

2.3 125 volt DC available.

2.4 480 volt buses energized.

2.5 Phase rotation checked on motor control centers.

3.0 Test Methods

3.1 Rack in and close motor control center supply breakers.

3.2 Measure voltage and verify phase relationship.

3.3 Simulate loss of power.

4.0 Acceptance Criteria

4.1 Motor control centers are capable of being energized from their normal sources, and proper phase relationship is exhibited.

4.2 The 480 volt motor control centers respond correctly to a loss of power.

4.3 System interlocks and alarms function properly.

Table 14.1-11
120 Volt AC

1.0 Objective

Demonstrate the capabilities of the 120 volt vital instrument power system and the 120 volt AC regulated instrument power system to supply power to instrumentation and control loads under normal and emergency conditions at full load.

2.0 Prerequisites

2.1 120 volt instrument power systems installation and component checks completed.

2.2 480 volt motor control centers available.

2.3 125 volt DC system operable

3.0 Test Methods

3.1 Energize 120 volt instrument power buses from their normal power sources and load to full load using a load bank.

3.2 Demonstrate ability to transfer each vital instrument bus manually to a backup instrument bus and back to its static inverter.

3.3 Trip the normal power supplies to the static inverters. Verify automatic transfer to alternate DC source. Verify transfer back to normal supply when re-energized.

3.4 Demonstrate ability to transfer each instrument panel manually to its alternate source.

4.0 Acceptance Criteria

4.1 Vital buses or panels can be manually transferred to alternate sources.

4.2 Vital inverters will transfer to the alternate 125V DC input source upon loss of normal 480V AC input source. Normal 120V AC is maintained during the transfer.

4.3 System interlocks and alarms function properly.

4.4 Vital AC inverters will supply their design load at 60 amps.

Table 14.1-12
DC System

1.0 Objective

Demonstrate the capability of the DC system to provide a source of reliable, uninterruptible DC power for normal and emergency instrumentation, control, and power loads.

2.0 Prerequisites

2.1 480 volt AC power available.

2.2 Battery Room Ventilation System operable.

2.3 Batteries, battery chargers, and DC distribution system, including protective devices, installation, and component checks completed.

2.4 DC breakers are open.

3.0 Test Methods

3.1 Energize the battery chargers and verify this normal feed to bus.

3.2 Verify alarms and interlocks.

3.3 Discharge the batteries at a controlled rate and determine ampere-hour capacity.

3.4 Adjust chargers to supply DC load and charge batteries simultaneously.

3.5 De-energize battery chargers while the applicable buses are carrying their normal station load to verify that battery will maintain load.

3.6 Verify that 125 volt bus can be fed from the backup charger upon loss of normal charger (manual transfer).

3.7 Verify ground detection by connecting variable load resistor to ground.

4.0 Acceptance Criteria

4.1 System interlocks and alarms function properly.

4.2 Batteries are capable of supplying plant DC power upon de-energization of their chargers.

Table 14.1-12 (continued)
DC System

4.3 Battery chargers are capable of maintaining normal bus loads concurrent with charging the batteries.

4.4 Bus can be supplied by backup charger.

Table 14.1-13
Plant Paging and Communication System

1.0 Objective

1.1 Demonstrate the adequacy of the plant paging systems intracommunication between all local stations in each separate system, and interconnection of the plant PABX system to the commercial telephone service and SCE&G microwave system.

1.2 Demonstrate that the radiation emergency (site evacuation) alarm can be heard from any location in the plant under all required conditions.

1.3 Demonstrate operability of Reactor Building evacuation alarm and fire alarm.

2.0 Prerequisites

2.1 Communications systems installation and component checks completed.

2.2 Sound levels established for locations where noise levels might interfere with communication.

3.0 Test Methods

3.1 Test the portable stations, page/party line phone station, and redundant communication phone stations for proper operation.

3.2 Test interconnection of the plant PABX system to the commercial telephone service, and SCE&G microwave system.

3.3 Verify alarms.

3.4 Shift PABX equipment to alternate power sources and verify operation.

4.0 Acceptance Criteria

4.1 Communication systems provide for paging, normal plant communications, shutdown communications, interconnection to SCE&G microwave system and commercial telephone service and alarm signaling in accordance with design requirements and Section 9.5.2.

4.2 Evacuation alarm can be heard from any location in the plant.

4.3 Paging systems and alarms will not produce sound pressure levels above 130 dB level where personnel will conduct normal plant communications.

Table 14.1-14
Diesel Fuel Oil Transfer and Storage System

1.0 Objective

Demonstrate that the Diesel Fuel Oil Transfer and Storage System supplies fuel oil to the diesel fuel oil day tanks and verify modes of operation.

2.0 Prerequisites

2.1 Fire protection is available.

2.2 Diesel Fuel Oil System installation and component checks completed.

3.0 Test Methods

3.1 Align system for operation and establish normal transfer flow paths.

3.2 Verify capability to transfer fuel oil to each day tank.

3.3 Verify alarms and automatic pump operations.

4.0 Acceptance Criteria

Fuel transfer capability of the system meets the design requirements.

Table 14.1-15
Emergency Diesel Generators

1.0 Objective

1.1 Demonstrate manual start and synchronization of the diesel generators.

1.2 Demonstrate load-carrying capacity of diesel generators.

1.3 Demonstrate fuel consumption of diesels.

1.4 Demonstrate proper operation of diesel auxiliaries during the load carrying capacity test.

2.0 Prerequisites

2.1 Station batteries charged and DC control power available.

2.2 Relays calibrated and all normal bus protective devices checked and in service.

2.3 Diesel engine auxiliary systems installation and component checks completed as specified.

2.4 Diesel room ventilation and fire protection available.

2.5 Diesel Fuel Oil System operable.

3.0 Test Methods

3.1 Demonstrate manual start and synchronization of each diesel generator, including synchronizing the diesel generator unit to offsite power while the unit is connected to the emergency load, isolating the diesel generator unit, and restoring it to standby status.

3.2 Verify timing of diesel generators starting sequence and available for load.

3.3 Verify capability to control diesel generators in local and remote operation.

3.4 The diesel generators will be operated at continuous rated load for 22 hours. The load will then be increased to the two hour rating and held at this condition for a period of two hours. During this 24 hour period, the indicated readings from supervisory instrumentation will be recorded to establish base line operating conditions.

3.5 Conduct load-carrying duration test.

Table 14.1-15 (continued)
Emergency Diesel Generators

3.6 Verify load rejection and overspeed trip.

3.7 Demonstrate diesel generator reliability by performing 69/N starts (where N is the number of diesel generator units).

4.0 Acceptance Criteria

4.1 Diesel generators function in maintaining the 7200 volt ESF buses as designed.

4.2 Diesel generators do not overspeed when load is removed.

4.3 Each redundant onsite power source and its load group can function without any dependence upon any other redundant load group or portion thereof.

4.4 Diesel auxiliaries perform their design requirements.

4.5 Diesel generators demonstrate required reliability.

Table 14.1-16
Response to Loss of Instrument Air

1.0 Objective

Demonstrate that pneumatically operated “Active” valves fail to their safe position on a loss of instrument air.

2.0 Prerequisites

2.1 Instrument Air System installation and component checks completed.

2.2 Associated systems completed to the extent necessary to allow conduct of this test.

2.3 System has been blown down and cleanliness requirements met.

3.0 Test Methods

Note: Specific valves and systems may be tested individually.

3.1 Align system for normal operation.

3.2 Reduced instrument air pressure to zero psig.

3.3 Observe the response of pneumatically operated “Active” valves during loss of air pressure and record the position to which each valve fails.

3.4 Air operated valves equipped with safety related volume tanks will be isolated from the instrument air header and stroked to verify their operability.

4.0 Acceptance Criteria

4.1 Pneumatically operated “Active” valves fail to their “safe” position on loss of instrument air.

4.2 Components with “safety related” air volume tanks operate in accordance with design.

Table 14.1-17
Auxiliary Building Ventilation System (Radioactive Portion)

1.0 Objective

1.1 Demonstrate the capabilities of the Auxiliary Building Ventilation System to provide for control and disposal of airborne radioactivity.

1.2 Confirm the proper operation of system interlocks and controls.

2.0 Prerequisites

2.1 Auxiliary Building Ventilation System installation and component checks completed.

2.2 Associated systems completed to the extent necessary to allow conduct of this test.

3.0 Test Methods

3.1 Align system for normal operation.

3.2 Verify building internal negative pressure differential with respect to atmosphere.

3.3 Test positioning on pneumatically operated dampers.

3.4 Simulate isolation actuation signal and observe system response.

3.5 Verify fan and damper, interlocks and permissives.

4.0 Acceptance Criteria

4.1 System provides for control and disposal of airborne radioactivity in accordance with design requirements and Section 9.4.

4.2 Fans and dampers function as per design.

4.3 Auxiliary Building internal pressure is less than atmospheric.

Table 14.1-18
Fuel Handling Building Ventilation System (Radioactive Portion)

1.0 Objective

Demonstrate the capabilities of the Fuel Handling Building Ventilation System to provide for control and disposal of airborne radioactivity.

2.0 Prerequisites

2.1 Fuel Handling Building Ventilation System installation and component checks completed.

2.2 Associated systems completed to the extent necessary to allow conduct of this test.

3.0 Test Methods

3.1 Align system for normal operation.

3.2 Verify fan and damper, interlocks, and permissives.

3.3 Test positioning on pneumatically operated dampers.

3.4 Simulate isolation actuation signal and observe system response.

3.5 Verify building internal negative pressure differential with respect to atmosphere.

4.0 Acceptance Criteria

4.1 System provides for control and disposal of airborne radioactivity in accordance with design requirements and Section 9.4.

4.2 Fans and dampers function as per design.

4.3 Building internal pressure with respect to atmospheric pressure is per design.

Table 14.1-19
Process and Area Radiation Monitoring System

1.0 Objective

Demonstrate the capability of the Process and Area Radiation Monitoring Systems to monitor effectively the levels of radiation in the plant or its effluents and to initiate isolation and alarms as required.

2.0 Prerequisites

2.1 Process and Area Radiation Monitoring Systems installation and component checks completed.

2.2 Associated systems completed to the extent necessary to allow the conduct of this test.

3.0 Test Methods

3.1 Align system for normal operation. Position valves in associated systems as necessary to allow response to isolation signals.

3.2 Verify proper functioning of system detectors by utilizing test sources and other procedures as appropriate.

3.3 Verify proper system response to simulated alarm conditions by monitoring controller outputs, alarm indications, and the operation of isolation valves where possible.

4.0 Acceptance Criteria

System effectively monitors and responds to levels of radiation in the plant areas and effluents in accordance with design requirements and Sections 11.4, 12.1.4, and 12.2.4.

Table 14.1-20
Component Cooling Water System

1.0 Objective

Demonstrate the capability of the Component Cooling System to supply design flow to system components.

2.0 Prerequisites

2.1 Component Cooling (CC) System installation and component checks completed.

2.2 Adequate supply of demineralized water available.

2.3 Associated systems completed to the extent necessary to allow conduct of this test.

3.0 Test Methods

3.1 Verify the ability of the CC pumps to deliver design low and high speed flows to system components.

3.2 Verify the ability of the CC system to perform its design functions for SI and recirculation modes of operation.

3.3 Verify CC system controls operate as designed.

4.0 Acceptance Criteria

4.1 System flows, pressures, and automatic functions are in accordance with design requirements identified on the applicable flow diagrams.

4.2 System interlocks, instrumentation, and alarms function properly.

Table 14.1-21
Service Water System

1.0 Objective

Demonstrate the capability of the Service Water System to provide adequate cooling water.

2.0 Prerequisites

2.1 Service Water System installation and component checks completed.

2.2 Associated systems completed to the extent necessary to allow conduct of this test.

3.0 Test Methods

3.1 Align system for normal operation.

3.2 Verify system flow rates and system control.

4.0 Acceptance Criteria

4.1 System flows, pressures, and automatic functions are in accordance with design requirements of Section 9.2.1.

Table 14.1-22
Boric Acid Batching and Transfer System

1.0 Objective

Verify proper functioning of equipment and instrumentation utilized in batching, storage, transfer, and recirculation of boric acid solutions.

2.0 Prerequisites

2.1 Boric Acid System installation and component checks completed.

2.2 Adequate supply of Grade A water available.

2.3 Steam supply available to batching tank jacket heater.

2.4 Associated systems completed to the extent necessary to allow conduct of this test.

3.0 Test Methods

3.1 Align system for normal operation.

3.2 Verify boric acid tank and batching tank level setpoints, controller functions, and steam delivery to batching tank heaters.

3.3 Verify capability of boric acid transfer pumps to deliver water from the batching tank to the boric acid tanks and to recirculate each boric acid tank.

3.4 Verify capability of supplying the charging pump suction header.

4.0 Acceptance Criteria

4.1 System provides for batching, storage, transfer, and recirculation flow paths in accordance with Section 9.3.4.

4.2 Interlocks, automatic functions, alarms, flows, and pressures are within design limits.

Table 14.1-23
Heat Tracing for Boron Injection Tank and Associated Piping

1.0 Objective

Demonstrate the ability of the Heat Tracing System to maintain proper temperature control in the various piping systems involved with the boron injection tank.

2.0 Prerequisites

2.1 Heat Tracing System installation and component checks completed.

2.2 Associated systems completed to the extent necessary to allow the conduct of this test.

3.0 Test Methods

3.1 Energize Heat Tracing System.

3.2 Monitor temperatures maintained by each heat tracing circuit with the system in a static condition.

3.3 Place boron injection recirculation pump in operation and establish transfer flow path.

3.4 Monitor temperatures maintained by each heat tracing circuit.

4.0 Acceptance Criteria

Each heat tracing circuit maintains temperature within allowable design limits.

Table 14.1-24
Reactor Building Cooling System

1.0 Objective

1.1 Demonstrate the operation of the Reactor Building cooling equipment for normal plant operating conditions.

1.2 Demonstrate the capacity of the Reactor Building cooling units to maintain area temperatures within design limits during normal operating conditions.

2.0 Prerequisites

2.1 Reactor Building Cooling System installation and component checks completed.

2.2 Service Water and Industrial Cooling Water Systems operable.

2.3 Associated systems completed to the extent necessary to allow conduct of this test.

3.0 Test Methods

3.1 Align system for normal operation.

3.2 Verify fan, damper, and cooling unit controls, interlocks, and permissives.

3.3 With the plant at, or near, normal operating conditions, survey various areas to verify that temperatures do not exceed design limits.

4.0 Acceptance Criteria

4.1 System interlocks and controls function properly.

4.2 Temperature survey does not show any hot spots or exceed design limits.

Table 14.1-25
Chemical and Volume Control System

1.0 Objective

Demonstrate that the Chemical and Volume Control System (CVCS) performs as required during plant operation.

2.0 Prerequisites

2.1 CVCS installation and component checks completed.

2.2 Reactor Coolant System at the condition specified in the approved test procedure.

2.3 Adequate supply of Grade A water available in refueling water storage tank or reactor makeup tank.

2.4 Associated systems completed to the extent necessary to allow conduct of this test.

3.0 Test Methods

3.1 Align CVCS for normal operation and establish normal flow paths.

3.2 Verify capacities of letdown orifices and pressure drop of reactor coolant filter.

3.3 Check operation of the letdown line temperature and pressure controllers with the demineralizers bypassed.

3.4 Verify operation of excess letdown and seal water subsystems.

3.5 Verify flow rates and pressure drops of demineralizers.

3.6 Verify charging pumps' flow rates and the seal water flow rate for each reactor coolant pump.

3.7 Verify volume control tank level controller operation. Check reactor makeup control system response to inventory changes of volume control tank.

4.0 Acceptance Criteria

System performance, interlocks, and automatic functions are in accordance with Section 9.3.4.

Table 14.1-26
Pressurizer Relief Tank

1.0 Objective

Verify that the pressurizer relief tank provides for adequate control of the discharge from the primary reliefs and safety valves.

2.0 Prerequisites

2.1 Hydrostatic test of pressurizer relief tank completed.

2.2 Pressurizer relief tank installation checks completed.

2.3 Radioactive waste disposal system completed to the extent necessary to allow conduct of this test.

2.4 Adequate supply of Grade A water available.

2.5 Adequate supply of nitrogen available.

3.0 Test Methods

3.1 Verify alarms, interlock operations, and spray flow control.

3.2 Demonstrate ability to maintain nitrogen blanket in pressurizer relief tank.

3.3 Verify transfer flow paths from pressurizer relief tank.

4.0 Acceptance Criteria

Pressurizer relief tank provides disposal of primary plant coolant discharge in accordance with design requirements and Section 5.5.11.

Table 14.1-27
Reactor Coolant System Heatup for Hot Functional Testing

1.0 Objective

Perform functional checks on the Reactor Coolant System and associated systems components and instrumentation required to bring the plant from a cold shutdown condition to normal operating temperature and pressure.

2.0 Prerequisites

2.1 Reactor Coolant System and supporting systems valve lineups for normal operation completed and normal flow paths established.

2.2 Reactor Coolant System cold hydrostatic test completed.

2.3 Preoperational and acceptance tests completed as necessary.

2.4 Instrumentation and control checkouts and calibrations completed as necessary.

2.5 Secondary system ready to receive steam and return feedwater to the steam generators.

2.6 Diesel generators fully operable. Batteries and battery chargers are in service.

2.7 Systems completed to the extent necessary to allow conduct of this test.

3.0 Test Methods

3.1 Establish specified charging and letdown flow rate and seal water flow to the reactor coolant pumps.

3.2 Operate reactor coolant pumps.

3.3 Energize pressurizer heaters and conduct solid system pressure control demonstration.

3.4 Perform chemistry adjustment demonstrations.

3.5 Form pressurizer steam bubble.

3.6 At approximately 100°F intervals, stabilize system parameters and record required data, measurements, and observations for incore thermocouple and RTD cross calibration, reactor coolant pump vibration measurements, and Reactor Coolant System thermal expansion measurements.

Table 14.1-27 (continued)
Reactor Coolant System Heatup for Hot Functional Testing

3.7 Verify ability to maintain steam generator levels by operation of the atmospheric steam dump and the Emergency Feedwater System.

3.8 Check operability of pressurizer power operated relief valves, spray valves, and steam generator atmospheric steam dump valves by either placing in service or performing functional check.

3.9 Main steam power operated relief valves are functionally checked.

4.0 Acceptance Criteria

Systems, components, instrumentation, and controls function within allowable design limits.

Table 14.1-28
Systems Thermal Expansion

1.0 Objective

1.1 Verify that the applicable systems piping can expand without obstruction during initial heatup to normal operating conditions.

1.2 Confirm that systems piping and components return to their approximate baseline cold position after cooldown to ambient conditions.

2.0 Prerequisites

2.1 To commence with the Reactor Coolant System heatup for hot functional testing.

2.2 Hanger lock pins removed and expansion clearances set to the proper cold values.

2.3 Reference points for measurements established.

2.4 Piping supports are verified for proper installation prior to heatup for thermal expansion measurements.

3.0 Test Methods

3.1 Record cold baseline data.

3.2 Obtain a set of measurements during Reactor Coolant System heatup at approximately 250, 350, 450, and 550°F.

3.3 Upon completion of Reactor Coolant System cooldown, obtain a set of measurements.

4.0 Acceptance Criteria

4.1 Piping movements do not cause piping rubs or interference with other equipment.

4.2 Piping movements do not cause undue stresses as determined by inspection.

4.3 Piping and components return to approximate baseline position on cooldown.

Table 14.1-29
Hot Functional Testing

1.0 Objective

Perform functional checks on the Reactor Coolant System and associated systems components and instrumentation required during normal hot plant operation.

2.0 Prerequisites

2.1 Reactor Coolant System heatup completed, Reactor Coolant System conditions of 525-557°F and 2235 psig being maintained.

2.2 Systems completed to the extent necessary to allow conduct of this test.

3.0 Test Methods

3.1 Check the response, stability, and general control characteristics of the pressure control system.

3.2 Perform other tests which required the Reactor Coolant System to be at normal operating no-load temperature and pressure as outlined in the hot functional testing procedures.

4.0 Acceptance Criteria

Systems, components, instrumentation, and controls function within allowable design limits.

Table 14.1-30
Emergency Feedwater System

1.0 Objective

Demonstrate that the Emergency Feedwater System is capable of providing adequate quantities of feedwater for the removal of decay heat.

2.0 Prerequisites

2.1 Emergency Feedwater System installation and component checks completed.

2.2 Condensate storage tank adequately filled to supply the required water for the duration of the test.

3.0 Test Methods

3.1 Verify flow rates of the pumps and system control.

3.2 Verify that the turbine driven emergency feedwater pump cold starts successfully five successive times.

4.0 Acceptance Criteria

4.1 Emergency flow capability of the system meets the design requirements.

4.2 System interlocks and alarms function within allowable design limits.

4.3 The turbine driven emergency feedwater pump cold starts successfully five successive times.

Table 14.1-31
Engineered Safety Features Circuitry

1.0 Objective

1.1 Verify proper operation of motor and air operated valves to the different ESF signals and various interlocks.

1.2 Verify proper operation of breakers to ESF signals.

2.0 Prerequisites

2.1 Associated systems have been checked.

2.2 Necessary breakers are racked out and other conditions are as outlined in test.

3.0 Test Methods

Simulate various ESF signals and note component responses to signals.

4.0 Acceptance Criteria

Valves and breaker respond properly to actuation signals.

Table 14.1-32
Nuclear Sampling System

1.0 Objective

Verify that a quantity of representative fluid can be obtained from each sampling point.

2.0 Prerequisites

2.1 Reactor Coolant System at operating pressure and temperature.

2.2 Installation checks complete.

3.0 Test Methods

3.1 From each nuclear sampling point take a sample.

3.2 Check operation of remotely and manually operated valves.

4.0 Acceptance Criteria

Flows are adequate for gathering samples. Remote valve actuation signals get proper response.

Table 14.1-33
Reactor Coolant System Cooldown from Hot Functional Testing

1.0 Objective

Perform functional checks on the Reactor Coolant System and associated systems components and instrumentation required to bring the plant to the cooled-down, depressurized condition.

2.0 Prerequisites

2.1 Reactor Coolant System hot functional testing completed, Reactor Coolant System conditions of 525-557°F and 2235 psig being maintained.

2.2 Reactor makeup water storage tank contains sufficient quantity of Grade A water to accommodate the contraction of the primary coolant during cooldown.

2.3 Specified systems completed to the extent necessary to allow conduct of this test.

3.0 Test Methods

3.1 Demonstrate the Reactor Coolant System degassing procedure.

3.2 Secure two reactor coolant pumps and commence plant cooldown by decreasing the set pressure of the steam dump valves.

3.3 Record data as required for incore thermocouple and RTD cross calibration.

3.4 When reactor coolant temperature and pressure are below 350°F and 425 psig, place the Residual Heat Removal System in operation.

3.5 Collapse the steam bubble.

3.6 Continue pressurizer and Reactor Coolant System cooldown to 140°F and reduce pressure to 50 psig.

3.7 Establish conditions for Reactor Coolant System draining.

4.0 Acceptance Criteria

Systems, components, instrumentation, and controls function within allowable design limits.

Table 14.1-34
Residual Heat Removal System Flow Tests

1.0 Objective

1.1 To record actual RHR pump data (flow versus head) and compare this to the manufacturer's pump curve.

1.2 To demonstrate proper flow rates in the cold leg injection, cold leg recirculation, and hot leg recirculation modes.

1.3 To demonstrate that motor operated valves in the LHSI system stroke properly against maximum differential pressure.

1.4 Verify proper operation of flow control valves (603A & B, 605A & B).

1.5 To verify the friction loss in the sump suction lines to the RHR pumps and verify vortex control.

1.6 To demonstrate the automatic opening of the RHR sump isolation valves (8811A & B, 8812A & B) on receipt of a RWST lo-lo level signal coincident with a safety injection signal.

1.7 To demonstrate proper RHR system flow rate in the cooldown lineup (RHR pumps taking suction from the Reactor Coolant System loops and discharging back into the Reactor Coolant System cold legs with the reactor vessel head removed).

1.8 To demonstrate that interlocks associated with the following valves operate properly; 8701A, 8701B, 8702A, 8702B, 8706A, and 8706B.

2.0 Prerequisites

2.1 Reactor vessel head is not installed and the internals are not in the vessel.

2.2 Sufficient water available in the RWST to conduct the test.

3.0 Test Methods

3.1 Each RHR pump will be run at various flow rates to record pressure and flow data (motor currents and vibration data will be recorded at full flow).

3.2 Each RHR pump will be run in the cold leg injection, cold leg recirculation (with suction from the RWST instead of the containment sump), and hot leg recirculation (with suction from the RWST instead of the containment sump) modes to record flow rates.

Table 14.1-34 (continued)
Residual Heat Removal System Flow Tests

3.3 Each motor operated valve in the low head safety injection system will be stroked against maximum differential pressure.

3.4 The RHR pumps will be run at various flow rates using flow control valves 603A & B, and 605A & B.

3.5 Each RHR recirculation sump will be flooded with water and each RHR pump will be operated taking suction from its respective sump to verify friction losses in each sump suction line and to demonstrate vortex control.

3.6 Each of the sump isolation valves (8811A & B and 8812A & B) will receive a lo-lo RWST level coincident with a safety injection signal to verify that each of the four valves open.

3.7 Each of the RHR pumps will take a suction from the Reactor Coolant System (with the level in the vessel at least one foot above the nozzles) and discharge back into the Reactor Coolant System cold legs.

3.8 Demonstrate that the interlocks associated with valves 8701A, 8701B, 8702A, 8702B, 8706A, and 8706B operate properly.

4.0 Acceptance Criteria

4.1 Pump performance characteristics and required flow rates in the injection and recirculation modes will be in accordance with design requirements.

4.2 Each motor operated valve will be observed locally for proper operation and timed to verify the valve strokes in less than the maximum allowable time.

4.3 Flow control valves will be monitored to verify no abnormal system flow oscillations.

4.4 Actual friction loss in the sump suction lines will be compared to the calculated friction losses for acceptability. Each sump will be monitored during pump operation to verify that no vortices are formed.

4.5 RHR system flow rate in the cooldown lineup will be in accordance with design requirements.

4.6 Valve interlocks operate as required by design.

Table 14.1-35
Nuclear Instrumentation System

1.0 Objective

Verify that the Nuclear Instrumentation System performs the required indication and control functions through the source, intermediate, and power ranges of operation.

2.0 Prerequisites

2.1 Nuclear Instrumentation System installed with calibration and initial alignments completed.

2.2 System energized for stabilization prior to commencing this test.

2.3 Systems complete as required for conducting this test.

3.0 Test Methods

Using the installed test facilities, verify proper performance of instrumentation, including output signals to the Reactor Protection System, and remote indications.

4.0 Acceptance Criteria

System performance is in accordance with Section 7.2.

Table 14.1-36
Control Building Ventilation Systems

1.0 Objective

1.1 Demonstrate the operation of the following Control Building HVAC systems during normal and abnormal plant operating conditions.

1.1.1 Control Room Ventilation

1.1.2 Relay Room Ventilation

1.1.3 Computer Room Ventilation

1.1.4 Controlled Access Ventilation

1.2 Confirm the proper operation of system equipment interlocks and controls.

1.3 Measure the total Control Room boundary leak rate.

2.0 Prerequisites

2.1 Individual Control Building Ventilation systems installation and component checks completed.

2.2 Associated systems completed to the extent necessary to allow conduct of this test.

2.3 Control Room pressure boundaries are sealed properly.

3.0 Test Methods

3.1 Verify fan, damper, heater, humidifier, and cooling unit controls, interlocks, and permissives for all systems.

3.2 Verify isolation damper operation on applicable systems.

3.3 Verify actuations from radiation monitors and safety injection signals on applicable systems.

3.4 Verify that Control Room internal pressure is greater than atmospheric pressure with a maximum of 400 cfm admitted from outside air.

Table 14.1-36 (continued)
Control Building Ventilation Systems

4.0 Acceptance Criteria

4.1 The dampers and fans respond to recirculation signals in accordance with Sections 6.5.1 and 9.4 for applicable systems.

4.2 Fans, dampers, heaters, humidifiers, and cooling units function correctly for each system.

4.3 Control Room is maintained at positive (1/8”) differential pressure with respect to atmosphere in the normal and emergency modes of operation.

4.4 Control Room leak rate does not exceed its maximum design value.

Table 14.1-37
Core Loading Instrumentation

1.0 Objective

Verify proper operation of the source range instrumentation channels prior to fuel loading operations.

2.0 Prerequisites

2.1 Temporary source range instrumentation installation checks completed.

2.2 Permanent source range channels operable.

3.0 Test Methods

3.1 Perform calibration of each source range channel.

3.2 Verify response of each channel to a neutron source.

3.3 Verify audible signal from at least one permanent channel available in Control Room and Reactor Building.

4.0 Acceptance Criteria

Instrumentation provides monitoring of source range neutron level for loading fuel as required by the Technical Specifications.

Table 14.1-38
Reactor Components and Fuel Handling Tools and Fixtures

1.0 Objective

Verify the adequacy of the special equipment required for refueling operations.

2.0 Prerequisites

Equipment to be checked out is onsite and inspected in accordance with the routine receiving inspection.

3.0 Test Methods

3.1 Check each tool for smooth performance and complete actuation.

3.2 Check adequacy of locating devices, guides, and chambers.

3.3 Verify operation of interlocks and/or safety devices.

3.4 Verify load test lifting devices.

4.0 Acceptance Criteria

Equipment provides for safe handling of fuel assemblies and reactor components.

NOTES:

1. Test may be conducted with a dummy fuel element when a fuel element is necessary for test.

2. Testing was conducted on the polar crane in accordance with standard crane testing procedures during the construction of the station. This test included:

   a. Hoists upper and lower limit switches verified.

   b. Load test to 125 percent.

   c. Operational performance under load.

   The polar crane is under the administrative controls of the nuclear operations department.

Table 14.1-39
Fuel Transfer System

1.0 Objective

Provide functional demonstration of the Fuel Transfer System and fuel handling tools prior to initial core load.

2.0 Prerequisites

2.1 Reactor components and fuel handling tools and fixtures test completed.

2.2 Fuel Transfer System installation and component checks completed.

2.3 Reactor vessel head and upper internals stored in the refueling positions.

2.4 Dummy fuel assembly stored in a new fuel storage rack.

3.0 Test Methods

With canal drained, conduct the various fuel handling evolutions with the dummy fuel assembly.

4.0 Acceptance Criteria

System provides for storage, transfer, and handling of fuel assemblies as designed.

NOTE: Test may be conducted with a dummy fuel element when an element is needed.

Table 14.1-40
Safety Injection High Head Flow Balancing Test

1.0 Objective

1.1 To establish proper positioning of the high head cold leg injection and recirculation throttle valve (8996A, B, C, 9884A, B, C) to balance injection flows to each loop and to limit charging pump runout flow.

1.2 To establish proper positioning of the high head hot leg recirculation throttle valves (8989A, B, C, 8991A, B, C) to balance injection flows to each loop and to limit charging pump runout flow.

1.3 To record actual charging pump data (flow versus head) and compare this to manufacturer's pump curve.

1.4 To demonstrate that motor operated valves in the high head S. I. System stroke properly against maximum expected differential pressure.

1.5 To demonstrate that the charging pumps are capable of taking a suction from the RHR pumps.

2.0 Prerequisites

2.1 Reactor vessel head is not installed and the internals are not in the vessel.

2.2 Sufficient water available in RWST to conduct test.

3.0 Test Methods

3.1 Each charging pump will be run through the cold leg injection path. Throttle valves will be adjusted to provide the minimum required branch line flows from the pump whose flow path has the highest resistance (lowest flow) to the throttle valves. The throttle valves will then be locked in position and flow from each pump will be run through the branch lines to verify that minimum flow rates are still met and charging pump runout flow is limited. This method of testing will also be used for positioning throttle valves in the cold leg recirculation and hot leg recirculation flow paths.

3.2 Each charging pump will be run at various flow rates through the high head injection lines to record pressure and flow data (motor currents and vibrations data will be recorded at full flow).

Table 14.1-40 (continued)
Safety Injection High Head Flow Balancing Test

3.3 Each charging pump will be operated while taking suction from an RHR pump. The charging pumps will be lined up to provide flow through one of the four high head safety injection flow paths.

4.0 Acceptance Criteria

Pump performance characteristics and minimum required flow rates in the injection and recirculation flow paths will be in accordance with design requirements. Each motor operated valve will be observed locally for proper operation and timed to verify the valve strokes in less than the maximum allowable time. Each charging pump will be observed for any abnormal vibration under full flow when taking suction from the RHR pumps.

Table 14.1-41
S. I. Accumulator Blowdown Test

1.0 Objective

1.1 To demonstrate accumulator blowdown and verify that the accumulator blowdown data are within the acceptable L/D range for each accumulator.

1.2 Time the opening of each accumulator discharge valve (8808A, B, & C) under flow conditions.

2.0 Prerequisites

2.1 The reactor vessel head is not installed and the internals are not in the vessel.

3.0 Test Methods

3.1 Fill each accumulator to a level consistent with vendor supplied accumulator blowdown prerequisites.

3.2 Connect a brush recorder to accumulator pressure and level instrumentation and to the accumulator discharge valve indication circuitry.

3.3 Pressurize each accumulator to 100 psig.

3.4 Start the brush recorder and then open the accumulator discharge valve.

3.5 Using data obtained during accumulator blowdowns, calculate the L/D for each accumulator discharge line.

4.0 Acceptance Criteria

The L/D values for each accumulator discharge line are within design limits and that each accumulator discharge valve opens in less than the maximum allowable stroke time.

4.1 Pressure and level alarm setpoints are proper.

4.2 Valve opening times and blowdown rates satisfy design requirements.

Table 14.1-42
Spent Fuel Cooling System

1.0 Objective

Demonstrate flow capabilities of the Spent Fuel Cooling System.

2.0 Prerequisites

2.1 Spent Fuel Cooling System installation and component checks completed.

2.2 Adequate supply of Grade B water available.

2.3 No fuel is stored in the spent fuel pool.

3.0 Test Methods

3.1 Demonstrate filling and draining of the spent fuel pool, fuel transfer canal, cask loading area, and the refueling water storage tank.

3.2 Demonstrate circulation through demineralizer loop, heat exchangers, and skimmer loop.

4.0 Acceptance Criteria

System provides for filling, draining, and/or purification of the water in the spent fuel pool, fuel transfer canal, the cask loading area, and refueling water storage tank in accordance with Section 9.1.3.

Table 14.1-42a
Spent Fuel Cooling System

1.0 Objective

Demonstrate flow capabilities of the Spent Fuel Cooling System.

2.0 Prerequisites

2.1 Spent Fuel Cooling System installation and component checks.

2.2 Reactor coolant drain tank and pumps installation and component checks completed.

2.3 Adequate supply of Grade B water available.

3.0 Test Methods

3.1 Demonstrate filling and draining of the refueling canal and refueling cavity.

3.2 Demonstrate circulation through demineralizer loop and skimmer loop.

4.0 Acceptance Criteria

System provides for filling, draining, and/or purification of the water in the refueling canal and refueling cavity, in accordance with Section 9.1.3.

Table 14.1-43
Containment Isolation System

1.0 Objective

Demonstrate the capability of the containment isolation system to respond properly to an isolation signal.

2.0 Prerequisites

2.1 Containment isolation system installation and component checks completed.

2.2 Associated systems completed to the extent necessary to allow the conduct of this test.

2.3 Containment isolation system and the applicable isolation valves in associated systems aligned for normal operation.

3.0 Test Methods

3.1 Verify component response to Phase A containment isolation by manually initiating a Phase A containment isolation signal from the MCB.

3.2 Verify component response to Phase B containment isolation by manually initiating a spray actuation signal from the MCB.

4.0 Acceptance Criteria

System response to containment isolation actuation signals is in accordance with Section 6.2.4.

Table 14.1-44
Reactor Protection Operational Check

1.0 Objective

Verify the correct installation and proper operation of the reactor trip portion of the Reactor Protection System.

2.0 Prerequisites

2.1 Reactor plant in cold shutdown condition.

2.2 Instrumentation and Reactor Protective Systems installation checks and calibrations completed.

3.0 Test Methods

3.1 Utilizing the appropriate train test panels, conduct individual tests of each train's tripping logic.

3.2 Conduct overall logic test for both trains.

4.0 Acceptance Criteria

System performance is in accordance with Section 7.2 and the approved test procedure.

Table 14.1-45
Engineered Safety Features System Operational Check

1.0 Objective

Verify the operation of the ESF logic systems for all conditions of trip logic.

2.0 Prerequisites

2.1 Instrumentation and ESF systems installation checks and calibration completed.

2.2 Reactor plant in cold shutdown condition prior to core loading.

3.0 Test Methods

3.1 Conduct individual train logic tests.

3.2 Conduct overall logic test for both trains.

3.3 Verify redundant tripping of each ESF channel through to the relay or controller that actuates the ESF device.

4.0 Acceptance Criteria

System performance is in accordance with Section 7.3.

Table 14.1-46
Integrated Engineered Safety Features Test

1.0 Objective

Demonstrate the capability of the ESF equipment during a simulated accident condition to function in the proper sequence of manner within acceptable parameters.

2.0 Prerequisites

2.1 ESF systems checks and component checks completed.

2.2 Emergency diesel generators are fully operational.

2.3 Systems to be tested are filled and aligned in recirculation with the appropriate storage tanks.

3.0 Test Methods

3.1 Verify the train A ESF load group assignment and component response to an ESF signal by defeating the automatic start of the train B diesel generator and de-energizing the train B ESF 7200 volt bus 1DB, then manually initiating a safety injection and spray actuation from the MCB.

3.2 Verify the train B ESF load group assignment and component response to an ESF signal by defeating the automatic start of the train A diesel generator and de-energizing the train A ESF 7200 volt bus 1DA, then manually initiating a safety injection and spray actuation signal from the MCB.

3.3 Verify the train A & B ESF component response to ESF signals with offsite power by manually initiating a safety injection and spray actuation signal from the MCB.

3.4 Verify the train A & B ESF component response to ESF signals with only onsite power by simultaneously de-energizing offsite power and manually initiating a safety injection and spray actuation signal from the MCB. Diesel generator starting time and loading sequence will be recorded.

4.0 Acceptance Criteria

4.1 Emergency diesel generators respond within acceptable design limits.

4.2 ESF systems and components respond as required.

Table 14.1-47
Reactor Building Spray System

1.0 Objective

1.1 To record actual Reactor Building Spray pump data (flow vs. head) and compare this to the manufacturer's pump curve.

1.2 To demonstrate that motor operated valves in the Reactor Building Spray System stroke properly against maximum differential pressure.

1.3 To determine the friction loss in the sump suction lines to each Reactor Building Spray pump and verify vortex control.

1.4 To demonstrate that the spray ring nozzles are free of obstructions.

1.5 To record the NaOH drawdown rates using various combinations of ECCS pumps.

2.0 Prerequisites

2.1 Reactor Building Spray System installation and component checks completed.

2.2 Sufficient Grade A water available in the refueling water storage tank and sodium hydroxide storage tank.

3.0 Test Methods

3.1 Each Reactor Building Spray pump will be run at various flow rates to record pressure and flow data (motor currents and vibration data will be recorded at full flow).

3.2 Each motor operated valve in the Reactor Building Spray System will be stroked against maximum differential pressure.

3.3 Each Reactor Building Spray pump recirculation sump will be flooded with water and each Reactor Building Spray pump will be run taking a suction from its respective sump to determine friction losses in each pump suction line and to demonstrate vortex control.

3.4 Air will be forced through each spray nozzle to verify that nozzles are free of obstructions.

3.5 Various combinations of ECCS pumps will be run and the NaOH drawdown rates will be recorded for each combination.

Table 14.1-47 (continued)
Reactor Building Spray System

4.0 Acceptance Criteria

4.1 Actual pump performance characteristics will be in accordance with design requirements.

4.2 Each motor operated valve will be observed locally for proper operation and timed to verify the valve strokes in less than the maximum allowable time.

4.3 Actual friction loss in the sump suction lines will be compared to the calculated friction losses for acceptability. Each sump will be monitored during pump operation to verify no vortexes are formed.

4.4 Each spray nozzle will be checked to ensure it passes air.

4.5 Actual NaOH drawdown rates will be analyzed for acceptability.

Table 14.1-48
Leak Detection Monitoring System

1.0 Objective

Demonstrate system capability of detecting the presence of significant leakage from the reactor coolant loops to the Reactor Building atmosphere during normal operations.

2.0 Prerequisites

2.1 Leak Detection Monitoring System installation and component checks completed.

2.2 Associated system completed to the extent necessary to allow the conduct of this test.

3.0 Test Methods

3.1 Verify proper functioning of containment air particulate monitor and radioactive gas monitor detectors by exposure to standard test sources.

3.2 Verify monitor's flow rates and associated controls, indications, and alarms.

3.3 Verify proper functioning of leak detection instrumentation associated with the system.

4.0 Acceptance Criteria

System provides for monitoring of Reactor Coolant System leakage within design acceptance limits.

Table 14.1-49
Post Accident Hydrogen Removal System

1.0 Objective

Demonstrate the capability of the Post Accident Hydrogen Removal System to provide adequate flow and heat for removal of combustible gases.

2.0 Prerequisites

Post Accident Hydrogen Removal System installation and component checks completed.

3.0 Test Methods

3.1 Verify remote actuation.

3.2 Demonstrate ability to obtain atmospheric samples from each sample point.

3.3 Verify proper operation of each hydrogen recombiner.

4.0 Acceptance Criteria

Hydrogen recombiners function as designed.

Table 14.1-50
Radioactive Waste Disposal System

1.0 Objective

Demonstrate the ability of the Radioactive Waste Disposal System to provide controlled handling and disposal of solid, liquid, and gaseous radioactive wastes.

2.0 Prerequisites

2.1 Solid Waste Processing, Liquid Waste Processing, and Gaseous Waste Processing Systems installation and component checks completed.

2.2 Associated systems completed to the extent necessary to allow the conduct of this test.

3.0 Test Methods

3.1 The system will be tested in a series of functional Phase I tests as described in Table 14.1-85 for the following subsystems:

a. Reactor coolant drain tank and pumps

b. Waste evaporator feed pump and holdup tank

c. Floor drain tank and pump

d. Waste evaporator condensate tank and pump

e. Waste evaporator

f. Chemical drain tank and pump

g. Spent resin storage and transfer

h. Laundry and hot shower tank and pump

i. Waste monitor tank and pump

j. Waste evaporator concentrates tank and pump

k. Radwaste solidification module

l. Excess waste holdup tank and pump

Table 14.1-50 (continued)
Radioactive Waste Disposal System

m. Decontamination pit collection tank and pump

n. Nuclear drain sump pumps

o. Waste gas compressors and control valves

p. Waste gas hydrogen recombiners

q. Waste gas decay tank drain pump

4.0 Acceptance Criteria

System provides controlled handling and disposal of radioactive wastes in accordance with Sections 11.2, 11.3, and 11.5.

Table 14.1-51
Boron Thermal Regeneration System

1.0 Objective

Operationally checkout the Boron Thermal Regeneration System (BTRS) and operate the system with letdown flow.

2.0 Prerequisites

2.1 BTRS installation and component checks completed.

2.2 The Reactor Coolant System at normal operating temperature and pressure.

2.3 Associated systems completed to the extent necessary to allow the conduct of this test.

3.0 Test Methods

3.1 Align the system for normal operation.

3.2 Operate the system in the dilution and the boration modes.

4.0 Acceptance Criteria

System flow, pressures, and temperatures are within design limits.

Table 14.1-52
Reactor Protection System Time Response Measurement

1.0 Objective

Verify the Reactor Protection System response times and function of each trip path including sensor response time. Response time measurements will be verified for all sensors for which response time measurements are required by Technical Specifications, Tables 3.3-2 and 3.3-5.

2.0 Prerequisites

2.1 To be performed prior to initial fuel loading.

2.2 Instrumentation and Reactor Protective System installation checks and calibrations completed.

3.0 Test Methods

3.1 Utilizing test panels and temporary instrumentation as required, measure the time response and verify the functioning of each trip path in the reactor protective circuitry by simulating the sensor input to the process protection cabinets.

For ESF trip paths, the time response measured will include the sensor input to the process protection cabinets through the energization of the slave relay in the solid state protection cabinets.

Component response times (i.e., the valves travel to their required position, pump discharge pressures reach their required values, etc.) will be obtained from the preoperational test performed on the systems for which the component is a part.

Diesel generator starting and sequence loading delays will be obtained from the Integrated Engineered Safety Features Test (Table 14.1-46).

Sensors response times will be obtained by vendor testing, by onsite bench testing, or by in-place testing.

The response times measured by this test and those sensor time responses obtained as outlined above and the component time response obtained from preoperational tests will be algebraically summed to obtain an overall response time for each trip path.

Delays in sensing lines will be determined analytically.

Table 14.1-52 (continued)
Reactor Protection System Time Response Measurement

4.0 Acceptance Criteria

Response times of the individual "trip paths" including process to sensor coupling delay are less than the maximum allowable times specified in the Technical Specifications, Tables 3.3-2 and 3.3-5.

Table 14.1-53
Initial Fuel Loading

1.0 Objective

To accomplish initial fuel loading in a safe, orderly manner.

2.0 Prerequisites

2.1 All the tests required to be performed before fuel loading is completed.

2.2 The Residual Heat Removal System is maintaining the coolant in constant recirculation.

2.3 Boron concentration is sufficient to maintain $K_{eff} \leq .95$.

2.4 Five source range neutron detectors are installed; two permanently installed, two temporary incore, and a third temporary to act as a spare.

2.5 Containment integrity has been established.

3.0 Test Methods

3.1 An initial nucleus of eight fuel assemblies with a source is loaded.

3.2 Using an inverse neutron count rate plot as a guide to ensure safe loading, fuel assemblies are placed in the core until core loading is complete.

4.0 Acceptance Criteria

The core is loaded in the specified configuration barring mechanical damage to an assembly.

Table 14.1-54
Incore Movable Detectors

1.0 Objective

Verify proper response of the individual channels of instrumentation and the ability to accurately position the detectors of the Incore Movable Detector System.

2.0 Prerequisites

2.1 Incore Movable Detector System installation and component checks completed.

2.2 “Manual local” operation has been checked using a dummy cable.

2.3 Core installed.

2.4 Gas Purge System and Leak Detection System installation and component checks completed.

3.0 Test Methods

3.1 Align system for normal operation.

3.2 Verify proper operation of all transfer devices, isolation valves, safety and limit switches, and readout and control equipment.

3.3 Compare position readouts with observed position of detectors.

4.0 Acceptance Criteria

4.1 System provides mapping capability as described in Section 7.7.

Table 14.1-55
Rod Drop Time Measurement

1.0 Objective

Determine the drop time for each full length control rod at no flow cold conditions and at full flow hot conditions. Also, the slowest rod and the fastest rod are tripped 10 times at no flow/cold conditions and at full flow/hot conditions.

2.0 Prerequisites

2.1 Core installed and reactor vessel head in place.

2.2 Boron concentration equal to or greater than that required for refueling shutdown.

2.3 Rod Position Indication System operable.

2.4 Both source range protection channels available in the control room.

3.0 Test Methods

3.1 Withdraw selected bank to the fully withdrawn position.

3.2 Conduct individual rod drop tests, recording rod drop time, rod travel time, and other specified data.

3.3 Repeat for all banks of full length rods in required conditions of flow and temperature.

3.4 Drop the slowest rod and the fastest rod 10 times at the required flow and temperature conditions.

4.0 Acceptance Criteria

4.1 Drop time for all rods is less than the maximum value specified in the Technical Specifications.

4.2 Operation of the dashpot for all rods, as indicated by recorder traces, will be verified.

Table 14.1-56
Rod Drive Mechanism Timing

1.0 Objective

Verify proper timing of each Rod Control System slave cycler and conduct an operational check of each full length control rod drive mechanism.

2.0 Prerequisites

2.1 All full length control rod drive mechanism equipment installed with rod control cluster assemblies attached.

2.2 Reactor Coolant System filled and vented.

2.3 Boron concentration equal to or greater than that required for refueling shutdown.

2.4 Baseline count rates established for each source range channel.

2.5 Test is to be performed at cold and hot standby conditions.

3.0 Test Methods

3.1 Verify the timing of each power cabinet's slave cycler.

3.2 Conduct individual mechanism operational checks by withdrawing and inserting each mechanism a specified number of steps while obtaining an oscillograph trace.

4.0 Acceptance Criteria

Mechanism timing and operational checks verified to be within acceptable design limits.

Table 14.1-57
Rod Position Indication

1.0 Objective

1.1 Demonstrate that the Rod Position Indication System performs the required indication and alarm functions for each full length rod control cluster assembly.

1.2 Demonstrate performance of the full length rod control cluster assemblies over their full range of travel.

2.0 Prerequisites

2.1 Reactor Coolant System at normal operating no load temperature and pressure.

2.2 Boron concentration equal to or greater than that required for refueling shutdown.

2.3 Cold shutdown alignment and adjustments of Rod Position Indication System completed.

3.0 Test Methods

3.1 The rods are withdrawn in groups and their indicated positions are compared with the group step counters.

4.0 Acceptance Criteria

4.1 Indicators and alarms function in accordance with Section 7.7.

Table 14.1-58
Reactor Coolant System Flow Measurement

1.0 Objective

Obtain the data to compute actual Reactor Coolant System flow rates as they relate to the design flow rates.

2.0 Prerequisites

2.1 Core installed.

2.2 Reactor plant is in hot standby condition with all control rods fully inserted.

2.3 Reactor coolant pumps operable.

3.0 Test Methods

3.1 Measure loop temperatures, loop elbow tap Δp's, and reactor coolant pump input power and speed for various configurations of reactor coolant pumps.

3.2 Compute actual Reactor Coolant System flow rate. Density variation of cold leg fluid will be accounted for in the data reduction method to provide direct comparison to full power conditions.

4.0 Acceptance Criteria

4.1 Reactor Coolant System flow rates are determined to be greater than or equal to the thermal design minimum less than or equal to the mechanical design maximum as per FSAR Table 5.1-1.

4.2 If the criteria as described in 4.1 are not met, the power level will be restricted to the rated thermal power which the measured Reactor Coolant System flow rate will support.

Table 14.1-59
Reactor Coolant System Flow Coastdown

1.0 Objective

1.1 Measure the rate at which Reactor Coolant System flow changes subsequent to reactor coolant pump stops and starts.

1.2 Measure time delays associated with the loss of flow accident.

2.0 Prerequisites

2.1 Core installed.

2.2 Reactor plant is in hot standby condition with all control rods fully inserted.

3.0 Test Methods

3.1 Selectively trip reactor coolant pumps from various configurations of pump operation.

3.2 Measure required flow data and response times for each configuration of pump operation.

4.0 Acceptance Criteria

4.1 Time delays associated with the loss of flow accident are within the design values.

4.2 Rate of change of reactor coolant flow is within the design limits for the various pump configurations.

Table 14.1-60
Resistance Temperature Detector Bypass Loop Flow Verification

1.0 Objective

To ensure the flow necessary to achieve the design objective for reactor coolant transport time in each resistance temperature detector (RTD) bypass loop and to verify flow setpoint.

2.0 Prerequisites

2.1 The Reactor Coolant System is at normal operating no load temperature and pressure.

2.2 Installed pipe measurements have been made and necessary construction and tests are finished.

3.0 Test Methods

3.1 Measure flow in RTD bypass loops.

3.2 Reduce flow to verify alarm setpoints.

3.3 Increase flow and verify alarm setpoints.

4.0 Acceptance Criteria

4.1 Flow gives a transport time of 1 second or less in the RTD bypass loops such that the total time response given in Technical Specification Table 3.3-2, item 7, is not exceeded.

4.2 Alarms actuate and clear at proper setpoints.

Table 14.1-61
Reactor Vessel O-Ring Leak Test

1.0 Objective

Verify that there is no leakage past the reactor vessel head and vessel seal following installation of the reactor vessel head after core loading.

2.0 Prerequisites

2.1 Core installed, reactor vessel head installed, and reactor vessel head studs torqued.

2.2 Reactor Coolant System pressure integrity verified in accordance with ASME Code prior to core loading.

3.0 Test Methods

3.1 Establish normal operating no load temperature and pressure conditions for Reactor Coolant System.

3.2 Increase system pressure to 100 psi above operating pressure and check for leakage past the head and vessel seal.

4.0 Acceptance Criteria

Acceptable leakage past reactor vessel head and vessel seal is determined.

Table 14.1-62
Pressurizer Spray and Heater Capability and Setting Continuous Spray Flow

1.0 Objective

1.1 Establish proper continuous spray flow rates.

1.2 Verify pressurizer normal control spray effectiveness.

1.3 Verify pressurizer heater effectiveness.

2.0 Prerequisites

2.1 Core installed.

2.2 Plant is in shutdown condition at approximately the normal operating no load temperature and pressure.

3.0 Test Methods

3.1 Adjust continuous spray flow rates such that ΔT between the pressurizer and spray lines is less than or equal to 200°F and the spray line low-temperature alarms are clear.

3.2 Check normal control spray effectiveness by spraying down to approximately 2000 psig.

3.3 Check heater effectiveness by energizing heaters with power operated relief valves in “close” and spray and level controls in manual. Allow pressure to increase to approximately 2300 psig.

4.0 Acceptance Criteria

4.1 Continuous spray flow adjusted in accordance with design requirements.

4.2 Heater and normal control spray effectiveness are in accordance with design requirements.

Table 14.1-63
Water Quality Test

1.0 Objective

Verify acceptable water quality of Reactor Coolant System fill and makeup water prior to initial criticality.

2.0 Prerequisites

2.1 Reactor Coolant System filled and vented in preparation for initial criticality.

2.2 Reactor makeup water storage tank at operating level.

3.0 Test Methods

3.1 Sample Reactor Coolant System and analyze for chlorides, conductivity, total dissolved solids, pH, clarity, and fluorides.

3.2 Sample Reactor Makeup Water System and analyze for the above.

4.0 Acceptance Criteria

Analyses are within the limits specified in the Technical Specifications.

Table 14.1-64
Initial Criticality

1.0 Objective

To bring the reactor critical.

2.0 Prerequisites

2.1 All tests to be performed before the initial criticality have been performed.

2.2 Reactor Coolant System is at normal operating temperature and pressure.

3.0 Test Methods

3.1 Withdraw shutdown bank.

3.2 Withdraw control banks leaving the last bank far enough in to provide effective control.

3.3 Dilute the reactor coolant until critical.

3.4 Achieve steady-state hot zero power by using control rod movement.

4.0 Acceptance Criteria

The reactor achieves criticality in an orderly, safe manner.

Table 14.1-65
Low Power Test

1.0 Objective

1.1 Verify nuclear instrumentation overlap.

1.2 Verify point of adding heat.

1.3 Measure rods out boron concentration.

1.4 Determine moderator temperature coefficient.

1.5 Determine integral and differential worths for sequenced control banks.

1.6 Determine differential boron worth.

1.7 Measure ejected control cluster assembly worth at hot zero power.

2.0 Prerequisites

2.1 The Reactor Coolant System is in the hot zero power condition with the reactor critical.

2.2 Reactor Coolant System temperature is being maintained.

2.3 Required signals for data collection and recording are available.

3.0 Test Methods

3.1 The neutron flux level will be increased by outward control rod motion and the nuclear instrumentation overlap recorded. Adjustments will be made as necessary to ensure minimum overlap as described in the Technical Specifications.

3.2 The neutron flux level will be increased by outward control rod motion until temperature feedback effects are noted. The upper limit for zero power physics testing is defined as approximately one decade below this level.

3.3 The all rods out, critical boron concentration is determined by measuring the just critical boron concentration with bank D near the fully withdrawn position. The amount of reactivity held down by bank D is then dynamically determined by withdrawal of bank D, noting the amount of reactivity inserted and converting this value to an equivalent amount of boron.

Table 14.1-65 (continued)
Low Power Test

3.4 The moderator temperature coefficient for various boron concentrations is obtained by dynamically measuring the reactivity change due to a temperature change in the primary system.

3.5 The sequenced bank differential rod worth is determined by either borating the Reactor Coolant System while withdrawing the control banks or by diluting the Reactor Coolant System while inserting the control banks to maintain nominal system criticality. Integral worth is then determined from the differential reactivity data.

3.6 Differential boron worth at hot zero power is determined by obtaining and analyzing reactor coolant samples for boron content in conjunction with control bank movement to maintain nominal criticality during boration. Boron concentration as a function of time in combination with integrated reactivity as a function of time is used to plot reactivity versus boron concentration, the slope of which yields differential boron worth.

3.7 Ejected rod cluster control assembly worth at hot zero power is determined by obtaining a critical configuration with the sequenced rod banks at their insertion limit as defined in the Technical Specifications. The most reactive inserted rod is withdrawn to maintain nominal criticality during boration. The reactivity addition is determined by summing the differential reactivity insertions as the rod is withdrawn to its withdrawal limit.

4.0 Acceptance Criteria

4.1 Nuclear instrumentation overlap meets the minimum requirements.

4.2 The all rods out, critical boron concentration is within ± 50 ppm of design prediction.

4.3 The moderator temperature coefficient is negative under the allowed conditions of normal critical operation.

4.4 Measured integral worths for control banks are within 10 percent of predicted worths and total worth of all rods less the most reactive rod exceeds the shutdown reactivity requirements throughout the fuel cycle.

4.5 Differential boron worth, over the range measured, is within ± 10 percent of the predicted value.

Table 14.1-65 (continued)
Low Power Test

4.6 The measured integral reactivity worth of the RCCA withdrawn during the rod ejection test, and the resultant hot channel factor, F_Q, are less than or equal to the values used in the safety analysis with adequate allowance for measurement uncertainty.

Table 14.1-65a
Augmented Low-Power Test

1.0 Objective

1.1 Demonstrate decay heat removal capability of natural circulation.

1.2 Determine the depressurization rate following a loss of pressurizer heaters for evaluation of the loss of all AC emergency procedure.

1.3 Demonstrate to the plant operators the effect of increased charging flow and reduced steam generator pressure on the saturation margin.

1.4 Demonstrate under simulated loss of offsite power conditions that decay heat can be removed via the steam generators by maintaining steam generator level with the Emergency Feedwater System.

1.5 Demonstrate under simulated loss of onsite and offsite power conditions that decay heat can be removed via the steam generators by maintaining steam generator level with the Emergency Feedwater System.

1.6 Demonstrate boron mixing and Reactor Coolant System cooldown using natural circulation (credit for this objective may be taken for testing completed on a similar plant).

1.7 Train Operators on a simulator in:

a. Natural circulation operations

b. The use of auxiliary pressurizer spray

c. Loss of offsite, and loss of offsite and onsite AC power

2.0 Prerequisites

2.1 The Reactor Coolant System and all emergency and auxiliary systems are at the conditions specified in the appropriate approved test procedure.

2.2 Required signals for data collection and recording are available.

2.3 Reactor Power is maintained less than or equal to 5 percent.

Table 14.1-65a (continued)
Augmented Low-Power Test

3.0 Test Methods

3.1 In hot standby with the reactor coolant pumps supplying heat input to the secondary side, simulate removal of onsite AC power sources and operate the plant utilizing manual control and the steam driven emergency feedwater pump. HVAC to the pump room is isolated to verify pump operability in this environment.

3.2 After fuel loading, but prior to Initial Criticality, establish stable condition at T_{no} Load and 2235 psig with RCP B in operation. Reduce pressure by turning off pressurizer heaters noting depressurization rate. Re-establish heaters and reduce pressure by use of auxiliary spray noting depressurization rate and effect on margin to saturation temperature. At reduced pressure, observe the effects of changes in charging flow and steam flow on margin to saturation temperature.

3.3 With the reactor critical at approximately 3 percent reactor power, place the plant in natural circulation mode observing the length of time for plant to stabilize, flow distribution, power distribution, and ability to maintain cooling mode.

3.4 Perform Loss-of-Offsite Power/Station Blackout Test with plant trip from 10-20 percent Rated Thermal Power. Operate Plant establishing stable conditions in natural circulation using batteries and emergency diesels.

3.5 Referencing boration and cooldown tests performed at Sequoyah I, North Anna II, Farley II, and Diablo Canyon I, verify similar plant response by parameter and plant comparison. Operator training for cooldown on natural circulation provided on a simulator.

4.0 Acceptance Criteria

4.1 Natural circulation was established and maintained under steady state conditions in all cases.

4.2 Operator training during natural circulation was accomplished.

4.3 Adequate boron mixing during Reactor Coolant System cooldown on natural circulation has been proven at Virgil C. Summer Nuclear Station or credit has been taken for this test performed on a similar plant.

Table 14.1-66
Incore Movable Detector and Thermocouple Mapping at Power

1.0 Objective

To obtain and analyze core power distributions for various control rod configurations at each major power plateau.

2.0 Prerequisites

2.1 The reactor is critical at a steady-state power level.

2.2 Incore Instrumentation System functional test is complete and the system is operable.

2.3 Computer systems are operable as necessary for incore map processing.

3.0 Test Methods

Reactor power level is stabilized and complete incore flux maps are obtained and processed.

4.0 Acceptance Criteria

Core peaking factors are within acceptable limits as defined in the Technical Specifications.

Table 14.1-67
Power Coefficient and Power Defect Measurement

1.0 Objective

To determine the differential power coefficient of reactivity and the integral power defect.

2.0 Prerequisites

2.1 The reactor is in the hot zero power condition with rods in the specified maneuvering band.

2.2 The instrumentation necessary for collection of data is installed, calibrated, and operable.

3.0 Test Methods

Reactor power is maintained congruent with turbine load demand by control bank adjustment throughout the range of each load change from the hot zero power condition to the hot full power condition. Reactivity increments due to periodic control bank steps are determined and recorded throughout each load change. At selected power levels, conditions are stabilized and a heat balance obtained to accurately determine core power. Power coefficient and power defect are calculated with data obtained over the range from hot zero power to hot full power.

4.0 Acceptance Criteria

4.1 The best estimate of the measured power coefficient as a function of power, derived from experimental data, is equal to or more conservative than that used in the accident analysis.

4.2 The measured power defect is compatible with design predictions.

Table 14.1-68
Effluent Radiation Monitor Test

1.0 Objective

To verify the performance of the effluent monitors under actual discharge conditions. This test is to be performed at each major power plateau.

2.0 Prerequisites

2.1 The reactor has been operating for a time sufficient to generate representative effluents.

2.2 The effluent monitors have been checked against known sources.

3.0 Test Methods

Following standard procedures, the suitability of effluents for discharge is verified by radiochemical analysis. Discharge is commenced and the response of effluent monitors is observed and recorded. Effluent is sampled in accordance with established procedures and effluent monitor performance is verified through radiochemical analysis.

4.0 Acceptance Criteria

The installed effluent monitors perform in accordance with design standards and properly indicate the radioactive content of the effluent.

Table 14.1-69
Radiation Shielding Survey

1.0 Objective

To measure radiation dose levels at preselected points throughout the plant to verify shielding effectiveness.

2.0 Prerequisites

2.1 Radiation survey instruments to be used are calibrated against known sources.

2.2 The reactor is critical at a steady-state power.

3.0 Test Methods

In accordance with procedures for radiation surveys, dose levels are measured at points throughout the station.

4.0 Acceptance Criteria

Measured radiation levels are within the limits for the zone designation of each area surveyed.

Table 14.1-70
Process Computer

1.0 Objective

Verify the output value printout of the nonsafety related process computer for computer inputs.

2.0 Prerequisites

Computer has been functionally checked out.

3.0 Test Methods

Data comparisons are made between simulated process signals and the printout of the process computer.

4.0 Acceptance Criteria

4.1 Errors between simulated process signals and computer output are within acceptable design limits.

4.2 Alarm functions are within acceptable design limits.

Table 14.1-71
Thermal Power Measurements and Instrument Calibration

1.0 Objective

To determine the power output of the core at major power plateaus for nuclear instrumentation calibration.

2.0 Prerequisites

2.1 The plant is in a steady-state condition.

2.2 Necessary process instruments have been checked and calibrated.

2.3 Steam generator blowdown has been stopped.

3.0 Test Methods

3.1 For each loop, check to ensure steam flow and feed flow are equal, then record the mass flow rate.

3.2 Record steam pressure and find steam enthalpy of saturated liquid conditions.

3.3 Record feedwater temperature and find feedwater enthalpy for saturated liquid conditions.

3.4 Using the proper equation, determine thermal output.

3.5 Calibrate nuclear instrumentation to agree with core thermal output.

4.0 Acceptance Criteria

Instrumentation is calibrated to indicate core output.

I

Table 14.1-72
Automatic Control Systems Checkout

1.0 Objective

To demonstrate that the automatic control systems for pressurizer pressure and level control, rod control, steam generator level control, and turbine generator control respond properly to changes in controlling parameters.

2.0 Prerequisites

2.1 The reactor and turbine generator are at approximately 25 percent power with normal operating parameters.

2.2 Related instrumentation has been checked and calibrated.

3.0 Test Methods

3.1 Using manual control of pressure control devices (sprays, reliefs, and heaters), increases and decreases are made in system pressure. The controls are placed in automatic and the responses noted.

3.2 Using manual control of pressurizer level control, changes are made from the normal level. The controller is placed in automatic and the responses to high and low levels are noted.

3.3 Using manual rod control, errors in Reactor Coolant System average temperature are initiated. The rod control is placed in automatic and the responses to high and low average temperatures are noted.

3.4 Using manual control of the various controllers (three main feedwater valve controllers and the master feed pump controller), steam generator level and feedwater pressure changes are made. The controllers are placed in automatic and the responses noted.

3.5 With turbine control in automatic, changes in steam pressure are made by manual manipulations of control rods. Closing of a stop and control valve is used to change steam conditions. The turbine generator responses to these manipulations are noted.

4.0 Acceptance Criteria

4.1 Automatic controllers return plant parameters to normal values without excessive overshoot.

4.2 The recorded process variables are not more limiting than stated in the setpoint study document.

Table 14.1-73
Plant Response to Step Load Changes

1.0 Objective

To demonstrate satisfactory plant response to a 10 percent load change from various power levels.

2.0 Prerequisites

2.1 The various control systems have been tested and are in automatic.

2.2 All pressurizer and main steam relief and safety valves are operable.

2.3 The control rods are in the maneuvering band for the power level existing at the commencement of the test.

2.4 Plant conditions are stabilized and pertinent parameters to be measured are connected to high speed recorders.

3.0 Test Methods

3.1 Output is manually reduced at a rate sufficient to simulate a step load change equivalent to approximately a 10 percent load decrease.

3.2 After stabilization of systems, output is manually increased at a rate sufficient to simulate a step load change equivalent to approximately a 10 percent load increase.

3.3 Pertinent parameters affected by a load change are measured and recorded.

3.4 At various power levels, as required by the test procedure, the test is repeated.

4.0 Acceptance Criteria

4.1 Neither the turbine nor the reactor trips, and no initiation of safety injection is experienced.

4.2 No pressurizer or main steam relief or safety valves lift.

4.3 No operator action is required to restore conditions to steady state.

4.4 Control systems maintain their parameters within their design transient limits per NSSS Supplier Setpoint Study Document.

Table 14.1-74
Pseudo Rod Ejection Tests

1.0 Objective

To verify the rod worth and hot channel factors assumed in the safety analysis.

2.0 Prerequisites

2.1 The reactor is critical and at a steady-state power level of greater than or equal to 10 percent but no more than 50 percent.

2.2 All of the excore instrumentation channels are operable.

2.3 The incore detectors and thermocouples are operable.

3.0 Test Methods

3.1 The affected rod bank is placed at the full power insertion limit.

3.2 Single rod motion is accomplished by disconnecting the lift coils on all the rods in the affected bank except the coil on the selected rod.

3.3 The selected rod is withdrawn from the core while power and reactor coolant temperature are held constant by boron concentration changes.

3.4 Data are gathered by use of the incore detectors and thermocouples and boron concentration.

4.0 Acceptance Criteria

The measured worth of the pseudo ejected rod and the associated hot channel factors is more conservative than that assumed in the safety analyses.

Table 14.1-75
Rod Drop Test

1.0 Objective

To demonstrate the operations of the negative rate trip circuitry in detecting the simultaneous insertion of two cluster control assemblies.

2.0 Prerequisites

2.1 All power range nuclear instrumentation channels are operable.

2.2 The reactor is at the steady-state power level specified in the procedure with the controlling bank near the full power insertion limit.

2.3 Pertinent parameters to be measured are connected to recording devices.

3.0 Test Methods

3.1 All four power range nuclear instrumentation channel positive and negative rate trips are defeated with instrumentation set up to monitor the negative rate trip bistables.

3.2 Two rods from a common group most difficult to detect by excore detectors due to low worth and core location are simultaneously dropped by removing voltage to both the movable and stationary gripper coils of the designated rod.

3.3 Following the transient, recorded data are evaluated for system and instrumentation response.

4.0 Acceptance Criteria

4.1 The negative rate trip circuitry is initiated on a minimum of three power range nuclear instrumentation channels as a result of simultaneously dropping two control rods.

Table 14.1-76
Below-Bank Rod Test

1.0 Objective

To demonstrate the response of the nuclear and incore instrumentation to a rod cluster control assembly below the nominal bank position and to determine hot channel factors associated with this misalignment.

2.0 Prerequisites

2.1 All power range nuclear instrumentation channels are operable.

2.2 The moveable incore detectors are operable.

2.3 Power escalation testing is completed to approximately the 50 percent reactor power level.

3.0 Test Methods

3.1 Single rod movement is accomplished by disconnecting the lift coils of all rods in the affected bank except the selected rod.

3.2 During rod cluster control assembly insertion, power range detector currents, thermocouple maps, and moveable incore detector traces are periodically recorded to demonstrate sensitivity to RCCA misalignment. The power range detector data provide information to relate core quadrant tilt to rod cluster control assembly position. With the RCCA fully misaligned, a moveable detector flux map is obtained to verify resultant core hot channel factors.

4.0 Acceptance Criteria

4.1 The measured radial hot channel factor resultant from a single RCCA fully misaligned from its bank is less than or equal to the value assumed in the safety analysis (Table 15.2-2) and does not exceed the Technical Specification limit for the power level at which the test is performed.

4.2 Incore and/or nuclear instrumentation is demonstrated to detect any significant power maldistribution caused by the misaligned rod cluster control assembly.

Table 14.1-77
Plant Trip from 100% Power

1.0 Objective

1.1 To demonstrate the ability of the primary and secondary plant and the plant automatic control systems to sustain a trip from 100 percent power and to bring the plant to a stable condition following the transient.

1.2 To determine the overall response time of the reactor coolant hot leg resistance temperature detectors.

1.3 To obtain data which are to be evaluated to determine if changes in the control system setpoints are warranted to improve transient response based on actual plant operation.

2.0 Prerequisites

2.1 The various control systems are in the automatic mode and functioning properly.

2.2 The reactor is steady state of 100 percent power, with the rods in the maneuvering band.

2.3 Pressurizer and main steam safety and relief valves are in service and operable.

2.4 Pertinent parameters to be measured are connected to recording devices.

3.0 Test Methods

3.1 Initiate a plant trip by manually initiating a turbine generator trip.

3.2 Pertinent parameters are recorded on recording devices.

3.3 Following the transient, recorded data are evaluated for system and controller response and possible abnormalities.

4.0 Acceptance Criteria

4.1 The parameters recorded are not more limiting than those in the setpoint study document.

Table 14.1-78
Loss of Offsite Power

1.0 Objective

To demonstrate that the necessary equipment, controls, and indication are available following the isolation of the Offsite Power Distribution System to remove decay heat from the core using only emergency power supplies.

2.0 Prerequisites

The plant is at a steady-state condition with greater than 10 percent generator output.

3.0 Test Methods

3.1 Simulate loss of power by manually de-energizing the offsite power supplies to all 7.2 kV buses, and initiating a turbine generator trip.

3.2 Using approved operating procedures, bring the plant to a hot standby condition and maintain the plant in a hot standby condition for at least 30 minutes using the only emergency onsite power sources.

4.0 Acceptance Criteria

The hot standby condition is achieved and maintained for at least 30 minutes using only emergency onsite power sources.

Table 14.1-79
Shutdown from Outside the Control Room

1.0 Objective

The purpose of this test is to demonstrate the following:

1.1 That the plant can be taken off the line from power operations and maintained in hot standby from outside the control room.

1.2 That cooldown from hot standby can be initiated and maintained from outside the control room by reducing the Reactor Coolant System temperature approximately 50°F without exceeding the cooldown rate.

1.3 That the Residual Heat Removal System can be initiated and controlled from outside the control room by placing the Residual Heat Removal System in service and reducing the Reactor Coolant System temperature approximately 50°F without exceeding the cooldown rate.

2.0 Prerequisites

2.1 The plant is at some power level greater than or equal to 10 percent output on the generator.

2.2 Two shifts of operators are onsite, one observes from control room, the other performs the test.

3.0 Test Methods

3.1 The plant is tripped off the line from outside the control room.

3.2 Using switchgear, manual operators on valves, local indicators, and local panels of controls and indicators, hot standby (approximately no load temperature) is maintained through the assistance of the plant communication system for a period of at least 30 minutes.

3.3 The plant is cooled from approximately no-load temperature approximately 50°F without exceeding the cooldown rate.

3.4 Residual Heat Removal System is initiated from outside the control room and the plant is cooled approximately 50°F without exceeding the cooldown rate.

4.0 Acceptance Criteria

Hot standby is maintained by the members of one shift from outside the control room for at least 30 minutes.

The plant is cooled approximately 50°F below the approximately no-load Reactor Coolant System temperature without exceeding the cooldown rate.

The RHR system is initiated from outside the control room and is used to reduce the Reactor Coolant System temperature approximately 50°F.

Note: Steps 3.3 and 3.4 may be performed during hot functional testing.

Table 14.1-79a
Emergency Lighting

1.0 Objective

Verify that the Emergency DC Lighting System meets design requirements.

2.0 Prerequisites

All construction checks have been completed.

3.0 Test Methods

3.1 Interrupt the standby lighting sources to provide illumination solely from the emergency system.

3.2 Record foot-candle level data at selected locations.

4.0 Acceptance Criteria

Emergency Lighting System meets requirements of Section 9.5.3.3.

Table 14.1-79b
Heat Tracing for Safety Related Outdoor Piping

1.0 Objective

Demonstrate the ability of the Heat Tracing System to maintain proper temperature control in safety related outdoor piping.

2.0 Prerequisites

2.1 Heat Tracing System installation and component checks completed.

2.2 Associated systems completed to the extent necessary to allow conduct of this test.

3.0 Test Methods

3.1 Energize Heat Tracing System.

3.2 Monitor temperatures maintained by each heat tracing circuit with the system in a static condition.

4.0 Acceptance Criteria

Each heat tracing circuit maintains temperature within design limits.

Table 14.1-79c
Pressure Boundary Integrity Test

1.0 Objective

Demonstrate pressure boundary integrity conforms to applicable codes.

2.0 Prerequisites

2.1 Reactor vessel internals, head, and studs installed.

2.2 Required weld non-destructive testing is complete and accepted.

3.0 Test Methods

3.1 The Reactor Coolant System is filled with Grade “A” water.

3.2 The Reactor Coolant System is brought to hydrostatic test temperature utilizing the system pumps.

3.3 The Reactor Coolant System is brought to the required test pressure utilizing the Chemical Volume Control System.

4.0 Acceptance Criteria

4.1 The pressure boundary satisfactorily withstands the test pressure as required by applicable ASME codes.

Table 14.1-79d
Seismic Instrumentation

1.0 Objective

Verify operability of the seismic instrumentation.

2.0 Prerequisites

Installation and calibration of the seismic instrumentation is complete.

3.0 Test Methods

3.1 Verify system response to a simulated signal.

3.2 Verify operability of system alarms.

4.0 Acceptance Criteria

4.1 System response to a simulated signal meets design intent.

4.2 System alarms function as designed.

Table 14.1-80
Power Ascension Test Program

Test	Low Power	30%	50%	75%	90%	100%
Initial Criticality	N/A					
Low Power Test	X					
Incore Moveable Detector and Thermocouple Mapping at Power	X	X	X	X	X	X
Power Coefficient and Power Defect Measurement	X	X	X	X		X
Effluent Radiation Monitor Test	X	X	X	X	X	X
Radiation Shielding Survey	X		X			X
Thermal Power Measurements and Instrument Calibration		X	X	X	X	X
Automatic Control Systems Checkout		X				
Plant Response to Step Load Changes		X		X		X
Pseudo Rod Ejection Test			To be specified in the test			
Rod Drop Test			To be specified in the test			
Below-Bank Rod Test			X			
Plant Loss of Electrical Load						X
Loss of Offsite Power		Greater than or equal to 10% gen. load				
Shutdown from Outside the Control Room		Greater than or equal to 10% gen. load				

X - To be performed

Note: Tests at each given power test plateau will be reviewed before increasing power to the next test plateau.

Table 14.1-81
Initial Test Program Schedule

Startup Activity	Months Before Commercial Operation	Approximate Duration Weeks
Reactor Coolant System Cold Hydro	15	1
Hot Functional Testing	10	3
Core Loading	6	2
Low Power Test	5	4
Power Ascension	3	8

Startup group staffing will begin approximately 30 months prior to commercial operation. The startup group will be completely staffed and trained approximately 20 months prior to commercial operation.

Table 14.1-82
Generic Flush Procedure

1.0 Objective

Flush plant systems to the appropriate level class of cleanliness.

2.0 Prerequisites

2.1 Construction is completed and the system is turned over to the point to allow flushing.

2.2 Adequate source of clean water is available.

2.3 Permanent plant equipment, i.e., pump or temporary flush equipment, i.e., Hydrolaser, is available for the flush.

3.0 Test Methods

3.1 Align the system valves to flush the system.

3.2 Using permanent plant equipment or Hydrolaser, flush the system.

4.0 Acceptance Criteria

4.1 By flush cloth or visual observation, verify that the system meets the desired cleanliness class.

Table 14.1-83
Generic Hydrostatic/Pneumatic Test

1.0 Objective

Prove structural integrity of the systems being tested to the design requirements as specified in the particular design specification.

2.0 Prerequisites

2.1 The system to be tested must be completed sufficiently enough by construction to alleviate the need for system boundary re-entry and test invalidity.

2.2 The system is to be flushed, if practical, before the test is to be conducted.

2.3 The document research and quality control requirements must be completed before testing can begin.

3.0 Test Methods

3.1 Calibrated test gages are installed at selected locations for test pressure verification.

3.2 The system is filled with the appropriate hydrostatic or pneumatic test medium at a temperature higher than the minimum specified in the design specification.

3.3 By use of test pumps, compressors, or other appropriate means, the system is pressurized to the test pressure and held for the specified time limit, then lowered to the inspection pressure and structural integrity is verified.

3.4 After the test, the system is drained or vented, then it is put in the proper layup condition.

4.0 Acceptance Criteria

4.1 No external leakage is allowed except at (1) temporary connections, installed for the purpose of making the test, (2) at gaskets, seals, leak offs, etc., on previously tested components, (3) items noted on the test report as being permitted by specification.

4.2 The leakage shall not exceed the capacity of the pressure source to maintain the required test pressure.

Table 14.1-84
Instrument Control Procedure

1.0 Objective

1.1 Verify and, if required, re-establish the accuracies and control functions of the channel sensors, associated signal processing equipment, indicating equipment, and alarms associated with the analog process signals.

2.0 Prerequisites

2.1 Process control cabinets are installed and energized.

2.2 Process control sensors are installed and connected to the process control cabinets.

2.3 Interconnection between the process control cabinets and the main control board is complete.

3.0 Test Methods

3.1 Using test equipment to simulate the process parameter, the correction conversion, by the sensor, of the process parameter to an analog signal will be verified.

3.2 Using a signal simulator to simulate an analog signal from the sensor, the correct processing of the analog signal by the process equipment, setpoints of comparators, and operation of indicating equipment will be verified.

4.0 Acceptance Criteria

4.1 The process instrumentation provides intolerance conversion of the process parameter and performs its as-designed indication and control functions.

Table 14.1-85
Functional Test

1.0 Objective

To test the operability of subsystems and non-safety related systems to demonstrate their ability to meet their functional requirements.

2.0 Prerequisites

2.1 Specify any tests or portions of tests which must be completed prior to conduct of this test.

2.2 Specify plant status necessary to start the test.

3.0 Test Methods

3.1 Step by step method to accomplish the test.

3.2 Specify data to be taken during the test such as; vibration, bearing temperatures, pressure and flow characteristics, automatic control functions, valve open and closing under actual pressure conditions.

3.3 Restore the system to a safe post test condition.

4.0 Acceptance Criteria

4.1 Specify those qualitative or quantitative requirements that demonstrate the system's ability to meet its functional requirements.

Table 14.1-86
Steam Generator Power Operated Relief Valve

1.0 Objective

1.1 Demonstrate that the steam generator power operated relief valves respond as designed to control Reactor Coolant System temperature utilizing steam pressure as the input signal.

1.2 Demonstrate that the steam generator power operated relief valves respond as designed to control Reactor Coolant System temperature utilizing T_{avg} as the input signal.

2.0 Prerequisites

2.1 Phase I testing complete on steam generator power operated relief valves and associated process instrumentation control loops.

3.0 Test Methods

3.1 During hot functional testing, verify proper operation of the power operated relief valves in the pressure control mode at Reactor Coolant System temperatures of 350°F, 450°F, and approximately 557°F.

3.2 Verify the proper operation of the steam generator power operated relief valves in the temperature control mode by inducing a simulated T_{avg} signal in the process control racks.

4.0 Acceptance Criteria

4.1 Visual observation of the valves stroking to full flow at a reactor coolant temperature of approximately 557°F detects no abnormal movement of valves or associated piping.

4.2 Steam generator power operated relief valves respond as required to simulated inputs of T_{avg}.

Table 14.1-87
Condensate System

1.0 Objective

1.1 Demonstrate that the Condensate System delivers condensed steam from the main condenser hotwell through the low pressure feedwater heaters to the deaerator.

1.2 Demonstrate that the Hotwell Level Control System automatically makes up and rejects water to the condensate storage tank.

1.3 Demonstrate the system interlocks and automatic devices perform their intended functions.

2.0 Prerequisites

2.1 Condensate System installation is complete and component checks are completed.

2.2 Deaerator and hotwell are capable of receiving water.

3.0 Test Methods

3.1 System is aligned for operation.

3.2 Check operation of condensate pump speed controls.

3.3 Verify pump head and flow rates.

3.4 Verify that the Hotwell Level Control System functions to maintain hotwell level.

3.5 Check operation of pump trips and interlocks.

4.0 Acceptance Criteria

4.1 Pump flow capabilities meet or exceed design requirements.

4.2 Interlocks, pump trips, and protective devices function per design requirements.

4.3 Verify control system function per design requirements.

Table 14.1-88
Feedwater System

1.0 Objective

1.1 Demonstrate that the Feedwater System provides heated and deaerated water to the steam generators during normal and transient plant conditions.

1.2 Demonstrate that plant and component protection devices perform their intended functions.

2.0 Prerequisites

2.1 Feedwater System installation is complete and component checks are completed.

2.2 Steam generators are capable of receiving water.

3.0 Test Methods

3.1 System is aligned for operation.

3.2 Check operation of feedwater pump turbine speed controls to provide programmed differential pressure between the steam generator and feedwater pump.

3.3 Verify pump head and flow rates.

3.4 Check operation of pump trips and interlocks.

4.0 Acceptance Criteria

4.1 Pump flow capabilities meet or exceed design requirements.

4.2 Interlocks, pump trips, and protective devices function per design requirements.

4.3 Verify control system function per design requirements.

Table 14.1-89
Main Condenser Dump Valves

1.0 Objective

1.1 Demonstrate that the main condenser dump valves respond properly to simulated temperature and pressure input signals.

1.2 During hot functional testing, cycle each steam dump valve full open.

2.0 Prerequisites

2.1 Phase I testing complete on main condenser dump valves and associated process instrumentation control loops.

3.0 Test Methods

3.1 Simulate temperature and pressure inputs to the control circuitry for the main steam dump valves and verify proper system response.

3.2 During hot functional testing, cycle each steam dump valve fully open and fully closed and verify no abnormal valve or pipe movement.

4.0 Acceptance Criteria

4.1 Main condenser dump valves respond properly to simulated temperature and pressure inputs.

4.2 Each main steam dump valve cycles fully open and closed with no abnormal valve or pipe movement.

Table 14.1-90
Circulating Water System

1.0 Objective

1.1 Demonstrate the capability of the Circulating Water System to provide adequate cooling water.

2.0 Prerequisites

2.1 Circulating Water System installation, piping flushes, and component checks are completed.

2.2 Associated systems are completed to the extent necessary to allow conduct of this test.

3.0 Test Methods

3.1 Align the system for operation.

3.2 Verify system protective interlocks.

3.3 Verify flows and pressures for normal operations.

4.0 Acceptance Criteria

4.1 System flows, pressures, and automatic functions are in accordance with design requirements.

4.2 System interlocks function in accordance with design.

Table 14.1-91
Chemical Feed System

1.0 Objective

1.1 Demonstrate that the Condensate Chemical Injection System can maintain established limits of pH and dissolved oxygen in the Condensate and Feedwater Systems.

1.2 Demonstrate that the Steam Generator Standby Chemical Injection System can maintain established limits of pH and dissolved oxygen in the secondary side of the steam generators during wet layup.

2.0 Prerequisites

2.1 Chemical Injection System installation and component checks are complete.

3.0 Test Methods

3.1 Align systems for normal operation and establish flow paths.

3.2 Check operation of metering controls for injection systems.

4.0 Acceptance Criteria

4.1 Condensate System delivers calibrated volume to the Condensate System.

4.2 Steam Generator Standby Chemical Injection System delivers a calibrated volume to the steam generator.

Table 14.1-92
Nuclear Blowdown Processing System

.0 Objective

1.1 Demonstrate flow capabilities of the Nuclear Blowdown Processing System.

2.0 Prerequisites

2.1 Nuclear Blowdown Processing System installation and component checks are completed.

3.0 Test Methods

3.1 Demonstrate circulation through different loops of the Nuclear Blowdown Processing System and verify ability to demineralize water to Condensate System grade water.

4.0 Acceptance Criteria

4.1 System provides the capability to demineralize steam generator nuclear blowdown to Condensate System cleanliness criteria.

Table 14.1-93
Control Rod Drive

1.0 Objective

1.1 Demonstrate that the circuitry and components comprising the Control Rod Drive System will perform their design requirements without control rod drives installed.

2.0 Prerequisites

2.1 Wiring and component installation complete.

3.0 Test Methods

3.1 Initially energize the rod position indication system and verify proper signal response from the detection coils to the indication display.

3.2 Verify proper control rod drive mechanism polarity and coil currents.

3.3 Verify proper control rod drive M-G set operation.

3.4 Verify proper control rod drive mechanism magnetic coil sequencing.

4.0 Acceptance Criteria

4.1 Control rod drive components and circuitry function as required by design.

Table 14.1-94
Miscellaneous Plant Drains

1.0 Objective

1.1 Demonstrate the ability of Miscellaneous Plant Drains System to remove water from the plant.

2.0 Prerequisites

2.1 Miscellaneous Plant Drains System installation and component checks are completed as necessary.

3.0 Test Methods

3.1 Verify capability of the sump pumps to remove water form the sumps.

3.2 Verify sump level interlocks to applicable plant equipment.

4.0 Acceptance Criteria

4.1 Sump level interlocks to plant equipment function as designed.

4.2 System provides for water removal in accordance with design requirements.

Table 14.1-95
Fuel Handling Building Pool Liner Leak Test

1.0 Objective

1.1 Demonstrate watertight integrity of spent fuel pit, fuel transfer canal, and cask loading pit.

1.2 Demonstrate watertight integrity of the fuel transfer tube isolation valve and blind flange.

1.3 Demonstrate watertight integrity of spent fuel pit gate and cask loading pit gate.

1.4 Demonstrate airtight integrity of the inflatable seals on the spent fuel pit and cask loading pit gates.

2.0 Prerequisites

2.1 Pool liners have been installed and cleaned.

2.2 Spent fuel racks are not installed.

2.3 Adequate source of water is available.

3.0 Test Methods

3.1 Fill pools with water and monitor liner leakage.

3.2 Install transfer canal isolation gates, drain canal and monitor leakage through the gates.

4.0 Acceptance Criteria

4.1 Total leakage for liner is less than design maximums.

4.2 Fuel transfer tube isolation valve.

4.2.1 Blind flange and valve is less than design maximums.

4.2.2 Valve stem is less than design maximums.

4.3 Isolation gates.

4.3.1 Inflatable seal on gates - no visible bubbles.

4.3.2 Spent fuel pit gate is less than design maximums.

4.3.3 Cask loading pit gate is less than design maximums.

Table 14.1-96
Reactor Building Ventilation "Post Accident Operation"

1.0 Objective

1.1 Demonstrate that the Reactor Building cooling units have the capacity to cool the Reactor Building within the design load during the worst postulated accident conditions.

1.2 Demonstrate during the integrated leak rate test that the Reactor Building cooling fan motor over current protection will allow operation of the motors under the maximum load.

1.3 Demonstrate during the integrated leak rate test that the Reactor Building cooling unit bypass damper closes.

2.0 Prerequisites

2.1 Installation of components and support systems is complete and operational.

2.2 The integrated leak rate test is in progress for objective 1.2.

2.3 Adjusts fan pitch settings to accommodate increased containment air density (for ILRT).

3.0 Test Methods

3.1 Align the Reactor Building coolers for system operation in the "post-accident" mode.

3.2 Measure the flow rate and temperature drop across the cooling coil air and water sides at ambient conditions.

3.3 Calculate the heat removal capacity and extrapolate for worst conditions using the coil data sheets and measured data.

3.4 Align system for operation during the containment integrated leak rate test and monitor the fan motor operation.

3.5 During the integrated leak rate test, reposition the Reactor Building cooling unit dampers from the bypass to the closed position.

4.0 Acceptance Criteria

4.1 The cooling units are shown to have the capacity to remove the designed heat load at the worst postulated conditions.

4.2 The fan motor operates in accordance with design requirements during the integrated leak rate test.

4.3 Reactor Building cooling unit dampers operate from the bypass to the closed position.

Table 14.1-97
ESF Equipment Rooms Cooling Systems

1.0 Objective

1.1 Demonstrate that the cooling systems for the following ESF Equipment Rooms have the capacity to cool the areas within design loads during the worst postulated conditions.

1.1.1 Reactor Building Cooling Units (Normal Mode)

1.1.2 Charging Pump Room Cooling Unit

1.1.3 RHR-Spray Pump Room Cooling Units

1.1.4 Safety Related MCC Switchgear Cooling Units

1.1.5 Relay Room Cooling System (Recirc. Mode)

1.1.6 Control Room Ventilation System (Recirc. Mode)

1.1.7 ESF Switchgear Room Cooling

1.1.8 Speed Switch Room Cooling

1.1.9 Service Water Booster Pump Cooling Units

1.1.10 Emergency Feedwater Pump Cooling Units

2.0 Prerequisites

2.1 Installation of components and support systems is complete and operational.

3.0 Test Methods

3.1 Align the cooler for system operation and measure the flow rate and temperature drop across the cooling coil air and water sides at ambient conditions.

3.2 Calculate the heat removal capacity at ambient conditions. Verify that the coils are operating on their characteristic curve by comparing test data results to manufacturer’s design program data.

4.0 Acceptance Criteria

4.1 The cooling units are shown to operate on their characteristic curve, thereby verifying that they have the capacity to remove the design heat load at the worst postulated conditions for each of their respective areas.

Table 14.1-98
S. I. Accumulator Discharge Valve Functional Test

1.0 Objective

1.1 To demonstrate that each accumulator isolation valve (8808A, B, & C) will open under the maximum differential pressure conditions of zero Reactor Coolant System pressure and maximum expected accumulator precharge pressure upon receipt of a safety injection signal by each valve.

1.2 To verify the actual accumulator level matches the indicated accumulator level at the minimum technical specification level.

1.3 To demonstrate that each accumulator isolation valve (8808A, B, & C) will open on an increasing Reactor Coolant System pressure signal.

2.0 Prerequisites

2.1 The Reactor Coolant System is depressurized and adequately vented.

2.2 A source of nitrogen is available to pressurize the accumulators.

2.3 A tygon hose is connected to the accumulator for level indication.

3.0 Test Methods

3.1 Close valves 8808A, B, & C and then fill each accumulator with Grade A water. As each accumulator fills, compare the accumulator actual level with the indicated level when actual level reaches the minimum technical specification level. Isolate the tygon hose before pressurizing the accumulators.

3.2 Pressurize each accumulator to the maximum expected accumulator precharge pressure.

3.3 Initiate a safety injection signal to the control circuitry of each valve.

3.4 Increase the Reactor Coolant System pressure signal to each valve.

4.0 Acceptance Criteria

4.1 That each accumulator isolation valve will open in less than the maximum allowable stroke time under maximum differential pressure conditions.

4.2 That indicated accumulator level is within tolerance at the actual minimum technical specification level in the accumulator.

Table 14.1-98 (continued)
S. I. Accumulator Discharge Valve Functional Test

4.3 That each accumulator isolation valve will open when required on an increasing RCS pressure signal.

Table 14.1-99
ECCS Check Valve Leak Testing System Operational Test

1.0 Objective

1.1 Demonstrate proper functioning of the ECCS Check Valve Leak Testing System and perform a backleakage test on each check valve monitored by the ECCS Check Valve Leak Testing System.

2.0 Prerequisites

2.1 Instrumentation in the ECCS Check Valve Leak Testing System has been calibrated.

2.2 Hot functional testing is in progress.

3.0 Test Methods

3.1 Perform a leak test on each check valve in the ECCS normally checked using the ECCS Check Valve Leak Testing System.

4.0 Acceptance Criteria

4.1 System operates satisfactorily during leak check tests.

Table 14.1-100
S. I. Accumulator Check Valve Hot Operational Test

1.0 Objective

1.1 To demonstrate that the accumulator discharge check valves (8948A, B & C and 8956A, B & C) will function under normal operating temperature and pressure conditions.

2.0 Prerequisites

2.1 Hot functional testing is in progress.

3.0 Test Methods

3.1 Inject or pump water through each check valve during hot functional testing.

4.0 Acceptance Criteria

4.1 That each check valve passes water into the RCS during hot functional testing.

Table 14.1-101
Instrument Air System

1.0 Objective

1.1 Demonstrate the ability of the Instrument Air System to supply instrument and service air.

2.0 Prerequisites

2.1 Instrument Air System installation and component checks are completed as necessary.

2.2 System has been blown down and cleanliness requirements met.

3.0 Test Methods

3.1 Verify operability of system alarms.

3.2 Verify operability of system interlocks.

3.3 Verify ability of air compressors to maintain system pressure.

3.4 Verify start of standby compressor on reduction of air pressure.

3.5 Verify isolation of service air on reduction of air pressure.

3.6 Verify backup supply to Reactor Building header on reduction of pressure.

3.7 Verify operability of dryers.

4.0 Acceptance Criteria

4.1 System interlocks and alarms function as designed.

4.2 Instrument Air System supplies air to Reactor Building instrument air services on loss of Reactor Building instrument air.

4.3 Service air is isolated on loss of instrument air.

4.4 Air compressors and dryers function as designed.

Table 14.1-102
Pressurizer Pressure and Level Control

1.0 Objective

1.1 To demonstrate the response, stability, and control characteristics of the Pressurizer Pressure and Level Control System.

1.2 To demonstrate the operation of the pressurizer power relief valves.

2.0 Prerequisites

2.1 The Reactor Coolant System is at hot no-load conditions as required by hot functional testing.

2.2 The pressurizer relief tank is operable.

2.3 Pressurizer pressure and level process instrumentation has been calibrated.

3.0 Test Methods

3.1 Place the pressurizer pressure control in manual and increase (decrease) the setpoint of the automatic controller 50 psig. Switch the pressurizer pressure control back to automatic control and observe the system response as pressure increases (decreases) to the new setpoint.

3.2 Using manual control, increase the system pressure to the pressurizer high pressure reactor trip value, then lower the pressure to the pressurizer low pressure reactor trip value, and verify the operation of the alarms and interlocks associated with the Pressurizer Pressure Control System.

3.3 Place the pressurizer level control in manual and decrease (increase) the pressurizer level 5 percent. Switch the pressurizer level control to automatic and observe the system response as pressurizer level increases (decreases) to the normal setpoint.

3.4 Using manual control, increase pressurizer level to the high level reactor trip, then lower the pressurizer level to the low level heater cutout and letdown isolation value, and verify the operation of alarms and interlocks associated with the Pressurizer Level Control System.

3.5 Verify the operation and response time of the pressurizer power relief valves by opening and closing the valves from the MCB and allowing a blowdown for 10 seconds or until 1900 psig is reached.

Table 14.1-102 (continued)
Pressurizer Pressure and Level Control

3.6 Verify the operation of the pressurizer backup heaters from the control room evacuation panel.

4.0 Acceptance Criteria

4.1 System operation is in accordance with design requirements.

14.2 Augmentation of Staff for Initial Test and Operation

During the initial test program at Virgil C. Summer Nuclear Station, SCE&G is using a special startup organization. In addition to the plant operating staff, the startup organization is augmented by representatives from Westinghouse, Gilbert, and other contractors and vendors as required. Competent technical personnel from other SCE&G departments may be called upon to assist and advise the startup organization as necessary.

14.2.1 Organizational Functions, Responsibilities, and Authorities

The functions, responsibilities, and authorities of organizations participating in the startup program are discussed in Sections 14.2.1.1 through 14.2.1.3.

14.2.1.1 Plant Operating Staff

Under the direction of the Manager, Virgil C. Summer Nuclear Station qualified plant personnel to assist in preparation of test procedures and performance of tests. Test procedure preparation includes writing and review of the procedure and approval of the procedure by the Manager, Virgil C. Summer Nuclear Station. Test performance includes checking of prerequisites, operation of equipment, and recording of data. All functions requiring an NRC license are performed by licensed personnel.

Prior to receiving nuclear fuel at the plant site, SCE&G will establish industrial security and health physics programs under the control and administration of the Manager, Virgil C. Summer Nuclear Station. Also, under the direction of the Manager, Virgil C. Summer Nuclear Station, plant operating and maintenance personnel will assume responsibility for operation and maintenance of tested and accepted systems.

14.2.1.2 Westinghouse Electric Corporation

Westinghouse provides onsite technical assistance to SCE&G during the installation, startup, testing, and initial operation of each nuclear steam supply system (NSSS). In this manner, Westinghouse aids the owner and assures that each NSSS is installed, started, tested, and operated in conformance with design intent. Westinghouse onsite personnel provide direct assistance and act as technical liaison with Westinghouse headquarters to resolve problems within the Westinghouse scope. Personnel assignments are made as required by site activities.

14.2.1.3 Gilbert Associates, Inc.

Gilbert provides experienced personnel to assist in the startup activities. Liaison is maintained between the Gilbert Reading, PA, offices and field personnel to facilitate resolution of problems related to test specifications and system operation for which Gilbert has design responsibility.

14.2.2 Interrelationships and Interfaces

Onsite representatives of Westinghouse, Gilbert, and other contractors and vendors are responsible to the Manager, Virgil C. Summer Nuclear Station. If any of the above personnel participate in the performance of a test, they will be responsible to the person above them in the startup organization, that is a Test Supervisor or the Startup Supervisor. For activities related to construction, they will be responsible to the SCE&G Manager of Construction.

14.2.3 Personnel Functions, Responsibilities, and Authorities

The functions, responsibilities, and authorities of major augmenting personnel are as discussed in Sections 14.2.3.1 through 14.2.3.3.

14.2.3.1 Plant Staff

Members of the Virgil C. Summer Nuclear Station operating, maintenance, and technical groups who meet the requirements for Test Supervisor or test personnel are utilized in these capacities. Their functions, responsibilities, and authorities are described in Section 14.1.1.4.

14.2.3.2 Westinghouse Electric Corporation

Westinghouse startup specialists assigned to the Virgil C. Summer Nuclear Station act as technical advisors to the Plant Manager and assist him in NSSS startup activities. Their function and responsibilities include, but are not limited to, assisting the startup group in procurement of procedures, system checkout, functional testing, and coordination of the test program. Resolution of technical problems within the Westinghouse scope of supply shall be resolved by the startup specialists by direct liaison with Westinghouse headquarters.

14.2.3.3 Gilbert Associates, Inc.

Gilbert personnel assigned to the Virgil C. Summer Nuclear Station site assist in startup activities. Liaison is maintained between the site personnel and the Gilbert home office to facilitate resolution of problems and questions which may arise during startup and testing and are related to Gilbert design activities. Gilbert site personnel may assist SCE&G in actual performance of startup and testing of the plant.

14.2.4 Personnel Qualifications

Personnel who manage, supervise, or perform preoperational or startup tests shall satisfy the qualifications stated in Section 14.1.1.4.

V.C. Summer Nuclear Station

15.0 ACCIDENT ANALYSIS

Since 1970 Westinghouse has been using the ANS classification of plant conditions which divides plant conditions into four categories in accordance with anticipated frequency of occurrence and potential radiological consequences to the public. The four categories are as follows:

1. Condition I:Normal Operation and Operational Transients
2. Condition II:Faults of Moderate Frequency
3. Condition III:Infrequent Faults
4. Condition IV:Limiting Fault

The basic principle applied in relating design requirements to each of the conditions is that the most probable occurrences should yield the least radiological risk to the public and those extreme situations having the potential for the greatest risk to the public shall be those least likely to occur. Where applicable, Reactor Trip System and Engineering Safety Features functioning is assumed to the extent allowed by considerations such as the single failure criterion, in fulfilling this principle.

In the evaluation of the radiological consequences associated with initiation of a spectrum of accident conditions, numerous assumptions must be postulated. In many instances, these assumptions are a product of extremely conservative judgments. This is due to the fact that many physical phenomena, in particular fission product transport under accident conditions, are not understood to the extent that accurate predictions can be made. Therefore, the set of assumptions postulated would predominantly determine the accident classification.

The specific accident sequences analyzed in this chapter include those required by Revision 1 of Regulatory Guide 1.70, Standard Format and Content of Safety Analysis Reports for Nuclear Power Plants, and others considered significant for V. C. Summer. Because the V. C. Summer design differs from other plants, some of the accidents identified in Table 15-1 of Regulatory Guide 1.70, Revision 1, are not applicable to this plant. Some comments on these items are as follows:

(Item 10) - There are no pressure regulators or regulating instruments in the Westinghouse PWR design whose failure could cause heat removal greater than heat generation.

(Item 11) - Reactor coolant flow controller is not a feature of the Westinghouse PWR designs. Treatment of the performance of the reactivity controller in a number of accident conditions is offered in this chapter.

(Item 12) - The analysis of specific effects of internal and external events such as major and minor fires, floods, storms, or earthquakes are generally discussed in Chapter 3. Refer to Section 3.1.2.1 for guidance on which FSAR sections specifically address GDCs 2, 3, and 4.

(Item 22) - No instrument lines from the Reactor Coolant System boundary in the Westinghouse PWR design penetrate the Reactor Building (1).

(Item 26) - Control room habitability is discussed. Chapter 7 contains an analysis showing that the plant can be brought to, and maintained in, the hot shutdown condition from outside the control room.

(Item 27) - Overpressurization of the Residual Heat Removal System is not considered credible due to the isolation valve interlocks described in Section 7.6.

(Item 28) - Loss of condenser vacuum is covered by the analyses of <hot spots>Section 15.2.7, Loss of External Electric Load and/or Turbine Trip.

(Item 29) - Turbine trip is covered by the analyses of <hot spots>Section 15.2.7, Loss of External Electric Load and/or Turbine Trip.

(Item 30) - Loss of the Service Water System is discussed in Section 9.2.

(Item 31) - Loss of one D-C system is discussed in Chapter 8.

(Item 33) - Turbine trip with failure of generator breakers to open is discussed in Chapter 10. The effect of turbine trip on the Reactor Coolant System are presented in <hot spots>Section 15.2.7.

(Item 34) - Loss of the Instrument Air System is discussed in Chapter 9.

(Item 35) - Loss of the turbine gland seal is of no significance for PWRs.

(1) For the definition of the Reactor Coolant System boundary, refer to ANSI-N18.2, "Nuclear Safety Criteria for the Design of Stationary PWR Plants," Section 5, 1973.

The Nuclear Steam Supply System (NSSS) is designed to afford proper protection against the possible effects of natural phenomena, postulated environmental conditions, and dynamic effects. In addition, the design incorporates features which minimize the probability and effects of fires and explosions. Chapter 17 discusses the Quality Assurance Program which has been implemented to assure that the NSSS will satisfactorily perform its assigned safety functions. The incorporation of these features in the NSSS, coupled with the reliability of the design, ensures that the normally operating systems and components listed in <hot spots>Table 15.0-1 will be available for mitigation of the events discussed in Chapter 15. In determining which systems are necessary to mitigate the effects of these postulated events, Westinghouse utilizes the classification system of ANSI-N18.2, 1973. The design of "systems important to safety" (including protection systems) is consistent with IEEE Standard 379-1972 and Regulatory Guide 1.53 in the application of the single failure criterion.

15.1 CONDITION I - NORMAL OPERATION AND OPERATIONAL TRANSIENTS

Condition I occurrences are those which are expected frequently or regularly in the course of power operation, refueling, maintenance, or maneuvering of the plant. As such, Condition I occurrences are accommodated with margin between any plant parameter and the value of that parameter which would require either automatic or manual protective action. Since Condition I occurrences occur frequently or regularly, they must be considered from the point of view of affecting the consequences of fault conditions (Conditions II, III, and IV). In this regard, analysis of each fault condition described is generally based on a conservative set of initial conditions corresponding to the most adverse set of conditions which can occur during Condition I operation.

A typical list of Condition I events follows:

1. Steady state and shutdown operations

   Mode 1 - Power operation (> 5% of rated thermal power)
   Mode 2 - Startup ($K_{eff} \geq 0.99$, ≤ 5% of rated thermal power)
   Mode 3 - Hot standby ($K_{eff} < 0.99$, $T_{avg} \geq 350°F$
   Mode 4 - Hot shutdown (subcritical, residual heat removal system in operation, $K_{eff} < 0.99$, $200°F < T_{avg} \leq 350°F$
   Mode 5 - Cold shutdown (subcritical, residual heat removal system in operation, $K_{eff} < 0.99$, $T_{avg} \leq 200°F$
   Mode 6 - Refueling ($K_{eff} \leq 0.95$, $T_{avg} \leq 140°F$)

2. Operation with permissible deviations

   Various deviations which may occur during continued operation as permitted by the plant Technical Specifications (Reference 1) must be considered in conjunction with other operational modes. These include:

   a. Operation with components or systems out of service
   b. Leakage from fuel with clad defects
   c. Leakage from fuel with clad defects
      (1) Fission products
      (2) Corrosion products
      (3) Tritium
   d. Operation with steam generator leaks up to the maximum allowed by the Technical Specifications
   e. Testing as allowed by the Technical Specifications

3. Operational transients

a. Plant heatup and cooldown (up to 100°F/hour for the Reactor Coolant System; 200°F/hour cooldown for the pressurizer, 100°F/hour heatup for the pressurizer)

b. Step load changes (up to ± 10 percent)

c. Ramp load changes (up to 5 percent/minute)

d. Load rejection up to and including design load rejection transient

15.1.1 Optimization of Control Systems

A control system setpoint study (Reference 2) has been performed in order to simulate performance of the reactor control and protection systems. Emphasis was placed on the development of a control system which will automatically maintain prescribed conditions in the plant, even under the most conservative set of reactivity parameters with respect to both system stability and transient performance.

For each mode of plant operation, a group of optimum controller setpoints is determined. In areas where the resultant setpoints are different, compromises based on the optimum overall performance are made and verified. A consistent set of control system parameters is derived satisfying plant operational requirements throughout the core life and for power levels between 15 and 100 percent.

The study comprised an analysis of the following control systems: rod cluster control assembly, steam dump, steam generator level, pressurizer pressure and pressurizer level.

Due to the revised parameters associated with replacement steam generators, the control system setpoint study described in (Reference 2) was reviewed for applicability. Several of the setpoints required revision in order to provide acceptable control system performance for the entire core life and over the entire design range of Reactor Coolant System operating conditions. The control systems requiring revision included the steam generator level control (due to the replacement steam generator), rod control, steam dump, and pressurizer level control systems (due to the revised range of the full power T_{avg}).

15.1.2 Initial Power Conditions Assumed In Accident Analyses

15.1.2.1 Power Rating

Table 15.1-1 lists the principal power rating values which are assumed in analyses performed in this section. This rating is the guaranteed Nuclear Steam Supply System (NSSS) thermal power output. This power output includes the thermal power generated by the reactor coolant pumps.

Where initial power operating conditions are assumed in accident analyses, the “guaranteed nuclear steam supply system thermal power output” (plus allowance for errors in steady-state power determination for some accidents) is assumed. The thermal power values used for each transient analyzed are given in Table 15.1-4.

15.1.2.2 Initial Conditions

For most accidents which are Departure from Nucleate Boiling limited, nominal values of initial conditions are assumed. The allowances on power, temperature, and pressure are determined on a statistical basis and are included in the limit Departure from Nucleate Boiling Ratio, as described in (Reference 3). This procedure is known as the “Revised Thermal Design Procedure” (RTDP) and these accidents utilize the WRB-1 and WRB-2 Departure from Nucleate Boiling correlations (References 4 and 5). RTDP allowances may be more restrictive than non-RTDP allowances. The initial conditions for other key parameters are selected in such a manner to maximize the impact on Departure from Nucleate Boiling Ratio. Minimum measured flow is used in all RTDP transients. For accident evaluations that are not Departure from Nucleate Boiling-limited, or for which the Revised Thermal Design Procedure is not employed, the initial conditions are obtained by adding maximum steady state errors to rated values. The following steadystate errors are considered.

(1) Core power	± 2.0% allowance calorimetric error
(2) Average RCS temperature	+ 6.3 / - 5.3 allowance for deadband and measurement error
(3) Pressurizer pressure	+54 / -65 psi allowance for steady state fluctuations and measurement error
(4) RCS Flow	2.1% allowance on flow measurement error

15.1.2.3 Power Distribution

The transient response of the reactor system is dependent on the initial power distribution. The nuclear design of the reactor core minimizes adverse power distribution through the placement of control rods and operating instructions. The power distribution may be characterized by the radial factor ($F_{\Delta H}$) and the total peaking factor F_Q. The peaking factor limits are given in the Technical Specifications and the Core Operating Limits Report (COLR).

For transients which may be DNB limited, the radial peaking factor is of importance. The radial peaking factor increases with decreasing power level due to rod insertion. This increase in $F_{\Delta H}$ is included in the core limits illustrated in (Figure 15.1-1). All transients that may be DNB limited are assumed to begin with a $F_{\Delta H}$ consistent with the initial power level defined in the Technical Specifications.

The axial power shape used in the DNB calculation is discussed in Section 4.4.3.

For transients that may be overpower-limited, the total peaking factor (F_Q) is of importance. The value of F_Q may increase with decreasing power level so that the full power hot spot heat flux is not exceeded, i.e., F_Q x Power = design hot spot heat flux. All transients that may be overpower-

limited are assumed to begin with a value of F_Q consistent with the initial power level as defined in the Technical Specifications.

The value of peak kW/ft can be directly related to fuel temperature using steady state fuel rod performance predictions. For transients that are slow with respect to the fuel rod thermal time constant (approximately 5 seconds), the fuel temperatures follow the steady state predictions. For transients that are fast with respect to the fuel rod thermal time constant (for example, rod ejection), a detailed heat transfer calculation is made.

15.1.3 Trip Points and Time Delays to Trip Assumed in Accident Analysis

A reactor trip signal acts to open 2 trip breakers, connected in series, feeding power to the control rod drive mechanisms. The loss of power to the mechanism coils causes the mechanisms to release the rod cluster control assemblies which then fall by gravity into the core. There are various instrumentation delays associated with each trip function, including delays in signal actuation, in opening the trip breakers, and in the release of the rods by the mechanisms. The total delay to trip is defined as the time delay from the time that trip conditions are reached to the time the rods are free and begin to fall. Limiting trip setpoints assumed in accident analyses and the time delay assumed for each trip function are given in Table (Figure 15.1-2).

Reference is made in that table to the overtemperature and overpower ΔT trip shown on (Figure 15.1-1). This figure presents the allowable reactor coolant loop average temperature and ΔT for the design flow and the NSSS Design Thermal Power distribution as a function of primary coolant pressure. The boundaries of operation defined by the Overpower ΔT trip and the Overtemperature ΔT trip are represented as “protection lines” on this diagram. The protection lines are drawn to include all adverse instrumentation and setpoint errors so that under nominal conditions, a trip would occur well within the area bounded by these lines. The utility of this diagram is in the fact that the limit imposed by any given DNBR can be represented as a line. The DNB lines represent the locus of conditions for which the DNBR equals the safety analysis limit values (1.43 and 1.42 for typical cell, and thimble cell respectively) for RTDP accidents. All points below and to the left of a DNB line for a given pressure have a DNBR greater than the limit values. The diagram shows that DNB is prevented for all cases if the area enclosed with the maximum protection lines is not traversed by the applicable DNBR line at any point.

The area of permissible operation (power, pressure and temperature) is bounded by the combination of reactor trips: high neutron flux (fixed setpoint); high pressurizer pressure (fixed setpoint); low pressurizer pressure (fixed setpoint); Overpower and Overtemperature ΔT (variable setpoints).

The limit values, which were used as the DNBR limits for all accidents analyzed with the Revised Thermal Design Procedure, are conservative compared to the actual design DNBR values required to meet the DNB design basis.

The difference between the limiting trip point, assumed for the analysis, and the normal trip point represents an allowance for instrumentation channel error and setpoint error. During startup tests,

it is demonstrated that actual instrument errors and time delays are equal to or less than the assumed values.

15.1.4 Instrumentation Drift and Calorimetric Errors - Power Range Neutron Flux

The instrumentation drift and calorimetric uncertainties used in establishing the Technical Specification power range neutron flux (High) reactor trip setpoint are included in the report "Westinghouse Setpoint Methodology for Protection Systems -Virgil C. Summer", WCAP-11770 (Class 2) (Reference 19) and WCAP-11814 (Class 3) (Reference 20). These uncertainties are based on the installed instrumentation, on the calibration limits, and on the calibration methods for the power range neutron flux channels. The Technical Specification Power Range Neutron Flux (High) reactor trip setpoint preserves the analyzed limit used in the safety analysis.

The calorimetric uncertainty is the uncertainty determined for the core thermal power measurement as obtained from secondary side plant measurements. The power range neutron flux channels (sum of the top and bottom sections) are required by Technical Specifications to be calibrated (set equal) to the measured power on a daily basis. The calorimetric (power measurement) uncertainty is included in the report "Westinghouse Revised Thermal Design Procedure Instrument Uncertainty Methodology - Virgil C. Summer", WCAP-13812 (Class 2) (Reference 21) and WCAP-13813 (Class 3) (Reference 22).

A high accuracy calorimetric Reactor Coolant System flow measurement is performed at the beginning of each fuel cycle to calibrate (set equal to) the Reactor Coolant System elbow tap flow channels. This calibration or normalization allows a simplified periodic Reactor Coolant System flow measurement that is independent of feedwater venturi fouling. For the high accuracy Reactor Coolant System flow measurement, feedwater venturi fouling is accounted for by inspecting and cleaning (if necessary) each venturi at each refueling outage.

15.1.5 Rod Cluster Control Assembly Insertion Characteristics

The negative reactivity insertion following a reactor trip is a function of the acceleration of the rod cluster control assemblies and the variation in rod worth as a function of rod position. With respect to accident analyses, the critical parameter is the time of insertion up to the dashpot entry or approximately 85 percent of the rod cluster travel. For accident analyses the insertion time to dashpot entry is conservatively taken as 2.7 seconds. The rod cluster control assembly position versus time assumed in accident analyses is shown in Figure 15.1-2.

Figure 15.1-3 shows the fraction of total negative reactivity insertion versus rod position for a core where the axial distribution is skewed to the lower region of the core. This curve is used to compute the negative reactivity insertion versus time following a reactor trip which is input to all point kinetics core models used in transient analyses.

There is inherent conservatism in the use of this curve in that it is based on a skewed flux distribution which would exist relatively infrequently. For cases other than those associated with xenon oscillations, significant negative reactivity would have been inserted due to the more favorable axial distribution existing prior to trip.

The normalized rod cluster control assembly negative reactivity insertion versus time is shown in Figure 15.1-4. The curve shown in this figure was obtained from Figure 15.1-2 and Figure 15.1-3. A total negative reactivity insertion following a trip of 4.8 percent ΔK is assumed in the transient analyses except where specifically noted otherwise. This assumption is conservative with respect to the calculated trip reactivity worth available as shown in Tables 4.3-2 and 4.3-3.

The normalized rod cluster control assembly negative reactivity insertion versus time curve for an axial power distribution skewed to the bottom (Figure 15.1-4) is used in those transient analyses for which a point kinetics core model is used. Where special analyses require use of three dimensional or axial one dimensional core models, the negative reactivity insertion resulting from the reactor trip is calculated directly by the reactor kinetics code and is not separable from the other reactivity feedback effects. In this case, the rod cluster control assembly position versus time of Figure 15.1-2 is used as code input.

15.1.6 Reactivity Coefficients

The transient response of the reactor system is dependent on reactivity feedback effects, in particular the moderator temperature coefficient and the Doppler power coefficient. These reactivity coefficients and their values are discussed in detail in Chapter 4.

In the analysis of certain events, conservatism requires the use of large reactivity coefficient values whereas in the analysis of other events, conservatism requires the use of small reactivity coefficient values. Some analyses such as loss of reactor coolant from cracks or ruptures in the reactor coolant system do not depend on reactivity feedback effects. The values used are given in Table 15.1-4. Reference is made in that table to Figure 15.1-5 which shows the upper and lower bound Doppler power coefficients as a function of power, used in the transient analysis. The justification for use of conservatively large versus small reactivity coefficient values are treated on an event by event basis.

15.1.7 Fission Product Inventories

15.1.7.1 Radioactivity in the Core

The fission product inventories for all isotopes, which are important from a health hazards standpoint, were calculated using the ORIGEN code (Reference 17) and are given in Table 15.1-5. This code uses a data base of fission product yields, cross sections, and decay constants taken from the ENDFB IV/V fission product library. The calculation of the core iodine fission product inventory is consistent with TID 14844 (Reference 18). The ORIGEN code takes into account fuel burnup as well as fission product buildup and decay. Continuous operation at full power is assumed during the fuel residence time to provide an upper limit estimate of the fission product inventory. The isotopes included in Table 15.1-5 are the isotopes controlling from considerations of inhalation dose (iodines) and from direct dose due to immersion (noble gases).

The isotopic yields used in the calculations are from the data of APED 5398 (Reference 23), utilizing the isotopic yield data for thermal fissioning of U 235 as the sole fissioning source. The

change in fission product inventory resulting from the fissioning of other fissionable atoms has been reviewed. The results of this review indicated that inclusion of all fission source data would result in small (less than 10 percent) change in the isotopic inventories due to the overall conservatism.

15.1.7.2 Radioactivity in the Fuel Pellet Clad Gap

This section was deleted by Amendment 96-02.

15.1.8 Residual Decay Heat

Residual heat in a subcritical core consists of:

1. Fission product decay energy,
2. Decay of neutron capture products, and
3. Residual fissions due to the effect of delayed neutrons.

These constituents are discussed separately in the following paragraphs.

15.1.8.1 Fission Product Decay Energy

Transient-specific decay heat curves are calculated in the LOCA analyses based on the 1979 ANS decay heat standard (Reference 11) as described in Section 9 of Reference 6. For the non-LOCA analyses the 1979 ANS decay heat curve is used (Reference 15). Figure 15.1-7 presents this curve as a function of time after shutdown for non-LOCA analyses.

15.1.8.2 Decay of U-238 Capture Products

Betas and gammas from the decay of U-239 (23.5 minute half life) and Np-239 (2.35 day half life) contribute significantly to the heat generation after shutdown. The cross section for production of these isotopes and their decay schemes are relatively well known. For long irradiation times their contribution can be written as:

$$\frac{P_1}{P_0} = \frac{E_{\gamma 1} + E_{\beta 1}}{200\text{Mev}} c(1+\alpha) e^{-\lambda_1 t} \text{ watts/watt}$$

$$\frac{P_2}{P_0} = \frac{E_{\gamma 2} + E_{\beta 2}}{200\text{Mev}} c(1+\alpha) \left[\frac{\lambda_2}{\lambda_1 - \lambda_2} \left(e^{-\lambda_2 t} - e^{-\lambda_1 t} \right) + e^{-\lambda_2 t} \right] \text{watts/watt}$$

Where:

P_1/P_o = the energy from U-239 decay

P_2/P_o = the energy from Np-239 decay

t = the time after shutdown (seconds)

c (1+α) = the ratio of U-238 captures to total fissions = 0.6 (1+0.2)

$\lambda 1$ = the decay constant of U-239 = 4.91×10^{-4} seconds^{-1}

$\lambda 2$ = the decay constant of Np-239 = 3.41×10^{-6} seconds^{-1}

$E\gamma_1$ = total γ-ray energy from U-239 decay = 0.06 Mev

$E\gamma_2$ = total γ-ray energy from Np-239 decay = 0.30 Mev

$E_{\beta 1}$ = total β-ray energy from U-239 decay = 1/3 x 1.18 Mev

$E_{\beta 2}$ = total β-ray energy from NP-239 decay = 1/3 x 0.43 Mev

(Two-thirds of the potential β-energy is assumed to escape by the accompanying neutrinos).

For the LOCA analyses, the heat from the radioactive decay of U-239 and Np-239 is calculated as described in Section 9 of Reference 6. The decay of other actinides is neglected, as justified in Section 9.9.1 of Reference 6. The effect of neutron capture in fission products is included, as discussed in Reference 11. For the non-LOCA analysis, the decay of U-238 capture products is included as an integral part of the 1979 decay heat curve presented as Figure 15.1-7.

15.1.8.3 Residual Fissions

The time dependence of residual fission power after shutdown depends on core properties throughout a transient under consideration. Core average conditions are more conservative for the calculation of reactivity and power level than actual local conditions as they would exist in hot areas of the core. Thus, unless otherwise stated in the text, static power shapes have been assumed in the analyses and these are factored by the time behavior of core average fission power calculated by a point model kinetics calculation with 6 delayed neutron groups.

For the LOCA analyses, the residual fission energy is calculated using a point kinetics model as described in Section 9 of Reference 6. Fission product decay heat is calculated using the 1979 ANS decay heat standard (Reference 11). Implementation of the model includes consideration of the spatial distribution, and uncertainty of the decay heat itself.

15.1.8.4 Distribution of Decay Heat Following Loss of Coolant Accident

For the LOCA analyses, the energy deposition modeling is performed as described in Section 9 of Reference 6. The LOCA analyses model the energy sources within the reactor fuel in three distinct categories. These categories are prompt fission, fission product decay, and actinide nuclide decay.

The energy from fission events appears in varying forms with large differences in spatial transport characteristics. The degree to which a radiation source will propagate through a medium is strongly related to whether the radiation is expressed as a charged particle (e.g., fission fragment or beta particle), an uncharged particle (e.g., neutron), or a photon, (e.g., gamma-ray). Charged particles emitted from within a nuclear fuel material are, from a practical viewpoint, unable to penetrate the confines of the fuel rod and, therefore, deposit essentially all of their energy within the fuel rod as heat. The vast majority of the total energy released due to a fission event is expressed as the kinetic energy of the fission products. The fission fragments are emitted as highly charged particles, essentially instantaneously after the fission event, and are deposited almost exclusively within the fuel pin in which they are generated. The beta particle energy from both the decay of fission fragments and the transmutation of the actinide activation products are also charged particles which are, like the fission fragments, deposited almost exclusively within the fuel pin in which they are generated. The beta particle energy is released as a result of the radioactive decay process, which is not directly related to the fission rate; rather it is related to the concentration of the various radio-nuclides which compose the source. The LOCA analyses explicitly model the spatial distribution and temporal relationships which describe all heat sources and deposits the energy from non-penetrating radiation sources. The fraction of the total heat source which is deposited in this manner is independent of coolant conditions.

The balance of the energy released as a result of the fission event is expressed as uncharged particles, i.e., neutrons and gamma photon energy. These penetrating radiation sources, due to their lack of charged particles, easily escape the confines of the fuel rod. The LOCA analyses model the spatial deposition of spatially varying penetrating radiation sources using a generalized energy deposition model (GEDM).

15.1.9 Computer Codes Utilized

Summaries of some of the principal computer codes used in transient analyses are given below. Other codes, in particular, very specialized codes in which the modeling has been developed to simulate one given accident, and which consequently have a direct bearing on the analysis of the accident itself, are summarized in their respective accident analyses sections. The codes used in the analyses of each transient have been listed in Table 15.1-4.

15.1.9.1 FACTRAN

FACTRAN calculates the transient temperature distribution in a cross section of a metal clad UO_2 fuel rod (see Figure 15.1-8) and the transient heat flux at the surface of the clad using as input the nuclear power and the time dependent coolant parameters (pressure, flow, temperature, and density). The code uses a fuel model which exhibits the following features simultaneously:

1. A sufficiently large number of finite difference radial space increments to handle fast transients such as rod ejection accidents.
2. Material properties which are functions of temperature and a sophisticated fuel to clad gap heat transfer calculation.

3. The necessary calculations to handle post DNB transients: film boiling heat transfer correlations, Zircaloy water reaction, and partial melting of the materials.

The gap heat transfer coefficient is calculated according to an elastic pellet model. The thermal expansion of the pellet is calculated as the sum of the radial (one dimensional) expansions of the rings. Each ring is assumed to expand freely. The clad diameter is calculated based on thermal expansion and internal and external pressures.

If the outside radius of the expanded pellet is smaller than the inside radius of the expanded clad, there is no fuel clad contact and the gap conductance is calculated on the basis of the thermal conductivity of the gas contained in the gap. If the pellet outside radius so calculated is larger than the clad inside radius (negative gap), the pellet and the clad are pictured as exerting upon each other a pressure sufficient to reduce the gap to zero by elastic deformation of both. This contact pressure determines the heat transfer coefficient.

FACTRAN is further discussed in Reference 12

15.1.9.2 LOFTRAN

The LOFTRAN program is used for studies of transient response of a pressurized water reactor system to specified perturbations in process parameters. LOFTRAN simulates a multiloop system by modeling the reactor core and vessel, hot and cold leg piping, steam generator (tube and shell sides), reactor coolant pumps, and the pressurizer with up to 4 reactor coolant loops. The pressurizer heaters, spray, relief, and safety valves are also considered in the program. Point model neutron kinetics, and reactivity effects of the moderator, fuel, boron and rods are included. The secondary side of the steam generator utilizes a homogeneous, saturated mixture for the thermal transients and a water level correlation for indication and control. The reactor protection system is simulated to include reactor trips on neutron flux, overpower and overtemperature reactor coolant delta T, high and low pressure, low flow, and high pressurizer level. Control systems are also simulated including rod control, steam dump, feedwater control and pressurizer pressure control. The Safety Injection System, including the accumulators, is also modeled.

LOFTRAN is a versatile program which is suited to both accident evaluation and control studies as well as parameter sizing.

LOFTRAN also has the capability of calculating the transient value of DNBR based on the input from the core limits illustrated on Figure 15.1-7. The core limits represent the minimum value of DNBR as calculated for typical or thimble cell.

LOFTRAN is further discussed in Reference 13.

15.1.9.3 LEOPARD

The LEOPARD computer program determines fast and thermal neutron spectra, using only basic geometry and temperature data. The code optionally computes fuel depletion effects for a dimensionless reactor and recomputes the spectra before each discrete burnup step.

LEOPARD is further described in Reference 14.

15.1.9.4 TURTLE

TURTLE is a two group, two dimensional neutron diffusion code featuring a direct treatment of the nonlinear effects of xenon, enthalpy, and Doppler. Fuel depletion is allowed.

TURTLE was written for the study of azimuthal xenon oscillations, but the code is useful for general analysis. The input is simple, fuel management is handled directly, and a boron criticality search is allowed.

TURTLE is further described in Reference 15.

15.1.9.5 TWINKLE

The TWINKLE program is a multi dimensional spatial neutron kinetics code, which was patterned after steady state codes presently used for reactor core design. The code uses an implicit finite difference method to solve the two group transient neutron diffusion equations in 1, 2, and 3 dimensions. The code uses 6 delayed neutron groups and contains a detailed multi region fuel clad coolant heat transfer model for calculating point wise Doppler and moderator feedback effects. The code handles up to 8000 spatial points, and performs its own steady state initialization. Aside from basic cross section data and thermal hydraulic parameters, the code accepts as input basic driving functions such as inlet temperature, pressure, flow, boron concentration, control rod motion, and others. Various edits are provided, e.g., channel wise power, axial offset, enthalpy, volumetric surge, point wise power, and fuel temperatures.

The TWINKLE Code is used to predict the kinetic behavior of a reactor for transients which cause a major perturbation in the spatial neutron flux distribution.

TWINKLE is further described in Reference 16.

15.1.9.6 THINC

The THINC Code is described in Section 4.4.3.

15.1.9.7 WCOBRA/TRAC-TF2

WCOBRA/TRAC-TF2 is the principal thermal-hydraulics code for FSLOCA and is described in Reference 6.

15.2 CONDITION II - FAULTS OF MODERATE FREQUENCY

These faults, at worst, result in a reactor trip with the plant being capable of returning to operation. By definition, these faults (or events) do not propagate to cause a more serious fault (i.e., Condition III or IV category). In addition, Condition II events are not expected to result in fuel rod failures or Reactor Coolant System overpressurization. For the purposes of this report, the following faults have been grouped into this category:

1. Uncontrolled rod cluster control assembly bank withdrawal from a subcritical condition.
2. Uncontrolled rod cluster control assembly bank withdrawal at power.
3. Rod cluster control assembly misalignment.
4. Uncontrolled boron dilution.
5. Partial loss of forced reactor coolant flow.
6. Startup of an inactive reactor coolant loop.
7. Loss of external electrical load and/or turbine trip.
8. Loss of normal feedwater.
9. Loss of offsite power to the station auxiliaries.
10. Excessive heat removal due to feedwater system malfunctions.
11. Excessive load increase incident.
12. Accidental depressurization of the Reactor Coolant System.
13. Accidental depressurization of the Main Steam System.
14. Inadvertent operation of the Safety Injection System (SIS) during power operation.

Each of these faults of moderate frequency are analyzed in this section. In general, each analysis includes an identification of causes and description of the accident, an analysis of effects and consequences, a presentation of results, and relevant conclusions.

An evaluation of the reliability of the Reactor Protection System actuation following initiation of Condition II events has been completed and is presented in Reference 1 for the relay protection logic. Standard reliability engineering techniques were used to assess likelihood of the trip failure due to random component failures. Common-mode failures were also qualitatively investigated. It was concluded, from the evaluation, that the likelihood of no trip following initiation of Condition II events is extremely small (2×10^{-7} derived for random component failures).

The Solid State Protection System design has been evaluated by the same methods as used for the relay system and the same order of magnitude of reliability is provided.

In order to satisfy the positions set forth in WASH-1270, Appendix A, Part 11.13, anticipated transients without trip have been analyzed for Westinghouse Pressurized Water Reactors (PWR's).

The results of these analyses are presented in References 11, 12, and 13 and demonstrate that a Westinghouse PWR is inherently self-limiting within well defined safety limits.

The time sequence of events during applicable Condition II events is shown in Table 15.2-1.

15.2.1 Uncontrolled Rod Cluster Control Assembly Bank Withdrawal From a Subcritical Condition

15.2.1.1 Identification of Causes and Accident Description

Branch Technical Position (BTP), ICSB 14, discusses spurious withdrawals of control rods in Pressurized Water Reactors General Design Criteria (Appendix A to 10CFR50) 20 and 25 require protection systems which at all times limit the consequences of anticipated operational occurrences or malfunctions, and for reactivity control systems the fuel design limits may not be exceeded. The following discussion provides evidence that the Rod Control System in conjunction with the Reactor Protection System at VCSNS assures the GDC requirements are met. This BTP is also applicable to Section 15.2.2 and 15.3.6.

A rod cluster control assembly (RCCA) withdrawal accident is defined as an uncontrolled addition of reactivity to the reactor core caused by withdrawal of RCCAs resulting in a power excursion. Such a transient could be caused by a malfunction of the reactor control or rod control systems. This could occur with the reactor either subcritical, hot zero power, or at power. The “at power” case is discussed in Section Section 15.2.2.

Although the reactor is normally brought to power from a subcritical condition by means of RCCA withdrawal, initial startup procedures with a clean core, call for boron dilution. The maximum rate of reactivity increase in the case of boron dilution, is less than that assumed in this analysis (see Section 15.2.4).

The RCCA drive mechanisms are wired into preselected bank configurations, which are not altered during reactor life. These circuits prevent the RCCAs from being automatically withdrawn in other than their respective banks. Power supplied to the banks is controlled such that no more than 2 banks can be withdrawn at the same time. The RCCA drive mechanisms are of the magnetic latch type and coil actuation is sequenced to provide variable speed travel. The maximum reactivity insertion rate analyzed in the detailed plant analysis is that occurring with the simultaneous withdrawal of the combination of 2 control banks having the maximum combined worth at maximum speed.

The neutron flux response to a continuous reactivity insertion is characterized by a very fast rise terminated by the reactivity feedback effect of the negative Doppler coefficient. This self-limitation of the power excursion is of primary importance since it limits the power to a tolerable level during the delay time for protective action. Should a continuous RCCA withdrawal accident occur, the transient will be terminated by the following automatic features of the Reactor Protection System:

1. Source Range Neutron Flux Reactor Trip

   The source range high neutron flux reactor trip is actuated when either of 2 independent source range channels indicates a neutron flux level above a preselected manually adjustable setpoint. This trip function may be manually bypassed only after an intermediate range flux channel indicates a flux level above a specified level. It is automatically reinstated when both intermediate range channels indicate a flux level below a specified level.

2. Intermediate Range High Neutron Flux Reactor Trip

   The intermediate range high neutron flux reactor trip is actuated when either of 2 independent intermediate range channels indicates a flux level above a preselected manually adjustable setpoint. This trip function may be manually bypassed only after 2 of the 4 power range channels are reading above approximately 10% of full power and is automatically reinstated when 3 of the 4 channels indicate a power level below this value.

3. Power Range High Neutron Flux Reactor Trip (Low Setting)

   The power range high neutron flux trip (low setting) is actuated when 2 out of the 4 power range channels indicate a power level above approximately 25% of full power. This trip function may be manually bypassed when 2 of the 4 power range channels indicate a power level above approximately 10% of full power and is automatically reinstated only after 3 of the 4 channels indicate a power level below this value.

4. Power Range High Neutron Flux Reactor Trip (High Setting)

   The power range high neutron flux reactor trip (high setting) is actuated when 2 out of the 4 power range channels indicate a power level above a preset setpoint. This trip function is always active.

5. High Positive Neutron Flux Rate Trip

   In addition, control rod stops on high intermediate range flux level (1 of 2) and high power range flux level (1 out of 4) serve to discontinue rod withdrawal and prevent actuation of the intermediate range flux level trip and the power range flux level trip, respectively.

15.2.1.2 Analysis of Effects and Consequences

15.2.1.2.1 Method of Analysis

The analysis of the uncontrolled rod withdrawal from subcritical accident is performed in 3 stages: first a core average nuclear power transient calculation is performed, followed by an average core heat transfer calculation, and finally a DNBR calculation. The core average nuclear power transient calculation is performed using a spatial neutron kinetics code, TWINKLE (Reference 2) , to determine the average power generation with time including the various total core feedback effects, i.e., Doppler and moderator reactivity. The average

heat flux and temperature transients are determined by performing a fuel rod transient heat transfer calculation in FACTRAN (Reference 3). Note that the effects of fuel thermal conductivity degradation with burnup, consistent with the PAD5 fuel performance code (Reference 19), were accounted for in the core hot spot FACTRAN calculations.The average heat flux is next used in THINC (Reference 9) for the transient DNBR calculation.

The core axial power distribution is severely peaked to the bottom of the core for the limiting transient. The W-3 DNB correlation is used to evaluate DNBR in the span between the lower non-mixing vane grid and the first mixing vane grid. The WRB-2 correlation remains applicable for the rest of the fuel assembly.

In order to give conservative results for a startup accident, the following assumptions are made concerning the initial reactor conditions:

1. Since the magnitude of the power peak reached during the initial part of the transient for any given rate of reactivity insertion is strongly dependent on the Doppler coefficient, conservative values (low absolute magnitude) as a function of temperature are used. See Section 15.1.6 and Table 15.1-4.
2. Contribution of the moderator reactivity coefficient is negligible during the initial part of the transient because the heat transfer time between the fuel and moderator is much longer than the neutron flux response time. However, after the initial neutron flux peak, the succeeding rate of power increase is affected by the moderator reactivity coefficient. A conservative value, given in Table 15.1-4, is used in the analysis to yield the maximum peak heat flux.
3. The reactor is assumed to be at hot zero power. This assumption is more conservative than that of a lower initial system temperature. The higher initial system temperature yields a larger fuel-water heat transfer coefficient, larger specific heats, and a less negative (smaller absolute magnitude) Doppler coefficient, all of which tend to reduce the Doppler feedback effect, thereby, increasing the neutron flux peak. The initial effective multiplication factor is assumed to be 1.0 since this results in the worst nuclear power transient.
4. Reactor trip is assumed to be initiated by power range high neutron flux (low setting). The most adverse combination of instrument and setpoint errors, as well as delays for trip signal actuation and rod cluster control assembly release, is taken into account. A 10% increase is assumed for the power range flux trip setpoint, raising it from the nominal value of 25% to 35%. Previous results, however, show that rise in the neutron flux is so rapid that the effect of errors in the trip setpoint on the actual time at which the rods are released is negligible.
5. The maximum positive reactivity insertion rate assumed is greater than that for the simultaneous withdrawal of the combination of the 2 control banks having the greatest combined worth at maximum speed (45 inches/minute). Control rod drive mechanism design is discussed in Section 4.2.3.
6. The initial power level was assumed to be below the power level expected for any shutdown condition. The combination of highest reactivity insertion rate and lowest initial power produces the highest peak heat flux.
7. Two (2) reactor coolant pumps are assumed to be operating.

8. A 1% core flow statepoint reduction was applied to incorporate the effects of asymmetric loop flow, assuming a maximum RCS loop-to-loop flow asymmetry of 5%.

15.2.1.2.2 Results

The calculated sequence of events for this accident is shown on Table 15.2-1.

Figure 15.2-1 and Figure 15.2-2 show the transient behavior for the indicated reactivity insertion rate with the accident terminated by reactor trip at 35% nominal power. This insertion rate is greater than that for the 2 highest worth control banks, both assumed to be in their highest incremental worth region.

Figure 15.2-1 shows the nuclear power transient. The nuclear power overshoots the full power nominal value but this occurs for only a very short time period. Hence, the energy release and the fuel temperature increases are relatively small. The heat flux response, of interest for DNB considerations, is shown in Figure 15.2-1. The beneficial effect of the inherent thermal lag in the fuel is evidenced by a peak heat flux less than the full power nominal value.

Figure 15.2-2 shows the response of the hot spot average fuel and clad temperature. The average fuel temperature increases to a value lower than the nominal full power value.

15.2.1.3 Conclusions

In the event of an RCCA withdrawal accident from the subcritical condition, the core and the Reactor Coolant System are not adversely affected, since the combination of thermal power and the coolant temperature result in a departure from nucleate boiling ratio (DNBR) greater than the design limit value. Thus, no fuel or clad damage is predicted as a result of DNB.

15.2.2 Uncontrolled Rod Cluster Control Assembly Bank Withdrawal at Power

15.2.2.1 Identification of Causes and Accident Description

Uncontrolled rod cluster control assembly (RCCA) bank withdrawal at power results in an increase in the core heat flux. Since the heat extraction from the steam generator lags behind the core power generation until the steam generator pressure reaches the relief or safety valve setpoint, there is a net increase in the reactor coolant temperature. Unless terminated by manual or automatic action, the power mismatch and resultant coolant temperature rise would eventually result in DNB. Therefore, in order to avert damage to the cladding, the Reactor Protection System is designed to terminate any such transient before the DNBR falls below the safety analysis limit value.

The automatic features of the Reactor Protection System, which prevent core damage following the postulated accident, include the following:

1. Power range neutron flux instrumentation actuates a reactor trip if 2 out of 4 channels exceed a high flux setpoint, or a high positive flux rate setpoint.

2. Reactor trip is actuated if any 2 out of 3 ΔT channels exceed an overtemperature ΔT setpoint. This setpoint is automatically varied with axial power imbalance, coolant temperature, and pressure to protect against DNB.
3. Reactor trip is actuated, if any 2 out of 3 ΔT channels exceed an overpower ΔT setpoint, to ensure that the allowable heat generation rate (kW/ft) is not exceeded.
4. A high pressurizer pressure reactor trip actuated from any 2 out of 3 pressure channels that are set at a fixed point. This set pressure is less than the set pressure for the pressurizer safety valves.
5. high pressurizer water level reactor trip, actuated from any 2 out of 3 level channels, is set at a fixed point.

In addition to the above listed reactor trips, there are the following RCCA withdrawal blocks:

1. High neutron flux (1 out of 4)
2. Overpower ΔT (2 out of 3)
3. Overtemperature ΔT (2 out of 3)

The manner in which the combination of overpower and overtemperature ΔT trips provide protection over the full range of Reactor Coolant System conditions is described in Chapter 7. Figure 15.1-1 presents allowable reactor coolant loop average temperature and ΔT for the design power distribution and flow as a function of primary coolant pressure. The boundaries of operation defined by the overpower ΔT trip and the overtemperature ΔT trip are represented as “protection lines” on this diagram. The protection lines are drawn to include all adverse instrumentation and setpoint errors so that under nominal conditions the trip would occur well within the area bounded by these lines. The utility of this diagram is in the fact that the limit imposed by any given DNBR can be represented as a line. The DNB lines represent the locus of conditions for which the DNBR equals the safety analysis limit value. All points below and to the left of a DNB line for a given pressure have a DNBR greater than the limit. The diagram shows that DNB is prevented for all cases if the area enclosed with the maximum protection lines is not traversed by the applicable DNBR line at any point.

The area of permissible operation (power, pressure, and temperature) is bounded by the combination of reactor trips: high neutron flux (fixed setpoint); high pressure (fixed setpoint); low pressure (fixed setpoint); overpower and overtemperature ΔT (variable setpoints).

15.2.2.2 Analysis of Effects and Consequences

The analyses described below demonstrate conformance to fuel design limits. A conservative analysis has also been performed that verifies that the RCS overpressure limit will not be exceeded.

15.2.2.2.1 Method of Analysis

This transient is analyzed by the LOFTRAN (Reference 4) Code. This code simulates the neutron kinetics, Reactor Coolant System, pressurizer, pressurizer relief and safety valves, pressurizer spray, steam generator, and steam generator safety valves. The code computes pertinent plant variables including temperatures, pressures, and power level. The core limits as illustrated in Figure 15.1-1 are used as input to LOFTRAN to determine the minimum DNBR during the transient.

In order to obtain conservative results, the following assumptions are made:

1. To analyze the accident for DNB concerns, the accident is analyzed using the Revised Thermal Design Procedure. Therefore, the initial reactor power, pressure, and RCS temperatures are assumed to be at their nominal values. Uncertainties in the initial conditions are included in the limit DNBR. To analyze the accident for maximum RCS pressure, uncertainties in the initial conditions are applied to produce limiting RCS pressures.
2. Reactivity Coefficients - Both minimum and maximum reactivity conditions are considered.
   e. Minimum reactivity feedback. A positive moderator coefficient of reactivity of + 7 pcm/°F is assumed. A variable Doppler power coefficient with core power is used in the analysis. A conservatively small (in absolute magnitude) value is assumed.
   f. Maximum reactivity feedback. A conservatively large positive moderator density coefficient and a large (in absolute magnitude) negative Doppler power coefficient are assumed.
3. The reactor trip on high neutron flux is assumed to actuate at a conservative value of 118% of nominal full power. The DT trips include all adverse instrumentation and setpoint errors. The reactor trip on high pressurizer pressure actuates when the pressurizer pressure exceeds a setpoint of 2455 psia. The delays for the trip signal actuations for all of the trips are assumed at conservatively high values.
4. The RCCA trip insertion characteristics is based on the assumption that the highest worth assembly is stuck in its fully withdrawn position.
5. The maximum positive reactivity insertion rate is greater than that which would be obtained for the simultaneous withdrawal of the 2 control banks having the maximum combined worth at maximum speed.
6. The overtemperature ΔT setpoint used in the analyses is higher than the safety analysis limit used in the setpoints study to account for a 4°F allowance for temperature related effects.

The effect of RCCA movement on the axial core power distribution is accounted for by causing a decrease in overtemperature and overpower ΔT trip setpoints proportional to decrease in margin to DNB.T trip setpoints proportional to decrease in margin to DNB.

15.2.2.2.2 Results

The calculated sequence of events for the cases analyzed for DNB concerns is shown on Table 15.2-1.

Figure 15.2-3 and Figure 15.2-4 show the transient response to a rapid RCCA withdrawal starting from full power. Reactor trip on high neutron flux occurs shortly after the start of the accident. Since this is rapid with respect to the thermal time constants of the plant, small changes in T_{avg} and pressure result and a large margin to DNB is maintained.

The transient response for a slow control rod assembly withdrawal from full power is shown on Figure 15.2-5 and Figure 15.2-6. Reactor trip on overtemperature ΔT occurs after a longer period and the rise in temperature and pressure is consequently larger than for rapid RCCA withdrawal. Again, the minimum DNBR is never less than the safety analysis limit values.

Figure 15.2-7, Figure 15.2-8, and Figure 15.2-9 illustrate the minimum DNBR calculated for minimum and maximum reactivity feedbacks.

Figure 15.2-7 shows the minimum DNBR as a function of reactivity insertion rate from initial full power operation for minimum and maximum reactivity feedback. It can be seen that 2 reactor trip channels provide protection over the whole range of reactivity insertion rates. These are the high neutron flux and overtemperature ΔT trip channels. The minimum DNBR is never less than the safety analysis limit values.

Figure 15.2-8 and Figure 15.2-9 show the minimum DNBR as a function of reactivity insertion rate for RCCA withdrawal incidents starting at 60 and 10% power respectively. The results are similar to the 100% power case, except as the initial power is decreased, the range over which the overtemperature ΔT trip is effective is increased. In neither case does the DNBR fall below the safety analysis limit values.

The shape of the curves of minimum DNBR versus reactivity insertion rate in the referenced figures is due both to reactor core and coolant system transient response and to protection system action in initiating a reactor trip.

Referring to Figure 15.2-9, for example, it is noted that:

1. For high reactivity insertion rates of about ~5 pcm/sec, reactor trip is initiated by the high neutron flux trip for the minimum reactivity feedback cases. The neutron flux level in the core rises rapidly for these insertion rates while core heat flux and coolant system temperature lag behind due to the thermal capacity of the fuel and coolant system fluid. Thus, the reactor is tripped prior to significant increase in heat flux or water temperature with resultant high minimum DNBR's during the transient. As the reactivity insertion rate decreases, core heat flux and coolant temperatures can remain more nearly in equilibrium with the neutron flux; minimum DNBR during the transient thus decreases with decreasing insertion rate.

2. The overtemperature ΔT reactor trip circuit initiates a reactor trip when measured coolant loop ΔT exceeds a setpoint based on measured Reactor Coolant System average temperature and pressure. This trip circuit is described in detail in Chapter 7; however, it is important to note that the average temperature contribution to the circuit is lead-lag compensated in order to decrease the effect of the thermal capacity of the Reactor Coolant System in response to power increases.
3. For reactivity insertion rate below ~ 15 pcm/sec the overtemperature ΔT trip terminates the transient for the minimum reactivity feedback cases.

   For reactivity insertion rates below ~ 20 pcm/sec the effectiveness of the overtemperature ΔT trip increases (in terms of increased minimum DNBR) due to the fact that with lower insertion rates the power increase rate is slower, the rate of rise of average coolant temperature is slower, and the system lags and delays become less significant.

Referring to Figure 15.2-8, it is noted that:

For reactivity insertion rates less than ~ 50 pcm/sec, the rise in the reactor coolant temperature is sufficiently high so that the steam generator safety valve setpoint is reached prior to trip. Opening of these valves, which act as an additional heat load on the Reactor Coolant System, sharply decreases the rate of increase of Reactor Coolant System average temperature. This decrease in rate of increase of the average coolant system temperature during the transient is accentuated by the lead-lag compensation causing the overtemperature ΔT trip setpoint to be reached later with resulting lower minimum DNBR.

For transients initiated from higher power levels (for example, see Figure 15.2-7) the effect described above, which results in the sharp peak in minimum DNBR at approximately 50 pcm/sec, does not occur since the steam generator safety valves are not actuated prior to trip.

Since the RCCA withdrawal at power incident is an overpower transient, the fuel temperatures rise during the transient until after reactor trip occurs. For high reactivity insertion rates, the overpower transient is fast with respect to the fuel rod thermal time constant, and the core heat flux lags behind the neutron flux response. Due to this lag, the peak core heat flux does not exceed 118% of its nominal value (i.e., the high neutron flux trip setpoint assumed in the analysis). Taking into account the effect of the RCCA withdrawal on the axial core power distribution, the peak fuel centerline temperature will still remain below the fuel melting temperature.

For slow reactivity insertion rates, the core heat flux remains more nearly in equilibrium with the neutron flux. The overpower transient is terminated by the overtemperature ΔT reactor trip before a DNB condition is reached. The peak heat flux again is maintained below 118% of its nominal value. Taking into account the effect of the RCCA withdrawal on the axial core power distribution, the peak fuel centerline temperature will remain below the fuel melting temperature.

Since DNB does not occur at any time during the RCCA withdrawal at power transient, the ability of the primary coolant to remove heat from the fuel rod is not reduced. Thus, the fuel cladding temperature does not rise significantly above its initial value during the transient.

The calculated sequence of events for the cases analyzed for DNB concerns is shown on Table 15.2-1. With the reactor tripped, the plant eventually returns to a stable condition. The plant may subsequently be cooled down further by following normal plant shutdown procedures.

15.2.2.3 Conclusions

The high neutron flux, overtemperature ΔT, and high pressurizer pressure reactor trip functions provide adequate protection against DNB or overpressure over the entire range of possible reactivity insertion rates. The minimum value of DNBR is always larger than the safety analysis limit value and the RCS pressure is maintained below 110% of the design pressure. Therefore, the results of the analysis show that an uncontrolled RCCA bank withdrawal at power does not adversely affect the core or the RCS.

15.2.3 Rod Cluster Control Assembly Misoperation

This section discusses RCCA misoperation that can result from system malfunction or operator error.

15.2.3.1 Identification of Causes and Accident Description

Rod cluster control assembly (RCCA) misalignment accidents include:

1. One (1) or more dropped RCCAs within the same group;
2. A dropped RCCA bank;
3. Statically misaligned RCCA.

Each RCCA has a position indicator channel which displays position of the assembly. The displays of assembly positions are grouped for the operator’s convenience. Fully inserted assemblies are further indicated by a rod bottom signal, which actuates a local alarm and a control room annunciator. Group demand position is also indicated. RCCAs are always moved in preselected banks, and the banks are always moved in the same preselected sequence. Each bank of RCCAs is divided into 2 groups. The rods comprising a group operate in parallel through multiplexing thyristors. The 2 groups in a bank move sequentially such that the first group is always within one step of the second group in the bank. A definite schedule of actuation (or deactuation of the stationary gripper, movable gripper, and lift coils of a mechanism) is required to withdraw the RCCA attached to the mechanism. Since the stationary gripper, movable gripper, and lift coils associated with the 4 RCCAs of a rod group are driven in parallel, any single failure that would cause rod withdrawal would affect a minimum of one group. Mechanical failures are in the direction of insertion, or immobility.

A dropped RCCA or RCCA bank is detected by:

1. A sudden drop in the core power level as seen by the nuclear instrumentation system;
2. Asymmetric power distribution as seen on excore neutron detectors or core exit thermocouples;

3. Rod at bottom signal;
4. Rod deviation alarm;
5. Rod position indication.

Misaligned assemblies are detected by:

1. Asymmetric power distribution as seen on excore neutron detectors or core exit thermocouples;
2. Rod deviation alarm;
3. Rod position indicators.

The deviation alarm alerts the operator whenever an individual rod position signal deviates from the other rods in the bank by a preset limit. If the rod deviation alarm is not operable, the operator is required to take action as required by the Technical Specifications (Reference 6).

If 1 or more rod position indicator channels should be out of service, detailed operating instructions are followed to ensure the alignment of the nonindicated RCCAs. The operator is also required to take action as required by the Technical Specifications.

15.2.3.2 Analysis of Effects and Consequences

15.2.3.2.1 Method of Analysis

1. One (1) or more dropped RCCAs from the same group.
   For evaluation of the dropped RCCA event, the transient system response is calculated using the LOFTRAN (Reference 4) code. The code simulates the neutron kinetics, Reactor Coolant System, pressurizer, pressurizer relief and safety valves, pressurizer spray, steam generator, and steam generator safety valves. The code computes pertinent plant variables including temperatures, pressures, and power level.

   Statepoints are calculated and nuclear models are used to obtain a hot channel factor consistent with the primary system conditions and reactor power. By incorporating the primary conditions from the transient and the hot channel factor from the nuclear analysis, the DNB design basis is shown to be met using the THINC code (Reference 9). The transient response, nuclear peaking factor analysis, and DNB design basis confirmation are performed in accordance with the methodology described in Reference 10

2. Dropped RCCA Bank

   A dropped RCCA bank results in a symmetric power change in the core. As discussed in Reference 10, assumptions made for the dropped RCCA(s) analysis provide a bounding analysis for the dropped RCCA bank.

3. Statically Misaligned RCCA

Steady state power distributions are analyzed using the computer codes as described in Table 4.1-2. The peaking factors are then used as input to the THINC code to calculate the DNBR.

15.2.3.2.2 Results

1. One (1) or more Dropped RCCAs

   Single or multiple dropped RCCAs within the same group result in a negative reactivity insertion. The core is not adversely affected during this period since power is decreasing rapidly. Either reactivity feedback or control bank withdrawal will re-establish power.

   Following a dropped rod event in manual control, the plant will establish a new equilibrium condition. Without control system interaction, a new equilibrium is achieved at a reduced power level and reduced primary temperature. Thus, the automatic rod control mode of operation is the limiting case.

   For a dropped RCCA event in the automatic rod control mode, the Rod Control System detects the drop in power and initiates control bank withdrawal. Power overshoot may occur due to this action by the automatic rod controller after which the control system will insert the control bank to restore nominal power. Figure 15.2-10 and Figure 15.2-11 show a typical transient response to a dropped RCCA (or RCCAs) in automatic control. In all cases, the minimum DNBR remains above the safety analysis limit value

2. Dropped RCCA Bank

   A dropped RCCA bank results in a negative reactivity insertion greater than 500 pcm. The core is not adversely affected during the insertion period, since power is decreasing rapidly. The transient will proceed as described in Part 1; however, the return to power will be less due to the greater worth of the entire bank. The power distribution during a dropped bank transient is symmetric. Following plant stabilization, normal procedures are followed.

3. Statically Misaligned RCCA

   The most severe misalignment situations with respect to DNBR at significant power levels arise from cases in which 1 RCCA is fully inserted, or where bank D is fully inserted with 1 RCCA fully withdrawn. Multiple independent alarms, including a bank insertion limit alarm, alert the operator well before the postulated conditions are approached. The bank can be inserted to its insertion limit with any one assembly fully withdrawn without the DNBR falling below the safety analysis limit value.

   The insertion limits in the Technical Specifications may vary from time to time depending on a number of limiting criteria. It is preferable, therefore, to analyze the misaligned RCCA case at full power for a position of the control bank as deeply inserted as the criteria on minimum DNBR and power peaking factor will allow. The full power insertion limits on control bank D must then be chosen to be above that position and will usually be dictated by other criteria. Detailed results will vary from cycle to cycle depending on fuel arrangements.

For this RCCA misalignment, with bank D inserted to its full power insertion limit and one RCCA fully withdrawn, DNBR does not fall below the safety analysis limit value. This case is analyzed assuming the initial reactor power, pressure, and RCS temperatures are at their nominal values but with the increased radial peaking factor associated with the misaligned RCCA.

DNB calculations have not been performed specifically for RCCAs missing from other banks; however, power shape calculations have been done as required for the fully withdrawn analysis. Inspection of the power shapes shows that the DNB and peak kw/ft situation is less severe than the bank D case discussed above, assuming insertion limits on the other banks equivalent to a bank D full-in insertion limit.

For RCCA misalignments with 1 RCCA fully inserted, the DNBR does not fall below the limit value. This case is analyzed assuming the initial reactor power, pressure, and RCS temperatures are at their nominal values, but with the increased radial peaking factor associated with the misaligned RCCA.

DNB does not occur for the RCCA misalignment incident and thus the ability of the primary coolant to remove heat from the fuel rod is not reduced. The peak fuel temperature corresponds to a linear heat generation rate based on the radial peaking factor penalty associated with the misaligned RCCA and the design axial power distribution. The resulting linear heat generation is well below that which would cause fuel melting.

Following the identification of a RCCA group misalignment condition by the operator, the operator is required to take action as required by the plant Technical Specifications and operating instructions.

15.2.3.3 Conclusions

It is shown for all cases of dropped RCCAs or dropped banks that the DNBR remains greater than the safety analysis limit value and, therefore, the DNB design basis is met.

For all cases of any RCCA fully inserted, or bank D inserted to its rod insertion limits with any single RCCA in that bank fully withdrawn (static misalignment), the DNBR remains greater than the safety analysis limit value. Therefore, the DNB design basis is met.

15.2.4 Uncontrolled Boron Dilution

15.2.4.1 Identification of Causes and Accident Description

Reactivity can be added to the core by feeding primary grade water into the Reactor Coolant System (RCS) via the reactor makeup portion of the Chemical and Volume Control System (CVCS). Boron dilution is a manual operation under strict administrative controls with procedures calling for a limit on the rate and duration of dilution. A boric acid blend system is provided to permit the operator to match the boron concentration of reactor coolant makeup water during normal charging to that in the RCS. The CVCS is designed to limit, even under various

postulated failure modes, the potential rate of dilution to a value which, after indication through alarms and instrumentation, provides the operator sufficient time to correct the situation in a safe and orderly manner.

The opening of the primary water makeup control valve provides makeup to the RCS which can dilute the reactor coolant. Inadvertent dilution from this source can be readily terminated by closing the control valve. In order for makeup water to be added to the RCS at pressure, at least 1 charging pump must be running in addition to a primary makeup water pump.

The rate of addition of unborated makeup water to the RCS is limited by a flow limiting orifice between the reactor makeup water pumps and the boric acid blender. As demonstrated by tests at the plant, flow is within the bounds of unborated water used in analyses in this section.

The boric acid from the boric acid tank is blended with primary grade water in the blender and the composition is determined by the preset flow rates of boric acid and primary grade water on the control board. In order to dilute 2 separate operations are required:

1. The operator must switch from the automatic makeup mode to the dilute mode.
2. The start/stop switch is placed in the start position.

Omitting either step would prevent dilution.

The status of the RCS makeup is continuously available to the operator by:

1. Indication of the boric acid and blended flow rates,
2. CVCS and RMWS pump status lights,
3. Deviation alarms if the boric acid or blended flow rates deviate by more than 10% from the preset values.

Indication of a dilution event is available to the operator by:

1. Source Range Neutron Flux - when the reactor is subcritical:
   a. High flux at shutdown alarm. A separate main control board (MCB) and computer generated alarm is provided for each channel.
   b. Indicated source range neutron flux count rates.
   c. Audible source range neutron flux count rate.
2. With the reactor critical:
   a. Axial flux difference alarm (reactor power ≥ 50% RTP),
   b. Control rod insertion limit low and low-low alarms,
   c. Overtemperature ΔT alarm (at power),
   d. Overtemperature ΔT turbine runback (at power),

e. Overtemperature ΔT reactor trip, and

f. Power range neutron flux - High, both high and low setpoint reactor trips.

15.2.4.2 Analysis of Effects and Consequences

To cover all phases of the plant operation, boron dilution during refueling, cold shutdown, hot standby, startup, and power operation are considered in this analysis. Table 15.2-1 contains the time sequence of events for this accident.

1. Dilution During Refueling

   An uncontrolled boron dilution accident based on a failure in the primary water makeup system cannot occur during refueling. This accident is prevented by administrative controls which isolate the RCS from the potential source unborated water.

   Valves 8454, 8441, 8430, and 8439 will be locked closed during refueling operations. These valves will block the flow paths which could allow unborated makeup water to reach the RCS. Any makeup which is required during refueling will be added to the Reactor Coolant System by unlocking these valves as appropriate and initiating the required blended makeup water flow. After the required volume of blended makeup flow has been added, these valves will again be locked closed. An alternate source of borated water that could be used is from the refueling water storage tank to the charging pump suction.

   Demineralized water may be used to decontaminate the refueling cavity walls while draining the refueling cavity. When the cavity water level is above the RV flange, water is pumped back to the refueling water storage tank through the Residual Heat Removal System. Administrative controls preclude an uncontrolled boron dilution accident by limiting the amount of demineralized water used such that the boron concentrations within the refueling cavity, Reactor Coolant System, and refueling water storage tank remain above minimum Technical Specification limits.

   The most limiting alternate source of unborated water is from the Boron Thermal Regeneration System (BTRS). For this case, highly borated RCS water is depleted of boron as it passes through the BTRS and is returned via the volume control tank. The following conditions are assumed for an uncontrolled boron dilution during refueling.

   Technical Specifications require the reactor to be borated to at least 2,000 ppm or shutdown by at least 5.0% Δk at refueling.

   If an inadvertent dilution from the BTRS occurs during refueling, with the reactor vessel head off, and the refueling cavity filled with borated water (i.e., in a condition to move fuel), the maximum dilution capability of the BTRS is insufficient to cause a return to criticality.

The maximum dilution capability of the BTRS at these conditions is conservatively estimated to be 250 ppm. However, the minimum change in boron concentration necessary to bring the reactor critical at these conditions is conservatively estimated to be 590 ppm. An initial boron concentration of 2000 ppm is assumed. Therefore, a dilution to criticality from the BTRS at these refueling conditions cannot occur.

The most limiting conditions for an inadvertent boron dilution from the BTRS during refueling occur when the reactor coolant level is at the vessel/head junction. The dilution capability of the BTRS at these conditions is sufficient to cause a return to criticality. The minimum volume in the Reactor Coolant System corresponding to this condition is conservatively estimated to be 3075 ft^3. The critical boron concentration is conservatively estimated to be 1410 ppm.

2. Dilution During Cold Shutdown

Technical Specifications specify the required shutdown margin as a function of RCS boron concentration during cold shutdown. The specified shutdown margin ensures sufficient time for the operator to terminate the dilution. If the reactor is in cold shutdown and on the Residual Heat Removal System with RCS piping filled and vented, the following conditions are assumed for an uncontrolled boron dilution. Dilution flow is assumed to be a maximum of 150 gpm, which is the capability of 1 primary water makeup pump to deliver unborated water to the RCS. Mixing of the reactor coolant is accomplished by the operation of 1 residual heat removal pump.

A volume of 5240.5 ft^3 in the Reactor Coolant System is used. This corresponds to the active volume of the Reactor Coolant System minus the pressurizer volume, while on the Residual Heat Removal System.

If the reactor is in cold shutdown and the RCS water level is drained down from a filled and vented condition while on RHR, an inadvertent dilution is prevented by administrative controls which isolate the RCS from the potential source of unborated water. Valves 8454, 8441, 8430, and 8439 will be locked closed during operation in these conditions. These valves block all flow paths that could allow unborated makeup water to reach the RCS. Any makeup, which is required, will be added to the Reactor Coolant System by unlocking these valves, as appropriate, and initiating the required blended makeup water flow. After the required volume of blended makeup flow has been added, these valves will again be locked closed. An alternate source of borated water which may be used is from the refueling water storage tank to the charging pump suction.

3. Dilution During Hot Shutdown

   Technical Specifications specify the required shutdown margin as a function of RCS boron concentration. The analysis assumes that the RCS is filled and vented on the Residual Heat Removal System. This is more conservative than if 1 or more reactor coolant pumps are assumed operating. The following conditions are assumed for a continuous boron dilution during hot standby. Dilution flow is assumed to be a maximum of 150 gpm, which is the capacity of 1 primary water makeup pump to deliver unborated water to the RCS. A minimum water volume of 5240.5 ft^3 in the Reactor Coolant System is used. This corresponds to the active volume of the Reactor Coolant System minus the pressurizer volume, while on the Residual Heat Removal System.

4. Dilution During Hot Standby

   Technical Specifications specify the required shutdown margin as a function of RCS boron concentration. The following conditions are assumed for a continuous boron dilution during hot standby. Dilution flow is assumed to be a maximum of 150 gpm, which is the capability of one primary water makeup pump to deliver unborated water to the RCS. A minimum RCS water volume of 8126 ft^3 is assumed. This is a conservative estimate of the active RCS volume with one reactor coolant pump operating.

5. Dilution During Startup

   Prior to startup, the RCS is filled with borated water at a boron concentration of 2200 ppm. This is a conservative estimate with the reactor at a 1.77% Δk shutdown margin at 557°F. Dilution flow is assumed to be a maximum of 150 gpm, which is the capability of one primary water makeup pump to deliver unborated water to the RCS. A minimum volume of 8126 ft^3 in the Reactor Coolant System is used. This is a conservative estimate of the active volume of the RCS excluding the pressurizer.

6. Dilution During Full Power Operation

   During power operation, the plant may be operated 2 ways, under manual operator control or under automatic T_{avg}/rod control. The Technical Specifications require 3 reactor coolant pumps operating and a shutdown margin of at least 1.77% Δk. The RCS is conservatively assumed to be filled with borated water at a boron concentration of 2200 ppm. While the plant is in manual control, the dilution flow is assumed to be a maximum of 150 gpm, which is the capacity of one reactor makeup water pump to deliver unborated water to the RCS. When in automatic control, the dilution flow is limited by the maximum letdown flow (approximately 125 gpm). A minimum RCS water volume of 8126 ft^3 is used. This is a conservative estimate of the active volume of the RCS excluding the pressurizer.

15.2.4.3 Results

Dilution During Refueling

During refueling, an inadvertent dilution from the Reactor Makeup Water System is prevented by administrative controls which isolate the RCS from the potential source of unborated makeup water. The most limiting conditions for an inadvertent dilution from the BTRS occur when the reactor vessel head is unbolted and the vessel water level is at the vessel/head junction. The high flux at shutdown alarm, set at twice the background flux level measured by the source range nuclear instrumentation, is available at these conditions to alert the operator that a dilution event is in progress. For this case, the operator has more than 30 minutes from the high flux at shutdown alarm to recognize and terminate the dilution before shutdown margin is lost and the reactor becomes critical.

Dilution During Cold Shutdown

While in cold shutdown the high flux at shutdown alarm, set at twice the background flux level measured by the source range nuclear instrumentation, is available to alert the operator that a dilution event is in progress. During the cold shutdown mode while operating on the Residual Heat Removal System (RHRS) with the RCS piping filled and vented, the shutdown margin requirement ensures that the operator has at least 13.6 minutes from the high flux at shutdown alarm to recognize and terminate the uncontrolled reactivity insertion before shutdown margin is lost. During the cold shutdown mode, while operating on the RHRS with the RCS drained down from a filled and vented condition, an inadvertent dilution is precluded by administrative controls which isolate the RCS from the potential source of unborated water.

Dilution During Hot Shutdown

While in hot shutdown, the high flux at shutdown alarm, set at twice the background flux level measured by the source range nuclear instrumentation, is available to alert the operator that a dilution event is in progress. During hot shutdown, the shutdown margin requirement ensures that the operator has at least 13.6 minutes from the high flux at shutdown alarm to recognize and terminate the uncontrolled reactivity insertion before shutdown margin is lost.

Dilution During Hot Standby

While in hot standby, the high flux at shutdown alarm, set at twice the background flux level measured by the source range nuclear instrumentation, is available to alert the operator that a dilution event is in progress. During hot standby, the shutdown margin requirement ensures that the operator has at least 13.4 minutes from the high flux at shutdown alarm to recognize and terminate the uncontrolled reactivity insertion before shutdown margin is lost.

Dilution During Startup

In the event of an unplanned approach to criticality or dilution during power escalation while in the startup mode, the operator is alerted to an uncontrolled reactivity insertion by a reactor trip at

the Source Range High Neutron Flux Setpoint. After reactor trip there is more than 15 minutes for operator action prior to return to criticality.

Dilution at Power

During the at power mode with manual control, the operator is alerted to an uncontrolled reactivity insertion by an overtemperature ΔT trip. More than 15 minutes are available from the trip for the operator to recognize and terminate the uncontrolled dilution before shutdown margin is lost. The sensitivity and alarm thresholds are already assumed to be degraded to the maximum extent allowable for the overtemperature ΔT trip function (see Section 15.2.2).

During the at power mode with automatic control, the operator is alerted to an uncontrolled reactivity insertion by the rod insertion limit alarms. Two (2) insertion limit alarms are available: The first occurs when the rods are 10 steps above the insertion limit (Lo Insertion Limit Alarm) and the second occurs at the insertion limit (Lo-Lo Insertion Limit Alarm). The analysis assumed that the operator is alerted to the need for action by the Lo-Lo alarm although action would be taken when the first alarm occurs. Thus the analysis already assumes a 10 step allowance for rod position indicator inaccuracies. Even with this conservatism, more than 15 minutes are available from the time of alarm until all shutdown margin is lost. In addition to the above, other indications are available. The main indication would be a violation of the axial offset control band which could result in a reactor trip (reduction in overtemperature ΔT setpoint).

15.2.4.4 Event Detection Immediately Following Reactor Shutdown

Following a reactor trip or shutdown, the high flux at shutdown alarms for the MCB are implemented via a manual calibration of the alarm bistable based on the existing source range counts. Following the initial calibration, the MCB alarms are recalibrated at approximately 12, 24, and 48 hours after shutdown to compensate for the anticipated decrease in source range counts to stable levels. Consistent with Generic Letter 85-05, computer generated alarms, which account for decreasing source range counts, and administrative controls are also utilized to provide increased assurance that an inadvertent dilution event, should it occur, will be terminated prior to a loss of shutdown margin.

15.2.4.5 Conclusions

The analysis presented above shows that, for an inadvertent boron dilution, the operator has sufficient time to recognize and terminate the dilution before shutdown margin is lost and the reactor becomes critical.

15.2.5 Partial Loss of Forced Reactor Coolant Flow

15.2.5.1 Identification of Causes and Accident Description

A partial loss of coolant flow accident can result from a mechanical or electrical failure in a reactor coolant pump, or from a fault in the power supply to the pump or pumps. If the reactor is at power at the time of the accident, the immediate effect of loss of coolant flow is a rapid increase

in the coolant temperature. This increase could result in DNB with subsequent fuel damage if the reactor is not tripped promptly.

The necessary protection against a partial loss of coolant flow accident is provided by the low primary coolant flow reactor trip which is actuated by 2 out of 3 low flow signals in any reactor coolant loop. Above approximately 38% power (Permissive 8), low flow in any loop will actuate a reactor trip. Between approximately 10% power (Permissive 7) and power level corresponding to Permissive 8, low flow in any 2 loops will actuate a reactor trip. Reactor trip on low flow is blocked below Permissive 7.

A reactor trip signal from the pump breaker position is also provided. When operating above Permissive 7, a breaker open signal from any 2 pumps will actuate a reactor trip. This serves as a backup to the low flow trip. Reactor trip on reactor coolant pump breakers open is blocked below Permissive 7.

Normal power for each pump is supplied through individual buses connected to the isolated phase bus duct between the generator circuit breaker and the main transformer. Faults in the substation may cause a trip of the main transformer high side circuit breaker leaving the generator to supply power to the reactor coolant pumps. When a generator circuit breaker trip occurs because of electrical faults, the pumps are automatically transferred to an alternate power supply and the pumps will continue to supply coolant flow to the core. Following any turbine trip where there are no electrical faults the generator circuit breaker is tripped and the reactor coolant pumps remain connected to the network through the transformer high side breaker. Continuity of power to the pump buses is achieved without motoring the generator since means are provided to isolate the generator without isolating the pump buses from the external power lines (e.g., a generator output breaker is provided as well as station output breaker).

15.2.5.2 Analysis of Effects and Consequences

15.2.5.2.1 Method of Analysis

The following case has been analyzed:

All loops operating, one loop coasting down.

This transient is analyzed by 3 digital computer codes. First the LOFTRAN code is used to calculate the loop and core flow during the transient. The LOFTRAN code is also used to calculate the time of reactor trip, based on the calculated flows and the nuclear power transient following reactor trip. The FACTRAN code is then used to calculate the heat flux transient based on the nuclear power and flow from LOFTRAN. Finally, the THINC code (Reference 9) is used to calculate the minimum DNBR during the transient based on the heat flux from FACTRAN and the flow from LOFTRAN.

1. Initial Conditions

   Initial operating conditions assumed are the most adverse with respect to the margin to DNB (i.e., nominal steady-state power level, nominal steady-state pressure, and nominal steady-state coolant average temperature). See Section 15.1.2 for an explanation of initial conditions. The accident is analyzed using the Revised Thermal Design Procedure as described in Reference 5.

2. Reactivity Coefficients

   A conservatively large absolute value of the Doppler-only power coefficient is used (see Table 15.1-4). The total integrated Doppler reactivity from 0 to 100% power is assumed to be -0.016 ΔK.

   The least negative moderator temperature coefficient for full power conditions (0 pcm/°F) is assumed since this results in the maximum core power during the initial part of the transient when the minimum DNBR is reached.

3. Flow Coastdown

   The flow coastdown analysis is based on a momentum balance around each reactor coolant loop and across the reactor core. This momentum balance is combined with the continuity equation, a pump momentum balance, and the pump characteristics and is based on high estimates of system pressure losses to calculate the flow coastdown.

15.2.5.2.2 Results

The calculated sequence of events is shown in Table 15.2-1. Figure 15.2-12 and Figure 15.2-13 show the vessel flow coastdown, the faulted loop flow coastdown, the nuclear power, and heat flux transient. The minimum DNBR is not less than the safety analysis limit value. (See Figure 15.2-14).

15.2.5.3 Conclusions

The analysis shows that the DNBR will not decrease below the safety analysis limit value at any time during the transient. Thus, no core safety limit is violated.

15.2.6 Startup of an Inactive Reactor Coolant Loop

In accordance with Technical Specification 3/4.4.1, V. C. Summer operation during startup and power operation with less than 3 loops operating is not permitted. Therefore, this section is not applicable.

15.2.7 Loss of External Electrical Load and/or Turbine Trip

15.2.7.1 Identification of Causes and Accident Description

A major load loss on the plant can result from loss of external electrical load or from a turbine trip. For either case, offsite power is available for the continued operation of plant components such as the reactor coolant pumps. The case of loss of offsite power to the station auxiliaries is analyzed in Section 15.2.9.

For a turbine trip, the reactor would be tripped directly (unless below approximately 50% power) from a signal derived from the turbine autostop oil pressure and turbine stop valves.

The automatic steam dump system would accommodate the excess steam generation. Reactor coolant temperatures and pressure do not significantly increase if the steam dump system and pressurizer pressure control system are functioning properly. If the main condenser was not available, the excess steam generation would be dumped to the atmosphere. Additionally, main feedwater flow would be lost if the main condenser was not available. For this situation, steam generator level would be maintained by the Emergency Feedwater System.

For a loss of external electrical load without subsequent turbine trip, a direct reactor trip signal may be generated. However, with full load rejection capability the plant may be expected to continue without a reactor trip. A continued steam load of approximately 5% would exist after total loss of external electrical load because of the steam demand of plant auxiliaries.

Onsite power supplies plant auxiliaries during plant operation, e.g., the reactor coolant pumps. Engineered safety features (ESF) loads are supplied from offsite power or, alternately, from emergency diesels. Reactor Protection System equipment is supplied from the 120V a-c instrument power supply system, which in turn is supplied from the inverters; the inverters are supplied from a d-c bus energized from batteries or rectified a-c from ESF buses. Thus, for postulated loss of load and subsequent turbine generator overspeed, any overfrequency condition is not seen by safety-related pump motors, Reactor Protection System equipment, or other ESF loads. Any increased frequency to the reactor coolant pump motors will result in slightly increased flowrate and subsequent additional margin to safety limits.

Should a safety limit be approached following the loss of load, protection would be provided by high pressurizer pressure and overtemperature ΔT trips. Power and frequency relays associated with the reactor coolant pump provide no additional safety function for this event. Following a complete loss of load the maximum turbine overspeed would be approximately 8 to 9%, resulting in an overfrequency of less than 6 Hz. This resulting overfrequency is not expected to damage the sensors (non-NSSS). However, it is noted that frequent testing of this equipment is required by the Technical Specifications. Any degradation in their performance could be ascertained at that time.

In the event the steam dump valves fail to open following a large loss of load, the steam generator safety valves may lift and the reactor may be tripped by the high pressurizer pressure signal, the high pressurizer water level signal, or the overtemperature ΔT signal. The steam generator shell side pressure and reactor coolant temperatures will increase rapidly. The pressurizer safety valves

and steam generator safety valves are, however, sized to protect the Reactor Coolant System (RCS) and steam generator against overpressure for all load losses without assuming the operation of the steam dump system, pressurizer spray, pressurizer power operated relief valves, automatic control of the rod cluster control assembly nor direct reactor trip on turbine trip.

The steam generator safety valve capacity is sized to remove the steam flow at the ESF rating (104.5% steam flow at rated power) from the steam generator without exceeding 110% of the steam system design pressure. The pressurizer safety valve capacity is sized based on a complete loss of heat sink with the plant initially operating at the maximum calculated turbine load (along with operation of the steam generator safety valves). The pressurizer safety valves are then able to maintain the RCS pressure within 110% of the RCS design pressure without direct or immediate reactor trip action.

A more complete discussion of overpressure protection can be found in Reference 8.

15.2.7.2 Analysis of Effects and Consequences

15.2.7.2.1 Method of Analysis

In this analysis, the behavior of the unit is evaluated for a complete loss of steam load from full power without a direct reactor trip. This is done to show the adequacy of the pressure-relieving devices and to demonstrate core protection margins. The reactor is not tripped until conditions in the RCS result in a trip. The turbine is assumed to trip without actuating all the turbine stop valve limit switches. This assumption delays reactor trip until conditions in the RCS result in a trip due to other signals. Thus, the analysis assumes a worst case transient. In addition, no credit is taken for steam dump. Main feedwater flow is terminated at the time of turbine trip, with no credit taken for emergency feedwater (except for long-term recovery) to mitigate the consequences of the transient.

The total loss of load transients are analyzed with the LOFTRAN computer program (see Section 15.1). The program simulates the neutron kinetics, RCS, pressurizer, pressurizer relief and safety valves, pressurizer spray, steam generator, and steam generator safety valves. The program computes pertinent plant variables including temperatures, pressures, and power level.

Major assumptions are summarized below:

1. Initial Operating Conditions

   This accident is analyzed using the Revised Thermal Design Procedure (RTDP). For the DNB (pressure control) case, initial core power, reactor coolant temperature, and pressurizer pressure are assumed to be at their nominal fullpower values consistent with steady-state full power operation. Uncertainties in initial conditions and instrument errors are included in the limit departure from nucleate boiling ratio (DNBR) as described in Reference 5 For the pressure transient case, the initial core power and reactor coolant temperature are assumed to be at their nominal full-power values plus uncertainty. The initial pressurizer pressure is assumed to be the nominal full-power value minus uncertainty.

2. Moderator and Doppler Coefficients of Reactivity

   The turbine trip is analyzed with minimum reactivity feedback which assumes a moderator temperature coefficient of zero and the least negative Doppler coefficient.

3. Reactor Control

   From the standpoint of the maximum pressures attained and DNBR, it is conservative to assume that the reactor is in manual control. If the reactor were in automatic control, the control rod banks would move prior to trip and reduce the severity of the transient.

4. Steam Release

   No credit is taken for the operation of the steam dump system or steam generator power operated relief valves. The steam generator pressure rises to the safety valve setpoint where steam release through safety valves limits secondary steam pressure at the setpoint value.

5. Pressurizer Spray and Power Operated Relief Valves
   a. For evaluating the minimum DNBR, full credit is taken for the effect of pressurizer spray and power operated relief valves in reducing or limiting the coolant pressure. Safety valves are also available.
   b. For evaluating the maximum RCS and steam generator pressures, no credit is taken for the effect of pressurizer spray and power operated relief valves in reducing or limiting the coolant pressure. Safety valves are available.
6. Feedwater Flow

   Main feedwater flow to the steam generators is assumed to be lost at the time of turbine trip. No credit is taken for emergency feedwater flow since a stabilized plant condition will be reached before emergency feedwater initiation is normally assumed to occur; however, the emergency feedwater pumps would be expected to start on a trip of the main feedwater pumps. The emergency feedwater flow would remove core decay heat following plant stabilization.

7. Reactor trip is actuated by the first Reactor Protection System trip setpoint reached with no credit taken for the direct reactor trip on the turbine trip. Trip signals are expected due to high pressurizer pressure and overtemperature ΔT.
8. The overtemperature ΔT setpoint used in the analyses is higher than the safety analysis limit used in the setpoints study to account for a 4°F allowance for temperature related effects.

15.2.7.2.2 Results

The transient responses for a total loss of load from full power operation are shown for 2 cases for the beginning of core life; 1 case for DNBR and 1 case for peak pressure, in Figures 15.2-19

through 15.2-21 and Figure 15.2-25 through Figure 15.2-27. The calculated sequence of events for the accident is shown in Table 15.2-1.

Figure 15.2-19, Figure 15.2-20, and Figure 15.2-21 show the transient responses for the total loss of steam load at beginning of life assuming full credit for the pressurizer spray and pressurizer power operated relief valves. No credit is taken for the steam dump. The reactor is tripped by the high pressurizer pressure trip channel. The minimum DNBR is well above the limit value. The pressurizer safety valves are actuated for this case and maintain system pressure below 110% of the design value. The steam generator safety valves open and limit the secondary steam pressure increase.

The total loss of load accident was also studied assuming the plant to be initially operating at full power with no credit taken for the pressurizer spray, pressurizer power operated relief valves, or steam dump. The reactor is tripped on the high pressurizer pressure signal. Figure 15.2-25, Figure 15.2-26, and Figure 15.2-27 show the beginning of life transients. The neutron flux remains constant at full power until the Reactor is tripped. In this case, the pressurizer safety valves are actuated and maintain system pressure below 110% of the design value.

Reference 8 presents additional results of analysis for a complete loss of heat sink including loss of main feedwater. This analysis shows the overpressure protection that is provided by the pressurizer and steam generator safety valves.

15.2.7.3 Conclusions

Results of the analyses, including those in Reference 8, show that the plant design is such that a total loss of external electrical load without a direct or immediate reactor trip presents no hazard to the integrity of the RCS or the Main Steam System. Pressure relieving devices incorporated in the 2 systems are adequate to limit the maximum pressures to within the design limits.

The integrity of the core is maintained by operation of the Reactor Protection System, i.e., the DNBR will be maintained above the safety analysis limit values. Thus, no core safety limit will be violated.

15.2.8 Loss of Normal Feedwater

15.2.8.1 Identification of Causes and Accident Description

A loss of normal feedwater (from pump failures, valve malfunctions, or loss of offsite power) results in a reduction in capability of the secondary system to remove the heat generated in the reactor core. If the reactor were not tripped during this accident, core damage would possibly occur from a sudden loss of heat sink. If an alternative supply of feedwater were not supplied to the plant, residual heat following reactor trip would heat the primary system water to the point where water relief from the pressurizer occurs. Significant loss of water from the Reactor Coolant System (RCS) could conceivably lead to core damage. Since the plant is tripped well before the steam generator heat transfer capability is significantly reduced, the primary system variables never approach a DNB condition.

The following provides the necessary protection against a loss of normal feedwater:

1. Reactor trip on low-low water level in any steam generator.
2. Reactor trip on steam flow-feedwater flow mismatch in coincidence with low generator water level.
3. Two (2) motor driven emergency feedwater (EFW) pumps which are started on:
   a. Low-low level in any steam generator.
   b. Trip of all main feedwater pumps.
   c. Any safety injection signal.
   d. Loss of offsite power (automatic transfer to diesel generator).
   e. Manual actuation.
4. One (1) turbine driven emergency feedwater pump is started on:
   a. Low-Low level in any 2 steam generators.
   b. Loss of offsite power.
   c. Manual actuation.

   The motor driven emergency feedwater pumps are connected to vital buses and are supplied by Class 1E electric power from the diesels if a loss of offsite power occurs. The turbine driven pump utilizes steam from the safety class portions of the Main Steam System and exhausts it to the atmosphere. Both the motor driven and turbine driven emergency feedwater pumps are designed to start within 1 minute even if a loss of offsite power occurs simultaneously with the loss of normal feedwater. The emergency feedwater pumps take suction from the condensate storage tank for delivery to the steam generators.

   The analysis shows that following a loss of normal feedwater, the Emergency Feedwater System is capable of removing the stored and residual heat, thus preventing either overpressurization of the RCS or loss of water from the reactor core.

15.2.8.2 Analysis of Effects and Consequences

15.2.8.2.1 Method of Analysis

A detailed analysis using the LOFTRAN (Reference 4) Code is performed in order to obtain the plant transient following a loss of normal feedwater. The code describes the plant thermal kinetics, RCS including the natural circulation, pressurizer, steam generators and feedwater system, and computes pertinent variables including the steam generator level, pressurizer water level, pressurizer pressure, and reactor coolant average temperature.

Major assumptions are:

1. Reactor trip occurs on steam generator low-low level at 17.5% of narrow range span.

2. The plant is initially operating at 102% of the NSSS design rating.
3. Conservative core residual heat generation based on long-term operation at the initial power level preceding the trip is assumed. The 1979 decay heat ANSI 5.1 +2 SIGMA was used for calculation of residual decay heat levels.
4. The Emergency Feedwater System is actuated by the low-low steam generator water level signal.
5. The worst single failure in the Emergency Feedwater System occurs (turbinedriven pump) and 1 motor-driven pump is assumed to be unavailable. The emergency feedwater system is assumed to supply a total of 400 gpm equally split to all 3 steam generators from the motor-driven pump.
6. The pressurizer sprays are assumed operable while the pressurizer PORVs are assumed inoperable. This maximizes the peak transient pressurizer water volume.
7. Secondary system steam relief is achieved through the self-actuated safety valves. Note that steam relief will, in fact, be through the power-operated relief valves or condenser dump valves for most cases of a loss of normal feedwater. However, these have been assumed unavailable.
8. The initial reactor coolant average temperature is 6.3°F higher than the nominal value to allow for uncertainty on nominal temperature. The initial pressurizer pressure is 65 psi lower than the nominal value to allow for uncertainty on nominal pressure.

15.2.8.2.2 Results

Figure 15.2-31 and Figure 15.2-32 show the significant plant parameters following a loss of normal feedwater.

Following the reactor and turbine trip from full load, the water level in the steam generators will fall due to the reduction of steam generator void fraction and because steam flow through the safety valves continues to dissipate the stored and generated heat. One (1) minute following the initiation of the low-low level trip, the motor driven EFW pump is automatically started, reducing the rate of water level decrease.

The capacity of the motor driven EFW pump is such that the water level in the steam generator being fed does not recede below the lowest level at which sufficient heat transfer area is available to dissipate core residual heat without water relief from the RCS relief or safety valves.

From Figure 15.2-32 it can be seen that at no time is there water relief from the pressurizer. If the emergency feed delivered is greater than that of 1 motor driven pump, the initial reactor power is less than 102% of the NSSS design rating, or if the steam generator water level in 1 or more steam generators is above the low-low level trip point at the time of trip, then the result for this transient will be less limiting.

The calculated sequence of events for this accident is listed in Table 15.2-1. As shown in Figure 15.2-31 and Figure 15.2-32, the plant approaches a stabilized condition following reactor

trip and emergency feedwater initiation. Plant procedures may be followed to further cool down the plant.

15.2.8.3 Conclusions

Results of the analysis show that a loss of normal feedwater does not adversely affect the core, the RCS, or the steam system since the emergency feedwater capacity is such that the reactor coolant water is not relieved from the pressurizer relief or safety

15.2.9 Loss of Offsite Power to the Station Auxiliaries

15.2.9.1 Identification of Causes and Accident Description

During a complete loss of offsite power and a turbine trip there will be a loss of power to the plant auxiliaries, i.e., the reactor coolant pumps, condensate pumps, etc.

The events following a loss of offsite power with turbine and reactor trip are described in the sequence listed below:

1. Plant vital instruments are supplied from emergency power sources.
2. As the steam system pressure rises following the trip, the steam generator power operated relief valves are automatically opened to the atmosphere. Steam dump to the condenser is assumed not to be available. If the power relief valves are not available, the steam generator self-actuated safety valves may lift to dissipate the sensible heat of the fuel and coolant plus the residual decay heat produced in the reactor.
3. As the no load temperature is approached, the steam generator power operated relief valves (or the self-actuated safety valves, if the power operated relief valves are not available) are used to dissipate the residual decay heat and to maintain the plant at the hot standby condition.
4. The emergency diesel generators start on loss of voltage on the plant ESF buses and begin to supply plant vital loads.

The Emergency Feedwater System is started automatically as discussed in the loss of normal feedwater analysis. The steam driven emergency feedwater pump utilizes steam from the safety class portions of the Main Steam System and exhausts to the atmosphere. The 2 motor driven emergency feedwater pumps are supplied by power from the diesel generators. The pumps take suction directly from the condensate storage tank for delivery to the steam generators.

Upon the loss of power to the reactor coolant pumps, coolant flow necessary for core cooling and the removal of residual heat is maintained by natural circulation in the reactor coolant loops.

15.2.9.2 Analysis of Effects and Consequences

A detailed analysis using the LOFTRAN code (Reference 4) is performed in order to determine the plant transient following Loss of Offsite Power. The code describes the plant thermal kinetics,

RCS including natural circulation, pressurizer, steam generators, and feedwater system, and computes pertinent variables, including the pressurizer pressure, pressurizer water level, and reactor coolant average temperature. Major assumptions differing from those in a loss of normal feedwater are:

1. No credit is taken for immediate response of control rod drive mechanisms caused by a loss of offsite power.
2. A heat transfer coefficient in the steam generator associated with RCS natural circulation is assumed following the reactor coolant pump coastdown.
3. The pressurizer PORVs are assumed operable.
4. The initial reactor coolant average temperature is 6.4°F lower than the nominal value to allow for uncertainty on nominal temperature.

The time sequence of events for the accident is given in Table 15.2-1. The first few seconds after the loss of power to the reactor coolant pumps will closely resemble a simulation of the complete loss of flow incident (see Section 15.3.4); i.e., core damage due to rapidly increasing core temperatures is prevented by promptly tripping the reactor. After the reactor trip, stored and residual heat must be removed to prevent damage to either the RCS or the core. The LOFTRAN code results show that the natural circulation flow available is sufficient to provide adequate core decay heat removal following reactor trip and RCP coastdown.

15.2.9.3 Conclusions

Results of the analysis show that, for the loss of offsite power to the station auxiliaries event, all safety criteria are met. EFW capacity is sufficient to prevent water relief through the pressurizer relief and safety valves; this assures that the RCS is not overpressurized.

Analysis of the natural circulation capability of the RCS demonstrates that sufficient long-term heat removal capability exists following reactor coolant pump coastdown to prevent fuel or clad damage.

It is assumed that there is leakage from the RCS to the secondary system in the steam generators and that radioactivity will be released to the atmosphere through the relief or safety valves. Parameters used in determining the amount of radioactivity released are given in Table 15.2-5.

15.2.9.4 Environmental Consequences of a Postulated Loss of Offsite Power to the Station Auxiliaries

The postulated incidents involving release of steam from the secondary system will not result in a release of radioactivity unless there is leakage from the RCS to the secondary system within the steam generators. A realistic and conservative analysis of the potential offsite doses resulting from this accident is presented.

These analyses incorporate assumptions for operating with defective fuel and steam generator leakage for a sufficient time prior to the postulated accident to establish equilibrium specific

activity levels in the secondary system. Parameters used in both the realistic and conservative analyses are listed in Table 15.2-5.

The assumptions used to determine the equilibrium concentrations of isotopes in the secondary system are as follows:

1. Primary to secondary leakage in steam generators occurs when the reactor is started and the leakage remains constant during the plant operation. For the conservative analysis, the Technical Specification limit on leakage rate of 1 gpm is used whereas 100 lbs/day is used in the realistic analysis.
2. Primary to secondary leakage is evenly distributed in the steam generators.
3. For the unconservative analysis, the reactor coolant activity is 1% defective fuel (see Table 11.1-2). For the realistic analysis, 12% of these values are used.
4. No noble gas is dissolved or contained in the steam generator water, i.e., all noble gas leaked to the secondary system is continuously released with steam from the steam generators through the condenser air removal system.
5. The blowdown rate from steam generators is continuous at 12,756 and 42,000 lbs/hr per steam generator for the conservative and realistic cases, respectively.

Secondary system equilibrium concentrations are provided in Table 15.2-6.

The following additional assumptions and parameters are used to calculate the activity releases and offsite doses for the postulated loss of offsite power to plant auxiliaries:

1. Offsite power is lost; main condensers are not available for steam dump.
2. Eight (8) hours after the accident the Residual Heat Removal System commences operation to cooldown the plant.
3. After 8 hours following the accident, no steam and activity are released to the environment.
4. No condenser air removal system release and no steam generator blowdown during the accident.
5. No noble gas is dissolved in steam generator water.
6. The iodine partition factor in the steam generators is 0.01 between the steam generator steam and water phases.
7. During the postulated accident, iodine carryover from the primary side is uniformly mixed with the water in the steam generators and is diluted by the incoming feedwater.
8. The steam release for cooling down the plant is equally contributed by all steam generators.
9. The 0-2 and 2-8 hour atmospheric diffusion factors, given in Appendix 15A, and the 0-8 hour breathing rate of 3.47×10^{-4} m^3/sec are applicable.
10. Dose model used to evaluate the environmental consequence of this accident is given in Appendix 15A.

11. Steam releases to the atmosphere for the loss of offsite power are given by Table 15.2-5.

Using the previously listed assumptions, isotopic releases to the environment are summarized by Table 15.2-7 and Table 15.2-8 for realistic and conservative analyses, respectively.

Gamma, beta, and thyroid doses in the first 2 hours of the loss of offsite power to plant auxiliaries for the realistic analysis at the site boundary are 9.51×10^{-7} rem, 1.85×10^{-6} rem and 1.77×10^{-5} rem, respectively. The corresponding doses at the low population zone are 2.20×10^{-7} rem, 4.30×10^{-7} rem, and 3.11×10^{-6} rem, respectively.

The gamma, beta, and thyroid doses in the first 2 hours of the loss of offsite power to plant auxiliaries for the conservative analysis at the site boundary are 9.69×10^{-4} rem, 1.86×10^{-3} rem, and 4.68×10^{-2} rem, respectively. Corresponding doses at the low population zone are 2.23×10^{-4} rem, 4.31×10^{-4} rem and 7.91×10^{-3} rem, respectively, for the duration of the accident.

The doses for this accident are well within the limits defined in 10 CFR 100 (25 Rem, whole body and 300 Rem, thyroid).

15.2.10 Excessive Heat Removal Due to Feedwater System Malfunction

15.2.10.1 Identification of Causes and Accident Description

Excessive feedwater additions or reductions in feedwater enthalpy are a means of increasing core power above full power. Such transients are attenuated by the thermal capacity of the secondary plant and of the RCS. The overpower and overtemperature protection (high neutron flux, overtemperature ΔT, and overpower ΔT trips) prevent any power increase that could lead to fuel melting or a DNBR that is less than the DNBR limit.

An example of excessive feedwater flow would be a full opening of a feedwater control valve due to a feedwater control system malfunction or an operator error. At power this excess flow causes a greater load demand on the RCS due to increased subcooling in the steam generator. With the plant at no-load conditions, the addition of cold feedwater may cause a decrease in RCS temperature and thus a reactivity insertion due to the effects of the negative moderator coefficient of reactivity. Continuous addition of excessive feedwater is prevented by the steam generator high-high level trip, which closes the feedwater valves.

An example of a reduction in feedwater enthalpy is the transient associated with a postulated failure of the feedwater digital control system that causes the loss of feedwater heating. This results in a sudden reduction in feedwater temperature at the inlet to the steam generators and a consequential greater load demand on the RCS due to increased subcooling in the steam generator. In the presence of a negative moderator temperature coefficient, positive reactivity will be inserted causing an increase in power.

15.2.10.2 Analysis of Effects and Consequences

15.2.10.2.1 Method of Analysis

The excessive heat removal due to feedwater system malfunction transient is analyzed with the LOFTRAN code. This code simulates a multi-loop system, neutron kinetics, the pressurizer, pressurizer relief and safety valves, pressurizer spray, steam generator, and steam generator safety valves. The code computes pertinent plant variables including temperatures, pressures, and power level. The detailed thermal-hydraulic THINC code is used for the limiting case to calculate the DNBR using transient information from LOFTRAN.

The system is analyzed to evaluate plant behavior in the event of a feedwater system malfunction.

Excessive feedwater addition due to a control system malfunction or operator error which allows a feedwater control valve to open fully is considered. Evaluations have shown that an excessive feedwater addition event from no-load conditions is less limiting than one from full power conditions due to the large DNBR margin that exists at subcooled conditions. Therefore, two (2) cases are analyzed as follows:

1. Accidental opening of one (1) feedwater control valve with the reactor in manual control at full power.
2. Accidental opening of one (1) feedwater control valve with the reactor in automatic control at full power.

The transient response following an excessive feedwater addition event is calculated with the following assumptions:

1. For the feedwater control valve accident at full power, one (1) feedwater control valve is assumed to malfunction resulting in a step increase to 250% of nominal feedwater flow to one (1) steam generator.
2. No credit is taken for the heat capacity of the RCS and steam generator thick metal in attenuating the resulting plant cooldown.
3. No credit is taken for the heat capacity of the steam and water in the unaffected steam generators.
4. The feedwater flow resulting from a fully open control valve is terminated by the steam generator high-high level signal that closes all feedwater control valves, closes all feedwater bypass valves, trips the main feedwater pumps, and shuts the feedwater isolation valves. The steam generator high-high level signal also produces a signal to trip the turbine.

A bounding feedwater enthalpy reduction due to loss of all feedwater heaters is considered. Two (2) cases are analyzed as follows:

1. Loss of all feedwater heaters with the reactor in manual control at full power.
2. Loss of all feedwater heaters with the reactor in automatic control at full power.

The failure of the digital control system is limiting at full power; thus, a zero load case is not analyzed.

The transient response following a feedwater enthalpy reduction event is calculated with the following assumptions:

1. The feedwater temperature cooldown profile resulting from the failure of the feedwater digital control system is conservatively modeled with two successive step changes. The first step decrease from the nominal full power feedwater temperature to the nominal outlet temperature of the deaerator downstream of the low pressure feedwater heater string, occurs at time zero. The second step decrease to the nominal outlet temperature of the condensate system (inlet to the low pressure heaters) occurs after the water downstream of the low pressure feedwater heaters at the time of the event has been purged.
2. The feedwater flow rate to the steam generators remains at the nominal full power value throughout the transient.
3. The transient is terminated by a reactor trip from an overpower ΔT signal, and by a low pressurizer pressure safety injection system actuation signal, which closes all feedwater control valves, closes all feedwater bypass valves, trips the main feedwater pumps, and shuts the feedwater isolation valves.
4. No credit is taken for the heat capacity of the RCS and steam generator thick metal in attenuating the resulting plant cooldown.

Normal reactor control systems and engineered safety systems are not required to function. The reactor protection system will actuate to trip the reactor due to an overpower condition (feedwater enthalpy reduction) or trip the turbine (excessive feedwater addition). No single active failure in any system or component required for mitigation will adversely affect the consequences of this event.

15.2.10.2.2 Results

Excessive Feedwater Addition

The full power excessive feedwater flow case with the reactor in manual control results in the greatest power increase. Assuming the reactor to be in the automatic control mode results in a slightly less severe transient. The rod control system is not required to function for an excessive feedwater flow event. A turbine trip and feedwater isolation are actuated when the steam generator level reaches the high-high level setpoint. For convenience, reactor trip is assumed to be initiated upon turbine trip. However, this function is not necessary for core protection. Should turbine trip not initiate a reactor trip signal, reactor trip will eventually occur on low-low steam generator level following feedwater isolation.

For excessive feedwater flow cases, continuous addition of cold feedwater is prevented by closure of feedwater control valves, a trip of the feedwater pumps, and closure of the feedwater pump bypass and isolation valves on steam generator high-high level signal.

Transient results (see Figure and Figure) show the core heat flux, pressurizer pressure, core T_{avg}, and DNBR, as well as the increase in nuclear power and loop ΔT associated with the increased thermal load on the reactor. Steam generator level rises until the feedwater is terminated as a result of the high-high steam generator level trip. The DNBR does not drop below the safety analysis limit DNBR value.

Feedwater Enthalpy Reduction

For the feedwater enthalpy reduction cases, the manual reactor control case results in the greatest power increase. This case is also more severe than the limiting excessive feedwater addition case. The reduction in feedwater temperature caused by the failure of the feedwater digital control system increases the thermal load on the primary system. The resultant temperature and power transients cause a reactor trip on an overpower ΔT signal. When the pressurizer pressure reaches the safety injection low pressure setpoint, the feedwater control and isolation valves are closed and feedwater isolation occurs. Following reactor trip and feedwater isolation, the plant will approach a stabilized condition at which point normal operating procedures may be followed.

Transient results (see Figure 15.2-33 and Figure 15.2-33a) show the core heat flux, pressurizer pressure, core T_{avg}, and DNBR, as well as the increase in nuclear power and loop ΔT associated with the increased thermal load on the reactor. Since the power level increases during the feedwater enthalpy reduction event, the fuel temperature will also increase until reactor trip occurs. However, the peak linear heat rate produced in the fuel rods remains below a value which would result in exceeding the fuel melting temperature. Hence, fuel melting is precluded for this event. The transient results also show that the DNBR does not fall below the safety analysis DNBR limit value.

15.2.10.3 Conclusion

The DNBRs encountered for the full power cases (excessive feedwater addition and feedwater enthalpy reduction cases) are above the safety analysis limit DNBR value and fuel melting is precluded.

15.2.11 Excessive Load Increase Incident

15.2.11.1 Identification of Causes and Accident Description

An excessive load increase incident is defined as a rapid increase in the steam flow that causes a power mismatch between the reactor core power and the steam generator load demand. The reactor control system is designed to accommodate a 10% step load increase or a 5% per minute ramp load increase in the range of 15 to 100% of full power. Any loading rate in excess of these values may cause a reactor trip actuated by the Reactor Protection System.

This accident could result from either an administrative violation such as excessive loading by the operator or an equipment malfunction in the steam dump control or turbine speed control.

During power operation, steam dump to the condenser is controlled by reactor coolant condition signals; i.e., high reactor coolant temperature indicates a need for steam dump. A single controller malfunction does not cause steam dump; an interlock is provided which blocks the opening of the valves unless a large turbine load decrease or a turbine trip has occurred.

Protection against an excessive load increase accident is provided by the following Reactor Protection System signals:

1. Overpower ΔT.
2. Overtemperature ΔT.
3. Power range high neutron flux.

15.2.11.2 Analysis of Effects and Consequences

15.2.11.2.1 Method of Analysis

This accident is analyzed using the LOFTRAN (Reference 4) Code. The code simulates the neutron kinetics, reactor coolant system, pressurizer, pressurizer relief and safety valves, pressurizer spray, steam generator, steam generator safety valves, and feedwater system. The code computes pertinent plant variables including temperatures, pressures, and power level.

Four (4) cases are analyzed to demonstrate the plant behavior following a 10% step load increase from rated load. These cases are as follows:

1. Reactor control in manual with BOL minimum moderator reactivity feedback,
2. Reactor control in manual with EOL maximum moderator reactivity feedback,
3. Reactor control in automatic with BOL minimum moderator reactivity feedback,
4. Reactor control in automatic with EOL maximum moderator reactivity feedback.

For the BOL minimum moderator feedback cases, the core has the least negative moderator temperature coefficient of reactivity and the least negative Doppler only power coefficient curve; therefore the least inherent transient response capability. For the EOL maximum moderator feedback cases, the moderator temperature coefficient of reactivity has its highest absolute value and the most negative Doppler only power coefficient curve. This results in the largest amount of reactivity feedback due to changes in coolant temperature.

A conservative limit on the turbine valve opening is assumed, and all cases are studied without credit being taken for pressurizer heaters.

This accident is analyzed with the Revised Thermal Design Procedure as described in Reference 5. Initial reactor power, RCS pressure and temperature are assumed to be at their nominal values. Uncertainties in initial conditions are included in the limit DNBR as described in Reference 5.

Plant characteristics and initial conditions are further discussed in Section 15.1.

15.2.11.2.2 Results

The calculated sequence of events for the excessive load increase incident are shown on Table 15.2-1.

Figure 15.2-35 through Figure 15.2-38 illustrate the transient with the reactor in the manual control mode. As expected, for the BOL minimum moderator feedback case there is a slight power increase, and the average core temperature shows a large decrease. This results in a DNBR which increases above its initial value. For the EOL maximum moderator feedback manually controlled case there is a much larger increase in reactor power due to the moderator feedback. A reduction in DNBR is experienced but DNBR remains above the limit value.

Figure 15.2-39 through Figure 15.2-42 illustrate the transient assuming the reactor is in the automatic control mode. Both the BOL minimum moderator feedback and the EOL maximum moderator feedback cases show that core power increases, thereby reducing the rate of decrease in coolant average temperature and pressurizer pressure. For both the beginning of life and end of life cases, the minimum DNBR remains above the limit value.

For all cases, the plant rapidly reaches a stabilized condition at the higher power level. Normal plant operating procedures would then be followed to reduce power.

The excessive load increase incident is an overpower transient for which the fuel temperatures will rise. Reactor trip does not occur for any of the cases analyzed, and the plant reaches a new equilibrium condition at a higher power level corresponding to the increase in steam flow.

Since DNB does not occur at any time during the excessive load increase transients, the ability of the primary coolant to remove heat from the fuel rod is not reduced. Thus, the fuel cladding temperature does not rise significantly above its initial value during the transient.

15.2.11.3 Conclusions

The analysis presented above shows that for a 10% step load increase, the DNBR remains above the safety analysis limit value, thereby precluding fuel or clad damage. The plant reaches a stabilized condition rapidly, following the load increase.

15.2.12 Accidental Depressurization of the Reactor Coolant System

15.2.12.1 Identification of Causes and Accident Description

An accidental depressurization of the Reactor Coolant System could occur as a result of an inadvertent opening of a pressurizer relief or safety valve. Since a safety valve is sized to relieve approximately twice the steam flowrate of a relief valve, and will therefore allow a much more rapid depressurization upon opening, the most severe core conditions resulting from an accidental depressurization of the RCS are associated with an inadvertent opening of a pressurizer safety

valve. Initially, the event results in a rapidly decreasing RCS pressure, which could reach hot leg saturation conditions without Reactor Protection System intervention.If saturated conditions are reached, the rate of depressurization is slowed considerably. However, the pressure continues to decrease throughout the event. The effect of the pressure decrease is to increase power via moderator density feedback. However, if the plant is in the automatic mode, the rod control system functions to maintain the power essentially constant throughout the initial stages of the transient. The average coolant temperature remains approximately the same, but the pressurizer level increases until reactor trip because of the decreased reactor coolant density.

The reactor will be tripped by the following Reactor Protection System signals:

1. Overtemperature ΔT.
2. Pressurizer low pressure

15.2.12.2 Analysis of Effects and Consequences

15.2.12.2.1 Method of Analysis

The accidental depressurization transient is analyzed with the LOFTRAN code (Reference 4). The code simulates the neutron kinetics, reactor coolant system, pressurizer, pressurizer relief and safety valves, pressurizer spray, steam generator, and steam generator safety valves. The code computes pertinent plant variables including temperatures, pressures, and power level.

This accident is analyzed with the Revision Thermal Design Procedure as described in Reference 5.

In calculating the DNBR the following conservative assumptions are made:

1. Plant characteristics and initial conditions are discussed in Section 15.1. Uncertainties and initial conditions are included in the limit DNBR as described in Reference 5.
2. A positive moderator temperature coefficient of reactivity for BOL operation in order to provide a conservatively high amount of positive reactivity feedback due to changes in moderator temperature. The spatial effect of voids due to local or subcooled boiling is not considered in the analysis with respect to reactivity feedback or core power shape. These voids would tend to flatten the core power distribution.
3. A low (absolute value) Doppler coefficient of reactivity such that the resultant amount of negative feedback is conservatively low in order to maximize any power increase due to moderator reactivity feedback.

15.2.12.2.2 Results

Figure 15.2-43 illustrates the nuclear power transient following the RCS depressurization accident. The flux increases until the time reactor trip occurs on overtemperature ΔT, thus resulting in a rapid decrease in the nuclear flux. The time of reactor trip is shown in Table 15.2-1.

The pressure decay transient following the accident is given on Figure 15.2-44. The resulting DNBR never goes below the safety analysis limit value as shown on Figure 15.2-45.

15.2.12.3 Conclusion

The pressurizer low pressure and the overtemperature ΔT Reactor Protection System signals provide adequate protection against this accident, and the minimum DNBR remains in excess of the safety analysis limit value.

15.2.13 Accidental Depressurization of the Main Steam System

NOTE: Section 15.2.13 is being retained for historical purposes only. The DNB results for Section 15.2.13 events are bounded by those presented in Section 15.4.7 which show that the minimum DNBR remains above the limit value for ruptures of the main steam line.

15.2.13.1 Identification of Causes and Accident Description

The most severe core conditions resulting from an accidental depressurization of the Main Steam System are associated with an inadvertent opening of a single steam dump, relief or safety valve. The analyses performed assuming a rupture of a main steam line are given in Section 15.4.

The steam release as a consequence of this accident results in an initial increase in steam flow which decreases during the accident as the steam pressure falls. The energy removal from the Reactor Coolant System causes a reduction of coolant temperature and pressure. In the presence of a negative moderator temperature coefficient, the cooldown results in a reduction of core shutdown margin.

The analysis is performed to demonstrate that the following criterion is satisfied:

Assuming a stuck rod cluster control assembly and a single failure in the engineered safety features, the limit DNBR value will be met after reactor trip for a steam release equivalent to the spurious opening, with failure to close, of the largest of any single steam dump, relief or safety valve.

The following systems provide the necessary mitigation of an accidental depressurization of the main steam system.

1. Safety injection system actuation from any of the following:
   a. Two (2) out of 3 low pressurizer pressure signals.
   b. Two (2) out of 3 high-1 containment pressure signals.
2. The overpower reactor trips (neutron flux and ΔT) and the reactor trip occurring in conjunction with receipt of the safety injection signal.

3. Redundant isolation of the main feedwater lines: Sustained high feedwater flow would cause additional cooldown. Therefore, a safety injection signal will rapidly close all feedwater control valves, trip the main feedwater pumps, and close the feedwater isolation valves.

15.2.13.2 Analysis of Effects and Consequences

15.2.13.2.1 Method of Analysis

The following analyses of a secondary system steam release are performed for this section based on methodologies documented in Reference 16.

1. A full plant digital computer simulation (LOFTRAN (Reference 4)) to determine Reactor Coolant System temperature and pressure during cooldown, and the effect of safety injection.
2. An analysis to ascertain that the reactor does not exceed the limit DNBR value.

The following conditions are assumed to exist at the time of a secondary steam system release.

1. End of life shutdown margin at no load, equilibrium xenon conditions, and with the most reactive rod cluster control assembly stuck in its fully withdrawn position. Operation of rod cluster control assembly banks during core burnup is restricted in such a way that addition of positive reactivity in a secondary system steam release accident will not lead to a more adverse condition than the case analyzed.
2. A negative moderator coefficient corresponding to the end of life rodded core with the most reactive rod cluster control assembly in the fully withdrawn position. The variation of the coefficient with temperature and pressure is included. The K_{eff} versus temperature at 1150 psia corresponding to the negative moderator temperature coefficient plus the Doppler temperature effect used is shown in Figure 15.2-46.
3. Minimum capability for injection of high concentration boric acid solution corresponding to the most restrictive single failure in the Safety Injection System. The injection curve is shown on Figure 15.2-47. This corresponds to the flow delivered by 1 charging pump delivering its full contents to the cold leg header. No credit has been taken for the low concentration boric acid that must be swept from the safety injection lines downstream of the refueling water storage tank (RWST) isolation valves prior to the delivery of high concentration boric acid (2300 ppm) to the reactor coolant loops.
4. The case studied is an initial steam flow of 255 pounds per second at 1100 psia from 1 steam generator with offsite power available. This is the maximum capacity of any single steam dump, relief or safety valve. Initial hot shutdown conditions at time 0 are assumed since this represents the most conservative initial condition.

   Should the reactor be just critical or operating at power at the time of a steam release, the reactor will be tripped by the normal overpower protection when power level reaches a trip point. Following a trip at power, the Reactor Coolant System contains more stored energy than at no load, the average coolant temperature is higher than at no load, and there is appreciable energy stored in the fuel.

Thus, the additional stored energy is removed via the cooldown caused by the steam release before the no load conditions of Reactor Coolant System temperature and shutdown margin assumed in the analyses are reached. After the additional stored energy has been removed, the cooldown and reactivity insertions proceed in the same manner as in the analysis which assumes no load condition at time zero. However, since the initial steam generator water inventory is greatest at no load, the magnitude and duration of the Reactor Coolant System cooldown are less for steam line release occurring at power.

5. In computing the steam flow, the Moody Curve for fl/D = 0 is used.
6. Perfect moisture separation in the steam generator is assumed.
7. No credit was taken for secondary side safety injection actuation on low steam pressure.

15.2.13.2.2 Results

This calculated time sequence of events for this accident is listed in Table 15.2-1.

The results presented are a conservative indication of the events which would occur assuming a secondary system steam release since it is postulated that all of the conditions described above occur simultaneously.

Figure 15.2-48 and Figure 15.2-49 show the transient arising as the result of an initial steam flow of 255 lbs/second at 1100 psia with steam release from 1 safety valve. The assumed steam release is the maximum capacity of any single steam dump or safety valve. In this case safety injection is initiated automatically by low pressurizer pressure. Operation of 1 centrifugal charging pump is considered. Boron solution at 2300 ppm from the refueling water storage tank enters the Reactor Coolant System providing sufficient negative reactivity to terminate the transient. The reactivity transient for the case shown in Figure 15.2-49 is more severe than the case of a failed steam generator safety or relief valve, which is terminated by steam line differential pressure, or a failed condenser dump valve that is terminated by low pressurizer pressure and level.

The transient is quite conservative with respect to cooldown, since no credit is taken for the energy stored in the system metal other than that of the fuel elements or the energy stored in the other steam generators. Since the transient occurs over a period of about 5 minutes, the neglected stored energy is likely to have a significant effect in slowing the cooldown.

15.2.13.3 Conclusions

The analysis has shown that the criteria stated earlier in this section are satisfied. For an accidental depressurization of the Main Steam System, the DNB design basis is met. This case is less limiting than the rupture of a main steam pipe case presented in Section 15.4.

15.2.14 Inadvertent Operation of the Emergency Core Cooling System During Power Operation

15.2.14.1 Identification of Causes and Accident Description

Spurious Emergency Core Cooling System (ECCS) operation at power could be caused by operator error or a false electrical actuating signal. A spurious signal in any of the following channels could cause this accident:

1. High containment pressure.
2. Low pressurizer pressure.
3. High steam line differential pressure.
4. Low steam line pressure.
5. Manual actuation.

Following the actuation signal, the suction of the coolant charging pumps is diverted from the volume control tank to the refueling water storage tank. The charging pumps then force highly concentrated (2300 ppm) boric acid solution from the RWST, through the header and injection line, and into the cold legs of each loop. The low head safety injection pumps also start automatically but provide no flow when the Reactor Coolant System is at normal pressure.

A Safety Injection System signal normally results in a reactor trip followed by a turbine trip. However, it cannot be assumed that any single fault that actuates the safety injection system will also produce a reactor trip. Therefore, 2 different courses of events are considered.

Case A - Trip occurs at the same time spurious injection starts.

Case B - The Reactor Protection System produces a trip later in the transient.

1. Case A

   For Case A, the operator should determine if the spurious signal was transient or steady state in nature, i.e., an occasional occurrence or a definite fault. The operator will determine this by following approved procedures. In the transient case, the operator would stop the safety injection and bring the plant to the hot shutdown condition. If the SIS must be disabled for repair, boration should continue and the plant brought to cold shutdown.

2. Case B

   For Case B, the Reactor Protection System does not produce an immediate trip and the reactor experiences a negative reactivity excursion due to the injected boron causing a decrease in the reactor power. At beginning of life, the power mismatch causes a drop in T_{avg} and consequent coolant shrinkage, and pressurizer pressure and level drop. Load will decrease due to the effect of reduced steam pressure on load when the turbine throttle valve is fully open. If automatic rod control is used, these effects will be lessened until the rods have moved out of the core. The transient is eventually terminated by the Reactor Protection System low-pressure trip or by manual trip.

   Results at end of life are similar except that moderator feedback effects result in a slower transient. he pressurizer pressure and level increase slowly and the coolant T_{avg} decreases slowly. The transient is eventually terminated by the Reactor Protection System high pressurizer pressure or high pressurizer level trip or by manual trip.

   The time to trip is affected by initial operating conditions including core burnup history which affects initial boron concentration, rate of change of boron concentration, Doppler and moderator coefficients.

   Recovery from this incident for Case B is made in the same manner described for Case A. The only difference is the lower T_{avg} and pressure associated with the power mismatch during the transient. The time at which reactor trip occurs is of no concern for this occurrence. At lower loads coolant contraction will be slower resulting in a longer time to trip.

15.2.14.2 Analysis of Effects and Consequences

15.2.14.2.1 Method of Analysis

The spurious operation of the Safety Injection System is analyzed with the LOFTRAN (Reference 4) code. The code simulates the neutron kinetics, reactor coolant system, pressurizer, pressurizer relief and safety valves, pressurizer spray, steam generator, steam generator safety valves, and the effect of the safety injection system. The program computes pertinent plant variables including temperatures, pressures, and power level.

Because of the power and temperature reduction during the transient, operating conditions do not approach the core limits. Analysis of several cases shows that the results are relatively independent of time to trip.

A typical transient is considered representing conditions at beginning of core life. This accident is analyzed with the Revised Thermal Design Procedure as described in Reference 5. The assumptions made in the analysis are:

1. Initial Operating Conditions

   The initial reactor power, pressure, and reactor coolant system temperatures are assumed at their nominal values. Uncertainties in initial conditions are included in the limit DNBR as described in Reference 5.

2. Moderator and Doppler Coefficients of Reactivity

   A positive beginning of life moderator temperature coefficient was used. A low absolute value Doppler power coefficient was assumed.

3. Reactor Control

   The reactor was assumed to be in manual control.

4. Pressurizer Heaters

   Pressurizer heaters were assumed to be inoperable in order to increase the rate of pressure drop.

5. Boron Injection

   At time 0, 2 charging pumps inject 2300 ppm borated water into the cold legs of each loop.

6. Turbine Load

   Turbine load was assumed constant until the governor drives the throttle valve wide open. Then turbine load drops as steam pressure drops.

7. Reactor Trip

   Reactor trip was initiated by low pressurizer pressure. The trip was conservatively assumed to be delayed until the pressure reached 1775 psia.

15.2.14.2.2 Results

The calculated time sequence of events for this accident is listed in Table 15.2-1.

The transient response for the minimum feedback case is shown in Figure 15.2-50 and Figure 15.2-51. Nuclear power starts decreasing immediately due to boron injection, but steam flow does not decrease until 36 seconds into the transient when the turbine throttle valve goes wide open. The mismatch between load and nuclear power causes T_{avg}, pressurizer water level, and pressurizer pressure to drop. The low pressure trip setpoint is reached at 52 seconds and rods start moving into the core at 54 seconds.

15.2.14.3 Conclusions

Results of the analysis show that spurious safety injection with or without immediate reactor trip presents no hazard to the integrity of the Reactor Coolant System.

DNBR is never less than the initial value. Thus, there will be no cladding damage and no release of fission products to the reactor coolant system.

If the reactor does not trip immediately, the low pressure reactor trip will be actuated. This trips the turbine and prevents excess cooldown thereby expediting recovery from the incident.

15.2.15 Anticipated Transients Without Trip

The worst common mode failure which is postulated to occur is the failure to scram the reactor after an anticipated transient has occurred. A series of generic studies (Reference 11 and Reference 14) on Anticipated Transients Without Scram (ATWS) showed acceptable consequences would result provided that the turbine trips and emergency feedwater flow is initiated in a timely manner. The effects of ATWS events are not considered as part of the design basis for transients analyzed in Chapter 15. The final NRC ATWS rule (Reference 15) requires that Westinghouse designed plants install ATWS Mitigation System Actuation Circuitry (AMSAC) to initiate a turbine trip and actuate emergency feedwater flow independent of the Reactor Protection System. The V. C. Summer AMSAC design is described in Section 7.8 of the FSAR.

15.3 CONDITION III - INFREQUENT FAULTS

By definition Condition III occurrences are faults which may occur very infrequently during the life of the plant. They will be accommodated with the failure of only a small fraction of the fuel rods although sufficient fuel damage might occur to preclude resumption of the operation for a considerable outage time. The release of radioactivity will not be sufficient to interrupt or restrict public use of those areas beyond the exclusion radius. A Condition III fault will not, by itself, generate a Condition IV fault or result in a consequential loss of function of the Reactor Coolant System or containment barriers. For the purposes of this report the following faults have been grouped into this category:

1. Loss of reactor coolant, from small ruptured pipes or from cracks in large pipes which actuates the Emergency Core Cooling System (ECCS).
2. Minor secondary system pipe breaks.
3. Inadvertent loading of fuel assembly into an improper position.
4. Complete loss of forced reactor coolant flow.
5. Waste gas decay tank rupture.
6. Single rod cluster control assembly withdrawal at full power.

Each of these infrequent faults are analyzed in this section. In general, each analysis includes an identification of causes and description of the accident, an analysis of effects and consequences, a presentation of results, and relevant conclusions.

The time sequence of events during applicable Condition III faults 1 and 4 above is shown in Table 15.4-3 and Table 15.3-3.

15.3.1 Loss of Reactor Coolant From Small Ruptured Pipes or From Cracks in Large Pipes Which Actuates the Emergency Core Cooling System

A small break loss-of-coolant accident (SBLOCA) analysis has been performed for V.C. Summer using the FULL SPECTRUM™1 loss-of-coolant accident (FSLOCA™) evaluation model (EM) (Reference 1).

The break sizes considered in the Westinghouse FSLOCA EM include what traditionally are defined as Small and Large Break LOCA (LBLOCA). The traditional SBLOCA analysis is referred to as the Region I analysis, and the traditional LBLOCA analysis is referred to as the Region II analysis.

The FSLOCA EM analysis for V.C. Summer is discussed in Section 15.4.1 since the LBLOCA (Region II) analysis is more limiting than the SBLOCA (Region I) analysis.

The FSLOCA EM methods, models, and demonstrations for 10 CFR 50.46 compliance are discussed in Section 15.4.1, which describes both Region I and Region II analyses.

15.3.1.1 Identification of Causes and Accident Description

A loss of coolant accident is defined as a rupture of the Reactor Coolant System piping or of any line connected to the system. See Section 15.2 for a more detailed description of the loss of reactor coolant accident boundary limits. Ruptures of small cross section will cause expulsion of the coolant at a rate which can be accommodated by the charging pumps which would maintain an operational water level in the pressurizer, permitting the operator to execute an orderly shutdown. The coolant which would be released to the containment contains the fission products existing in it.

The maximum break size for which the normal makeup system can maintain the pressurizer level is obtained by comparing the calculated flow from the Reactor Coolant System through the postulated break against the charging pump makeup flow at normal Reactor Coolant System pressure, i.e., 2250 psia. A makeup flow rate from one centrifugal charging pump is typically adequate to sustain pressurizer level at 2250 psia for a break through a 3/8 inch diameter hole. This break results in a loss of approximately 17.5 lb/sec.

Should a larger break occur, depressurization of the Reactor Coolant System causes fluid to flow to the Reactor Coolant System from the pressurizer, resulting in a pressure and level decrease in the pressurizer. Reactor trip occurs when the pressurizer low pressure trip setpoint is reached. The Safety Injection System is actuated when the appropriate setpoint is reached.

15.3.1.2 Additional Analysis

NUREG-0737 (Reference 12), Section II.K.3.31, required plant-specific small break LOCA analysis using an Evaluation Model revised per Section II.K.3.30 (Revised Small-Break Loss-of-Coolant-Accident Methods to Show Compliance with 10 CFR Part 50, Appendix K). The analysis method for small break LOCA is a realistic evaluation model (EM) in compliance with 10 CFR Part 50.46(a)(1)(i). An Appendix K method is no longer used for the small break LOCA analysis, but the use of a realistic method has been approved for use in small break LOCA analyses. The methodology accounts for comparisons with experimental data, including data from the Loss-of-Fluid Test (LOFT), semiscale, and Rig-of-Safety Assessment (ROSA) test facilities.

Analyses of a LOCA in the pressurizer vapor space such as that caused by opening a pressurizer relief valve or a safety valve were provided in WCAP 9600 (Reference 11). The conclusion presented in WCAP 9600 is that these breaks are not limiting since little or no core uncovery will take place. WCAP 9600 states that the analyses reported therein apply to all Westinghouse designed plants.

RCS loop-to-loop flow imbalance of 5% was considered, to incorporate the effects of RCS Flow Asymmetry, per Westinghouse Nuclear Safety Advisory Letter (NSAL) 00 008. The results show that the effect of 5% Loop Flow Asymmetry is inconsequential for LOCA PCT calculations.

15.3.1.3 Impact of ECCS Evaluation Model Changes

The October 17, 1988, revision to 10CFR50.46 requires applicants and holders of operating licenses or construction permits to notify the NRC of errors and changes in the ECCS Evaluation Models, which are not significant, on an annual basis. Reference 19 defines a significant error or change as one which results in a calculated peak fuel cladding temperature (PCT) different by more than 50° F from the temperature calculated for the limiting transient using the last acceptable model, or is an accumulation of changes and errors such that the sum of the absolute temperature change is greater than 50° F. The current ECCS evaluation model changes for Virgil C. Summer Nuclear Station that affect the small break LOCA PCT and their effect are identified in the latest 10CFR50.46 annual or 30 day report.

15.3.2 Minor Secondary System Pipe Breaks

15.3.2.1 Identification of Causes and Accident Description

Included in this grouping are ruptures of secondary system lines which would result in steam release rates equivalent to a 6 inch diameter break or smaller.

15.3.2.2 Analysis of Effects and Consequences

Minor secondary system pipe breaks must be accommodated with the failure of only a small fraction of the fuel elements in the reactor. Since the results of analysis presented in Section 15.4.7 for a major secondary system pipe rupture also meet this criteria, separate analysis for minor secondary system pipe breaks is not required.

The analysis of the more probable accidental opening of a secondary system steam dump, relief or safety valve is presented in Section 15.2.13. These analyses are illustrative of a pipe break equivalent in size to a single valve opening.

15.3.2.3 Conclusions

The analyses presented in Section 15.4.7 demonstrate that the consequences of a minor secondary system pipe break are acceptable since a DNBR of less than the design limit does not occur even for a more critical major secondary system pipe break.

15.3.3 Inadvertent Loading of a Fuel Assembly Into An Improper Position

15.3.3.1 Acceptance Criteria

This event is classified as a Condition III event. Condition III events are defined as those events that do not cause more than a small fraction of fuel rods to fail, although sufficient fuel damage might occur to preclude immediate resumption of operation. The specific acceptance criteria for this event are as follows:

a. To meet the requirements of General Design Criteria 13, plant operating procedures should include a provision requiring that reactor instrumentation be used to search for potential fuel loading errors after fueling operations.

b. In the event the error is not detectable by the instrumentation system and fuel rod failure limits could be exceeded during normal operation, the offsite consequences should be a small fraction of the 10 CFR Part 100 guidelines.

15.3.3.2 Identification of Causes and Accident Description

The Inadvertent Loading Event comprises core misloading scenarios such as the loading of one or more fuel assemblies into improper positions, the loading of a fuel rod during manufacture with one or more pellets of the wrong enrichment, or the loading of a full fuel assembly during manufacture with pellets of the wrong enrichment. In addition to these scenarios, misloading events involving burnable absorbers are theoretically possible, scenarios such as the placement of a cluster of 20 burnable absorbers into a core location slated to have 24 burnable absorbers. All of these misloading scenarios potentially result in a core reactivity distribution that differs from the intended core reactivity distribution. As a result, the core power distribution and peaking factors may differ from predictions. Specifically, misloading errors can lead to increased local power peaking at the location of the misloading if the misloading results in a local reactivity increase relative to the intended pattern. If the misloading results in a local reactivity decrease, power peaking increases away from the location of the misloading are possible due to unintended power tilts. These kinds of increases, however, are generally distributed over a large core volume and are small relative to those where the local reactivity is increased.

Fuel misloads are prevented by the manufacturing controls employed to build the fuel and the core loading controls used to assemble the core. The manufacturing controls include checks on fuel rod weight to confirm the uranium loading in the fuel rod, active and passive gamma scans of individual fuel rods to confirm fuel enrichments, pellet stack lengths, pellet types, and the absence of pellet gaps during fuel manufacturing, and bar coding of each fuel rod to confirm its proper placement in the fuel assembly.

To reduce the probability of core loading errors during fuel loading, each fuel assembly and core component is marked with an identification number and loaded in accordance with a core loading diagram. During core loading, the identification numbers are checked before the assembly is moved into the core. Identification numbers read during fuel movement are subsequently recorded on the loading diagram as a further check on proper placement after the loading is completed. These procedures make the likelihood of core misloadings very small.

The severity and detectability of fuel misloads are influenced by several factors: the local reactivity perturbation relative to the intended core loading pattern, the core position of the misload, the local environment of the misloaded fuel assembly, and the number of operable incore detector locations and their proximity to the misload location. Should misloadings occur, the incore system of movable flux detectors, which is used to verify power distributions during startup and throughout the operating cycle, is capable of revealing enrichment errors or misloadings which would cause the kind of substantial power distribution perturbation that would

be necessary to induce large numbers of fuel rod failures. In addition, thermocouples and excore detectors can provide additional indications of power distribution anomalies. This instrumentation, along with the startup testing performed each cycle, make the detection of severe misloadings highly likely.

15.3.3.3 Evaluation

The incore moveable detector system is used to search for potential fuel misloads at the start of each operating cycle. Following fuel loading and low power physics testing, an initial core power distribution measurement is made. The core power level of this initial flux map is typically between ~30% and ~50% of rated thermal power. This initial power distribution measurement is used to confirm that the measured power distribution is consistent with the predicted power distribution. Observed flux map deviations in excess of the flux map review criteria (see Table 15.3-9) would prompt an investigation of a possible core anomaly. This satisfies the first acceptance criterion given in Section 15.3.3.1a above.

In Reference 29, a large number of misloads were evaluated for representative core designs employing current fuel types and fuel features. The simulated misloads, involving one or two fuel assemblies, covered a wide range of local reactivity perturbations and core positions. The resulting hot full power (HFP) $F\Delta H$ peaking factors ranged from benign to very severe. Severe misloads with peaking factors that exceed the $F\Delta H$ limit for DNB at normal operation conditions have the potential for fuel failure if they remain undetected. The simulated misloads were assessed with respect to severity and detectability.

The detectability assessments of Reference 29 demonstrated that the incore detector system is very robust with respect to detection of misloads severe enough to fail fuel during normal operation. By examining a large number of moveable detector thimble patterns, the detectability assessments considered the effect of inoperable moveable detector thimbles on misload detectability. Even when the minimum number of operable detector locations allowed per the plant licensing bases was assumed, the incore detector system was capable of reliably detecting misloads severe enough to fail fuel during normal operation.

Fuel misloads involving a single fuel rod or fuel pellet were not evaluated as part of Reference 29. Such misloads, in general, will not be detectable using the incore detector system due to the very small power distribution perturbation. In terms of increased peaking factors and reduced DNBR values, however, the consequences of such misloads will be very small and limited to the affected fuel rod and the immediately adjacent fuel rods.

Detection of fuel misloads is, in part, a function of the number of available incore detector locations. Reference 29 demonstrated that the flux map review criteria of Table 15.3-9 are effective in detecting fuel misloads that could lead to fuel failures during normal operation. To enhance the probability that significant misloads will be detected, tighter review criteria are employed when the number of available detector locations is reduced. These review criteria will be used for startup and subsequent at power flux maps.

The detectability assessments of Reference 29 confirm that the moveable detector system can reliably detect fuel misloads that could fail fuel during normal operation when the Table 15.3-9 review criteria are employed. Specifically, Reference 29 demonstrated that only a small fraction of 1% of misloads severe enough to fail fuel during normal operation would be undetected at startup using these limited review criteria. Furthermore, it was judged that even these “undetected” misloads would very likely be detected if other attributes of the startup power distribution measurement (e.g., tilts and reaction rate error contours) were considered along with the results of low power physics testing. Given that detection of >99% of misloads severe enough to fail fuel is expected using these review criteria, a radiological consequences analysis is deemed unnecessary. Failures in fresh fuel during startup would have negligible radiological consequences since there is only a small fission product inventory. Following startup, any fuel rod failures would occur gradually and would be detected by coolant activity monitoring. Since the number of potential fuel rod failures due to a core misload would be extremely small and such failures would occur gradually, any coolant activity releases would initially be well within the cleanup capacity of the plant. Any trend in increased coolant activity would warrant further investigation and evaluation. Therefore, the second acceptance criterion for this event would be satisfied since failures would be gradual, detectable, and the operations would be maintained within Technical Specification coolant activity guidelines.

15.3.3.4 Conclusions

Fuel misloads are prevented by manufacturing controls and core loading controls. In the unlikely event that a fuel misload should occur, the incore moveable detector system is capable of reliably detecting misloads that could fail fuel at normal operation conditions. Exceeding the review criteria herein would initiate an investigation to identify potential core anomalies. Any failures associated with an undetected fuel misload would be gradual, detectable, and the operations would be maintained within Technical Specification coolant activity guidelines.

15.3.4 Complete Loss of Forced Reactor Coolant Flow

15.3.4.1 Identification of Causes and Accident Description

A complete loss of forced reactor coolant flow may result from a simultaneous loss of electrical supplies to all reactor coolant pumps. If the reactor is at power at the time of the accident, the immediate effect of loss of coolant flow is a rapid increase in the coolant temperature. This increase could result in DNB with subsequent fuel damage if the reactor were not tripped promptly. The following reactor trips provide necessary protection against a loss of coolant flow accident:

1. Undervoltage or underfrequency on reactor coolant pump power supply buses.
2. Low reactor coolant loop flow.

The reactor trip on reactor coolant pump bus undervoltage is provided to protect against conditions that can cause a loss of voltage to all reactor coolant pumps, i.e., Loss of Offsite Power. The reactor trip on reactor coolant pump underfrequency is provided to open the reactor coolant

pump breakers and trip the reactor for an underfrequency condition, resulting from frequency disturbances on the major power grid. The trip disengages the reactor coolant pumps from the power grid so that the pumps' flywheel kinetic energy is available for full coastdown. Both trips are blocked below approximately 10% power (Permissive 7).

The reactor trip on low primary coolant loop flow is provided to protect against loss of flow conditions that affect only one reactor coolant loop. It also serves as a backup to the undervoltage and underfrequency trips. This function is generated by two out of three low flow signals per reactor coolant loop. Above approximately 38% power (Permissive 8), low flow in any loop will actuate a reactor trip. Between approximately 10 and 39% power (Permissive 7 and Permissive 8), low flow in any two loops will actuate a reactor trip.

Normal power for each pump is supplied through individual busses connected to the isolated phase bus duct between the generator circuit breaker and the main transformer. Faults in the substation may cause a trip of the main transformer high side circuit breaker leaving the generator to supply power to the reactor coolant pumps. When a generator circuit breaker trip occurs because of electrical faults, the pumps are automatically transferred to an alternate power supply and the pumps will continue to supply coolant flow to the core. Following any turbine trip where there are no electrical faults, the generator circuit breaker is tripped and the reactor coolant pumps remain connected to the network through the transformer high side breaker. Continuity of power to the pump buses is achieved without motoring the generator since means are provided to isolate the generator without isolating the pump buses from the external power lines (e.g., a generator output breaker is provided as well as a station output breaker).

15.3.4.2 Analysis of Effects and Consequences

15.3.4.2.1 Method of Analysis

This transient is analyzed by three digital computer codes. First the LOFTRAN (Reference 17) Code is used to calculate the loop and core flow during the transient. The LOFTRAN Code is also used to calculate the time of reactor trip, based on the calculated flows, and the nuclear power transient following reactor trip. The FACTRAN (Reference 9) Code is then used to calculate the heat flux transient based on the nuclear power and flow from LOFTRAN. Finally, the THINC (Reference 18) Code is used to calculate the minimum DNBR during the transient based on the heat flux from FACTRAN and flow from LOFTRAN.

The following case has been analyzed:

All loops operating, all loops coasting down.

The method of analysis and the assumptions made regarding initial operating conditions and reactivity coefficients are identical to those discussed in Section 15.2.5 for the partial loss of flow event, except that following the loss of supply to all pumps at power, a reactor trip is actuated by either bus undervoltage or bus underfrequency.

15.3.4.2.2 Results

The calculated sequence of events is shown in Table 15.3-3. Figure 15.3-27 and Figure 15.3-28 show the flow coastdown, nuclear power, and heat flux transients and minimum DNBR for the limiting complete loss of flow event. The reactor is assumed to trip on the undervoltage signal.

15.3.4.3 Conclusions

The analysis performed has demonstrated that for the complete loss of forced reactor coolant flow, the DNBR does not decrease below the safety analysis limit value during the transient, and thus, no core safety limit is violated.

15.3.5 Waste Gas Decay Tank Rupture

15.3.5.1 Identification of Causes and Accident Description

The Gaseous Waste Processing System, as discussed in Chapter 11, is designed to remove fission product gases from the reactor coolant. The system consists of a closed loop with waste gas compressors, hydrogen recombiners, waste gas decay tanks for service at power, and other waste gas decay tanks for service at shutdown and startup.

The maximum amount of waste gases stored occurs after a refueling shutdown at which time the gas decay tanks store the radioactive gases stripped from the reactor coolant.

The accident is defined as an unexpected and uncontrolled release of radioactive xenon and krypton fission product gases stored in a waste decay tank as a consequence of a failure of a single gas decay tank or associated piping.

15.3.5.2 Analysis of Effects

Nonvolatile fission product concentrations are greatly reduced as the coolant being let down is passed through the purification demineralizers. An iodine removal factor of 10 is expected in the mixed bed demineralizers, and an iodine partition factor of the order of 10,000 is expected between the liquid and vapor phases. Based on the above analysis and operating experience at Yankee Rowe and Saxton, activity stored in a gas decay tank consists of that from the noble gases released from the processed coolant and only negligible quantities of less volatile isotopes.

15.3.5.3 Environmental Consequences

The quantity of noble gases contained in each gas decay tank is restricted to assure that in the event of an uncontrolled release of the tank's contents, the resulting total body exposure to an individual at the nearest exclusion area boundary will not exceed 0.5 Rem. Using the methodology outline in Section 5.6.1 of NUREG-0133, the maximum allowable limit is 131,000 curies of noble gases (considered as 133Xe). The corresponding beta/gamma skin dose will also not exceed 2.05 Rem.

To supplement the above evaluation, a realistic analysis and a conservative analysis of potential environmental consequences is performed using the NUREG-0133 methodology with the maximum expected noble gas inventory shown in Table 15.3-5. These supplemental dose projections resulting from the postulated rupture of a gas decay tank are based on the following assumptions:

1. The decay tank rupture is assumed to occur immediately after isolation of the decay tank from the gaseous waste processing system, releasing the entire contents of the tank to the outside atmosphere at ground level. The assumption of the release of the noble gas inventory from only a single tank is based upon the fact that the valving of the decay tanks in the gaseous waste processing system has been designed so that a release from one decay tank by any means does not result in any additional release of radioactivity stored in any of the other decay tanks.
2. The 0-1 hour atmospheric diffusion factor given in Section 15.A is applicable for the conservative offsite dose analysis. The average annual atmospheric diffusion factors of 3.25 x 10^{-6} and 3.65 x 10^{-7} sec/m^3 at the site boundary and low population zone are used for the realistic offsite dose analysis.

The site boundary gamma whole body and gamma/beta skin doses for the realistic analysis are 2.1x 10^{-3} Rem and 1.22 x 10^{-2} Rem respectively.

The low population zone gamma whole body and gamma/beta skin doses for the realistic analysis are 2.29 x 10^{-4} Rem and 1.37 x 10^{-3} Rem respectively.

The site boundary gamma whole body and gamma/beta skin doses for the conservative analysis are 2.56 x 10^{-1} Rem and 1.54 Rem respectively.

The low population zone gamma whole body and gamma/beta skin doses for the conservative analysis are 6.34 x 10^{-2} Rem and 0.38 Rem respectively.

Since there is no significant amount of the iodine radioisotope within the gas decay tank, a thyroid dose is not calculated.

The calculated doses are well within the limits of 10CFR100 and fall below the 10CFR20 yearly instantaneous dose rate limits (≤ 00 mrem total body & ≤ 3000 mrem skin) for unrestricted areas.

15.3.6 Single Rod Cluster Control Assembly Withdrawal at Full Power

15.3.6.1 Identification of Causes and Accident Description

No single electrical or mechanical failure in the Rod Control System could cause the accidental withdrawal of a single Rod Cluster Control Assembly (RCCA) from the inserted bank at full power operation. The operator could deliberately withdraw a single RCCA in the control bank since this feature is necessary in order to retrieve an assembly should one be accidentally dropped. In the extremely unlikely event of simultaneous electrical failures which could result in single

RCCA withdrawal, rod deviation and rod control urgent failure would both be displayed on the plant annunciator, and the rod position indicators would indicate the relative positions of the assemblies in the bank. The urgent failure alarm also inhibits automatic rod motion in the group in which it occurs. Withdrawal of a single RCCA by operator action, whether deliberate or by a combination of errors, would result in activation of the same alarm and the same visual indications.

Each bank of RCCAs in the system is divided into 2 groups of 4 mechanisms each. The rods comprising a group operate in parallel through multiplexing thyristors. The 2 groups in a bank move sequentially such that the first group is always within 1 step of the second group in the bank. A definite schedule of actuation (or deactuation of the stationary gripper, movable gripper, and lift coils of a mechanism) is required to withdraw the RCCA attached to the mechanism. Since the 4 stationary gripper, movable gripper, and lift coils associated with the 4 RCCAs of a rod group are driven in parallel, any single failure which would cause rod withdrawal would affect a minimum of 1 group, or 4 RCCAs. Mechanical failures are in the direction of insertion or immobility.

15.3.6.2 Analysis of Effects and Consequences

15.3.6.2.1 Method of Analysis

Power distributions within the core are calculated by the ANC (Reference 21) Code based on macroscopic cross section generated by PHOENIX-P (Reference 21) or PARAGON (Reference 22). The peaking factors calculated by ANC are then used by THINC to calculate the minimum DNB for the event. The plant was analyzed for the worst rod withdrawn from Bank D inserted at the insertion limit, with the reactor initially at full power.

15.3.6.2.2 Results

Two (2) cases have been considered as follows:

1. If the reactor is in the manual control mode, continuous withdrawal of a single RCCA results in both an increase in core power and coolant temperature, and an increase in the local hot channel factor in the area of the failed RCCA. In terms of the overall system response, this case is similar to those presented in Section 15.2.2; however, the increased local power peaking in the area of the withdrawn RCCA results in lower minimum DNBR's than for the withdrawn bank cases. Depending on initial bank insertion and location of the withdrawn RCCA, automatic reactor trip may not occur sufficiently fast to prevent the minimum core DNBR from falling below the safety limit value. Evaluation of this case at the power and coolant conditions at which the overtemperature T trip would be expected to trip the plant, shows that an upper limit for the number of rods with a DNBR less than the safety limit value is 5 percent.
2. If the reactor is in automatic control mode, continuous withdrawal of a single RCCA will result in the immobility of the other RCCAs in the controlling bank. The transient will then proceed in the same manner as Case 1 described above. For such cases as above, a trip will

ultimately ensue, although not sufficiently fast, in all cases to prevent a minimum DNBR in the core of less than the safety limit.

15.3.6.3 Conclusions

For the case of one RCCA fully withdrawn, with the reactor in the automatic or manual control mode, and initially operating at full power with Bank D at the insertion limit, an upper bound of the number of fuel rods experiencing DNBR less than the design limit is 5 percent or less of the total fuel rods in the core.

For both cases discussed, the indicators and alarms mentioned would function to alert the operator to the malfunction before DNB could occur. For case 1 discussed above, the insertion limit alarms (low and low-low alarms) would also serve to alert the operator.

15.3.7 Break In Instrument Line or Other Lines From Reactor Coolant Pressure Boundary That Penetrate Containment

There are no instrument lines connected to the reactor coolant system that penetrate containment. However, grab sample lines from reactor coolant loop 2 and loop 3 hot legs, the pressurizer steam and liquid spaces, and the 3 inch chemical and volume control system (CVCS) letdown line do penetrate containment. he grab sample lines are equipped with normally closed isolation valves both inside and outside containment and are designed in accordance with General Design Criterion 55.

The most severe pipe rupture, with regard to release of radioactivity during normal plant operation, would be complete severance of the 3 inch CVCS letdown line just outside containment, upstream of the outer containment isolation valve, (see Figure 9.3 16, Sheet 1) at rated power. Complete severance of the letdown line would result in the loss of reactor coolant at the rate of up to 165 gpm based on the use of two (60 gpm) letdown orifice prior to the accident. Following such a break, the RCS pressure decreases due to the loss of reactor coolant. When the pressurizer pressure has reached the low pressure setpoint, a reactor trip is initiated. A turbine trip follows a reactor trip and results in an increase in secondary side pressure to the steam generator safety valve set pressure. The safety injection signal on low pressurizer pressure terminates the break flow by isolating the letdown line inside containment. The reactor coolant inventory is replenished by the charging pumps. Operation of these pumps ensure that the core will not be uncovered and prevents any significant increases in clad temperature. For smaller breaks within the capability of the Reactor Makeup System, Engineered Safety Features actuation would not occur. Frequent automatic operation of the Reactor Makeup System would provide some indication of reactor coolant loss to the operator.

For this event, environmental consequences are evaluated for both a realistic and a conservative case. Assumptions and parameters used to calculate the activity released and the offsite doses resulting from this event for both the realistic and conservative cases are summarized in Table 15.3-6 and are listed as follows:

1. The operator will be able to detect the rupture and isolate the break within 10 minutes by use of the following:

   a. Low flow alarm on the reactor coolant letdown monitor, RM L1 (see Section 11.4.2).

   b. Leakage greater than 45 gpm which actuates an alarm in the control room. The alarm drain system is discussed in Section 9.3.3.3 and illustrated schematically by Figure 9.3 7.

   c. Indication of letdown line flow on the main control board.

   However, for this offsite dose analysis it is conservatively assumed that the time required for the operator to identify the accident and isolate the break is 30 minutes.

2. Reactor coolant is lost through the break at a rate of 165 gpm. No activity is released from the break after the isolation time of 30 minutes.
3. The iodine partition factor for activity released from the break is 0.4.
4. The concentration of radioactive nuclides in the reactor coolant is listed in Table 11.1 2. For the realistic case these values were multiplied by a factor of 0.12. For the conservative case it is assumed that concurrent iodine spikes occur as a result of the accident.
5. For the concurrent iodine spike, the increase in the reactor coolant iodine concentration is estimated using a spiking model which assumes that the iodine release rate from the fuel rods to the coolant increases to a value 500 times greater than the release rate corresponding to the iodine concentration at the equilibrium value associated with reactor coolant activities at 1 Ci/gm dose equivalent I-131. The iodine release rate during the concurrent spike is based on a maximum letdown flow of 143 gpm which includes the maximum normal letdown of 120 gpm plus 12 gpm to account for uncertainty in flow and 11 gpm primary coolant leakage.

Using the previously listed assumptions, isotopic releases to the environment are determined to be those listed in Table 15.3-7 and Table 15.3-8 for the realistic and conservative cases, respectively.

Gamma, beta and thyroid doses at the site boundary for the realistic case are 4.27×10^{5} Rem, 7.11×10^{-5} Rem, and 3.17×10^{-3} Rem, respectively. Corresponding doses at the low population zone are 4.82×10^{-6} Rem, 8.03×10^{-6} Rem, and 3.58×10^{-4} Rem, respectively.

Gamma, beta and thyroid doses at the site boundary for the conservative case with a concurrent iodine spike are 2.31×10^{-1} Rem, 1.35×10^{-1} Rem, and $2.17 \times 10^{+1}$ Rem, respectively. Corresponding doses at the low population zone are 1.34×10^{-2} Rem, 7.83×10^{-3} Rem, and 1.26 Rem, respectively.

Doses resulting from this accident are well within the limits defined in 10 CFR 100 (25 Rem whole body and 300 Rem thyroid).

15.4 CONDITION IV - LIMITING FAULTS

Condition IV occurrences are faults which are not expected to take place, but are postulated because their consequences would include the potential for the release of significant amounts of radioactive material. They are the most drastic which must be designed against and represent limiting design cases. Condition IV faults are not to cause a fission product release to the environment resulting in an undue risk to public health and safety in excess of guideline values of 10 CFR 50.67. A single Condition IV fault is not to cause a consequential loss of required functions of systems needed to cope with the fault including those of the Emergency Core Cooling System and the containment. For the purposes of this report the following faults have been classified in this category:

1. Major rupture of pipes containing reactor coolant up to and including double ended rupture of the largest pipe in the Reactor Coolant System (RCS), i.e., loss-of-coolant accident (LOCA).
2. Major secondary system pipe ruptures.
3. Steam generator tube rupture.
4. Single reactor coolant pump locked rotor.
5. Fuel handling accident.
6. Rupture of a control rod drive mechanism housing (rod cluster control assembly ejection).

Each of these six limiting faults is analyzed in Section 15.4 in accordance with USNRC Regulatory Guide 1.183 guidelines. In general, each analysis includes an identification of causes and description of the accident, an analysis of effects and consequences, a presentation of results, and relevant conclusions

15.4.1 Major Reactor Coolant System Pipe Ruptures (Loss of Coolant Accident)

An analysis with the FULL SPECTRUM loss-of-coolant accident (FSLOCA) evaluation model (EM) has been completed for V.C. Summer. Sections 15.4.1.1.1 through 15.4.1.1.5 discuss the LOCA analysis.

15.4.1.1 FULL SPECTRUM LOCA Evaluation Model and Analysis

15.4.1.1.1 Introduction

The FSLOCA EM (Reference 1) was developed to address the full spectrum of loss-of-coolant accidents (LOCAs) which result from a postulated break in the reactor coolant system (RCS) of a pressurized water reactor (PWR). The break sizes considered in the Westinghouse FSLOCA EM include any break size in which break flow is beyond the capacity of the normal charging pumps, up to and including a double-ended guillotine (DEG) rupture of an RCS cold leg with a break flow area equal to two times the pipe area, including what traditionally are defined as Small and Large Break LOCAs.

The break size spectrum is divided into two regions. Region I includes breaks that are typically defined as Small Break LOCAs (SBLOCAs). Region II includes break sizes that are typically defined as Large Break LOCAs (LBLOCAs).

The FSLOCA EM explicitly considers the effects of fuel pellet thermal conductivity degradation (TCD) and other burnup-related effects by calibrating to fuel rod performance data input generated by the PAD5 code (Reference 2), which explicitly models TCD and is benchmarked to high burnup data in Reference 2. The fuel pellet thermal conductivity model in the WCOBRA/TRAC-TF2 code used for system and fuel response predictions explicitly accounts for pellet thermal conductivity degradation.

Three of the Title 10 of the Code of Federal Regulations (CFR) 50.46 criteria (peak cladding temperature (PCT), maximum local oxidation (MLO), and core-wide oxidation (CWO)) are considered directly in the FSLOCA EM. The MLO is defined as the sum of pre-transient corrosion and transient oxidation consistent with the position in Information Notice 98-29 (Reference 4). Compliance with demonstrating the maintenance of core cooling geometry and of long-term core cooling is discussed in Section 15.4.1.1.5.

10 CFR 50.46 (Reference 3) states that "[…] *uncertainty must be accounted for, so that, when the calculated ECCS cooling performance is compared to the criteria set forth in paragraph (b) of this section, there is a high level of probability that the criteria would not be exceeded*." A statistical statement which estimates or bounds the 95th percentile of the population with a 95-percent confidence level has been suggested by the NRC as acceptable to demonstrate the required "high probability." In the FSLOCA EM, the uncertainties are combined with a direct Monte Carlo simulation. A sample of the predicted short-term LOCA population is generated, and non-parametric statistical inference procedures are applied to develop probabilistic statements based on the predicted LOCA population. Upper tolerance limits for PCT, MLO, and CWO are calculated at the 95-percent confidence level to bound 95% of the population of predicted LOCA results. A "high level of probability" that 10 CFR 50.46 acceptance criteria (b)(1), (b)(2), and (b)(3) would not be exceeded is assured by confirming that the upper tolerance limits are within the acceptance criteria.

The FSLOCA EM has been generically approved by the Nuclear Regulatory Commission (NRC) for Westinghouse 3-loop and 4-loop plants with cold leg Emergency Core Cooling System (ECCS) injection (Reference 1). Since V.C. Summer is a Westinghouse designed 3-loop plant with cold leg ECCS injection, the approved method is applicable.

Sections 15.4.1.1.3 and 15.4.1.1.4 summarize the application of the Westinghouse FSLOCA EM to V.C. Summer. The application of the FSLOCA EM to V.C. Summer is consistent with the NRC-approved methodology (Reference 1), with the corrections and changes reported in Reference 5 pursuant to 10 CFR 50.46. The application of the FSLOCA EM is also applicable for the V.C. Summer plant design and operating conditions.

The major plant parameter and analysis assumptions used in the V.C. Summer analysis with the FSLOCA EM are provided in Tables 15.4-1a through 15.4-1f.

15.4.1.1.2 Method of Analysis

15.4.1.1.2.1 FULL SPECTRUM LOCA Evaluation Model Development

In 1988, the NRC Staff amended the requirements of 10 CFR 50.46 (Reference 3 and Reference 6) and Appendix K, "ECCS Evaluation Models," to permit the use of a realistic EM to analyze the performance of the ECCS during a hypothetical LOCA. Under the amended rules, best-estimate thermal-hydraulic models may be used in place of models with Appendix K features. After the rule change, Westinghouse developed and received approval for a best-estimate LBLOCA EM, which is discussed in Reference 7. The EM is referred to as the Code Qualification Document (CQD), and was developed following Regulatory Guide (RG) 1.157 (Reference 8).

When the FSLOCA EM was being developed, the NRC issued RG 1.203 (Reference 9) which expands on the principles of RG 1.157, while providing a more systematic approach to the development and assessment process of a PWR accident and safety analysis EM. Therefore, the development of the FSLOCA EM followed the Evaluation Model Development and Assessment Process (EMDAP), which is documented in RG 1.203. While RG 1.203 expands upon RG 1.157, there are certain aspects of RG 1.157 which are more detailed than RG 1.203; therefore, both RGs were used for the development of the FSLOCA EM.

15.4.1.1.2.2 WCOBRA/TRAC-TF2 Computer Code

The FSLOCA EM (Reference 1) uses the WCOBRA/TRAC-TF2 code to analyze the system thermal-hydraulic response for the full spectrum of break sizes. WCOBRA/TRAC-TF2 was created by combining a 1D module (TRAC-P) with a 3D module (based on Westinghouse modified COBRA-TF). The 1D and 3D modules include an explicit non-condensable gas transport equation. The use of TRAC-P allows for the extension of a two-fluid, six-equation formulation of the two-phase flow to the 1D loop components. This new code is WCOBRA/TRAC-TF2, where "TF2" is an identifier that reflects the use of a three-field (TF) formulation of the 3D module derived by COBRA-TF and a two-fluid (TF) formulation of the 1D module based on TRAC-P.

This best-estimate computer code contains the following features:

1. Ability to model transient three-dimensional flows in different geometries inside the reactor vessel
2. Ability to model thermal and mechanical non-equilibrium between phases
3. Ability to mechanistically represent interfacial heat, mass, and momentum transfer in different flow regimes
4. Ability to represent important reactor components such as fuel rods, steam generators (SGs), reactor coolant pumps (RCPs), etc.

A detailed assessment of the computer code WCOBRA/TRAC-TF2 was made through comparisons to experimental data. These assessments were used to develop quantitative estimates of the ability of the code to predict key physical phenomena for a LOCA. Modeling of a LOCA

introduces additional uncertainties which are identified and quantified in the plant-specific analysis. The reactor vessel and loop noding scheme used in the FSLOCA EM is consistent with the noding scheme used for the experiment simulations that form the validation basis for the physical models in the code. Such noding choices have been justified by assessing the model against large and full scale experiments.

15.4.1.1.3 Region I Analysis

Identification of Cause and Accident Description

The Region I analysis considers a spectrum of small breaks to ensure that those breaks with the likelihood of the more severe core uncovery are captured.

Before the break occurs, the plant is in an equilibrium condition, i.e., the heat generated in the core is being removed via the steam generator into the secondary system. Following the postulated break, a depressurization of the RCS and a loss of coolant would result. During the blowdown phase, heat from decay, hot reactor vessel internals, and the reactor vessel continues to be transferred to the RCS. A reactor trip occurs when the pressurizer low pressure trip setpoint is reached.

Safety injection (SI) is actuated when the low pressurizer pressure SI setpoint is reached. For a SBLOCA, the RCS pressure can remain high for an extended period, and the high pressure SI system functions to partially mitigate the RCS inventory lost through the break. The low pressurizer pressure SI signal also terminates normal feedwater flow by closing the main feedwater line isolation valves and initiates auxiliary feedwater flow by starting auxiliary feedwater pumps.

The heat transfer between the RCS and the secondary system may be in either direction depending on the relative temperatures between the RCS and the steam generator secondary side. In the case of continued heat addition to the steam generator secondary side, the pressure increases and is relieved by the main steam safety valves (MSSVs). Make-up to the steam generator secondary side is automatically provided by the auxiliary feedwater pumps.

When the RCS depressurizes below the accumulator cover pressure, the accumulators begin to inject water into the reactor coolant loops and recover the RCS inventory, effectively ending the transient.

The consequences of the accident are mitigated in two ways:

1. The reactor trip and borated water injection complement void formation in the core resulting in a rapid reduction in nuclear power to a residual level corresponding to the delayed fission and fission product decay.
2. The injection of borated water ensures sufficient flooding of the core to prevent excessive fuel rod cladding temperatures.

The availability of offsite power affects the timing of the initiation of safety injection flow and the reactor coolant pump trip following a small break LOCA. With a loss-of-offsite power (LOOP), the delayed SI results in a longer period of time when the vessel inventory is lost without being replaced by high head safety injection (HHSI) flow, although the HHSI flow is relatively small in magnitude early in the transient compared to the break flow due to the high RCS pressure. The reactor coolant pumps trip very early in the transient for LOOP, while operator action is assumed to result in an RCP trip 5 minutes after the plant-specific trip criterion is reached for offsite power available (OPA). Continued pump operation with OPA can work to pump more flow toward the break, depleting vessel inventory at a greater rate than otherwise would occur for a given break size. For small breaks, however, the continued pump operation can also maintain the positive flow in the broken cold leg, impeding flow reversal from the vessel directly to the break and reducing the total flow out the break.

15.4.1.1.3.1 Phenomenological Description of Region I LOCA

The small break LOCA transient can be divided into time periods in which specific phenomena are occurring, as discussed below.

Blowdown

The rapid depressurization of the RCS coincides with subcooled liquid flow through the break. Following the reactor trip on the low pressurizer pressure setpoint, the pressurizer drains, and safety injection is initiated on the low pressurizer pressure SI setpoint. After reaching this setpoint and applying the safety injection delays, high pressure safety injection flow begins. Phase separation begins in the upper head and upper plenum near the end of this period until the entire RCS eventually reaches saturation, ending the rapid depressurization slightly above the steam generator secondary side pressure near the modeled MSSV setpoint.

Natural Circulation

This quasi-equilibrium phase persists while the RCS pressure remains slightly above the secondary side pressure. The system drains from the top down, and while significant mass is continually lost through the break, the vapor generated in the core is trapped in the higher elevations of the RCS because of the seal formed by liquid in the crossover leg (cold leg pump suction) loop seals. Throughout this period, the core remains covered by a two-phase mixture and the fuel cladding temperatures remain at the saturation temperature.

Loop Seal Clearance

As the system drains through the break, the liquid levels in the downhill side of the pump suction (crossover leg) decrease to the lower elevations of the piping, allowing the vapor trapped during the natural circulation phase to also vent to the break. This is the loop seal clearing process. The break flow and the flow through the RCS loops become primarily vapor. Relief of a static head imbalance allows for a quick but temporary recovery of liquid levels in the core region.

Boil-Off

With a vapor vent path established after the loop seal clearance, the RCS depressurizes at a rate controlled by the critical flow, which continues to be a primarily high quality mixture of water and steam. The RCS pressure may remain high enough such that safety injection flow cannot make up for the primary system fluid inventory lost through the break in time, potentially leading to core uncovery and a fuel rod cladding temperature heatup.

Core Recovery

The RCS pressure continues to decrease, and once it reaches that of the accumulator gas pressure, the introduction of additional ECCS water from the accumulators replenishes the reactor vessel inventory and recovers the core mixture level. The accident analysis is terminated when the break flow is matched, then exceeded, by the injected flow.

15.4.1.1.3.2 Analysis Results

The V.C. Summer Region I analysis was performed in accordance with the NRC-approved methodology in Reference 1 with the corrections and changes reported in Reference 5. The transient that produced the analysis PCT result is a cold leg break with a break diameter of 2.6-inches. The most limiting ECCS single failure of one ECCS train is assumed in the analysis as identified in Table 15.4-1a. Control rod drop is modeled for breaks less than 1 square foot assuming a 2.0-second signal delay time and a 4.0-second rod drop time. RCP trip is modeled coincident with reactor trip on the low pressurizer pressure setpoint for LOOP transients. When the low pressurizer pressure SI setpoint is reached, there is a delay to account for emergency diesel generator start-up, filling headers, etc., after which safety injection is initiated into the reactor coolant system.

The results of the V.C. Summer Region I uncertainty analysis are summarized in Table 15.4-2.

Table 15.4-3 contains a sequence of events for the transient that produced the Region I analysis PCT result. Figures 15.4-2 through 15.4-13 illustrate the calculated key transient response parameters for this transient.

15.4.1.1.4 Region II Analysis

Identification of Cause and Accident Description

Before the break occurs, the reactor is assumed to be in a full power equilibrium condition, i.e., the heat generated in the core is being removed by the steam generators. The entire RCS contains sub-cooled liquid which transfers heat from the core by forced convection with some nucleate boiling. Should a large break occur, rapid depressurization of the RCS to a pressure nearly equal to the containment pressure occurs in approximately 40 seconds, with nearly a complete loss of liquid inventory.

During blowdown, heat from fission product decay and stored energy in the fuel pellets continues to be transferred to the fuel rod cladding, and departure from nucleate boiling occurs. Rapid voiding in the core shuts down the reactor. The SI system is actuated when the low pressurizer pressure setpoint (SI signal) is reached. As the RCS pressure decreases to the accumulator cover pressure, injection of accumulator liquid into the cold leg begins. However, significant accumulator inventory is lost out of the break due to the phenomenon of emergency core cooling bypass. After the initial surge of accumulator inventory is lost out of the break, core bypass breaks down and the remaining accumulator liquid refills the lower portion of the reactor vessel.

The heat transfer between the RCS and the secondary system may be in either direction, based on the progression of the transient and the relative fluid temperatures. In the case of the large break LOCA, the primary pressure rapidly decreases below the secondary system pressure, and the steam generators become an additional heat source. Reflood of the core and eventual quench of the fuel rods is accomplished by the injection of water from the refueling water storage tank (RWST).

The consequences of the accident are mitigated in two ways:

1. The borated water injection complements void formation in causing a rapid reduction in nuclear power to a residual level corresponding to fission product decay heat. The level of RCS mixed boron concentration is sufficient to ensure that the post-LOCA core remains subcritical. However, no credit is taken for the insertion of control rods to shut down the reactor in the large break analysis.
2. The injection of borated water provides core cooling and prevents excessive fuel rod cladding temperatures.

The availability of offsite power affects the timing of the initiation of safety injection flow and the reactor coolant pump trip following a large break LOCA. With a LOOP, there is an extended delay in safety injection. Also, the effect of the RCS pumps on the LOCA transient may be significantly different, depending on whether they are assumed to coast down with LOOP or continue running with OPA.

15.4.1.1.4.1 Phenomenological Description of Region II LOCA

A large-break LOCA transient can be divided into phases in which specific phenomena are occurring. A convenient way to divide the transient is in terms of the various heatup and cooldown phases that the fuel assemblies undergo. For each of these phases, specific phenomena and heat transfer regimes are important, as discussed below.

Blowdown – Critical Heat Flux (CHF) Phase

In this phase, the break flow is subcooled, the discharge rate of coolant from the break is high, the core flow reverses, the fuel rods go through departure from nucleate boiling (DNB), and the cladding rapidly heats up and the reactor is shut down due to the core voiding.

The regions of the RCS with the highest initial temperatures (upper core, upper plenum, and hot legs) begin to flash during this period. This phase is terminated when the water in the lower plenum and downcomer begins to flash. The mixture level swells and a saturated mixture is pushed into the core by the intact loop RCPs, still rotating in single-phase liquid. As the fluid in the broken cold leg reaches saturation conditions, the discharge flow rate at the break decreases significantly.

Blowdown – Upward Core Flow Phase

Heat transfer is increased as the two-phase mixture is pushed into the core. The break discharge rate is reduced because the fluid becomes saturated at the break. This phase ends as the lower plenum mass is depleted, the fluid in the loops become two-phase, and the RCP head degrades with increasing voiding.

Blowdown – Downward Core Flow Phase

The break flow begins to dominate and pulls flow down through the core as RCP head decreases, while liquid and entrained liquid flows also provide core cooling. Heat transfer in this period may be enhanced by liquid flow from the upper head. Once the system has depressurized to less than the accumulator cover pressure, the accumulators begin to inject cold water into the cold legs.

During this period, due to steam upflow in the downcomer, a portion of the injected ECCS water is lost to the break or bypasses the core around the downcomer and exits via the break due to the phenomenon of emergency core cooling bypass. After the initial surge of accumulator inventory is lost out of the break, core bypass breaks down and the remaining accumulator liquid refills the lower portion of the reactor vessel. As the system pressure continues to decrease, the break flow and consequently the downward core flow are reduced. The system pressure approaches the containment pressure at the end of this last period of the blowdown phase.

During this phase, the core begins to heat up as the system equilibrates with containment pressure, and the phase ends when the reactor vessel begins to refill with ECCS water.

Refill Phase

The core continues to heat up as the lower plenum refills with ECCS water. This phase is characterized by a rapid increase in fuel cladding temperature at all elevations due to the lack of liquid and steam flow in the core region. The water completely refills the lower plenum and the refill phase ends. As ECCS water enters the core, the fuel rods in the lower core region begin to quench and liquid entrainment begins, resulting in increased fuel rod heat transfer.

Reflood Phase

During the early reflood phase, the accumulators begin to empty and nitrogen is discharged into the RCS. The nitrogen surge forces water into the core, causing system re-pressurization and a temporary reduction of pumped ECCS flow. During this time, core cooling may increase due to

vapor generation and liquid entrainment, but conversely the early reflood pressure spike results in loss of mass out through the broken cold leg.

The pumped ECCS water aids in the filling of the downcomer throughout the reflood period. As the quench front progresses further into the core, the PCT elevation moves increasingly higher in the fuel assembly.

As the transient progresses, continued injection of pumped ECCS water refloods the core, effectively removes the reactor vessel metal mass stored energy and core decay heat, and leads to an increase in the reactor vessel fluid mass. Eventually the core inventory increases enough that liquid entrainment is able to quench all the fuel assemblies in the core.

15.4.1.1.4.2 Analysis Results

The V.C. Summer Region II analysis was performed in accordance with the NRC-approved methodology in Reference 1 with the corrections and changes reported in Reference 5. The analysis was performed assuming both LOOP and OPA, and the results of both of the LOOP and OPA analyses are compared to the 10 CFR 50.46 acceptance criteria. The most limiting ECCS single failure of one ECCS train is assumed in the analysis as identified in Table 15.4-1a. The results of the V.C. Summer Region II LOOP and OPA uncertainty analyses are summarized in Table 15.4-2.

Table 15.4-4 contains a sequence of events for the transient that produced the more limiting analysis PCT result relative to the offsite power assumption. Figures 15.4-14 through 15.4-27 illustrate the key response parameters for this transient.

The effects of containment backpressure on the LOCA analysis are determined by a containment response analysis separate from that described in Chapter 6. The containment pressure is calculated for each LOCA transient in the analysis using the COCO code (References 10 and 11). The COCO containment code is integrated into the WCOBRA/TRAC-TF2 thermal-hydraulic code. The transient-specific mass and energy releases calculated by the thermal-hydraulic code at the end of each timestep are transferred to COCO. COCO then calculates the containment pressure based on the containment model (the inputs are summarized in Tables 15.4-1b, 15.4-1c, and 6.2-60) and the mass and energy releases, and transfers the pressure back to the thermal-hydraulic code as a boundary condition at the break, consistent with the methodology in Reference 1. The containment model for COCO calculates a conservatively low containment pressure, including the effects of all the installed pressure reducing systems and processes such as assuming all trains of containment spray are operable and assuming fan cooler operation. The containment backpressure for the transient that produced the analysis PCT result is provided in Figure 15.4-21.

15.4.1.1.5 Compliance with 10 CFR 50.46

It must be demonstrated that there is a high level of probability that the following criteria in 10 CFR 50.46 are met:

(b)(1) The analysis PCT corresponds to a bounding estimate of the 95th percentile PCT at the 95-percent confidence level. Since the resulting PCT is less than 2,200°F, the analysis with the FSLOCA EM confirms that 10 CFR 50.46 acceptance criterion (b)(1), i.e., "Peak Cladding Temperature less than 2,200°F," is demonstrated.

The results are shown in Table 15.4-2 for V.C. Summer.

(b)(2) The analysis MLO corresponds to a bounding estimate of the 95th percentile MLO at the 95-percent confidence level. Since the resulting MLO is less than 17 percent when converting the time-at-temperature to an equivalent cladding reacted using the Baker-Just correlation and adding the pre-transient corrosion, the analysis confirms that 10 CFR 50.46 acceptance criterion (b)(2), i.e., "Maximum Local Oxidation of the cladding less than 17 percent," is demonstrated.

The results are shown in Table 15.4-2 for V.C. Summer.

(b)(3) The analysis CWO corresponds to a bounding estimate of the 95th percentile CWO at the 95-percent confidence level. Since the resulting CWO is less than 1 percent, the analysis confirms that 10 CFR 50.46 acceptance criterion (b)(3), i.e., "Core-Wide Oxidation less than 1 percent," is demonstrated.

The results are shown in Table 15.4-2 for V.C. Summer.

(b)(4) 10 CFR 50.46 acceptance criterion (b)(4) requires that the calculated changes in core geometry are such that the core remains in a coolable geometry.

This criterion is met by demonstrating compliance with criteria (b)(1), (b)(2), and (b)(3), and by assuring that fuel assembly grid deformation due to combined LOCA and seismic loads is specifically addressed. Criteria (b)(1), (b)(2), and (b)(3) have been met for V.C. Summer as shown in Table 15.4-2.

It is discussed in Section 32.1 of the NRC-approved FSLOCA EM (Reference 1) that the effects of LOCA and seismic loads on the core geometry do not need to be considered unless fuel assembly grid deformation extends beyond the core periphery (i.e., deformation in a fuel assembly with no sides adjacent to the core baffle plates). Inboard grid deformation due to combined LOCA and seismic loads is not calculated to occur for V.C. Summer.

(b)(5) 10 CFR 50.46 acceptance criterion (b)(5) requires that long-term core cooling be provided following the successful initial operation of the ECCS.

Long-term cooling is dependent on the demonstration of the continued delivery of cooling water to the core. The actions that are currently in place to maintain long-term cooling are not impacted by the application of the NRC-approved FSLOCA EM (Reference 1).

Based on the analysis results for Region I and Region II presented in Table 15.4-2 for V.C. Summer, it is concluded that V.C. Summer complies with the criteria in 10 CFR 50.46.

15.4.1.1.6 Long Term Cooling

In the long term, the core remains subcritical and amenable to cooling. For the limiting cold leg break, evaluations show:

1. At initiation of cold leg recirculation, the sump boron concentration is sufficient to keep the core subcritical (K_{eff} less than 1.0) with all control rods out and no Xenon.
2. Boron levels within the core are limited to less than the precipitation level by supplying ECCS water to the hot legs within 8 hours after initiation of the LOCA.
3. At the initiation of hot leg recirculation, the sump boron concentration is sufficient to keep the core subcritical (K_{eff} less than 1.0) with N-1 rods inserted (per WCAP-15704 (Reference 50) and Xenon.

15.4.1.1.7 Impact of ECCS Evaluation Model Changes

The October 17, 1988 revision to 10CFR50.46 requires applicants and holders of operating licenses or construction permits to notify the NRC of errors and changes in the ECCS Evaluation Models, which are not significant, on an annual basis. Reference 47 defines a significant error change as one which results in a calculated peak fuel cladding temperature (PCT) different by more than 50°F from the temperature calculated for the limiting transient using the last acceptable model, or is a cumulation of changes and errors such that the sum of the absolute temperature change is greater than 50°F. The current ECCS evaluation model changes that affect the large break LOCA PCT are identified in the latest 10CFR50.46 annual or 30 day report.

15.4.1.2 Hydrogen Production and Accumulation

Hydrogen accumulation in the containment atmosphere following a design basis accident can be the result of production from several sources. The potential sources of hydrogen are the zirconium water reaction, corrosion of construction materials, and radiolytic decomposition of the emergency core cooling solution. The latter source, solution radiolysis, includes both core solution radiolysis and sump solution radiolysis.

15.4.1.2.1 Method of Analysis

Methods and assumptions used in the analysis of post-accident hydrogen generation and control are specified by Regulatory Guide 1.7 (Reference 53). In determining the amount of hydrogen generated by reaction of the core Zircaloy cladding with water, Regulatory Guide 1.7 states that the amount of hydrogen generated by zirc-water reaction should be the greater of either five times the maximum amount calculated by ECCS evaluation or the amount that would result from reaction of all the metal in the outside surfaces of the fuel cladding to a depth of 0.00023 inches. The 10CFR50.46 acceptance criteria for ECCS performance requires that total hydrogen generated by cladding oxidation be less than 0.01 times (1.0%) the amount generated by oxidation of the whole core cladding. The amount of cladding oxidation following the design basis LOCA is shown by the ECCS evaluation to be less than the 1.0% acceptance criteria (Table 15.4-2). Five times that amount, then, is 5.0%. Since 0.00023 inches is approximately 1% of the cladding thickness, the conservative assumption for Zirc-water reaction under Regulatory Guide 1.7 is 5.0% of the whole core cladding Zircaloy.

The use of aluminum inside the containment is limited, and it is not used in safety related components which are in contact with the recirculating core cooling fluid. Aluminum is much more reactive with the containment spray alkaline borate solution than other plant materials such as galvanized steel, copper, and copper nickel alloys.

By limiting the use of aluminum and zinc, the aggregate source of hydrogen over the long term is primarily due to that arising from radiolytic decomposition and can be predicted with reasonable certainty to permit the design of effective countermeasures.

It should be noted that the zirconium water reaction and aluminum zinc corrosion with containment spray are chemical reactions and thus essentially independent of the radiation field inside the containment following a loss of coolant accident. Radiolytic decomposition of water is dependent on the radiation field intensity. The radiation field inside the containment is calculated for the maximum credible accident in which the fission product activities given in TID 14844 (Reference 15) are used.

The hydrogen generation calculations are performed using the NRC model discussed in Regulatory Guide 1.7 and NRC Standard Review Plan, Section 6.2.5 with no recombiner operating; also, a calculation is made using the NRC model and recombiner operation after the first day following a LOCA. Recombiner operation is discussed in Section 6.2.5.

15.4.1.2.2 Assumptions

The following discussion outlines the assumptions used in the calculations.

1. Zirconium water reaction

   The zirconium water reaction is described by the chemical equation:

   $Zr + 2H_2O \quad Zr\,O_2 + 2H_2 + Heat$

The hydrogen generation due to this reaction will be completed during the first day following the loss of coolant accident. The quantity of hydrogen generated from the zirconium water reaction is 14,987 scf, and is based on 5% of the total zirconium mass reacted. The hydrogen generated is assumed to be released immediately to the containment atmosphere following the loss of coolant accident.

2. Hydrogen from the Reactor Coolant System

   The maximum quantity of hydrogen contained in the primary coolant system is 909 scf. This includes both hydrogen dissolved in the coolant water [35 cc (STP)/kg] and the corresponding equilibrium hydrogen in the pressurizer gas space. The 909 scf of hydrogen is assumed to be released immediately to the containment atmosphere following the loss of coolant accident.

3. Corrosion of plant materials

   Oxidation of metals in aqueous solution results in the generation of hydrogen gas as one of the corrosion products. Extensive corrosion testing has been conducted to determine the behavior of the various metals used in the containment in the

   emergency core cooling solution at design basis accident conditions. Metals tested include Zircaloy, Inconel, aluminum alloys, cupronickel alloys, carbon steel, galvanized carbon steel, and copper.

   Tests conducted at Oak Ridge National Laboratory (ORNL) (Reference 17) (Reference 18) have also verified the compatibility of the various materials (exclusive of aluminum) with alkaline borate solution. As applied to the quantitative definition of hydrogen production rates, the results of the corrosion tests have shown that only aluminum and zinc will corrode at a rate that will significantly add to the hydrogen accumulation in the containment atmosphere.

   The corrosion of aluminum may be described by the overall reaction:

   $2\,Al + 3\,H_2O \rightarrow Al_2O_3 + 3\,H_2$

   Therefore, three moles of hydrogen are produced for each two moles of aluminum oxidized. This corresponds to 20 scf hydrogen produced for each pound of aluminum corroded.

   The corrosion of zinc may be described by the overall reaction:

   $Zn + 2\,H_2O \leftrightarrows Zn(OH)_2 + H_2$

   Therefore, one mole of hydrogen is produced for each mole of zinc oxidized. This corresponds to 5.5 scf hydrogen produced for each pound of zinc corroded.

The time temperature cycle (Table 15.4-6) used in the calculation of aluminum and zinc corrosion is based on a conservative representation of the postulated post accident containment transient. The corrosion rates at the various steps were determined from the aluminum and zinc corrosion rate design curve shown in Figure 15.4-68 and Figure 15.4-69. The corrosion data points include the effects of temperature, alloy, and spray solution conditions. Based on these corrosion rates and the aluminum and zinc inventory given in Table 15.4-7, the contribution of aluminum and zinc corrosion to hydrogen accumulation in the containment following a design basis accident has been calculated. For conservative estimation, no credit was taken for protective shielding effects of insulation or enclosures from the spray, and complete and continuous immersion was assumed.

4. Radiolysis of core and sump water

   Water radiolysis is a complex process involving reactions of numerous intermediates. However, the overall radiolytic process may be described by the reaction:

   $2\ H_2O \leftrightarrows 2\ H_2 + O_2$

   Of interest here is the quantitative definition of the rates and extent of radiolytic hydrogen production following a design basis accident.

   As the emergency core cooling solution flows through the core, it is subjected to gamma radiation by decay of fission products in the fuel. This energy deposition results in solution radiolysis and the production of molecular hydrogen and oxygen. The initial production rate of these species will depend on the rate of energy absorption and the specific radiolytic yields. Another source of hydrogen for the post-accident period arises from water contained in the reactor containment sump being subjected to radiolytic decomposition by fission products.

   For the purposes of this analysis, the calculations are based on Regulatory Guide 1.7 assumptions.

   Calculations based on Regulatory Guide 1.7 assume a hydrogen yield value of 0.5 molecules per 100 ev, 10% of the gamma energy produced from fission products in the fuel rods is absorbed by the solution in the region of the core, 100% of the gamma and beta energy produced from fission products intimately mixed with coolant.

15.4.1.2.3 Results

Figure 15.4-71 and Figure 15.4-72 show the hydrogen production and accumulation in the containment following a loss of coolant accident for the NRC model. Figure 15.4-73 shows the volume percent of hydrogen in the containment for the NRC model assuming no recombiner and recombiner start at one day.

15.4.1.3 Deleted

15.4.1.4 Environmental Consequences of a Postulated Loss of Coolant Accident

The results of analyses presented in this section demonstrate that the amounts of radioactivity released to the environment in the event of a LOCA do not result in doses which exceed guideline values.

Two analyses have been performed:

1. An analysis based upon Regulatory Guide 1.183 (see Appendix 3A).
2. A realistic analysis.

15.4.1.4.1 Fission Product Release to the Containment

To evaluate the radiological consequences of a postulated LOCA, the following 2 cases of fission product releases to the containment have been analyzed.

1. Core Activity Release (Regulatory Guide 1.183 Analysis)

   Acceptable assumptions regarding core inventory and the release of radionuclides from the core are provided in Regulatory Position 3 of Regulatory Guide 1.183.

   The inventory of fission products in the reactor core available for release from the containment is based on a core thermal power of 2958 MWt. A list of the 60 isotopes used in the Regulatory Guide 1.183 analysis is given in Table 15.4-11. The release fractions and timing associated with these isotopes are taken from RG 1.183 and reproduced in Table 15.4-12.

2. Primary Coolant Activity Release (Realistic Case)

   The inventory of fission products available for release from the containment are based on the 1% failed fuel primary coolant activities. In addition, the iodines and bromines in the coolant are conservatively assumed to be increased by a factor of 50 and the noble gases by a factor of 1.5 due to the spiking phenomenon. The resulting values available for release from containment are listed in Table 15.4-13.

15.4.1.4.2 Radioactive Releases from Recirculation Loops

In addition to the fission product release to the containment, the effect of leakage of recirculating sump fluid from engineered safety features equipment located outside the Reactor Building needs to be considered in evaluating the radiological consequences of a LOCA. The following assumptions are utilized in estimating the radiological consequences of post LOCA radioactive releases from these systems (i.e., emergency core cooling and Reactor Building spray) to the Auxiliary Building.

1. With the exception of noble gases, the fission products released to the containment listed in Table 15.4-11 and Table 15.4-13 are assumed to instantaneously and homogeneously mix in the primary containment sump water.
2. The leakage from these systems is conservatively assumed to be 12,000 cc/hr which is approximately 2 times the operational leakage estimated for the RHR and RB Spray systems as indicated in Tables 6.2 52b and 6.3 4. The release from these systems is assumed to start at the earliest time that the recirculation mode is initiated and continue for the duration of the accident
3. It is conservatively assumed that the recirculation loop leakage flashes and that 10% of the iodine is released to the Auxiliary Building atmosphere.
4. No credit is taken for the holdup or filtration of this leakage in the auxiliary building, i.e., the iodine released by the recirculation loop leakage is assumed to be immediately available for release to the environs.

15.4.1.4.3 Radiological Consequences Offsite

The RADTRAD (Reference 64) computer code was used to calculate the offsite doses for the LOCA event. Schematics showing the code modeling of the activity flow paths are shown on Figure 15.4-74 and Figure 15.4-74A. Parameters and assumptions used in evaluating the offsite doses for the LOCA are summarized in Table 15.4-15.

The calculated offsite doses for LOCA are provided in Table 15.4-16. The dose limits as defined in 10 CFR 50.67 are included in Table 15.4-16. The doses resulting from this accident are well within the limits defined in 10 CFR 50.67.

15.4.1.4.4 Radiological Consequences to the Control Room

The radiological effects that could exist in the control room as a consequence of this event would be due to direct radiation from the radioactive cloud in the atmosphere which results from leakage of fission products from the containment and from the postulated recirculation loop leakage in the Auxiliary Building; direct exposure from, the containment; and exposure to radioactive materials which might leak into the control room from these sources.

For the Regulatory Guide 1.183 Case the integrated dose to the control room operators was calculated using the following methods and assumptions:

1. The RADTRAD (Reference 64.) computer code was used to calculate the control room doses for the Regulatory Guide 1.183 case. Schematics showing the code modeling of the activity flow paths are shown on Figure 15.4-74 and Figure 15.4-74A. Parameters and assumptions used in evaluating the control room doses for the LOCA are summarized in Table 15.4-17.
2. The analytical model used to calculate the direct dose from the external radioactive cloud in the atmosphere is calculated as the unprotected control room dose utilizing the RADTRAD computer code and is adjusted to reflect the shielding effects of the control building structure.

3. The direct whole body dose from the radioactivity in the reactor building is calculated utilizing the MicroShield (Reference 65) shielding computer code based on a cylindrical source model, applicable post-accident source terms, and reactor/control building shielding.
4. The atmospheric diffusion parameters for the control room are provided in Table 2.3-123. The limiting control room release point for the LOCA is the Reactor Building nearest point (intake A).
5. As described in Section 9.4.1, the Control Room Ventilation system is automatically placed in the emergency mode, with filtration of incoming and recirculated air, following receipt of a Safety Injection (SI) or high radiation signal from the gaseous activity channel of RM-A1. If both trains are operating, one train will be isolated within 30 minutes by the Operator in accordance with the Emergency Operating Procedures to minimize dose consequences. This condition is bounded by the analysis which only credits one train control room ventilation for the duration of the accident.
6. The modeling of the Control Room Ventilation assumed for the Regulatory Guide 1.183 case is shown on Figure 15.4-74 and Figure 15.4-74A. The emergency mode of operation is assumed to occur at time zero since a SI signal occurs quickly after the accident.

The resulting control room doses for this LOCA are summarized in Table 15.4-18.

15.4.2 Major Secondary System Pipe Rupture

Two (2) major secondary system pipe ruptures are analyzed in this section: rupture of a main steam line and rupture of a main feedwater pipe. The time sequence of events for each of these events is provided in Table 15.4-19.

15.4.2.1 Major Rupture of a Main Steam Line

15.4.2.1.1 Identification of Causes and Accident Description

The steam release arising from a rupture of a main steam line would result in an initial increase in steam flow which decreases during the accident as the steam pressure falls. The energy removal from the RCS causes a reduction of coolant temperature and pressure. In the presence of a negative moderator temperature coefficient, the cooldown results in a reduction of core shutdown margin. If the most reactive rod cluster control assembly (RCCA) is assumed stuck in its fully withdrawn position after reactor trip, there is an increased possibility that the core will become critical and return to power. A return to power following a steam line rupture is a potential problem mainly because of the high power peaking factors which exist assuming the most reactive RCCA to be stuck in its fully withdrawn position. The core is ultimately shut down by the boric acid injection delivered by the safety injection system.

The limiting main steam line break was selected based upon the sensitivity studies performed in “Reactor Core Response to Excessive Secondary Steam Releases,” WCAP 9226, January, 1978 (Reference 42).

The analysis of a main steam line rupture is performed to demonstrate that, assuming a stuck RCCA (with and without offsite power), and a single failure in the engineered safety features (ESF) there is no consequential damage to the primary system and the core remains in place and intact.

Energy release to containment for the worst steam pipe break is discussed in FSAR Chapter 6.

Although departure from nucleate boiling (DNB) and possible clad perforation following a steam pipe rupture are not necessarily unacceptable, the following analysis, in fact, shows that no DNB occurs for any rupture assuming the most reactive assembly stuck in its fully withdrawn position.

The following functions provide the necessary protection for a steam line rupture:

1. Safety Injection System actuation from any of the following:
   a. Two (2) out of 3 low pressurizer pressure signals.
   b. Two (2) out of 3 high 1 containment pressure signals.
2. The overpower reactor trips (neutron flux and ΔT) and the reactor trip occurring in conjunction with receipt of the safety injection signal.
3. Redundant isolation of the main feedwater lines sustained high feedwater flow would cause additional cooldown. Therefore, a safety injection signal will rapidly close all feedwater control valves and feedwater isolation valves that backup the control valves.
4. Trip of the main steam line isolation valves (See Technical Specification (Reference 24) (Table 3.3 5) on:
   a. High 2 containment pressure.
   b. High steam line flow in 2 out of 3 steam lines in coincidence with 2 out of 3 low-low RCS average temperature.
   c. Two (2) out of 3 low steam line pressure.

For breaks downstream of the isolation valves, closure of all valves would completely terminate the blowdown. For any break, in any location, no more than one steam generator would blowdown even if one of the isolation valves fails to close. A description of steam line isolation is included in Chapter 10.

Steam flow is measured by monitoring dynamic head in nozzles located in the throat of the steam generator. The effective throat area of the nozzles is 1.4 square feet, which is considerably less than the main steam pipe and thus the nozzles also serve to limit the maximum steam flow for a break at any location.

Table 15.4-21 lists the equipment required in the recovery from a high energy line rupture. Not all equipment is required for any one particular break, since it will vary depending upon postulated break location and details of balance of plant design and pipe rupture criteria. Design criteria and methods of protection of safety related equipment from the dynamic effects of postulated piping

ruptures are provided in FSAR Section 3.6.

15.4.2.1.2 Analysis of Effects and Consequences

15.4.2.1.2.1 Method of Analysis

The analysis of the steam pipe rupture has been performed based on the methodologies documented in Reference 42 to determine:

1. The core heat flux and RCS temperature and pressure resulting from the cooldown following the steam line break. The LOFTRAN (Reference 25) Code has been used.
2. The thermal and hydraulic behavior of the core following a steam line break. A detailed thermal and hydraulic digital computer code, THINC (Reference 26), has been used to determine if DNB occurs for the core conditions computed in item 1 above.

The following conditions were assumed to exist at the time of a main steam line break accident.

1. End of life shut down margin at no load, equilibrium xenon conditions, and the most reactive RCCA stuck in its fully withdrawn position. Operation of the control rod banks during core burnup is restricted in such a way that addition of positive reactivity in a steam line break accident will not lead to a more adverse condition than the case analyzed.
2. The negative moderator coefficient corresponding to the end of life rodded core with the most reactive RCCA in the fully withdrawn position. The variation of the coefficient with temperature and pressure has been included. The k_{eff} versus temperature coefficient used is shown in Figure 15.2-46. The effect of power generation in core on overall reactivity is shown in Figure 15.4-75.

   The core properties associated with the sector nearest the affected steam generator and those associated with the remaining sector were conservatively combined to obtain average core properties for reactivity feedback calculations. Further, it was conservatively assumed that the core power distribution was uniform. These 2 conditions cause underprediction of the reactivity feedback in the high power region near the stuck rod. To verify the conservatism of this method, the reactivity as well as the power distribution was checked. These core analyses considered the Doppler reactivity from the high fuel temperature near the stuck RCCA, moderator feedback from the high water enthalpy near the stuck RCCA, power redistribution, and non uniform core inlet temperature effects. For cases in which steam generation occurs in the high flux regions of the core, the effect of void formation was also included. It was determined that the reactivity employed in the kinetics analysis was always larger than the true reactivity. These results verified conservatism; i.e., underprediction of negative reactivity feedback from power generation.

3. Minimum capability for injection of high concentration boric acid (2300 ppm) solution corresponding to the most restrictive single failure in the Safety Injection System (SIS). The characteristics of the injection unit used are shown on Figure 15.2-47. This corresponds to the flow delivered by one charging pump delivering its full flow to the cold leg header. No

credit has been taken for the low concentration of boric acid that must be swept from the safety injection lines downstream of the refueling water storage tank (RWST) isolation valves prior to the delivery of highly concentrated boric acid to the reactor coolant loops. This effect has been allowed for in the analysis. The modeling of the SIS in LOFTRAN is described in (Reference 2).

When offsite power is available, the sequence of events in the high head injection system is the following. After the generation of the safety injection signal (appropriate delays for instrumentation, logic, and signal transport included), the appropriate valves begin to operate and the charging pump starts. In 27 seconds, the valves are assumed to be in their final position and the pump is assumed to be at full speed. The volume containing the low concentration borated water is swept before the 2300 ppm water from the refueling water storage tank reaches the core. This delay is inherently included in the modeling.

When offsite power is not available, an additional ten second delay is assumed to start the diesels and to load the necessary safety injection equipment onto them. That is, after a total of 37 seconds following a safety injection signal, safety injection is assumed to be capable of delivering flow to the RCS. For conservatism, both the with and without offsite power available cases were analyzed using 37 seconds.

The choice of having loss of power near the beginning of the transient is made to maximize the delay of boron reaching the core. Having full RCS flow and immediate safety injection startup during the early stage of the transient facilitates boron delivery by minimizing pump startup time, thereby immediately purging unborated water from the safety injection lines, and minimizing RCS transport time. Loss of power after the break occurs, therefore, will allow a partial or total purge of unborated water from the safety injection lines, thus reducing the amount of time before which boron can be injected into the core, and loss of power prior to the break will allow for immediate safety injection startup and thus almost immediate purging of unborated water from the safety injection lines. Furthermore, since the steamline break with loss of offsite power is less severe than the case with offsite power available, the latter will be more conservative and bound the case of loss of offsite power.

4. Since the steam generators are provided with integral flow restrictors with a 1.4 square foot throat area, any rupture with a break area greater than 1.4 square feet, regardless of location would have the same effect on the Nuclear Steam Supply System (NSSS) as the 1.4 square foot break. The following cases have been considered in determining the core power and RCS transients:

   a. Complete severance of a pipe, with the plant initially at no load conditions, full reactor coolant flow with offsite power available.

   b. Complete severance of a pipe with the plant initially at no load conditions with offsite power unavailable.

5. Power peaking factors corresponding to one stuck RCCA and non uniform core inlet coolant temperatures are determined at end of core life. The coldest core inlet temperatures are assumed to occur in the sector with the stuck rod. The power peaking factors account for the effect of the local void in the region of the stuck control assembly during the return to power

phase following the steam line break. This void in conjunction with the large negative moderator coefficient partially offsets the effect of the stuck assembly. The power peaking factors depend upon the core power, temperature, pressure, and flow, and thus, are different for each case studied.

Both the cases assume initial hot shutdown conditions at time zero since this represents the most pessimistic initial condition. Should the reactor be just critical or operating at power at the time of a steam line break, the reactor will be tripped by the normal overpower protection system when power level reaches a trip point. Following a trip at power the RCS contains more stored energy than at no load, the average coolant temperature is higher than at no load, and there is appreciable energy stored in the fuel. Thus the additional stored energy is removed via the cooldown caused by the steam line break before the no load conditions of RCS temperature and shutdown margin assumed in the analyses are reached. After the additional stored energy has been removed, the cooldown and reactivity insertions proceed in the same manner as in the analysis which assumed no load condition at time zero.

However, since the initial steam generator water inventory is greatest at no load, the magnitude and duration of the RCS cooldown are less than steam line breaks occurring at power.

6. In computing the steam flow during a steam line break, the Moody Curve (Reference 27) for fl/D = 0 is used. The Moody Multiplier is 1 with a discharge at dry saturated steam conditions.
7. Perfect moisture separation in the steam generator is assumed. The assumption leads to conservative results since, in fact, considerable water would be discharged. Water carryover would reduce the magnitude of the temperature decrease in the core and the pressure increase in the containment.
8. No credit was taken for secondary side safety injection actuation on low steam pressure.
9. A flow imbalance of 5% between loops (faulted vs. intact) was assumed to incorporate the effects of loop-to-loop RCS flow asymmetry in the limiting steamline rupture event (with offsite power available).
10. To maximize primary-to-secondary heat transfer, 0 percent (0%) steam generator tube plugging is assumed in the limiting steamline rupture event (with offsite power available).

15.4.2.1.2.2 Results

The results presented are a conservative indication of the events which would occur assuming a steam line rupture since it is postulated that all of the conditions described above occur simultaneously. The calculated sequence of events is listed in Table 15.4-19.

Figure 15.4-76 and Figure 15.4-77 show the response of pertinent system parameters following a main steam pipe rupture. Offsite power is assumed to be available such that full reactor coolant flow exists.The transient shown assumes an uncontrolled steam release from only one steam generator, with all 3 steam generators blowing down through the break until steamline isolation.

As can be seen, the core attains criticality with RCCAs inserted (with the design shutdown assuming one stuck RCCA) before boric acid solution at 2300 ppm enters the RCS from the SIS which is drawing from the Refueling Water Storage Tank (RWST). The delay time consists of the time to receive and actuate the safety injection signal and the time to completely open valve trains in the safety injection lines. The safety injection pumps are then ready to deliver flow. At this stage, a further delay is incurred before 2300 ppm boron solution can be injected to the RCS due to the low concentration solution being swept from the safety injection lines. Should a partial loss of offsite power occur such that the power is lost to the ESF functions while the reactor coolant pumps remain in operation, an additional safety injection delay of 10 seconds would occur while the diesel generators startup and the necessary safety injection equipment is loaded onto them. This additional 10 second delay is included in the limiting analyzed case (with offsite power available). A peak core power well below the nominal full power value is attained.

The calculation assumes the boric acid is mixed with, and diluted by the water flowing in the RCS prior to entering the reactor core. The concentration after mixing depends upon the relative flow rates in the RCS and in the high head injection system. The variation of mass flow rate in the RCS due to water density changes is included in the calculation as is the variation of flow rate from the high head injection system and the accumulator due to changes in the RCS pressure. The high head injection system flow calculation includes the line losses in the system as well as the pump head curve. The accumulators provide an additional source of borated water after the RCS pressure has decreased to below 600 psia.

Should the core be critical at near zero power when the rupture occurs low steam line pressure will trip the reactor. Automatic trip of the isolation valves in the steam lines by low steam line pressure or the high steam flow signal in coincidence with low-low RCS temperature will prevent continued steam release from more than one steam generator. The steam line isolation valves are designed to be fully closed in less than 7 seconds after receipt of closure signal. The analysis assumes a 10 second closing time for conservatism.

Figure 15.4-78 and Figure 15.4-79 show the responses of the salient parameters for the case with a total loss of offsite power at the time of the rupture. This results in a coastdown of the reactor coolant pumps. In this case, the core power increases at a slower rate and reaches a lower peak value than in the cases in which offsite power is available to the reactor coolant pumps. The ability of the emptying steam generator to extract heat from the RCS is reduced by the decreased flow in the RCS.

It should be noted that following a steam line break only one steam generator blows down completely while the intact steam generators only blow down for a short time. Thus, the intact steam generators are still available for dissipation of decay heat after the initial transient is over. In the case of loss of offsite power this heat is removed to the atmosphere via the steam line safety valves.

15.4.2.1.3 Conclusions

A DNB analysis was performed for both these cases. It was found that the DNB design basis (Reference 39) is met.

15.4.2.1.4 Environmental Consequences of a Postulated Steam Line Break

The postulated accidents involving release of steam from the secondary system will not result in a release of radioactivity unless there is leakage from the RCS to the secondary system in the steam generators. A realistic and a conservative analysis based upon Regulatory Guide 1.183 of the potential offsite and control room doses resulting from a steam line break outside containment is presented below. The analyses incorporate defective fuel and steam generator leakage assumptions prior to the postulated accident for a time sufficient to establish equilibrium specific activity levels in the secondary system. In addition, the conservative analysis includes considerations of iodine spiking effects, both pre-existing and concurrent iodine spike occurrences. Parameters used in both the realistic and conservative analyses are listed in Table 15.4-23.

The RADTRAD (Reference 64) computer code was used to calculate the offsite and control room doses for the main steam line break (MSLB). A schematic showing the code modeling of the activity flow paths is shown on Figure 15.4-143.

For the conservative analysis, the primary and secondary coolant activity equilibrium concentrations, prior to the accident, are based upon 1% fuel defects with iodine activity scaled to technical specification limits for dose equivalent (DE) I 131. In addition, 2 iodine spike scenarios are addressed as follows:

a. Pre-accident Iodine Spike

A reactor transient has occurred prior to the postulated MSLB and has raised the primary coolant iodine concentration to 60 μCi/gm DE I 131. Based upon the assumed 1 gpm primary to secondary leakage, the secondary system coolant specific activity, during this iodine spike, is assumed to increase to an equilibrium value based on the 60 μCi/gm DE I 131. The RCS and secondary system coolant specific activities are provided in Table 15.4-24a.

b. Concurrent Iodine Spike

A reactor trip and/or primary system depressurization associated with the MSLB creates an iodine spike in the primary system. The increase in the reactor coolant iodine concentration is estimated using a spiking model which assumes that the iodine release rate from the fuel rods to the coolant increases to a value 500 times greater than the release rate corresponding to the iodine concentration at the equilibrium value associated with reactor coolant activities at 1 μCi/gm dose equivalent I-131.

The iodine release rate during the concurrent spike is based on a maximum letdown flow of 143 gpm which includes the maximum normal letdown of 120 gpm plus 12 gpm to account for uncertainty in flow and 11 gpm primary coolant leakage and is shown in Table 15.4-24b. The secondary system coolant specific activity is assumed to be at an equilibrium value based on 0.1 μCi/gm DE I-131.

The RCS and secondary system coolant specific activities are provided in Table 15.4-24c.

The following additional assumptions and parameters are used to calculate the activity releases and offsite doses for a steam line break:

1. The faulted steam generator was assumed to be isolated from AFW 30 minutes after the accident.
2. The primary-to-secondary leak rate in the steam generators is assumed to be the leak-rate-limiting condition for operation specified in the plant requirements of 1 gpm for all three steam generators. The leakage is apportioned between the steam generators in such a manner that the calculated dose is maximized. Prior to the accident this leakage is assumed to be distributed throughout the three steam generators. To be consistent with preferred plant procedures for shutdown, the shutdown cooling rate following this type of event is taken as 25 °F /hr. Therefore, to go from 557 °F to 212 °F would require about 14 hours. The MSLB is conservatively analyzed using 24 hours for the cooldown time. The activity associated with the 1 gpm leak is assumed to be released to the environment via the faulted steam generator at a rate of 0.35 gpm for the 24 hour duration with no credit taken for any reduction or mitigation, i.e. a partition factor of 1.0. The remaining 0.65 gpm is assumed to be released to the environment via the two intact steam generators for the 24 hour duration crediting a partition factor of 100 in accordance with Regulatory Guide 1.183, Appendix E. In addition, the secondary coolant activity initially contained in the faulted steam generator is released to the environment with a partition factor of 1.0.
3. Offsite power is lost and the main condenser is not available.
4. As a result of the accident, no fuel failures occur.
5. Steam and reactor coolant releases for the faulted and the intact steam generators are given in Table Table 15.4-23. Implementation of PAD5 does not impact the steam releases for the MSLB dose analysis because the steam releases for the dose analysis are based on a generic core stored energy value that is more conservative than the V. C. Summer specific core stored energy (3.45 fps). Therefore, the steam releases for MSLB dose analysis remain valid for use as input to the subsequent dose consequence analyses.
6. No steam generator blowdown during the accident.
7. No noble gas is dissolved in the steam generator secondary system water. Before the MSLB, all noble gases are assumed to be released via the condenser air removal system. After the MSLB occurs, all noble gases are assumed to be released to the environment without mitigation.

The RADTRAD (Reference 64) computer code was used to calculate the control room doses for the main steam line break (MSLB). The following assumptions and parameters are used to calculate the control room doses for the MSLB.

1. The atmospheric diffusion parameters for the control room are provided in Table 2.3-123. The limiting control room source-receptor pair for the MSLB is the Main Steam Safety Relief Valve “A” (Reliefs B, C, D, E), Control Room Intake B.
2. The control room emergency filtration system is credited after 30 minutes.

3. The control room ventilation system flow rates are shown on Figure 15.4-143.
4. The control room breathing rate is assumed as 3.5E-04 m^3/sec for the duration of the accident.
5. Additional control room parameters are shown on Table 15.4-17.

Isotopic releases to the environment using these assumptions are summarized by Table 15.4-25 and Table 15.4-26.

The resultant doses calculated at the site boundary, low population zone and control room for the steam line break accident, based upon the realistic and conservative analysis assumptions are given in Table 15.4-27. The doses resulting from this accident are within the limits defined by 10 CFR 50.67 and RG 1.183.

15.4.2.2 Major Rupture of a Main Feedwater Line

15.4.2.2.1 Identification of Causes and Accident Description

A major feedwater line rupture is defined as a break in a feedwater line large enough to prevent the addition of sufficient feedwater to the steam generators to maintain shell side fluid inventory in the steam generators. If the break is postulated in a feedline between the check valve and the steam generator, fluid from the steam generator may also be discharged through the break. (A break upstream of the feedline check valve would affect the NSSS only as a loss of feedwater. This case is covered by the evaluation in Section 15.2.8.)

Depending upon the size of the break and the plant operating conditions at the time of the break, the break could cause either a reactor coolant system cooldown (by excessive energy discharge through the break), or a RCS heatup. Potential reactor coolant system cooldown resulting from a secondary pipe rupture is evaluated in Section 15.4.2.1. Therefore, only the RCS heatup effects are evaluated for a feedline rupture.

A feedline rupture reduces the ability to remove heat generated by the core from the RCS because of the following reasons:

1. Feedwater to the steam generators is reduced. Since feedwater is subcooled, its loss may cause reactor coolant temperatures to increase prior to reactor trip;
2. Liquid in the steam generator may be discharged through the break, and would then not be available for decay heat removal after trip;
3. The break may be large enough to prevent the addition of any main feedwater after trip.

An Emergency Feedwater System is provided to assure that adequate feedwater will be available such that:

1. No substantial overpressurization of the RCS shall occur; and
2. Liquid in the RCS shall be sufficient to cover the reactor core at all times.

The following provides the necessary protection for a main feedwater rupture:

1. A reactor trip on any of the following conditions:
   a. High pressurizer pressure.
   b. Overtemperature Delta T.
   c. Low low steam generator water level in any steam generator.
   d. Low steam generator level plus steam/feed flow mismatch in any steam generator.
   e. Safety injection signals from any of the following:
      (1) Low steam line pressure.
      (2) High containment pressure (Hi-1).
      (3) High steam line differential pressure.

(Refer to Chapter 7 for a description of the actuation system)

2. An emergency feedwater system to provide an assured source of feedwater to the steam generators for decay heat removal. (Refer to Section 10.4.9 for a description of the emergency feedwater system.)

15.4.2.2.2 Analysis of Effects and Consequences

15.4.2.2.2.1 Method of Analysis

A detailed analysis using the LOFTRAN (Reference 25) Code is performed in order to determine the plant transient following a feedline rupture. The code describes the plant thermal kinetics, reactor coolant system including natural circulation, pressurizer, steam generators and feedwater system, and computes pertinent variables including the pressurizer pressure, pressurizer water level, and reactor coolant average temperature.

Major assumptions are:

1. The plant is initially operating at 102% of the nominal NSSS design rating.
2. Initial reactor coolant average temperature is 4.0°F above the nominal value, and the initial pressurizer pressure is 50 psi below its nominal value.
3. A conservatively high initial pressurizer level is assumed; initial steam generator water level is at the nominal value plus 5% in the faulted steam generator, and at the nominal value minus 5% in the intact steam generators.
4. No credit is taken for the pressurizer spray.
5. Cases with and without pressurizer power operated relief valves are analyzed.
6. No credit is taken for the high pressurizer pressure reactor trip.

7. Main feedwater to all steam generators is assumed to stop at the time the break occurs. (All main feedwater spills out through the break.)
8. The worst possible break area is assumed which minimizes the steam generator fluid inventory at the time of trip and maximizes the blowdown discharge rate following the time of trip, and thereby maximizes the resultant heatup of the reactor coolant.
9. Detailed iterative calculations were performed to determine the break flow and enthalpy based on transient conditions utilizing a multi-nodal transient steam generator model.
10. Reactor trip is assumed to be initiated when the low-low level trip setpoint in the ruptured steam generator is reached. A low-low level setpoint of 0% narrow range span is assumed.
11. The emergency feedwater system (EF) is actuated by the low-low steam generator water level signal and is assumed to supply 120°F EF at total of 380 gpm to the unaffected SGs within 114 seconds of the main feedwater line rupture. The assumed time delay includes the following allowances: 60 seconds to account for instrumentation delays and startup of the diesels and EF pumps, 48 seconds to automatically isolate EF flow to the faulted SG and 6 seconds to purge 5 cubic feet of hot water contained in the EF lines prior to the event. Note that after the installation of cavitating venturis per ECR50695E, automatic isolation of the faulted SG will not occur following secondary side breaks and is no longer necessary to ensure at least 380 gpm is delivered to the intact SGs following this event. The intact SGs could receive 120°F emergency feedwater beginning at 66 seconds after the event; however, the analysis conservatively continues to assume the original additional delay of 48 seconds for EF isolation. Although a substantial amount of EF will be added to the intact SGs during the 48 seconds, no credit is taken for the additional EF flow during this delay.
12. No credit is taken for heat energy deposited in RCS metal during the RCS heatup.
13. Steam generator heat transfer area is assumed to decrease as the shell side liquid inventory decreases.
14. Conservative core residual heat generation based on long term operation at the initial power level preceding the trip is assumed. The 1979 ANS 5.1 (Reference 28) decay heat standard plus uncertainty was used for calculation of residual decay heat levels.
15. No credit is taken for charging or letdown.
16. A flow imbalance of 5% between loop (faulted vs. intact) was assumed to incorporate the effects of loop-to-loop RCS flow asymmetry for the limiting cases (with PORVs only).
17. The maximum steam generator tube plugging level (10%) is assumed for the faulted loop, and the minimum steam generator tube plugging level (0%) is assumed for the intact loops.
18. A conservatively large feedwater isolation delay time was assumed.

15.4.2.2.2.2 Results

Results for two feedline break cases are presented. Results for a case in which offsite power is assumed to be available are presented in Section 15.4.2.2.2.1. Results for a case in which offsite power is assumed to be lost following reactor trip are presented in Section 15.4.2.2.2.2.2. The calculated sequence of events for both cases is listed in Table 15.4-19. Both of the presented

feedline break cases credit the power operated relief valves, because these cases were found to be the most limiting.

15.4.2.2.2.2.1 Feedline Rupture with Offsite Power Available

The system response following a feedwater line rupture, assuming offsite power is available, is presented in Figure 15.4-83 through Figure 15.4-86. Results presented in Figure 15.4-84 and Figure 15.4-86 show that pressures in the RCS and Main Steam System remain below 110% of the respective design pressures. Pressurizer pressure decreases after reactor trip on low-low steam generator water level due to the reduction of heat input. Following this initial decrease, pressurizer pressure increases to the pressurizer power operated relief valve setpoint. This increase in pressure is the result of coolant expansion caused by the reduction in heat transfer capability in the steam generators. Figure 15.4-87 shows that the water volume in the pressurizer increases in response to the heatup and pressurizer water relief begins at 2134 seconds. At approximately 3300 seconds, decay heat generation decreases to a level such that the total RCS heat generation (decay heat plus pump heat) is less than emergency feedwater heat removal capability, and RCS pressure and temperature begin to decrease.

The results show that the core remains covered at all times and that no boiling occurs in the reactor coolant loops.

15.4.2.2.2.2.2 Feedline Rupture with Offsite Power Unavailable

The system response following a feedwater line rupture without offsite power available is similar to the case with offsite power available and is presented in Figure 15.4-87 through Figure 15.4-90. However, as a result of the loss of offsite power (assumed to occur at reactor trip), the reactor coolant pumps coast down. This results in a reduction in total RCS heat generation by the amount produced by pump operation.

The reduction in total RCS heat generation produces a milder transient than in the case where offsite power is available. Results presented in Figures Figure 15.4-88 and 1Figure 15.4-90 show that pressure in the RCS and main steam system remain below 110% of the respective design pressures. Pressurizer pressure decreases after reactor trip on low-low steam generator water level due to the reduction of heat input. Following this initial decrease, pressurizer pressure increases as a result of coolant expansion caused by the reduction in heat transfer capability in the steam generators. Figure 15.4-88 shows that the water volume in the pressurizer increases in response to the heatup. At approximately 800 seconds, decay heat generation decreases to less than the emergency feedwater heat removal capability, and RCS temperatures begin to decrease. The results show that the core remains covered at all times since the pressurizer does not empty.

15.4.2.2.3 Conclusions

Results of the analysis show that for the postulated feedline rupture, the assumed Emergency Feedwater System capacity is adequate to remove decay heat, to prevent overpressurizing the RCS, and to prevent uncovering the reactor core. Radioactivity doses from the postulated feedline rupture are less than those previously presented for the postulated steam line break.

15.4.3 Steam Generator Tube Rupture

15.4.3.1 Identification of Causes and Accident Description

The accident examined is the complete severance of a single steam generator tube. The accident is assumed to take place at power with the reactor coolant contaminated with fission products corresponding to continuous operation with a limited amount of defective fuel rods. The accident leads to an increase in contamination of the secondary system due to leakage of radioactive coolant from the reactor coolant system. In the event of a coincident loss of offsite power, or failure of the condenser steam dump system, discharge of activity to the atmosphere takes place via the steam generator safety and/or power operated relief valves.

In view of the fact that the steam generator tube material is Inconel 690 and is a highly ductile material, it is considered that the assumption of a complete severance is conservative. The more probable mode of tube failure would be one or more minor leaks of undetermined origin. Activity in the steam and power conversion system is subject to continual surveillance and an accumulation of minor leaks which exceed the limits established in the Technical Specifications is not permitted during the unit operation.

The operator is expected to determine that a steam generator tube rupture has occurred, and to identify and isolate the ruptured steam generator on a restricted time scale in order to minimize contamination of the secondary system and ensure termination of radioactive release to the atmosphere from the ruptured unit. The recovery procedure can be carried out on a time scale which ensures that break flow to the secondary system is terminated before water level in the affected steam generator rises into the main steam pipe.

Sufficient indications and controls are provided to enable the operator to carry out these functions satisfactorily.

Assuming normal operation of the various plant control systems, the following sequence of events is initiated by a tube rupture:

1. Pressurizer low pressure and low level alarms are actuated and charging pump flow increases in an attempt to maintain pressurizer level. On the secondary side there is a steam flow/feedwater flow mismatch before trip as feedwater flow to the affected steam generator is reduced due to the additional break flow which is now being supplied to that unit. The steam line radiation monitor for the ruptured steam generator will alarm.
2. Continued loss of reactor coolant inventory leads to a reactor trip signal generated by low pressurizer pressure or Overtemperature Delta-T. Resultant plant cooldown following reactor trip leads to a rapid change of pressurizer level, and the safety injection signal, initiated by low pressurizer pressure, follows soon after the reactor trip. The safety injection signal automatically terminates normal feedwater supply and initiates emergency feedwater addition.
3. The steam generator blowdown liquid radiation monitor and the condenser air removal system radiation monitor will alarm, indicating a sharp increase in radioactivity in the

secondary system and will automatically divert the steam generator blowdown flow to the Nuclear Blowdown Processing System.

4. The reactor trip automatically trips the turbine and if offsite power is available the steam dump valves open permitting steam dump to the condenser. In the event of a coincident loss of offsite power, the condenser steam dump valves would automatically close to protect the condenser. The steam generator pressure would rapidly increase resulting in steam discharge to the atmosphere through the main steam safety and/or power operated relief valves.
5. Following reactor trip, the continued action of emergency feedwater supply and borated high head injection flow (supplied from the refueling water storage tank) provide a heat sink which absorbs some of the decay heat. Thus, steam bypass to the condenser, or in the case of loss of offsite power, steam relief to atmosphere, is attenuated while the recovery procedure leading to break flow termination is being carried out.
6. High head injection flow results in increasing pressurizer water level. The time after trip at which the operator can clearly see returning level in the pressurizer is dependent upon the amount of operating auxiliary equipment.

15.4.3.2 Analysis of Effects and Consequences

15.4.3.2.1 Method of Analysis

In estimating the mass transfer from the RCS through the broken tube the following assumptions are made:

1. Reactor trip occurs automatically as a result of low pressurizer pressure.
2. Following the initiation of the safety injection signal, 2 centrifugal charging pumps are actuated and continue to deliver flow for 30 minutes.
3. After reactor trip, the break flow reaches equilibrium at the point where incoming safety injection flow is balanced by outgoing break flow as shown in Figure 15.4-91. The resultant break flow persists from plant trip until 30 minutes after the accident.
4. The steam generators are controlled at the safety valve setting rather than the power operated relief valve or steam dump setting.
5. The operator identifies the accident type and terminates break flow to the ruptured steam generator within 30 minutes of accident initiation.
6. Steam relief from the ruptured steam generator ceases at 30 minutes after accident initiation.
7. Steam relief from the intact steam generators continues until the Residual Heat Removal System is put into service for decay heat removal.

Mass and energy balance calculations are performed to determine primary to secondary mass release and to determine the amount of steam vented from each of the steam generators.

Although it is recognized that the operators may not be able to identify the accident and terminate break flow within 30 minutes for all postulated steam generator tube rupture events, these

licensing basis assumptions provide a conservative estimate of the mass releases. This has been confirmed by utilizing an NRC-approved thermal hydraulic code and analysis method (Reference 66) which simulates the plant response, and models specific operator actions based on those outlined in Section 15.4.3.2.2. Consistent with the original and current licensing basis analysis, single failures were not considered in this confirmatory analysis. Overall, the analysis demonstrates that even if break flow is not terminated until almost one hour after accident initiation, the radiological consequences for a postulated steam generator tube rupture are bounded by those presented in Section 15.4.3.4 for the licensing basis analysis.

15.4.3.2.2 Recovery Procedure

Immediately apparent symptoms of a tube rupture accident such as falling pressurizer pressure and level and increased charging pump flow are also symptoms of small steam line breaks and loss of coolant accidents. It is therefore important for the operator to determine that the accident is a rupture of a steam generator tube in order that he may carry out the correct recovery procedure. The accident under discussion can be identified by the following method. In the event of a complete tube rupture, it will be clear soon after trip that the level in one steam generator is rising more rapidly than in the others. This is a unique indication of a tube rupture accident. Also this accident could be identified by either a condenser air removal system radiation alarm, or main steamline radiation alarm, or a steam generator blowdown radiation alarm.

The operator carries out procedures subsequent to reactor trip which lead to isolation of the ruptured steam generator and to unit cooldown. These actions are based on the Pressurized Water Reactor Owner's Group Emergency Response Guidelines (ERGs) for Westinghouse plants.

With Offsite Power Available:

1. Identify the ruptured steam generator by one or more of the following means: increasing steam generator water level, high radiation from any steam generator sample, high radiation from any steam generator steam line, and/or high radiation from any steam generator blowdown line.
2. Close the main steam isolation valve and isolate all other steam paths from the ruptured steam generator.
3. Minimize emergency feedwater flow to the ruptured steam generator to control secondary water level.
4. Dump steam to the condenser from the intact steam generator at a maximum rate to establish subcooling margin for subsequent RCS depressurization. The amount of RCS cooldown is determined by the ruptured steam generator pressure.
5. Decrease RCS pressure by use of normal pressurizer spray until the water level returns in the pressurizer and RCS pressure and the ruptured steam generator pressure are equal, or high pressurizer water level is attained, or minimum subcooling is attained.
6. Based on the pressurizer water level, secondary heat sink(s), RCS subcooling and increasing RCS pressure, stop all but one charging pump to minimize break flow to the secondary

system. At this point, RCS pressure and the ruptured steam generator pressure should be maintained approximately equal.

7. Continue dumping steam to the condenser from the intact steam generators and simultaneously decrease RCS pressure by use of normal pressurizer spray. Decrease pressure in the ruptured steam generator by backfill, blowdown or steam release.
8. Initiate operation of residual heat removal system at the appropriate RCS conditions.

Without Offsite Power:

1. Identify the ruptured steam generator by one or more of the following means: increasing steam generator water level, high radiation from any steam generator blowdown line, and/or high radiation from any steam generator steam line.
2. Close the main steam isolation valve and isolate all other steam paths from the ruptured steam generator.
3. Minimize emergency feedwater flow to the ruptured steam generator to control secondary water level.
4. Dump steam through the intact steam generator power relief valves at a maximum rate to establish RCS subcooling margin for subsequent RCS depressurization. The amount of RCS cooldown is determined by the ruptured steam generator pressure.
5. Open pressurizer relief valve to reduce RCS pressure until water level returns in the pressurizer and RCS pressure and the ruptured steam generator pressure are equal, or high pressurizer water level is attained, or minimum subcooling is attained.
6. Based on the pressurizer water level, secondary heat sink(s), RCS subcooling, and increasing RCS pressure, stop all but one charging pump to minimize break flow to the secondary system. At this point, RCS pressure and the ruptured steam generator pressure should be maintained approximately equal.
7. Continue dumping steam through the intact steam generator power relief valves and simultaneously decrease RCS pressure. Decrease pressure in the ruptured steam generator by backfill, blowdown or steam release.
8. Initiate operation of Residual Heat Removal System at the appropriate RCS conditions.

After the residual heat removal system is placed in operation, the condensate accumulated in the secondary system can be examined and processed as required. Table 15.4-28 presents the balance of plant equipment required for the steam generator tube rupture accident.

There is ample time available to carry out the above recovery procedures such that isolation of the affected steam generator is established before water level rises into the main steam pipes.

This has been confirmed by utilizing an NRC-approved thermal hydraulic analysis code and analysis method (Reference 66) which simulated the plant response, and models specific operator actions based on those outlined above. Critical operator actions modeled in the simulation to terminate break flow and preclude steam generator overfill include:

1. Terminating emergency feedwater flow to the ruptured steam generator.
2. Isolating the ruptured steam generator.
3. Dumping steam from the intact steam generators to cooldown the reactor coolant system.
4. Opening a pressurizer relief valve to depressurize the reactor coolant system.
5. Terminating safety injection flow.

Consistent with the original and current licensing basis analysis, single failures were not considered in this confirmatory analysis. Conservative deviations from the Reference 66 method were taken to address the issues raised by NSAL-07 -11 (Reference 67). Overall, the analysis demonstrates that break flow is terminated approximately 50 minutes after initiation of the tube rupture and that overfill of the ruptured steam generator does not occur.

15.4.3.2.3 Results

Figure 15.4-91 illustrates the flow rate that would result through the ruptured steam generator tube. For conservatism, the equilibrium break flow rate is based on the maximum safety injection flow rate with three charging pumps operating. The previous assumptions lead to a conservative estimate of 92,900 pounds for the total amount of reactor coolant transferred to the secondary side of the ruptured steam generator as a result of a tube rupture accident.

15.4.3.3 Conclusions

A steam generator tube rupture will cause no subsequent damage to the reactor coolant system or the reactor core. An orderly recovery from the accident can be completed even assuming simultaneous loss of offsite power. Parameters used in determining the radioactivity released to the atmosphere for a steam generator tube rupture are listed in Table 15.4-29.

15.4.3.4 Environmental Consequences of a Postulated Steam Generator Tube Rupture

The postulated accidents involving release of steam from the secondary system will not result in a release of radioactivity unless there is leakage from the RCS to the secondary system in the steam generators. An analysis based on Regulatory Guide 1.183 of the potential offsite and control room doses from a postulated Steam Generator Tube Rupture (SGTR) is presented below. The analysis incorporates assumptions for defective fuel and steam generator leakage prior to the postulated accident for a time sufficient to establish equilibrium specific activity levels in the secondary system. In addition, the conservative analysis includes the consideration of iodine spiking effects caused by the SGTR. Both pre-existing and concurrent iodine spikes are evaluated coincident with the postulated tube rupture. Parameters used are listed in Table 15.4-29.

In the safety analysis to evaluate the radiological consequences of a steam generator tube rupture, calculations are performed to determine the primary to secondary mass transfer and steam releases from the ruptured and intact steam generators. The RCS depressurization rate due to the primary to secondary break flow is calculated to determine the time of reactor trip and actuation of the safety injection system. The average break flow rate during the time period from the tube

rupture initiation to reactor trip and safety injection was used to calculate the integrated break flow for this period. After reactor trip and safety injection, it was assumed that the RCS stabilizes at a pressure where the incoming safety injection flow equals the flow out the broken tube, with the assumption of maximum safeguards and no spillage (which gives the highest primary to secondary flow). The resultant break flow rate is assumed to persist from reactor trip and safety injection actuation until 30 minutes after the accident. The integrated break flow values for these two time periods were then summed to yield a total primary to secondary break flow of 92,900 lb for the 30 minutes.

The steam released to the atmosphere from the ruptured and intact steam generators is calculated for 30 minutes following the event by a mass and energy balance between the primary and secondary system. It is assumed that the ruptured steam generator is isolated after 30 minutes.

For the remainder of the transient, after ruptured steam generator isolation, steam releases from the intact steam generators are obtained by an energy balance between the primary and secondary systems. The energy in the primary system is calculated, including energy of the fluid, decay heat, and metal energy. This is equated with the amount of secondary steam which must be generated and released in order to remove this energy from the primary system and decrease the primary system pressure to the desired levels.

In summary, then, although a detailed analysis is not performed, the current analysis is a conservative estimate of the radiological consequences of the steam generator tube rupture as noted in Section 15.4.3.2.1.

The RADTRAD (Reference 64)computer code was used to calculate the offsite and control room doses for the steam generator tube rupture (SGTR). A schematic showing the code modeling of the activity flow paths is shown on Figure 15.4-144.

The following additional assumptions and parameters are used to calculate the activity releases and offsite doses for the postulated steam generator tube rupture.

1. It is assumed that prior to the accident an equilibrium fission product activity exists in the primary and secondary systems due to primary to secondary leakage in the steam generators. In the conservative analyses, the activity concentrations are assumed in combination with a pre accident iodine spike as well as an accident initiated iodine spike.
2. Offsite power is not available in the analysis.
3. The reactor coolant released to the defective steam generator and associated steam releases are given in Table 15.4-29.
4. No additional fuel failure as a result of the accident.
5. No steam generator blowdown during the accident.
6. Thirty minutes after the accident, the pressure between the ruptured steam generator and primary system is equalized. The ruptured steam generator is isolated. No steam and fission product activities are released from the defective steam generator after this time.

7. The primary to secondary leak rate in the intact steam generators is conservatively assumed to be 1 gpm. The iodine and particulate activity associated with the 1 gpm leak is assumed to mix with the bulk water. The radioactivity within the bulk water is assumed to become vapor at a rate that is a function of the steaming rate and the partition coefficient. A partition coefficient of 100 is assumed. All noble gas activity in the leakage is assumed to be immediately released to the environment.
8. To be consistent with preferred plant procedures for shutdown, the shutdown cooling rate is taken as 25°F/hr. Although conditions for start-up of the Residual Heat Removal system can be achieved in approximately 8 hours, the analysis conservatively accounts for cooldown times up to 24 hours.
9. The normal operation letdown is 60 to 120 gpm.
10. RCS mass is assumed to remain constant throughout the SGTR event; i.e., flow through the ruptured tube is offset by flow from the safety injection system.
11. Except for the iodine isotopes, the initial RCS activity is based on operation with defects in fuel producing 1% of the plant power.
12. The analysis for the pre-existing iodine spike assumes a reactor transient has occurred prior to the postulated steam generator tube rupture and raised the primary coolant iodine concentration to the maximum value permitted by the technical specifications (60 μCi/gm DE I-131). No dilution from the safety injection system is considered.
13. The analysis for the accident initiated iodine spike assumes the iodine release rate from the fuel rods to the primary coolant increases to a value 335 times greater than the release corresponding to the iodine concentration at the equilibrium value (1.0 μCi/gm DE I-131) specified in the technical specifications with a spike duration of 8 hours.

Key assumptions and parameters used to calculate control room and offsite doses with the RADTRAD (Reference 64) computer code are summarized in Table 15.4-12 and Table 15.4-29. The offsite and control room doses resulting from the postulated steam generator tube rupture accident based upon the specified analysis assumptions are summarized in Table 15.4-33. The doses from this accident are within the limits defined in 10 CFR 50.67 and Regulatory Guide 1.183: 5 Rem TEDE for the control room; 25 REM TEDE for the site boundary and LPZ with a pre-existing iodine spike; and 2.5 Rem TEDE for the site boundary and low population with a concurrent iodine spike.

15.4.4 Single Reactor Coolant Pump Locked Rotor

15.4.4.1 Identification of Causes and Accident Description

The accident postulated is an instantaneous seizure of a reactor coolant pump rotor such as is discussed in Section 5.5. Flow through the affected reactor coolant loop is rapidly reduced, leading to an initiation of a reactor trip on a low flow signal.

Following initiation of the reactor trip heat stored in the fuel rods continues to be transferred to the coolant causing the coolant to expand. At the same time, heat transfer to the shell side of the

steam generators is reduced, first because the reduced flow results in a decreased tube side film coefficient and then because the reactor coolant in the tubes cools down while the shell side temperature increases (turbine steam flow is reduced to zero upon plant trip). The rapid expansion of the coolant in the reactor core, combined with reduced heat transfer in the steam generators causes an insurge into the pressurizer and a pressure increase throughout the RCS. The insurge into the pressurizer compresses the steam volume, actuates the automatic spray system, opens the power operated relief valves, and opens the pressurizer safety valves, in that sequence.

The three power operated relief valves are designed for reliable operation and would be expected to function properly during the accident. However, for conservatism, their pressure reducing effect as well as the pressure reducing effect of the spray is not included in the analysis.

15.4.4.2 Analysis of Effects and Consequences

15.4.4.2.1 Method of Analysis

Two digital computer codes are used to analyze this transient. The LOFTRAN Code is used to calculate the resulting loop and core coolant flow following the pump seizure. The LOFTRAN Code is also used to calculate the time of reactor trip, based on the calculated flow, the nuclear power following reactor trip, and to determine the peak pressure. The thermal behavior of the fuel located at the core hot spot is investigated using the FACTRAN (Reference 29) Code, using the core flow and the nuclear power calculated by LOFTRAN. The FACTRAN Code includes the use of a film boiling heat transfer coefficient.

The following case is analyzed:

All loops operating, one locked rotor.

At the beginning of the postulated locked rotor accident, i.e., at the time the shaft in one of the reactor coolant pumps is assumed to seize, the plant is assumed to be in operation under the most adverse steady state operating conditions, i.e., maximum steady state power level, maximum steady state pressure, and maximum steady state coolant average temperature.

When the peak pressure is evaluated, the initial pressure is conservatively estimated as 50 psi above nominal pressure of 2250 psia to allow for errors in the pressurizer pressure measurement and control channels. This is done to obtain the highest possible rise in the coolant pressure during the transient. To obtain the maximum pressure in the primary side, conservatively high loop pressure drops are added to the calculated pressurizer pressure. A flow imbalance of 5% between loops (faulted vs. intact) was assumed to incorporate the effects of loop-to-loop RCS flow asymmetry.

15.4.4.2.2 Evaluation of the Pressure Transient

After pump seizure and reactor trip, the neutron flux is rapidly reduced by control rod insertion effect. Rod motion is assumed to begin one second after the flow in the affected loop reaches 87%

of nominal flow. No credit is taken for the pressure reducing effect of the pressurizer relief valves, pressurizer spray, steam dump or controlled feedwater flow after plant trip.

Although these operations are expected to occur and would result in a lower peak pressure, an additional degree of conservatism is provided by ignoring their effect.

The pressurizer safety valves are assumed to achieve rated flow at 2580 psia. No relief is credited prior to reaching this pressure. This conservatively accounts for uncertainties in the nominal setpoint of 2500 psia.

15.4.4.2.3 Evaluation of DNB in the Core During the Accident

For this accident, DNB is assumed to occur in the core and, therefore, an evaluation of the consequences with respect to fuel rod thermal transients is performed. Results obtained from analysis of this “hot spot” condition represent the upper limit with respect to clad temperature and zirconium water reaction.

In the evaluation, the rod power at the hot spot is conservatively assumed to be approximately 2.6 times the average rod power at the initial core power level.

15.4.4.2.4 Film Boiling Coefficient

The film boiling coefficient is calculated in the FACTRAN Code using the Bishop Sandberg Tong film boiling correlation. The fluid properties are evaluated at film temperature (average between wall and bulk temperatures). The program calculates the film coefficient at every time step based upon the actual heat transfer conditions at the time. The neutron flux, system pressure, bulk density, and mass flow rate as a function of time are used as program input.

For this analysis, the initial values of the pressure and the bulk density are used throughout the transient since they are the most conservative with respect to clad temperature response. For conservatism, DNB was assumed to start at the beginning of the accident.

15.4.4.2.5 Fuel Clad Gap Coefficient

The magnitude and time dependence of the heat transfer coefficient between fuel and clad (gap coefficient) has a pronounced influence on the thermal results. The larger the value of the gap coefficient, the more heat is transferred between pellet and clad. Based on investigations on the effect of the gap coefficient upon the maximum clad temperature during the transient, the gap coefficient was assumed to increase from a steady state value consistent with initial fuel temperature to 10,000 BTU/hr ft^2 °F at the initiation of the transient. Thus the large amount of energy stored in the fuel because of the small initial value is released to the clad at the initiation of the transient to maximize the cladding temperature during the transient.

15.4.4.2.6 Zirconium Steam Reaction

The zirconium steam reaction can become significant above 1800 F (clad temperature). The Baker-Just parabolic rate equation shown below is used to define the rate of the zirconium steam reaction.

$$\frac{d(w^2)}{dt} = 33.3 \times 10^6 \exp\left(-\frac{45{,}500}{1.968T}\right)$$

Where:

w	=	amount reacted, mg/cm^2.
t	=	time, sec.
T	=	temperature, ° Kelvin.

The reaction heat is 1510 cal/gm.

15.4.4.2.7 Results

Transient values of RCS flow, faulted loop flow, nuclear power, core heat flux, RCS pressure, and hot spot clad temperature are shown in Figure 15.4-95, Figure 15.4-96A, and Figure 15.4-96B.

Maximum RCS pressure, maximum clad average temperature, and amount of zirconium water reaction are contained in Table 15.4-34.

15.4.4.3 Conclusions

1. Since the peak RCS pressure reached during any of the transients is less than that which would cause stresses to exceed the faulted condition stress limits, the integrity of the primary coolant system is not endangered.
2. Since the peak clad average temperature calculated for the hot spot during the worst transient remains considerably less than the 2700°F limit for ZIRLO® material and the 2375°F limit for Optimized ZIRLOTM material, the core will remain in place and intact with no consequential loss of core cooling capability.
3. The results of the transient analysis show that less than 15.0% of the fuel rods will have DNBR's below the safety analysis limit values.

If it is assumed that there is leakage from the RCS to the secondary system in the steam generators and that offsite power is lost following the reactor coolant pump locked rotor accident, radioactivity will be released to the atmosphere through the relief or safety valves. Parameters used in determining the amount of radioactivity released are given in Table 15.4-34a.

15.4.4.4 Environment Consequences of a Postulated Reactor Coolant Pump Locked Rotor

The postulated accidents involving release of steam from the secondary system will not result in release of radioactivity unless there is leakage from the RCS to the secondary system in the steam generators. A realistic analysis and a conservative analysis based on Regulatory Guide 1.183 of the potential offsite and control room doses resulting from a reactor coolant pump locked rotor is presented. This analysis incorporates assumptions of defective fuel and steam generator leakage prior to the postulated accident for a time sufficient to establish equilibrium specific activity levels in the secondary system. Parameters used in both the realistic and conservative analyses are listed in Table 15.4-34a.

The RADTRAD (Reference 64) computer code was used to calculate the offsite and control room doses for the reactor coolant pump locked rotor accident (RCPLRA). A schematic showing the code modeling of the activity flow paths is shown on Figure 15.4-145.

The following assumptions and parameters are used to calculate the activity releases and offsite doses for a reactor coolant pump locked rotor:

1. Prior to the accident, an equilibrium activity of fission products exists in the primary and secondary systems due to primary to secondary leakage in the steam generators.
2. Offsite power is lost and the main condenser is not available for steam dump.
3. Twenty four hours after the accident the Residual Heat Removal System starts operation to cool down the plant.
4. After 24 hours following the accident, no steam and activity are released to the environment.
5. Primary to secondary leakage is 1 gpm and is evenly distributed in the steam generators.
6. Defective fuel prior to the accident is 1%.
7. As a result of the accident, 15% of the fuel rods in the core are considered to be failed and their gap activity is considered to be released to, and instantaneously mixed with, the reactor coolant. Per Regulatory Guide 1.183, Table 3, the non-LOCA fraction of fission products inventory in the gap is acceptable for use if the peak fuel burnup does not exceed 62,000 MWD/MTU and the maximum linear heat generation rate does not exceed 6.3 kw/ft. peak rod average power for burnups exceeding 54 GWD/MTU. To account for possible variation in burnup and rod power, the Table 3 non-LOCA fraction of fission products inventory in the gap is conservatively doubled. The Regulatory Guide 1.183, Table 3 gap fractions and the gap fractions used in the RCPLRA analysis are listed as follows:

Group	Regulatory Guide 1.183 Fraction	RCPLRA Analysis Fraction
I-131	0.08	0.16
Kr-85	0.10	0.20

Other Noble Gases	0.05	0.10
Other Halogens	0.05	0.10
Alkali Metals	0.12	0.24

8. No Condenser Air Removal System release and no steam generator blowdown occurs during the accident.
9. No noble gas is dissolved in the steam generator water.
10. The primary-to-secondary leak rate in the steam generators is assumed to be the leak-rate-limiting condition for operation specified in the plant requirements of 1 gpm for all three steam generators. The leakage is apportioned between the steam generators in such a manner that the calculated dose is maximized. To be consistent with preferred plant procedures for shutdown, the shutdown cooling rate following this type of event is taken as 25 °F /hr. Therefore, to go from 557 °F to 212 °F would require about 14 hours. The RCPLRA is conservatively analyzed using 24 hours for the cooldown time. The activity associated with the 1 gpm leak is assumed to be released to the environment via the steam generators for the 24 hour duration with a partition factor of 100 for iodine and particulates and 1.0 for noble gases. In addition, the secondary coolant activity initially contained in the steam generators is released to the environment with a partition factor of 100.

Steam releases to the atmosphere for the reactor pump locked rotor accident are given in Table 15.4-34a. Assumptions for the realistic analysis are also presented in Table 15.4-34a. Isotopic releases to the environment using these assumptions are summarized by Table 15.4-34b through Table 15.4-34c.

In addition, the following assumptions and parameters are used to calculate the control room doses for the RCPLRA:

1. The atmospheric diffusion parameters for the control room are provided in Table 2.3-123. The limiting control room release point for the LRA is the Main Steam Safety Relief Valve “A” (Reliefs B, C, D, E), Control Room Intake B.
2. The control room emergency filtration system is credited after 120 minutes.
3. The control room ventilation system flow rates are shown on Figure 15.4-145.
4. The control room breathing rate is assumed as 3.47E-04 m^3/sec for the duration of the accident.
5. Additional control room parameters are shown on Table 15.4-17.

The offsite and control room doses resulting from the RCPLRA are listed in Table 15.4-34d.

15.4.5 Fuel Handling Accidents

A fuel handling accident (FHA) during refueling could release a fraction of the fission product inventory in the plant to the environment. Two (2) accident scenarios are considered: (1) a

refueling accident occurring inside containment and (2) a refueling accident occurring outside containment.

The RADTRAD (Reference 64) computer code was used to calculate the offsite and control room doses for both of the fuel handling accident (FHA) scenarios. A schematic showing the code modeling of the activity flow paths is shown on Figure 15.4-146.

15.4.5.1 Fuel Handling Accident Inside of Containment

The postulated fuel handling accident inside containment is the dropping of a spent fuel assembly onto the core during refueling which results in damage to the fuel assemblies. For this postulated accident, two analyses bases are evaluated: (1) a realistic case and (2) a conservative case. The conservative case analysis is based on Regulatory Guide 1.183 assumptions. The assumed analysis parameters and radiological consequences associated with these cases are discussed below.

15.4.5.1.1 Identification of Causes and Accident Description

There are numerous administrative controls and physical limitations which are imposed to prevent a fuel handling accident from occurring during refueling operations. Nevertheless, an accident sequence has been postulated with the objective of assessing the potential risk to the public health and safety.

It is postulated that a spent fuel assembly is dropped onto the core during refueling resulting in breaching of the fuel rod cladding. As a result of the damage, a portion of the volatile fission gases are released to the water pool covering the core. Subsequently, a fraction of the water soluble gases are absorbed in the pool with the remainder being transported through the water and into the Reactor Building atmosphere. The escaped gases are assumed to be released instantaneously to the environment via the Reactor Building Purge System and dispersed into the atmosphere.

15.4.5.1.2 Analysis of Effects and Consequences

15.4.5.1.2.1 Method of Analysis

The following assumptions are postulated in the calculation of the radiological consequences of a fuel handling accident inside containment:

Realistic Analyses

1. The accident occurs at 100 hours after reactor shutdown, which is the minimum time after shutdown that refueling operations could commence. Radioactive decay of the fission product inventory for this time period is taken into account.

2. A total of 314 pins are assumed to be damaged as a result of this event. All 264 pins in the dropped spent fuel assembly and 50 pins in the impacted assembly are assumed to be ruptured.
3. The assembly damaged is the highest powered assembly in the core region to be discharged. The values for individual fission product inventories in the damaged assembly are calculated assuming full power operation at the end of core life immediately preceding shutdown.
4. All activity in the clad gap of the damaged fuel, as given in Table 15.4-36, is released to the reactor cavity pool.
5. The minimum water depth between the top of the damaged fuel rods and the reactor cavity pool surface is 23 feet.
6. Noble gases released to the reactor cavity pool are immediately released to the reactor building atmosphere.
7. The pool water retains a large fraction of the iodine species activity by virtue of their solubility and hydrolysis. An iodine/pool decontamination factor of 500 is used for this analysis, and is based upon the results of an experimental test program (Reference 40) conducted to evaluate the extent of the removal of iodines released from a damaged irradiated fuel assembly. The iodine/pool decontamination factor is discussed in Section 15.4.5.1.2.2.

Conservative Analysis

1. The accident occurs at 72 hours after reactor shutdown, which is a conservative minimum time after shutdown. Radioactive decay of the fission product inventory for this time period is taken into account.
2. A total of 314 pins are damaged as a result of this event. This includes all 264 pins in the dropped spent fuel assembly and 50 pins in the impacted fuel assembly. This is equivalent to 1.19 assemblies.
3. The assembly damaged is the highest-powered assembly in the core region to be discharged. The values for individual fission product inventories in the fuel are calculated using ORIGEN-S/ARP program (Reference 54) and the calculation assumes full power operation at the end of core life immediately preceding shutdown. The fission product inventory in the highest-rated assembly for the conservative case is given in Table 15.4-37 and is based on a peaking factor of 1.7. Per Regulatory Guide 1.183, Table 3, the non-LOCA fraction of fission products inventory in the gap is acceptable for use if the peak fuel burnup does not exceed 62,000 MWD/MTU and the maximum linear heat generation rate does not exceed 6.3 kw/ft. peak rod average power for burnups exceeding 54 GWD/MTU. To account for possible variation in burnup and rod power, the Table 3 non-LOCA fraction of fission products inventory in the gap is conservatively doubled. The Regulatory Guide 1.183, Table 3 gap fractions and the gap fractions used in the FHA analyses are listed as follows:

Group	Regulatory Guide 1.183 Fraction	FHA Analysis Fraction
I-131	0.08	0.16
Kr-85	0.10	0.20
Other Noble Gases	0.05	0.10
Other Halogens	0.05	0.10
Alkali Metals	0.12	0.24

4. All activity in the clad gap of the damaged fuel is released to the reactor cavity pool.
5. Noble gases released to the reactor cavity pool are immediately released to the reactor building atmosphere.
6. Per Regulatory Guide 1.183, Appendix B.1.3, the chemical form of radioiodine released from the fuel is 95% aerosol (Csl), 4.85% elemental and 0.15% organic. Due to the low pH of the water, Csl instantaneously disassociates and the iodine re-evolves as elemental, resulting in 99.85% elemental (4.85% + 95%) and 0.15% organic iodine within the water. The minimum fuel depth over the reactor core when handling fuel and over the spent fuel in the FHB is 23 feet. Therefore, consistent with Regulatory Guide 1.183, Appendix B.2, the overall effective iodine decontamination factor is 200, for the reactor core pool, with a resulting chemical species released from the water of 57% elemental and 43% organic iodine.

15.4.5.1.2.2 Iodine Decontamination Factors

An experimental test program (Reference 40) was performed to evaluate the extent of removal of iodine released from a damaged irradiated fuel assembly. Iodine removal from the released gas takes place as the gas rises through the body of solution in the fuel storage area to the pool surface. The extent of iodine removal is determined by mass transfer from the gas phase to the surrounding liquid and is controlled by the bubble diameter and contact time of the bubble in the solution.

In order to obtain all the necessary information regarding this mass transfer process, a number of small scale tests were conducted, using trace iodine and carbon dioxide in an inert carrier gas. Iodine testing was performed at the design basis solution conditions (temperature and chemistry) and data were collected for various bubble diameters and solution depths. This work resulted in the formulation of a mathematical expression for iodine decontamination factor in terms of bubble size and bubble rise time.

Similar tests were conducted with carbon dioxide in an inert carrier, except that the solution temperature and chemistry were patterned after that of a deep pool where large scale tests were also performed with carbon dioxide. The small scale carbon dioxide tests also resulted in a

mathematical expression for decontamination factor in terms of bubble size and bubble rise time through the solution.

To complete the experimental program, a full size fuel assembly simulator was fabricated and placed in a deep pool for testing, where gas released would be typical of that from the postulated damaged assembly. Tests were conducted with trace carbon dioxide in an inert carrier gas and overall decontamination factors were measured as a function of the total gas volume released. These measurements, combined with the analytical expression derived from small scale tests with carbon dioxide, permitted an in situ measurement of both the effective bubble diameter and rise time, both as a function of the volume of gas released. Having measured the characteristics of large scale gas releases, the decontamination factor for iodine was obtained, using the analytical expression from small scale iodine testing.

$$\text{Decontamination Factor} = 7.3\ e^{0.313\ t/d}$$

Where:

t = rise time

d = effective bubble diameter

The overall test results clearly indicate that iodine will be readily removed from the gas rising through the spent fuel pool and that the efficiency of removal will depend on the volume of gas released instantaneously from the full void space.

With consideration given to the total quantity of gas released from a fuel assembly, i.e., 6.9 scf for the 17 x 17 array, the pool decontamination factor for iodine is indicated to be a minimum of 760 for the 26 foot depth. Thus, a decontamination factor of 760 constitutes one parameter of the expected case. In the realistic case presented here, a lower decontamination factor is selected to provide for reasonable deviation in the factors that control iodine absorption by the pool water. For the realistic analysis, a decontamination factor value of 500 is used, which is a reduction of 66% of the expected value. For the conservative analysis, the decontamination factor is further reduced to a value of 200, or less than 30% of the value that would be expected.

15.4.5.1.3 Conclusions

A summary of the parameters and assumptions used to evaluate the consequences of a fuel handling accident are given in Table 15.4-38 for both the realistic and conservative analyses.

Activities released to the environment as a result of this event, are given in Table 15.4-40 for both the realistic and conservative cases.

15.4.5.1.4 Environmental Consequences of a Postulated Fuel Handling Accident Inside Containment

Following the postulated accident inside the Reactor Building, the activity released to the Reactor Building atmosphere is assumed to be released over a two hour duration to the environment

through the Reactor Building Purge System. In both the realistic and conservative analyses, no credit is taken for a reduction in the amount of activity released due to filtration or radioactive decay due to holdup in the containment. A summary of the pertinent parameters used to evaluate the consequences are presented in Table 15.4-38.

The following additional assumptions and parameters are used to calculate the control room doses for the FHA inside containment.

1. The atmospheric diffusion parameters for the control room are provided in Table 2.3-123. The limiting control room release point for the FHA inside of containment is the nearest point to the reactor building control room intake “A”.
2. The control room emergency filtration system is credited after 30 minutes.
3. The control room ventilation system flow rates are shown on Figure 15.4-146.
4. The control room breathing rate is assumed as 3.47E-04 m^3/sec for the duration of the accident.
5. Additional control room parameters are shown on Table 15.4-17.

The offsite and control room radiation doses resulting from both the realistic and conservative analyses of a postulated fuel handling accident inside containment are presented in Table 15.4-41.

15.4.5.2 Fuel Handling Accident Outside Containment

The fuel handling accident outside containment is postulated as the dropping of a spent fuel assembly into the Spent Fuel Pool which results in damage to the fuel assemblies and the release of the volatile gaseous fission products. Similar to the evaluation of the FHA inside containment, realistic and conservative analyses are performed for this postulated accident.

The identification of causes and description of this accident is identical to the FHA inside containment with the exception that the escaped gaseous fission products are released to the spent fuel pool and subsequently to the Fuel Handling Building. These gases are released to the environment via the fuel handling building charcoal exhaust system.

The conditions and parameters assumed in analyzing the effects and consequences of this accident are identical to those utilized in the FHA inside containment except that the activity released to the environment is treated by the HEPA and charcoal filters of the Fuel Handling Building Exhaust System. No credit is taken for these filters in the analysis of the environmental doses. Accordingly, the activity released to the environment is identical to that presented for the FHA inside containment and shown in Table 15.4-40 for the realistic and conservative cases respectively.

15.4.5.2.1 Environmental Consequences of a Postulated Fuel Handling Accident Outside of Containment

Following a postulated FHA outside containment, a quantity of airborne radioactivity would be released to the environment via the fuel handling building charcoal exhaust system.

In both the realistic and conservative analyses, no credit is taken for the mixing of the activity released with the fuel building atmosphere nor for radioactive decay due to holdup in the building or transit time after release to the environs. A summary of the pertinent parameters used to evaluate the consequences are presented in Table 15.4-38. Isotopic releases to the environment are presented in Table 15.4-40.

The following additional assumptions and parameters are used to calculate the control room doses for the FHA outside containment.

1. The atmospheric diffusion parameters for the control room are provided in Table 2.3-123. The limiting control room release point for the FHA outside of containment is the Main Plant Vent.
2. The control room emergency filtration system is credited after 30 minutes.
3. The control room ventilation system flow rates are shown on Figure 15.4-146.
4. The control room breathing rate is assumed as 3.47E-04 m^3/sec for the duration of the accident.
5. Additional control room parameters are shown on Table 15.4-17.

The offsite and control room radiation doses resulting from both the realistic and conservative analyses of the postulated fuel handling accident outside containment are presented in Table 15.4-50.

15.4.6 Rupture of a Control Rod Drive Mechanism Housing (Rod Cluster Control Assembly Ejection)

15.4.6.1 Identification of Causes and Accident Description

This accident is defined as the mechanical failure of a control rod mechanism pressure housing resulting in the ejection of a rod cluster control assembly (RCCA) and drive shaft. The consequence of this mechanical failure is a rapid positive reactivity insertion together with an adverse core power distribution, possibly leading to localized fuel rod damage.

15.4.6.1.1 Design Precautions and Protection

Certain features in Westinghouse Pressurized Water Reactors are intended to preclude the possibility of a rod ejection accident, or to limit the consequences if the accident were to occur. These include a sound, conservative mechanical design of the rod housings, together with a thorough quality control (testing) program during assembly, and a nuclear design which lessens

the potential ejection worth of RCCAs and minimizes the number of assemblies inserted at high power levels.

15.4.6.1.1.1 Mechanical Design

The mechanical design is discussed in FSAR Section 4.2. Mechanical design and quality control procedures intended to preclude the possibility of a RCCA drive mechanism housing failure are listed below:

1. The mechanism and travel housings were hydrotested after they were attached to the head adapters in the reactor vessel head, and checked during the hydrotest of the Replacement Reactor Vessel Closure Head.
2. Stress levels in the mechanism are not affected by anticipated system transients at power, or by the thermal movement of the coolant loops. Moments induced by the design earthquake can be accepted within the allowable primary working stress range specified by the ASME Code, Section III, for Class 1 components.
3. The latch mechanism housing and rod travel housing are each a single length of forged Type 304 stainless steel. This material exhibits excellent notch toughness at all temperatures which will be encountered.

A significant margin of strength in the elastic range together with the large energy absorption capability in the plastic range gives additional assurance that gross failure of the housing will not occur. The latch mechanism housing and head adapter are connected by a full penetration weld joint. The latch mechanism housing and rod travel housing, are connected by threaded joints, reinforced by canopy type seal welds, which are subject to periodic inspections.

15.4.6.1.1.2 Nuclear Design

Even if a rupture of a RCCA drive mechanism housing is postulated, the operation of a plant utilizing chemical shim is such that the severity of an ejected RCCA is inherently limited Reactivity changes caused by core depletion and xenon transients are compensated by boron changes. Further, the location and grouping of control RCCA banks are selected during the nuclear design to lessen the severity of a RCCA ejection accident. Therefore, should a RCCA be ejected from its normal position during full power operation, only a minor reactivity excursion, at worst, could be expected to occur.

However, it may be occasionally desirable to operate with larger than normal insertions. For this reason, a rod insertion limit is defined as a function of power level. Operation with the RCCAs above this limit guarantees adequate shutdown capability and acceptable power distributions. The position of all RCCAs is continuously indicated in the control room. An alarm will occur if a bank of RCCAs approaches its insertion limit or if one RCCA deviates from its bank. There are low and low-low level insertion monitors with visual and audio signals. Operating instructions require boration at low level alarm and emergency boration at the low-low alarm.

15.4.6.1.1.3 Reactor Protection

The reactor protection in the event of a rod ejection accident has been described in (Reference 30). The protection for this accident is provided by high neutron flux trip (high and low setting) and high rate of neutron flux increase trip. These protection functions are described in detail in Section 7.2.

15.4.6.1.1.4 Effects on Adjacent Housings

Disregarding the remote possibility of the occurrence of a RCCA mechanism housing failure, investigations have shown that failure of a housing due to either longitudinal or circumferential cracking would not cause damage to adjacent housing leading to an increase in severity of the initial accident.

The operating coil stack assembly of this mechanism has a 10.718 inch by 10.718 cross section and 39.875 inch length. The position indicator coil stack assembly is located above the operating coil stack assembly. It surrounds the rod travel housing over nearly its entire 163.24 inch length. The rod travel housing outside diameter is 3.75 inches and the position indicator coil stack assembly inside and outside diameters are 3.75 inches and 7.0 inches, respectively. This assembly consists of a steel tube surrounded by a continuous stack of copper wire coils. The assembly is held together by two end plates, an outer sleeve, and four axial tie rods.

15.4.6.1.1.5 Effects of Rod Travel Housing Longitudinal Failures

If a longitudinal failure of the rod travel housing should occur, the region of the position indicator assembly opposite the break would be stressed by the reactor coolant pressure of 2250 psia. The most probable leakage path would be provided by the radial deformation of the position indicator coil assembly, resulting in the growth of axial flow passages between the rod travel housing and the steel tube.

If failure of the position indicator coil assembly should occur, the resulting free radial jet from the failed housing could cause it to bend and contact adjacent rod housings. If the adjacent housings were on the periphery, they might bend outward from their bases. The housing material is quite ductile; plastic hinging without cracking would be expected. Housings adjacent to a failed housing, in locations other than the periphery, would not be bent because of the rigidity of multiple adjacent housings.

15.4.6.1.1.6 Effect of Rod Travel Housing Circumferential Failures

If circumferential failure of a rod travel housing should occur, the broken off section of the housing would be ejected vertically because the driving force is vertical and the position indicator coil stack assembly and the drive shaft would tend to guide the broken off piece upwards during its travel. Travel is limited by the missile shield, thereby limiting the projectile acceleration. When the projectile reached the missile shield it would partially penetrate the shield and dissipate its kinetic energy. The water jet from the break would continue to push the broken off piece against the missile shield.

If the broken off piece of the rod travel housing were short enough to clear the break when fully ejected, it would rebound after impact with the missile shield. The top end plates of the position indicator coil stack assemblies would prevent the broken piece from directly hitting the rod travel housing of a second drive mechanism. Even if a direct hit by the rebounding piece were to occur, the low kinetic energy of the rebounding projectile would not be expected to cause significant damage.

15.4.6.1.1.7 Possible Consequences

From the above discussion, the probability of damage to an adjacent housing must be considered remote. However, even if damage is postulated, it would not be expected to lead to a more severe transient since RCCAs are inserted in the core in symmetric patterns, and control rods immediately adjacent to worst ejected rods are not in the core when the reactor is critical. Damage to an adjacent housing could, at worst, cause that RCCA not to fall on receiving a trip signal, however this is already taken into account in the analysis by assuming a stuck rod adjacent to the ejected rod.

15.4.6.1.1.8 Summary

The considerations given above lead to the conclusion that failure of a control rod housing, due either to longitudinal or circumferential cracking, would not cause damage to adjacent housings that would increase severity of the initial accident.

15.4.6.1.2 Limiting Criteria

Due to the extremely low probability of a RCCA ejection accident, some fuel damage could be considered an acceptable consequence.

Comprehensive studies of the threshold of fuel failure and of the threshold of significant conversion of the fuel thermal energy to mechanical energy, have been carried out as part of the SPERT project by the Idaho Nuclear Corporation (Reference 31). Extensive tests of UO2 zirconium clad fuel rods representative of those in Pressurized Water Reactor type cores have demonstrated failure thresholds in the range of 240 to 257 cal/gm. However, other rods of a slightly different design have exhibited failures as low as 225 cal/gm. These results differ significantly from the TREAT (Reference 32) results, which indicated a failure threshold at 280 cal/gm. Limited results have indicated that this threshold decreases by about 10% with fuel burnup. The clad failure mechanism appears to be melting for zero burnup rods and brittle fracture for irradiated rods. Also important is the conversion ratio of thermal to mechanical energy. This ratio becomes marginally detectable above 300 cal/gm for unirradiated rods and 200 cal/gm for irradiated rods; catastrophic failure, (large fuel dispersal, large pressure rise) even for irradiated rods, did not occur below 300 cal/gm.

In view of the above experimental results, conservative criteria (Reference 49) are applied to ensure that there is little or no possibility of fuel dispersal in the coolant, gross lattice distortion, or severe shock waves. These criteria are:

1. Average fuel pellet enthalpy at the hot spot below 225 cal/gm for unirradiated fuel and 200 cal/gm for irradiated fuel.
2. Peak reactor coolant pressure less than that which would cause stresses to exceed the faulted condition stress limits;
3. Fuel melting will be limited to less than 10% of the fuel volume at the hot spot even if the average fuel pellet enthalpy is below the limits of criterion 1 above.

15.4.6.2 Analysis of Effects and Consequences

15.4.6.2.1 Method of Analysis

The analysis of the RCCA ejection accident is performed in two stages, first an average core nuclear power calculation and then a hot spot heat transfer calculation. The average core calculation is performed using spatial neutron kinetics methods to determine the average power generation with time including the various total core feedback effects, i.e., Doppler reactivity and moderator reactivity. Enthalpy and temperature transients in the hot spot are then determined by multiplying the average core energy generation by the hot channel factor and performing a fuel rod transient heat transfer calculation. The power distribution calculated without feedback is pessimistically assumed to persist throughout the transient. A detailed discussion of the method of analysis can be found in Reference (Reference 33).

15.4.6.2.2 Average Core Analysis

The spatial kinetics computer code, TWINKLE (Reference 34), is used for the average core transient analysis. This code solves the 2 group neutron diffusion theory kinetic equation in one, two or three spatial dimensions (rectangular coordinates) for 6 delayed neutron groups and up to 8000 spatial points. The computer code includes a detailed multiregion, transient fuel clad coolant heat transfer model for calculation of pointwise Doppler and moderator feedback effects.

In this analysis, the code is used as a 1 dimensional axial kinetics code since it allows a more realistic representation of the spatial effects of axial moderator feedback and RCCA movement. However, since the radial dimension is missing, it is still necessary to employ very conservative methods (described below) of calculating the ejected rod worth and hot channel factor. Further description of TWINKLE appears in Section 15.1.9.

15.4.6.2.3 Hot Spot Analysis

In the hot spot analysis, the initial heat flux is equal to the nominal times the design hot channel factor. During the transient, the heat flux hot channel factor is linearly increased to the transient value in 0.1 second, the time for full ejection of the rod. Therefore, the assumption is made that the hot spot before and after ejection are coincident. This is very conservative since the peak after ejection will occur in or adjacent to the assembly with the ejected rod, and prior to ejection the power in this region will necessarily be depressed.

The hot spot analysis is performed using the detailed fuel and clad transient heat transfer computer code, FACTRAN (Reference 29). This computer code calculates the transient temperature distribution in a cross section of a metal clad UO2 fuel rod, and the heat flux at the surface of the rod, using as input the nuclear power versus time and the local coolant conditions. The zirconium water reaction is explicitly represented, and all material properties are represented as functions of temperature. A parabolic radial power distribution is used within the fuel rod. Also, consistent with the PAD5 fuel performance code (Reference 68), the effects of fuel thermal conductivity degradation with burnup are accounted for in the analysis.

FACTRAN uses the Dittus-Boelter (Reference 35) or Jens-Lottes (Reference 36) correlation to determine the film heat transfer before DNB, and the Bishop-Sandberg-Tong correlation (Reference 37) to determine the film boiling coefficient after DNB. The DNB heat flux is not calculated, instead the code is forced into DNB by specifying a conservative DNB heat flux. The gap heat transfer coefficient can be calculated by the code; however, it is adjusted in order to force the full power steady state pellet temperature distribution to agree with the fuel heat transfer design codes.

For full power cases, the design initial hot channel factor (F_Q) is input to the code. The hot channel factor during the transient is assumed to increase from steady state design value to the maximum transient value in 0.1 seconds, and remain at the maximum for the duration of the transient. This is conservative, since detailed spatial kinetics models show that the hot channel factor decreases shortly after the nuclear power peak due to power flattening caused by preferential feedback in the hot channel. Further description of FACTRAN appears in Section 15.1.9.

15.4.6.2.4 System Overpressure Analysis

Because safety limits for fuel damage specified earlier are not exceeded, there is little likelihood of fuel dispersal into the coolant. The pressure surge may therefore be calculated on the basis of conventional heat transfer from the fuel and prompt heat generation in the coolant.

The pressure surge is calculated by first performing the fuel heat transfer calculation to determine the average and hot spot heat flux versus time. Using this heat flux data, a THINC calculation is conducted to determine the volume surge. Finally, the volume surge is simulated in a plant transient computer code. This code calculates the pressure transient taking into account fluid transport in the RCS and heat transfer to the steam generators. No credit is taken for the possible pressure reduction caused by the assumed failure of the control rod pressure housing. (Reference 38)

15.4.6.2.5 Calculation of Basic Parameters

Input parameters for the analysis are conservatively selected on the basis of values calculated for this type of core. The more important parameters are discussed below. Table 15.4-42 presents the parameters used in this analysis.

15.4.6.2.6 Ejected Rod Worths and Hot Channel Factors

The values for ejected rod worths and hot channel factors are calculated using three dimensional calculations. Standard nuclear design codes are used in the analysis. No credit is taken for the flux flattening effects of reactivity feedback. The calculation is performed for the maximum allowed bank insertion at a given power level, as determined by the rod insertion limits. Adverse xenon distributions are considered in the calculations.

Appropriate margins are added to the results to allow for calculational uncertainties.

15.4.6.2.7 Reactivity Feedback Weighting Factors

The largest temperature rises, and hence the largest reactivity feedbacks occur in channels where the power is higher than average. Since the weight of a region is dependent on flux, these regions have high weights. This means that the reactivity feedback is larger than that indicated by a simple single channel analysis. Physics calculations have been carried out for temperature changes with a flat temperature distribution, and with a large number of axial and radial temperature distributions. Reactivity changes were compared and effective weighting factors determined. These weighting factors take the form of multipliers which when applied to single channel feedbacks correct them to effective whole core feedbacks for the appropriate flux shape. In this analysis, since a one dimensional (axial) spatial kinetics method is employed, the axial weighting is not necessary. In addition, no weighting is applied to the moderator feedback. A conservative radial weighting factor is applied to the transient fuel temperature to obtain an effective fuel temperature as a function of time accounting for the missing spatial dimension. These weighting factors have also been shown to be conservative compared to 3 dimensional analysis.

15.4.6.2.8 Moderator and Doppler Coefficient

The critical boron concentrations at the beginning of life and end of life are adjusted in the nuclear code in order to obtain moderator density coefficient curves which are conservative compared to actual design conditions for the plant. As discussed above, no weighting factor is applied to these results.

The Doppler reactivity defect is determined as a function of power level using a one dimensional steady state computer code with a Doppler weighting factor of 1. The resulting curve is conservative compared to design predictions for this plant. The Doppler weighting factor should be larger than 1.0 (approximately 1.2), just to make the present calculation agree with design predictions before ejection. This weighting factor will increase under accident conditions, as discussed above. The Doppler defect used as an initial condition is 955 pcm at the beginning of life (BOL) and 893 pcm at the end of life (EOL).

15.4.6.2.9 Delayed Neutron Fraction

Calculations of the effective delayed neutron fraction (β_{eff}) typically yield values of 0.70% at beginning of life and 0.50% at end of life for the first cycle. The accident is sensitive to β_{eff} if the

ejected rod worth is nearly equal to or greater than β_{eff} as in zero power transients. In order to allow for future cycles, pessimistic estimates of β_{eff} of 0.54% at beginning of cycle and 0.44% at end of cycle were used in the analysis.

15.4.6.2.10 Trip Reactivity Insertion

The trip reactivity insertion assumed is given in Table 15.4-42 and includes the effect of one stuck RCCA. These values are reduced by the ejected rod reactivity. The shutdown reactivity was simulated by dropping a rod of the required worth into the core. The start of rod motion occurred 0.5 seconds after the high neutron flux trip point is reached. This delay is assumed to consist of 0.2 seconds for the instrument channel to produce a signal, 0.15 seconds for the trip breaker to open and 0.15 seconds for the coil to release the rods. The analyses presented are applicable for a rod insertion time of 2.7 seconds from coil release to entrance to the dashpot. The choice of such a conservative insertion rate means that there is over one second after the trip point is reached before significant shutdown reactivity is inserted into the core. This is a particularly important conservatism for hot full power accidents.

The minimum design shutdown margin available for this plant at hot zero power (HZP) may be reached only at end of life in the equilibrium cycle. This value includes an allowance for the worst stuck rod, and adverse xenon distribution, conservative Doppler and moderator defects, and an allowance for calculational uncertainties. Physics calculations for this plant have shown that the effect of 2 stuck RCCAs (one of which is the worst ejected rod) is to reduce the shutdown by about an additional 1% Δk. Therefore, following a reactor trip resulting from an RCCA ejection accident, the reactor will be subcritical when the core returns to HZP.

Depressurization calculations have been performed for the Virgil C. Summer Nuclear Station assuming the maximum possible size break (2.75 inch diameter) located in the reactor pressure vessel head. The results show a rapid pressure drop and a decrease in system water mass due to the break. The safety injection system is actuated on low pressurizer pressure within one minute after the break. The RCS pressure continues to drop and reaches saturation (1100 to 1300 psi depending on the system temperature) in about 2 to 3 minutes. Due to the large thermal inertia of primary and secondary system, there has been no significant decrease in the RCS temperature below no load by this time, and the depressurization itself has caused an increase in shutdown margin by about 0.2% Δk due to the pressure coefficient. The cooldown transient could not absorb the available shutdown margin until more than ten minutes after the break. The addition of borated safety injection flow starting one minute after the break is much more than sufficient to ensure that the core remains subcritical during the cooldown.

15.4.6.2.11 Results

The values of the parameters used in the analysis, as well as the results of the analysis, are presented in Table 15.4-42 and discussed below.

1. Beginning of Cycle, Full Power

Control bank D was assumed to be inserted to its insertion limit. The worst ejected rod worth and hot channel factor were conservatively assumed to be 0.20% Δk and 4.5 respectively. The peak hot spot clad average temperature was 2158°F. The peak hot spot fuel center temperature exceeded the BOL melting temperature of 5024.2°F. However, melting was restricted to less than 10% of the pellet.

2. Beginning of Cycle, Zero Power

   For this condition, control bank D was assumed to be fully inserted and bank C was at its insertion limit. The worst ejected rod is located in control bank D and was conservatively assumed to have a worth of 0.855% Δk and a hot channel factor of 13. The peak hot spot clad average temperature reached 2680°F. The peak hot spot fuel center temperature was 4468°F.

3. End of Cycle, Full Power

   Control bank D was assumed to be inserted to its insertion limit. The ejected rod worth and hot channel factors were conservatively assumed to be 0.21% Δk and 5.0, respectively. This resulted in a peak hot spot clad average temperature of 2136°F. The peak hot spot fuel center temperature exceeded the EOL melting temperature of 5024.2°F. However, melting was restricted to less than 10% of the pellet.

4. End of Cycle, Zero Power

   Control Bank D was assumed to be fully inserted and C was at its insertion limit. The ejected rod worth and hot channel factor were conservatively assumed to be 0.91% Dk and 22.5, respectively. The peak clad average and fuel center temperatures were 2839°F and 4402°F, respectively.

   A summary of the cases presented above is given in Table 15.4-42. The nuclear power and hot spot fuel and clad temperature transients are presented in Figure 15.4-100 through Figure 15.4-103.

15.4.6.2.12 Fission Product Release

It is assumed that fission products are released from the gaps of all rods entering DNB. In all cases considered, less than 10% of the rods entered DNB based on a detailed three dimensional THINC analysis. Although limited fuel melting at the hot spot was predicted for the full power cases, in practice melting is not expected since the analysis conservatively assumed that the hot spots before and after ejection were coincident.

15.4.6.2.13 Pressure Surge

A detailed calculation of the pressure surge for an ejection reactivity worth of one dollar at beginning of life, hot full power, indicates that the peak pressure does not exceed that which would cause stress to exceed the faulted condition stress limits. Since the severity of the present

analysis does not exceed this “worst case” analysis, the accident for this plant will not result in an excessive pressure rise or further damage to the reactor coolant system.

15.4.6.2.14 Lattice Deformations

A large temperature gradient will exist in the region of the hot spot. Since the fuel rods are free to move in the vertical direction, differential expansion between separate rods cannot produce distortion. However, the temperature gradients across individual rods may produce a force tending to bow the midpoint of the rods toward the hot spot. Physics calculations indicate that the net result of this would be a negative reactivity insertion. In practice, no significant bowing is anticipated, since the structural rigidity of the core is more than sufficient to withstand the forces produced. Boiling in the hot spot region would produce a net flow away from that region. However, the heat from the fuel is released to the water relatively slowly, and it is considered inconceivable that cross flow will be sufficient to produce significant lattice forces. Even if massive and rapid boiling, sufficient to distort the lattice, is hypothetically postulated, the large void fraction in the hot spot region would produce a reduction in the total core moderator to fuel ratio, and a large reduction in this ratio at the hot spot. The net effect would therefore be a negative feedback. It can be concluded that no conceivable mechanism exists for a net positive feedback resulting from lattice deformation. In fact, a small negative feedback may result. The effect is conservatively ignored in the analysis.

15.4.6.3 Conclusions

Even on a conservation basis, the analyses indicate that the described fuel and limits are not exceeded. It is concluded that there is no danger of sudden fuel dispersal into the coolant. Since the peak pressure does not exceed that which would cause stresses to exceed the faulted condition stress limits, it is concluded that there is no danger of further consequential damage to the reactor coolant system. The analyses have demonstrated that upper limit in fission product release as a result of a number of fuel rods entering DNB amounts to 10% (Reference 38).

15.4.6.4 Environmental Consequences of a Postulated Rod Ejection Accident

Two analyses of a postulated rod ejection accident are performed: a realistic analysis and a conservative Regulatory Guide 1.183 analysis. The parameters used for each of these analyses are listed in Table 15.4-43.

The realistic analysis of the doses resulting from a rod ejection accident is based upon the release to the containment of all volatile fission products in the RCS.

Prior to the accident it is assumed that the plant has been operating with 0.12% fuel defects and steam generator tube leakage of 100 lb./day for a sufficient period of time to establish equilibrium levels of activity in the primary and secondary systems. Release from contaminated steam dumped to the condenser is considered negligible.

For the conservative Regulatory Guide 1.183 analysis, it is assumed that the plant is operating at equilibrium levels of radioactivity in the primary and secondary systems prior to the postulated

rod ejection accident as a result of coincident fuel defects (1%) and steam generator tube leakage (1 gpm). Following a postulated rod ejection accident, two activity release paths are considered. The first release path is via containment leakage of activity released to the containment from the reactor coolant. The second path is via the contaminated steam from the secondary system which is released through the relief valves since it is assumed that offsite power is lost.

15.4.6.4.1 Model

The RADTRAD (Reference 64) computer code was used to calculate the offsite and control room doses for the control rod ejection accident (CREA). Schematics showing the code modeling of the activity flow paths are provided on Figure 15.4-147 (steam generator release path) and Figure 15.4-148 (containment release path). Parameters and assumptions used in evaluating offsite doses for this event are summarized in Table 15.4-43.

Prior to the accident it is assumed that the plant has been operating with simultaneous fuel defects and steam generator tube leakage for a sufficient period of time to establish equilibrium levels of activity in the primary and secondary systems.

Following a postulated rod ejection accident, the activity released is assumed to be instantaneously mixed uniformly throughout the reactor coolant. Thus, the total activity released from the fuel rod gaps is assumed to be immediately available for release from the RCS.

Of the activity released with the reactor coolant to the containment by the postulated failure of the RCCA mechanism pressure housing, 100% is assumed to be mixed instantaneously throughout the containment and to be available for leakage from the containment at the design leak rate. The only removal processes considered within containment are radioactive decay and leakage from the containment.

The model for the activity available for release to the atmosphere from the relief valves assumes that the release consists of the activity in the secondary coolant prior to the accident plus that fraction of the activity leaking from the reactor coolant through the steam generator tubes following the accident. The leakage of reactor coolant to the secondary side of the steam generators is assumed to continue at its initial rate, i.e., the same leakage rate that existed prior to the accident, until primary and secondary system pressure is equalized. No mass transfer from the primary to the secondary system through steam generator tube leakage is assumed after system pressures are equalized.

15.4.6.4.2 Assumptions for Conservative Analysis

The following conservative assumptions were used in the analysis of the release of radioactivity to the environment in the event of a postulated rod ejection accident. A summary of parameters used in the analysis is given by Table 15.4-43.

1. The primary-to-secondary leak rate in the steam generators is assumed to be the leak-rate-limiting condition for operation specified in the plant requirements of 1 gpm for all three steam generators. To be consistent with preferred plant procedures for shutdown, the

shutdown cooling rate following this type of event is taken as 25 °F /hr. Therefore, to go from 557 °F to 212 °F would require about 14 hours. The CREA is conservatively analyzed using 24 hours for the cooldown time. The activity associated with the 1 gpm leak is assumed to be released to the environment via the intact steam generators for the 24 hour duration with a partition factor of 100 for iodine and particulates and 1.0 for noble gases. In addition, the secondary coolant iodine and particulate activity initially contained in the secondary system is released to the environment with a partition factor of 100.

2. Per Regulatory Guide 1.183, Table 3, the non-LOCA fraction of fission products inventory in the gap is acceptable for use if the peak fuel burnup does not exceed 62,000 MWD/MTU and the maximum linear heat generation rate does not exceed 6.3 kw/ft. peak rod average power for burnups exceeding 54 GWD/MTU. To account for possible variation in burnup and rod power, the Table 3 non-LOCA fraction of fission products inventory in the gap is conservatively doubled. The Regulatory Guide 1.183, Table 3 gap fractions and the gap fractions used in the CREA analysis are listed as follows:

Group	Regulatory Guide 1.183 Fraction	CREA Analysis Fraction
Noble Gases	0.10	0.20
Halogens	0.10	0.20
Alkali Metals	0.12	0.24

3. Instantaneous mixing of all activity released from the reactor coolant into the containment is assumed.
4. No credit is assumed for removal of iodine within containment by the reactor building sprays.

Design criteria applied to ensure that fuel dispersal into the reactor coolant will not occur include:

“Fuel melting limited to less than the innermost10% of the fuel pellet at the hot spot” (Reference 38)

Even though centerline melting in a small fraction of the core is not expected, a conservative upper limit of fission product release from the core as a result of a postulated rod ejection accident can be estimated. This limit would include the release of 100% of the noble gases and 50% of the iodines from that portion of the fuel which could experience centerline melting under the above criteria.

The upper limit of fission product release from the core for this very conservative case is determined using the following assumptions:

1. It is assumed that 100% of the noble gases and iodines in the clad gaps of the fuel rods experiencing clad damage (assumed to be 10% of the rods in the core (Reference 38) is assumed to be released to the reactor coolant.

2. It is assumed that 50% of the iodines and 100% of the noble gases in the fuel that melts are released to the reactor coolant. This is a very conservative assumption since only centerline melting could occur for a maximum time period of six seconds.
3. The fraction of fuel melting is conservatively assumed to be one quarter of one percent of the core, determined by the following method:
   a. A conservative upper limit of 50% of the rods experiencing clad damage may experience centerline melting (a total of 5% of the core).
   b. Of rods experiencing centerline melting, only a conservative maximum of the innermost 10% of the rod volume will actually melt (equivalent to 0.5% of the core that could experience melting).
   c. A conservative maximum of 50% of the axial length of the rod will experience melting due to the power distribution (0.5 of the 0.5% of the core equals 0.25% of the core).

The release fraction from the melted fuel is based on Attachment H and Regulatory Position 3.2, Table 2 of Regulatory Guide 1.183, 100% for the nobles, 25% for the iodines, and 30% for the alkali metals for the containment release pathway and 100% for the nobles, 50% for the iodines, and 50% for the alkali metals for the steam generator release pathway.

The following additional assumptions and parameters are used to calculate the control room doses for the CREA.

1. The atmospheric diffusion parameters for the control room are provided in Table 2.3-123. The limiting CR release point for the CREA is the RB nearest point - Control Room Intake A for the containment release pathway and the Main Steam Safety Relief Valve “A” (Reliefs B, C, D, E), Control Room Intake B for the SG release pathway.
2. The control room emergency filtration system is credited after 30 minutes for the containment release case and 120 minutes for the SG release case.
3. The control room ventilation system flow rates are shown on Figure 15.4-147 and Figure 15.4-148.
4. The control room breathing rate is assumed as 3.47E-04 m^3/sec for the duration of the accident.
5. Additional control room parameters are shown on Table 15.4-17.

The remainder of the assumptions and parameters used to calculate the activity release from the plant and the subsequent offsite doses for the ultraconservative analysis are identical to those used for the conservative analysis.

15.4.6.4.3 Results

Isotopic releases are summarized in Table 15.4-44 through Table 15.4-46. The calculated offsite and control room doses are provided in Table 15.4-47.

Table 15.4-17
Parameters Used in Analysis of Control Room Dose
Following Design Basis Accidents

	Parameters
Control Room Free Volume	226,040 ft^3
Filtered Recirculation Flow	19,125 cfm(1)
Recirculation Filter Efficiencies	95% for all species of iodine
Maximum Control Room Filtered Air Infiltration Rate per Operating Train	1265 cfm
Control Room Unfiltered Air infiltration Rate	243 cfm including 10 cfm for ingress/egress
Maximum Control Room Outleakage	Equal to total inleakage (1508 cfm)
Meteorology	Table 2.3-123
Percent of Time Operator Is in Control Room Following Accident	0-24 hrs 100% 1-4 days 60% 4-30 days 40%
Duration of Accident	30 days
Breathing Rate of Operators in Control Room	3.47×10^{-4} m^3/sec
Activity Release Parameters	Table 15.4-15
Method of Dose Calculation	RADTRAD (Reference 64)
Time to Initiate Control Room Emergency Ventilation System (2,3)	
Loss of Coolant Accident	0
Fuel Handling Accidents	30 minutes
Main Steam Line Break	30 minutes
Steam Generator Tube Rupture	30 minutes
Reactor Coolant Pump Locked Rotor	120 minutes
Control Rod Ejection	
Steam Generator Release Case	120 minutes
Containment Release Case	30 minutes

Notes:

Table 15.4-17 (CONTINUED)
Parameters Used in Analysis of Control Room Dose
Following Design Basis Accidents

Parameters

(1) 90% of 21,250 cfm.
(2) The Control Room Ventilation system is automatically placed in the emergency mode, with filtration of incoming and recirculated air, following receipt of a Safety Injection or high radiation signal from the gaseous activity channel of RM-A1. If both trains are operating, one train will be isolated within 30 minutes by the Operator in accordance with the Emergency Operating Procedures to minimize dose consequences. This condition is bounded by the analysis which only credits one train control room ventilation for the duration of the accident.
(3) Within the analysis, the emergency mode of operation is assumed to occur at the following times by either automatic isolation or manual initiation.

Table 15.4-18
Control Room Doses Following a LOCA

Table 15.4-19
Time Sequence of Events for
Major Secondary System Pipe Ruptures

Accident	Event	Time (sec)
Major Steam Line Rupture		
Offsite Power available	Steam line ruptures	0
	Criticality attained	25
	Boron from RWST reaches core	57
	Accumulators actuate	74
	Peak heat flux attained	76
	Core becomes subcritical	~ 108
Without offsite power	Steam line ruptures	0
	Criticality attained	22
	Boron from RWST reaches core	72
	Peak heat flux attained	~ 261
	Core becomes subcritical	~ 313
Rupture of Main Feedwater Pipe		
(Offsite Power Available)	Feedline rupture occurs	10
	Low-low SG water level setpoint reached	28.3
	Rods begin to drop	30.3
	Low steamline pressure setpoint reached	47.8
	Steamline isolation occurs	57.8
	Feedline isolation occurs	60.8
	Emergency Feedwater is started	136.3
	Feedwater lines are purged and emergency feedwater is delivered to two intact SGs	148.2
	First steam generator safety valve lifts in intact loop	217.5
	Pressurizer water relief begins	2134

Table 15.4-19 (CONTINUED)
Time Sequence of Events for
Major Secondary System Pipe Ruptures

Accident	Event	Time (sec)
Rupture of Main Feedwater Pipe (Continued)	Total RCS heat generation (decay heat + pump heat) decreases to emergency feedwater heat removal capability	~ 3300
(Offsite Power Unavailable)	Feedline rupture occurs	10
	Low-low SG water level setpoint reached	27.4
	Rods begin to drop	29.4
	Reactor coolant pump coastdown	31.4
	Low steamline pressure setpoint reached	45.8
	Steamline isolation occurs	55.8
	Feedwater isolation occurs	58.8
	Emergency Feedwater is started	135.4
	Feedwater lines are purged and emergency feedwater is delivered to two intact SGs	147.3
	First steam generator safety valve lifts in intact loop	304.4
	Total RCS heat generation (decay heat + pump heat) decreases to emergency feedwater heat removal capability	~ 800

Table 15.4-21
Equipment Required Following a High Energy Line Break

Short Term (Required For Mitigation of Accident)	Hot Standby	Required For Cooldown
Reactor trip and safeguards actuation channels including sensors, circuitry, and processing equipment (the protection circuits used to trip the reactor on undervoltage, underfrequency, and turbine trip may be excluded)	Emergency Feedwater System including pumps, water supply, and system valves and piping (Emergency Feedwater System automatically supplies water, see section 10.4.9).	Steam generator power operated relief valves (can be manually operated locally).
Safety Injection System including the pumps, the refueling water storage tank, and the systems valves and piping	Reactor Building emergency cooling units. Capability for obtaining a Reactor Coolant System sample	Controls for defeating automatic safety injection actuation during a cooldown and depressurization.
Diesel generators and emergency power distribution equipment	Capability for obtaining a Reactor Coolant System sample	Residual Heat Removal System including pumps, heat exchanger, and system valves and piping necessary to cool and maintain the Reactor Coolant System in a cold shutdown condition.
Service Water System		
Reactor Building emergency cooling units.		
Emergency Feedwater System including pumps, water supplies, piping, valves		
Main feedwater control valves(1) (trip closed feature)		
Primary and secondary safety valves		

Table 15.4-21 (continued)
Equipment Required Following a High Energy Line Break

Short Term (Required For Mitigation of Accident)	Hot Standby	Required For Cooldown
Circuits and/or equipment required to trip the main feedwater pumps(1)		
Main feedwater isolation valves(1) (trip closed feature)		
Main steam line isolation valves(1) (trip closed feature)		
Main steam line isolation valve bypass valves(1) (trip closed feature)		
Steam generator blowdown isolation valves (automatic closure feature)		
Batteries (Class IE)		
Control room ventilation		
Control room equipment must not be damaged to an extent where any equipment will be spuriously actuated or any of the equipment contained elsewhere in this list cannot be operated.		
Emergency lighting		
Post Accident Monitoring System(2)		

Table 15.4-21 (continued)
Equipment Required Following a High Energy Line Break

Short Term (Required For Mitigation of Accident)	Hot Standby	Required For Cooldown
Wide range T_{hot} or T_{cold} (preferably T_{hot}) for each reactor coolant loop		
Pressurizer water level		
Wide range Reactor Coolant System pressure		
Steam line pressure for each steam generator		
Wide range or narrow range steam generator level for each steam generator		
Containment pressure		

(1) Require for steam line, feed line, and steam generator blowdown line break only.
(2) See Section 7.5 for a discussion of the Post Accident Monitoring System.

Table 15.4-23
Parameters Used in Steam Line Break Analysis

Parameter	Conservative Case	Realistic Case
Core thermal power	2958 MWt	2958 MWt
Fuel defects	1%	0.12%
Fuel damaged	0%	0%
Steam generator tube leak	1,0 gpm	100 lb/day
Iodine spiking basis	Pre-accident/concurrent	None
Noble gas partition factor faulted and intact steam generator	1	1
Iodine and particulate partition factor faulted steam generator	1	1
Iodine and particulate partition factor intact steam generator	100	100
Form of iodine release		
Particulate iodine	97%	97%
Organic iodine	3%	3%

The following parameters are common to both cases:

Integrated Mass of Steam and Reactor Coolant Release Rates

Time Period	Integrated Steam Release from Faulted SG (lbm)	Integrated Steam Release from Intact SGs (lbm)	Reactor Coolant Release to Faulted SG (gpm) [1]	Reactor Coolant Release to Intact SGs (gpm)
0 -3 0 min	406,000		0.35	0.65
0 - 2 hours		390,000	0.35	0.65
2 - 8 hours		830,000	0.35	0.65

Table 15.4-23 (continued)
Parameters Used in Steam Line Break Analysis

Parameter	Conservative Case		Realistic Case	
Integrated Mass of Steam and Reactor Coolant Release Rates (continued)				
	Integrated Steam Release from Faulted SG	Integrated Steam Release from Intact SGs	Reactor Coolant Release to Faulted SG	Reactor Coolant Release to Intact SGs
Time Period	(lbm)	(lbm)	(gpm) (1)	(gpm)
8-24 hours		1,200,000	0.35	0.54

(1) For the realistic case the 100 lb/day reactor coolant release is assumed to be released to the faulted steam generator.

Offsite Atmospheric Dispersion Factors

Time	Site Boundary	Low Population Zone
0 - 2 hours	1.24E-04	-
0 - 8 hours		2.42E-05
8 - 24 hours		1.68E-05

Table 15.4-27
Offsite and Control Room (CR) Doses
Main Steam Line Break Accident

	Dose (rem TEDE)		
Case	EAB	LPZ	CR
Pre-existing Iodine Spike Design CR Leakage	0.70	0.20	1.40
Concurrent Iodine Spike Design CR Leakage	0.40	0.30	0.50
Realistic Design CR Leakage	0.00006	0.00003	0.0002

The dose acceptance criteria provided in 10 CFR 50.67 and Regulatory Guide 1.183 are given as follows:

Pre-existing Iodine Spike MSLB – 25rem TEDE for the EAB and LPZ and 5 Rem TEDE for the CR.
Concurrent Iodine Spike MSLB – 2.5rem TEDE for the EAB and LPZ and 5 Rem TEDE for the CR.

Table 15.4-28
Plant Equipment Required For Recovery From Steam
Generator Tube Rupture Accident

1. Emergency Feedwater System including pumps, water supply, and system valves and piping.
2. Steam generator shell side fluid sampling system.
3. Steam generator safety valves.
4. Steam generator power operated relief valves (can be manually operated locally).
5. Refueling Water Storage Tank.
6. Main steam line isolation and bypass valves.
7. Diesel generators and emergency power distribution equipment.
8. Residual Heat Removal System.
9. Pressurizer power operated relief valves.
10. Charging system including pumps and system valves.
11. RCS and steam generator instrumentation including RCS temperature and pressure, pressurizer and SG water level instrumentation.
12. Diesel driven air compressor.

Note: Range of acceptable values are discussed in the recovery procedure.

Table 15.4-29
Parameters Used In Steam Generator Tube Rupture Analysis

Core thermal power	2958 MWt
Steam generator tube leak rate prior to and during accident	1.0 gpm
Offsite power	Lost
Fuel defects	1% for Noble Gases and other nuclides modeled except iodines
Iodine Spiking Basis	Pre-accident / Concurrent
Failed Fuel	0.0
Initial RC Iodine Activities	60 µCi/gm and 1 µCi/gm Dose Equivalent I-131 for Pre-accident /Concurrent Spike
Iodine partition factors in steam generators	100 except for flashed break flow
Time to isolate defective steam generator	30 min
Duration of plant cooldown by secondary system after accident	24 hrs
Steam release from defective steam generator	56,800 lbs (0-30 min)
Steam release from 2 unaffected steam generators	381,400 lbs (0-2 hrs) 924,900 lbs (2-8 hrs) 1,200,000 lbs (8-24 hrs)
Reactor coolant released to defective steam generator	92,900 lbs
Flashed Break Flow	3880 lbs (0-385 sec) 9188 lbs (385 sec-30 min)
Meteorology (Atmospheric Dispersion Factors)*	
Site Boundary	1.25E-04 (0-2 hr)
Low Population Zone	5.97E-05 (0-2 hr) 2.91E-05 (2-8 hr) 2.03E-05 (> 8 hr)

Table 15.4-29 (CONTINUED)
Parameters Used In Steam Generator Tube Rupture Analysis

Control Room	1.50E-3 (0-2 hrs) 1.12E-3 (2-8 hrs) 1.12E-3 (0-8 hrs) 5.24E-3 (8-24 hrs) 3.61E-3 (1-4 days) 2.33E-3 (4-30 days)

*The atmospheric dispersion factors reflect the 2012-2014 monitoring period, and were found to be acceptable because dose values in <hot spots 9 pt>Table 15.4-43 reflect a penalty of + 25%. However, these atmospheric dispersion values may not be considered acceptable for use in other dose assessments or other meteorological applications without further NRC review and approval.

15.A DOSE MODELS USED TO EVALUATE THE ENVIRONMENTAL CONSEQUENCES OF ACCIDENTS

15.A.1 Introduction

This appendix identifies the models used to calculate offsite radiological doses that would result from releases of radioactivity due to various postulated accidents. The postulated accidents using this Appendix are as follows:

1. Loss of Offsite Power.
2. CVCS Line Rupture.

The following accidents are evaluated using the methods and models based on USNRC Regulatory Guide 1.183:

1. Loss of Coolant Accident.
2. Steam Line Break.
3. Steam Generator Tube Rupture.
4. Fuel Handling Accident.
5. Rod Ejection Accident.
6. Reactor Coolant Pump Locked Rotor Accident.

15.A.2 Assumptions

The following assumptions are basic to both the model for the gamma and beta doses due to immersion in a cloud of radioactivity and the model for the thyroid dose due to inhalation of radioactivity:

1. Direct radiation from the source point is negligible compared to gamma and beta radiation due to submersion in the radioactivity leakage cloud.
2. All radioactivity releases are treated as ground level releases regardless of the point of discharge.
3. The dose receptor is a standard man as defined by the International Commission on Radiological Protection (ICRP) (<hot spots>Reference 1).
4. Isotopic data, such as decay rates and decay energy emissions, are taken from Table of Isotopes (<hot spots>Reference 2) and Kocher (<hot spots>Reference 6).
5. No correction is made for depletion of the effluent plume due to deposition on the ground or for the radiological decay in transit.
6. The receptor is located at a point on or beyond the site boundary where the maximum ground level concentration is expected to occur.

15.A.3 Gamma Dose and Beta Skin Dose

External whole body doses are calculated using "infinite cloud" assumptions (i.e., the dimensions of the cloud are assumed to be large compared to the distance that the gamma rays and beta particles travel). Such a cloud is considered an infinite cloud for a receptor at the center because any additional gamma and beta emitting material beyond the cloud dimensions does not alter the flux of gamma rays and beta particles to the receptor. Under these conditions, the rate of energy absorption per unit volume is equal to the rate of energy release per unit volume. The dose at any distance from the reactor is calculated based on the maximum ground level concentration at that distance. The infinite cloud methods for calculating whole body beta and gamma doses are as follows:(<hot spots>Reference 3)

1. For the infinite uniform cloud containing χ Ci of beta radioactivity per cubic meter, the beta dose rate in air at the cloud center is:

   $$_{\beta}D'_{\infty} = 0.457E_{\beta}\chi$$

   Where:

   $_{\beta}D'_{\infty}$ = Beta dose rate from an infinite cloud (rem/sec).

   E_{β} = Average beta energy per disintegration (Mev/dis).

   χ= Concentration of beta emitting isotope in the cloud (Ci/m^3).

   Because of the limited range of beta particles in tissue, the surface body dose rate from beta emitters in the infinite cloud can be approximated as being one-half this amount or:

   $$_{\beta}D'_{\infty} = 0.23E_{\beta}\chi$$

   Thus, in terms of integrated dose, the total beta dose to an individual located at the center of the cloud path is approximated as:

   $$_{\beta}D_{\infty} = 0.23E_{\beta}A\chi/Q$$

   Where:

   $_{\beta}D_{\infty}$ = Total beta dose to an individual located at the center of the cloud path (rem).

   E_{β} = Average beta energy per disintegration (Mev/ dis).

   A= Isotopic activity released (Ci).

   χQ= Atmospheric diffusion factor at receptor location (sec/m^3).

2. For an infinite uniform cloud containing ÷ curies of gamma radioactivity per cubic meter, the gamma dose rate in tissue at the cloud center is:

$${}_{\beta}D'_{\infty} = 0.507E\gamma\chi$$

Where:

${}_{\beta}D'_{\infty}$ = Gamma dose rate from an infinite cloud (rem/sec).

$E\gamma$ = Average gamma energy per disintegration (Mev/dis).

χ= Concentration of gamma emitting isotope in the cloud (Ci/m^3).

However, because of the presence of the ground, the receptor is assumed to be exposed to only one-half of the cloud (semi-infinite) and the equation becomes:

$${}_{\gamma}D' = 0.25E\gamma\chi$$

Where:

${}_{\gamma}D'$ = Gamma dose rate from a semi-infinite cloud (rem/sec).

Thus, in terms of integrated dose, the total gamma dose to an individual located at the center of the cloud path is approximated at:

$$\gamma D = 0.25E\gamma A\chi/Q$$

Where:

γD = Total gamma dose to an individual located at the center of the cloud path (rem).

$E\gamma$ = Average gamma energy per disintegration (Mev/dis)

A = Isotopic activity released (Ci).

χ/Q = Atmospheric diffusion factor at receptor location (sec/m^3).

15.A.4 Thyroid Inhalation Dose

The integrated inhalation dose to the thyroid from a release of activity is approximated by use of the following equation (<hot spots>Reference 5):

${}_{I}D$ = Inhalation dose to the thyroid (rem).

A = Isotopic activity released (Ci).

K = Adult thyroid dose conversion factor for the isotope of interest (rem/Ci).

BR = Breathing rate (m^3/sec)

χ/Q = Atmospheric diffusion rate at receptor location (sec/m^3).

The isotopic data and "standard man" data are given in <hot spots>Table 15.A-2. The atmospheric dilution factors can be used in the analysis of the environmental consequences of accidents are given in <hot spots>Table 15.A-3.

CHAPTER 17 - QUALITY ASSURANCE

NOTE 17.1

Section 17.1 is being retained for historical purposes only.

17.1 INTRODUCTION

South Carolina Electric & Gas Company (SCE&G) recognizes the need for a comprehensive, formalized, documented method of specifying and verifying that the Virgil C. Summer Nuclear Station design, procurement, construction, modification, maintenance, inservice inspection, and operation has been and will continue to be accomplished without undue risk to the health and safety of the public. Cognizant of its responsibilities as an applicant for an operating license, SCE&G has established and will execute an effective Quality Assurance (QA) Program for Virgil C. Summer Nuclear Station which meets the requirements of Title 10 CFR Part 50, Appendix B. The QA Program provides the necessary systematic activity and administrative control to provide checks to assure activities which affect quality and safety-related functions during design, procurement, construction, modification, maintenance, inservice inspection, and operation are performed in accordance with established requirements. The SCE&G QA Program is applied to those items identified as safety-related in Table 3.2-1.

SCE&G also recognizes that in addition to providing a high degree of confidence that structures, systems, and components; as designed, manufactured, constructed, maintained, and modified; reflect all safety-related requirements, the reliability and availability of the plant will be enhanced by the implementation of the Program. The philosophy used in the QA Program development ensures that systems, components, and structures have optimum quality consistent with safety, reliability, and plant availability considerations, as well as consideration for sound engineering.

17.1.1 Quality Assurance During Design, Construction, and Major Modification

The responsibility for the overall nuclear project rests with the SCE&G Executive Vice President Operations. On an independent organizational chain from Production Engineering and Construction, the responsibility for administration of the overall QA Program is delegated to the SCE&G Vice President and Group Executive, Nuclear Operations, who reports to the Executive Vice President Operations. He is assisted in executing this responsibility by the SCE&G Group Manager Nuclear Services, the Manager of QA, Gilbert Associates, Inc. (Gilbert), and other consultants, as needed, who have been or will be retained to implement the QA Program. Westinghouse provides a QA Program on the nuclear steam supply (NSSS) structures, systems, and components. Gilbert provides a balance of plant (BOP) QA Program on safety-related structures, systems, and components not included in NSSS scope. SCE&G, assisted by the Gilbert QA Division and others as agents, audits these programs to assure the effectiveness of the portion of the program performed by Gilbert and Westinghouse. The following sections describe the QA responsibilities and authorities of each major organization during construction and potentially during major outages.

17.1.1.1 South Carolina Electric and Gas Company

The Virgil C. Summer Nuclear Station QA organization chart (Figure 17.1-1) shows the lines of responsibility for design, procurement, construction, and QA for safety-related activities of the Virgil C. Summer Nuclear Station.

The overall responsibility for this nuclear project rests with SCE&G Executive Vice President of Operations. The executive management responsibility for assurance of provision of an adequate QA Program has been assigned to the SCE&G Vice President and Group Executive, Nuclear Operations, who is on an independent organization chain from production engineering and construction. Execution of this responsibility is by the SCE&G Group Manager Nuclear Services with implementation by the Manager of Quality Assurance.

The Gilbert QA Division and other consultants, as needed, have been and are expected to be retained to assist SCE&G QA in auditing the QA Program on the NSSS and safety-related structures, systems, and components. SCE&G QA and/or their agents audit these programs and perform surveillance to verify compliance with and effectiveness of the overall QA Program.

The SCE&G Vice President and Group Executive, Engineering and Construction directs the project construction with the assistance of the Group Manager, Construction and Quality Control, the QC Manager (Construction), and the Nuclear Site Manager. Construction is under the overall supervision of the SCE&G Nuclear Site Manager, with quality control (QC) the responsibility of the SCE&G QC Manager. Both report independently to the Group Manager of Construction and Quality Control.

The SCE&G Vice President and Group Executive, Rates/Purchasing assisted by the General Manager, Purchasing, and the Manager of Production and Construction Purchasing is responsible for procurement of equipment, material, and services.

17.1.1.1.1 Quality Assurance Program Organization

QA Figures 17.1-1 and 17.1-2 show the lines of responsibility for the QA Program. QA activities pertaining to the design, procurement, fabrication, handling, installation, and testing of safety-related structures, systems, and components are carried out in accordance with procedures that have been developed to conform to the 18 criteria as set forth in Appendix B of 10 CFR 50. These procedures are assembled in the SCE&G QA Procedures Manual, the Gilbert QA Manual, the SCE&G QC Manual, the SCE&G Nuclear Engineering Procedures Manual, the SCE&G Purchasing Procedures Manual, the Westinghouse WRD Quality Assurance Plan, the Daniel Construction Company (Daniel) Construction Procedures Manual, the Gilbert Project Management Manual, and vendor and contractor procedures manuals.

The SCE&G QA Program involves personnel from various organizational groups within the company. The general responsibilities of these groups are as follows:

1. Quality Assurance Group

The Group Manager, Nuclear Services provides administrative control and coordination of the role and mission of the QA section. He has the responsibility to evaluate the performance of the QA Program to assure adequacy and allocation of sufficient resources to perform the role and mission. The Group Manager is the link to effective executive corrective action whenever identified. The Group Manager, Nuclear Services through the Vice President Nuclear Operations has the responsibility to identify needed senior management action. The Manager of QA reports to the Group Manager. The Manager of QA is responsible for the direction and implementation of the total QA Program. These responsibilities include:

a. Preparation and revision of the overall QA Program, assisted as needed by the Gilbert QA Division, Westinghouse, each group or organization performing quality activities and/or other agents.

b. Review and approval of the QA Program and associated documents generated by SCE&G and its agents, Gilbert, Westinghouse, Daniel, vendors, and contractors.

c. Review and/or approve revisions to the QA program and associated documents.

d. Schedule, perform, and/or direct performance of audits of SCE&G, its agents, Gilbert, Westinghouse, Daniel, vendors, and contractors; and the surveillance of Daniel, vendors, and contractors.

e. Audit and approve solutions to safety-related interface problems which arise.

f. Monitor the status of the QA Program to assure effective implementation.

g. Identify that appropriate corrective action is taken to accomplish changes where activities do not comply with QA and QC plans or procedures.

h. Stop work on safety-related structures, systems, and/or components when designated codes, standards, design documents, or procedures are not being adhered to and cannot be immediately corrected.

i. Ensure that the collection, distribution, audit, and filing of all project QA records are accomplished in a controlled manner.

j. Notify the Nuclear Regulatory Commission of any significant breakdown in any portion of the QA Program.

k. Provide for the indoctrination, training and certification of SCE&G QA personnel in the performance of activities affecting quality.

Site QA personnel under the direction of the SCE&G QA Director of Surveillance Systems are responsible for surveillance of site quality-related activities including such areas as receiving, handling, site fabrication, installation, construction, and testing. When the scope of work activity during construction or major outage warrants it, a Quality Assurance coordinator may be assigned who reports to the Director of Surveillance Systems.

2. Nuclear Engineering and Licensing Department

   During the Construction phase of the project, the Nuclear Engineering and Licensing Department, under the direction of the Group Manager, Nuclear Engineering and Licensing; who is assisted by the Manager, Nuclear Engineering; the Manager, Nuclear Licensing; the Manager, Independent Safety Engineering Group; and the Manager, Corporate Health Physics and Environmental Programs, has the following responsibilities:

   a. Direct the activities of Gilbert through Gilbert's Project Manager and coordinate the activities of the Gilbert, Westinghouse, Dames and Moore (D&M), and other consultants and agents as needed.
   b. Review and approve basic designs as developed by the Gilbert, D&M, and other consultants.
   c. Review bidder's lists.
   d. Review and approve specifications.
   e. Evaluate vendor proposals and make recommendations for procurement sources.
   f. Participate in, review, and approve the preparation and distribution of the Safety Analysis Reports, Environmental Reports, and other documentation, as required by the Nuclear Regulatory Commission and other regulatory agencies.
   g. Review and approve amendments to the documents noted in item f, above.
   h. Review and approve Field Change Requests and Engineering Change Notices.
   i. Review and disposition Nonconformance Notices.
   j. Prepare bid documents for SCE&G purchases.
   k. Participate in plant testing and acceptance as required.
   l. Participate in the inspection program as required.
   m. Participate in the test control program as required.
   n. Perform functions as required in connection with the licensing of the Virgil C. Summer Nuclear Station.

3. Procurement

   Procurement is the responsibility of the Vice President and Group Executive, Rates/Purchasing who is assisted by the General Manager, Purchasing and the Manager of Purchasing, Production and Construction.

   a. Select qualified bidders with the assistance of engineering, operating, and QA groups.
   b. Solicit bids for equipment, materials, and services.
   c. Submit commercial, QA, and technical evaluations to the SCE&G Purchasing Committee which selects vendors.

d. Issue and control changes to purchase orders.

e. Prepare, in cooperation with the QA and nuclear engineering groups, procurement procedures.

4. Nuclear Site Manager

The SCE&G Nuclear Site Manager has the overall responsibilities for the construction activities performed on the site by Daniel, contractors, and subcontractors. Administratively, the SCE&G Nuclear Site Manager reports to the Group Manager Construction and Quality Control and is responsible for the cost and scheduling of the work done on the site. All work done on the site by the various crafts of Daniel, contractors, and subcontractors is under the jurisdiction of the Daniel Project Manager. The Daniel Project Manager also has the responsibility for compliance with the Daniel QA Manual for Nuclear construction in the fabrication and installation of ASME Code, Section III components. For major modifications, a project manager having the same responsibilities as the Nuclear Site Manager above may be appointed.

5. Quality Control Manager

The SCE&G QC Manager also reports to the Group Manager Construction and Quality Control. The SCE&G QC Manager supervises the QC efforts at the site in accordance with the SCE&G QC Plan. The QC organization performs the following major functions but are not limited to these:

a. Work and communicate with Daniel, Daniel QC and QA, and SCE&G QA groups at the site.

b. Supervise the activities of commercial testing organizations at the site, who are under contract with SCE&G.

c. Prepare QC procedures for inspection of construction activities.

d. Stop work on structures, systems, and/or components when work is not in compliance with specified standards, codes, design documents, or procedures.

e. Be responsible for the testing and inspection of work performed by Daniel, contractors, and subcontractors at the construction site except when QC is provided by Daniel (ASME Code Work), or ASME contractors or subcontractors. SCE&G/QC will be responsible for testing and inspection of piping hangers where the intent of ASME Code requirements is being met.

f. Inspect on receipt, material and equipment for conformity to purchase documents and perform acceptance tests as required except when QC is provided by Daniel (ASME Code work). File test reports, certificates of release, and other documents necessary to verify quality.

g. Perform warehousing functions.

h. Maintain the permanent file for QA records, inspection reports, tests, certificates of release, and other QA documents.

i. Report potentially significant deficiencies found in construction in accordance with approved procedures.

17.1.1.1.2 Lines of Authority and Communication

As noted in Figure 17.1-1, the complex multi-organizational QA Program requires definite lines of authority and communication with control by independent checks. These relationships warrant discussion to illustrate how overall administrative control of the Program by SCE&G is achieved.

1. Overall Project

   The line of authority within the organization clearly provides the flexibility for quality related problems to be identified and resolved. The SCE&G Manager of QA, having a direct line through the Group Manager Nuclear Services to the Vice President Nuclear Operations and the Senior Vice President Power Operations, can inform SCE&G top management of unresolved QA issues.

2. Quality Assurance

   The Vice President and Group Executive, Engineering and Construction is made aware of the QC activities by the SCE&G QC Manager through his line of authority to the Group Manager Construction and Quality Control.

   The QC staff and the independent test laboratories are under the direction and supervision of the SCE&G QC Manager.

   The General Manager, Purchasing, has a direct line of authority through the Vice President and Group Executive, Rates/Purchasing through which the Executive Vice President Finance is kept informed of the status of the purchasing operations. The line of authority extends downward such that the SCE&G Group Manager Nuclear Services monitors and controls the direction of QA activities through the Manager, Quality Assurance, his staff, QA organization onsite, the Gilbert Project Quality Coordinator, and other agents, as needed.

   As can be seen in Figure 17.1-1, there are five key Group Managers (General Managers) within the SCE&G organization who provide the necessary coordination and communication channels to allow information and project status to flow into the QA Program.

   a. The SCE&G manager QA is responsible for the overall functional control of the QA Program and provides guidance and coordination through communications with the Manager, Nuclear Engineering; the Manager, Nuclear Licensing; and the Manager, Purchasing, Production and Construction. The Manager of QA is responsible to review and comment on safety-related (including ASME Code) construction and QC procedures. Audits and site surveillance are performed to assure that safety-related work (including

ASME Code) is accomplished in accordance with the QA Program requirements described herein. This enables the QA functions and responsibilities within the overall administration of the project to be under the guidance and coordination of the SCE&G Manager of QA with the cooperation of SCE&G management. Thus, problem areas anywhere within the QA Program are resolved through the responsible SCE&G management.

b. The Gilbert Project Quality Coordinator provides the SCE&G Manager of QA with a focal point within the Gilbert organization, thus extending the authority and visibility of the QA Program. By communications with Gilbert project engineering and management, as well as Westinghouse and other vendors, the Gilbert Project Quality Coordinator provides the SCE&G Manager of QA with additional information for directing the QA Program.

c. The SCE&G Director of Site Surveillance and/or QA Coordinator, in close cooperation with the Nuclear Site Manager, SCE&G QC Manager, Daniel Project Manager, the Daniel Project Quality Manager (ASME Code work), and other constructor site managers, assures the understanding and implementation of quality associated requirements.

d. The SCE&G Construction QC Manager directs inspection and quality item control activities at the construction site except as defined in item e, below. Reporting offsite to the Manager of Construction and Group Manager Production Engineering, Quality Control and Construction; the SCE&G QC Manager effectively communicates and coordinates quality activities with the Daniel Project Manager and other contractors for effective implementation of the QC Program.

e. The Daniel Project Quality Inspector directs the inspection and QC activities required for the ASME Code work. The Daniel Project Quality Inspector reports to the Daniel Project Quality Manager onsite for effective coordination of ASME Code quality activities.

3. Functional Relationships

The functional relationships within the SCE&G QA Program provide control to assure effective program compliance.

a. Construction site work is verified by inspection performed by the SCE&G QC and Daniel QC Groups (ASME Code work only) or by contractor or subcontractor QC.

b. Site QC and construction activities are monitored by a formal surveillance program conducted by the SCE&G QA organization onsite.

c. Vendors are required to provide internal independent QA Programs to check design and fabrication work unless working under the SCE&G QA Program.

d. Gilbert QA, SCE&G QA, and/or its agents perform vendor audits and surveillance to verify vendor performance.

e. Westinghouse, for the NSSS components, is required to provide an internal QA Program (see Section 17.1.1.3).

f. Gilbert, for design and engineering, is required to provide a Design Control Program including internal audits.

g. SCE&G QA periodically audits Westinghouse, as NSSS supplier, Gilbert as architect-engineer, Gilbert QA Division as QA consultant, Daniel as the constructor, SCE&G QC, and internal SCE&G safety related activities. These or any other contractor or agent utilized during major modification will have equivalent controls imposed.

h. Daniel QA periodically audits the Daniel ASME Code program onsite, as required to maintain the Daniel ASME Certificate of Authorization.

17.1.1.1.3 Control of Contractors

1. General

The Virgil C. Summer Nuclear Station QA Program is effectively administered and controlled by SCE&G through close association with, supervision, and audit of the contractors who perform the duties and tasks outlined and delineated herein. The QA programs of the contractors were reviewed by SCE&G QA and/or its agents to assure that they contained adequate requirements and procedures to control the attainment of quality. All contractors performing safety-related work must have a QA Program reviewed and concurred with by SCE&G QA or its agents; unless the contractors are providing only labor for utilization under the direct control of the SCE&G QA Program. In some cases a contract specific QA plan, jointly approved by SCE&G and the contractor, may be used in lieu of a program manual. Contractors impose on their subcontractors a QA program commensurate with the complexity of the item and its importance to nuclear safety to assure that the high level of quality set forth in the contract documents is maintained.

2. Control Methods

Major responsibilities for implementation of the various QA activities included in the SCE&G QA Program during design, procurement, and manufacturing have been delegated to Gilbert and Westinghouse. These responsibilities are described in the Gilbert QA Plan and in the Westinghouse Electric Corporation Water Reactor Divisions QA Plan (Reference (1)). Primary responsibilities for the construction site QA and QC programs lie with SCE&G QA and the SCE&G QC organizations, respectively. The SCE&G Manager of QA controls, coordinates, and administers the overall QA Program by the use of the following planned and systematic checks of program status and progress:

a. Review and approval of the QA Program of contractors (including the Daniel ASME QA Program).

b. Regular QA Program development and implementation status checks.

c. Scheduled QA Program audits.

d. QA Program surveillance and corrective measures.

17.1.1.2 Gilbert Associates, Inc.

The corporate organizational chart of Gilbert is shown in Figure 17.1-4. In retaining Gilbert, SCE&G has two distinct groups providing professional services in the areas of engineering and QA. Gilbert Power Engineering, Reading, provides the design services of the various engineering departments including, but not limited to, Hydraulic and Civil, Structural, Architectural, Environmental, Mechanical, Electrical, Chemical, and Nuclear. QA services are provided by the Gilbert QA Division as shown in Figure 17.1-5. Gilbert has been retained to provide experienced personnel to assist SCE&G with the overall QA Program. The general responsibilities of the Gilbert Power Engineering, Reading, are described in the Gilbert Project Management Manual and general responsibilities of the Gilbert QA Division are described in the Gilbert QA Plan.

1. Engineering

   Engineering is responsible through the Gilbert Project Manager for the design of all areas of the plant with the exception of the equipment supplied by Westinghouse. The various engineering disciplines are responsible for their respective areas of design and preparation of specifications and drawings. Engineering specifies the level of quality inspection and test requirements, acceptance criteria, and documentation requirements. Any deviation or waiver request from approved drawings, specifications, or procedures must be acted upon by the same (or an SCE&G approved equivalent) engineering group which was responsible for the original design. They also review and approve vendor drawings and documents as appropriate. Design reviews are performed by engineering personnel not responsible for the original design. Design document control is under the control of the Gilbert Project Manager.

2. Quality Assurance

   The Gilbert QA Division and other QA agents or consultants assist the SCE&G Manager QA, as requested, in implementing the QA Program in the areas of specification review, A/E audit, vendor proposal review, NSSS supplier audits, vendor surveillance, and construction audits.

17.1.1.3 Westinghouse Electric Corporation

The Westinghouse QA Plans are given in References 1 and 2. The degree of QA for Westinghouse NSSS components is given in Table 3.2-1.

The original QA Program implemented by Westinghouse for the Virgil C. Summer Nuclear Station was described in Appendix 1C of the Virgil C. Summer PSAR. Over the course of performing the design and initial procurement activities for the Virgil C. Summer Nuclear Station, the Westinghouse QA Program was upgraded to reflect changes in regulatory requirements and industry standards as shown in References 1 and 2. These changes first culminated in WCAP-8370, Revision 7A. This revision of the Westinghouse QA Program was applicable to activities within Westinghouse scope performed for the Virgil C. Summer Nuclear Station which were initiated after January 1, 1975 to October 1, 1977. Subsequently, the present Westinghouse QA Program, which is described in WCAP-8370, Revision 8A, is applicable to activities within

Westinghouse scope which were initiated after October 1, 1977 to October 15, 1979. Presently, the Westinghouse QA Program is described in WCAP-8370, Revision 9, and is applicable to activities within the Westinghouse scope which were initiated after October 15, 1979.

17.1.1.4 Daniel Construction Company

Daniel has been retained by SCE&G as the constructor to perform the actual construction activities at the project site except for specialized phases of the work which will be performed by other qualified contractors and subcontractors. The Daniel organization for the Virgil C. Summer Nuclear Station project is shown in Figure 17.1-6. Daniel is under the direction of the Daniel Project Manager who is responsible to the SCE&G Nuclear Site Manager. Daniel is responsible for the development and implementation of effective controls over the construction and erection of the safety-related structures, systems, and components to assure their conformance to the design specifications and drawings, (including the fabrication and installation of ASME Code work). Daniel responsibilities include:

1. Selection and indoctrination of qualified personnel.
2. Direct supervision of work performed by the crafts.
3. Responsibility for the quality of work done.
4. Scheduling and planning of work.
5. Preparation of construction procedures as indicated in Gilbert construction specifications and as determined to be needed by Daniel construction management to complete a quality installation.
6. Reporting monthly on the status of the construction.
7. Ensuring that only the latest revisions or issues of field documents, i.e., drawings, specifications, procedures, etc., are used for construction.
8. Providing the Daniel QA Program for the Daniel scope of work which includes the Daniel QA Manual for ASME Code work.
9. Providing the QA, QC, and Construction procedures necessary to perform field fabrication and installation of ASME Code stamped work.
10. Regularly review the status and adequacy of the construction QA Program being executed by Daniel.

The Daniel QA Program is contained in the Daniel Construction Procedures Manual and the QA Manual for Nuclear Construction. Work procedures for performing the assigned construction activities are contained in the Daniel Construction Procedures Manual (procedures for ASME Code work are included).

Construction site QC is performed by SCE&G QC and/or its agents for Daniel activities in accordance with the SCE&G QA Plan and Field Quality Control Plan, except for specialized phases of work by other contractors and subcontractors who will perform the required QA and

QC; and the ASME Code work by Daniel who will perform the QA and QC required by the Daniel Certificates of Authorization. The construction site QA is provided by SCE&G QA in accordance with the SCE&G QA Plan and Manual, except as noted above.

17.1.2 Quality Assurance Program

The Virgil C. Summer Nuclear Station QA Program is comprised of planned and systematic activities and independent verification during design, procurement, equipment fabrication, site construction and erection, and system final inspection and testing. This QA Program is organized to provide an integrated plan under the direct control of SCE&G. A system of audit and surveillance provides assurance that elements of the Program are functioning as planned.

17.1.2.1 Applicability

The SCE&G QA Program is applicable to those structures, systems, and components classified as safety-related. These items are identified in Section 3.2. The items identified as within Westinghouse scope of supply are the responsibility of Westinghouse subject to SCE&G audit, assuring appropriate QA measures. The remaining safety-related items are controlled directly by SCE&G, using the assistance of Gilbert, Daniel, and other contractors for construction and installation. The QA Program is in force throughout the design and construction of the Virgil C. Summer Nuclear Station. During future major maintenance or modification, all or parts of the organizational structure shown on Figure 17.1-1 may be employed commensurate with the complexity of the activity. A QA Coordinator reporting to the Director of S. S. may be assigned if the scope of the activity requires dedicated QA follow-up. Agents and/or contractors including those herein discussed may be employed in accordance with QA program requirements herein specified.

17.1.2.2 Administrative Controls

The SCE&G corporate QA policies and procedures are aimed at the goal of obtaining a plant which is safe and reliable in accordance with the requirements of 10 CFR 50, Appendix B. The procedures used in implementing the QA Program incorporate provisions for proceeding to successive levels of management until resolution is obtained, with ultimate resolution by the Executive Vice President, Operations.

The Vice President Nuclear Operations performs a continuing review of the SCE&G QA Program with and through the SCE&G Group Manager Nuclear Services and Manager of Quality Assurance; and reports on the effectiveness of the programs to the Executive Vice President, Operations through the Senior Vice President Power Operations.

The Manager of QA through the SCE&G Group Manager Nuclear Services has been delegated the responsibility for the establishment, maintenance, control, distribution, and verification of implementation of the QA Program by the Vice President and Group Executive, Nuclear Operations. The Group Manager Nuclear Services shall annually, or as deemed necessary, have the SCE&G QA Program reviewed and revised where required. Affected organizations may submit recommended changes as they see fit. Proposed revisions, as a result of the QA review or

recommended changes by others, are submitted to SCE&G groups having responsibilities in the QA Program for comment prior to revision of the Program. Conflicting comments are resolved by the SCE&G Manager of QA with the concerned parties. Revisions affecting Code requirements shall be submitted to the Authorized Inspection Agency for acceptance prior to implementation.

The procedures and instructions which govern the activities of SCE&G in the design and construction of the Virgil C. Summer Nuclear Station are contained in the QA Manual, the Nuclear Engineering Procedures Manual, the QC Procedures Manual, and the Purchasing Procedures Manual. When required by the contract documents, each contractor of safety-related structures, systems, or components is required to develop and implement his own QA Program which is reviewed and audited by SCE&G. Audits of the contractors are conducted by SCE&G or its agents to ensure that the QA requirements are met.

The QA procedures in the area of procurement control require the Manager of QA to evaluate and accept contractor's QA Programs, by review of QA information submittals, review of QA activities on active purchase orders, and, where necessary, preaward surveys of the prospective contractor's QA Program, prior to award of a purchase order. During performance of the contract, SCE&G QA personnel or Gilbert QA personnel, at the request of the SCE&G Manager of QA, will conduct surveillance of the contractor to assure continued implementation of the accepted QA Program. These activities are recorded in surveillance reports, and findings of the reports resolved with the contractors.

QA personnel, in their reviews of programs and special process procedures implementing the QA Program, shall assure that procedures require that all prerequisites for a given action are satisfied, such as the presence and use of suitable equipment (certified or qualified when necessary), a suitable environment for accomplishing the activity, such as adequate cleanliness and lighting levels, and that necessary prerequisites for the activity have been met, e.g., prior specified examinations and processing operations or the establishment of test or inspection acceptance criteria. The QA Program requires that the procedures be prepared and made available for use prior to the need for each at the point of use. These special process procedures controlling safety-related work shall be reviewed and concurred with and a "release to fabricate" or "release to work" (for site activity) granted before work begins in the area, see Section 17.1.7.

17.1.2.3 Indoctrination and Training

The indoctrination and training is described in the indoctrination and training procedures for each organization within SCE&G with quality related responsibilities. The procedures require that personnel be familiar with the requirements of their position, and maintain expertise in their specialty. The SCE&G QA organization conducts a training course in the basics of plant familiarization and QA, with detailed emphasis on the conduct of surveillance and audits, for all personnel in the SCE&G QA organization. Expertise is also maintained by continuing experience in surveillance and auditing on the part of each member of the SCE&G QA organization.

The SCE&G Manager of QA shall have a B. S. Degree in engineering, or its equivalent in experience and/or correspondence courses. He shall be experienced in design, manufacturing, operations, construction, and/or administration in utility or related industries; have at least 1 year

experience in QA management and policies; and be knowledgeable of applicable codes and standards. QA Directors, QA Engineers, and the Site QA coordinator shall be graduates of accredited engineering curricula, or the equivalent, and, preferably, have had experience in the design, manufacturing, operation, construction, or QA areas relative to the nuclear and/or utility fields. QA specialists shall be graduates of a two year engineering technical school or have the equivalent in practical experience and/or correspondence courses.

17.1.3 Design Control

17.1.3.1 South Carolina Electric & Gas Company

During the construction phase, the SCE&G Nuclear Engineering and Licensing Department performs design control functions relative to design interface control, specification, drawing technical reviews, and SAR deviation control. The Nuclear Engineering and Licensing Department's Manager, Nuclear Licensing performs design control functions relative to SAR deviation control. The SCE&G activities are described in the SCE&G Nuclear Engineering Procedures Manual. SCE&G Nuclear Engineering Department monitors; through its reviews of design documents, and SCE&G QA or its agents audits; the design control activities of Gilbert, Westinghouse, and other vendors.

17.1.3.2 Gilbert Associates, Inc.

1. Design Review and Verification

   Safety-related design activity is reviewed and verified by a formalized and documented system described by the Gilbert Project Management Manual. The types of review used are:

   a. Checks to compare information presented on a drawing or other document with a definite, stipulated figure, criterion, or design base,

   b. Supervisory reviews which are critical inspections of design work, conducted by a superior in a given discipline, of work by a project team member in that discipline,

   c. Interface reviews by personnel of one discipline or company of work performed by another discipline or company to determine, with reasonable assurance, that the reviewers discipline requirements are provided for, and that specification requirements are satisfied for the reviewers discipline or company,

   d. Design verification which is independent confirmation of design adequacy and compliance with requirements, performed by an individual other than the originator, who did not perform work on the item being reviewed.

   Each discipline prepares a Design Verification Status Report identifying each item to be verified and indicating the status of each item. System design may be verified in whole or in parts. When in parts, separate verification attestations must be completed and the Design Verification Status Report must define and reflect the verification of each part. Each review and verification must be indicated on the specified form or by signature or reference to the

acceptance letter of the responsible engineering company on the document reviewed. Suitable equivalent controls will also be maintained during major modifications.

2. Specification Reviews

It is the responsibility of the Gilbert Project Engineer to ensure that the necessary QC and QA requirements are included in the specifications for structures, systems, and components for which he has design responsibility. In addition to reviews by SCE&G and other Gilbert design engineers, specifications are reviewed by the Gilbert QA Division and/or the SCE&G QA organization to assure that sufficient quality requirements have been incorporated for safety-related items. Procedures for the review of specifications are contained in the SCE&G QA and Gilbert QA Manuals.

3. Design Requirements Control

Interface and technical reviews are performed by Gilbert Project Engineering, the Gilbert QA Division, and/or the SCE&G QA organization. They also review vendor proposals, bills of material, and vendor and construction procedures to verify consistency with Gilbert procurement specifications. Procedures for these reviews are contained in Gilbert Project Management Manual for Virgil C. Summer Nuclear Station, and the Gilbert QA and SCE&G QA Manuals.

4. Design Document Control

Design documents are controlled as follows:

a. Specifications are issued and controlled from a controlled distribution section which maintains the record copy of specifications and a master distribution list.

b. Drawings are prepared and checked by designers and draftsmen. After review and approval by the Gilbert Project Engineer, they are issued through a central distribution group. Record copies and master distribution lists are used to provide assurance that the latest revisions are promptly forwarded to the proper organizations. Lists of latest available revisions of drawings are furnished to those on distribution lists to ensure that the latest revision is in use.

c. Changes to the SAR requirements are controlled by use of a form which is initiated by the cognizant project engineer. Significant changes and associated justifications are reviewed by the SCE&G Nuclear Engineering and Licensing Department.

d. Significant field or shop changes to drawings and specifications for safety-related equipment are allowed only after approval by Gilbert and/or SCE&G Manager Nuclear Engineering, or his designee. All authorized changes are documented and controlled as described below:

(1) Design initiated changes are accomplished by Engineering Change Notices (ECNs) and are included in the drawings, specifications, and bills of material by subsequent revision. ECNs for specifications and bills of materials are approved by the SCE&G

Nuclear Engineering Department before implementation, unless the ECN is written to implement a previously accepted Field Change Request (FCR), to respond to a letter from SCE&G requesting the change, or to change drawings which did not require original approval by SCE&G.

(2) Field initiated changes are handled by FCRs. A field engineer requests authorization to make a field change from the SCE&G Nuclear Engineering Department. ECNs are distributed as a followup to reflect the field change after acceptance of the FCR by the SCE&G Nuclear Engineering Department. Minor field changes which do not affect the design are documented by the SCE&G QC organization and approved by the resident engineer or SCE&G Nuclear Engineering Department on field prepared "as built documents" (ABDs). Field changes and applicable ABDs are incorporated into revised drawings as directed by the resident engineer or SCE&G Nuclear Engineering Department. FCRs may be authorized by telephone in accordance with approved procedures.

5. Record Accumulation and Control

The records associated with the design activity are maintained by the individual design group. Copies of these records are indexed and stored in a safe Record Retention Storage Area. These records are audited by the Gilbert QA Division, the SCE&G QA organization, and/or its agents.

17.1.3.3 Westinghouse Electric Corporation

The Westinghouse Design Control Program is described in Reference 1 and Section 17.1.1.3.

17.1.4 Procurement Document Control

The procurement of equipment for the Virgil C. Summer Nuclear Station involves activities performed by SCE&G, Westinghouse, and Gilbert. SCE&G makes the final selection of suppliers, except those under Westinghouse scope of supply. Procurement for the remainder of the plant is referred to as BOP. The purchase documents for safety-related equipment include requirements to the extent considered necessary based on safety classification, complexity, and other engineering considerations.

17.1.4.1 NSSS Purchases

NSSS purchases of safety-related structures, systems, and components are controlled under the QA Program described in Reference 1 and Section 17.1.1.3.

17.1.4.2 Balance of Plant Purchases

Safety-related BOP structures, systems, and components are procured by the use of procurement specifications which include QA requirements. Procurement documents require the bidder to have a QA Program which meets the requirements of 10 CFR 50, Appendix B unless working under the SCE&G QA Program, or when the quality of the item to be furnished can be verified by

receipt inspection, testing, or verification by an independent laboratory or performance testing prior to placing the affected system into service. This method is used when nonsafety related items are “upgraded” to safety related application or to confirm the quality of a safety-related commercial grade item. Any such actions will require QA concurrence prior to utilization. Procurement documents may also require the contractor to give the purchaser such rights as: access for inspection and audit, review and concurrence with certain special process procedures or instructions, design drawings and specifications, inspection and test records, and QA documents relative to the purchase.

Selected items; such as commercial items, repair parts, and services; may be procured by SCE&G and by the use of Gilbert or SCE&G prepared bills of material and/or SCE&G purchase requisitions. Applicable QA requirements are included in the contract documents.

For purchases made to Gilbert procurement specifications; proposals for materials, equipment, and services are subjected to a technical evaluation by Gilbert Engineering and/or SCE&G Nuclear Engineering with a QA review by the SCE&G QA organization and/or the Gilbert QA Division. Proposals for purchase from safety-related bills of material or SCE&G purchase requisitions are subject to a technical review by SCE&G Nuclear Engineering with a QA review by the SCE&G QA organization and/or the Gilbert QA Division except for the procurement of QA services. Proposals in this latter category are reviewed by the SCE&G QA organization only. The QA review is based on the requirements of the procurement specification or bill of material to ascertain that the proposed QA Program is adequate. The technical and QA reviews of the proposal request documents assure the inclusion of such requirements as correct and accurate regulatory, code, and design statements; technical and quality document preparation and submittal for review or approval, and the retention, control, and maintenance of the records; and acceptance criteria beyond which the vendor would have to request acceptance by SCE&G. These requirements are placed on the purchase order, including safety-related spares. SCE&G QA concurrence of acceptable bidders must be obtained before a request for proposal can be forwarded to a potential supplier. The bids are evaluated for technical, quality, and commercial acceptability. A preferred bidder is then selected. The preferred bidder must be accepted by SCE&G QA before a purchase order can be placed. The SCE&G QA organization and/or the Gilbert QA Division review available quality history information and QA Program submittals for the preferred bidder to determine whether the bidder is acceptable, and where sufficient QA Program information is not available from these sources, will perform a preaward survey of the preferred bidder’s QA Program, until an acceptable preferred bidder is determined.

For material, equipment, or services purchased from a Gilbert procurement specification; Gilbert prepares a bill of material based on the procurement specification, the successful bidder’s proposal, and any other pertinent documents. The actual provisions of the contract will appear within the bill of material by reference to the specification or incorporation of requirements in lieu of or in addition to the specification within the bill. For material, equipment, or services purchased from a bill of material without a procurement specification, Gilbert conforms the bill of material to the successful bidder’s proposal and other pertinent documents, as necessary. Again, the bill contains the actual requirements in lieu of references to correspondence (pricing excepted). These bills of material are used as contract documents and include technical and quality requirements. The bill of material is attached to the standard contractual provisions and

together they form the purchase order. The bill of material is reviewed and initialed by the SCE&G QA organization and/or the Gilbert QA Division, Gilbert Engineering, and/or SCE&G Nuclear Engineering. The preparation, review, approval, and issuance of bills of material are described in the SCE&G and Gilbert procedures which implement the QA Program.

17.1.5 Instructions, Procedures, and Drawings

Each of the organizations involved in safety-related work on the Virgil C. Summer Nuclear Station has been required to prepare program documents, instructions, procedures, and drawings to describe the work to be accomplished and the method by which the work is to be accomplished. This requirement has been imposed by contractual requirements, as with Westinghouse, or by specifications, as described in Section 17.1.4.

The SCE&G Manager of QA has been assigned the responsibility to review and concur with the QA Programs and associated documents of SCE&G and its agents; Gilbert, Westinghouse, Daniel, vendors, and contractors. The review of documents of vendors and contractors may be assigned to the Gilbert QA Division or any other qualified agent by the SCE&G Manager of QA. The reviews are performed to verify that:

1. Applicable requirements of 10 CFR 50, Appendix B have been included.
2. The plans and associated documents cover the required design, procurement, manufacturing, construction, and testing activities.
3. Adequate internal control methods have been provided for subcontractor activities.
4. Intended specific work functions are identified and established to afford a status check of planned activities, including the determination of that status (acceptance criteria).

17.1.6 Document Control

The procedures for the preparation, review, approval, and distribution of instructions, procedures, and drawings described in Section 17.1.5 require that all specified approvals be obtained prior to the issuance of the documents. These same requirements are imposed on such design and descriptive documents as specifications and SARs. The required reviews and approvals ensure that issued documents are adequate and correct for the use intended. The procedures controlling these documents require review and approval of changes to the documents by the same organizations which approved the original document, or SCE&G approved and designated equivalent.

Specifications are issued and controlled from a controlled distribution section which maintains the record copy of all specifications and a master distribution list.

Drawings are prepared and checked by designers and draftsmen. After review and approval by the project engineer, and/or by SCE&G, they are issued through a central distribution group. Record copies and master distribution lists are used to provide assurance that the latest revisions are promptly forwarded to the proper organizations.

Construction phase changes to the SAR's requirements are controlled by the use of a form which is initiated by the cognizant project engineer. Significant changes and associated justifications are reviewed by the SCE&G Nuclear Engineering and Licensing Department.

Significant field or shop construction phase changes to drawings and specifications for safety-related equipment are allowed only after written approval by the Gilbert Engineer and/or the SCE&G Group Manager, Nuclear Engineering and Licensing, or his designee as described in Section 17.1.3.2.

All construction drawings, procedures, and specifications are issued by the SCE&G Document Control Center, including distribution to Daniel. Construction personnel assigned controlled documents are responsible for maintenance and use of the latest documents as described by construction procedures. Records and reports are developed and maintained as required by construction procedures and are available for review and audit by QA and QC personnel on request.

The issue and control of field construction documents such as working drawings, specifications, procedures, and instructions are controlled in such a manner as to ensure that only the latest revisions or issues of the documents are used for construction and erection. Documents onsite are stamped to identify those being revised, and the area of revision indicated to limit use of the documents until the approved Engineering Change Notice, Field Change Request, or revised document is received. Procedures which control the field or engineering changes ensure that any changes made are properly authorized, documented, and distributed.

Document control within Westinghouse is described in Reference 1 and Section 17.1.1.3.

17.1.7 Control of Purchased Material, Equipment, and Services

The procurement of equipment for the Virgil C. Summer Nuclear Station involves activities performed by SCE&G, Westinghouse, and Gilbert. SCE&G makes the final selection of suppliers, except those under Westinghouse scope of supply. The purchase documents for safety-related equipment include QA requirements to the extent considered necessary based on safety classification, complexity, and other engineering considerations. The Westinghouse control program is described in Reference 1 and Section 17.1.1.3.

17.1.7.1 Construction Phase Source Selection

Upon receipt of bids; the SCE&G QA organization and/or the Gilbert QA Division, SCE&G Nuclear Engineering, and Gilbert Engineering will evaluate the bidder's capabilities, as described in Section 17.1.4. These evaluations are forwarded to the SCE&G General Manager, Purchasing, and used to select a preferred bidder. The SCE&G Purchasing Committee then selects a vendor, and requests concurrence of the SCE&G Manager of QA.

The SCE&G Manager of QA will accept or reject the preferred vendor, on the basis of current QA performance or preaward surveys conducted by the SCE&G organization, the Gilbert QA Division, or other agents, at the direction of the SCE&G Manager of QA when sufficient current

performance information is not available. In some cases, verification of the vendor's QA Program may not be necessary if quality can be verified by receipt inspection, testing, or verification by an independent laboratory or performance testing prior to returning the affected system to service. This method is used when nonsafety related items are "upgraded" to safety related application or to confirm the quality of a safety-related commercial grade item. Any such actions will require QA concurrence prior to utilization. Should the preferred vendor be unacceptable due to a deficient QA Program, the SCE&G Purchasing Committee selects another vendor, and requests concurrence of the SCE&G Manager of QA.

17.1.7.2 Work Release

Vendors or contractors may be required to submit a Contractor's QA Data Identification Report, including a listing of all special process procedures to be used on the contract. In such cases, the vendor must then submit the relevant manufacturing QC, inspection, and test procedures to the owner's QA representative. Fabrication cannot begin until all special process and QC procedures have been reviewed and concurred with, and a Release of Fabrication has been issued by the QA representative. The requirement for submittal of a Contractor's QA Data Identification Report will be determined at the qualification of the vendor.

Similar controls exist for contractors onsite, with the QA Group onsite performing the procedure reviews, and the Director, Surveillance Systems or Site QA Coordinator or their designees issuing a Release to work indicating procedure concurrence and permitting the contractor to begin work.

17.1.7.3 Audit, Surveillance, and Inspection

Regular review of each contractor's QA Program status is accomplished by various techniques depending on the contractor and stage of program implementation. Audits and surveillance of contractors are generally conducted during contract performance to assure that the contractor maintains an acceptable QA Program. These activities assure that control programs and methods are in place throughout performance. The reports of these activities provide a continuing status check to the SCE&G Manager of QA of the contractor's QA capabilities. The frequency of audit and surveillance is determined on the basis of safety classification of the item or service provided, complexity, other engineering considerations, and the current status of the contractor's QA Program, as evidenced by evaluation of the surveillance and audit reports, as well as evaluation of receipt inspections.

The QA specification which is imposed on applicable safety-related vendors requires the vendor to submit a schedule of major events and all inspections and tests for each procurement. A list of suggested inspection notification points is also submitted by the vendor on the Contractor's QA Data Identification Report. The SCE&G QA organization and/or the Gilbert QA Division selects inspection points as notification points, beyond which work may not proceed until acknowledgment of satisfactory notification and issues the list to the vendor. The QA representative performing surveillance for the procurement then either performs physical surveillance of inspection, or waives surveillance by letter or TWX. The list of notification points becomes part of the contractual requirements placed on the vendor.

17.1.7.4 Acceptance

Where required in the contract documents; a vendor of safety-related material, equipment, or services is required to obtain either a Certificate of Inspection (COI), which records physical surveillance of the vendor's final inspection and/or tests, or a Waiver of Inspection (WOI), which records acceptance of the vendor's final inspection and certificate of conformance without physical surveillance. COIs and WOIs are prepared by the SCE&G QA organization and/or the Gilbert QA Division to authorize product shipment. When the requirement exists for a WOI, COI, or Quality Release (in the case of Westinghouse equipment), safety-related hardware cannot be accepted onsite without appropriate documentation.

17.1.7.5 Documentation

When required in the contract documents, a vendor of safety-related material, equipment, or services prepares a Contractor's QA Data Identification Report identifying the documentation to be submitted by the vendor in satisfaction of the purchase order requirements, and submits the report to the SCE&G QA organization and/or the Gilbert QA Division. The SCE&G QA organization and/or the Gilbert QA Division then issues a list of required documentation to the vendor. The identified documentation becomes a part of the contractual requirements for the vendor. Westinghouse forwards the QA data package in support of their Quality Release to SCE&G within 120 days of the final shipment on orders for the Virgil C. Summer Nuclear Station project.

17.1.8 Identification and Control of Materials, Parts, and Components

When required in the contract documents; a vendor of safety-related BOP items is required to establish and maintain an identification system for materials, parts, and components; including partially fabricated assemblies which will assure that identity is maintained on the item or records traceable to the item throughout fabrication and, where required, installation. This identification system is to be capable of preventing the use of incorrect or defective items and verifying that only correct and acceptable items have been used. Each item shipped to the site is to be identified by its bill of material number or other tagging information as specified in the contract documents.

The existence and implementation of such a system is one of the areas covered during preaward evaluation and continuing audits and surveillance of each vendor conducted by the SCE&G QA organization, the Gilbert QA Division, or any other agent of the SCE&G QA organization. The surveillance of each vendor shall be conducted to assure that materials, parts, and components on SCE&G products are identified, and that this identification can be used to verify the correct application of materials, parts, and components for these products.

The Westinghouse program in this area is described in Reference 1 and Section 17.1.1.3.

At receipt onsite, the identification of equipment is verified and maintained by applying an identification tag giving the bill of material numbers, Westinghouse SPIN number, or other suitable identification. This identification tag maintains identification through installation. Control is maintained by the status tags, described in Section 17.1.4, applied by the SCE&G QC

organization. These tags are used to identify equipment in the warehouse area and after installation in the plant prior to startup.

Gilbert has generated an Equipment List, a Valve List, and an Instrumentation List, combining the NSSS and BOP purchase order information, to identify equipment within the Virgil C. Summer Nuclear Station. These lists will be used for control of plant equipment identification during construction.

17.1.9 Control of Special Processes

The control of special processes for NSSS vendors is described in Reference [1] and Section 17.1.1.3.

Vendors of safety-related items are required to identify and submit special process procedures for review and concurrence before use when required. Fabrication may not begin until these procedures have been reviewed and concurred with and the vendor notified of this by the Release of Fabrication Procedures from the SCE&G QA representative. Audits and surveillance of vendors conducted by the SCE&G QA organization, the Gilbert QA Division, or other agents of the SCE&G QA organization will assure that the qualifications of personnel, procedures, and equipment are obtained and maintained, and that documentation of these qualifications is maintained and available. A QA specification identifies the minimum special process procedures to be, as applicable: welding procedures, welding procedure qualifications, nondestructive examination (NDE) procedures, forming and bending procedures, cleaning procedures, heat treating procedures, performance test procedures, hydrostatic procedures, leak test procedures, electrical test procedures, painting procedures, seismic procedure or test results, packaging procedures, storage procedures, shipping procedures, and procedures for verifying wall thickness of pressure boundaries of castings and forgings for valve bodies, pump casings, pipe and pipe fittings, etc.

Special process procedures and qualifications of onsite contractors are subject to review and concurrence by the QA organization onsite. Site contractors may not begin work until the Release to Work has been issued by the Director, Surveillance Systems or the QA Coordinator. During the performance of site work, the Site QA organization performs surveillance to verify proper and complete implementation of the contractor’s special process procedures.

17.1.10 Inspection

17.1.10.1 Vendor Inspection

The control of inspection for NSSS suppliers is described in Reference 1 and Section 17.1.1.3.

Safety-related BOP vendors must satisfy the requirements of QA specifications. The submission of an Inspection Point Program, describing inspections to be performed by the vendor, concurrence with inspection procedures, and establishment of notification points is described in Sections 17.1.7 and 17.1.9. The review of the Inspection Point Plan and inspection procedures includes determination that the inspections are proper and adequate for the type of item and stage

of manufacture or fabrication, to determine that items do or will satisfy the requirement for a quality product, and that direct inspection or indirect process monitoring, or both, are used as necessary to determine quality.

Surveillance and audit of the vendor's QA Program and procedures by the SCE&G QA organization, the Gilbert QA Division, or any other SCE&G QA organization agent assures the existence of program elements requiring qualification or certification of inspectors, the existence and presence of inspection procedures, instructions, and/or drawings necessary to the inspection prior to performance of the inspection, and that items replaced, reworked, modified, or repaired are reinspected by the original inspection procedure or procedures equivalent to the original inspection procedure. Surveillance performed by the SCE&G QA organization, the Gilbert QA Division, or other SCE&G QA organization agents will verify implementation of such requirements. The independence of inspection personnel from those performing the activity being inspected is determined during review and evaluation of the vendor's QA Program at the preaward stage of procurement.

17.1.10.2 Onsite Inspection

Onsite inspection of the performance of contractors is performed by the SCE&G QC Organization, the Daniel QC Group (for ASME Code work), or by contractors or subcontractors. Test laboratories are utilized in the QC programs as needed. These laboratories are under the direction of the SCE&G QC Manager (except as noted below for ASME Code work). The general responsibilities of these laboratories are as follows:

1. Concrete material testing and sampling.
2. Concrete testing and sampling.
3. Soil testing and sampling.
4. Rebar Cadweld testing and sampling.
5. Concrete inspections.
6. Nondestructive examination.
7. Welding inspection.

Specific responsibilities are set forth in the SCE&G QC Manual.

The Onsite Laboratory NDE contractor will perform examinations and inspections required, including those required by Daniel in the fabrication and installation of ASME Code stamped work under the direction of the Daniel Project Quality Manager.

The final acceptance of a completed system, structure, or component is based on the completion of a final inspection. This inspection is performed by the appropriate QC organization in coordination with the QA group. Installation acceptance and release for testing will be made only after final inspection by QC with concurrence of QA.

The Programs of Daniel, site contractors, and the SCE&G QC organization are reviewed and audited by the SCE&G QA organization for the program requirements quoted in Section 17.1.10.1, above. The Site QA Staff reviews and comments on inspection procedures before they are implemented, and performs surveillance on the inspections of Daniel, site contractors, and the SCE&G QC organization to assure that the accepted procedures and instructions are implemented. Reports on the surveillance activities are prepared by QA personnel onsite to apprise the SCE&G Manager of QA of the status of site QC and construction activities.

17.1.11 Test Control

17.1.11.1 Vendor Testing

The control of NSSS supplier testing is described in Reference 1 and Section 17.1.1.3.

As required by contract documents, vendors of safety-related BOP equipment shall submit a schedule of major events and inspections and test within six weeks of the receipt of contract documents. The tests identified on the schedule are those performed to verify conformance to document requirements given in such documents as instructions, procedures, drawings, specifications, etc. The procedures for control of testing are submitted for review by SCE&G and/or Gilbert or other SCE&G agents and are required to describe what testing is to be performed, when tests will be performed, the instructions provided the person performing testing, including the acceptance criteria and tolerances, the personnel qualifications required to perform the test, what special environmental conditions must be provided, if any, and the type of report to be prepared to verify that the test results are acceptable. The procedures are reviewed and concurred with by SCE&G, Gilbert, or other SCE&G agents. Proper performance of tests and test evaluations to the accepted procedures is verified by surveillance of vendor performance and documentation by SCE&G QA, Gilbert QA, or other SCE&G QA agents.

17.1.11.2 Site Testing

Site testing by site contractors is performed to procedures submitted to SCE&G QA organization for review and concurrence as described in Sections 17.1.7 and 17.1.9. These procedures are reviewed to the requirements described in Section 17.1.11.1. Site testing performed by Daniel for ASME Code work is performed under the requirements of the ASME Certificate for Daniel at the site to procedures reviewed and accepted by SCE&G QA organization. The performance of tests is subjected to surveillance by SCE&G Site QA to assure that testing is performed in accordance with the accepted procedures.

The evaluation of onsite testing is conducted by the contractors, SCE&G Nuclear Engineering, and the SCE&G QA organization with technical assistance from Gilbert, Westinghouse, and other contractors and consultants, as necessary to determine that test results are acceptable.

17.1.12 Control of Measuring and Test Equipment

17.1.12.1 Vendor Controls

The control of measuring and test equipment for NSSS suppliers is described in Reference 1 and Section 17.1.1.3.

Vendors and contractors of safety-related materials, parts, components, and services for the Virgil C. Summer Nuclear Station are required to have a program to control measurement, inspection, and test equipment, as required, by the SCE&G QA Program, unless the quality of items furnished can be established by onsite receipt inspection, test, or other methods as indicated in Section 17.1.7.1. The program review and evaluation, surveillance, and audits of each vendor conducted by the SCE&G QA organization, the Gilbert QA Division, or other SCE&G Organization agents assures the existence of an acceptable program. When required by the control document, the following will be defined by the vendor:

1. A listing of measuring and test devices affecting quality that require calibration. Measuring equipment such as steel rules, levels, and similar equipment will not require calibration when their usage does not require a precise degree of accuracy.
2. The method of calibration for each item in the listing specified in item 1 above, including the National Bureau of Standards recognized standard used, for certification of calibrating equipment.
3. The established frequency of calibration.
4. The method of identification for each item under calibration control.
5. The method of determining the calibration status of each item, such as the attachment of a sticker showing the last calibration date, date when due for recalibration, and the person’s stamp, initials, or signature who performed the last calibration.
6. The type of records that will be maintained.
7. The method for determining and recalling equipment when calibration is due.
8. The measures to be exercised when equipment that is out of calibration has been found to have been used to accept parts, components, assemblies, etc.

17.1.12.2 Site Controls

The SCE&G QC Manager is responsible for maintaining the calibration of tools, gauges, instruments, and other inspection, measuring, and testing equipment and devices used by SCE&G onsite in activities affecting quality.

The calibration and control procedure approved by the SCE&G QC Manager assigns each discipline QC Supervisor the responsibility for establishing the criteria and documents required for the procurement of test and measuring equipment relating to his field of work and for assigning qualified personnel to perform calibrations. He is also responsible for developing

checklists or special calibration instructions for all instruments, gauges, tools, and equipment for which special calibration and control is required, and for assigning identifying numbers to equipment that requires calibration, as well as classifying the equipment as to standard or field measurement use, and assigning the frequency of calibration.

QC inspectors are responsible for: applying a calibration tag upon receipt and at recalibration; the accurate calibration of equipment; and inspection of equipment prior to use for damage, proper working order, a current calibration tag, and for proper use of equipment in accordance with procedures or manufacturer's instructions.

The Warehouse Supervisor is responsible for adequate storage facilities until equipment is issued, and for maintaining an issue log for all instruments, gauges, tools, and equipment showing the discipline QC Supervisor to whom the equipment was issued.

The Document Supervisor maintains records of calibration and control of test and measuring equipment by retaining the Calibration Record forwarded to him by the discipline QC Supervisor. The Calibration Record shows identification for each item of equipment, giving the required calibration accuracy, frequency of calibration, and the date of each calibration for an item of equipment.

Standards are purchased from suppliers which can provide certified traceability to the National Bureau of Standards, when possible. When this cannot be done, the discipline QC Supervisor documents the calibration method to be used, justifying its use. The discipline QC Supervisor establishes the frequency at which standards are to be recertified.

Each discipline QC Supervisor maintains a recall system for equipment recalibration.

Additional calibrations are required whenever calibration is suspect, and equipment found consistently out of calibration is repaired or replaced. Out of tolerance equipment may be used temporarily only if correction factors are available and applied. The discipline QC Supervisor approves all such temporary use and documents this use. Accuracy and tolerance of test and measuring equipment shall in no case be of lower order of accuracy than the equipment under test.

Test equipment which is found to be out of calibration during a periodic test is clearly identified as such, and an evaluation is made by the discipline QC Supervisor of the validity of all equipment tests performed with this equipment since its last acceptable calibration.

The QC Group regularly assures that calibration equipment and records are used properly and maintained in good order.

The SCE&G/QA organization performs audits and surveillance of the SCE&G QC organization to assure that the requirements of the QC calibration procedure are followed.

17.1.13 Handling, Storage, and Shipping

17.1.13.1 Vendor Controls

The handling, storage, shipping, cleaning, and preservation control measures used for NSSS suppliers are described in Reference 1 and Section 17.1.1.3.

The handling, storage, shipping, cleaning, and preservation measures of safety-related BOP vendors and site contractors are controlled by the requirements of current QC specifications.

The QA specifications require documented measures for protection of equipment during handling, storage, and shipping, including the use of specific procedures for control of special environmental controls or special handling equipment and verification of conformance to controls. Periodic inspections must be programmed for special handling equipment, as necessary, to ensure safe and adequate handling.

The QA specifications require that each item be identified, marked, and labeled to provide identity of the item and easy identification of special handling and storage requirements.

The documented measures required by the QA specifications must describe:

1. The methods and equipment that will be used for normal handling of items during fabrication, processes, storage, shipping, and installation.
2. The measures that will be utilized to protect items requiring special handling, storage, and shipping techniques.
3. Identification, marking, and labeling methods, i.e., stenciling (steel, paint), tag (metal, other).
4. Measures that will be used to protect identification, marking, and labeling from deterioration and loss of recognition when the method is not a permanent type.
5. Special protective environments that will be used for special products.

In addition, vendor procedures for cleaning, painting, packaging, storage, and shipping are regarded as special process procedures, and controlled as described in Section 17.1.9.

The SCE&G QA organization, the Gilbert QA Division, or other SCE&G QA agents review the QA Program of vendors, and perform audits and surveillance of vendors to ensure the existence and implementation of these requirements. The SCE&G QA organization performs audits and surveillance of site contractors to ensure the existence and application of these requirements.

17.1.13.2 Site Controls

Storage services onsite are provided by the SCE&G QC Group. The QC procedure for storage requires the classification of safety-related items to one of four protection levels provided. These are:

1. Level D includes those items not so sensitive to the environment as Level C (below), which may or may not require some protection against the elements, airborne contamination, and physical and mechanical damage. Level D items are stored outdoors in an area marked and designated for storage.
2. Level C items require protection from exposure to airborne contaminants, the environment, physical damage, and g-forces. Protection from water vapor and condensation may be required, but is not so important as for Level B (below). Level C items are stored indoors or in an environment equivalent to indoors. Temperature control is not required.
3. Level B items are sensitive to environmental conditions and require protection from the effects of temperature extremes in addition to the requirements for Level C, including protection from humidity and vapors. Level B items are stored within a fire resistant, weathertight and well ventilated building or equivalent tear resistant structure. Items are placed to allow air circulation, and temperatures are held within a range of 40°F minimum and 140° maximum.
4. Level A items are those which are exceptionally sensitive to environmental conditions or require special measures for protection from the effects of high or low temperature, sudden temperature changes, humidity and vapors, g-forces, physical damage, and airborne contamination such as rain, snow, dust, dirt, salt sprays, or fumes. Level A items are stored under conditions similar to those for Level B items, with additional requirements such as temperature control within a range of 60°F to 90°C, relative humidity to less than 60 percent, a filtered ventilation system, and other appropriate requirements.

The storage of items is periodically inspected by the SCE&G QC Group to ensure that the storage requirements are being satisfied.

The Constructor and Site Contractors prepare handling instructions for items which require special handling because of weight, size, or fragility. These instructions are reviewed by the SCE&G QA organization to ensure inclusion of quality criteria. The SCE&G QC Group observes these handling operations and the SCE&G QA organization performs surveillance on selected handling operations, to assure that accepted handling procedures and instructions are followed, and to preclude damage to the items handled.

Review of handling procedures and instructions, and inspection of hoisting and rigging equipment, is performed to assure that appropriate equipment and methods are used in handling.

17.1.14 Inspection, Test, and Operating Status

17.1.14.1 Vendor Controls

Requirements for the identification of inspection and test status for NSSS suppliers are described in Reference 1 and Section 17.1.1.3.

The QA specification requires vendors of safety-related items to have, within their material identification and control and nonconformance control programs, identification methods to assure

that only correct and acceptable materials, parts, and/or components are used in the fabrication, assembly, processing, installation, and repair of items. These measures must include provisions for control of nonconforming items to prevent further processing of the item by such methods as segregation, tagging, marking, or other positive means. The SCE&G QA organization, the Gilbert QA Division, or other SCE&G QA agents will review vendors programs and perform audits and surveillance of vendors to assure the existence and implementation of these requirements.

17.1.14.2 Site Controls

The SCE&G QC Group is responsible for applying inspection status tags to items onsite. These tags indicate that an item is accepted, on hold, conditionally accepted, or rejected.

Items with an ACCEPTED or CONDITIONAL tag applied may be installed in plant systems. Items with the CONDITIONAL tag applied are subject to further testing or inspection after issuance from the warehouse. Actions taken on items with a HOLD or REJECTED tag applied are described in Section 17.1.15.

Procedure requirements for identification of operating status for preoperational testing are described in Section 13.5.

The programs and procedures for identification of inspection, test, and operating status onsite are reviewed and commented on by the SCE&G QA organization. The SCE&G QA organization conducts audits and surveillance of onsite records and actions to verify the performance of site organizations to the accepted procedures.

17.1.15 Nonconforming Materials, Parts, or Components

17.1.15.1 Vendor Controls

The requirements placed on NSSS suppliers for control of nonconforming materials, parts, or components are described in Reference 1 and Section 17.1.1.3.

Normally the QA specification requires the vendor to establish documented measures to control items when there is evidence of nonconformance to established requirements, including the identification, documentation, segregation, disposition, and notification of all concerned parties of the nonconforming condition. The only exception is when the contractor is working under the SCE&G/QA Program and the nonconformances are processed in accordance with SCE&G/QA Program. The review of nonconformances and disposition authority must be defined. Dispositions may be; accepted “as is,” repair, rework, or scrap. The measures must include controls to prevent further processing where justified until the disposition has been approved. When the disposition is acceptance “as is”, repair, or rework; the documentation shall verify acceptability and describe the “as built” item. Approval must be obtained from the SCE&G Nuclear Engineering Department and QA organizations, or their agents, whenever the disposition would result in an item which would not satisfy the contract documents. The request for such approval must be in writing to the SCE&G Production Engineering Department, or their agent.

17.1.15.2 Site Controls

At receiving inspection, the QC Inspector will identify those items which do not conform to requirements by placing a HOLD or REJECT tag on the item. REJECT items are removed from the site.

HOLD items are placed in segregated storage when practical, and maintained there until disposition of the nonconformance. Large items, or those which may not practically or physically be segregated, shall have the HOLD tag placed on the item in a conspicuous location.

The QC Inspector or Engineer initiates a Deficiency Notice for the nonconformance or, after consulting the discipline QC Supervisor, a Nonconformance Notice for nonconformances which require SCE&G Production Engineering resolution. Deficiencies are those nonconformances which can be corrected by existing approved instructions or procedures or by replacement of a broken or nonconforming part. The discipline QC Supervisor reviews all Deficiency Notices to determine whether a Nonconformance Notice must be prepared. Deficiency Notices and Nonconformance Notices are distributed to SCE&G QA and other involved organizations.

The QC Inspector or Engineer follows disposition action determined by the discipline QC Supervisor and records the completion of action and acceptance of the item, and replaces the HOLD tag with an ACCEPTED tag or CONDITIONAL tag when further action must be taken after issuance from the warehouse. The completed Deficiency Notice is filed and copies sent to the SCE&G QA organization and other involved organizations.

Nonconformance Notices, except Daniel NCN Bs, are sent to SCE&G Nuclear Engineering for determination of disposition, with copies to the SCE&G QA organization and other concerned organizations. SCE&G Nuclear Engineering determines disposition for the nonconformance and forwards the disposition to the SCE&G QC Group for action. SCE&G Nuclear Engineering evaluates the nonconformance to determine whether it should be considered a potential significant deficiency, and be processed by the applicable Nuclear Engineering procedure.

Comments on the nonconformance are obtained from the SCE&G QA organization and a disposition prepared on the Nonconformance Notice. The disposition may involve acceptance “as is”, repair, rework, or direction to classify the item REJECT. Disposition action will be directed by SCE&G Nuclear Engineering. The SCE&G QC Group, and the SCE&G QA organization, under direction of the Director of Surveillance Systems or the QA Coordinator, follow-up on corrective action and assure that the QC Inspector or Engineer completes the disposition action portion of the Nonconformance Notice, documenting the final condition of the item, and forwards the form to the Document Supervisor for retention in the files.

Minor civil, mechanical, and electrical construction items which do not comply with the design documents but do not affect the design of the structures, systems, or components may be documented on “As-Built Documents” (ABDs). ABDs are filed with the associated quality records, and may be incorporated into drawing revisions as described in Section 17.1.3.2.

The discipline QC Supervisors analyze the logs of Deficiency Notices and Nonconformance Notices to determine whether any trend exists or any correction should be made to construction or QC procedures, and reports on this analysis quarterly to the SCE&G QC Manager.

Conformance to the SCE&G QC and SCE&G Nuclear Engineering procedures for the control of nonconformances is assured by audit and surveillance by the SCE&G QA organization and the Site QA organization.

17.1.16 Corrective Action

17.1.16.1 Vendor Controls

The corrective action controls for the NSSS supplier are described in Reference 1 and Section 17.1.1.3.

The QA specification requires vendors of safety-related items to have corrective action measures to assure that conditions adverse to quality are promptly identified, documented, and corrected. The only exception is when the contractor is working under the SCE&G/QA Program and the corrective measures are accomplished in accordance with the SCE&G/QA Program. These measures must identify the responsibilities for identification of the need for corrective action, and the preparation and approval of corrective action. The cause of the detrimental condition must be determined. When the corrective action is taken to preclude repetition of significant nonconforming conditions, the corrective actions must be monitored to assure that the corrective actions are effective. Guidelines for determining the need for corrective action must be given in the measures, and management distribution for notification identified.

The SCE&G QA organization, the Gilbert QA Division, or other SCE&G QA agents evaluate the vendor’s QA Program to ensure the existence of adequate corrective action measures, and perform surveillance of the vendors to ensure the implementation of these measures.

17.1.16.2 Site Controls

The SCE&G QA organization conducts audits and surveillance of organizations and contractors performing safety-related actions, and prepares reports on these audits and surveillances. Whenever a condition is discovered which indicates a significant omission of controls in an approved QA Program, or a deficient QA Program, a Corrective Action Request (CAR) is issued. The CAR must be acknowledged by the responsible individual and corrective action initiated to correct the condition.

The SCE&G Site QA staff also reviews Nonconformance Notices, Deviation Notices, and ABDs; and evaluates and examines the trend analysis data gathered by the SCE&G QC Group described in Section 17.1.15.2 to determine the existence of conditions significantly adverse to quality requiring the issuance of a CAR.

The SCE&G QC Group and the Site QA staff follow the implementation and effectiveness of corrective action.

SCE&G has established a Field Review Board and assigned it prime responsibility for identification and follow-up onsite corrective action.

The Field Review Board is composed of the SCE&G QC Manager as chairman, the SCE&G Nuclear Site Manager, the Daniel Project Manager, the Daniel Project Quality Manager (for ASME Code activities), SCE&G Group Manager, Nuclear Engineering and Licensing, the SCE&G Manager of QA, and the SCE&G Group Manager Production Engineering QC and Construction or their designee as permanent members. Other temporary members may be included to lend technical support as the need arises. Each permanent member designates a replacement to act in his stead in the case he is absent.

The Field Review Board reviews major Deficiency and Nonconformance Notices, change requests, stop work orders, and SCE&G QA Corrective Action Request, as deemed necessary by its members, and quality trend analyses. Through review of these documents, overall site quality performance is evaluated. Requests for corrective action are made for the purpose of improvements to construction and quality control operations.

The SCE&G QC Group ensures implementation of Field Review Board specified corrective action. The SCE&G QC Group also conducts trend analyses of deficiencies and nonconformances for presentation to the Field Review Board, as described in Section 17.1.15.2.

17.1.17 Quality Assurance Records

17.1.17.1 Vendor Records

The program for control of QA records for NSSS suppliers is described in Reference 1 and Section 17.1.1.3. In addition, the data packages in support of the Westinghouse Quality Release are forwarded to SCE&G for retention and storage at the Virgil C. Summer Nuclear Station.

The QA specification requires vendors of safety-related items to submit a list of required documentation as a part of the Contractor’s QA Identification Report. The SCE&G QA representative then prepares the list of minimum required documentation based on this submission and transmits it to the vendor for compliance. The required documentation package is forwarded to SCE&G for retention and storage at the Virgil C. Summer Nuclear Station.

The following are examples of the minimum records to be forwarded to the owner:

1. NDE reports.
2. Material test reports (shall be available for review prior to fabrication).
3. Final inspection reports/certificates.
4. Performance test reports.
5. Code data inspection reports.
6. Hydrostatic and leak test reports.

7. Electrical test reports.
8. Design changes/specification deviation requests.
9. Radiographs.
10. Weld maps and joint history records.
11. Verification of wall thicknesses.

The vendor's inspection and test procedures must require documentation of results and acceptability, identification of the inspector or data recorder, the type of observation performed, action taken to resolve nonconforming conditions, and the indexing of the documents for ready retrieval. Data related to the qualification of personnel, procedures, and equipment used to perform special processes is a part of the vendors records. Document packages bear identification of the owner (SCE&G), the owner's purchase order number, and the station name. The vendor must provide secure and fire-resistive or other acceptable storage for the nonreplacable records.

When required by contract documents, the data packages forwarded to SCE&G by the vendors will include, in addition to QA records specified in procurement packages, a certificate of conformance, a Certificate of Inspection or Waiver of Inspection provided by SCE&G QA or its agent and an index of the required documentation, and the documentation.

The existence of requirements for these actions is verified by audit, and their implementation by surveillance by the SCE&G organization, the Gilbert QA Division, or other SCE&G agents, and by audits of data packages onsite conducted by the Site QA organization.

17.1.17.2 Site Controls

The preparation and retention of documents onsite is controlled by the QA specification for site contractors and the SCE&G QA Plan and SCE&G QC Procedures. The requirements for inspection and test document preparation are as given in Section 17.1.17.1, above.

During the construction phase, the SCE&G QC Group maintains the Plant Numerical Records System, which is the permanent file for QA records at the Virgil C. Summer Nuclear Station. Complete records are maintained covering all aspects of QC activity. Inspection reports, fabrication and test procedures, radiographs and other nondestructive examination test reports, and any other documentation as required by applicable procedures, specifications, codes, and standards are retained and handled in accordance with written procedures. Receiving record reports, documentation packages, and other records are placed in the permanent QA file where they are available for record, information, and QA audit. The storage area affords protection against destruction or deterioration caused by fire, water, humidity, temperature, tornadoes, insects, and rodents as required by the QA and QC procedures and all records are required to be indexed for proper placement and ready retrieval. Access to the permanent files is controlled by the SCE&G QC Group through the site Documents Supervisor, who controls access to the records vault and files.

The SCE&G QC Group inspects equipment data packages against the package index before placement in the Plant Numerical Records System, and directs indexing and placement of the package. The SCE&G QA organization audits these records to assure that data packages are correct and complete.

SCE&G has prepared a Records Accumulation and Retention Chart giving the retention period for plant records by the type of record, and the SCE&G QC procedure for record filing and retention requires that the retention requirements be adhered to. The Chart is revised as necessary to assure adequate identification, accumulation, and retention of records.

The SCE&G QA audits the site records filing and retention function to assure conformance to the SCE&G QC procedures on QA record filing and retention.

17.1.18 Audits

The overall SCE&G Audit Program is composed of two sources of input, surveillances and audits. In the SCE&G program, an audit is normally a broad based multi Appendix B criteria programmatic evaluation which considers “could it work” system functionality. Surveillance is normally much narrower in scope (one or several criteria) and is deeper penetrating into examining sufficient evidence of actual work activity (in-process or documentation) to confirm satisfactory results. Extensive system surveillance (system attribute and type II) provides a much sharper, more detailed conclusion of the implementation status and adequacy of any QA program provided that a series of surveillance is evaluated to cover all applicable criteria. A lead auditor is able to judge QA program compliance and adequacy by a thorough evaluation of surveillance report, corrective action, followup, and quality history. In the most positive case, a combination of surveillances may confirm adequacy and implementation of a complete QA program therefore may, upon evaluation and documentation by a certified lead auditor, preclude the need for audit. In the most negative case, the evaluation will identify to the lead auditor where further audit activity should be concentrated.

17.1.18.1 Internal Audits

The internal audit program of Westinghouse is described in Reference 1 and Section 17.1.1.3.

The Gilbert Design Control Program includes procedures requiring audits of each Project Engineer, Project Management, and the Service Department, using the Gilbert QA Division as a consultant to the Gilbert Utilities Division. These audits are conducted across all Project lines to assure that the Design Control Program is operating successfully. Audits are conducted in accordance with the Gilbert QA Manual procedures with formal written reports transmitted to Department Heads for resolution, with copies to the Engineering Manager and Project Manager involved. The Departmental Head response is transmitted to the QA Audit Team Leader for evaluation. When necessary to assure that adequate action is taken in response to audits, reaudit is scheduled during subsequent design control audits.

The SCE&G QA organization conducts audits/surveillances of the SCE&G activities affecting quality to assure compliance with the SCE&G QA Plan, the QA Manual, the Nuclear Engineering

Procedures Manual, the Purchasing Procedures Manual, the SCE&G Site QC and Inspection Plan, and the Field QC Procedures Manual. These audits/surveillances are scheduled to cover each area of SCE&G performing safety-related work annually, or as frequently as deemed necessary to ensure that policies and procedures are effective.

The QA specification requires all vendors of safety-related materials, equipment, or services to conduct audits to determine the effectiveness of the vendor's QA Program. A description of the following is required of each vendor:

1. The criteria for determining when and at what frequency audits will be performed,
2. The system that will be used to conduct the audits,
3. How the audit findings, corrective actions, and results will be documented and to whom they will be distributed, and
4. The titles and duties of persons having responsibility for the audit.

17.1.18.2 External Audits

The audit program for suppliers of NSSS materials, equipment, or services is described in Reference 1 and Section 17.1.1.3.

Safety-related BOP purchases are made by SCE&G purchase order, and each vendor of safety-related materials, equipment, or services is required to have a QA Program consistent with the complexity and importance of the materials, equipment, or services to be provided. The SCE&G QA organization, or the Gilbert QA Division or other SCE&G QA agents, conducts audits of each of these vendors to assess their program, and evaluates the capability of their vendor evaluation programs, including the audits conducted by the vendors.

The SCE&G QA organization conducts audits and surveillance of vendors of safety related materials, parts, components, and services to verify continuing existence of an acceptable QA program. The audits and surveillances are conducted and reports are forwarded to the management of the vendor for response to the deficiencies identified during the audit, and to concerned management within SCE&G. The frequency of audits and surveillance is commensurate with the item or service to be provided. Each vendor which is required to have formal written QA program will be audited at least once during the performance of his work and vendors performing work over an extended period of time will be evaluated at least annually and audited on a triennial basis. Sufficient system surveillance or other inspection, testing, and verification defined in 17.1.7.3 will be performed to satisfy the intent of and preclude the need for audit, when properly evaluated and documented by a certified lead auditor.

The SCE&G QA organization, or the Gilbert QA Division as agent for the SCE&G organization, conducts audits of Westinghouse WRD to determine the effectiveness of the NSSS QA Program. The SCE&G QA organization audits Gilbert to determine the effectiveness of the Gilbert QA Program for BOP design.

Personnel from the Gilbert QA Division, acting through the Gilbert Project Quality Coordinator, may participate in or conduct these audits as agents of the SCE&G QA organization.

The SCE&G QA organization also audits the Gilbert QA Division and Gilbert Project Quality Coordinator to assure that the requirements of the Gilbert QA Program are being applied as described in the Gilbert QA Plan for the SCE&G project.

17.1.18.3 Audit Requirements

SCE&G conducts audits under the following requirements, and requires its agents, the NSSS supplier, contractors, and vendors to have an audit program applying similar requirements, consistent with the complexity and importance of the materials, equipment, or service being provided.

In all cases, audits are performed by a group which does not have direct responsibility for the area being audited. Audits are conducted in accordance with established procedures by appropriate individuals with the necessary education, training, and experience. The areas of design, procurement, shipping, storage, installation, manufacturing, and construction are audited for conformance to previously established QA requirements which have an effect on product quality. Audits include a review of completed and accepted operations, a review of documentation and records, and an evaluation of the adequacy and effectiveness of QA Program systems. Procedures for audits to be performed by the SCE&G QA organization are contained in the SCE&G QA Manual.

When required to fully assess a preferred bidder’s QA Program, a pre-award survey is conducted to determine whether the bidder has an effective QA Program. Audits of each vendor or contractor are conducted as frequently as necessary during the term of a contract to determine that an effective QA Program is being applied. The frequency of audits is scheduled commensurate with the item or service being provided and the vendor history of supplying quality related items or services.

An SCE&G QA Procedure provides guidelines and a format for the preparation of reports on audits conducted by SCE&G QA personnel. Program audit results are reported to the management of the organization being audited and to SCE&G QA management. The organization’s QA management in cooperation with SCE&G QA management takes appropriate action to ensure corrective action when it is required. The SCE&G QA organization reviews and analyzes pertinent quality assurance reports and data submitted for information by contractors and reports generated by agents of the SCE&G QA organization.

Similar controls on the preparation of audit reports and the forwarding of reports to management are required of vendors and contractors.

CHAPTER 18 - AGING MANAGEMENT PROGRAMS AND ACTIVITIES

18.0 AGING MANAGEMENT PROGRAMS AND ACTIVITIES

18.1 INTRODUCTION

South Carolina Electric & Gas Company prepared an Application for a Renewed Operating License of the Virgil C. Summer Nuclear Station (Application) (Reference 1). The application, including information provided in additional correspondence, provides sufficient information for the NRC to complete their technical and environmental reviews and provides the basis for the NRC to make the findings required by 10 CFR 54.29 (Final Safety Evaluation Report – Final SER) (Reference 2). Pursuant to the requirements of 10 CFR 54.21(d), the FSAR supplement for the facility must contain a summary description of the programs and activities for managing the effects of aging and the evaluation of time-limited aging analyses for the period of extended operation determined by 10 CFR 54.21 (a) and (c), respectively.

Table 18.1-1 provides a summary listing of the aging management programs and activities required for license renewal. Furthermore, Table 18.1-2 provides a summary listing of the evaluations of time-limited aging analyses (TLAA) required for license renewal. The first column of Table 18.1-1 and Table 18.1-2 provides a listing of aging management programs/activities and TLAA evaluations respectively. The second column of each table indicates where the issue is addressed in the Application. The third column of each table identifies where the description of the program/activity or TLAA is located in the Virgil C. Summer Nuclear Station FSAR.

The implementing documents are subject to administrative controls, including a formal review and approval process, and are implemented in accordance with the requirements of 10 CFR 50, Appendix B, “Quality Assurance Criteria for Nuclear Power Plants and Fuel Reprocessing Plants”, and ANSI/ASME NQA-1-1994, “Quality Assurance Requirements for Nuclear Facility Applications”, as committed to in the FSAR. The confirmation process is part of the Aging Management Program implementing procedures and the Corrective Action Program, which are implemented in accordance with the requirements of 10 CFR 50, Appendix B, “Quality Assurance Criteria for Nuclear Power Plants and Fuel Reprocessing Plants”, and ANSI/ASME NQA-1-1994, “Quality Assurance Requirements for Nuclear Facility Applications”, as committed to in the FSAR. The aging management activities required by this program would also reveal any unsatisfactory condition due to ineffective corrective action.

The implementing documents are subject to administrative controls, including a formal review and approval process, are implemented in accordance with the requirements of 10 CFR 50, Appendix B, “Quality Assurance Criteria for Nuclear Power Plants and Fuel Reprocessing Plants”, and ANSI/ASME NQA-1-1994,“Quality Assurance Requirements for Nuclear Facility Applications”, as committed to in the FSAR.

For all programs a condition evaluation report (CER) is generated to provide a thorough description of identified aging problems along with a disposition specifying the corrective action(s). The VCSNS Corrective Action Program is utilized to provide specific corrective and confirmatory actions. Engineering reviews the inspection results for completeness and

acceptability. The corrective action processes ensure that degraded conditions are tracked and corrected in a timely manner. Engineering reviews the previous inspection reports to ensure implementation of recommended corrective actions and to determine their effectiveness. The license renewal programs and inspections are implemented in accordance with station procedures and work processes controlled by the quality assurance requirements of 10 CFR Part 50 Appendix B.

Table 18.1-1
Summary Listing of the Aging Management Programs and Activities

Program/Activity	Application Location	FSAR Location
10 CFR 50 Appendix J General Visual Inspection	B.1.11	18.2.1
10 CFR 50 Appendix J Leak Rate Testing	B.1.12	18.2.2
Above Ground Tank Inspection	B.2.1	18.2.3
Alloy 600 Aging Management Program	B.1.1	18.2.4
ASME Section XI ISI Program - IWF	B.1.13	18.2.5
Battery Rack Inspection	B.1.14	18.2.6
Boric Acid Corrosion Surveillances	B.1.2	18.2.7
Bottom-Mounted Instrumentation Inspection	B.1.3	18.2.8
Buried Piping and Tanks Inspection	B.2.10	18.2.9
Chemistry Program	B.1.4	18.2.10
Containment Coating Monitoring and Maintenance Program	B.1.15	18.2.11
Containment ISI Program – IWE/IWL	B.1.16	18.2.12
Diesel Generator Systems Inspection	B.2.2	18.2.13
Environmental Qualification (EQ) Program	B.3.1	18.2.14
Fire Protection Program (including Mechanical, Fire Barriers and Fire Barrier Penetration Seals, and Fire Doors activities)	B.1.5	18.2.15
Flood Barrier Inspection	B.1.17	18.2.16
Flow-Accelerated Corrosion Monitoring Program	B.1.6	18.2.17
Non-EQ Insulated Cables and Connections Inspection Program	B.2.9	18.2.18
In-Service Inspection (ISI) Plan	B.1.7	18.2.19
Inspections for Mechanical Components	B.2.11	18.2.20
Liquid Waste System Inspection	B.2.3	18.2.21
Maintenance Rule Structures Program	B.1.18	18.2.22
Material Handling System Inspection Program	B.1.19	18.2.23
Pressure Door Inspection Program	B.1.20	18.2.24

Reactor Vessel Neutron Embrittlement – Pressure-Temperature (P-T) Limits	4.2.3	18.3.1.3
Service Water Intake Structure Settlement	4.7.3	18.3.6.2

18.2 AGING MANAGEMENT PROGRAMS AND ACTIVITIES

The programs and activities described in the subsequent sections are credited for the management of aging under all current licensing basis conditions. Evaluation of the programs and activities provides reasonable assurance that subject systems, structures, and components are capable of performing their intended function(s) under all current licensing basis conditions. Aging management is provided through activities such as continued monitoring and assessment of conditions, trending and/or through control of system/structure parameters to preclude degradation. Under certain circumstances, one-time inspections are performed to ascertain plant conditions and/or confirm that degradation is not occurring.

Herein, the names of the programs, or activities are used only in the context of aging management during the period of extended operation and do not necessarily align with existing formalized VCSNS programs and/or procedures. The program and activity names used in this Application are intended to describe the collection of activities that are necessary to effectively manage aging.

18.2.1 10 CFR 50 Appendix J General Visual Inspection

Prior to conducting a 10 CFR 50 Appendix J Type A Integrated Leak Rate Test (ILRT), a general visual structural examination of the containment system is conducted. The general visual examination satisfies Technical Specification surveillance requirement 4.6.1.6.3. The inspection manages loss of material, cracking of welds, deformed structural attachments, and surface discontinuities associated with the containment liner, deterioration of moisture barriers, and deterioration of the Reactor Building structure.

18.2.2 10 CFR 50 Appendix J Leak Rate Testing

10 CFR 50 Appendix J Leak Rate Tests are required by Technical Specifications Surveillance Requirement 4.6.1.2. Type A and Type B Leak Rate Tests are performed as described further in FSAR Section 6.2.6. The testing program consists of monitoring of leakage rates through containment liner/welds, penetrations, fittings and other access openings for detection of degradation of the containment pressure boundary.

18.2.3 Above Ground Tank Inspection

The Above Ground Tank Inspection is a new one-time inspection activity intended to determine if aging management is required for the internal surfaces of certain tanks and associated components (including pipe and valves) during the period of extended operation. The Above Ground Tank Inspection was created to detect and characterize loss of material due to galvanic and general corrosion in locations with exposure to ambient air conditions, loss of material due to general corrosion in locations with exposure to treated water in which dissolved oxygen levels are not controlled, and loss of material and/or cracking due to the corrosive effects of alternate wetting and drying of treated or borated water. The Above Ground Tank Inspection used suitable examination techniques at the most susceptible (sample) locations, including visual and volumetric techniques. It was concluded, based on the results of the one-time inspection program,

that additional aging management is not required during the period of extended operation for the Above Ground Tank Inspection.

18.2.4 Alloy 600 Aging Management Program

The purpose of the Alloy 600 Aging Management Program is to manage primary water stress corrosion cracking (PWSCC) of nickel-based alloy (Alloy 600 and 82/182) subcomponents of the reactor vessel, pressurizer, and steam generators that are exposed to borated water to ensure that the pressure boundary function is maintained during the period of extended operation. The Alloy 600 Aging Management Program includes elements of the Boric Acid Corrosion Surveillances and the ASME Section XI System Pressure Test Program, which detect the presence of system leakage, and the ASME Section XI In-service Examination Program, which specifies the NDE techniques and acceptance criteria applied to the evaluation of identified cracks.

18.2.5 ASME Section XI ISI Program - IWF

The ASME Section XI Subsection IWF In-service Inspection (ISI) Program manages loss of material for ASME Class 1, 2, and 3 piping supports (not including shock suppressors) and ASME Class 1, 2, and 3 major equipment supports for the period of extended operation. The ASME Section XI ISI Program - IWF was developed to implement the applicable requirements of 10 CFR 50.55a in accordance with ASME Section XI, Subsection IWF. The Subsection IWF scope of inspection for supports is based on sampling of the total support population. The inspection program includes periodic volumetric, surface and/or visual examination of component supports for signs of degradation and provides for corrective actions.

18.2.6 Battery Rack Inspection

The regulatory basis for inspecting battery racks is found in Technical Specifications Surveillance Requirement 3/4.8.2.1.c for the Electrical DC System. A visual inspection for loss of material due to corrosion is conducted for the Electrical DC System, in accordance with commitments in FSAR Section 8.3.2.2.2. A similar examination is conducted for the Fire Service System.

18.2.7 Boric Acid Corrosion Surveillances

The purpose of the Boric Acid Corrosion Surveillances is to manage loss of material due to boric acid corrosion of mechanical and structural components constructed of susceptible materials located in the Reactor Building and in specific areas of the Auxiliary, Intermediate, or Fuel Buildings where borated water leakage is possible. The Boric Acid Corrosion Surveillances also manage boric acid intrusion into electrical equipment located in proximity to borated water systems. Elements of the Boric Acid Corrosion Surveillances include the identification of leakage locations, procedures for locating small leaks, and corrective actions to ensure that boric acid corrosion does not lead to degradation of structures and components that could cause loss of intended function.

The Boric Acid Corrosion Surveillances program relies on implementation of Nuclear Regulatory (NRC) Generic Letter (GL) 88-05, as well as subsequent NRC bulletins and guidance, to monitor

the reactor coolant pressure boundary for borated water leakage. As a result of guidance in NUREG-1801, the program also includes monitoring for borated water leakage in all systems containing borated water.

18.2.8 Bottom-Mounted Instrumentation Inspection

The purpose of the Bottom-Mounted Instrumentation Inspection is to identify loss of material due to fretting (wear) in the bottom mounted instrumentation (BMI) thimble tubes prior to leakage in order to preclude a breach of the reactor coolant pressure boundary. Suitable inspection techniques are utilized and trended. The frequency of examination is based on wear rate relationships developed from Westinghouse research data.

18.2.9 Buried Piping and Tanks Inspection

The purpose of the Buried Piping and Tanks Inspection is to manage loss of material on the external surfaces of buried components. The conditions of coatings and wrappings are determined by visual inspection whenever buried components are excavated, such as for maintenance. Degraded coatings or wrappings are indicative of potential surface corrosion of the external piping or tank surfaces and require further evaluation.

18.2.10 Chemistry Program

The Chemistry Program controls the water chemistry in plant systems to minimize contaminant concentrations and adds chemicals, such as corrosion inhibitors and biocides, to manage loss of material, cracking, and fouling. The Chemistry Program is based on Electric Power Research Institute (EPRI) guidelines for water chemistry, specifically, Pressurized Water Reactor Primary Water Chemistry Guidelines, Pressurized Water Reactor Secondary Water Chemistry Guidelines, and Closed Cooling Water Chemistry Guideline. The Chemistry Program includes specifications for chemical species, limits, sampling and analysis frequencies, and corrective actions for primary, secondary, and auxiliary (borated or treated) water systems, as well as for oil and fuel oil.

Chemistry one-time inspections were also completed for low-alloy/carbon steel, stainless steel, and copper/copper alloy components to determine if aging management is required during the period of extended operation. The Chemistry one-time inspections were performed to detect and characterize loss of material due to crevice, pitting, general and galvanic corrosion and stress corrosion cracking. The inspections used a combination of volumetric and visual examination techniques at the most susceptible (sample) low-flow locations. It was concluded, based on the results of the one-time inspection program, that additional aging management is not required during the period of extended operation for the Chemistry Program.

18.2.11 Containment Coating Monitoring and Maintenance Program

The Containment Coating Monitoring and Maintenance Program provides for maintenance of protective coatings inside the containment. Maintenance of protective coatings manages loss of material due to corrosion. Visual inspections and condition assessments of certain coatings inside containment are periodically conducted as part of the containment structural integrity verification,

Maintenance Rule monitoring, general maintenance planning, and during recovery from refueling outages. Containment coatings are visually inspected via walkdowns from accessible floors, platforms or other permanent vantage points. The degree of examination depends on many factors such as accessibility, environmental and radiological conditions, and safety. In cases of inaccessibility, sampling approaches based on plant specific characteristics, industry wide experience and testing history are evaluated in lieu of actual visual inspections. Further discussions relevant to containment coatings is located in FSAR Appendix 3A (RG 1.54) and FSAR Section 6.2.1.6.

18.2.12 Containment ISI Program - IWE/IWL

10CFR 50.55a(g)(4) requires a detailed visual examination of the containment system for structural anomalies in accordance with ASME Section XI Subsection IWE, “Requirements for Class MC and Metallic Liners for Class CC Components for Light- Water Cooled Plants”, and Subsection IWL, “Requirements for Class CC Concrete Components of Light-Water Cooled Power Plants” throughout the service life of nuclear power plants.

The VCSNS inspection program includes periodic visual examination of liner and concrete surfaces for signs of degradation and provides for corrective action. The CISI Program is conducted in accordance with the requirements of ASME Section XI, Subsections IWE and IWL, as modified by NRC rulemaking to 10CFR50.55a (initially published in the Federal Register on August 8, 1996). Consult the CISI Program Plan, ISE-4, for current CISI interval and ASME code information.

18.2.13 Diesel Generator Systems Inspection

The Diesel Generator Systems Inspection is a new one-time inspection activity intended to determine if aging management is required for certain carbon steel diesel generator support system components during the period of extended operation. The Diesel Generator Systems Inspection was created to detect and characterize loss of material due to general corrosion and/or corrosive impacts of alternate wetting and drying in pertinent starting air and exhaust air components. The Diesel Generator Systems Inspection used suitable examination techniques at the most susceptible (sample) locations, including visual and volumetric techniques. It was concluded, based on the results of the one-time inspection program, that additional aging management is not required during the period of extended operation for the Diesel Generator Systems Inspection.

18.2.14 Environmental Qualification (EQ) Program

The NRC has established environmental qualification (EQ) requirements in 10 CFR 50.49 and Appendix A (Criterion 4) to 10 CFR Part 50. EQ component aging limits are not based on condition or performance monitoring. However, such monitoring programs are an acceptable basis for modifying aging limits. Monitoring or inspection of environmental, condition, or component parameters may be used to ensure that the component is within its qualification, or to provide a basis to modify the qualification analyses. The EQ Program quantifies the plant service conditions (i.e., the operating environments) for defined environmental zones, such that the

severity of the aging effects (in comparison to other plant locations) can be determined. Further discussion of the EQ Program is contained in FSAR Section 3.11 and Appendix 3A (RG 1.89).

18.2.15 Fire Protection Program

The Fire Protection Program utilizes the concept of defense-in-depth to achieve a high degree of fire safety as discussed in Section 9.5.1. The Fire Protection Program provides administrative requirements for ensuring the operability of equipment required to ensure safe plant shutdown. The program includes visual inspections, system flushing, and performance tests of fire barriers, fire doors, and fire suppression system components. As described in Section 9.5.1, the Fire Protection Program includes the requirements 10 CFR 50.48 (c), which endorses, with exceptions, the National Fire Protection Association's (NFPA) 805, "Performance-Based Standard for Fire Protection for Light Water Reactor Electric Generating Plants, 2001 Edition." Additional description of the portions of the program pertinent to the management of aging is provided below.

18.2.15.1 Mechanical

The Fire Protection Program includes the performance of flow tests and flushes to ensure that blockage of flow will not occur, performance testing of individual components to ensure they maintain their component intended function, and visual inspections to verify sprinkler and associated component condition. Fire suppression system components (e.g. piping, valves, nozzles, sprinkler heads, hydrants) are included within the scope of the mechanical inspections and tests. The normal Fire Service System pressure is monitored to provide further indication of the ability to maintain system function. Flow tests and flushes are conducted on the main distribution loops via hydrant testing. Performance testing is conducted on selected Fire Service System components based on NFPA recommendations. Visual inspections of Fire Service System components (e.g. sprinklers, hydrants, above ground piping) are periodically conducted to identify corrosion on the exterior surface, physical damage or obstructions that might impede performance of the intended functions.

In addition, disassembly/replacement of representative sprinkler heads in branch lines that do not receive flow during periodic testing is to be conducted in accordance with NFPA standards. Ultrasonic testing of a representative sample of these stagnant section of piping will to be conducted at 10-year intervals. The initial implementation of ultrasonic testing was completed in 2021, prior to the period of extended operation.

A one-time inspection of the Fire Service System will be performed to determine if aging management is required for brass and cast iron components during the period of extended operation. The inspection activity will detect and characterize loss of material due to selective leaching. This inspection will use suitable hardness measurement techniques at the most susceptible (sample) locations.

18.2.15.2 Fire Barriers and Fire Barrier Penetration Seals

The fire barrier inspection program requires periodic visual inspection of fire barrier penetration seals, fire dampers, and fire barrier walls, ceilings, and floors to ensure that their operability is maintained.

18.2.15.3 Fire Doors

Fires rated door inspections are performed. Examination guidelines and results of periodic inspections of fire rated doors are provided. Inspections are credited with managing loss of material of doors and door hardware for the period of extended operation.

18.2.16 Flood Barrier Inspection

Periodic visual inspections are performed for flood barriers (walls, curbs, equipment pedestals), flood doors, and flood barrier penetration seals. The Flood Barrier Inspection activity is a subset of the Maintenance Rule Structures Program and the Fire Protection Program. The inspections serve to detect cracking and loss of material prior to loss of component intended function.

18.2.17 Flow-Accelerated Corrosion Monitoring Program

The purpose of the Flow-Accelerated Corrosion Monitoring Program is to manage loss of material for components located in systems within the scope of license renewal which are susceptible to flow-accelerated corrosion (FAC) (also called erosion-corrosion). The FAC program is also responsible for managing material loss due to Erosive wear due to Liquid Droplet Impingement (LDI), Cavitation, Flashing, and Solid Particle Erosion via the Erosion program. This program consists of (a) conducting appropriate analysis and baseline inspections, (b) determining the extent of thinning and replacement/repair of components, and (c) performing follow-up inspections to confirm or quantify and take long-term corrective actions. The program relies on implementation via EPRI Guidelines, NUREG guidelines, and applicable station and industry OE.

18.2.18 Non-EQ Insulated Cables and Connections Inspection Program

The Non-EQ Insulated Cables and Connections Inspection Program provides the inspection of accessible cables and connections including splices, terminal blocks and fuse holders that are found susceptible to potential degradation in adverse thermal and radiological areas of the plant. Accessible areas for cable and connection inspections were defined as those that can be approached and viewed easily. Those located in vaults or manholes were not considered accessible and therefore not within the scope of these inspections. While certain areas of the Intermediate and Auxiliary Buildings will be the focus, there will be flexibility to inspect cables and connections in a variety of Environmental Zones as determined by the responsible Electrical Engineering group at VCSNS. The program will be performed at 10-year intervals. The initial inspections were completed in 2017 (inside the Reactor Building) and 2018 (outside the Reactor Building), prior to the period of extended operation. In addition to the visual inspections of in-scope passive fuse holders, the metallic fuse clip portion that are found to be susceptible to age

related degradation will receive a continuity check or will undergo thermography or other appropriate tests on a representative sample basis to assure the metallic fuse clips are still making good connections. The visual inspections will assess the accessible cables to determine if the cable jackets show any signs of cracking, embrittlement, discoloration, crazing, melting, or any other visible evidence of age-related degradation which might indicate loss of insulation resistance.

18.2.19 In-Service Inspection (ISI) Plan

The In-Service Inspection (ISI) Plan implements the requirements of 10 CFR 50.55a for Class 1, 2 and 3 components is in accordance with ASME Section XI, Subsections IWB (Class 1), IWC (Class 2), and IWD (Class 3). The program consists of periodic volumetric, surface, and/or visual examination of components for signs of degradation and provides for corrective actions. The examinations are performed to the extent practicable within the limitations of design, geometry, and materials of construction of the component. The period of extended operation for VCSNS will contain the fourth, fifth, and sixth ten-year in-service inspection intervals. The program is addressed further in FSAR Section 5.7.

18.2.20 Inspections For Mechanical Components

The Inspections for Mechanical Components manage loss of material and cracking for mechanical components constructed of susceptible materials and exposed to ambient conditions. The inspections involve a visual examination of the exposed external surfaces of representative mechanical components. The inspections and associated evaluations also address conditions in locations susceptible to external pitting corrosion due to the presence of insulation materials and the potential for condensation to occur.

18.2.21 Liquid Waste System Inspection

The Liquid Waste System Inspection is a new one-time inspection activity intended to determine if aging management is required for certain stainless steel pipe, valves and heat exchanger components during the period of extended operation. The Liquid Waste System Inspection was created to detect and characterize loss of material due to crevice and pitting corrosion, and cracking due to stress corrosion cracking in systems and components containing unmonitored and uncontrolled water. The Liquid Waste System Inspection used a combination of volumetric and visual examination techniques at the most susceptible (sample) locations. It was concluded, based on the results of the one-time inspection program, that additional aging management is not required during the period of extended operation for the Liquid Waste System Inspection.

18.2.22 Maintenance Rule Structures Program

The Maintenance Rule Structures Program for the inspections of structures and structural components meets the regulatory requirements of 10 CFR 50.65, the Maintenance Rule. This program is implemented in accordance with NUMARC 93-01, Rev. 4F and Regulatory Guide 1.160, Rev. 4. Visual inspections and condition assessments of structures and structural components are conducted in accordance with the requirements of the Maintenance Rule. These

inspections include penetrations and associated piping at structural interfaces, which may be subject to degradation mechanisms (including microbiologically induced corrosion). The structures and structural components are visually inspected via walkdowns from accessible floors, platforms or other permanent vantage points. In cases of inaccessibility, sampling approaches are evaluated. The Maintenance Rule Structures Program includes chemical analysis of raw water (groundwater and Service Water Pond) per the Maintenance Rule intervals in support of condition assessment.

18.2.23 Material Handling System Inspection Program

The Material Handling System Inspection Program manages loss of material for applicable steel rails and girders. The Material Handling System Inspection Program has been in effect for many years at VCSNS and includes Nuclear Safety Related and Quality Related (seismically restrained) material handling system components. Material handling systems steel support structures (rails, runways, monorails, girders, jib cranes, seismic restraints, and associated connections) are inspected in accordance with guidance provided by ANSI standards. Inspections are implemented in the course of routine maintenance.

18.2.24 Pressure Door Inspection Program

The Pressure Door Inspection Program provides examination guidelines for periodic inspections of pressure doors. VCSNS pressure doors are Nuclear Safety Related or Quality Related. Most Nuclear Safety Related pressure doors are also fire doors. Pressure door inspection attributes include freedom of movement, function (closed during normal plant operation), structural deterioration, and loss of door/door hardware material. Pressure doors are required to be operable in Plant Operating Modes 1, 2, 3, and 4. The surveillance requirements include monitoring of door position and visual inspection that the door is closed and not impaired.

18.2.25 Preventative Maintenance Activities - Ventilation System Inspections

The Preventive Maintenance Activities – Ventilation Systems Inspections manage loss of material and fouling in susceptible components. Susceptible components include those components in the Air Handling, Local Ventilation and Component Cooling Systems that are exposed internally to ambient air. Routine maintenance inspections are conducted which include detection of age-related degradation.

18.2.26 Reactor Building Cooling Units Inspection

The Reactor Building Cooling Units Inspection is a new one-time inspection activity that will determine if aging management is required for reactor building cooling unit drain lines during the period of extended operation. The Reactor Building Cooling Unit Inspection will detect and characterize loss of material or cracking resulting from exposure to an unmonitored and uncontrolled (alternately wetted/dried) water environment. The Reactor Building Cooling Unit Inspection will use volumetric and/or visual examination techniques at the most susceptible (sample) locations in the reactor building cooling unit drain lines.

18.2.27 Reactor Vessel Closure Studs Program

The purpose of the Reactor Head Closure Studs Program is to manage loss of mechanical closure integrity due to stress relaxation, stress corrosion cracking, and wear for the alloy steel components of the reactor vessel closure stud assembly. The In-Service Inspection (ISI) Plan portion of the Reactor Head Closure Studs Program detects cracking and loss of material through the use of surface examination (magnetic particle or liquid penetrant) and/or ultrasonic examination. Reactor vessel studs may be examined in place (under tension), when the connection is disassembled, or when the studs are removed. Further discussions of the inspection and protection of reactor vessel closure stud assemblies is contained in FSAR Section 5.4.

18.2.28 Reactor Vessel Internals Inspection

The Reactor Vessel Internals Inspection (RVI) supplements the In-Service Inspection (ISI) Plan to assess the condition of reactor vessel internals in order to ensure that the intended functions are maintained during the period of extended operation. The RVI Program fulfills the NEI 03-08 requirements to implement MRP-227, Pressurized Water Reactor Internals Inspection and Evaluation Guidelines and MRP-228, Inspection Standards for PWR Intervals. The RVI Program also incorporates applicable NEI 03-08 Interim Guidance requirements. The inspection provides examination techniques and engineering evaluations to address the aging effects listed below:

- Changes in dimensions due to irradiation creep and void swelling
- Cracking due to irradiation-assisted stress corrosion cracking
- Cracking due to primary water stress corrosion cracking (PWSCC) for nickel-based materials
- Loss of material due to wear
- Loss of preload due to stress relaxation
- Reduction of fracture toughness due to irradiation embrittlement and void swelling

For those components that are accessible or can be rendered accessible by the removal of the core and other internals for examination, a visual inspection is performed to detect the presence and extent of cracking and loss of material. For bolts and for inaccessible components, a volumetric inspection is performed to detect the presence and extent of changes in dimensions, cracking, loss of preload, and reduction of fracture toughness. With respect to changes in dimensions due to void swelling, industry activities (including WOG and EPRI) are under way to better characterize the effect and, if necessary, to develop and qualify methods for detection and management. These activities will be monitored by VCSNS and implemented, as applicable.

18.2.29 Reactor Vessel Surveillance Program

The purpose of the Reactor Vessel Surveillance Program is to manage reduction of fracture toughness due to irradiation embrittlement of reactor vessel beltline materials to assure that the pressure boundary function is maintained for the period of extended operation. The program includes an evaluation of radiation damage based on testing of Charpy V-notch and tensile specimens. The Reactor Vessel Surveillance Program conforms to 10 CFR 50, Appendix H. Further discussions of this program are contained in FSAR Section 5.4.3.

Additionally, a one-time demonstration was performed to ensure that materials in the upper shell/nozzle course of the Reactor Vessel would not become limiting during the period of extended operation, with respect to radiation damage.

18.2.30 Service Air System Inspection

The Service Air System Inspection is a new one-time inspection activity intended to determine if aging management is required for certain carbon steel pipe and valves during the period of extended operation. The Service Air System Inspection was created to detect and characterize loss of material due to general corrosion on internal surfaces of subject components resulting from exposure to moist air. The Service Air System Inspection used a combination of volumetric and visual examination techniques at the most susceptible (sample) locations. It was concluded, based on the results of the one-time inspection program, that additional aging management is not required during the period of extended operation for the Service Air System Inspection.

18.2.31 Service Water Pond Dam Inspection Program

The purpose of the Service Water Dam Inspection Program is to assess the condition of the Service Water Pond Dams and the West Embankment with respect to loss of material (erosion), alignment (movement), surface cracking and seepage(1) that could result in loss of component intended function. This program is based on the recommendations of Regulatory Guide 1.127, Rev. 1. Additionally, the submerged slope stability of the West Embankment in the vicinity of the Intake Structure is monitored as specified by VCSNS Operating License Number NPF-12, Condition 2.C.5. Dominion Energy South Carolina (DESC) also conducts annual walkdowns of the Service Water Pond Dams scheduled in the course of routine maintenance. A visual inspection of the North Berm and piezometer monitoring of accessible piezometers on the North Dam and West Embankment are both performed on 5 year intervals.

18.2.32 Service Water Structures Survey Monitoring Program

Survey monitoring is required for structures that are supported by earthen fill material and which have exhibited the potential for settlement. Settlement is not considered to be adverse unless it imposes stresses on a structure that could exceed the design values. Initial settlement of the Service Water Pumphouse and Service Water Intake Structure was much more than the original pre-construction estimates. As a result, survey monitoring of the Service Water Pumphouse, Service Water Intake Structure, Electrical Duct Banks, and Service Water Intake Line “A” is conducted to satisfy the requirements specified by Operating License Condition 2.C.5 and FSAR Section 2.5.4.10.6.2. The purpose of the surveys is to monitor and evaluate any differential in vertical and horizontal displacement in order to identify settlement issues prior to their resulting in significant degradation or loss of function.

---

(1) In accordance with Service Water Pond Dam Inspection Program implementing procedures, seepage monitoring is performed only in the event that the Monticello Reservoir is drawn down below elevation 415.0 feet. Seepage monitoring is not performed during normal plant conditions.

18.2.33 Service Water System Reliability and In-Service Testing Program

The purpose of the Service Water System Reliability and In-Service Testing Program is to manage cracking, fouling, and loss of material for susceptible materials located in systems that contain raw water from the Service Water Pond. The Service Water System Reliability and In-Service Testing Program is intended to detect the presence of and assess the extent of cracking, fouling and loss of material. The program also serves to mitigate aging effects through the use of chemical additives in order to minimize fouling. Visual inspections of Service Water System piping and components are conducted on a periodic basis to monitor the extent of cracking, fouling, and loss of material. The heat transfer capabilities of heat exchangers serviced by the Service Water System are evaluated to detect the presence of fouling.

18.2.34 Small Bore Class 1 Piping Inspection

The Small Bore Class 1 Piping Inspection is a new one-time inspection activity intended to determine if aging management is required for cracking due to flaw growth and stress corrosion cracking for Reactor Coolant System stainless steel piping and fittings less than four inches NPS. The Small Bore Class 1 Piping Inspection serves to increase confidence in the current condition of small bore Reactor Coolant System piping which does not receive a volumetric examination per the ASME Code. The Small Bore Class 1 Piping Inspection used suitable volumetric examination techniques at the most susceptible (sample) locations. It was concluded, based on the results of the one-time inspection program, that additional aging management is not required during the period of extended operation for the Small Bore class 1 Piping Inspection.

18.2.35 Steam Generator Management Program

The purpose of the Steam Generator Management Program is to perform examinations to ensure that cracking and loss of material of nickel-based alloy steam generator tubes and tube plugs are identified and corrected prior to exceeding allowable limits. The program implements the requirements of Technical Specification 4.4.5 for tube inspections. Other components, in addition to tubes, are inspected under this program. The program follows the recommendations provided by NEI 97-06 and associated EPRI guidelines for Steam Generator component inspections and chemistry controls.

18.2.36 Tendon Surveillance Program

The Tendon Surveillance Program meets the requirements of 10CFR50.55a(b)(2)(viii) and, as incorporated by reference therein, the requirements of ASME Section XI, Subsection IWL. The tendon lift-off forces are evaluated to ensure that the rate of tendon force loss is within predicted limits and that a minimum required tendon force level exists in the Reactor Building. Degradation of the Reactor Building post-tensioning system is detected by periodic inspections of randomly selected tendons. Further discussion pertinent to tendon stresses is contained in FSAR Section 3.8.1.5.1.2 and Regulatory Guide 1.35.1 (see Appendix 3A).

18.2.37 Thermal Fatigue Management Program

As defined for license renewal, the Thermal Fatigue Management Program seeks to preclude cracking due to low-cycle thermal fatigue by managing the thermal fatigue basis. Management of the fatigue basis is accomplished by continually showing that the severity and number of occurrences of the actual transients are enveloped (bounded) by the severity and number of occurrences of the analyzed transients. The program documents and evaluates plant operational transients/cycles using a specially designed computer program. The evaluation process includes comparison of the number of thermal cycles incurred against the design transient limit and/or calculation of cumulative usage factors (CUF) and verification that adequate margin exists. The Thermal Fatigue Management Program will incorporate applicable industry guidance once it is finalized to account for environmental effects of the reactor coolant fluid.

18.2.38 Underwater Inspection Program (SWIS and SWPH)

Underwater inspections of the Service Water Intake Structure are conducted and the conditions assessed in accordance with the requirements of VCSNS Operating License NPF-12, Condition 2.C.5.d. The purpose of the inspection is to monitor the condition of existing cracks in the Service Water Intake Structure that originated due to greater than expected settlement of the structure. Underwater inspections of the Service Water Intake Structure and the Service Water Pumphouse also serve to monitor corrosion and fouling within the Service Water System.

18.2.39 Waste Gas System Inspection

The Waste Gas System Inspection is a new one-time inspection activity intended to determine if aging management is required for certain stainless steel components of the Gaseous Waste Processing System during the period of extended operation. The Waste Gas System Inspection was created to detect and characterize loss of material due to crevice and pitting corrosion in portions of the system exposed to unmonitored and uncontrolled treated water, and cracking due to stress corrosion cracking in portions of the system containing gas. The Waste Gas System Inspection used a combination of volumetric and visual examination techniques at the most susceptible (sample) locations. It was concluded, based on the results of the one-time inspection program, that additional aging management is not required during the period of extended operation for the Waste Gas System Inspection.

18.2.40 Heat Exchanger Inspection

The Heat Exchanger Inspection is a new one-time inspection activity intended to determine if aging management is required for certain malleable heat exchanger components during the period of extended operation. The Heat Exchanger Inspection was created to detect and characterize loss of material due to selective leaching and erosion-corrosion, as well as particulate fouling. The Heat Exchanger Inspection used a combination of volumetric and visual examination and hardness measurement techniques at the most susceptible (sample) locations.

Selective leaching was identified as part of the program during original license renewal scoping; however, it was later determined to no longer be an applicable aging effect since there were no in

scope susceptible components (i.e., no copper/copper alloy/brass components with >15% zinc). It was concluded, based on the results of the one-time inspection program, that additional aging management is not required during the period of extended operation for the Heat Exchanger Inspection.

18.2.41 Preventative Maintenance Activities - Terry Turbine

The purpose of the Preventive Maintenance Activities - Terry Turbine is to manage loss of material in carbon steel due to general corrosion of the turbine casing and associated components in the steam inlet and exhaust paths that are normally exposed to ambient conditions with periodic exposure to steam allowing moisture to accumulate. The Preventive Maintenance Activities - Terry Turbine is a condition monitoring program composed of controlled plant procedures. Routine maintenance inspections are conducted which include detection of age-related degradation and initiation of corrective actions as necessary.

18.2.42 Area Based Inspections For Refined 10CFR 54.4(A)(2) Criteria

The Area Based Inspections for Refined 10 CFR 54.4(a)(2) Criteria is a new one-time inspection activity intended to determine if aging management is required for components that have an anti falldown requirement during the period of extended operation. The Area Based Inspections for Refined 10 CFR 54.4(a)(2) Criteria detects and characterizes loss of material or cracking resulting from exposure to an unmonitored and uncontrolled water environment. The Area Based Inspections for Refined 10 CFR 54.4(a)(2) Criteria uses a combination of volumetric and visual examination techniques at the most susceptible (sample) locations in the piping in carbon steel piping anti falldown systems with uncontrolled water, including reinspection of five (5) locations in Sewer and Miscellaneous Drain piping to trend wall thickness to further ensure intended function is not challenged during the period of extended operation.

18.2.43 Aging Management Program For Electrical Cables and Connections Not Subject To 10CFR50.49 Environmental Qualification Requirements Used In Instrumentation Circuits

The “Aging Management Program for Electrical Cables and Connections Not Subject to 10CFR50.49 Environmental Qualification Requirements Used in Instrumentation Circuits” provides for reasonable assurance that the intended functions of electrical cables and connections that are not subject to the environmental qualification requirements of 10 CFR 50.49 and are used in instrumentation circuits with sensitive, low-level signals exposed to adverse localized environments caused by heat, radiation or moisture will be maintained consistent with the current licensing basis through the period of extended operation. In this aging management program, calibration results or findings of surveillance testing programs are used to identify the potential existence of aging degradation. This program applies to the in scope instrumentation cables and connections that are included in the circuit during loop calibrations.

This program will be implemented as appropriate at least once every 10 years. The initial implementation was completed in 2018 and 2019, prior to the period of extended operation.

18.2.44 License Renewal Aging Management Program For Non-EQ Electrical Cables and Connections Used In Instrumentation Circuits

High-range-radiation and neutron flux monitoring instrumentation cables and connections used in high voltage, low-level signal applications that are sensitive to reduction in insulation resistance for which calibrations are performed without the cable and connections in the “loop calibration” circuit will be subject to the “License Renewal Aging Management Program for Non-EQ Electrical Cables and Connections Used in Instrumentation Circuits”. In this program, an appropriate test, such as an insulation resistance test, will be used to identify the potential existence of a reduction in cable insulation resistance (IR). This program is an acceptable alternative to aging management program 18.2.43.

This program will be implemented at least once every 10 years. The initial implementation was completed in 2021, prior to the period of extended operation.

18.2.45 Aging Management Program For Inaccessible Medium-Voltage Cables Not Subject To 10CRFR50.49 Environmental Qualification Requirements

The purpose of this aging management program is to provide reasonable assurance that the intended functions of inaccessible medium-voltage cables that are not subject to the environmental qualification requirements of 10 CFR 50.49 and are exposed to adverse localized environments caused by moisture while energized will be maintained consistent with the current licensing basis through the period of extended operation.

In this aging management program periodic actions are taken to prevent or minimize the possibility that cables may be exposed to moisture, such as inspecting for water collection in cable manholes and conduit, and draining water, as needed. In-scope, medium-voltage cables exposed to moisture and significant voltage are tested to provide an indication of the condition of the conductor insulation. The initial baseline cable testing was completed in 2012 and 2014 for in-scope circuits associated with Service Water Pump Motor power cables ESM191A and ESM221B, respectively. Initial testing frequency was established to occur at 10 year intervals, thereafter, in accordance with NUREG-1801 Rev.0 XI.E3. However, this frequency has since been changed to 6 years to align with the station’s response to NRC Generic Letter 2007-01, Inaccessible or Underground Power Cable Failures That Disable Accident Mitigation Systems or Cause Plant Transients, captured under RC-07-0074 and NUREG-1801 Rev. 2 XI.E3.

18.2.46 Neutron Absorbing Material Monitoring Program

The Neutron Absorbing Material Monitoring Program is an aging management program based on the guidance in NUREG-1801 Revision 2, XI.M40, Monitoring of Neutron-Absorbing Materials Other than Boraflex. The purpose of the program is to assure that degradation of the neutron-absorbing material used in spent fuel pool storage racks that could compromise the criticality analysis will be detected prior to loss of intended function. The program relies on periodic inspection, testing, monitoring, and analysis of the criticality design to assure that the required sub-criticality margin is maintained during the license renewal period of extended operation. The

program complies with the requirements of Generic Letter 2016-01, Monitoring of Neutron-Absorbing Materials in Spent Fuel Pools.

18.3 TIME-LIMITED AGING ANALYSES (TLAA) EVALUATIONS

As part of the application for a renewed license, 10 CFR 54.21(c) requires that an evaluation of time-limited aging analyses (TLAAs) be provided for the period of extended operation. The following TLAAs have been identified and evaluated to meet this requirement.

18.3.1 Reactor Vessel Neutron Embrittlement

The reactor vessel is subjected to neutron irradiation from the core. This irradiation results in the embrittlement of the reactor vessel materials. Analyses have been performed that address the following:

- Upper-Shelf Energy
- Pressurized Thermal Shock
- Pressure-Temperature (P-T) Limits

18.3.1.1 Upper-Shelf Energy

The requirements on reactor vessel Charpy upper-shelf energy are included in 10 CFR 50, Appendix G. The Charpy upper-shelf energy must be maintained at no less than 50 ft-lb. throughout the life of the reactor vessel.

The upper shelf energy (USE) for VCSNS reactor vessel materials have been estimated for the end of the 60 year period of extended operation, 56 Effective Full Power Years (EFPY). The estimates were made using Figure 2 from Regulatory Guide 1.99, Revision 2, the estimated fluence and chemistry of the materials and the Charpy test data from surveillance capsules. The fluence projections were obtained from WCAP-16298-NP, Revision 0, “Analysis of Capsule Z from the SCE&G V. C. Summer Radiation Surveillance Program”, August 2004. The USE values are developed in WCAP-16306-NP, Revision 0, “Evaluation of Pressurized Thermal Shock for V. C. Summer”, August 2004, at ¼ the reactor vessel wall thickness. The calculated USE values for the limiting reactor vessel material is above 50 ft-lb for 56 EFPY.

18.3.1.2 Pressurized Thermal Shock

The requirements of 10 CFR 50.61 provide rules for protection against pressurized thermal shock events for pressurized water reactors. The screening criteria established by 10 CFR 50.61 are 270°F for plates, forgings, and axial weld materials and 300°F for circumferential weld materials. According to 10 CFR 50.61, if the calculated reference temperature (RT_{PTS}) for the limiting beltline materials is less than the specified screening criteria, then the vessel is acceptable with regard to the risk of vessel failure during postulated pressurized thermal shock transients. The regulations require updating the pressurized thermal shock assessment upon a request for a change in the expiration date of the facility operating license.

The RT_{PTS} values for VCSNS have been calculated for the end of the 60 year period of extended operation, 56 EFPY. The projected RT_{PTS} values are based upon surveillance capsule data. The

last capsule removed from the reactor vessel was exposed to a neutron fluence estimated to be equivalent to that exposed to the vessel wall at the end of 60 years. The RT_{PTS} fracture toughness of the reactor vessel beltline region has been evaluated according to the requirements of the Pressurized Thermal Shock (PTS) rules of 10 CFR 50.61. Using the PTS rules and surveillance capsule data, the evaluation is documented in WCAP-16306-NP, Revision 0, “Evaluation of Pressurized Thermal Shock for V. C. Summer “, August 2004. This evaluation shows maximum calculated RT_{PTS} values at 56 EFPY for the most limiting plate/axial weld and for the most limiting circumferential weld to be well below the screening criteria of 270° F and 300° F, respectively, as specified in the PTS rule.

18.3.1.3 Pressure-Temperature (P-T) Limits

Appendix G to 10 CFR 50 requires that heatup and cooldown of the reactor pressure vessel shall be accomplished within established pressure-temperature limits. The pressure-temperature limits are established by calculations that utilize the materials and fluence data obtained through the site reactor surveillance capsule program. Normally, the pressure-temperature limits are calculated for several years into the future and remain valid for an established period of time not to exceed the current operating license term.

Pressure-temperature limit curves have been developed for 56 EFPY in WCAP-16305-NP, Revision 0, “V. C. Summer Heatup and Cooldown Limit Curves for Normal Operation”, August 2004, that corresponds to the end of the 60 year extended operational period. These curves are based upon data from the last capsule removed from the reactor vessel which was exposed to a neutron fluence estimated to be equivalent to that exposed to the vessel wall at the end of 60 years. The Technical Specification has been updated to include these curves as required by 10 CFR 50. Therefore, the curves that are now in the Technical Specifications are valid for the period of extended operation.

18.3.2 Metal Fatigue

The thermal fatigue analyses of the station’s mechanical components have been identified as time-limited aging analyses.

18.3.2.1 ASME Boiler and Pressure Vessel Code, Section III, Class 1

The ASME Boiler and Pressure Vessel Code, Section III, Class 1 requires a design analysis to address fatigue and to establish limits such that the initiation of fatigue cracks is precluded.

Experience has shown that the transients used to analyze the ASME III requirements are often very conservative. The magnitude and frequency of the design transients are more severe than those occurring during plant operation. The magnitude and number of actual transients are monitored. This monitoring assures that the existing frequency and magnitude of transients are conservative and bounding for the period of extended operation, and that the existing ASME III equipment will perform their intended functions for the period of extended operation. A program for thermal transient cycle counting and analysis is in place and provides reasonable assurance

that the actual transients are smaller in magnitude and within the number of transients used in the design.

Prior to the end of year 40, the fatigue monitoring program will be revised to account for environmentally assisted fatigue using a Staff approved methodology. The present Staff approved methodology re-computes the CUF for the locations listed in NUREG/CR-6260 using the interim fatigue curves found in NUREG/CR-6583 (for carbon and low alloy steels), NUREG/CR-5704 (for austenitic stainless steel), and NUREG/CR-6909 (for carbon/low alloy steels, austenitic stainless steels, and nickel alloys).

Component CUF will be maintained below 1.0. If predictions show CUF could exceed 1.0, further action is required for management of environmental fatigue of the components for the period of extended operation. Fatigue will be managed using one or more of the following options:

1. CUF below 1.0.
2. Further refinement of the fatigue analyses to maintain the environmentally assisted fatigue CUF below 1.0.
3. Repair of the affected locations.
4. Replacement of the affected locations.
5. Manage the effects of fatigue through the use of an augmented in-service inspection program that has been reviewed and approved by the NRC. If this option is selected, the scope, qualification, method, and frequency will be provided to the NRC for review and approval prior to the CUF exceeding 1.0.

18.3.2.2 Leak-Before-Break Analyses

Leak-before-break analyses evaluate postulated flaw growth in the primary loop piping of the Reactor Coolant System. These analyses consider the thermal aging of the cast austenitic stainless steel material of the piping as well as the fatigue transients that drive the flaw growth over the operating life of the plant.

The leak-before-break analyses have been updated to demonstrate that the design is adequate for the extended period of operation, and the analyses are valid for 60 years.

18.3.2.3 ASME Boiler and Pressure Vessel Code, Section III, Class 2 and 3

Piping systems, designed in accordance with ASME Section III, Class 2 and 3 or ANSI B31.1, utilize allowable stress values based on a stress reduction factor to account for thermal cycles during normal operation. Adequate margin is available to account for 60 years of plant operation in the current analyses for the majority of the plant systems reviewed. Restrictions on sampling activities are required on the “B” Reactor Coolant System loop sampling line in order to account for 60 years of plant operation.

18.3.3 Environmental Qualification

The qualification analyses for some electrical equipment included in the Environmental Qualification (EQ) Program have been identified as time-limited aging analyses for license renewal. The qualification analyses for electrical equipment with a 40-year or greater qualified life have been determined as time-limited aging analyses.

Equipment included in the Virgil C. Summer EQ Program will be evaluated to determine if existing environmental qualification analyses can be projected to the end of the period of extended operation by reanalysis or additional analysis. Qualification into the license renewal period is treated the same as for equipment currently qualified at Virgil C. Summer for 40 years or less. When aging analyses cannot justify a qualified life to the end of the period of extended operation then the components or parts will be replaced prior to exceeding their qualified lives in accordance with the EQ Program.

The existing EQ process, in accordance with 10 CFR 50.49, will adequately manage aging of EQ equipment for the period of extended operation.

18.3.4 Reactor Building Tendon Prestress

The Reactor Building was prestressed in order to have low-strain linear response at design loads and thus assure integrity of the liner. The exterior wall is post-tensioned in both vertical and hoop directions. On the dome a three-way post-tensioning system is employed. The pre-stress of the containment tendons decreases over the life of the plant due to elastic deformation, creep, anchorage seating losses, tendon wire friction, stress relaxation and corrosion. Periodic inspections include examination of selected tendon parameters and provide data for prestress analyses. Tendon prestress analyses are used to determine if additional retensioning is required before the next scheduled inspection based on the state of the tendon stress. Therefore reactor building tendon prestress is a time-limited aging analysis.

The existing Tendon Surveillance Program will ensure that the Reactor Building tendons are analyzed for the period of extended operation.

18.3.5 Reactor Building Liner

The Reactor Building is lined on the inside face with a steel plate liner that provides an essentially leak-tight barrier. The liner is designed to remain within strain limits associated with serviceability in accordance with the ASME B&PV for normal operation.

The reactor building liner calculations evaluate liner fatigue for a 40 year period and conclude that the liner meets the criteria of ASME NB 3222.4 (d) for the suitability for cyclic condition and no fatigue analysis is required. The reactor building liner analyses have been revised for the period of extended operation.

18.3.6 Other Plant-Specific Time-Limited Aging Analyses

18.3.6.1 Crane Load Cycle Limit

The crane load cycle limit was identified as a time-limited aging analysis for the cranes within the scope of license renewal. The cranes within the scope of license renewal are listed below.

- Reactor Building Polar Crane
- Fuel Handling Machine (Spent Fuel Pit Bridge and Hoist)
- Refueling Machine (Reactor Cavity Manipulator Crane)
- Spent Fuel Cask Handling Crane

The cranes listed above are classified as Class “A” cranes by the Crane Manufacturers Association of America (CMAA) Specification No. 70 (CMAA 70) which specifies a design limit for the number of load cycles for the life of a crane. The load cycles for these cranes have been evaluated for the period of extended operation. For each crane, the actual usage over the projected life through the period of extended operation will be far less than the analyzed quantity of cycles. All the cranes in the scope of license renewal will continue to perform their intended function through the period of extended operation.

Therefore, the analyses associated with crane design, including fatigue, are valid for the period of extended operation.

18.3.6.2 Service Water Intake Structure Settlement

The Service Water Intake Structure is a reinforced concrete rectangular box culvert with two reinforced concrete wing walls at the intake end. The structure is mostly buried within the West Embankment. The portion not covered with soil is submerged within the Service Water Pond. The function of the Service Water Intake Structure is to draw water from the Service Water Pond into the Service Water Pump House. Excessive non-uniform settlement of the intake structure occurred during construction resulting in cracking of the structure. The settlement of the structure was analyzed based on a plant design life of 40 years. Therefore, Service Water Intake Structure settlement is a time-limited aging analysis for Virgil C. Summer.

The Service Water Intake Structure settlement calculation has been revised to evaluate the settlement of the structure for the period of extended operation.

18.3.6.3 Reactor Coolant Pump Flywheel

The reactor coolant pump motors are provided with flywheels to increase rotational inertia, thus prolonging pump coast-down and assuring a more gradual loss of main coolant flow to the core in the event that pump power is lost. The aging effect of concern is fatigue crack initiation in the flywheel bore keyway from stresses due to starting the motor. An analysis has been performed to estimate the magnitude of fatigue crack growth during the plant life. The analysis assumes 6,000 cycles of pump starts and stops for a 60-year plant life.

The analysis associated with the reactor coolant pump flywheel has been evaluated and determined to remain valid for the period of extended operation.
