On December 20, 1988, the NRC issued Bulletin No. 88-11 regarding pressurizer surge line thermal stratification. The Bulletin requested utilities to establish and implement a program to confirm pressurizer surge line integrity in view of the occurrence of thermal stratification.

Thermal stratification in the pressurizer surge line is the direct result of the difference in densities between the pressurizer water and the generally cooler hot leg water. The lighter pressurizer water tends to float on the cooler heavier hot leg water. The potential for stratification is increased as the difference in temperature between the pressurizer and the hot leg increases and as the insurge or outsurge flow rates decrease.

At power, when the difference in temperature between pressurizer and hot leg is relatively small, the extent and effects of stratification have been observed to be small. However, during certain modes of plant heatup and cooldown, this difference in system temperature could be as large as 320°F, in which case the effects of stratification must be accounted for.

The heatup and cooldown transients for the surge line were developed from monitoring data, historical operation, and operator interviews conducted at a large number of plants. The transients were built upon the extensive work done for the Westinghouse Owners Group coupled with plant specific considerations for Virgil C. Summer.

Transients in the surge line are characterized as either insurges, outsurges, or fluctuations. Insurges and outsurges are the more severe transients and result in the greatest change in temperature in the top or bottom of the pipe. An insurge may cool the entire pipe cross section significantly, to very close to the temperature of the RCS hot leg. Conversely, an outsurge can sweep the line and heat the pipe to close to the temperature of the pressurizer.

Fluctuations, as opposed to the insurge-outsurge transients, are caused by relatively insignificant surges and result in variations in the hot-cold interface level. These variations in the interface level do not change the overall global displacement of the pipe and, hence, are analyzed as changes in local stress only.

The redefinition of the thermal fluid transients experienced by the surge line during normal conditions was necessary to reflect the indirectly observed fluid temperature distributions. These redefined thermal fluid transients were developed based on the existing design transient system parameters assumed to exist at the time of the postulated transient and the knowledge gained from the monitoring programs. The redefined thermal fluid transients conservatively account for the thermal stratification phenomena.

7. Feedwater Heaters Out of Service

   These transients occur when one or more feedwater heaters are taken out of service. For conservatism, it is assumed that one entire train of high pressure heaters is removed from service, thereby making the transient bounding with regard to the possibility of either a low pressure or high pressure heater train being removed from service. Upon identification of the transient, power should be reduced to 80% of nominal, and the plant allowed to stabilize. The affected heater train must be taken out of service.

5.2.1.5.2 Upset Conditions

The following primary system transients are considered upset conditions:

1. Loss of load (without immediate reactor trip).
2. Loss of power.
3. Partial loss of flow.
4. Reactor trip from full power.
5. Inadvertent auxiliary spray.
6. Operating basis earthquake (OBE).
7. Excessive feedwater flow.

1. Loss of Load (Without Immediate Reactor Trip)

   This transient applies to a step decrease in turbine load from full power (turbine trip) without immediately initiating a reactor trip and represents the most severe pressure transient on the RCS under upset conditions. The reactor eventually trips as a consequence of a high pressurizer level trip initiated by the Reactor Protection System (RPS). Since redundant means of tripping the reactor are provided as part of the RPS, transients of this nature are not expected, but are included to ensure a conservative design.

2. Loss of Power

   This transient applies to a blackout situation involving the loss of all outside electrical power to the station, followed by reactor and turbine trips. Under these circumstances, the reactor coolant pumps are de-energized and, following coastdown of the reactor coolant pumps, natural circulation builds up in the system to some equilibrium value. This condition permits removal of core residual heat through the steam generators which at this time are receiving feedwater from the Emergency Feedwater System. Steam is removed for reactor cooldown through atmospheric relief valves provided for this purpose.

3. Partial Loss of Flow

   This transient applies to a partial loss of flow from full power, in which a reactor coolant pump is tripped out of service as the result of a loss of power to that pump.

   The consequences of such an accident are a reactor and turbine trip on low reactor coolant flow, followed by automatic opening of the steam dump system and flow reversal in the affected loop. The flow reversal causes reactor coolant, at cold leg temperature, to pass through the steam generator and be cooled still further. This cooler water then flows through the hot leg piping and enters the reactor vessel outlet nozzles. The net result of the flow reversal is a sizable reduction in the hot leg coolant temperature of the affected loop.

4. Reactor Trip From Full Power

   A reactor trip from full power may occur from a variety of causes resulting in temperature and pressure transients in the RCS and in the secondary side of the steam generator. This is the result of continued heat transfer from the reactor coolant in the steam generator. The transient continues until the reactor coolant and steam generator secondary side temperatures are in equilibrium at zero power conditions. A continued supply of feedwater and controlled dumping of steam remove the core residual heat and prevent the steam generator safety valves from lifting. The reactor coolant temperature and pressure undergo a rapid decrease from full power values as the RPS causes the control rods to move into the core.

5. Inadvertent Auxiliary Spray

   The inadvertent pressurizer auxiliary spray transient will occur if the auxiliary spray valve is opened inadvertently during normal operation of the plant. This will introduce cold water into the pressurizer with a very sharp pressure decrease as a result.

6. Operating Basis Earthquake

   The mechanical stresses resulting from the OBE are considered on a component basis. Fatigue analysis, where required by the codes, is performed by the supplier as part of the stress analysis report. The earthquake loads are a part of the mechanical loading conditions specified in the equipment specifications. The origin of their determination is separate and distinct from those transients resulting from fluid pressure and temperature. They are, however, considered in the design analysis. The number of occurrences for fatigue evaluation is given in Section 3.7.3.1.

7. Excessive Feedwater Flow

   The pressure and temperature variations associated with this transient are considered in connection with analyzing the primary and secondary sides of the steam generator, the RCS, and the pressurizer.

This transient is conservatively defined as an umbrella case to cover the occurrence of several events of the same general nature. These include:

- Inadvertent opening of a feedwater control valve;
- Turbine overspeed (110%) with an open feedwater control valve;
- Small steam break with an open feedwater control valve.

The excessive feedwater flow transient results from inadvertent opening of a feedwater control valve when the plant is at hot shutdown and the steam generator is in the no-load condition. The Feedwater, Condensate, and Heater Drain Systems are in operation. The stem of a feedwater control valve has been assumed to fail, with the valve immediately reaching the full-open position. The feedwater flow to the affected loop is assumed to start from essentially zero flow to the value determined by the system resistance and the developed head of all operating feedwater pumps, with no main feedwater flow. Steam flow is assumed to remain at zero, and the temperature of the feedwater entering the steam generator is conservatively assumed to be 32°F. Feedwater flow is isolated on a reactor coolant low T_{avg} signal; a low pressurizer pressure signal actuates the Safety Injection System. Emergency feedwater flow, initiated by the safety injection signal, is assumed to continue with all pumps discharging into the affected steam generator. It is also assumed, for conservatism in the secondary side analysis, that emergency feedwater flows to the steam generators not affected by the malfunctioned valve, in the "unfailed loops." Plant conditions stabilize at the values reached in 600 seconds, at which time emergency feedwater flow is terminated. The plant is then either taken to cold shutdown, or returned to the no-load condition at a normal heatup rate with the Auxiliary Feedwater System under manual control.

For design purposes, this transient is assumed to occur 30 times during the life of the plant.

5.2.1.5.3 Emergency Conditions

No transient is classified as an emergency condition.

5.2.1.5.4 Faulted Conditions

The following primary system transients are considered faulted conditions:

1. Reactor coolant pipe break (large loss of coolant accident).
2. Large steam line break.
3. Steam generator tube rupture.
4. Safe shutdown earthquake (SSE).

1. Reactor Coolant Pipe Break (Large Loss of Coolant Accident)

Following rupture of a reactor coolant pipe resulting in a large loss of coolant, the primary system pressure decreases, causing the primary system temperature to decrease. Because of

the rapid blowdown of coolant from the system and the comparatively large heat capacity of the metal sections of the components, it is likely that the metal will still be at or near the operating temperature by the end of blowdown. It is conservatively assumed that the ECCS is actuated to introduce water at a minimum temperature of 32°F into the RCS. The safety injection signal will also result in reactor and turbine trips.

2. Large Steam Line Break

   This transient is based on the complete severance of the largest steam line. The following conservative assumptions were made:

   a. The reactor is initially in a hot, zero-power condition.
   b. The steam line break results in immediate reactor trip and ECCS actuation.
   c. A large shutdown margin, coupled with no feedback or decay heat, prevents heat generation during the transient.
   d. The ECCS operates at design capacity and repressurizes the RCS within a relatively short time.

   The above conditions result in the most severe temperature and pressure variations which the primary system will encounter during a steam break accident.

3. Steam Generator Tube Rupture

   This accident postulates the double ended rupture of a steam generator tube, resulting in a decrease in pressurizer level and reactor coolant pressure. Reactor trip will occur due to the resulting safety injection signal. In addition, safety injection actuation automatically isolates the feedwater lines by closing the feedwater isolation and control valves. When this accident occurs, some of the reactor coolant blows down into the affected steam generator causing the shell side level to rise. The primary system pressure is reduced below the secondary safety valve setting. Subsequent recovery procedures call for isolation of the steam line leading from the affected steam generator. This accident will result in a transient which is no more severe than that associated with a reactor trip from full power. Therefore it requires no special treatment insofar as fatigue evaluation is concerned, and no specific number of occurrences is postulated.

4. Safe Shutdown Earthquake

   The mechanical dynamic or static equivalent loads due to the vibratory motion of the SSE are considered on a component basis.

5.2.1.5.5 Test Conditions

The following primary system transients under test conditions are discussed:

1. Turbine roll test.
2. Primary side hydrostatic test.
3. Secondary side hydrostatic test.
4. Primary side leakage test.

1. Turbine Roll Test

   This transient is imposed upon the plant during the hot functional test period for turbine cycle checkout. Reactor coolant pump power will be used to heat the reactor coolant to operating temperature (no-load conditions) and the steam generated will be used to perform a turbine roll test. However, the plant cooldown during this test will exceed the 100°F per hour design rate.

   This transient occurs before plant startup and the number of cycles is therefore independent of other operating transients.

2. Primary Side Hydrostatic Test

   The pressure tests include both shop and field hydrostatic tests which occur as a result of component or system testing. This hydrotest is performed at a water temperature which is compatible with reactor vessel material ductility requirements and a test pressure of 3107 psig (1.25 times design pressure). In this test, the RCS is pressurized to 3107 psig coincident with steam generator secondary side pressure of 0 psig. The number of cycles is independent of other operating transients.

3. Secondary Side Hydrostatic Test

   The secondary side of the steam generator is pressurized to 1.25 design pressure with a minimum water temperature of 120°F coincident with the primary side at 0 psig.

   These tests may be performed either prior to plant startup, or subsequently following shutdown for major repairs or both. The number of cycles is therefore independent of other operating transients.

4. Primary Side Leakage Test

   Subsequent to each time the primary system has been opened, a leakage test will be performed. During this test, the primary system pressure is, for design purposes, raised to 2500 psia, with the system temperature above the minimum temperature imposed by reactor vessel material ductility requirements, while the system is checked for leaks. In actual

practice, the primary system is pressurized to less than 2500 psia as measured at the pressurizer, to prevent the pressurizer safety valves from lifting during the test.

During this leakage test, the secondary side of the steam generator must be pressurized so that the pressure differential across the tubesheet does not exceed 1600 psi. This is accomplished with the steam, feedwater, and blowdown lines closed off.

5.2.1.6 Identification of Active Pumps and Valves

Valves in the RCPB are tabulated in Section 3.9.2. These valves are identified as being either active or inactive.

Active valves are those whose operability through a mechanical motion is relied upon to perform a safety function during the transients or events considered in each operating condition category. Inactive valves have no required motion, they must only retain their structural integrity.

There are no active pumps in the RCPB. The reactor coolant pumps are classified as inactive.

The design methods and procedures which are used to show that active valves listed in Section 3.9.2 will operate during a faulted condition are described in Section 3.9.2.4.

5.2.1.7 Design of Active Pumps and Valves

The methods that will be used to assure that pumps required to function and valves required to open or close during (or following) a specified plant condition are described in Section 3.9.2.4.

5.2.1.8 Inadvertent Operation of Valves

Those valves which are used in the isolation of the RCPB during normal plant operation, and are not relied on to function after an accident, are redundant valves and their inadvertent operation will not increase the severity of any transient.

5.2.1.9 Stress and Pressure Limits

Inactive components are designed in accordance with the ASME Code, Section III. The codes and stress limits used for Class 1 components are summarized in Section 5.2.1.10.

5.2.1.10 Stress Analysis for Structural Adequacy

5.2.1.10.1 Loading Conditions

The structural stress analyses performed on the RCS consider the loadings specified as shown in Table 5.2-3. These loads result from thermal expansion, pressure, weight, OBE, SSE, design basis loss of coolant accident, and plant operational thermal and pressure transients.

5.2.1.10.2 Analysis of the Reactor Coolant Loop and Supports

The loads used in the analysis of the reactor coolant loop piping are described in detail below:

1. Pressure

   Pressure loading is identified as either membrane design pressure or general operating pressure, depending upon its application. The membrane design pressure is used in connection with the longitudinal pressure stress and minimum wall thickness calculations in accordance with the ASME Code.

   The term operating pressure is used in connection with determination of the system deflections and support forces. The steady-state operating hydraulic forces based on the system initial pressure are applied as general operating pressure loads to the reactor coolant loop model at changes in direction or flow area.

2. Weight

   A dead weight analysis is performed to meet Code requirements by applying a 1.0 g load downward on the complete piping system. The piping is assigned a distributed mass or weight as a function of its properties. This method provides a distributed loading to the piping system as a function of the weight of the pipe and contained fluid during normal operating conditions.

3. Seismic

   The forcing functions for the coupled building/loop non-linear time history analysis are derived from dynamic response analyses of the reactor building with soil springs subjected to seismic ground motion. Input is in the form of time history ground acceleration that is applied at the anchor point of the soil springs.

   For the OBE and SSE seismic analyses, 2 and 4% critical damping, respectively, are used in the reactor coolant loop/supports system analysis. When combining the results of the SSE seismic analysis with the loss of coolant accident analysis results, 5% critical damping is used for the SSE.

4. Loss of Coolant Accident

   Blowdown loads are developed in the broken and unbroken reactor coolant loops as a result of transient flow and pressure fluctuations following a postulated pipe break in one of the reactor coolant loops branch lines. Structural consideration of dynamic effects of postulated pipe breaks requires postulation of a finite number of break locations. Postulated pipe break locations are given in Section 3.6.2.

   Broken loop time history dynamic analysis is performed for these postulated break cases. Hydraulic models are used to generate time-dependent hydraulic forcing functions used in

the analysis of the reactor coolant loop for each break case. For further description of the hydraulic forcing functions, refer to Section 3.6.2.2.

5. Transients

   The Code requires satisfaction of certain requirements relative to operating transient conditions. Operating transients are tabulated in Section 5.2.1.5.

   The vertical thermal growth of the reactor pressure vessel nozzle centerlines is considered in the thermal analysis to account for equipment nozzle displacement as an external movement.

   The hot moduli of elasticity E, the coefficient of thermal expansion at the metal temperature a, the external movements transmitted to the piping due to vessel growth, and the temperature rise above the ambient temperature °T, define the required input data to perform the flexibility analysis for thermal expansion.

   To provide the necessary high degree of integrity for the RCS, the transient conditions selected for fatigue evaluation are based on conservative estimates of the magnitude and anticipated frequency of occurrence of the temperature and pressure transients resulting from various plant operation conditions.

5.2.1.10.3 Reactor Coolant Loop Models and Methods

The analytical methods used in obtaining the solution consist of the transfer matrix method and stiffness matrix formulation for the static structural analysis, the time-history method for seismic dynamic analysis, and time history integration method for the loss of coolant accident dynamic analysis.

The integrated reactor coolant loops/supports system model is the basic system model used to compute loadings on components, component supports, and piping. The system model includes the stiffness and mass characteristics of the reactor coolant loop piping and components, the stiffness of supports, the stiffnesses of auxiliary line piping which affect the system, and the stiffness of piping restraints. The deflection solution of the entire system is obtained for the various loading cases from which the internal member forces and piping stresses are calculated.

1. Static

   The reactor coolant loop/supports system model, constructed for the WESTDYN computer program, is represented by an ordered set of data which numerically describes the physical system. Figure 5.2-1 shows an isometric line schematic of this mathematical model. The steam generator and reactor coolant pump vertical and lateral support members are described in Section 5.5.14.

   The spatial geometric description of the reactor coolant loop model is based upon the reactor coolant loop piping layout and equipment drawings. The node point coordinates and incremental lengths of the members are determined from these drawings. Geometrical

properties of the piping and elbows along with the modulus of elasticity E, the coefficient of thermal expansion α, the average temperature change from ambient temperature °T, and the weight per unit length are specified for each element. The primary equipment supports are represented by stiffness matrices which define restraint characteristics of the supports. Due to the symmetry of the static loadings, the reactor pressure vessel centerline is represented by a fixed boundary in the system mathematical model. The vertical thermal growth of the reactor vessel nozzle centerline is considered in the construction of the model.

The model is made up of a number of sections, each having an overall transfer relationship formed from its group of elements. The linear elastic properties of the section are used to define the stiffness matrix for the section. Using the transfer relationship for a section, the loads required to suppress all deflections at the ends of the section arising from the thermal and boundary forces for the section are obtained. These loads are incorporated into the overall load vector.

After all the sections have been defined in this matter, the overall stiffness matrix and associated load vector to suppress the deflection of all the network points is determined. By inverting the stiffness matrix, the flexibility matrix is determined. The flexibility matrix is multiplied by the negative of the load vector to determine the network point deflections due to the thermal and boundary force effects. Using the general transfer relationship, the deflections and internal forces are then determined at all node points in the system.

The static solutions for deadweight, thermal, and general pressure loading conditions are obtained by using the WESTDYN computer program. The derivation of the hydraulic loads for the loss of coolant accident analysis of the loop is covered in Section 3.6.4.

2. Seismic

The model used in the static analysis is modified for the dynamic analysis by including the mass characteristics of the piping and equipment. All of the piping loops coupled with the reactor building with soil springs, equipment, and equipment support system are included in the system model. The effect of the equipment motion on the reactor coolant loop/supports system is obtained by modeling the mass and the stiffness characteristics of the equipment in the overall system model.

The steam generator is typically represented by 4 discrete masses. The lower mass is located at the intersection of the centerlines of the inlet and outlet nozzles of the steam generator. The second mass is located at the steam generator upper support elevation, the third mass is located at the feedwater nozzle elevation, and the fourth mass is at the top of the steam generator.

The reactor coolant pump is typically represented by a two discrete mass model. The lower mass is located at the intersection of the centerlines of the pump suction and discharge nozzles.

The reactor vessel and core internals are represented by approximately 14 discrete masses. The masses are lumped at various locations along the length of the vessel and along the length of the representation of the core internals.

The component upper and lower lateral supports are inactive during plant heatup, cooldown, and normal plant operating conditions. However, these restraints become active when the plant is at power and under the rapid motions of the reactor coolant loop components that occur from the dynamic loadings and are represented by stiffness matrices and/or individual tension or compression spring members in the dynamic model. The analyses are performed at the full power condition.

The seismic analysis consists of applying an acceleration time history to a coupled reactor building, reactor coolant loop piping, equipment, and equipment support system.

The time history seismic analyses were performed using the proprietary Westinghouse computer code WECAN.

The reduced modal analysis method and modal superposition method are used in the time history seismic analyses. The reduced modal analysis option is used to determine the natural frequencies and mode shapes for a linear, undamped structure.

The modal superposition method gives a time history solution for the response of an arbitrary structure subjected to known nodal forces or ground acceleration time histories. The structure may include linear and non-linear elements.

The seismic responses of the reactor coolant loop support system are computed by performing a time history analysis for each of the three shock directions. The results of the three shock directions are combined by:

$$R_T = [\Sigma_{i=1}^{i=3} R_i^2]^{1/2}$$

where:

R_T = total combined response where i corresponds to each of three orthogonal shock direction combined responses (two horizontal and one vertical shock).

3. Loss of Coolant Accident

The mathematical model used in the static analyses is modified for the loss of coolant accident analysis to represent the severance of the reactor coolant loop piping at the postulated break location. Modifications include addition of the mass characteristic of the piping and equipment. To obtain the proper dynamic solution, a mass, located at the break, is included in the mathematical model. The natural frequencies and eigenvectors are determined from this pipe break model.

The time-history hydraulic forces at the node points are combined to obtain the forces and acting at the corresponding structural lumped-mass node points.

The dynamic structural solution for the full power loss of coolant accident is obtained by using a modified-predictor-corrector- integration technique and normal mode theory.

When elements of the system can be represented as single acting members (tension or compression members), they are considered as nonlinear elements, which are represented mathematically by the combination of a gap, a spring, and a viscous damper. The force in this nonlinear element is treated as an externally applied force in the overall normal mode solution. Multiple nonlinear elements can be applied at the same node, if necessary.

The time-history solution is performed in program WESTDYN. The input to this subprogram consists of the natural frequencies, normal modes, applied forces, and nonlinear elements. The natural frequencies and normal modes for the modified reactor coolant loop dynamic model are determined with the WESTDYN program. To properly simulate the release of the strain energy in the pipe, the internal forces in the system at the postulated break location due to the initial steady-state hydraulic forces are determined. The release of the strain energy is accounted for by applying the negative of these internal forces as a step function loading. The initial conditions are equal to zero because the solution is only for the transient problem (the dynamic response of the system from the static equilibrium position). The time-history displacement solution of all dynamic degrees of freedom is obtained using subprogram WESTDYN and employing 4% critical damping.

The loss of coolant accident displacements of the reactor vessel is applied in time history form as input to the dynamic analysis of the reactor coolant loop. The loss of coolant accident analysis of the reactor vessel includes all the forces acting on the vessel including internals reactions, cavity pressure loads, and loop mechanical loads. The reactor vessel analysis is described in Section 5.2.1.10.6.

The time-history displacement response of the loop is used in computing support loads and in performing stress evaluation of the reactor coolant loop piping.

The support loads [F] are computed by multiplying the support stiffness matrix [K] and the displacement vector [δ] at the support point. The support loads are used in the evaluation of the supports.

The time-history displacements are used to determine the internal forces, deflections, and stresses at each end of the piping elements. For this calculation the displacements are treated as imposed deflections on the reactor coolant loop masses. The results of this solution are used in the piping stress evaluation.

4. Transients

Operating transients in a nuclear power plant cause thermal and/or pressure fluctuations in the reactor coolant fluid. The thermal transients cause time-varying temperature distributions

across the pipe wall. These temperature distributions resulting in pipe wall stresses may be further subdivided in accordance with the Code into three parts, a uniform, a linear, and a nonlinear portion. The uniform portion results in general expansion loads. The linear portion causes a bending moment across the wall and the nonlinear portion causes a skin stress.

The transients as defined in Section 5.2.1.5 are used to define the fluctuations in plant parameters. A one-dimensional finite difference heat conduction program is used to solve the thermal transient problem. The pipe is represented by at least 50 elements through the thickness of the pipe. The convective heat transfer coefficient employed in this program represents the time varying heat transfer due to free and forced convection. The outer surface is assumed to be adiabatic while the inner surface boundary experiences the temperature of the coolant fluid.

Fluctuations in the temperature of the coolant fluid produce a temperature distribution through the pipe wall thickness which varies with time. An arbitrary temperature distribution across the wall is shown in Figure 5.2-2.

The average through-wall temperature, T_A, is calculated by integrating the temperature distribution across the wall. The integration is performed for all time steps so that T_A is determined as a function of time.

$$T_A(t) = \frac{1}{H}\int_0^H T(X,t)dX$$

The range of temperature between the largest and smallest value of T_A is used in the flexibility analysis to generate the moment loadings caused by the associated temperature changes.

$$M = E\alpha\int_0^H \left(X - \frac{H}{2}\right)T(X,t)dX$$

The equivalent thermal moment produced by the linear thermal gradient as shown in Figure 5.2-3 about the mid-wall thickness is equal to:

$$M_L = E\alpha_1\frac{\Delta T_1}{2}H^2$$

Equating ML and M, the solution for ΔT_1 as a function of time is:

$$\Delta T_1(t) = \frac{12}{H^2}\int_0^H \left(X - \frac{H}{2}\right)T(X,t)dX$$

The maximum nonlinear thermal gradient, ΔT_2, will occur on the inside surface and can be determined as the difference between the actual metal temperature on this surface and half of the average linear thermal gradient plus the average temperature.

$$\Delta T_2(t) = \left|T(0,t) - T_A(t)\right| - \frac{\left|\Delta T_1(t)\right|}{2}$$

5. Load Set Generation

A load set is defined as a set of pressure loads, moment loads, and through-wall thermal effects at a given location and time in each transient. The method of load set generation is based on Reference 2. The through-wall thermal effects are functions of time and can be subdivided into four parts:

a. Average temperature (T_A) is the average temperature through-wall of the pipe which contributes to general expansion loads.

b. Radial linear thermal gradient which contributes to the through-wall bending moment (ΔT_1).

c. Radial nonlinear thermal gradient (ΔT_2) which contributes to a peak stress associated with shearing of the surface.

d. Discontinuity temperature (T_A - T_B) represents the difference in average temperature at the cross sections on each side of a discontinuity.

Each transient is described by at least one load set representing the maximum and minimum stress state during each transient. The construction of the load sets is accomplished by combining the following to yield the maximum (minimum) stress state during each transient.

a. ΔT_1

b. ΔT_2

c. $\alpha_A T_A$ - $\alpha_B T_B$

d. Moment loads due to T_A

e. Pressure loads

This procedure produces at least twice as many load sets as transients for each point.

As a result of the normal mode spectral technique employed in the seismic analysis, the load components cannot be given signed values. Eight load sets are used to represent all possible sign permutations of the seismic moments at each point, thus ensuring the most conservative combination of seismic loads are used in the stress evaluation.

For all possible load set combinations, the primary-plus-secondary and peak stress intensities, fatigue reduction factors (K_e), and cumulative usage factors, U, are calculated. The WESTDYN-7 program is used to perform this analysis in accordance with the ASME

Code, Section III, Subsection NB-3650. Alternatively, detailed finite element stress analyses may be used to determine primary-plus-secondary and peak stress intensities for the load set combinations. Since it is impossible to predict the order of occurrence of the transients over the plant life, it is assumed that the transients can occur in any sequence. This is a very conservative assumption.

The combination of load sets yielding the highest alternating stress intensity range is used to calculate the incremental usage factor. The next most severe combination is then determined and the incremental usage factor calculated. This procedure is repeated until all combinations having allowable cycles $<10^6$ are formed. The total cumulative usage factor at a point is the summation of the incremental usage factors.

5.2.1.10.3.1 Reactor Coolant Loop Analysis Results for Steam Generator Replacement

With the implementation of Leak-Before-Break (LBB) methodology to the V. C. Summer reactor coolant loops, the large RCL breaks have been eliminated from the LOCA analysis inputs. The only sets of LOCA inputs re-analyzed to support steam generator replacement and their associated revised operating conditions were the large auxiliary lines, RHR line/primary coolant loop connection, accumulator line/primary coolant loop connection, and pressurizer surge line/primary coolant loop connection. Documentation of the reactor coolant loop analysis as affected by steam generator replacement is furnished in WCAP-9119, Revision 3. The conclusions of the report indicate that the impact of steam generator replacement will not result in reactor coolant loop piping stresses and fatigue usage that exceeds the ASME Code requirements for normal, upset, emergency, and test conditions. The structural integrity and safety-related design requirements of the RCL will be maintained during all conditions of the design specification.

5.2.1.10.4 Primary Component Supports Models and Methods

The static and dynamic structural analyses employ the matrix method and normal mode theory for the solution of lumped-parameter, multi-mass structural models. The equipment support structure models are dual-purpose since they are required (1) to quantitatively represent the elastic restraints which the supports impose upon the loop, and (2) to evaluate the individual support member stresses due to the forces imposed upon the supports by the loop.

Models for the STRUDL or WECAN computer program are constructed for the steam generator lower, steam generator upper lateral, reactor coolant pump lower, and reactor vessel supports. Structure geometry, topology, and member properties are used in the modeling.

A description of the supports is found in Section 5.5.14. Detailed models are developed using beam elements and plate elements, where applicable.

The computer programs are used with these models to obtain support stiffness matrices and member influence coefficients for the steam generator and reactor coolant pump supports. Unit force along and unit moment about each coordinate axis are applied to the models at the

equipment vertical centerline joint. Stiffness analyses are performed for each unit load for each model.

Joint displacements for applied unit loads are formulated into flexibility matrices. These are inverted to obtain support stiffness matrices which are included in the reactor coolant loop model.

Loads acting on the supports obtained from the reactor coolant loop analysis, support structure member properties, and influence coefficients at each end of each member are input into the WESAN program.

For each support case used, the following is performed:

1. Combine the various types of support plane loads to obtain operating condition loads (normal, upset, or faulted).
2. Multiply member influence coefficients by operating condition loads to obtain all member internal forces and moments.
3. Solve appropriate stress or interaction equations for the specified operating condition. Maximum normal stress, shear stress, and combined load interaction equation values are printed as a ratio of maximum actual values divided by limiting values.

Tables 5.2-16 through 5.2-18 present maximum stresses in each member of the steam generator and reactor coolant pump support structures expressed as a percentage of maximum permissible values for all operating condition loadings. Figures 5.2-10 through 5.2-12 illustrate the support models and show the member locations.

The reactor vessel support structures were analyzed for all loading conditions using a finite element model with the WECAN computer program. Vertical and horizontal forces delivered to the support structures from the reactor vessel shoes were applied to the structure. The maximum stresses in the reactor vessel supports for all loading conditions are presented in Table 5.2-20, expressed as a percentage of the maximum permissible values.

In addition, member compressive axial loads for all Class 1 primary equipment supports do not exceed 0.67 times the critical buckling strength for the faulted condition.

5.2.1.10.5 Analysis of Primary Components

Equipment which serves as part of the pressure boundary in the reactor coolant loop includes the steam generators, the reactor coolant pumps, the pressurizer, and the reactor vessel. This equipment is Safety Class 1 and the pressure boundary meets the requirements of the ASME Code, Section III, Subsection NB. This equipment is evaluated for the loading combinations outlined in Table 5.2-3. The equipment is analyzed for (1) the normal loads of dead-weight, pressure and thermal, (2) mechanical transients of OBE, SSE, and pipe ruptures, and (3) pressure and temperature transients outlined in Section 5.2.1.5.

The results of the reactor coolant loop analysis are used to determine the loads acting on the nozzles and the support/component interface locations. These loads are supplied for all loading conditions on an "umbrella" load basis. That is, on the basis of previous plant analyses, a set of loads is determined which should be larger than those seen in any single plant analysis. The umbrella loads represent a conservative means of allowing detailed component analysis prior to the completion of the system analysis. Upon completion of the system analysis, conformance is demonstrated between the actual plant loads and the loads used in the analyses of the components. Any deviations where the actual load is larger than the umbrella load will be handled by individualized analysis.

Seismic analyses are performed individually for the reactor coolant pumps, the pressurizer, and the steam generators. Detailed and complex dynamic models are used for the dynamic analyses. The response spectra corresponding to the building elevation at the highest component/building attachment elevation is used for the component analysis. Seismic analyses for the steam generators are performed using 2% damping for the OBE and 4% damping for the SSE. The analysis of the reactor coolant pump for determination of loads on the motor, main flange, and pump internals is performed using the damping for bolted steel structures; that is, 4% for the OBE and 7% for the SSE (2% for OBE and 4% for SSE is used in the system analysis). This damping is applicable to the reactor coolant pump since the main flange, motor stand, and motor are all bolted assemblies (see Section 5.5). The reactor pressure vessel is qualified by static stress analysis based on loads that have been derived from dynamic analysis.

RCPB components are further qualified to ensure against unstable crack growth under faulted conditions by performing detailed fracture analyses of the critical areas of this boundary. Actuation of the Emergency Core Cooling System produces relatively high thermal stresses in the system. Regions of the pressure boundary which come into contact with Emergency Core Cooling System water are given primary consideration. These regions include the reactor vessel beltline region, the reactor vessel inlet nozzles, and the safety injection nozzles in the piping system.

Two methods of analysis are used to evaluate thermal effects in the regions of interest. The first method is Linear Elastic Fracture Mechanics (LEFM). The LEFM approach to the design against failure is basically a stress intensity consideration in which criteria are established for fracture instability in the presence of a crack. Consequently, a basic assumption employed in LEFM is that a crack or crack-like defect exists in the structure. The essence of the approach is to relate the stress field developed in the vicinity of the crack tip to the applied stress on the structure, the material properties, and the size of defect necessary to cause failure.

The elastic stress field at the crack-tip in any cracked body can be described by a single parameter designated as the stress intensity factor, K. The magnitude of the stress intensity factor K is a function of the geometry of the body containing the crack, the size and location of the crack, and the magnitude and distribution of the stress.

The criterion for failure in the presence of a crack is that failure will occur whenever the stress intensity factor exceeds some critical value. For the opening mode of loading (stresses perpendicular to the major plane of the crack), the stress intensity factor is designated as K_I and the critical stress intensity factor is designated K_{IC}. Commonly called the fracture toughness, K_{IC}

is an inherent material property which is a function of temperature and strain rate. Any combination of applied load, structural configuration, crack geometry, and size which yields a stress intensity factor K_{IC} for the material will result in crack instability.

The criterion of the applicability of LEFM is based on plasticity considerations at the postulated crack tip. Strict applicability (as defined by ASTM) of LEFM to large structures where plane strain conditions prevail requires that the plastic zone developed at the tip of the crack does not exceed 2.25% of the crack depth. In the present analysis, the plastic zone at the tip of the postulated crack can reach 20% of the crack depth. However, LEFM has been successfully used quite often to provide conservative brittle fracture prevention evaluations, even in cases where strict applicability of the theory is not permitted due to excessive plasticity. Recently, experimental results from Heavy Section Steel Technology (HSST) Program intermediate pressure vessel tests have shown that LEFM can be applied conservatively as long as the pressure component of the stress does not exceed the yield strength of the material. The addition of the thermal stresses, calculated elastically, which result in total stresses in excess of the yield strength, does not affect the conservatism of the results, provided that these thermal stresses are included in the evaluation of the stress intensity factors. Therefore, for faulted condition analyses, LEFM is considered applicable for the evaluation of the vessel inlet nozzle and beltline region.

In addition, it has been well established that the crack propagation of existing flaws in a structure subjected to cyclic loading can be defined in terms of fracture mechanics parameters. Thus, the principles of LEFM are also applicable to fatigue growth of a postulated flaw at the vessel inlet nozzle and beltline region.

For the safety injection and charging line nozzles, which are fabricated from 304 stainless steel, LEFM is not applicable because of extreme ductility of the material. For these nozzles, the thermal effects are evaluated using the principles of Miner's hypothesis of linear cumulative damage in conjunction with fatigue data from constant stress or strain fatigue tests. The cumulative usage fatigue defined as the sum of the ratios of the number of cycles of each transient (n) to the allowable number of cycles for the stress range associated with the transient (N) must not exceed 1.0.

An example of a faulted condition evaluation carried out according to the procedure discussed above is given in Reference 3. This report discusses the evaluation procedure in detail as applied to a severe faulted condition (a postulated loss of coolant accident).

Valves in the RCS are designated ASME Class 1 and are designed and analyzed to the limits outlined in Table 5.2-4. Valves in sample lines connected to the RCS are not considered to be Safety Class 1 nor ASME Class 1. This is because the nozzles where the lines connect to the primary system piping are orificed to a 3/8 inch hole. This hole restricts the flow such that loss through a severance of one of these lines can be made up by normal charging flow.

To support steam generator replacement, the primary components (i.e., the reactor vessel, reactor internals, reactor coolant pumps, and pressurizer) were reevaluated with the Delta-75 steam generators modeled in the system, and with a NSSS power of 2912 MWt. Revised RCS design transients were compared with the original design basis transients. Where the revised transients

indicated a more severe loading, the original evaluation was revisited. The results of the evaluations indicate that, in most cases, the conservatively determined results of the original analyses remain bounding for these new conditions. As with the original stress report performed by Chicago Bridge and Iron, Inc. (CBI), the maximum range of primary plus secondary stress intensity exceeds the $3S_m$ limit defined by the ASME Code for the outlet nozzles and support pads, inlet nozzles and support pads, and closure head flange. The stress intensities calculated by CBI were not affected by the steam generator replacement. CBI performed a simple elastic-plastic analysis according to Paragraph NB-3228.3 of the ASME Code to justify these values. These results are not affected. The fatigue usages for all components which had stress intensities in excess of the Code limits were all less than the Code limit of 1.0. Some of the pressurizer components were calculated to experience a slight increase in fatigue usage; however, the cumulative fatigue usage factors for all pressurizer components evaluated remain less than 1.0. In all cases, the acceptance limits specified by the appropriate section of the ASME Code Edition applicable for that component were not exceeded. Details regarding the analysis of the reactor vessel and reactor vessel internals are furnished in References 14 and 15.

5.2.1.10.6 Reactor Vessel Support LOCA Loads

5.2.1.10.6.1 Introduction

As indicated in Section 3.6, postulated breaks in the reactor coolant loop piping, except for branch line connections, have been eliminated. Reactor coolant loop piping branch nozzle (i.e., accumulator connection, pressurizer surge line, residual heat removal, etc.) breaks are postulated.

5.2.1.10.6.2 Interface Information

Gilbert Associates, Inc. is responsible for reactor containment design and analysis. Stiffness of the primary shield wall beneath the reactor vessel supports and asymmetric cavity pressurization loading was provided by Gilbert to Westinghouse.

All other input information was developed within Westinghouse. These items are as follows: reactor internals properties, loop mechanical loads and loop stiffness, internal hydraulic pressure transients, and reactor support stiffnesses. These inputs allowed formulation of the mathematical models and performance of the analyses, as will be described.

5.2.1.10.6.3 Loading Conditions

As indicated in Section 3.6, postulated breaks in the reactor coolant loop piping, except for branch line connections, have been eliminated. Reactor coolant loop piping branch nozzle (i.e., accumulator connection, pressurizer surge line, residual heat removal, etc.) breaks are postulated.

The reactor internals hydraulic pressure transients were calculated, including the assumption that the structural motion is coupled with the pressure transients. This phenomenon has been referred to as hydroelastic coupling or fluid-structure interaction. The hydraulic analysis considers the fluid-structure interaction of the core barrel by accounting for the deflections of constraining boundaries which are represented by masses and springs. The dynamic response of the core barrel

in its beam bending mode responding to blowdown forces compensates for internal pressure variation by increasing the volume of the more highly pressurized regions. The analytical methods used to develop the reactor internals hydraulics are described in WCAP-8708 (Reference 12).

5.2.1.10.6.4 Reactor Vessel and Internals Modeling

The reactor vessel and internals general assembly is shown in Figure 3.9-1. The reactor vessel is restrained by two mechanisms: (1) the three attached reactor coolant loops with the steam generator and reactor coolant pump primary supports and (2) six reactor vessel supports, one beneath each reactor vessel nozzle. The reactor vessel supports are described in Section 5.5.14 and are shown in Figures 5.5-7, 5.2-4, and 5.2-5. The support shoe provides restraint in the horizontal directions and for downward reactor vessel motion.

The mathematical model of the reactor pressure vessel is a three-dimensional nonlinear finite element model which represents the dynamic characteristics of the reactor vessel and its internals in six geometric degrees of freedom. The model was developed using the WECAN computer code. The model consists of three concentric structural submodels connected by nonlinear impact elements and stiffness matrices. The first submodel represents the reactor vessel shell and the associated support system. The second submodel represents the reactor core barrel, neutron panels, lower support plate, tie plates, and secondary core support components. This submodel is physically located inside the first, and is connected to it by a stiffness matrix at the internals support ledge. Core barrel to vessel shell impact is represented by nonlinear elements at the core barrel flange, core barrel outlet nozzle, and lower radial support locations. The third and innermost submodel represents the upper support plate, guide tubes, support columns, upper and lower core plates, and fuel. The third submodel is connected to the first and second by stiffness matrices and nonlinear elements. The first, second, and third submodels are shown in Figures 5.2-6a, 5.2-6b, and 5.2-6, respectively.

The hydrodynamic mass matrices are a function of the properties of two cylinders with a fluid in the cylindrical annulus; specifically, inside and outside of the annulus, density of the fluid, and length of the cylinders. Vertical segmentation of the reactor core barrel allows inclusion of radii variations along the reactor core barrel height and approximates the effects of reactor core barrel beam deformation. These mass matrices were inserted between selected nodes on the core barrel and reactor vessel shell submodels as shown in Figure 5.2-7.

The structure is divided into a finite number of members or elements. The inertia and stiffness matrices, as well as the force array, are first calculated for each element in the local coordinates. Employing appropriate transformation, the element global matrices and arrays are then computed. Finally, the global element matrices and arrays are assembled into the global structural matrices and arrays, and used for dynamic solution of the differential equation of motion for the structure.

5.2.1.10.6.5 Analytical Methods

The time history effects of the cavity pressurization loads, internals loads, and loop mechanical loads are combined and applied simultaneously to the applicable nodes of the mathematical

model of the reactor vessel and internals. The analysis is performed by numerically integrating the differential equations of motion to obtain the transient response. The output of the analysis includes, among other things, the displacements of the reactor vessel and the loads in the reactor vessel supports. The loads from the postulated pipe break on the vessel supports are combined with other applicable faulted condition loads and subsequently used to calculate the stresses in the supports. Also, the reactor coolant loop is analyzed by applying the reactor vessel displacements to the reactor coolant loop model. The resulting loads and stresses in the piping, components, and supports are then combined with those from the loop dynamic blowdown analysis and the adequacy of the system is verified. Thus, the effect of vessel displacements upon loop response and the effect of loop blowdown upon vessel displacements are both evaluated.

5.2.1.10.6.6 Results of the Analysis

As previously discussed, the application of LBB methodology at V. C. Summer excludes the large RCL breaks from requiring analysis. The most limiting breaks considered for the dynamic analysis of V. C. Summer are the accumulator line break (cold leg) and pressurizer surge line break (hot leg).

LOCA loads applied to the V. C. Summer reactor pressure vessel system consist of reactor internal hydraulic loads (vertical and horizontal) and reactor coolant loop mechanical loads. All the loads are calculated individually and combined in a time history manner.

Reactor coolant loop mechanical loads are applied to the reactor pressure vessel nozzles by the primary coolant loop piping, and are given in Table 5.2-13.

The severity of a postulated break in a reactor vessel is related to two factors: the distance from the vessel to the break and the break opening area. Due to the interaction between the internals structure and the decompression wave, cold leg breaks result in larger reactor internal hydraulic forces. The reactor pressure vessel system LOCA analysis results consist of time history displacements and impact forces. The accumulator line break and the surge line break displacements are given in Table 5.2-14. Also, the reactor vessel/internals interface loads for these two breaks are given in Table 5.2-15. The results given in Tables 5.2-14 and 5.2-15 were compared with the original results from the reactor pressure vessel inlet nozzle break (large break). This comparison showed that the system LOCA response for the accumulator line break and the surge line break at uprated plant conditions with the Delta-75 steam generators are bounded by the main line loop breaks, eliminated by the application of leak-before-break methodology. Consequently, there is no adverse impact on the structural integrity of the V. C. Summer reactor internals.

5.2.1.10.7 Stress Criteria for Class 1 Components and Component Supports

1. Components

   All Class 1 components are designed and analyzed for the design, normal, and upset conditions to the rules and requirements of the ASME Code, Section III. The design analysis or test methods and associated stress or load allowable limits used in evaluation of faulted

conditions are those that are defined in Appendix F of the ASME Code with supplementary options outlined below:

a. Elastic System Analysis and Component Inelastic Analysis

This is an acceptable method of evaluation for faulted conditions if the rules provided below are met for component supports, and if primary stress limits for components are taken as greater of 0.70 S_u or S_y + 1/3 (S_u - S_y) for membrane stress and greater of 0.70 S_{ut} or S_y + 1/3 (S_{ut} - S_y) for membrane-plus-bending stress, where material properties are taken at appropriate temperature.

If plastic component analysis is used with elastic system analysis or with plastic system analysis, the deformations and displacements of the individual system members will be shown to be no larger than those which can be properly calculated by the analytical methods used for the system analysis.

b. Elastic/Inelastic System Analysis and Component/Test Load Method

The test load method given in F-1370(d) is an acceptable method of qualifying components in lieu of satisfying the stress/load limits established for the component analysis.

2. Component Supports

All Class 1 component supports are designed and analyzed, as discussed in Section 5.2.1.10.4, for the design, normal, upset, and faulted conditions. Allowable stresses for the Class 1 component supports are provided in Table 5.2-5.

Loading combinations and allowable stresses for ASME Code, Section III, Class 1 components and component supports are given in Tables 5.2-3, 5.2-4, and 5.2-5. For faulted condition evaluations, the effects of the SSE and loss of coolant accident are combined using the square root of the sum of the squares method. Justification for this method of load combination has been submitted to the NRC as WCAP-9279 and WCAP-9283.

5.2.1.10.8 Computer Program Descriptions

The following computer programs have been used in dynamic and static analyses to determine mechanical loads, stresses, and deformations of Seismic Category I components and equipment. These are described and verified in Reference 4.

1. WESTDYN - static and dynamic analysis of redundant piping systems.
2. STHRUST - hydraulic loads on loop components from blowdown information.
3. WESAN - reactor coolant loop equipment support structures analysis and evaluation.
4. WECAN - finite element structural analysis

5.2.1.11 Analysis Methods for Faulted Conditions

The methods used for the evaluation of the faulted conditions are contained in Section 5.2.1.10.

5.2.1.12 Protection Against Environmental Factors

A discussion of the protection provided for the principal components of the RCS against environmental factors is found in Section 3.11.

5.2.1.13 Compliance with Code Requirements

A brief description of the analyses and methods used to assure compliance with the applicable codes is provided in Section 5.2.1.10.

5.2.1.14 Stress Analysis for Emergency and Faulted Conditions Loadings

The stress analysis used for emergency and faulted condition loadings is discussed in Section 5.2.1.10.

5.2.1.15 Stress Levels in Category I Systems

Summary results of the typical analyses of the Category I systems are included in the latest revisions of Westinghouse Reports WCAP-9119, Vol. II and Vol. I; WCAP-9803, Vol. IV; and WCAP-9802, Vol. III.

5.2.1.16 Analytical Methods for Stresses in Pumps and Valves

The pressure boundary portions of the Class 1 pump in the RCS (the reactor coolant pumps) are designed and analyzed according to the requirements of NB-3400.

The pressure boundary portions of Class 1 valves in the RCS are designed and analyzed according to the requirements of NB-3500. These valves are identified in Section 3.9.2.

5.2.1.17 Analytical Methods for Evaluation of Pump Speed and Bearing Integrity

The reactor coolant pump shaft is designed so that its operating speed is below the first shaft critical speed as discussed in Section 5.5.1.3.6.

Reactor coolant pump bearing integrity is discussed in Section 5.5.1.3.4.

5.2.1.18 Operation of Active Valves Under Transient Loadings

The tests and analyses that are performed on active valves to assure operation under transient loadings are described in Section 3.9.2.4.

5.2.1.19 Field Run Piping

There is no field run safety class piping. All safety class piping down to one inch is depicted on and fabricated to plan and section drawings and any applicable analyses are performed accordingly. Approved design criteria are used for pipe hanger design.

5.2.2 Overpressurization Protection

5.2.2.1 Location of Pressure Relief Devices

Pressure relief devices for the RCS comprise the three pressurizer safety valves and three power operated relief valves shown in Figure 5.1-1, Sheet 2; these discharge to the pressurizer relief tank through a common header. Other relief valves in the reactor building that discharge to the pressurizer relief tank are itemized in Table 5.2-6.

5.2.2.2 Mounting of Pressure Relief Devices

The NSSS supplier provides protection pads for the pressurizer. The architect engineer designs the supports for the safety relief valves and the attached piping in accordance with the installation guidelines and suggests physical layout criteria provided by the NSSS supplier. The architect engineer determines the reactions on the valves and attached piping to limit the piping reaction loads to acceptable values.

5.2.2.3 Report on Overpressure Protection

The pressurizer is designed to accommodate pressure increases (as well as decreases) caused by load transients. The spray system condenses steam to prevent the pressurizer pressure from reaching the setpoint of the power operated relief valves during a step reduction in power level equivalent to 10% of full rated load.

The spray nozzle is located in the top head of the pressurizer. Spray is initiated when the pressure controlled spray demand signal is above a given setpoint. The spray rate increases proportionally with increasing compensated error signal until it reaches a maximum value. The compensated error signal is the output of Proportional plus Integral plus Derivative (PID) controller, the input to which is an error signal based on the difference between actual pressure and a reference pressure.

The pressurizer is equipped with power operated relief valves which limit system pressure for a large power mismatch, and thus prevent actuation of the fixed high pressure reactor trip. The relief valves are operated automatically or by remote manual control. The operation of these valves also limits the undesirable opening of the spring-loaded safety valves. Remotely operated stop valves are provided to isolate the power operated relief valves if excessive leakage occurs. The relief valves are designed to limit the pressurizer pressure to a value below the high pressure trip setpoint for all design transients up to and including the design percentage step load decrease with steam dump but without reactor trip.

Output signals from the pressurizer pressure protection channels are isolated and used for pressure control. These are used to control pressurizer spray and heaters and power operated relief valves. Pressurizer pressure is sensed by fast response pressure transmitters with a time response of better than 0.2 seconds.

In the event of a complete loss of heat sink, e.g., no steam flow, protection of the RCS against overpressure is afforded by pressurizer and steam generator safety valves along with any of the following reactor trip functions:

1. Reactor trip on turbine trip (if the turbine is tripped at above 50% power);
2. High pressurizer pressure reactor trip;
3. Overtemperature ΔT reactor trip;
4. Low feedwater flow reactor trip; or
5. Low-low steam generator water level reactor trip.

The ASME Code pressure limit is 110% of the 2485 psig design pressure. This limit is not exceeded as discussed in Reference 5. The report describes in detail the pressure relief devices, location, reliability, and sizing. Transient analysis data are provided for the worst cases that require safety valve actuation as well as those cases which do not.

A detailed functional description of the process equipment associated with the high pressure trip is provided in Reference 6.

The upper limit of overpressure protection is based upon the positive surge of the reactor coolant produced as a result of turbine trip under full load, i.e., a 100% load mismatch assuming that the core continues to produce full power with no steam dump. The self-actuated safety valves are sized on the basis of steam flow from the pressurizer to accommodate this surge at a setpoint of 2500 psia and a total accumulation of 3%.

The actual installed capacity of the safety valves is always greater than the capacity calculated from the sizing analysis and is indicated so by the ratio of safety valve flow to peak surge rate being greater than 1.0. Note that no credit is taken for the relief capability provided by the power operated relief valves during this surge.

The RCS design and operating pressure together with the safety, power relief and pressurizer spray valve setpoints, and the protection system setpoint pressures are listed in Table 5.2-7.

System components whose design pressure and temperature are less than the RCS design limits are provided with overpressure protection devices and redundant isolation means. System discharge from overpressure protection devices is collected in the pressurizer relief tank.

As specified in NUREG 0660, item II.K.3 Table C.3 item 3, SCE&G will report safety/relief valve failures and challenges during startup testing and plant operation.

5.2.2.4 ECCS Check Valve Testing

Check valves on the discharge side of low and high head safety injection systems, and the safety injection accumulator subsystems that are classified as ASME Code, Category AC, are listed in Table 5.2-7a.

The ECCS check valve system, shown by Figure 5.2-8, provides the means for leak testing individual check valves, classified Category AC, on the discharge side of the low head safety injection systems and safety injection accumulator subsystems independent of other valves. Testing of these valves will be performed during plant startup following refueling shutdowns on a performance-based frequency. Reactor coolant pressure will be at least 1000 psig. ECR 50650 added a back pressure regulator set at approximately 400 psig to allow controlled leakage to the PRT. By installing a back pressure regulator around XVT00037-SI, a method of preventing pressure building up in an isolated system is provided. This is done to reduce the potential for leakage into and pressurization of interfacing systems.

Acceptance criteria for leakage are in accordance with Technical Specification 3.4.6.2. Test results are documented in accordance with the ASME Code of Record, prescribed under 10 CFR 50.55a. These check valves are normally tested during plant startup following a refueling shutdown. Should a valve be found to leak excessively, it will be repaired and retested prior to a return to normal operation.

5.2.2.5 RCS Pressure Control During Low Temperature Operation

Administrative procedures are developed to aid the operator in controlling RCS pressure during low temperature operation.

Cold overpressurization protection will be provided by the RHR suction relief valves during low RCS temperature operation. Analysis has shown that one RHR suction relief valve is sufficient to prevent violation of 10 CFR 50, Appendix G limits due to anticipated mass and heat input transients.

5.2.2.5.1 System Operation

The RHR system is normally lined up to the RCS with the reactor shut down, primary coolant temperature ≤350°F, and pressure ≤450 psig. The RHR suction relief valves are set at 450 psig and provide the necessary overpressurization protection during cold plant operations. Annunciators are provided in the control room to alert the operator if reactor coolant temperature is < 300°F and any of the RHR suction isolation valves are not open.

5.2.2.5.2 Evaluation of Low Temperature Overpressure Transients

Pressure Transient Analyses

ASME Section III, Appendix G, establishes guidelines and limits for RCS pressure primarily for low temperature conditions (≤350°F). The relief system discussed in Section 5.2.2.5 satisfies these conditions as discussed in the following paragraphs.

Transient analyses were performed to ensure that an RHR relief setpoint of 450 psig is sufficient. This setpoint maintains RCS pressure within acceptable limits following all credible overpressurization incidents occurring in the plant during low temperature, water solid operation.

The mass input transient analysis was performed assuming the most severe event involving a single centrifugal charging pump. Specifically, a loss of air incident is postulated, whereby the flow control valve on the charging line fails open and, simultaneously, the flow control valve on the letdown line fails closed.

The heat input mechanism considered for analysis involved an RCS pump startup in one loop with a water solid condition and temperature asymmetry in the RCS, whereby the steam generators were at a higher temperature than the remainder of the system. A 50°F mismatch was assumed to exist between the RCS (100°F) and the secondary side of the steam generators. (At lower temperatures, the mass input case is the limiting transient condition.)

Both analyses took into account the single failure criteria and, therefore, the operation of one RHR suction relief valve was assumed to be available for pressure relief. Consistent with WCAP-14040-NP-A, Revision 2 (Reference 7), the design credits the fact that overpressure events mostly occur during isothermal conditions in the RCS and therefore use the steady state Appendix G limit in judging the adequacy of the RHR relief valve capacity and lift setting. Calculated peak pressures for both the design basis mass and heat addition transients remain substantially less than the allowable limits, which are reflected in the heatup and cooldown limit curves for normal operation within the Technical Specifications. Thus, low temperature overpressure transients do not constitute impairment to vessel integrity or plant safety.

OBE Evaluation

A fluid systems evaluation has been performed to analyze the potential for overpressure transients following an OBE. The basis of the evaluation assumes the plant air system is inoperable since it is not seismically qualified. The results of the evaluation follow and demonstrate that overpressure transients following an OBE are not a concern.

1. A loss of plant air during the first part of plant cooldown (i.e., decay heat removal via SG, normal CVCS letdown, and just prior to placing the Residual Heat Removal System (RHRS) on line at 350°F) would cause the low pressure letdown isolation valves to fail close and the charging flow control valve to fail open. These conditions would create a net mass addition to the RCS causing the pressure to increase. However, the pressure increase would be

acceptable since the pressurizer safety valves would limit system pressure (2485 psig) within allowable values (Technical Specification Figures 3/4 4-26 and 3/4 4-27).

2. A loss of plant air during the second part of plant cooldown (i.e., decay heat removal via the RHRS and temperature less than 350°F) would cause the low pressure letdown valve to fail close and charging flow control valve to fail open similar to that discussed above. These conditions would create a net mass addition to the system which would be relieved by the RHR relief valves which are set at 450 psig and thus maintain the pressure within allowable values.

   The flow paths of the common relief headers from the pressurizer safety and RHRS relief valves to the pressurizer relief tank are assured following an OBE by design of the headers for seismic loads.

For the various modes described above, the pressurizer safety and RHRS relief valves provide pressure relief for the postulated transients following an OBE and thus maintain the primary system within the allowable pressure/temperature limits.

5.2.2.5.3 Administrative Procedures

Although the system described in Section 5.2.2.5.1 is installed to maintain RCS pressure within allowable limits, administrative procedures are recommended for minimizing the potential for any transient that could actuate the overpressure relief system. The following discussion highlights these procedural controls, listed in hierarchy of their function in preventing RCS cold overpressurization transients.

Of primary importance is the basic method of operation of the plant. Normal plant operating procedures will maximize the use of a pressurizer cushion (steam/N_2 bubble) during periods of low pressure, low temperature operation. This cushion will dampen the plants' response to potential transient generating inputs, providing easier pressure control with the slower response rates.

An adequate cushion eliminates some potential transients such as reactor coolant pump induced heat input and slows the rate of pressure rise for others. In conjunction with the previously discussed alarms, this provides reasonable assurance that most potential transients can be terminated by operator action before the overpressure relief system actuates.

However, for those modes of operation when water solid operation may still be possible, procedures will further highlight precautions that minimize the potential for developing an overpressurization transient. The following specific recommendations will be made:

1. Do not isolate the residual heat removal inlet lines from the reactor coolant loop unless the charging pumps are stopped. This precaution is to assure there is a relief path from the reactor coolant loop to the residual heat removal suction line relief valves when the RCS is at low pressure (less than 500 psi) and is water solid.

2. Whenever the plant is water solid and the reactor coolant pressure is being maintained by the low pressure letdown pressure control valve (PCV-145), low pressure letdown from the RHRS (via HCV-142) must be in operation. During this mode of operation, all three letdown orifices must also remain open.
3. If all reactor coolant pumps have stopped for more than 5 minutes during plant heatup, and the reactor coolant temperature is greater than the charging and seal injection water temperature, do not attempt to restart a pump unless a steam bubble is formed in the pressurizer. This precaution will minimize the pressure transient when the pump is started and the cold water previously injected by the charging pumps is circulated through the warmer reactor coolant components. The steam bubble will accommodate the resultant expansion as the cold water is rapidly warmed.
4. If all reactor coolant pumps are stopped and the RCS is being cooled down by the residual heat exchangers, a non-uniform temperature distribution may occur in the reactor coolant loops. Do not attempt to restart a reactor coolant pump unless a steam bubble is formed in the pressurizer.
5. During plant cooldown, all steam generators should be connected to the steam header to assure a uniform cooldown of the reactor coolant loops.
6. At least one reactor coolant pump must remain in service until the reactor coolant temperature is reduced to 160°F.

These special precautions backup the normal operational mode of maximizing periods of steam bubble operation so that cold overpressure transient prevention is continued during periods of transitional operations.

The specific plant configurations of ECCS testing and alignment to prevent developing cold overpressurization transients during these limited periods of plant operation, given as follows:

1. To preclude inadvertent ECCS actuation during heatup and cooldown, procedures require blocking the pressurizer pressure safety injection signal when pressurizer pressure has decreased below 1985 psig and the steamline safety injection signal when T_{avg} decreases below 552°F.
2. During further cooldown, closure and power lockout of the accumulator isolation valves and power lockout of the non-operating charging pumps will be performed with the RCS pressure maintained between 900 and 950 psig, providing additional backup to step 1 above.
3. The recommended procedure for periodic ECCS pump performance testing will be to test the pumps during normal power operation or at hot shutdown conditions. This precludes any potential for developing a cold overpressurization transient.

   Should cold shutdown testing of the pumps be desired, it will be recommended that the test be done when the vessel is open to atmosphere, again precluding overpressurization potential.

If cold shutdown testing with the vessel closed is necessary, the procedures will require charging pump discharge valve closure and RHRS alignment to both isolate potential ECCS pump input and to provide backup benefit of the RHRS relief valves.

4. "S" signal circuitry testing, if done during cold shutdown, will also require RHRS alignment and non-operating charging pump power lockout to preclude developing cold overpressurization transients.

The above procedural recommendations covering normal operations with a steam bubble, transitional operations where potentially water solid, followed by specific testing operations provide in-depth cold overpressure prevention, augmenting the installed overpressure relief system.

5.2.3 General Material Considerations

5.2.3.1 Material Specifications

Material specifications used for the principal pressure retaining applications in each component comprising the RCPB are listed in Table 5.2-8 for ASME Class 1 primary components and Table 5.2-9 for ASME Class 1 and 2 auxiliary components. The materials are procured in accordance with the material specification requirements and include the special requirements of the ASME Code, Section III, plus Addenda and Code Cases as are applicable and appropriate to meet Appendix B of 10 CFR 50 in the Federal Register, Vol. 35, No. 125. In some cases, Table 5.2-9 may not be totally inclusive of the material specifications used in the listed applications. However, the listed specifications are representative of those materials utilized. All of the materials used are procured in accordance with ASME Code requirements.

The welding materials used for joining the ferritic base materials of the RCPB conform to or are equivalent to ASME Material Specifications SFA 5.1, 5.2, 5.5, 5.17, 5.18, and 5.20. They are tested and qualified to the requirements of ASME Section III rules. In addition the ferritic materials of the reactor vessel beltline are restricted to the following maximum limits of copper, phosphorous, and vanadium to reduce sensitivity to irradiation embrittlement in service:

Element	Base Metal (%)	Weld Metal (%)
Copper	0.10 (Ladle) 0.12 (Check)	0.10
Phosphorous	0.012 (Ladle) 0.017 (Check)	0.015
Vanadium	0.05 (Check)	0.05 (as residual)

Regulatory Guides 1.34, 1.43, 1.50, and 1.66 are discussed in Appendix 3A.

The welding materials used for joining the austenitic stainless steel base materials of the RCPB conform to ASME Material Specifications SFA 5.4 and 5.9. They are tested and qualified to the requirements of ASME Section III rules.

The welding materials used for joining nickel-chromium-iron alloy in similar base material combination and in dissimilar ferritic or austenitic base material combination conform to ASME Material Specifications SFA 5.11 and 5.14. They are tested and qualified to the requirements of ASME Section III rules and are used only in procedures which have been qualified to these same rules.

5.2.3.2 Compatibility With Reactor Coolant

All of the ferritic low alloy and carbon steels which are used in principal pressure retaining applications are provided with corrosion resistant cladding on all surfaces that are exposed to the reactor coolant. This cladding material has a chemical analysis which is at least equivalent to the corrosion resistance of Types 304 and 316 austenitic stainless steel alloys or nickel-chromium-iron alloy, martensitic stainless steel, and precipitation hardened stainless steel. Ferritic low alloy and carbon steel nozzles are safe ended with either stainless steel wrought materials, stainless steel weld metal analysis A-7, or nickel-chromium iron alloy weld metal F-Number 43. The latter buttering material requires further safe ending with austenitic stainless steel base material after completion of the post weld heat treatment when the nozzle is larger than a 4 inch nominal inside diameter and/or the wall thickness is greater than 0.531 inches. The reactor vessel main coolant nozzles are safe ended with nickel-chromium-iron alloy weld metal F-Number 43 and will necessitate dissimilar metal field welds of nickel-chromium-iron alloy to austenitic stainless steel.

The cladding on ferritic type base materials receives a post weld heat treatment.

All of the austenitic stainless steel and nickel-chromium-iron alloy base materials with primary pressure retaining applications are used in the solution anneal heat treat condition. These heat treatments are as required by the material specifications.

During subsequent fabrication, these materials are not heated above 800°F other than locally by welding operations. The solution annealed surge line material is subsequently formed by hot bending followed by a resolution annealing heat treatment.

All other austenitic stainless steel piping in contact with reactor coolant is required to be bent at temperatures above 1200°F. If the bending is performed below 1950°F, piping is solution annealed after bending. All stainless steel piping is cooled rapidly between temperatures of 1500°F and 800°F after bending or annealing.

Degreasing is also required prior to subjecting piping to elevated temperatures before, during, or after bending to prevent carbonization. Austenitic stainless steel material is subsequently tested in accordance with Practice E and the accompanying test Practice A of ASTM A 262.

5.2.3.3 Compatibility With External Insulation and Environmental Atmosphere

In general, all of the materials listed in Tables 5.2-8 and 5.2-9 which are used in principal pressure retaining applications and which are subject to elevated temperature during system operation are in contact with thermal insulation that covers their outer surfaces.

The thermal insulation used on the RCPB is either a metallic reflective stainless steel type or a mass type which is encapsulated in stainless steel.

In the event of coolant leakage, the ferritic materials will show increased general corrosion rates. Where minor leakage is anticipated from service experience, such as valve packing, pump seals, etc., only materials which are compatible with the coolant are used. These are as shown in Tables 5.2-8 and 5.2-9. Ferritic materials exposed to coolant leakage can be readily observed as part of the inservice visual and/or nondestructive inspection program to assure the integrity of the component for subsequent service.

5.2.3.4 Chemistry of Reactor Coolant

The RCS chemistry specifications are given in Table 5.2-10.

The RCS water chemistry is selected to minimize corrosion. A periodic analysis of the coolant chemical composition is performed to verify that the reactor coolant quality meets the specifications.

The Chemical and Volume Control System provides a means for adding chemicals to the RCS which control the pH of the coolant during initial startup and subsequent operation, scavenge oxygen from the coolant during startup and control the oxygen level of the coolant due to radiolysis during all power operations subsequent to startup, and to chemically degasify and oxygenate the RCS during shutdowns for refueling operations. The oxygen content and pH limits for power operations are shown in Table 5.2-10.

The pH control chemical employed is Lithium-7 hydroxide. This chemical is chosen for its compatibility with the materials and water chemistry of borated water/stainless steel/zirconium/ inconel systems. In addition, lithium is produced in solution from the neutron irradiation of the dissolved boron in the coolant. The Lithium-7 hydroxide is introduced into the RCS via the charging flow. The solution is prepared in the laboratory and poured into the chemical mixing tank. Reactor makeup water is then used to flush the solution to the suction header of the charging pumps. The concentration of Lithium-7 hydroxide in the RCS is maintained in the range specified for pH control. If the concentration exceeds this range, the cation bed demineralizer is employed in the letdown line in series operation with the mixed bed demineralizer. Since the amount of lithium to be removed is small and its buildup can be readily calculated and determined by analysis, the flow through the cation bed demineralizer is not required to be full letdown flow.

During reactor startup from the cold condition, hydrazine is employed as an oxygen scavenging agent. The hydrazine solution is introduced into the RCS in the same manner as described above for the pH control agent.

Dissolved hydrogen is employed to control and scavenge oxygen produced due to radiolysis of water in the core region. Sufficient partial pressure of hydrogen is maintained in the volume control tank such that the specified equilibrium concentration of hydrogen is maintained in the reactor coolant. A self-contained pressure control valve maintains a minimum pressure in the vapor space of the volume control tank. This can be adjusted to provide the correct equilibrium hydrogen concentration.

During reactor shutdown for subsequent refueling operations or to open the RCS, hydrogen peroxide is utilized to chemically degasify the reactor coolant and also may be utilized to oxygenate to RCS causing a release of corrosion products from the reactor vessel for subsequent cleanup using the CVCS system.

Components with stainless steel sensitized in the manner expected during component fabrication and installation will operate satisfactorily under normal plant chemistry conditions in PWR systems because chlorides, fluorides, and oxygen are controlled to very low levels.

5.2.4 Fracture Toughness

5.2.4.1 Compliance with Code Requirements

Assurance of adequate fracture toughness of ferritic materials in the RCPB (ASME Section III Class I Components) is provided by compliance with the requirements for fracture toughness testing included in NB 2300 of Section III of the ASME Code, Summer 1972 Addenda, and 10 CFR 50, Appendix G, to the extent possible. A summary of the fracture toughness data for the reactor pressure vessel material is given in Tables 5.2-11 and 5.2-21, and Figures 5.2-16 through 5.2-23.

The fracture toughness of the reactor vessel beltline region has been evaluated according to the requirements of the Pressurized Thermal Shock (PTS) rule (Reference 20). Using the PTS rule and surveillance capsule data (Reference 21), the evaluation documented in WCAP-16306-NP, Revision 0 (Reference 22), shows a maximum calculated RT_{PTS} value for the most limiting plate, A9154-1, of 152°F at 32 EFPY and 159°F at 56 EFPY. The limiting RT_{PTS} values are well below the screening criteria of 270°F specified in the PTS rule.

Ferritic bolting materials used in the RCPB are fabricated in accordance with the following addenda of the ASME Code Section III, all of which predate the issuance of 10 CFR 50, Appendix G:

Reactor Vessel (closure head bolts)	1971 Edition, thru Summer 1971 Addenda
Steam Generator (manway bolts)	1971 Edition, thru Summer 1971 Addenda

Pressurizer (manway bolts)	1971 Edition, thru Summer 1971 Addenda
Reactor Coolant Pump (main flange and seal housing bolts)	1971 Edition, thru Summer 1972 Addenda

These materials comply with the fracture toughness requirements of the applicable code. These requirements are compared to the requirements of 10 CFR Part 50, Appendix G below.

	Test Temperature	ft. lbs	MLE
1971 Edition, Summer 1971 Addendum	-	35	-
1971 Edition, Summer 1972 Addendum	≤40°F	-	25
10 CFR 50 Appendix G, 1980	Lower of preload or service temp. (usually ~50°F)	45	25

The fracture toughness data available for these materials are shown in Table 5.2-22.

5.2.4.2 Acceptable Fracture Energy Levels

Initial upper shelf fracture energy levels for materials of the reactor vessel beltline region (including welds) meet the minimum 75 foot-pound shelf energy requirement of 10 CFR 50, Appendix G.

5.2.4.3 Operating Limitations During Startup and Shutdown

Startup and shutdown operating limitations are based on the properties of the core region materials of the reactor pressure vessel. These limitations are reflected within the Technical Specifications in the form of heatup and cooldown limit curves which show allowable combination of pressure and temperature for specific temperature change rates. The heatup and cooldown limit curves for normal operation are derived in WCAP-16305-NP, Revision 0 (Reference 23) using the methodology from WCAP-14040-NP-A, Revision 4 (Reference 7).

As outlined in WCAP-16305-NP, Revision 0, heatup and cooldown limit curves are calculated using the unirradiated RT_{NDT} (reference nil-ductility temperature) corresponding to the limiting beltline region material of the reactor vessel. The adjusted RT_{NDT} (ART) of the limiting material in the core region of the reactor vessel is determined by using the unirradiated reactor vessel material fracture toughness properties, estimating the radiation-induced ΔRT_{NDT}, and adding a margin. The unirradiated RT_{NDT} is designated as the higher of either the drop weight nil-ductility transition temperature (NDTT) or the temperature at which the material exhibits at least 50 ft-lb of impact energy and 35-mil lateral expansion (transverse to the major rolling direction for late material) minus 60°F.

RT_{NDT} increases as the material is exposed to fast-neutron radiation. Therefore, to find the most limiting RT_{NDT} at any time period in the reactor's life, ΔRT_{NDT} due to the radiation exposure associated with that time period must be added to the unirradiated RT_{NDT} (IRT_{NDT}). The extent of the shift in RT_{NDT} is enhanced by certain chemical elements (such as copper and nickel) present in the reactor vessel steels. Regulatory Guide 1.99, Revision 2 (Reference 24) is used to predict radiation embrittlement and for the calculation of Adjusted Reference Temperature (ART) values ($IRT_{NDT} + \Delta RT_{NDT}$ + margin for uncertainties) at the ¼ T and ¾ T locations, where T is the thickness of the vessel at the beltline region measured from the clad/base metal interface. The most limiting ART values are used in the generation of heatup and cooldown limit curves for normal operation.

As required by Appendix G to 10 CFR Part 50, the Technical Specification heatup limit curves also include temperature limits for inservice leak tests and hydrotests which are used to define additional pressure-temperature limits for core operation (i.e., criticality limit curves) to provide additional margin during actual power production.

5.2.4.3.1 Temperature Difference Between the Pressurizer and Reactor Coolant Loop

Thermal stratification in the pressurizer surge line is a direct result of the difference in temperatures between the pressurizer water and the generally cooler RCS water during plant startup and shutdown. The hotter, lighter pressurizer water tends to float on the cooler, heavier RCS water. The potential for thermal stratification is directly proportional to the difference in temperature (system ΔT) between the pressurizer and the RCS. The potential for stratification is increased as the system ΔT increases. At power, when the system ΔT is relatively small, the extent and effects of thermal stratification have been observed to be negligible. However, during certain modes of plant startup and shutdown, the system ΔT could be as large as 320°F, in which case the effects of thermal stratification are significant.

As required by the NRC Bulletin 88-11, the effects of thermal stratification of the surge line were included in a structural and fatigue analysis of the piping. The analysis demonstrated that the pipe stress and fatigue factors conform the ASME Code limits for all anticipated thermal stratification conditions up to a system ΔT limit of 320°F.

In order to remain within the design basis parameters of this analysis, a system ΔT limit of 320°F is necessary during plant startup and shutdown.

5.2.4.4 Compliance with Reactor Vessel Material Surveillance Program Requirements

Refer to Section 5.4.

5.2.4.5 Reactor Vessel Annealing

Refer to Section 5.4.

5.2.5 Austenitic Stainless Steel

The unstabilized austenitic stainless steel material specifications used for the RCPB, systems required for reactor shutdown, and systems required for emergency core cooling are listed in Tables 5.2-8 and 5.2-9.

The unstabilized austenitic stainless steel material for the reactor vessel internals which are required for emergency core cooling for any mode of normal operation or under postulated accident conditions and for core structural load bearing members are listed in Table 5.2-12.

The above tabulated materials are procured in accordance with the material specification requirements and include the special requirements of the ASME Code, Section III, plus Addenda and Code Cases as are applicable to meet Appendix B of 10 CFR 50 in the Federal Register, Vol. 35, No. 125.

Regulatory Guide 1.44 is discussed in Appendix 3A.

5.2.5.1 Cleaning and Contamination Protection Procedures

It is required that austenitic stainless steel materials used in the fabrication, installation, and testing of nuclear steam supply components and systems be handled, protected, stored, and cleaned according to recognized and accepted methods which are designed to minimize contamination which could lead to stress corrosion cracking. The rules covering these controls are stipulated in process specifications. As applicable, these process specifications supplement the equipment specifications and purchase order requirements of every individual austenitic stainless steel component or system procured for the NSSS, regardless of the ASME Code Classification. The site cleaning procedures recommended in Regulatory Guide 1.37 are discussed in Appendix 3A.

To assure that manufacturers and installers adhere to the requirements of these specifications, surveillance of operations is conducted either in residence at the manufacturer’s plant and the construction site or, when residency is not practical, during periodic engineering and quality assurance visitations and audits at these locations. Any deviation from these rules requires corrective action.

5.2.5.2 Solution Heat Treatment Requirements

The austenitic stainless steels listed in Tables 5.2-8, 5.2-9, and 5.2-12 are utilized in the final heat treated condition required by the respective ASME Code Section II material specification for the particular type or grade of alloy.

5.2.5.3 Material Inspection Program

Austenitic stainless steel materials of product forms with simple shapes need not be corrosion tested provided that the solution heat treatment is followed by water quenching. Simple shapes are defined as all plates, sheets, bars, pipe and tubes, as well as forgings, fittings, and other shaped

products which do not have inaccessible cavities or chambers that would preclude rapid cooling when water quenched. When testing is required, the tests are performed in accordance with ASTM A 262-70, Practice A or E, as amended by Westinghouse Process Specification 84201 MW.

5.2.5.4 Unstabilized Austenitic Stainless Steels

The unstabilized austenitic stainless steels used in the RCPB and components are listed in Tables 5.2-8 and 5.2-9.

The materials are used in the as-welded condition as discussed in Section 5.2.5.2. The control of the water chemistry is stipulated in Section 5.2.3.4.

5.2.5.5 Prevention of Intergranular Attack of Unstabilized Austenitic Stainless Steels

Unstabilized austenitic stainless steels are subject to intergranular attack (IGA) provided that three conditions are present simultaneously. These are:

1. An aggressive environment, e.g., an acidic aqueous medium containing chlorides or oxygen.
2. A sensitized steel.
3. A high temperature.

If any one of the three conditions described above is not present, intergranular attack will not occur. Since high temperatures cannot be avoided in all components in the NSSS, Westinghouse relies on the elimination of conditions 1 and 2 to prevent intergranular attack on wrought stainless steel components.

The water chemistry in the RCS of a Westinghouse Pressurized Water Reactor (PWR) is rigorously controlled to prevent the intrusion of aggressive species. In particular, the maximum permissible oxygen and chloride concentrations are 0.10 ppm and 0.15 ppm, respectively. Reference 8 describes the precautions taken to prevent the intrusion of chlorides into the system during fabrication, shipping, and storage. The use of hydrogen overpressure precludes the presence of oxygen during operation. The effectiveness of these controls has been demonstrated by both laboratory tests and operating experience. The long time exposure of severely sensitized stainless in early plants to PWR coolant environments has not resulted in any sign of intergranular attack. Reference 8 describes the laboratory experimental findings and the Westinghouse operating experience. The additional years of operations since the issuing of Reference 8 have provided further confirmation of the earlier conclusions. Severely sensitized stainless steels do not undergo any intergranular attack in Westinghouse PWR coolant environments.

In spite of the fact there never has been any evidence that PWR coolant water attacks sensitized stainless steels, Westinghouse considers it good metallurgical practice to avoid the use of sensitized stainless steels in the NSSS components. Accordingly, measures are taken to prohibit the purchase of sensitized stainless steels and to prevent sensitization during component fabrication. Wrought austenitic stainless steel stock used for components that are part of the

RCPB, systems required for reactor shutdown, systems required for emergency core cooling, and reactor vessel internals that are relied upon to permit adequate core cooling for normal operation or under postulated accident conditions is utilized in one of the following conditions:

1. Solution annealed and water quenched.
2. Solution annealed and cooled through the sensitization temperature range within less than approximately 5 minutes.

It is generally accepted that these practices will prevent sensitization. Westinghouse has verified this by performing corrosion tests (ASTM 393) on as-received wrought material.

Westinghouse recognizes that the heat affected zones of welded components must, of necessity, be heated into the sensitization temperature range, 800 to 1500°F. However, severe sensitization, i.e., continuous grain boundary precipitates of chromium carbide, with adjacent chromium depletion, can still be avoided by control of welding parameters and welding processes.

The heat input (1) and associated cooling rate through the carbide precipitation range are of primary importance. Westinghouse has demonstrated this by corrosion testing a number of weldments.

(1) Heat input is calculated according to the formula:

$$H=\frac{(E)(I)(60)}{S}$$

Where: H = joules/in; E = volts; I = Amperes; and S = Travel Speed in inches/minute.

Of 25 production and qualification weldments tested, representing all major welding processes, an a variety of components, and incorporating base metal thicknesses from 0.10 to 4.0 inches, only portions of two were severely sensitized. Of these, one involved a heat input of 120,000 joules, and the other involved a heavy socket weld in relatively thin walled material. In both cases, sensitization was caused primarily by high heat inputs relative to the section thickness. However, in only the socket weld did the sensitized condition exist at the surface, where the material is exposed to the environment. The component has been redesigned to eliminate this weld.

Westinghouse controls the heat input in all austenitic pressure boundary weldments by:

1. Prohibiting the use of block welding.
2. Limiting the maximum interpass temperature to 350°F.

3. Exercising approval rights on all welding procedures.

To further assure that these controls are effective in preventing sensitization, Westinghouse per WCAP-8678 (Reference 16) conducted additional intergranular corrosion tests of qualification mock-ups of primary pressure boundary and core internal component welds, including the following:

1. Reactor vessel safe ends.
2. Pressurizer safe ends.
3. Surge line and reactor coolant pump nozzles.
4. Control rod drive mechanisms head adapters.
5. Control rod drive mechanisms seal welds.
6. Control rod extensions.
7. Lower instrumentation penetration tubes.

To summarize, Westinghouse has a four point program designed to prevent intergranular attack of austenitic stainless steel components.

1. Control of primary water chemistry to ensure a benign environment.
2. Utilization of materials in the final heat treated condition and the prohibition of subsequent heat treatments in the 800 to 1500°F temperature range.
3. Control of welding processes and procedures to avoid heat affected zone sensitization.
4. Confirmation that the welding procedures used for the manufacture of components in the primary pressure boundary and of reactor internals do not result in the sensitization of heat affected zones.

Both operating experience and laboratory experiments in primary water have conclusively demonstrated that this program is 100% effective in preventing intergranular attack in Westinghouse NSSS's utilizing unstabilized austenitic stainless steel.

5.2.5.6 Retesting Unstabilized Austenitic Stainless Steels Exposed to Sensitization Temperatures

Unstabilized austenitic stainless steels are not normally exposed to the sensitization range of 800 to 1500°F during fabrication into components except as described in Section 5.2.3.2. If, during the course of fabrication, the steel is inadvertently exposed to the sensitization temperature range, 800 to 1500°F, the material may be tested in accordance with ASME A393 or A262 as amended by Westinghouse Process Specification 84201 MW to verify that it is not susceptible to intergranular attack, except that testing is not required for:

1. Cast metal or weld metal with a ferrite content of 5% or more.

2. Material with a carbon content of 0.03% or less that is subjected to temperatures in the range of 800 to 1500°F for less than one hour.
3. Material exposed to special processing provided the processing is properly controlled to develop a uniform product and provided that adequate documentation exists of service experience and/or test data to demonstrate that the processing will not result in increased susceptibility to intergranular stress corrosion.

If it is not verified that such material is not susceptible to intergranular attack, the material will be resolution annealed and water quenched or rejected.

5.2.5.7 Control of Delta Ferrite in Austenitic Stainless Steel Welding

Regulatory Guide 1.31 describes a method for implementing General Design Criterion 1 of Appendix A to 10 CFR 50 and Appendix B to 10 CFR 50 with regard to control of welding austenitic stainless steel components and systems. The Interim Regulatory Position of this guide, March 1974, describes an alternative method of control. The following paragraphs describe the methods used by Westinghouse and the verification of these methods for austenitic stainless steel welding on this application. Additional discussion on the recommendations of Regulatory Guide 1.31 is given in Appendix 3A.

The welding of austenitic stainless steel is controlled to mitigate the occurrence of microfissuring or hot cracking in the weld. Although published data and experience have not confirmed that fissuring is detrimental to the quality of the weld, it is recognized that such fissuring is undesirable in a general sense. Also, it has been well documented in the technical literature that the presence of delta ferrite is one of the mechanisms for reducing the susceptibility of stainless steel welds to hot cracking. However, there are insufficient data to specify a minimum delta ferrite level below which the material will be prone to hot cracking. It is assumed that such a minimum lies somewhere between 0 and 3% delta ferrite.

The scope of these controls discussed herein encompasses welding processes used to join stainless steel parts in components designed, fabricated, or stamped in accordance with the ASME Code, Section III Class 1, 2, and core support components. Delta ferrite control is appropriate for the above welding requirements except where no filler metal is used or for other reasons such control is not applicable. These exceptions include electron beam welding, autogenous gas shielded tungsten arc welding, explosive welding, and welding using fully austenitic welding materials.

The fabrication and installation specifications require welding procedure and welder qualification in accordance with Section III, and include the delta ferrite determinations for the austenitic stainless steel welding materials that are used for welding qualification testing and for production processing. Specifically, the undiluted weld deposits of the "starting" welding materials are required to contain a minimum of 5% delta ferrite(2) as determined by chemical analysis and calculation using the appropriate weld metal constitution diagrams in Section III. When new

(2) The equivalent ferrite number may be substituted for percent delta ferrite.

welding procedure qualification tests are evaluated for these applications, including repair welding of raw materials, they are performed in accordance with the requirements of Section III and Section IX.

The results of the destructive and nondestructive tests are reported in the procedure qualification record in addition to the information required by Section III.

The "starting" welding materials used for fabrication and installation welds of austenitic stainless steel materials and components meet the requirements of Section III. The austenitic stainless steel welding material conforms to ASME weld metal analysis A-7, Type 308 for all applications except Type 308L weld metal analysis may be substituted for consumable inserts when used for weld root closures. Bare weld filler metal, including consumable inserts, used in inert gas welding processes conform to ASME SFA-5.9, and are procured to contain not less than 5% delta ferrite according to Section III. Weld filler metal materials used in flux shielded welding processes conform to ASME SFA-5.4 or SFA-5.9 and are procured in a wire-flux combination to be capable of providing not less than 5% delta ferrite in the deposit according to Section III. Welding materials are tested using the welding energy inputs to be employed in production welding.

Combinations of approved heats and lots of "starting" welding materials are used for all welding processes. The welding quality assurance program includes identification and control of welding material by lots and heats as appropriate. All of the weld processing is monitored according to approved inspection programs which include review of "starting" materials, qualification records, and welding parameters. Welding systems are also subject to quality assurance audit including calibration of gages and instruments; identification of "starting" and completed materials; welder and procedure qualifications; availability and use of approved welding and heat treating procedures; and documentary evidence of compliance with materials, welding parameters, and inspection requirements. Fabrication and installation welds are inspected using nondestructive examination methods according to Section III rules.

To further assure the reliability of these controls, Westinghouse has completed a verification program, which is described in Reference 9. The program has been approved as a valid approach to verify the Westinghouse hypothesis and is considered an acceptable alternative to production weld testing for conformance with the NRC Interim Position on Regulatory Guide 1.31. The Regulatory Staff’s acceptance letter and topical report evaluation were received on December 30, 1974. The results of the verification program, which do not support the original hypothesis, are summarized in Reference 10.

It should be noted that the criteria discussed above concerning delta ferrite determinations were incorporated in the Virgil C. Summer Nuclear Station components that were involved in the Westinghouse verification program; these components cannot necessarily be identified. Those components not involved in the verification program were fabricated in accordance with applicable ASME Code requirements, which do not include delta ferrite determinations. Therefore, the delta ferrite determinations performed on the Virgil C. Summer Nuclear Station components are in addition to the applicable ASME Code requirements.

5.2.6 Pump Flywheels

The integrity of the reactor coolant pump flywheel is assured on the basis of the following design and quality assurance procedures.

5.2.6.1 Design Basis

The calculated stresses at operating speed are based on stresses due to centrifugal forces. The stress resulting from the interference fit of the flywheel on the shaft is less than 2000 psi at zero speed, but this stress becomes zero at approximately 600 rpm because of radial expansion of the hub. The primary coolant pumps run at approximately 1190 rpm and may operate briefly at overspeeds up to 109% (1295 rpm) during loss of outside load. For conservatism, however, 125% of operating speed was selected as the design speed for the primary coolant pumps. The flywheels are given a preoperational test of 125% of the maximum synchronous speed of the motor.

5.2.6.2 Fabrication and Inspection

The flywheel consists of two thick plates bolted together. The flywheel material is produced by a process that minimizes flaws in the material and improves its fracture toughness properties, such as vacuum degassing, vacuum-melting, or electroslag remelting. Each plate is fabricated from A533, Grade B, Class 1 steel. Supplier certification reports are available for all plates and demonstrate the acceptability of the flywheel material on the basis of the requirements of Regulatory Guide 1.14.

No welding, including repair welding, is performed on the flywheels. The tensile (from material certifications) and Charpy-V-notch data for the flywheel discs are tabulated in Tables 5.2-23 and 5.2-24.

Flywheel blanks are flame-cut from the A533, Grade B, Class 1 plates with at least 1/2 inch of stock left on the outer and bore radii for machining to final dimensions. The finished machined bores, keyways, and drilled holes are subjected to magnetic particle or liquid penetrant examinations. The finished flywheels are subjected to 100% volumetric ultrasonic inspection per Paragraphs NB-2532.1 and NB-2532.2 of the ASME Code, Section III.

The reactor coolant pump motors are designed such that the flywheel is available by removing the cover to provide access to allow an inservice inspection program in accordance with requirements of Section XI of the ASME Code and the recommendations of Regulatory Guide 1.14 (see Appendix 3A).

5.2.6.3 Acceptance Criteria and Compliance with Regulatory Guide 1.14

The reactor coolant pump motor flywheel conforms to the following material acceptance criteria.

1. The nil-ductility transition temperature (NDTT) of the flywheel material is obtained by two drop weight tests (DWT) which exhibit "no-break" performance at 20°F in accordance with

ASTM E-208. The above drop weight tests demonstrate that the NDTT of the flywheel material is no higher than 10°F.

2. A minimum of three Charpy V-notch specimens from each plate are tested at ambient (70°F) temperature in accordance with the specification ASTM E-23. The Charpy V-notch (C_v) energy in both the parallel and normal orientation with respect to the rolling direction of the flywheel material is at least 50 foot pounds at 70°F to demonstrate that RT_{NDT} is no higher than 10°F. A lower bound K_{Ic} versus temperature curve from tests of SA-533 Grade B, Class 1 and SA-508 Class 2 steels is provided in ASME Boiler and Pressure Vessel Code, Section XI, Appendix A, Figure A-4200-1. The temperature scale of this figure is referenced to RT_{NDT}, the reference nil-ductility temperature. The fracture toughness K_{Ic} given in Figure A-4200-1 is based on lower bound data from static fracture toughness tests. Reference of this curve to the guaranteed RT_{NDT} of +10°F gives a minimum static fracture toughness of 150 ksi in1/2 at 90°F. The expected normal operating temperature of the Virgil C. Summer Nuclear Station reactor coolant pump motor flywheels is in excess of 110°F. Therefore, the minimum static fracture toughness requirement of 150 ksi in1/2 is exceeded. A lower bound K_{Id} reference curve (see Figure 5.2-3) has been constructed from dynamic fracture toughness data generated in A533, Grade B, Class 1 steel (Reference 11). All data points are plotted on the temperature scale relative to the NDTT. The construction of the lower bound curve below which no single test point falls, combined with the use of dynamic data when flywheel loading is essentially static, together represent a large degree of conservatism. Reference of this curve to the guaranteed NDTT of +10°F indicates that, at the predicted flywheel operating temperature of 110°F, the minimum fracture toughness is in dynamic stress intensity factor must be at least 100 KSI-$in^{1/2}$. This conforms to the Regulatory Guide 1.14 requirement that the dynamic stress intensity factor must be at least 100 KSI-$in^{1/2}$.

Precautionary measures taken to preclude missile formation from primary coolant pump components assure that the pumps will not produce missiles under any anticipated accident condition. Each component of the primary pump motors has been analyzed for missile generation. Any fragments of the motor rotor would be contained by the heavy stator. The same conclusion applies to the pump impeller because the small fragments that might be ejected would be contained by the heavy case.

Thus, it is concluded that flywheel plate materials are suitable for use and can meet Regulatory Guide 1.14 acceptance criteria on the bases of suppliers certification data.

5.2.7 Reactor Coolant Pressure Boundary Leakage Detection Systems

Leakage detection systems are required to detect and, to the extent practical, identify the source of reactor coolant leakage. The airborne radiation monitoring system, described in Sections 11.4 and 12.2.4, provides input which is sensitive to leakage detection when activity is present in reactor coolant. Portions of this system, in addition to quantitative leak detection systems located in the reactor building, enable the operator to adequately locate and analyze the RCPB leakage.

5.2.7.1 Leakage Detection Method

Leakage detection system instrumentation sensitivity is 1 gpm or less. Response time of less than one hour is consistent with the requirements of General Design Criterion 30. Sufficient range overlap and multiple instruments ensure shorter overall response time for leakage detection. Reactor building sump level instrumentation is Seismic Category I. The various methods of leakage detection employed are discussed in Sections 5.2.7.1.1 through 5.2.7.1.4 and 5.2.7.8.

5.2.7.1.1 Activity Detection

Consistent with the recommendations of Regulatory Guide 1.45 (see Appendix 3A), radioactivity detection systems are included for monitoring both particulate and gaseous activities because of their sensitivities and rapid responses to RCS leakage but have recognized limitations on achieving the recommended response time of one hour or less when there are few fuel cladding defects and reactor coolant activity levels are low.

The reactor building air sample line radiation monitor (RM-A2) is the most sensitive to reactor coolant leakage. Alarms are provided to alert the operator to the onset of or changes in reactor coolant leakage. The monitor is typically set to provide the most sensitive response without causing an excessive number of spurious alarms in order to provide an early indication of the onset of or changes in reactor coolant leakage, and an audible alarm is provided in the control room when the monitor’s setpoint is exceeded. Section 12.2.4 discusses airborne radiation monitoring instrumentation, sensitivities, and setpoints. The radiation monitor (RM-A2) satisfies the seismic requirements of Regulatory Guide 1.45.

Leakage from the RCPB into the component cooling water system is detected by process radiation monitors (RM-L2A and RM-L2B). These radiation monitors are described in Section 11.4.

5.2.7.1.2 Detection by Temperature, Pressure, or Drain Flows

Reactor building temperature and pressure monitors provide indirect indication of gross RCPB leakage. However, the most sensitive leakage detection system, other than activity detection, is the reactor building cooling unit condensate drain flow alarm. A flow meter is located in the common condensate drain header from the reactor building cooling units (see Figures 5.2-9 and 9.3-5). The flow meter actuates an alarm in the control room, should a flow rate exceeding 0.75 gpm nominal occur. The response time for this system to indicate a 1 gpm reactor coolant leak is approximately 20 minutes. The reactor building temperature and pressure monitors and the flow switches satisfy the seismic requirements of Regulatory Guide 1.45.

5.2.7.1.3 Leak Detection Sumps

The Reactor Building Sump is used to collect and quantify leakage originating in the Reactor Building. Detection of leakage is accomplished by obtaining a flow rate into the sump from comparison of level changes over a specified time period. Whenever the measured flow rate into the sump from unidentified sources exceeds 1 gallon per minute, a "greater than 1 gpm" alarm is

actuated. To ensure reliability, the level monitor for the RB sump is Seismic Category I. This detection method satisfies the requirements of Regulatory Guide 1.45 as one of the diverse methods for determination of reactor coolant leakage employed in the design of Virgil C. Summer Nuclear Station.

The Incore Instrument Sump, although not credited in the VCSNS SER nor in Technical Specifications, provides another means to collect and quantify unidentified leakage originating in the Reactor Building.

The CRDM condensate drain line flow transmitter installed under ECR 50677 monitors leakage in the range of 0.5 gpm to 1.0 gpm. The new flow transmitter provides enhanced RCS leak detection but is not credited in the VCSNS SER nor in the Technical Specifications.

5.2.7.1.4 Indirect Detection

Low pressurizer level indication or a discrepancy between net letdown and makeup flow, if unexplained, are good indications of reactor coolant leakage.

5.2.7.2 Indication in Control Room

Display instrumentation for the variables providing indirect indication for the leakage detection systems has audible alarms and measured variable recording devices in the control room. Instrumentation is of sufficient redundancy and quantity to assure that leakage is monitored. Regulatory Guide 1.45 is discussed in Appendix 3A.

5.2.7.3 Limits for Reactor Coolant Leakage

RCPB leakage is defined as leakage through a fault in an RCS component body, pipe wall, or vessel wall. Leakage past seals, packing, and gaskets is not PRESSURE BOUNDARY LEAKAGE. Unidentified leakage limitations are discussed in the Technical Specifications. Unidentified leakage is expected to be less than 1 gpm. Identified leakage less than 10 gpm is acceptable provided that it does not interfere with detection of unidentified leakage by the leakage detection systems.

5.2.7.4 Unidentified Leakage

Unidentified leakage is any RCS leakage which is not identified or controlled leakage (see Section 5.2.7.5).

5.2.7.5 Maximum Allowable Total Leakage

The maximum allowable total leakage includes controlled leakage and identified leakage.

Controlled leakage is defined as seal water flow to reactor coolant pump seals. Operation is limited if this flow exceeds 33 gpm with the supply modulating valve fully open and reactor

coolant system pressure at 2235 psig, nominal. Flow instrumentation is provided for the purpose of monitoring this leakage.

Identified leakage includes the following:

1. Leakage into closed systems, such as flange seals and valve leakoffs to collection tanks, normal letdown, sampling of auxiliary systems, and pressurizer relief valve discharge to pressurizer relief tank. These leakage paths contain temperature elements to indicate leakage flow, as well as high level tank, high flow rate, and radiation monitor alarms in auxiliary systems.
2. Other leakages not related to the RCPB which do not interfere with leakage detection system operation.
3. Reactor coolant leakage through a steam generator (not a steam generator tube rupture) to the secondary system. This leakage is limited to less than a total of 150 gal/day from each steam generator. This leakage is monitored by radiation monitors RM-L3 and RM-A9, as well as by periodic sampling discussed in Section 11.4.

5.2.7.6 Differentiation between Identified and Unidentified Leaks

The leakage detection system provides for differentiation between identified and unidentified leakage since identified leakage flows into closed containers or does not interfere with detection system operation. The leakage detection system provides both qualitative and quantitative information for use by the operator in determining the location and magnitude of leakage.

5.2.7.7 Sensitivity and Operability Tests

Proper functioning of leak detection instrumentation is assured by testing and calibration procedures. Sensitivity and calibration of radiation monitoring equipment are discussed in Sections 11.4 and 12.2.4.

5.2.7.8 Intersystem Leakage

Reliable methods of intersystem leakage detection for systems connected to the reactor coolant system are described below:

1. Safety Injection System

   Safety injection system cold leg connection leakage will be detected by lifting of residual heat removal relief valves 8864A or 8864B.

   Safety injection system hot leg connection leakage will be detected by lifting of residual heat removal relief valve 8865.

   Accumulator connection leakage will be detected by:

a. Redundant high accumulator level indication and alarm, and/or

b. Redundant high accumulator pressure indication and alarm.

High head cold leg injection and high head hot leg recirculation line leakage is not of concern since these are normally exposed to charging flow.

2. Residual Heat Removal System

Residual heat removal suction connection leakage will be detected by lifting of residual heat removal suction relief valves 8708A or 8708B accompanied by increased pressurizer relief tank level and temperature indication and alarm.

Residual heat removal discharge connection leakage will be detected by lifting of residual heat removal relief valves 8864A or 8864B.

3. Waste Processing System

Cold leg leakage into the waste processing system will be collected in the reactor coolant drain tank and detected by:

a. An increased load on the collection system, and/or

b. Lifting of reactor coolant drain tank relief valve 7169.

Leakage from the reactor vessel flange leakoff connection will be detected by high temperature indication and alarm from the leakage piping.

4. Pressurizer Relief Tank

Reactor coolant system leakage to the pressurizer relief tank will be detected by:

a. High temperature indication and alarm in the pressurizer safety valve and power operated relief valve discharge lines, and/or

b. High temperature or high level indication and alarms in the pressurizer relief tank, and

c. The acoustical type leak monitoring system and pressurizer safety valve alarm, and

d. PORV position indication.

5. Chemical and Volume Control System

Since the only chemical and volume control system to reactor coolant system connections are utilized for reactor coolant system letdown and charging, intersystem leakage detection is not relevant.

6. Valve Leakage

As discussed in Section 9.3.3.2, Item 10, and illustrated by Figures 9.3-13 and 9.3-13a, valve packing box leakage from various systems is monitored by means of level switches.

7. Main Steam System

   Steam generator tube leakage will be detected by:

   a. Use of steam generator blowdown and sampling (see Sections 9.3.2 and 10.4.8) which includes use of radiation monitors, RM-L3 and RM-L10 (see Section 11.4.2) and/or
   b. Main plant vent exhaust radiation monitor, RM-A3 (see Section 11.4.2) and/or
   c. Turbine room sump radiation monitor, RM-L8 (see Section 11.4) and/or
   d. Condenser exhaust monitor, RM-A9 (see Section 11.4).

8. Component Cooling Water System

   As discussed in Section 11.4.2, radiation monitors, RM-L2A and/or RM-L2B, will detect intersystem leakage into the component cooling water system.

   Residual heat removal heat exchanger leakage will be detected by high temperature indication and alarm.

   Reactor coolant drain tank heat exchanger leakage will be detected by:

   a. High temperature indication and alarm and/or
   b. High flow indication.

   Reactor coolant pump thermal barrier leakage will be detected by:

   a. High temperature indication and alarm and/or
   b. High flow indication and alarm.

   Reactor coolant pump upper and lower bearing leakage will be detected by:

   a. High temperature indication and alarm and/or
   b. High flow indication.

   Letdown heat exchanger leakage will be detected by:

   a. High temperature indication and alarm and/or
   b. High flow indication.

   Seal water heat exchanger leakage will be detected by:

a. High temperature indication and alarm and/or

b. High flow indication.

Residual heat removal pump leakage will be detected by:

a. High temperature indication and alarm and/or

b. High flow indication.

5.2.8 Inservice Inspection Program

Refer to Section 5.7.

Table 5.2-5
Allowable Stresses for Primary Equipment Supports

Loading Conditions	Stress Limits
Design/Normal	AISC, Seventh Edition(1), Part 1, Allowable Stresses
Upset	AISC, Seventh Edition, Part 1, Allowable Stresses
Faulted	Stresses ≤ yield strength of material. Local yielding is permitted but limited so that the structural integrity of the system is maintained. As an alternative to the above, 80 percent of L_T(2) may be used.

(1) Specification for the Design, Fabrication and Erection of Structural Steel for Buildings.
(2) L_T = The limits established for the analysis need not be satisfied if it can be shown from the test of a prototype or model that the specified loads (dynamic or static equivalent) do not exceed 80 percent of L_T, where L_T is the ultimate load or load combination used in the test. In using this method, account is taken of the size effect and dimensional tolerances (similitude relationships) which may exist between the actual component and the tested models to assure that the loads obtained from the test are a conservative representation of the load carrying capability of the actual component under postulated loading for faulted conditions.

Auxiliary Pumps	
Pump Casing & Heads	SA351 Gr CF8 or CF8M, SA182 Gr F304 or F316
Flanges & Nozzles	SA182 Gr F304 or F316, SA403 Gr WP316L Seamless
Piping	SA312 TP304 or TP316 Seamless
Stuffing or Packing Box Cover	SA351 Gr CF8 or CF8M, SA240 TP304 or TP316
Pipe Fittings	SA403 Gr WP316L Seamless
Closure Bolting & Nuts	SA193 Gr B6, B7, or B8M and SA194 Gr 2H or Gr 8M, SA193 Gr B6, B7 or B8M; SA453 Gr 660; and Nut 8, SA194 Gr 2H, Gr 8M, and Gr 6

Table 5.2-10
Reactor Coolant Water Chemistry Specification

Electrical Conductivity	Affected by the concentration of boric acid and alkali present. Expected range is < 1 to 40 μMhos/cm at 25°C.
Solution pH	Affected by the concentration of boric acid and alkali present. Expected values range between 4.2 (high boric acid concentration) to 10.5 (low boric acid concentration) at 25°C.
Oxygen, ppm, maximum	Oxygen concentration of the reactor coolant is maintained below 0.1 ppm for plant operation above 250°F. Hydrazine may be used to chemically scavenge oxygen during heatup.
Chloride, ppm, maximum	0.15
Fluoride, ppm, maximum	0.15
Hydrogen, cc (STP)/kg H_2O	
Reactor Power Level above 1 MWt, excluding decay heat during subcritical operation.	25-50
Total Suspended Solids	
ppm, maximum	1.0
pH Control Agent (Li^7OH)	Lithium concentration is coordinated with the boron concentration.
Boric Acid, ppm B	Variable from 0 to approximately 4000

Core Region Welds	***	.05	.013	-44	79,87,87	1.36/2.35	45.8/51.9
Weld HAZ	A9154-1	-	-	-70	137,135,118	1.36/2.35	45.8/51.9

* Determined from drop weight tests and full Charpy curve tests normal to the major working direction. Value reported is the higher of the NDTT temperature or the temperature 60°F below the 50 ft-lb/35 mil lateral expansion temperature.

** Based on WCAP-16298-NP, Revision 0, using methods identified in Regulatory Guide 1.99 Revision 2. Most limiting material is plate A9154-1. Test specimens from this plate are included in the reactor vessel surveillance program. The values were determined using results of capsules U, V, X, W, and Z test reports.

*** All core region welds were made with RACO INMM wire (heat no. 4P4784) and Linde 124 flux (lot no. 3930). The same heat of weld wire and lot of flux was also used to fabricate the surveillance program weldment. A post weld heat treatment at 1100°F-1175°F for 12 hours was applied to all the weld test material.

**** Calculated fast neutron fluence (E > 1.0 MeV) values at the inner surface of the reactor vessel (per WCAP-16298-NP, Revision 0). These values were projected using results of the Capsule Z radiation analysis.

5.3 Thermal Hydraulic System Design

5.3.1 Analytical Methods and Data

The thermal and hydraulic design bases of the Reactor Coolant System (RCS) are summarized in Table 5.1-1 and described further in Sections 4.3 and 4.4 in terms of core heat generation rates, departure from nucleate boiling ratio (DNBR), analytical models, peaking factors, and other relevant aspects of the reactor.

5.3.2 Operating Restrictions on Pumps

The minimum net positive suction head (NPSH) and minimum seal injection flowrate must be established before operating the reactor coolant pumps. With the minimum 6 gpm seal injection flowrate established, the operator will have to verify that the system pressure satisfies NPSH requirements and that the seal controlled bleed-off flow satisfies seal flow requirements.

5.3.3 Power-Flow Operating Map (BWR)

Not applicable to pressurized water reactors.

5.3.4 Temperature-Power Operating Map

The NSSS is designed to operate with a full power average coolant temperature ranging from 572°F to 587.4°F. The relationship between RCS temperature and power is shown in Figure 5.3-1 for thermal design conditions with a T_{avg} of 587.4°F at a core power of 2900 MWt.

The effects of reduced core flow due to inoperative pumps are discussed in Sections 5.5.1, 15.2.5, and 15.3.4.

5.3.5 Load Following Characteristics

The RCS is designed on the basis of steady-state operation at full power heat load. The reactor coolant pumps utilize single speed motors as described in Section 5.5 and the reactor power is controlled to maintain average coolant temperature at a value which is a linear function of load, as described in Section 7.7. Operation with one pump out of service requires adjustment only in reactor trip system setpoints as discussed in Section 7.2.

5.3.6 Transient Effects

\Transient effects on the RCS are evaluated in Chapter 15.

5.3.7 Thermal and Hydraulic Characteristics Summary Table

The thermal and hydraulic characteristics are given in Tables 4.3-1, 4.4-1, and 5.1-1.

5.4 Reactor Vessel and Appurtenances

Section 5.4 has been divided into four principal subsections, viz., design bases, description, evaluation, and tests and inspections for the reactor vessel and its appurtenances consistent with the requirements of the introductory paragraph of Section 5.4 of the "Standard Format and Content of Safety Analyses Reports for Nuclear Power Plants, Revision 1." The following specific information required by the guide is cross referenced below.

	Guide Reference	FSAR Section(s)
5.4.1	Protection of Closure Studs	5.4.2.2
5.4.2	Special Processes for Fabrication and Inspection	5.2.5, 5.4.2.1, 5.4.4
5.4.3	Features for Improved Reliability	5.4.1, 5.4.2.1
5.4.4	Quality Assurance Surveillance	5.4.2, 5.4.4
5.4.5	Materials and Inspections	5.2.3, 5.2.4, 5.4.4
5.4.6	Reactor Vessel Design Data	Table 5.4-1
5.4.7	Reactor Vessel Schematic (BWR)	Not Applicable

5.4.1 Design Bases

5.4.1.1 Codes and Specifications

The vessel is Safety Class 1. Design and fabrication of the reactor vessel is carried out in strict accordance with ASME Section III, Class 1.

Material specifications are in accordance with the ASME Code requirements and are given in Section 5.2.3.

5.4.1.2 Design Transients

Cyclic loads are introduced by normal power changes, reactor trip, startup, and shutdown operations. These design base cycles are selected for fatigue evaluation and constitute a conservative design envelope for the projected plant life. Vessel analysis results in a usage factor that is less than 1.

With regard to the thermal and pressure transients involved in the loss of coolant accident, the reactor vessel is analyzed to confirm that the delivery of cold emergency core cooling water to the vessel following a loss of coolant accident does not cause a loss of integrity of the vessel.

The results of the analysis required by the design specifications prove that the vessel is in compliance with the fatigue and stress limits of Section III of the ASME Boiler and Pressure Vessel Code. The loadings and transients specified for the analysis are based on the most severe conditions expected during service. The heatup and cooldown rates imposed by plant operating

limits are 50°F per hour for normal operations and 100°F per hour under abnormal or emergency conditions. These rates are reflected in the vessel design specifications.

A control rod housing failure does not cause propagation of failure to adjacent housings or to any other part of the Reactor Coolant System (RCS) boundary.

Design transients are discussed in detail in Section 5.2.1.5.

5.4.1.3 Protection Against Non-Ductile Failure

Protection against non-ductile failure is discussed in Section 5.2.4.

5.4.1.4 Inspection

The internal surface of the reactor vessel is capable of inspection periodically using visual and/or nondestructive techniques over the accessible areas. During refueling, the vessel cladding is capable of being inspected in certain small areas between the closure flange and the primary coolant inlet nozzles, and, if deemed necessary, the core barrel is capable of being removed, making the entire inside vessel surface accessible.

The closure head is examined visually during each refueling. Optical devices permit a selective inspection of the cladding, control rod drive mechanism nozzles, and the gasket seating surface. The knuckle transition piece inspection is eliminated with the single piece forged Replacement Reactor Vessel Closure Head. The closure studs can be inspected periodically using visual, magnetic particle and/or ultrasonic techniques.

5.4.2 Description

The reactor vessel fabricated by Chicago Bridge and Iron, Inc., is cylindrical, with a welded hemispherical bottom head and a removable, bolted, flanged, and gasketed, hemispherical upper head. The reactor vessel flange and head are sealed by two hollow metallic O-rings. Seal leakage is detected by means of two leakoff communications: one between the inner and outer ring and one outside the outer O-ring. The vessel contains the core, core support structures, control rods, and other parts directly associated with the core.

A Replacement Reactor Vessel Closure Head was designed by Westinghouse and fabricated by Doosan Heavy Industrial for installation in RF-23 in the spring of 2017. The replacement is a single piece forging eliminating the dome to flange weld. Head adapters are installed for CRDMs and are of an alloy 690 material and weld, which is much less susceptible to cracking then the original alloy 600 components. The head adapters are a tubular member welded to the head assembly. The assembly eliminates a lower canopy seal weld with a full penetration bimetal weld to the latch housing.

Part length and spare rod locations have been eliminated in the new design with dedicated core exit thermocouple nozzles with custom nozzle assemblies, which eliminated the canopy seals. Dedicated alloy 690 one inch pipe connections are also installed for head vent and reactor vessel

level indicator function. Inlet and outlet nozzles are located symmetrically around the vessel. Outlet nozzles are arranged on the vessel to facilitate optimum layout of the RCS equipment. The inlet nozzles are tapered from the coolant loop vessel interfaces to the vessel inside wall to reduce loop pressure drop.

The bottom head of the vessel contains penetration nozzles for connection and entry of the nuclear incore instrumentation. Each nozzle consists of a tubular member made of Inconel. Each tube is attached to the inside of the bottom head by a partial penetration weld.

Internal surfaces of the vessel which are in contact with primary coolant are weld overlay with 0.125 inch minimum of stainless steel. The exterior of the reactor vessel is insulated with canned stainless steel reflective sheets. The insulation is a minimum of three inches thick and contoured to enclose the top, sides, and bottom of the vessel. All the insulation modules are removable but the access to vessel side insulation is limited by the surrounding concrete.

The reactor vessel nozzle insulation consists of a noncrushable nonmetalic material clad with stainless steel.

5.4.2.1 Fabrication Processes

1. The use of severely sensitized stainless steel as a pressure boundary material has been prohibited and has been eliminated by both a select choice of material and by programming the method of assembly.

   Refer to Appendix 3A for a discussion of Regulatory Guide 1.44.

2. Minimum preheat requirements have been established for pressure boundary welds using low alloy weld material. Special preheat requirements have been added for stainless steel cladding of low stressed areas. Controlled limitations are placed on preheat requirements by Westinghouse. The purpose of placing limitations on preheat requirements is the addition of precautionary measures to decrease the probabilities of weld cracking by decreasing temperature gradients, lower susceptibility to brittle transformation, prevention of hydrogen embrittlement, and reduction in peak hardness.

   Refer to Appendix 3A for a discussion of Regulatory Guide 1.50.

3. The rod Travel Housing threads are chrome plated to prevent possible galling of the mated parts. Guide studs employed are materially qualified to prevent possible galling of their installation interfaces/threads.
4. At all locations in the reactor vessel where stainless steel and Inconel are joined, the final joining beads are Inconel weld metal in order to prevent cracking.
5. Core region shells fabricated of plate material have longitudinal welds which are angularly located away from the peak neutron exposure experienced in the vessel, where possible.

6. The location of full penetration weld seams in the upper closure head and vessel bottom head is restricted to areas that permit accessibility during inservice inspection.
7. The stainless steel clad surfaces are sampled to assure that composition and delta ferrite requirements are met.
8. The procedure qualification for cladding low alloy steel (SA508, GR 3, Class 1) requires a special evaluation to assure freedom from underclad cracking.

Refer to Appendix 3A for a discussion of Regulatory Guide 1.43.

Principal design parameters of the reactor vessel are given in Table 5.4-1.

5.4.2.2 Protection of Closure Studs

Procedures require the closure studs, nuts, and washers to be removed from the reactor cavity in preparation for refueling. These items may be placed in storage racks and stored at convenient locations on the reactor building operating deck prior to removal of the reactor closure head.

The reactor closure studs are removed from the refueling cavity prior to flooding and are never exposed to the borated refueling cavity water. The stud holes in the reactor vessel flange are sealed with special plugs before removing the reactor closure, thus preventing leakage of the borated refueling water into the stud holes.

5.4.3 Evaluation

5.4.3.1 Steady-State Stresses

Evaluation of steady-state stresses is discussed in Section 5.2.1.10.

5.4.3.2 Fatigue Analysis Based on Transient Stresses

Fatigue analysis of transient stresses is discussed in Sections 5.2.1.5 and 5.2.1.10.

5.4.3.3 Thermal Stresses Due to Gamma Heating

The stresses due to gamma heating in the vessel wall are also calculated by the vessel vendor and combined with the other design stresses.

They are compared with the code allowable limit for mechanical plus thermal stress intensities to verify that they are acceptable. The gamma stresses are low and thus have a negligible effect on the stress intensity in the vessel.

5.4.3.4 Thermal Stresses Due to Loss of Coolant Accident

Fracture mechanics evaluation of the reactor vessel due to thermal stresses following a loss of coolant accident is discussed in Section 5.2.1.10.

5.4.3.5 Heatup and Cooldown

Heatup and cooldown requirements for the reactor vessel material are discussed in Section 5.2.4 and the Technical Specifications.

5.4.3.6 Irradiation Surveillance Programs

10 CFR 50, Appendix H, requires that neutron dosimetry be present to monitor the reactor vessel and measure damage associated with fast neutron exposure (neutron fluence). The originally installed internal surveillance capsules are not sufficient to provide this monitoring capability throughout the Virgil C. Summer Nuclear Station extended license period.

ECR 50571 changed the methodology of the Irradiation Surveillance Program at the Virgil C. Summer Nuclear Station. During Refueling Outage 15, the last in-vessel surveillance specimen was removed from its in-vessel location and new dosimetry capsules were installed exterior to the reactor vessel (ex-vessel) for the measurement of neutron exposure.

Presented below are both a description of the new ex-vessel dosimetry program as well as a description of the former in-vessel program, used for the plant's first 14 operating cycles.

5.4.3.6.1 Ex-Vessel Irradiation Surveillance Program

5.4.3.6.1.1 Summary

An Ex-Vessel Neutron Dosimetry system is installed to monitor neutron fluence in the reactor vessel and vessel support structure. Passive neutron sensors are positioned in the reactor cavity annulus, between the reactor vessel and the biological shield wall. These sensor capsules are connected to, and supported by, stainless steel bead chains, which are suspended from a support bar installed just below the reactor vessel inlet and outlet nozzles. Capsules are then raised and lowered into position (from beneath the Reactor Vessel) to periodically remove the sensors for evaluation. This design ensures a correct and repeatable axial and azimuthal placement of the dosimetry relative to well-known reactor features, which is essential for a long-term monitoring program.

5.4.3.6.1.2 Background

The Code of Federal Regulations, Title 10, Part 50, Appendix H, requires that neutron dosimetry be present to monitor the reactor vessel throughout plant life and that material specimens be used to measure damage associated with the end-of-life fast neutron exposure of the reactor vessel. The Ex-Vessel Neutron Dosimetry Program is designed to provide a verification of fast neutron exposure distributions within the reactor vessel wall and to establish a mechanism to enable long term monitoring of those portions of the reactor vessel and vessel support structure that could experience significant radiation induced increases in reference nil ductility transition temperature (RT_{NDT}) over the service lifetime of the plant.

When used in conjunction with data from internal surveillance capsules and the results of neutron transport calculations, the reactor cavity neutron measurements allow the projection of embrittlement gradients through the reactor vessel wall with a minimum degree of uncertainty. Minimizing the uncertainty in the neutron exposure projections will help to assure that the reactor can be operated in the least restrictive mode possible with respect to:

- 10 CFR 50 Appendix G pressure/temperature limit curves for normal heatup and cooldown of the RCS,
- Emergency Response Guideline (ERG) pressure/temperature limit curves, and
- Pressurized thermal shock (PTS) RT_{NDT} screening criteria.

The installed ex-vessel surveillance program satisfies the regulatory guidance provided in the Generic Aging Lessons Learned (GALL) Report (NUREG-1801), Section XI.M31 Reactor Vessel Surveillance; which states in part:

> *A plant with a surveillance program containing capsules with projected fast neutron fluence exceeding a 60-year fluence at the end of 40 years, i.e., a lead factor greater than 1.5, should remove the capsules when they reach the 60-year exposure. One of these capsules should be tested to meet the requirements of ASTM E185 and the remaining capsules should be placed in storage without material testing. Subsequently, an alternative dosimetry program will need to be instituted to monitor reactor vessel neutron exposure through the license renewal period.*

5.4.3.6.1.3 Sensor Sets

To achieve its goals, the Ex-Vessel Neutron Dosimetry Program employs advanced sensor sets which consist of both encapsulated dosimeters and gradient chains.

Encapsulated dosimeters include radiometric monitors and are employed at discrete locations within the reactor cavity to measure axial variations in neutron spectrum over the core height, particularly near the top of the fuel where back scattering of neutrons from primary loop nozzles and reactor vessel support structures can produce significant differences.

Radiometric monitors include cadmium-shielded foils of the following metals: copper, titanium, iron, nickel, niobium, and cobalt-aluminum. Cadmium shielded fast fission reactions include U-238 and Np-237 in vanadium encapsulated oxide detectors. Bare iron and cobalt monitors are also included.

Stainless steel gradient chains are used in conjunction with the encapsulated dosimeters to complete the mapping of the neutron environment between the discrete locations chosen for spectrum determinations. At each of the azimuthal locations selected for spectrum measurements, stainless steel gradient chains extend over the full height of the active fuel.

Gradient chains are stainless steel bead chains which connect and support the dosimeter capsules containing the radiometric monitors. These segmented chains provide iron, nickel, and cobalt reactions that are used to complete the determination of the axial and azimuthal gradients. The

high purity iron, nickel, and cobalt-aluminum foils contained in the multiple foil sensor sets provide a direct correlation with the measured reaction rates from these gradient chains. These cross-comparisons permit the use of the gradient measurements to derive neutron flux distributions in the reactor cavity with a high level of confidence.

The design of the dosimetry support system and the gradient chains/chain stops ensures correct and repeatable axial and azimuthal placement of the dosimetry relative to well-known reactor features.

5.4.3.6.1.4 Physical Installation

The Ex-Vessel Neutron Dosimeters are located in the annular space between the reactor vessel reflective insulation and the primary biological shield wall. The dosimetry loops are suspended from a stainless steel support bar that is installed just below the reactor vessel nozzles (approximately eight inches above the top of the active fuel).

Located between the A-Loop inlet and B-Loop outlet nozzles, the gradient chain loops are aligned at 270, 285, 300, and 315 degrees (reactor coordinates). The bar is supported from above by two 1/8-inch stainless steel support chains. The support chains are, in turn, attached to spring hook attachment plates that are field-welded to the carbon steel reactor cavity liner plate.

These sensor sets consist of a small (1.0 x 0.5 x 3.875 inch-long) aluminum dosimeter capsule connected to and supported by a stainless steel bead chain. Clamps are installed at the bottom of each chain loop, which are in turn attached to the grating platform beneath the reactor vessel, to prevent relative movement of the capsule during plant operation.

5.4.3.6.1.5 Supporting Analysis

At the conclusion of the first irradiation cycle, the multiple foil sensor sets will be removed from the reactor cavity for evaluation. At the same time, replacement dosimetry will be installed in the reactor cavity to provide monitoring for subsequent irradiation cycles.

The evaluation of the dosimetry sets includes radiochemical analysis of each RM sensor. All laboratory procedures conform to the latest version of ASTM dosimetry standards and practices established for light-water reactor applications. Equivalent full-power reaction rates will be computed from the measured specific activities based on the irradiation history. The chemical composition of the stainless steel gradient chain is determined by taking the ratio of the Mn-54, Co-58, and Co-60 specific activities as measured in the pure metal foils and as measured in the bead chain segments adjacent to the dosimetry capsules containing the foils.

Plant specific discrete ordinates transport theory calculations will be performed to determine the neutron and gamma ray environment within the reactor geometry. The specific methods applied are consistent with those described in WCAP-15557, "Qualification of the Westinghouse Pressure Vessel Neutron Fluence Evaluation Methodology," S. L. Anderson, August 2000, and meet the requirements of Regulatory Guide RG-1.190, "Calculational and Dosimetry Methods for Determining Pressure Vessel Neutron Fluence," March 2001.

Analysis from the prior in-vessel surveillance capsules (U withdrawn at End of Cycle (EOC) 1, V withdrawn at EOC 3, X withdrawn at EOC 5, W withdrawn at EOC 10, Z withdrawn at EOC 14, and Y withdrawn at EOC 15) provides a consistent set of calculations and measurements detailing the integrated neutron exposure of the Virgil C. Summer reactor vessel from plant startup. The analysis of the ex-vessel neutron dosimetry removed at EOC 16 will build upon that work. This will provide the greatest accuracy in determining the fast neutron exposure rate distribution incident on and through the reactor vessel wall and will provide a sound basis for planning future evaluations of ex-vessel neutron dosimetry.

5.4.3.6.2 In-Vessel Irradiation Surveillance Program

5.4.3.6.2.1 Summary

In the In-Vessel Irradiation Surveillance Program, the evaluation of the radiation damage was based on pre-irradiation testing of Charpy V-notch and tensile specimens and post-irradiation testing of Charpy V-notch, tensile, and 1/2 T (thickness) compact tension (CT) fracture mechanics test specimens. The program was directed toward evaluation of the effect of radiation on the fracture toughness of reactor vessel steels based on the transition temperature approach and the fracture mechanics approach. The program conformed with ASTM-E-185 "Recommended Practice for Surveillance Tests for Nuclear Reactor Vessels," and 10 CFR 50, Appendix H.

5.4.3.6.2.2 Specimen Capsules

The reactor In-Vessel Surveillance Program used six specimen capsules. The capsules were located in guide baskets welded to the outside of the neutron shield pads and were positioned directly opposite the center portion of the core. The capsules were removed when the vessel head was removed and could be replaced when the internals are removed.

Each surveillance capsule contained the following materials:

a. Transverse orientation specimen from the limiting core region intermediate shell course plate A9154-1.

b. Longitudinal orientation specimen from the limiting core region intermediate shell course plate A9154-1.

c. Specimen of weldment joining sections of materials from intermediate shell plate A9154-1 and adjoining lower shell course plate C9923-2. The weldment is fabricated from the same heat of weld wire (Heat Number 4P4784) and Linde 124 flux (Lot Number 3930) as used to fabricate the core region girth and vertical weld seams.

d. Heat affected zone of plate A9154-1.

Each specimen was composed of the same material as the plate or weldment represented by the specimen. The copper and phosphorous content and fracture toughness data of each beltline plate and the core region weldments are provided in Table 5.2-21. The originally installed location of each capsule in the reactor vessel is shown on Figure 5.4-1.

The six capsules contained 54 tensile specimens, 360 Charpy V-notch specimens (which include weld metal and weld heat affected zone material), and 72 CT specimens. Archive material sufficient for two additional capsules will be retained.

The test specimen types, and their orientation, for each surveillance material were as follows:

	Quantity of Test Specimen Types		
Surveillance Material	Charpy	Tensile	1/2 - CT
Plate A9154-1 (transverse orientation)	15	3	4
Plate A9154-1 (longitudinal orientation)	15	3	4
Weld metal	15	3	4
Heat Affected Zone of Plate A9154-1	15	-	-

Dosimeters, including Ni, Cu, Fe, Co-Al, Cd shielded Co-Al, Cd shielded Np-237, and Cd shielded U-238, were placed in filler blocks drilled to contain them. The dosimeters permit evaluation of the flux seen by the specimens and the vessel wall. In addition, thermal monitors made of low melting point alloys were included to monitor the maximum temperature of the specimens. The specimens were enclosed in a tight fitting stainless steel sheath to prevent corrosion and ensure good thermal conductivity. The complete capsule was helium leak tested. As part of the surveillance program, a report of the residual elements in weight percent to the nearest 0.01 percent was made for surveillance material and as deposited weld metal.

Each of the six capsules contained the following specimens:

Material	Number of Charpys	Number of Tensiles	Number of CTs
Limiting Base Material(1)	15	3	4
Limiting Base Material(2)	15	3	4
Weld Metal(3)	15	3	4
Heat Affected Zone	15	-	-

(1) Specimens oriented in the major rolling or working direction.
(2) Specimens oriented normal to the major rolling or working direction.
(3) Weld metal to be selected per ASTM-E-185.

5.4.3.6.2.3 Removal Schedule

The schedule for removal of specimen capsules from the reactor vessel was as follows:

Capsule	Location (deg)	Capsule Lead Factor	Removal time(1)	Calculated Fluence (n/cm^2) (2)
U	343	3.32	1.12 (EOC 1)	6.542×10^{18}
V	107	3.72	2.93 (EOC 3)	1.538×10^{19}
X	287	3.84	5.03 (EOC 5)	2.543×10^{19}
W	110	3.40	10.78 (EOC 10)	4.664×10^{19}
Z	340	3.40	16.67 (EOC 14)	6.712×10^{19}
Y	290	3.40	17.28 (EOC 15)	(3)

(1) Effective full power years from plant startup. End of Cycle (EOC) value given in parenthesis. Note that core thermal power was uprated from 2775 to 2900 MW_{th} with operating cycle 10.
(2) Plant specific evaluation per WCAP-16298-NP, Revision 0 (Reference 2) using Capsule Z dosimetry data.
(3) Placed in storage for possible future use.

5.4.3.6.3 Measurement of Integrated Fast Neutron (E > 1.0 MeV) Flux at the Irradiation Samples

Measurement of Integrated Fast Neutron Flux and Fluence at the Irradiation Samples, and a description of how they were derived, are included in WCAP-16298-NP (Reference 2).

5.4.3.6.4 Calculation of Integrated Fast Neutron (E 1.0 MeV) Flux at the Irradiation Samples

Calculations of Integrated Fast Neutron Flux and Fluence at the Irradiation Samples, and a description of the methodology used, are included in WCAP-16298-NP (Reference 2).

5.4.3.7 Capability for Annealing the Reactor Vessel

There are no special design features which would prohibit the insitu annealing of the vessel. In the unlikely case that an annealing operation is required to restore the properties of the vessel material opposite the reactor core because of neutron irradiation damage, a metal temperature greater than 650°F would be applied for a maximum period of 168 hours. Various modes of heating may be used depending on the temperature.

The reactor vessel materials surveillance program is adequate to accommodate the annealing of the reactor vessel. Sufficient specimens are available to evaluate the effects of the annealing treatment.

5.4.4 Tests and Inspections

The reactor vessel quality assurance program is given in Table 5.4-2.

Inservice inspection is in accordance with the ASME Code, Section XI.

5.4.4.1 Ultrasonic Examinations

During fabrication, angle beam inspection of 100 percent of plate material is performed to detect discontinuities that may be undetected by longitudinal wave examination, in addition to the design code straight beam ultrasonic test.

5.4.4.2 Penetrant Examinations

The partial penetration welds for the control rod drive mechanism head adaptors and the bottom instrumentation tubes are inspected by dye penetrant after the root pass in addition to code requirements. Core support block attachment welds are inspected by dye penetrant after the first layer of weld metal and after each 1/2 inch of weld metal.

5.4.4.3 Magnetic Particle Examinations

The magnetic particle examination requirements below are in addition to the magnetic particle examination requirements of Section III of the ASME Code.

All magnetic particle examinations of materials and welds shall be performed in accordance with the following:

1. Prior to the final post weld heat treatment (only by the Prod, Coil or Direct Contact Method).
2. After the final post weld heat treatment (only by the Yoke Method).

The following surfaces and welds shall be examined by magnetic particle methods. The acceptance standards shall be in accordance with Section III of the ASME Code.

5.4.4.3.1 Surface Examinations

1. Magnetic particle examines all exterior vessel and heat surfaces after the hydrostatic test.
2. Magnetic particle examines all inside diameter surfaces of carbon and low alloy steel products that have their properties enhanced by accelerated cooling. This inspection to be performed after forming and machining (if performed) and prior to cladding.

5.4.4.3.2 Weld Examinations

Magnetic particle examines weld metal buildup for vessel supports, closure head lifting lugs, and refueling seal ledge to the reactor vessel after the first layer and each 1/2 inch of weld metal is

deposited. All pressure boundary welds are examined after back chipping or back grinding operations.

5.4.4.4 Inservice Inspection

The full penetration welds in the following areas of the installed irradiated reactor vessel are available for visual and/or nondestructive inspection.

1. Vessel shell (from the inside surface).
2. Primary coolant nozzles (from the inside surface).
3. Closure head (from the inside and outside surfaces). Bottom head (from the outside surface).
4. Closure studs, nuts, and washers.
5. Field welds between the reactor vessel, nozzles, and the main coolant piping.
6. Vessel flange seal surface.

The design considerations which have been incorporated into the system design to permit the above inspections are as follows:

1. All reactor internals are completely removable. The tools and storage space required to permit these inspections are provided.
2. The closure head is stored dry on the reactor operating deck during refueling to facilitate direct visual inspection.
3. All reactor vessel studs, nuts, and washers can be removed to dry storage during refueling.
4. Removable plugs are provided in the primary shield. The insulation covering the nozzle welds may be removed.
5. Access holes are provided in the lower internals barrel flange to allow remote access to the reactor vessel internal surfaces between the flange and the nozzles without removal of the internals.

The reactor vessel presents access problems because of the radiation levels and remote underwater accessibility to this component. Because of these limitations on access to the reactor vessel, several steps have been incorporated into the design and manufacturing procedures in preparation for the periodic nondestructive tests which are required by the ASME inservice inspection code. These are:

1. Shop ultrasonic examinations are performed on all internally clad surfaces to acceptance and repair standards to assure an adequate cladding bond to allow later ultrasonic testing of the base metal from inside surface. The size of cladding bonding defect allowed is 1/4 inch by 3/4 inch, with the greater direction parallel to the weld in the region bounded by 2T (T = wall thickness) on both sides of each full penetration pressure boundary weld. Unbonded areas exceeding 0.442 square inches (3/4 inch diameter) in all other regions are rejected.

2. The design of the reactor vessel shell is a clean, uncluttered cylindrical surface to permit future positioning of the test equipment without obstruction.
3. The weld deposited clad surface on both sides of the welds to be inspected are specifically prepared to assure meaningful ultrasonic examinations.
4. After the shop hydrostatic testing, selected areas of the reactor vessel are ultrasonically tested and mapped to facilitate the inservice inspection program.

The vessel design and construction enables inspection and compliance with the ASME Code, Section XI, 1974 Edition.

5.5 Component and Subsystem Design

5.5.1 Reactor Coolant Pumps

5.5.1.1 Design Bases

The reactor coolant pump ensures an adequate core cooling flowrate, and hence sufficient heat transfer, to maintain a departure from nucleate boiling ratio (DNBR) greater than 1.30 within the parameters of operation. The required net positive suction head is by conservative pump design always less than that available by system design and operation.

Sufficient pump rotation inertia is provided by a flywheel, in conjunction with the impeller and motor assembly, to provide adequate flow during coastdown. This flow, following an assumed loss of pump power, provides the core with adequate cooling.

The reactor coolant pump motor is tested, without mechanical damage, at overspeeds up to and including 125% of normal speed. The integrity of the flywheel during a LOCA is demonstrated in Reference 1. Reference 1 is undergoing generic review by the NRC.

The reactor coolant pump is shown in Figure 5.5-1. The reactor coolant pump design parameters are given in Table 5.5-1.

Code and material requirements are provided in Section 5.2.

5.5.1.2 Design Description

The reactor coolant pump is a vertical, single stage, centrifugal, shaft seal pump designed to pump large volumes of reactor coolant at high temperatures and pressures.

The pump consists of three areas from bottom to top. They are the hydraulics, shaft seals, and the motor.

1. The hydraulic section consists of an impeller, diffuser, casing, thermal barrier heat exchanger, lower radial bearing, bolting ring, motor stand, and pump shaft.
2. The shaft seal section consists of three identical sealing stages. Each stage consists of a hydrodynamic end face mechanical seal. For each stage, there is a separate tubular seal staging flow coil that allows flow around the stage so that the differential pressure across each stage is approximately one-third of reactor coolant system (RCS) pressure during normal operation. An additional sealing mechanism, termed the abeyance seal, is included in the shaft seal section to mitigate the effects caused by failure of all three mechanical seals. The three sealing stages and the abeyance seal are contained within the main flanges and seal housing.
3. The motor section consists of a vertical solid shaft, squirrel cage induction type motor, an oil lubricated double tilting pad Kingsbury type thrust bearing, two oil lubricated radial bearings, and a flywheel.

Attached to the bottom of the pump shaft is the impeller. The reactor coolant is drawn up through the impeller, discharged through passages in the diffuser, and out through the discharge nozzle in the side of the casing. Above the impeller is a thermal barrier heat exchanger which limits heat transfer between hot system water and seal injection water.

High pressure seal injection water is introduced through the thermal barrier wall. A portion of this water flows up around the bearing through the seals; the remainder flows down through the thermal barrier where it acts as a buffer to prevent system water from entering the radial bearing and seal section of the unit. The thermal barrier heat exchanger provides a means of cooling system water to an acceptable level in the event that seal injection flow is lost. The water lubricated journal type pump bearing, mounted above the thermal barrier heat exchanger, has a self-aligning spherical seat.

The reactor coolant pump motor bearings are of conventional design. The radial bearings are the segmented pad type, and the thrust bearings are tilting pad Kingsbury bearings. All are oil lubricated. The lower radial bearing and the thrust bearings are submerged in oil, and the upper radial bearing is oil fed from an impeller integral with the thrust runner.

The motor is an air-cooled, Class F thermalastic epoxy insulated, squirrel cage induction motor. The rotor and stator are of standard construction and are cooled by air. Six resistance temperature detectors are located throughout the stator to sense the winding temperature. The top of the motor consists of a flywheel and an anti-reverse rotation device.

Each of the reactor coolant pumps is equipped for continuous monitoring of reactor coolant pump shaft and frame vibration levels. Shaft vibration is measured by two relative shaft probes mounted on top of the pump seal housing. The probes are mounted in the same horizontal plane near the pump-to-motor coupling. Frame vibration is measured by two velocity velomitors located 90 degrees apart in the same horizontal plane and mounted at the top of the motor support stand. Proximeters and converters convert the probe signals to linear output which is displayed on monitor meters in the control room. The monitor meters automatically indicate the highest output from the relative probes and velomitors; manual selection allows monitoring of individual probes.

Indicator lights display caution and danger limits of vibration, which are adjustable over the full range of the motor scale.

All parts of the pump in contact with the reactor coolant are austenitic stainless steel except for special parts, such as seals and bearings. Component cooling water is supplied to the two oil coolers on the pump motor and to the pump thermal barrier heat exchanger.

In addition, the reactor coolant pumps receive pump shaft seal cooling water from the Chemical and Volume Control System (CVCS). The component cooling water supply to the thermal barrier is provided as a backup heat sink to the CVCS cooling water flow to the reactor coolant pump seals. A failure of the Component Cooling Water System (CCWS) supply to the thermal barrier would not jeopardize operation of the reactor coolant pump or cause loss of reactor coolant. The individual CCWS return lines from the upper and lower bearing oil coolers, as well as the return line from the thermal barrier, are equipped with seismically qualified flow indicators powered

from the vital bus (associated). These flow indicators actuate alarms on the main control board. The temperature indicator and alarms on the CCWS return lines are located on the main control board. The reactor coolant pump motor bearing temperatures are supplied as input to the process computer. A high temperature causes the computer to alarm and identify the out-of-limit temperatures. The CCWS isolation valve monitor lights, which would indicate valve closure, are located on the main control board.

The operator action necessary to trip the reactor and stop the reactor coolant pumps is not complicated and is a direct logical result of the event symptoms alarmed and indicated. An operator response time of 10 minutes is conservative and appropriate for this event during normal operation.

Actual tests performed by Westinghouse Electric Corporation on reactor coolant pumps of the type provided for the Virgil C. Summer Nuclear Station show that interruption of the CCWS flow for 10 minutes or less will not result in damage to the pump.

The pump shaft, seal housing, thermal barrier, main flange, and motor stand can be removed from the casing without disturbing the reactor coolant piping. The flywheel is available for inspection by removing the cover.

The performance characteristic, shown in Figure 5.5-2, is common to all of the fixed speed mixed flow pumps and the "knee" at about 45% design flow introduces no operational restrictions since the pumps operate at full speed.

5.5.1.3 Design Evaluation

5.5.1.3.1 Pump Performance

The reactor coolant pumps are sized to deliver flow at rates which equal or exceed the required flowrates. Initial RCS tests confirm the total delivery capability. Thus, assurance of adequate forced circulation coolant flow is provided prior to initial plant operation.

The Reactor Trip System ensures that pump operation is within the assumptions used for loss of coolant flow analyses, which also assures that adequate core cooling is provided to permit an orderly reduction in power if flow from a reactor coolant pump is lost during operation.

The original shaft seals from the pump manufacturer have been replaced with hydrodynamic shaft seals from another seal manufacturer. An extensive test program has been conducted for several years to develop the controlled leakage shaft seal for pressurized water reactor applications. Operating plants continue to demonstrate the satisfactory performance of the controlled leakage shaft seal pump design.

The shaft sealing system design consists of three identical seal stages that function based on hydrodynamic operating principles. Each of the three individual sealing stages is designed to withstand full RCS pressure for an extended period of time with the RCP idle and for a limited

period of time with the pump running at nominal speed. This design capability is to allow for a controlled shutdown.

The seal is designed to operate with a thin fluid film gap. The design allows short-term contact of the seal face rings, particularly during low pressure pump starts. The stationary seal face ring material is resin-impregnated carbon graphite. For the rotating face ring material, tungsten carbide is used because of its good fracture resistance, good thermal conductivity, and favorable tribologic properties.

In addition to the flow passes across the seal, there is flow through around each seal stage through a tubular coil. The coil is part of a subassembly designated the pressure breakdown device (PBD). The leakage flow across a given seal stage is in parallel with the coil for that stage so the pressure differential across the PBD and the seal stage must be equal. The design flow rate of each staging coil is 2.5 gpm with a differential pressure across the coil of 750 psid. Each coil acts as an orifice to reduce the pressure available at each seal stage. With three stages in the shaft sealing system, a pressure drop of approximately one-third of RCS pressure occurs across each stage during normal operation. An increase in leakage across one seal will cause the pressure differential across that stage to decrease. Because the total pressure drop across the three stages is constant, the total pressure differential increase across the two non-leaking seals will be equal to the decrease in pressure differential across the leaking seal stage. The RCP seal flow schematic is shown in Figure 5.5-18.

The effect of loss of offsite power on the pump itself is to cause a temporary stoppage in the supply of injection flow to the pump seals and also of the cooling water for seal and bearing cooling. The emergency diesel generators are started automatically due to loss of offsite power so that seal injection flow is automatically restored.

5.5.1.3.2 Coastdown Capability

It is important to reactor operation that the reactor coolant continues to flow for a short time after a reactor trip. In order to provide this flow in a station blackout condition, each reactor coolant pump is provided with a flywheel. Thus, the rotating inertia of the pump, motor, and flywheel is employed during the coastdown period to continue the reactor coolant flow. The coastdown flow transients are provided in the figures in Section 15.3.

The pump/motor system is designed for Seismic Category 1. The integrity of the bearings is described in Section 5.5.1.3.4. Hence, it is concluded that the coastdown capability of the pumps is maintained even under the most adverse case of a loss of offsite power coincident with the safe shutdown earthquake (SSE). Core flow transients and figures are provided in Section 15.2.

5.5.1.3.3 Flywheel Integrity

Demonstration of integrity of the reactor coolant pump flywheel is discussed in Section 5.2. Additional discussion is contained in Reference 1.

5.5.1.3.4 Bearing Integrity

The design requirements for the reactor coolant pump bearings are primarily aimed at ensuring a long life with negligible wear, so as to give accurate alignment and smooth operation over long periods of time. The surface bearing stresses are held at a very low value and even under the most severe seismic transients do not begin to approach loads which cannot be adequately carried for short periods of time.

Because there are no established criteria for short time stress-related failures in such bearings, it is not possible to make a meaningful quantification of such parameters as margins to failure, safety factors, etc. A qualitative analysis of the bearing design, embodying such considerations, gives assurance of the adequacy of the bearing to operate without failure.

Low oil levels in the lube oil sumps signal an alarm in the control room and require shutting down of the pump. Each motor bearing contains embedded temperature detectors, and so initiation of failure, separate from loss of oil, is indicated and alarmed in the control room as a high bearing temperature. This, again, requires pump shutdown. If these indications are ignored and the bearing proceeded to failure, the low melting point of Babbitt metal on the pad surfaces ensures that sudden seizure of the shaft will not occur. In this event the motor continues to operate, as it has sufficient reserve capacity to drive the pump under such conditions. However, the high torque required to drive the pump will require high current which will lead to the motor being shutdown by the electrical protection systems.

5.5.1.3.5 Locked Rotor

It may be hypothesized that the pump impeller might severely rub on a stationary member and then seize. Analysis has shown that under such conditions, assuming instantaneous seizure of the impeller, the pump shaft fails in torsion just below the coupling to the motor, disengaging the flywheel and motor from the shaft. This constitutes a loss of coolant flow in the loop. Following such a postulated seizure, the motor continues to run without any overspeed, and the flywheel maintains its integrity, as it is still supported on a shaft with two bearings. Flow transients are provided in the figures in Section 15.4 for the assumed locked rotor.

There are no other credible sources of shaft seizure other than impeller rubs. Any seizure of the pump bearing is precluded by graphite in the bearing. Any seizure in the seals results in a shearing of the elastomer drive key of the rotating face ring. The motor has adequate power to continue pump operation even after the above occurrences. Indications of pump malfunction in these conditions are initially by high temperature signals from the bearing water temperature detector. Following these signals, pump vibration levels are checked. Excessive vibration indicates mechanical trouble and the pump is shutdown for investigation.

5.5.1.3.6 Critical Speed

The reactor coolant pump shaft is designed so that its operating speed is below its first critical speed. This shaft design, even under the most severe postulated transient, gives low values of actual stress.

5.5.1.3.7 Missile Generation

Each component of the pump is analyzed for missile generation. Any fragments of the motor rotor would be contained by the heavy stator. The same conclusion applies to the pump impeller because the small fragments that might be ejected would be contained by the heavy casing. Further discussion and analysis of missile generation are contained in Reference 1.

5.5.1.3.8 Pump Cavitation

The minimum net positive suction head required by the reactor coolant pump at running speed is approximately a 192 foot head (approximately 85 psi). In order for the controlled leakage seal to operate correctly, it is necessary to have a minimum differential pressure of 75 psi across the seal assembly. When the net positive suction head requirement is met, the minimum differential pressure requirement for the seal is exceeded. The primary loop pressure is established to ensure sufficient net positive suction head is available to avoid pump cavitation.

5.5.1.3.9 Pump Overspeed Considerations

For turbine trips actuated by either the Reactor Trip System or the Turbine Protection System, the generator and reactor coolant pumps are maintained connected to the external network for at least 30 seconds to prevent any pump overspeed condition (see Section 8.2).

An electrical fault requiring immediate trip of the generator (with resulting turbine trip) could result in an overspeed condition. However, the turbine control system and the turbine intercept valves limit the overspeed to less than 120%. In case a generator trip de-energizes the pump buses, the reactor coolant pump motors will be transferred to offsite power within 6 to 10 cycles. Further discussion of pump overspeed considerations is contained in Reference 1.

5.5.1.3.10 Anti-Reverse Rotation Device

Each of the reactor coolant pumps is provided with an anti-reverse rotation device in the motor. This anti-reverse mechanism consists of five pawls mounted on the outside diameter of the flywheel, a serrated ratchet plate mounted on the motor frame, a spring return for the ratchet plate, and two shock absorbers.

After the motor has slowed and come to a stop, the dropped pawls engage the ratchet plate and, as the motor tends to rotate in the opposite direction, the ratchet plate also rotates until it is stopped by the shock absorbers. The rotor remains in this position until the motor is energized again. When the motor is started, the ratchet plate is returned to its original position by the spring return.

As the motor begins to rotate, the pawls drag over the ratchet plate. When the motor reaches sufficient speed, the pawls are bounded into an elevated position and are held in that position by friction resulting from centrifugal forces acting upon the pawls. Considerable shop testing and plant experience with the design of these pawls have shown high reliability of operation.

5.5.1.3.11 Shaft Seal Leakage

Leakage along the reactor coolant pump shaft is controlled by three shaft seals arranged in series such that reactor coolant leakage to the containment is essentially zero. Charging flow is directed to each reactor coolant pump via a ≤ 5 micron seal water injection filter. The flow is injected into the reactor coolant pump through a pipe in the thermal barrier flange and is directed down to a point between the pump shaft bearing and the thermal barrier cooling coils. Here the flow enters the shaft annulus; a portion flows down past the thermal barrier cooling cavity, labyrinth seals, and into the RCS; the remainder flows up the pump shaft annulus cooling the lower shaft bearing. This flow provides a controlled flow through the seal. Above the seal, most of the flow leaves the pump via the controlled bleed-off line and routed back to volume control tank. Minor flow passes through the seal face of the three stages and eventually diverted to reactor coolant drain tank via number 3 seal leakoff line. This arrangement assures essentially zero leakage of reactor coolant or trapped gases from the pump.

5.5.1.3.12 Seal Discharge Piping

Discharge pressure of the controlled bleed-off flow is reduced to that of the volume control tank. The controlled bleed-off flow is piped to a common manifold, through the seal water return filter, and through the seal water heat exchanger where the temperature is reduced to that of the volume control tank. There is no number 1 or number 2 seal leakoff piping. The number 3 leakoff line dumps number 3 seal leakage to the reactor coolant drain tank. An alternate overflow path with a vent line is provided to divert the number 3 seal leakage to the reactor building floor drain, in case there is a blockage in the number 3 leakoff line.

5.5.1.3.13 Loss of Component Cooling Water or Seal Injection

Component cooling water is provided to the reactor coolant pump thermal barrier heat exchanger, as well as to the upper and lower motor bearing oil coolers. In addition, seal injection flow is supplied to the pumps from the CVCS. These cooling supplies are discussed in the following paragraph and are shown schematically in Figure 5.5-16. Detailed flow diagrams of the CVCS and the CCWS are shown in FSAR Figures 9.3-16 and 9.2-5, respectively.

Consequences of the loss of either of these supplies are also discussed in the following paragraphs.

Seal injection flow, at a slightly higher pressure and at a lower temperature than the RCS, enters the pump through a pipe connection on the thermal barrier flange (see Figure 5.5-17) and is directed to a point between the pump radial bearing and the thermal barrier heat exchanger. Here the flow splits with a portion flowing down through the thermal barrier labyrinth (where it acts as a buffer to prevent reactor coolant from entering the radial bearing and seal section of the pump) and into the RCS. The remainder of the seal injection water flows up through the pump radial bearing and the shaft seals and is discharged via the seal leakoffs.

The pump shaft seal section consists of three identical seal stages in series, which are contained within a seal housing. Each seal stage is capable of withstanding full reactor pressure. The seal

schematic diagram is shown in Figure 5.5-18. The seal is a hydrodynamic end face mechanical seal that is designed to operate with a thin fluid film gap. Normal flow across the seal face is less than 0.1 gpm. There is a tubular coil that allows flow around each of the three stages so that, during normal operation, the differential pressure across each stage is about one-third of RCS pressure. The flow through this coil is referred to as controlled bleed-off (CBO). Most of the seal injection flow (directed to the seals) is discharged through this staging coil. Normal CBO flow is about 2.5 gpm. CBO from the third staging coil is routed back to the volume control tank. Leakage across the third stage seal face flows directly to the reactor coolant drain tank via a gravity drain line. This arrangement minimizes leakage of water and vapor into containment.

The thermal barrier is a welded assembly consisting of a flanged cylindrical shell, a series of concentric stainless steel cans, a heat exchanger coil assembly, and two flanged water connections.

Component cooling water enters the thermal barrier through a flanged connection on the thermal barrier flange (see Figure 5.5-17). The cooling water flows through the inside of the coiled stainless steel tubing in the heat exchanger and exits through another flanged connection on the thermal barrier flange. During normal operation, the thermal barrier limits the heat transfer from the reactor coolant to the pump internals.

The upper bearing assembly contains an oil-cooled pivoted-pad radial guide bearing (upper guide bearing), as well as a double acting oil-cooled Kingsbury-type thrust bearing (see Figure 5.5-19). The thrust bearing shoes are positioned above and below a common runner to accommodate thrust in both directions. The shoes are mounted on equalizing pads, which distribute the thrust load equally to all the shoes.

The oil is circulated through an external oil-to-water shell and tube heat exchanger (oil cooler) to which component cooling water is supplied.

The lower guide bearing is a pivoted-pad radial bearing, similar to the upper guide bearing.

The entire lower guide bearing assembly is located in the lower oil reservoir, which contains an integral oil-to-water coil type heat exchanger (see Figure 5.5-19).

Component cooling water is supplied to this heat exchanger.

Should a loss of seal injection to the RCPs occur, the pump radial bearing and seals are lubricated by reactor coolant flowing up through the pump. Under these conditions, the CCWS continues to provide flow to the thermal barrier heat exchanger and the heat exchanger, functioning in its backup capacity, cools the reactor coolant before it enters the pump radial bearing and the shaft seal area. The loss of seal injection flow may result in a temperature increase in the pump bearing area, a temperature increase in the seal area, and a resultant increase in the number 1 seal leak rate; however, pump operation can be continued (for up to 24 hours), provided these parameters remain within the allowable limits. Extended periods without seal injection may result in particulates from the RCS causing premature seal face wear.

Should a loss of CCW to the RCPs occur, the CVCS continues to provide seal injection flow to the RCPs; the seal injection flow is sufficient to prevent damage to the seals with a loss of thermal barrier cooling. Consequently, the RCP can continue to run following a loss of thermal barrier cooling provided that pump seal temperatures remain within allowable limits. However, the loss of CCW to the motor bearing oil coolers will result in an increase in oil temperature and a corresponding rise in motor bearing metal temperature. It has been demonstrated by testing that the reactor coolant pumps will incur no damage as a result of a CCW flow interruption of 10 minutes.

Two safety related transmitters are provided to redundantly monitor component cooling water flow to the upper and lower reactor coolant pump bearings. Two additional safety related transmitters are provided to redundantly monitor component cooling water flow to the reactor coolant pump thermal barriers. These transmitters provide flow indication and actuate low flow alarms in the control room.

A discussion of the loss of seal injection is provided above. This discussion justifies the use of non-safety grade instrumentation for seal injection flow since loss of seal injection is not limiting in terms of continued pump operation and does not require immediate operator action.

As discussed above, a loss of CCW to the motor bearing oil coolers will result in an increase in oil temperature and a corresponding rise in motor bearing temperature. Since the loss of CCW to the thermal barrier does not, in itself, affect operation of the RCP, a simultaneous loss of CCW to the thermal barrier and to the motor bearing oil coolers is no worse than a loss of CCW only to the motor bearing oil coolers. Westinghouse contends that the loss of CCW to the RCPs will not result in an instantaneous seizure of a single pump and, further, that instantaneous seizure of two pumps simultaneously is not a credible ultimate consequence.

Instead, it is Westinghouse’s technical opinion that a more realistic ultimate consequence will be an abbreviated coastdown. If a limiting condition of the babbitt metal is considered, an increasing coefficient of friction, as well as an increasing retarding torque, is expected. However, in view of the large rotational inertia of the pump/motor assembly, Westinghouse maintains that an instantaneous seizure will not result.

Because an initial seizure is not expected, it is not possible to define a precise point in time at which a sequential seizure would be anticipated. Therefore, for the purpose of defining the time expected between sequential seizures, the following discussion will be presented in terms of sequential occurrences of reaching a "high" bearing temperature. The upper thrust bearing exhibits the limiting temperature; therefore, an upper thrust bearing temperature of 240°F has been chosen arbitrarily as the "high" temperature. It should be noted that the use of this value does not imply pump seizure at this temperature.

Variables affecting the steady state operating temperature of the bearings include the following:

a. Surface finish of the bearing and runner.

b. Bearing (and oil pumping mechanism) clearances.

c. Inlet temperature of water to heat exchanger (oil cooler).

d. Condition of oil-to-water heat exchanger (oil cooler) (i.e., extent of fouling).

e. Condition of oil.

f. Amount of oil in oil pot.

g. Oil temperature.

These variables would be expected to interact concurrently in a manner which individualizes the performance of the bearings during actual steady state plant operation.

In order to quantify the resultant variation in performance, Westinghouse has collected data from an operating plant. The data demonstrate that the upper thrust bearings operate at different steady state temperatures (i.e., 128°F, 132°F, 135°F, and 145°F). It should be noted that the data were collected from a four loop plant; the following evaluation based on this data is applicable to a three loop plant (i.e., Virgil C. Summer).

Using these actual steady state operating values (A-128°F, B-132°F, C-135°F, D-145°F) and assuming a conservative 5°F/minute linear heatup rate after a loss of CCW, sequential occurrences of reaching the high bearing temperature could be expected at the time intervals tabulated below (see Figures 5.5-20 and 5.5-21).

Sequential Motors	Δ Operating Temperature (°F)	Time Interval (minutes)
A and B	4	0.8
B and C	3	0.6
C and D	10	2.0
A and C	7	1.4
B and D	13	2.6
A and D	17	3.4

To summarize, two bearings sequentially reaching a temperature of 240°F could be expected at a minimum time interval of 0.6 minutes and at a maximum time interval of 3.4 minutes.

Westinghouse has obtained motor bearing heatup data. These test data show actual values of bearing temperatures following a loss of CCW. The test data presented in Figure 5.5-22 will be examined relative to the above discussion. The test runs, which were performed at different times using different motors, demonstrate similar heatup rates; this fact supports the assumption of identical linear heatup rates made in the previous discussion. In addition, the average heatup rates evidenced in the test data are less than 3.3°F/minute, which substantiates the use of 5°F/minute as a conservative value. The actual test data, although limited, are supportive of the assumptions posed in defining the time intervals tabulated above.

In conclusion, Westinghouse contends that single or multiple pump seizures as the result of a loss of CCW to the RCPs is not a credible event. However, in our judgment and based on the above discussion, two RCP motor upper thrust bearings could sequentially reach a "high" bearing temperature of 240°F at a minimum time interval of 0.6 minutes (or approximately 40 seconds).

Section 15.4.4 of the Virgil C. Summer FSAR presents the analysis of a single RCP locked rotor. It should be pointed out that the Section 15 analysis assumes an instantaneous seizure of a reactor coolant pump rotor on a non-mechanistic basis. Westinghouse contends that a postulated mechanistic instantaneous seizure of a pump rotor due to a loss of CCW to the RCP will not occur and is not a credible event.

However, in response to the NRC request, the results of a second non-mechanistic instantaneous seizure occurring at 40 seconds after a first non-mechanistic instantaneous seizure have been evaluated. Although a Section 15 approach was utilized to evaluate this situation, Westinghouse does not recognize a postulated mechanistic instantaneous locked rotor as a credible consequence of the loss of CCW to the RCPs.

Assuming that a second pump seizure occurs 40 seconds after a first pump seizure, no noticeable change is seen in the RCS pressure and the clad temperature transients. Furthermore, even if the time interval between the sequential seizures is reduced to 10 seconds, no noticeable change is seen in the RCS pressure and the clad temperature transients.

The hypothetical seizure of one RCP results in a low flow reactor trip approximately one second after the initiation of the event. As a result of the fast reactor trip and the consequential decrease in core heat flux, the RCS pressure and the clad temperature reach the peak values at about 2.5 seconds and then start to decrease.

Because the core has been shut down, at 40 seconds–or even 10 seconds–after a pump seizure, the RCS pressure and the clad temperature transients have decreased to a point at which a second pump seizure results in no noticeable change in the transients.

Operating procedures are provided for a loss of component cooling water and seal injection to the reactor coolant pumps and/or motors. Included in these operating procedures is the provision to trip the reactor if component cooling water flow, as indicated by the instrumentation discussed previously, is lost to the reactor coolant pump motors and cannot be restored within 10 minutes. The reactor coolant pumps will also be tripped following the reactor trip.

This section provides a description of testing performed and the test results which constitute the basis of reactor coolant pump operation for 10 minutes without CCW with no resultant damage. Two RCP motors have been tested with interrupted CCW flow; these tests were conducted at the Westinghouse Electro Mechanical Division. In both cases, the reactor coolant pumps were operated to achieve "hot" (2230 psia, 552°F) equilibrium conditions. After the bearing temperatures stabilized, the cooling water flow to the upper and lower motor bearing oil coolers was terminated and bearing (upper thrust, lower thrust, upper guide, and lower guide) temperatures were monitored. A bearing metal temperature of 185°F was established as the

maximum test temperature. When that temperature was reached, the cooling water flow was restored.

In both tests, the upper thrust bearing exhibited the limiting temperatures. Figure 5.5-21 shows the upper thrust bearing temperature versus time. In both cases, 185°F was reached in approximately 10 minutes.

The maximum test temperature of 185°F is also the suggested alarm setpoint temperature and the suggested trip temperature is 195°F. It should be noted that the melting point of the babbitt bearing metal exceeds 400°F.

The information presented above constitutes the basis of the RCP qualification for 10 minute operation without CCW with no resultant damage.

5.5.1.4 Tests and Inspections

The reactor coolant pumps can be inspected in accordance with the ASME Code, Section XI, for Inservice Inspection of Nuclear Reactor Coolant Systems.

Any full penetration welds in the pressure boundary are prepared with a smooth surface transition between weld metal and parent metal for radiographic inspection. However, the pump casing is cast in one piece, eliminating welds in the casing.

Support feet are cast integral with the casing to eliminate a weld region.

The design enables disassembly and removal of the pump internals for usual access to the internal surface of the pump casing.

The reactor coolant pump quality assurance program is given in Table 5.5-2.

5.5.2 Steam Generators

5.5.2.1 Design Bases

The replacement steam generators installed in the V. C. Summer plant are Westinghouse Delta-75, feedring type steam generators. To facilitate replacement in the plant, the geometric characteristics of the Delta-75 steam generators are identical to the original D3 steam generators. Additionally, the Delta-75 steam generators must provide an equal or better level of performance than the original steam generators. The Delta-75 steam generators are expected to supply steam at about 1.3% higher than the original D3 steam generators at a plant thermal rating of 2787 MWt. At the Engineered Safeguards Power Rating of 2912 MWt, the Delta-75 steam generators are expected to deliver steam at about 2.0% above that projected for the original D3 steam generators.

The steam generators are designed and analyzed according to the requirements of Section III of the ASME Code, 1971 Edition through Summer 1971 Addenda, and constructed according to the

1986 Edition. To minimize the impact on steam generator supports and seismic considerations, the total weight of each empty Delta-75 steam generator is ≤ 360 tons.

Steam generator design data are given in Table 5.5-3. The design sustains transient conditions given in Section 5.2.1. Although the required secondary side ASME classification is Class 2, Class 1 requirements are applied for all pressure retaining portions of the steam generator. Assurance of adequate fracture toughness of all pressure boundary materials is, therefore, as described in Section 5.2.4 and complies with Article NB-2300 of Section III of the ASME Code. Rupture of a steam generator tube is discussed in Section 15.4.3.

The internal moisture separation equipment is designed to ensure that moisture carryover does not exceed 0.10% by weight under the following conditions:

1. Steady-state operation up to 100% of full load steam flow, with water at the normal operating level.
2. Loading or unloading at a rate of 5% of full load power steam flow per minute in the range from 15% to 100% of full load steam flow.
3. A step load change of 10% of full power in the range from 15% to 100% full load steam flow.

The water chemistry in the reactor side is selected to provide the necessary boron content for reactivity control and to minimize corrosion of RCS surfaces. The water chemistry of the steam side and its effectiveness in corrosion control is discussed in Section 10.3.5.

5.5.2.2 Design Description

The original VCSNS steam generators were Model D3 type, which employed the use of an integral preheater at the feedwater inlet. The original steam generators were replaced during the Refuel 8 outage, approximately September 1994, with Westinghouse Delta-75 steam generators. The Delta-75 steam generator has the same profile dimensions as the original D3 steam generator. Like the D3 steam generator, the Delta-75 is a vertical shell and U-tube evaporator with integral moisture separation equipment. The Delta-75 steam generator is shown in Figure 5.5-3. The reactor coolant flows through the inverted U-tubes, entering and leaving through the nozzles located in the hemispherical bottom head of the steam generator. The head is divided into inlet and outlet chambers by a vertical partition plate extending from the head to the tubesheet. Manways are provided for access to both sides of the divided head. The feedwater inlet on the original D3 steam generators was located several feet above the top surface of the tubesheet, on the cold leg or return side of the U-tube bundle. The incoming feedwater was forced through a back and forth path within the preheater by several staggered tube support plates. This path allowed the feedwater temperature to be rapidly heated almost to saturation temperature before entering the boiler section. In the Delta-75, the feedwater inlet is located at approximately 2/3 of the steam generator height and is distributed equally around the circumference of the steam generator shell. Feedwater enters the tube bundle by flowing downward between the steam generator external shell and inner wrapper barrel. An open area at the bottom of the wrapper barrel permits the feedwater to enter the tube bundle. The simplified design of the Delta-75 steam

generator supports a more simplified steam generator operating procedure and eliminates some of the low power operating restrictions applied to the D3 steam generators. The total steam generator heat transfer surface area is increased in the Delta-75 to account for the thermal performance characteristics of the preheater. Steam is generated and flows upward through the moisture separators and through the flow restrictor outlet nozzle at the top of the steam drum. The Delta-75 utilizes high efficiency centrifugal steam separators, which remove most of the entrained water. Chevron dryers are employed to increase the steam quality to a minimum of 99.90% (0.10% moisture).

The steam generator channel head and tubesheet are protected from the primary water by applying an autogenous weld deposited stainless steel cladding to the primary surfaces of the channel head and Inconel to the tubesheet. The cladding surface is machined to a smooth condition and electropolished, thereby reducing the collection of radioactive contamination inside the steam generators during refueling and maintenance periods.

Steam generator materials of construction are listed in Table 5.2-8. All materials are selected and fabricated in accordance with the requirements of the ASME Code, Section III, and Code Case N-20-3. The steam generator tubing material is Alloy 690. Alloy 690 material represents the state of the art technology for heat transfer tubing. The tubing receives a heat treatment process after forming which results in a grain boundary structure which has been shown by test to be exceptionally resistive to primary water stress corrosion cracking (PWSCC), which initiates tube degradation in the expansion region within the tubesheet area and has resulted in the majority of tube plugging in the original D3 steam generators at V. C. Summer. The tube expansion process used for the replacement steam generator is not expected to result in similar strain levels or patterns as observed in the original D3 steam generators. Alloy 690 tubing material is also exceptionally resistive to outer diameter stress corrosion cracking (ODSCC), which has affected the secondary side of the tubes in operating plants at the tube support plate intersections.

Ferritic material in the primary side of the steam generators includes the following: channel head casting, tubesheet, primary nozzles, manway covers, and manway studs and nuts. Fracture toughness data for the steam generator bolting materials are shown in Table 5.2-22. Fracture toughness data for the channel head, tubesheet, and associated weldments will be consistent with ASME Code. As-built data generally show the test data to far exceed the ASME Code minimum values. The materials of construction and general design of the steam generator shell of the Delta-75 have resulted in a reduction in the number of pressure boundary welds required for assembly of the shell.

5.5.2.3 Design Evaluation

5.5.2.3.1 Forced Convection

The effective heat transfer coefficient is determined by the physical characteristics of the Delta-75 steam generator and the fluid conditions in the primary and secondary systems for the nominal 100% design case. It includes a conservative allowance for fouling and uncertainty. A designed heat transfer area is provided to permit the achievability of the full-design heat-removal rate. Although margin for tube fouling is available, operating experience to date has not indicated that

steam generator thermal performance decreases over a long term period. Adequate tube surface area is selected to ensure that the full design heat removal rate is achieved.

5.5.2.3.2 Natural Circulation Flow

The steam generators, which provide a heat sink, are at a higher elevation than the reactor core, which is the heat source. Thus, natural circulation is assured for the removal of decay heat.

5.5.2.3.3 Tube and Tubesheet Stress Analyses

Tube and tubesheet stress analyses of the steam generator, which are discussed in Section 5.2, confirm that the steam generator tubesheet will withstand the loading caused by a loss of reactor coolant (LOCA). Routine inservice inspections of the steam generator tubing will assess tubing integrity and adequacy for continued operation based upon the 40% depth of indication limit specified by Section XI of ASME Code. Tube degradation existing at this level will maintain integrity consistent with the recommendations of Regulatory Guide 1.121 during the transient events identified in Section 5.2.

5.5.2.3.4 Corrosion

The Delta-75 steam generator utilizes thermally treated Alloy 690 tube material. This material is used in the replacement steam generators at North Anna Unit 1 and Indian Point Unit 3. Thermally treated Alloy 690 tubing is also used in a number of plants, which include the Turkey Point replacements, Surry replacements, D. C. Cook Unit 2 replacements, and Prairie Island replacements, Wolf Creek, Seabrook, and Millstone Unit 3.

To date, the only form of tube degradation which has been identified in Model F-type units is fretting wear between the tube and steam generator anti-vibration bars (AVB). Only a small number of tubes (expected to be less than 1% total over the life of the steam generators) would be subject to this phenomena. The AVB design in the Delta-75 steam generators maintains smaller, more tightly controlled tube-to-AVB gaps, increased tube-to-AVB contact area, and utilize more AVBs than do the Model F steam generators. These factors should greatly lower the potential for tube fretting at AVB intersections in the Delta-75 steam generators.

5.5.2.3.5 Compatibility of Steam Generator Tubing with Primary and Secondary Coolant

As previously discussed, the Alloy 690 tubing installed in the Delta-75 steam generators at V. C. Summer has been shown by test (and operating experience) to be exceptionally resistant to both PWSCC and ODSCC. The Delta-75 Alloy 690 tubing specification is in accordance with the requirements of ASME Code Case N-20-3, ASME Code Section III, ASME Code Section II Specification SB-163, and meets the EPRI Guidelines for Procurement of Alloy 690 steam generator tubing, NP-6743-L, February 1991.

The steam generator tube expansion process employed in the tubesheet region results in reduced residual stress levels compared to the original D3 steam generators. This reduced residual stress will lower the potential for PWSCC in this region. Additionally, no evidence of PWSCC has been

identified in either the Model F type steam generators operating today, or the replacement steam generators manufactured by Westinghouse.

The potential for ODSCC to develop in the Delta-75 steam generators is also greatly reduced. The axial flow paths around the steam generator tubes provided by the trifoil support design significantly reduce crevice area and contaminant hideout potential. The stainless steel tube support plate material does not represent a potential for magnetite generation or general corrosion product buildup. Also, the most recent revision of the EPRI Secondary Water Chemistry Guidelines has incorporated a sodium-chloride molar ratio control philosophy, which will help to maintain an as neutral as possible crevice chemistry within the entire steam generator secondary side.

5.5.2.3.6 Flow Induced Vibration

The potential for tube wall degradation attributable to mechanical or flow induced excitation is exceptionally low in a feedring type steam generator design. Flow induced vibration at the tube support plate intersections has not been observed in Model F type steam generators.

5.5.2.3.7 Tube Denting

Localized steam generator tube diameter reductions were first discovered during the April 1975 steam generator inspection at the Surry Unit 2 plant. This discovery was evidenced by eddy current signals, resembling those produced by scanning dents, and by difficulty in passing the standard 0.700 inch diameter eddy current probe through the tubes at their intersections with the support plates. Subsequent to the initial finding, steam generator inspections at other operating plants revealed essentially identical results.

The phenomenon of tube denting is attributed to a localized buildup of corrosion products (due to magnetite generation in the support plate crevice) in the tube-to-tube support plate crevice, which eventually deforms the tube wall as the corrosion products continue to build. The implementation of All Volatile Treatment (AVT) chemistry on the secondary side of the steam generator has minimized the potential of denting. Additionally, the Delta-75 steam generators at the V. C. Summer plant employ stainless steel tube support plates, which should preclude the formation of corrosion products within the crevice. The Delta-75 tube support plates employ a limited contact trifoil hole shape which permits axial flow around the tube, which also minimizes the buildup of corrosion products in this area. The original D3 steam generators utilized carbon steel support plates with drilled tube holes of a diameter approximately 0.013 inch larger in diameter than the tubes, which can be filled with corrosion products.

5.5.2.4 Test and Inspections

The steam generator quality assurance program is given in Table 5.5-4. During manufacture, cleaning is performed on the primary and secondary sides of the steam generator in accordance with written procedures which follow the guidance of Regulatory Guide 1.37 and other industry standards, such as those developed by the American Society of Testing and Materials (ASTM). Radiographic inspections, liquid penetrant inspections, magnetic particle inspections, ultrasonic

inspections, and the implementation of the associated acceptance criteria for each are instituted according to the requirements of the ASME Code.

The steam generators are designed to permit inservice inspections in accordance with the requirements of Section XI to the ASME Code, and steam generator tubing eddy current examination consistent with the requirements of V. C. Summer Technical Specifications 3/4.4.5, “Steam Generator Tube Integrity,” and 6.8.4.k, “Steam Generator Program.”

When required, tests, using a Lithium or radioactive Sodium tracer, are conducted to properly account for moisture carryover in the plants calorimetric and precision RCS flow measurement.

5.5.3 Reactor Coolant Piping

5.5.3.1 Design Bases

The RCS piping is designed and fabricated to accommodate the system pressures and temperatures attained under all expected modes of plant operation or anticipated system interactions. Stresses are maintained within the limits of Section III of the ASME Nuclear Power Plant Components Code. Code and material requirements are provided in Section 5.2.

Materials of construction are specified to minimize corrosion/erosion and ensure compatibility with the operating environment.

The piping in the RCS is Safety Class 1 and is designed and fabricated in accordance with the ASME Code, Section III, Class 1 requirements.

Stainless steel pipe conforms to ANSI B36.19 for sizes 1/2 inch through 12 inches and wall thickness Schedules 40S through 80S. Stainless steel pipe outside of the scope of ANSI B36.19 conforms to ANSI B36.10.

The minimum wall thicknesses of the loop pipe and fittings are not less than that calculated using the ASME Code, Section III, Class 1 formula of Paragraph NB-3641.1 (3) with an allowable stress value of 17,550 psi. The pipe wall thickness for the pressurizer surge line is Schedule 160. The minimum pipe bend radius is five nominal pipe diameters; ovality does not exceed 6%.

All butt welds, branch connection nozzle welds, and boss welds are of a full penetration design.

Processing and minimization of sensitization are discussed in Sections 5.2.3 and 5.2.5.

Flanges conform to ANSI B16.5.

Socket weld fittings and socket joints conform to ANSI B16.11.

Inservice inspection is discussed in Section 5.2.8.

5.5.3.2 Design Description

Principal design data for the reactor coolant piping are given in Table 5.5-5.

The piping is seamless forged; the fittings are cast without longitudinal welds and electroslag welds. Piping and fittings comply with the requirements of the ASME Code, Section II, Parts A and C, Section III, and Section IX.

The RCS piping is specified in the smallest sizes consistent with system requirements. This design philosophy results in the reactor inlet and outlet piping diameters given in Table 5.5-5. The line between the steam generator and the pump suction is larger to reduce pressure drop and improve flow conditions to the pump suction.

The reactor coolant piping and fittings which make up the loops are austenitic stainless steel. There is no electroslag welding on these components. All smaller piping which comprises part of the RCS such as the pressurizer surge line, spray and relief line, loop drains, and connecting lines to other systems is also austenitic stainless steel. The nitrogen supply line for the pressurizer relief tank is carbon steel. All joints and connections are welded, except for the pressurizer code safety valves, where flanged joints are used. Thermal sleeves are installed at some points in the system where high thermal stresses could develop due to rapid changes in fluid temperature during normal operational transients. These points include:

1. The pressurizer surge line connection at the pressurizer.
2. Pressurizer spray line connection at the pressurizer.

Piping connections from auxiliary systems are made above the horizontal centerline of the reactor coolant piping, with the exception of:

1. Residual heat removal pump suction lines, which are 45° down from the horizontal centerline. This enables the water level in the RCS to be lowered in the reactor coolant pipe while continuing to operate the Residual Heat Removal System (RHRS), should this be required for maintenance.
2. Loop drain lines and the connection for temporary level measurement of water in the RCS during refueling and maintenance operation.
3. The differential pressure taps for flow measurement, which are downstream of the steam generators on the first 90° elbow. The tap arrangement is discussed in Section 5.6.
4. The pressurizer surge line, which is attached at the horizontal centerline.
5. The safety injection connections to the hot leg, for which inservice inspection requirements and space limitations dictate location on the horizontal centerline.

Penetrations into the coolant flow path are limited to the following:

1. The spray line inlet connections extend into the cold leg piping in the form of a scoop so that the velocity head of the reactor coolant loop flow adds to the spray driving force.
2. The reactor coolant sample system taps protrude into the main stream to obtain a representative sample of the reactor coolant.
3. The resistance temperature detector (RTD) hot leg scoops extend into the reactor coolant at locations 120° apart in the cross sectional plane. In the original design, these scoops collected a representative temperature sample for the RTD manifold. In the current design, they provide a convenient location for the narrow range thermowell mounted RTDs.
4. The wide range temperature detectors and the cold leg fast response temperature detectors are located in resistance temperature detector wells that extend into the reactor coolant pipes.

The RCS piping includes those sections of piping interconnecting the reactor vessel, steam generator, and reactor coolant pump. It also includes the following:

1. Charging line and alternate charging line from the system isolation valve up to the branch connections on the reactor coolant loop.
2. Letdown line and excess letdown line from the branch connections on the reactor coolant loop to the system isolation valve.
3. Pressurizer spray lines from the reactor coolant cold legs to the spray nozzle on the pressurizer vessel.
4. Residual heat removal lines to or from the reactor coolant loops up to the designated check valve or isolation valve.
5. Safety injection lines from the designated check valve to the reactor coolant loops.
6. Accumulator lines from the designated check valve to the reactor coolant loops.
7. Loop fill, loop drain, sample (1), and instrument (1) lines to or from the designated isolation valve to or from the reactor coolant loops.
8. Pressurizer surge line from one reactor coolant loop hot leg to the pressurizer vessel inlet nozzle.
9. Resistance temperature detector scoop element, pressurizer spray scoop, sample connection (1) with scoop, reactor coolant temperature element installation boss, and the temperature element well itself.
10. All branch connection nozzles attached to reactor coolant loops.
11. Pressure relief lines from nozzles on top of the pressurizer vessel up to and through the power operated pressurizer relief valves and pressurizer safety valves.
12. Seal injection water and labyrinth differential pressure lines to or from the reactor coolant pump inside reactor building.

13. Auxiliary spray line from the isolation valve to the pressurizer spray line header.
14. Sample lines (1) from pressurizer to the isolation valve.

Details of the materials of construction and codes used in the fabrication of reactor coolant piping and fittings are discussed in Section 5.2.

5.5.3.3 Design Evaluation

Piping load and stress evaluation for normal operating loads, seismic loads, blowdown loads, and combined normal, blowdown, and seismic loads are discussed in Section 5.2.1.

5.5.3.3.1 Material Corrosion/Erosion Evaluation

The water chemistry is selected to minimize corrosion. A periodic analysis of the coolant chemical composition is performed to verify that the reactor coolant quality meets the specifications.

The design and construction are in compliance with the ASME Code, Section XI. Pursuant to this, all pressure containing welds out to the second valve that delineates the RCS boundary are available for examination with removable insulation.

Components constructed with stainless steel will operate satisfactorily under normal plant chemistry conditions in pressurized water reactor systems because chlorides, fluorides, and particularly oxygen are controlled to very low levels (see Section 5.2.3).

Periodic analysis of the coolant chemical composition is performed to monitor the adherence of the system to desired reactor coolant water quality listed in Table 5.2-10. Maintenance of the water quality to minimize corrosion is accomplished using the CVCS and process sampling system which are described in Sections 9.3.4 and 9.3.2, respectively.

5.5.3.3.2 Sensitized Stainless Steel

Sensitized stainless steel is discussed in Sections 5.2.3 and 5.2.5.

5.5.3.3.3 Contaminant Control

Contamination of stainless steel and Inconel by copper, low melting temperature alloys, mercury, and lead is prohibited. Only selected lubricants, which are not deleterious to stainless steel, are used.

1. Liquid filled lines with a 3/8 inch flow restricting orifice qualify as Safety Class 2a; in the event of a break in one of these Safety Class 2a lines, the normal makeup system is capable of providing makeup flow while maintaining pressurizer water level. Instrument impulse lines connected to the pressurizer steam space above the water level have been upgraded to Safety Class 1, since failure of these lines could cause automatic operation of the ECCS systems.

Prior to application of thermal insulation, the austenitic stainless steel surfaces are cleaned and analyzed to a halogen limit of 0.0015 mg Cl/dm^2 and 0.0015 F/dm^2.

5.5.3.3.4 Alloy 600 Dissimilar Metal Welds

The RCS Piping includes Alloy 600 dissimilar metal welds at the Reactor Vessel Nozzles, Steam Generator Nozzles, Pressurizer Surge Line Nozzle, Pressurizer Safety Valves, Power Operated Relief Valves, and Pressurizer Spray Nozzle.

A thru-wall leak was identified on the Reactor Vessel "A" Loop Hot Leg Nozzle to Pipe Weld during Refuel 12. The weld was completely removed and a pipe spool piece was welded in place. The root cause was determined to be PWSCC. The Reactor Vessel Nozzle to Pipe Weld was made using Alloy 690. Alloy 690 is a material with more resistance to PWSCC.

Due to the high susceptibility to PWSCC in the Reactor Vessel Hot Leg Nozzle to Pipe Welds, mitigative measures were taken during Refuel 13. The Mechanical Stress Improvement Process (MSIP) is a remediation process for pipe-to-pipe and pipe-to-nozzle welds that are susceptible to stress corrosion cracking from welding induced residual stresses. MSIP equipment applies a narrow permanent radial deformation adjacent to a pipe weld that redistributes the residual stresses in the weld region producing compressive stress at the inside diameter of the weld joint. This process removes one of the three factors (material susceptibility, environment, and high residual tensile stresses) required to create PWSCC in RCS components. MSIP was applied to the Reactor Vessel "B" and "C" Loop Hot Leg Nozzle to Pipe Welds.

The Pressurizer Nozzle Alloy 600 dissimilar metal welds were mitigated during Refuel 17 by the application of a full structural weld overlay. This weld overlay was applied to each of the nozzles on the pressurizer utilizing alloy 52M filler metal which is high in chromium and more resistant to PWSCC (consistent with alloy 690). This pre-emptive mitigation provided a full structural overlay to each of the nozzles and provides an ultrasonic NDE inspectable geometry which meets the ASME volumetric inspection requirements. The pre-weld overlay geometry did not meet the volumetric inspection requirements of the ASME XI code. Application of the weld overlay also provides a beneficial compressive stress to the underlying pipe, safe end, nozzle, and welds.

5.5.3.4 Tests and Inspections

The RCS piping quality assurance program is given in Table 5.5-6.

Volumetric examination is performed throughout 100% of the wall volume of each pipe and fitting in accordance with the applicable requirements of Section III of the ASME Code for all pipe 27-1/2 inches and larger. All unacceptable defects are eliminated in accordance with the requirements of the same section of the code.

A liquid penetrant examination is performed on both the entire outside and inside surfaces of each finished fitting in accordance with the criteria of the ASME Code, Section III. Acceptance standards are in accordance with the applicable requirements of the ASME Code, Section III.

The pressurizer surge line conforms to SA-376 Grade 304, 304N, or 316 with supplementary requirements S2 (transverse tension tests) and S6 (ultrasonic test). The S2 requirement applies to each length of pipe. The S6 requirement applies to 100% of the piping wall volume.

The end of pipe sections, branch ends, and fittings is machined back to provide a smooth weld transition adjacent to the weld path. All butt welds are ground smooth to permit inservice inspection in accordance with the ASME Code, Section XI. There is one pipe-to-pipe weld ("A" Hot Leg).

5.5.4 Steam Outlet Flow Restrictor (Steam Generator)

5.5.4.1 Design Bases

Each steam generator is provided with a flow restrictor having several small diameter venturi-type throats. The flow restrictors are designed to limit steam flowrate consequent to the unlikely event of a steam line rupture, thereby reducing the cooldown rate of the primary system and limiting stresses of internal steam generator components.

The flow restrictor is designed to minimize unrecovered pressure loss coincident with limiting accident flowrate to an acceptable value.

Although it is not considered to be part of the pressure vessel boundary, the restrictor is constructed of material specified in Section III of the ASME Code and is Seismic Category 1.

5.5.4.2 Design Description

The flow restrictor is an assembly of seven smaller nozzles installed within the steam outlet nozzle of the steam generator. Upper and lower internal discs support an outer circle of six nozzles and one central nozzle. The discs and outer cylinder are made of steel plates and pipe and the venturi nozzles are Inconel. The flow restrictor assembly is welded into the main steam generator outlet by a circumferential weld between the rim of the outer cylinder and the inside surface of the outlet nozzle.

5.5.4.3 Design Evaluation

The equivalent throat diameter of the steam generator outlet is 16 inches and the resultant pressure drop through the restrictors at 100% steam flow is approximately 3.4 psig. The steam side weld to the outlet nozzle is in compliance with manufacturing and quality control requirements of the ASME Code, Section III, and is Seismic Category 1.

5.5.4.4 Tests and Inspections

The restrictors are not a part of the steam system boundary. No tests or inspections of the restrictors are anticipated beyond those performed in the fabricator’s shop.

5.5.5 Main Steam Line Isolation System

The main steam line isolation system is discussed in Sections 10.3.2 and 10.3.3. The discussion presented in the referenced sections includes information on measures taken to reduce potential leakage of radioactivity to the environment in the event of a main steam line break.

5.5.6 Reactor Core Isolation Cooling System

Not applicable to pressurized water reactors.

5.5.7 Residual Heat Removal System

The RHRS transfers heat from the RCS to the CCWS to reduce the temperature of the reactor coolant to the cold shutdown temperature at a controlled rate during the second part of normal plant cooldown and maintains this temperature until the plant is started up again.

During the first phase of cooldown, the temperature of the RCS is reduced by transferring heat from the RCS to the steam and power conversion system through the steam generators.

Parts of the RHRS also serve as parts of the Emergency Core Cooling System (ECCS) during the injection and recirculation phases of a loss of coolant accident (see Section 6.3).

The RHRS is also used to transfer refueling water between the refueling cavity and the refueling water storage tank (RWST) at the beginning and end of the refueling operations.

5.5.7.1 Design Bases

RHRS design parameters are listed in Table 5.5-7.

The RHRS is placed in operation approximately 4 hours after reactor shutdown when the temperature and pressure of the RCS are approximately 350°F and less than 425 psig, respectively. The RHRS heat exchanger design heat load is based upon transferring 1/2 of the decay heat load at 20 hours after reactor shutdown (for the original RTP of 2775 MWt) with 5600 gpm CCWS flow (CCWS temperature is limited to 120°F maximum and will decrease towards 105°F as the cooldown proceeds) and 3750 gpm RHRS flow. With the current licensed RTP of 2900 MWt, each RHRS heat exchanger is capable of transferring 1/2 of the decay heat load at 24 hours after reactor shutdown with the same flowrates and CCWS temperature given above.

At the original RTP of 2775 MWt, the coupled RHRS/CCWS/SWS system is capable of cooling the RCS from 350°F beginning at 4 hours after reactor shutdown from an extended run at full power to 200°F within 4 hours after the start of the RHRS cooldown and to 140°F within 16 hours after the start of the RHRS cooldown. With the current licensed RTP of 2900 MWt, the coupled RHRS/CCW/SWS system is still capable of cooling the RCS from 350°F beginning at 4 hours after reactor shutdown from an extended run at full power to 200°F within 4 hours after the start of the RHRS cooldown and to 140°F within 20 hours after the start of the RHRS cooldown. The

RHRS heat load during the transient includes the heat from one RCP (RCP off after RCS reaches 160°F), core decay heat, and the sensible heat of the RCS metal and fluid; also, RCS cooldown rate is limited to 50°F/hr.

5.5.7.1.1 Compliance with BTP RSB 5-1

The safe shutdown design basis of the Virgil C. Summer Nuclear Station is hot standby. Under abnormal conditions, the plant is designed to remain in a safe hot standby condition until (a) normal systems can be restored to permit either return to power operation or cooldown to cold shutdown conditions, or (b) sufficient systems capability can be restored (depending on plant condition) to permit cooldown to cold shutdown conditions under abnormal plant conditions. This design basis is considered to constitute a safe design.

BTP RSB 5-1 establishes specific design requirements that address the various system functions that are required to achieve and maintain a safe hot standby and cold shutdown conditions. BTP RSB 5-1 requires plants with construction permits docketed after January 1, 1978, to comply in full with the design requirements of the BTP. Plants with construction permits docketed prior to January 1, 1978 (including Virgil C. Summer Nuclear Station) are required to address the BTP technical requirements and demonstrate partial compliance.

The following is a discussion of the Virgil C. Summer Nuclear Station compliance with the technical requirements of BTP RSB 5-1. This discussion demonstrates that under the postulated condition of BTP RSB 5-1 the Virgil C. Summer Nuclear Station can be maintained in a safe hot standby condition and taken to RHRS initiation conditions within approximately 36 hours, including credit for limited manual actions outside the control room to operate and/or repair a limited number of components that are not safety-grade or single failure proof.

Itemized below are the technical requirements of BTP RSB 5-1 followed by a general discussion of the Virgil C. Summer Nuclear Station compliance. The technical requirements section is then followed by more detailed discussion in sections entitled Cold Shutdown Scenario, Single Failure Evaluation, and Natural Circulation.

1. Provide safety-grade steam generator dump valves, operators, air, and power supplies which meet the single failure criterion.

   One safety grade steam generator power operated relief valve is provided for each of the three steam generators. Safety grade remote operators and power supplies are not required since hot standby can be achieved and maintained using the safety grade steam generator safety valves. The steam generator power operated relief valves are provided with handwheels and can be operated locally to permit plant cooldown. See the cold shutdown scenario and single failure evaluation provided below (Part II, Removal of Residual Heat).

2. Provide the capability to cooldown to cold shutdown in a reasonable period of time assuming the most limiting single failure and loss of offsite power or show that manual actions inside or outside containment or return to hot standby until the manual actions or maintenance can be performed to correct the failure provides an acceptable alternative.

If a condition occurred requiring cold shutdown of the plant, design features permit the maintenance of a hot standby condition for an indefinite period of time. The plant is capable of being cooled via natural convection and reaching RHRS initiating conditions including the time required to perform any manual actions.

3. Provide the capability to depressurize the RCS with only safety-grade systems assuming a single failure and loss of offsite power or show that manual actions inside or outside containment or remaining at hot standby until manual actions or repairs are complete provides an acceptable alternative.

   The plant can be maintained in a safe hot standby condition while any required manual actions are taken. See the cold shutdown scenario and single failure evaluation provided below (Part IV, Depressurization).

4. Provide the capability for borating with only safety-grade systems assuming a single failure and loss of offsite power or show that manual actions inside or outside containment or remaining at hot standby until manual actions or repairs are complete provides an acceptable alternative.

   The plant can be maintained in a safe hot standby condition while any required manual actions are taken. See the cold shutdown scenario and single failure evaluation provided below (Part III, Boration and Makeup).

5. Provide the system and component design features necessary for the prototype testing of both the mixing of the added borated water and the cooldown under natural circulation conditions with and without a single failure of a steam generator atmospheric dump valve.

The Virgil C. Summer Nuclear Station's ability to address boron mixing and cooldown test in natural circulation was originally to be demonstrated through referencing testing which was to be conducted at the Diablo Canyon nuclear plant. Since that time, other plants have demonstrated the following results.

During natural circulation testing at Farley 2, North Anna II, Salem II, and Sequoyah I, the following observations were made:

a. All plants (three or four loop) exhibited very similar RCS behavior indicating similar RCS characteristics.
b. By directly comparing North Anna and Farley natural circulation test results, these plants effectively exhibited identical behavior in terms of: time to stability following the reactor coolant pump trip; core flow distribution; core power distribution; and flow rates as indicated by the loop delta T's.

Results of the boron mixing and cooldown tests at Sequoyah, Salem, and North Anna indicate that:

a. The results of the North Anna test conclusively demonstrated the ability of the RCS to mix boron under natural circulation conditions as was also demonstrated by Salem and Sequoyah.

b. The tests performed at Salem and North Anna were performed at the end of cycle with a decay heat level on the order of 1% of the rated power where the Sequoyah test was done with nuclear heat of approximately 2% of the rated power. These power levels (and flow) are nominally lower than those expected following an emergency condition since the operator would initiate a boration quickly following the reactor trip to assure shutdown margin.

c. The capability of the RCS to perform a natural circulation cooldown at a rate of approximately 50°F/hr was demonstrated by all of these tests. This is at a higher rate than the Westinghouse emergency procedures (25°F/hr).

d. All plants demonstrated that no core temperature distribution anomalies were induced by the addition of boric acid into the RCS or the cooldown process while using natural circulation.

Since the tests at all plants successfully and conclusively demonstrated the capability of the plant to mix boric acid and cool down under natural circulation conditions, there would be no benefit from the Virgil C. Summer Nuclear Station performing this test.

a. Commit to providing specific procedures for cooling down using natural circulation and submit a summary of these procedures.

   Specific procedures for cooling down using natural circulation are provided in the Virgil C. Summer Nuclear Station "EOPs" which includes natural circulation cooldown with boron mixing. A summary of the procedures is provided in the cold shutdown scenario and single failure evaluation provided below.

b. Provide a seismic Category 1 AFW supply for at least 4 hours at Hot Shutdown plus cooldown to the RHRS cut-in based on the longest time (for only onsite or offsite power and assuming the worst single failure), or show that an adequate alternate Seismic Category 1 source will be available.

   Sufficient emergency feedwater is provided in the Seismic Category 1 condensate storage tank to permit 2 hours of operation at hot standby plus cooldown to RHR initiation conditions. In addition, a long term source of Emergency Feedwater is provided by a connection to the Seismic Category 1 Service Water System. See the cold shutdown scenario and single failure evaluation provided below (Part II, Removal of Residual Heat).

c. Provide for collection and containment of RHR pressure relief or show that adequate alternative methods of disposing of discharge are available.

   The RHR relief valves discharge to the pressurizer relief tank located inside containment.

5.5.7.1.2 Cold Shutdown Scenario

The safe shutdown design basis of Virgil C. Summer Nuclear Station is hot standby. The plant can be maintained in a safe hot standby condition while manual actions are taken to permit achievement of cold shutdown conditions following a SSE with loss of offsite power. Under such conditions, the plant is capable of achieving RHR initiation conditions (approximately 350°F and less than 425 psia), including the time required for any manual actions. To achieve and maintain cold shutdown, four key functions must be performed. These are: (1) circulation of the reactor coolant, (2) removal of residual heat, (3) boration and makeup, and (4) depressurization.

1. Circulation of Reactor Coolant

   Circulation of the reactor coolant has two stages in a cooldown from hot standby to cold shutdown. The first stage is from hot standby to 350°F. During this stage, circulation of the reactor coolant is provided by natural circulation with the reactor core as the heat source and steam generators as the heat sink. Steam release from the steam generators is initially via the steam generator safety valves and occurs automatically as a result of turbine and reactor trip. Steam release for cooldown is via the steam generator power operated relief valves. If air and control power are available, these valves will be operated from the main control board. A backup air compressor can be manually loaded on the diesel generator buses. If these power sources are not available, communications will be established between the control room and auxiliary operators at the valves. These valves can be manually operated by handwheel. The steam generator power operated relief valves are easily accessible for local operation at floor level or by permanently installed platforms in the Seismic Category 1 penetration access area. The ability to operate these valves locally by handwheel was verified in the plant hot functional testing program. As a result of the installed noise reduction features on the valve, noise levels were sufficiently low that plant personnel were able to communicate with the control room and operate the valves with no difficulty.

   The status of each steam generator can be monitored using Class 1E instrumentation located in the control room. Separate indication channels for both steam generator pressure and water level are available.

   Feedwater to the steam generators is provided from the Emergency Feedwater System which has a 500,000 gallon Seismic Category 1 condensate storage tank (160,054 usable gallons are reserved for emergency feedwater, see Section 9.2.6.1) as the primary source and two separate Seismic Category 1 piping subsystems. The first subsystem is composed of two motor driven pumps each powered from a different emergency power train, and the second subsystem incorporates a turbine driven pump which can receive motive steam from either of two steam generators. Backup is from the Seismic Category 1 Service Water System. There are additional sources of feedwater backup which can be manually accessed. The operation of the Emergency Feedwater System can be monitored using Class 1E instrumentation located in the control room.

   The second stage of reactor coolant circulation is from 350°F to cold shutdown. During this stage, circulation of the reactor coolant is provided by the residual heat removal pumps.

2. Removal of Residual Heat

   Removal of residual heat also has 2 stages in a cooldown from hot standby to cold shutdown. The first stage is from hot standby to 350°F.

   During this stage, the steam generators act as the means of heat removal from the RCS. When the operators are ready to begin the cooldown, the steam generator power operated relief valves are opened slightly. As the cooldown proceeds, the operators will occasionally adjust these valves to increase the amount they are open. This allows a reasonable cooldown rate to be maintained. Feedwater makeup to the steam generators is provided from the Emergency Feedwater System. The Emergency Feedwater System has the ability to remove decay heat by providing feedwater to all three steam generators for extended periods of operation.

   The second stage is from 350°F to cold shutdown. During this stage, the RHRS is brought into operation. The residual heat removal exchangers in the RHRS act as the means of heat removal from the RCS. In the RHR heat exchanger, the residual heat is transferred to the Component Cooling System which transfers the heat to the Service Water System. The Component Cooling and the Service Water Systems are both designed to Seismic Category 1. The RHRS includes two residual heat removal pumps and two residual heat removal heat exchangers. Each RHR pump is powered from different emergency power trains and each RHR heat exchanger is cooled by a different component cooling loop. If any component in one RHR loop becomes inoperable, cooldown of the plant is not compromised; however, the time for cooldown would be extended.

   The operation of the RHRS can be monitored using Class 1E instrumentation in the control room.

3. Boration and Makeup

   Boration is accomplished using portions of the CVCS. Boric acid 4 wt. % (approximately 7,000 ppm) from the boric acid tanks is supplied to the suction of the centrifugal charging pumps by the boric acid transfer pumps. The centrifugal charging pumps inject the borated water into the RCS via the normal charging and/or reactor coolant pump seal injection flow paths. The two boric acid tanks, two boric acid transfer pumps, centrifugal charging pumps, and the associated piping are of Seismic Category 1 design. There is sufficient boric acid capacity to provide for a cold shutdown with the most reactive rod withdrawn. The boric acid transfer pumps are each powered from different emergency power trains. The boric acid tank level can be monitored using Class 1E instrumentation in the control room to verify the operability of the boration portion of the CVCS.

   Makeup, in excess of that required for boration, can be provided from the RWST using centrifugal charging pumps and the same injection flow paths as described for boration. Two motor operated valves, each powered from different emergency power trains and connected in parallel, will transfer the suction of the charging pumps to the RWST. Makeup from the RWST can be monitored using Class 1E instrumentation in the control room.

4. Depressurization

   Depressurization is normally accomplished using the reactor coolant pumps and the normal spray lines to the pressurizer.

   Depressurization can be accomplished using the pressurizer power operated relief valves after boration and RCS cooldown to 450°F. This method consists of (1) discharging reactor coolant from the pressurizer to the pressurizer relief tank via the pressurizer power operated relief valves, and (2) allowing the pressurizer to cool via ambient heat losses as the RCS is maintained at 350°F via natural circulation.

5. Maintaining RCS Temperature and Pressure Without Letdown

   Letdown is isolated by fail closed air operated valves and is assumed to be unavailable during accident conditions. The cold shutdown scenario of maintaining RCS temperature and pressure without letdown is considered the limiting cold shutdown scenario and is presented to demonstrate cold shutdown capability under abnormal conditions. As additional components are assumed to be available, the cold shutdown scenario is simplified. For example, as the reactor vessel head vent valves or the pressurizer PORVs are assumed to be available, the boration and makeup function or the depressurization function, respectively, is simplified as RCS letdown becomes available.

   In performing the cooldown, the operator will integrate the functions of heat removal, boration and makeup, and depressurization so that these functions can be accomplished without letdown from the RCS. Boration, cooldown, and depressurization will be accomplished in a series of short steps arranged to keep RCS temperature and pressure and pressurizer level in the desired relationships. The boration requirements will be evaluated by the operator prior to initiating cooldown and depressurization. Based on initial plant conditions, the operator and/or the contents of the boric acid tanks. Once the plant is cooled to 350°F and depressurized to 425 psia, RHRS operation is initiated and the RCS is taken to cold shutdown conditions.

   To demonstrate that boration and depressurization can be done without letdown, a simpler scenario can be used. First the operators integrate the cooldown and boration functions, taking advantage of the RCS inventory contraction resulting from the cooldown. Finally, the operators use auxiliary spray from the CVCS to depressurize the plant to RHRS initiating conditions. The SCE&G calculation to demonstrate this capability assumes worst case boration requirements based on core end of life/peak xenon conditions and the following RCS initial conditions following plant trip:

RCS Temperature	557°F
RCS Pressure	2250 psia
Pressurizer Water Volume	350 ft^3
Pressurizer Steam Volume	1050 ft^3

The cooldown from 557°F to 350°F decreases the volume of water in the RCS by approximately 1420 cubic feet. This assumes that the pressurizer is not cooled and the water level is maintained at the initial condition. Makeup for contraction is supplied by 4 wt. % boric acid stored in the boric acid tanks at 70°F. A boric acid tank volume of approximately 1170 cubic feet is required to maintain the reactor within the technical specification shutdown requirements at 350°F. A boric acid tank volume of approximately 1170 cubic feet will expand to approximately 1310 cubic feet as it is heated to the RCS temperature of 350°F. The volume required for boration requirements at 350°F is less than the contraction volume available at 350°F.

To calculate if depressurization can be accomplished without letdown and without taking the plant water solid, it was assumed that the pressurizer was at saturated conditions with 350 cubic feet of water, 1050 cubic feet of steam, and the pressurizer metal at 653°F (2250 psia). It was further assumed that no additional water would be removed from the pressurizer by the cooldown contraction. With these assumptions, including the effect of heat input from the pressurizer metal, it was determined that spraying in approximately 450 cubic feet of 70°F water would provide saturated conditions at 425 psia (450°F) with a water volume of 913 cubic feet and a steam volume of 487 cubic feet.

Once depressurized to 425 psia, RHRS operation is initiated and cooldown is continued to cold shutdown conditions. The cooldown from 350°F to 200°F further decreases the volume of water in the RCS. This assumes that the pressurizer is not cooled and the pressurizer water level is maintained at the level resulting from depressurization. There is no additional boration required in going from Mode 4 (350°F) to Mode 5 (200°F). This is expected since the shutdown margin requirements are less restrictive in Mode 5 than in Mode 4.

The results of the calculations described above demonstrate that, based on the assumed initial conditions, boration and depressurization with 4 wt. % (approximately 7,000 ppm) boric acid can be accomplished without letdown and without taking full credit for the available volume created by the cooldown contraction. Should boration without letdown prove impractical due to any combination of plant conditions or equipment failures, letdown can be achieved by discharging RCS inventory via the pressurizer power operated relief valves or the reactor vessel head vent valves.

6. Instrumentation

Class 1E instrumentation is available in the control room to monitor the key functions associated with achieving cold shutdown. This instrumentation is discussed in Section 7.5 (Safety Related Display Instrumentation) and includes the following:

a. RCS wide range temperature

b. RCS wide range pressure

c. Pressurizer water level

d. Steam generator water level (per steam generator)

e. Steam line pressure (per steam line)

f. RWST level

g. Boric acid tank level (per boric acid tank)

h. Reactor building pressure

This instrumentation is sufficient to monitor the key functions associated with cold shutdown and to maintain the RCS within the desired pressure, temperature, and inventory relationships. Operation of the auxiliary systems that service the RCS can be monitored by the control room operator, if desired, via remote communication with an operator in the plant.

5.5.7.1.3 Single Failure Evaluation

1. Circulation of the Reactor Coolant

   a. From Hot Standby to 350°F (refer to FSAR Figures 5.1-1, 10.3-1, and 10.3-4) - Three reactor coolant loops and steam generators are provided, any two of which can provide sufficient natural circulation flow to provide adequate core cooling. Even with the most limiting single failure (of a steam generator power operated relief valve), two of the reactor coolant loops and steam generators remain available.

   b. From 350°F to cold shutdown (refer to FSAR Tables 5.5-7, 5.5-8, and Figure 5.5-4); two RHR pumps are provided, either one of which can provide adequate circulation of the reactor coolant.

2. Removal of Residual Heat

   a. From Hot Standby to 350°F [refer to FSAR Figures 10.3-1, 10.3-4, 10.4-16, 9.2-2 (Sheets 1 through 4), and 9.2-3].

      (1) Steam generator power operated relief valves - Three are provided (one per steam generator), any two of which are sufficient for residual heat removal. In the event of a single failure, two power operated relief valves remain available.

      (2) Emergency feedwater pumps - Two motor driven and one steam driven emergency feedwater pumps are provided. In the event of a single failure, two pumps remain available, either of which can provide sufficient feedwater flow.

      (3) Flow control valves - Air operated, fail open valves are provided. In the event of a single failure of one flow control valve (which effects flow to one steam generator from either a motor driven pump or the steam driven pump), emergency feed flow can still be provided to all three steam generators from the other pumps.

      (4) Backup source - A backup source of emergency feedwater can be provided to the suction of the emergency feedwater pumps from either train of the Seismic Category 1 Service Water System.

   b. From 350°F to 200°F [refer to FSAR Table 5.5-15 and Figure 5.5-4, and Figures 9.2-1, 9.2-2 (Sheets 1 through 4), 9.2-3, and 9.2-4].

(1) RHR Suction Isolation Valves 8701A and 8702A (RHR Pump 1) and 8701B and 8702B (RHR Pump 2) - The two valves in each RHR subsystem are each powered from different emergency power trains. Failure of either power train could prevent initiation of RHR cooling in the normal manner from the control room. In the event of such a failure, the affected valve can be de-energized and opened with its handwheel. Another method of operating these valves is by the use of alternate temporary power. Any other single failure can be tolerated as it would only affect one of the RHR subsystems, and adequate cooling can be provided by the redundant subsystem.

(2) RHR pumps 1 and 2 - Each pump is powered from a different emergency power train. In the event of a single failure, either pump can provide sufficient RHR flow.

(3) RHR heat exchangers 1 and 2 - If either heat exchanger is unavailable for any reason, the remaining heat exchanger is unavailable for any reason, the remaining heat exchanger can provide sufficient heat removal capability.

(4) RHR Flow Control Valves HCV603A and B - If either of these normally open fail open valves closes spuriously, sufficient RHR cooling can be provided by the unaffected RHR train.

(5) RHR/SIS Cold Leg Isolation Valves 8888A and B - If either of these normally open, motor operated valves, which are powered from different emergency power trains, closes spuriously, sufficient RHR cooling can be provided by the unaffected RHR train. The affected valve can be de-energized and opened with its handwheel.

(6) CCWS - Two redundant subsystems are provided for safety related loads. Either subsystem can provide sufficient heat removal via one of the RHR heat exchangers.

(7) Service Water System - Two redundant subsystems are provided for safety related loads. Either subsystem can provide sufficient heat removal via one of the CCW heat exchangers.

3. Boration and Makeup (refer to FSAR Figures 5.1-1, 6.3-1, and 9.3-16)

a. Boric Acid Tanks 1 and 2 - Two boric acid tanks are provided. Each tank contains sufficient 4% (approximately 7,000 ppm) boric acid to borate the RCS for cold shutdown.

b. Boric Acid Transfer Pumps 1 and 2 - Each pump is powered from a different emergency power train. In the event of a single failure, either pump can provide sufficient boric acid flow.

c. Isolation Valve 8104 - If valve 8104, which is supplied from emergency power and is normally closed, cannot be opened due to power train or operator failure, it can be opened locally with its handwheel. If valve 8104 cannot be opened with its handwheel, an alternate flow path is available via (1) air operated, fail open valve FCV-113A and normally closed manual valve 8439, or (2) gravity feed through normally closed manual valves 8329 and 8331.

d. Refueling Water Storage Tank Isolation Valves LCV-115B and LCV-115D - Each valve is powered from a different emergency power train, only one of these normally closed motor

operated valves needs to be opened to provide a makeup flow path from the RWST to the centrifugal charging pumps.

e. Centrifugal Charging Pumps A, B, and C - Pumps A and B are powered from a different emergency power train. In the event of a single failure, any one pump can provide sufficient boration or makeup flow.

f. Charging Pump Suction Isolation Valves 8130A, B and 8131A, B - If one of these normally open motor operated valves--each of which is powered from a different emergency power train--closes spuriously, operator action can be used to de-energize the valve operator and reopen the valve with its handwheel.

g. Normal Charging Flow Control Valve FCV-122 - This normally open valve fails open on loss of air or power. If FCV-122 closes spuriously, the charging pumps can operate on their miniflow circuits until operator action can open bypass valve 8403.

h. Normal Charging Isolation Valves 8107 and 8108 - If either of these normally open, motor operated valves--each of which is powered from a different emergency power train--closes spuriously, operator action can be used to de-energize the valve operator and reopen the valve with its handwheel.

i. Normal Charging Isolation Valve 8146 - If the normally open valve closes spuriously, alternate charging valve 8147, which fails open, can be used.

j. Charging Pump Discharge Isolation Valves 8132 A, B, and 8133 A, B - If one of these normally open motor operated valves--each of which is powered from a different emergency power train--closes spuriously, operator action can be used to de-energize the valve operator and reopen the valve with its handwheel. Power to valves 8133A, B is normally locked out to prevent spurious operation. Reference FSAR Section 6.3.2.20.

k. Reactor Coolant Pump Seal Injection Isolation Valve 8105 - If this normally open motor operated valve closes spuriously, operator action can be used to de-energize the valve operator and reopen the valve with its handwheel (also see item p.).

l. Reactor Coolant Pump Seal Injection Flow Control Valve HCV-186 - This normally open valve fails open on loss of air or power. If HCV-186 closes spuriously, the charging pumps can operate on their miniflow circuits until operator action can open bypass valve 8389 (also see item p.).

m. Reactor Coolant Pump Seal Injection Valves 8102 A, B, and C - If any of these normally open motor operated valves closes spuriously, operator action can be used to de-energize the valve operator and reopen the valve with its handwheel.

n. Cold Leg Injection Isolation Valves 8801 A and B - Each valve is powered from a different emergency power train; only one of these normally closed motor operated valves needs to be opened to provide a makeup path and source for boration.

o. Reactor Vessel Head Vent Valves 8095 A, B, and 8096 A, B - These valves fail as-is on loss of power. They are arranged with two valves in series in each of two parallel paths. The isolation valves in series in each flow path are powered from separate emergency power supplies. One normally closed isolation valve and one normally open valve are

located in each flow path. This valving and power supply arrangement ensures that one path from the reactor vessel head can be opened assuming a single failure. One path is sufficient to permit letdown from the RCS to augment boration and makeup operations.

p. If total RCP seal injection flow falls below 10 gpm, the Alternate Seal Injection (ASI) System (part of CVCS) is designed to automatically supply a total of 20 gpm RWST water downstream of HCV-186 and XVT-8105. The ASI system is an ASME Code Class 2 system (pressure boundary); however, the power source for the ASI pump (XPP0230) is from an NNS power supply.

4. Depressurization (refer to FSAR Figure 9.3-16)

   a. Pressurizer Power Operated Relief Valves PCV-444B and PCV-445A - These normally closed valves fail closed on loss of air or power. However, the valves are redundant, are powered by separate emergency electrical power supplies, and have backup seismic category air supply accumulators. The operability of either valve is sufficient to permit depressurization.

   b. Auxiliary Spray Valve 8145 - This normally closed valve fails closed on loss of air or power. If 8145 is stuck closed as a result of a single failure, the redundant Seismic Category 1 pressurizer PORVs can be used to depressurize the RCS as described in the alternate method for depressurization.

5. Instrumentation

   Sufficient instrumentation is provided to monitor from the control room the key function associated with cold shutdown. All necessary indications are redundant. Thus, in the event of a single failure, the operator can make comparisons between duplicate information channels or between functionally related channels in order to identify the particular malfunction. Refer to FSAR Section 7.5 (Safety Related Display Instrumentation) for applicable details.

6. Qualification

   The equipment discussed in the cold shutdown scenario is safety grade with the following exceptions. These are few in number and of such a nature that local manual actions and/or equipment repair could be performed while the plant is maintained in the hot standby condition while preparations are made to go to cold shutdown. These manual actions would not prevent the plant from achieving RHRS initiations within 36 hours.

   a. Steam generator power operated relief valves - These air operated valves are provided with safety grade remote operators; however, remote control provisions are control grade. Hot standby can be achieved and maintained using the safety grade steam generator safety valves. The steam generator power operated relief valves are provided with handwheels which can be operated locally to permit plant cooldown.

   b. Charging line isolation valves (8146, 8147), Charging line auxiliary spray valve (8145) - Seal injection line hand control valve (HCV-186). Charging line flow control valve (FCV-122).

These air operated valves are not provided with safety grade remote operators, air supplies, or power supplies. Their failure consequences were discussed in Parts 3 and 4 of the single failure evaluation.

c. RHRS Flow Control Valve HCV-603 A/B - This air operated valve is not provided with a safety grade remote operator, air supply, or power supply. Its failure consequence was discussed in Part 2 of the single failure evaluation.

d. Pressurizer relief tank - This tank is a non-nuclear safety class and non-Seismic Category 1 tank. Its failure does not affect the ability of the Virgil C. Summer Nuclear Station to achieve cold shutdown.

e. Pressurizer power operated relief valves - These air operated valves are not supplied with safety grade remote operators; however, they are powered from separate vital DC electrical power supplies and two of them have Seismic Category 1 air supply accumulators. These valves are discussed in Part 4 of the cold shutdown scenario.

5.5.7.1.4 Natural Circulation

The natural circulation capabilities of the Virgil C. Summer Nuclear Station are compared with three and four loop test results in Section 5.5.7.1.1, Item 5.

5.5.7.2 System Description

The RHRS, as shown in Figure 5.5-4, consists of two residual heat exchangers, two residual heat removal pumps, and the associated piping, valves, and instrumentation necessary for operational control. The inlet lines to the RHRS are connected to the hot legs of two reactor coolant loops, while the return lines are connected to each of the cold legs and to two hot legs of the reactor coolant loops. These return lines are also the ECCS low head cold leg injection/recirculation lines and the hot leg recirculation lines (see Figure 6.3-1).

The RHRS suction lines are isolated from the RCS by two motor operated valves in series and a relief valve, all located inside the reactor building. Each discharge line is isolated from the RCS by two check valves located inside the reactor building and by a motor operated valve located outside the reactor building. (The check valves and the motor operated valve on each discharge line are not shown as part of the RHRS; these valves are shown as part of the ECCS, see Figure 6.3-1.)

During RHRS operation, reactor coolant flows from the RCS to the residual heat removal pumps, through the tube side of the residual heat exchangers, and back to the RCS. The heat is transferred to the component cooling water circulating through the shell side of the residual heat exchangers.

Coincident with operation of the RHRS, a portion of the reactor coolant flow may be diverted from downstream of the residual heat exchangers to the CVCS low pressure letdown line for cleanup and/or pressure control. By regulating the diverted flowrate and the charging flow, the RCS pressure may be controlled. Pressure regulation is necessary to maintain the pressure range

dictated by the fracture prevention criteria requirements of the reactor vessel and net positive suction head requirements of the reactor coolant pumps.

The RCS cooldown rate is manually controlled by regulating the reactor coolant flow through the tube side of the residual heat exchangers. A line containing a flow control valve bypasses each residual heat exchanger and is used to maintain a constant return flow to the RCS. Instrumentation is provided to monitor system pressure, temperature, and total flow.

The RHRS is also used for filling the refueling cavity before refueling. After refueling operations, water is pumped back to the refueling water storage tank until the water level is brought down to the flange of the reactor vessel. The remainder of the water is removed via a drain connection at the bottom of the refueling cavity.

When the RHRS is in operation, the water chemistry is the same as that of the reactor coolant. Provision is made for the process sampling system to extract samples from the flow of reactor coolant downstream of the residual heat exchangers. A local sampling point is also provided on each residual heat removal train between the pump and heat exchanger.

The RHRS functions in conjunction with the high head portion of the ECCS to provide injection of borated water from the refueling water storage tank into the RCS cold legs during the injection phase following a loss of coolant accident.

In its capacity as the low head portion of the ECCS, the RHRS provides long term recirculation capability for core cooling following the injection phase of the loss of coolant accident. This function is accomplished by aligning the RHRS to take fluid from the reactor building sump, cool it by circulation through the residual heat exchangers, and supply it to the core directly as well as via the centrifugal charging pumps.

The use of the RHRS as part of the ECCS is more completely described in Section 6.3.

5.5.7.2.1 Component Description

The materials used to fabricate RHRS components are in accordance with the applicable code requirements. All parts of components in contact with borated water are fabricated or clad with austenitic stainless steel or equivalent corrosion resistant material.

Portions of the system that are designed to carry ECCS fluid outside containment during the recirculation phase of ECCS operation are designed to minimize leakage to the atmosphere as described in Section 6.3.2.11.3.

Component codes and classifications are given in Section 3.2 and component parameters are listed in Table 5.5-8.

5.5.7.2.1.1 Residual Heat Removal Pumps

Two pumps are installed in the RHRS. The pumps are sized to deliver reactor coolant flow through the residual heat exchangers to meet the plant cooldown requirements. The use of two separate residual heat removal trains assures that cooling capacity is adequately maintained should one pump become inoperative.

The residual heat removal pumps are protected from overheating and loss of suction flow by minimum flow bypass lines that assure flow to the pump suction. A valve located in each minimum flow line is regulated by a signal from the flow switch located in each heat exchanger discharge header. The control valves open when RHR discharge flow to the RCS reaches the minimum flow setpoint, which is set to prevent RHR pump flow from approaching the minimum design flow of 500 gpm. The control valves close when flow reaches the close setpoint at nearly the maximum range of the flow switch, or approximately 1500 gpm.

A pressure sensor in each pump discharge header provides a signal for an indicator in the control room. A high pressure alarm is also actuated by the pressure sensor. The two pumps are vertical, centrifugal units with mechanical seals on the shafts. All pump surfaces in contact with reactor coolant are austenitic stainless steel or equivalent corrosion resistant material.

5.5.7.2.1.2 Residual Heat Exchangers

Two residual heat exchangers are installed in the system. The heat exchanger design is based on heat load and temperature differences between reactor coolant and component cooling water existing at 20 hours after reactor shutdown from an extended full power run at 2775 MWt when the temperature difference between the two systems is small. For the current licensed RTP of 2900 MWt, the corresponding decay heat level occurs at 24 hours after reactor shutdown.

The installation of two heat exchangers in separate and independent residual heat removal trains assures that the heat removal capacity of the system is adequately maintained if one train becomes inoperative.

The residual heat exchangers are of the shell and U-tube type. Reactor coolant circulates through the tubes, while component cooling water circulates through the shell. The tubes are welded to the tubesheet to prevent leakage of reactor coolant.

5.5.7.2.1.3 Residual Heat Removal System Valves

Valves that perform a modulating function are equipped with two sets of packings and an intermediate leakoff connection that discharges to the drain header.

Manual and motor operated valves have backseats to facilitate repacking and to limit stem leakage when the valves are open. Leakage connections are provided where required by valve size and fluid conditions.

5.5.7.2.2 System Operation

5.5.7.2.2.1 Reactor Startup

Generally, while at cold shutdown condition, decay heat from the reactor core is being removed by the RHRS. The number of pumps and heat exchangers in service depends upon the heat load at the time.

At initiation of the plant startup, the RCS is completely filled, and the pressurizer heaters are energized. The RHRS is operating and is connected to the CVCS via the low pressure letdown line to control reactor coolant pressure. During this time, the RHRS acts as an alternate letdown path. The manual valves downstream of the residual heat exchangers leading to the letdown line of the CVCS are opened. The control valve in the line from the RHRS to the letdown line of the CVCS is then manually adjusted in the control room to permit letdown flow. Failure of any of the valves in the line from the RHRS to the CVCS has no safety implications, either during startup or cooldown.

After the reactor coolant pumps are started, the residual heat removal pumps are stopped but pressure control via the RHRS and the low pressure letdown line is continued until the pressurizer steam bubble is formed. Indication of steam bubble formation is provided in the control room by the damping out of the RCS pressure fluctuations, and by pressurizer level indication. The RHRS is then isolated from the RCS and the system pressure is controlled by normal letdown and the pressurizer spray and pressurizer heaters.

5.5.7.2.2.2 Power Generation and Hot Standby Operation

During power generation and hot standby operation, the RHRS is not in service but is aligned for operation as part of the ECCS.

5.5.7.2.2.3 Reactor Cooldown

Reactor cooldown is defined as the operation which brings the reactor from no-load temperature and pressure to cold shutdown conditions.

The initial phase of reactor cooldown is accomplished by transferring heat from the RCS to the steam and power conversion system through the use of the steam generators.

When the reactor coolant temperature and pressure are reduced to approximately 350°F and less than 425 psig, approximately 4 hours after reactor shutdown, the second phase of cooldown starts with the RHRS being placed in operation. It should be noted that given the decay heat models and the RCP heat assumed, the RHRS system, under worst case design conditions, cannot begin to cooldown the RCS until approximately 6 hours after an extended full power run at the current licensed RTP of 2900 MWt (although it can be placed into service in parallel with the steam dump system at approximately 4 hours after reactor shutdown). Plant procedures do verify that heat removal occurs via RHRS before fully transferring from the steam dump system.

Startup of the RHRS includes a warmup period during which time reactor coolant flow through the heat exchangers is limited to minimize thermal shock. The rate of heat removal from the reactor coolant is manually controlled by regulating the coolant flow through the residual heat exchangers. By adjusting the control valves downstream of the residual heat exchangers the mixed mean temperature of the return flows is controlled. Coincident with the manual adjustment, each heat exchanger bypass valve is regulated to give the required total flow.

The reactor cooldown rate is limited by RCS equipment cooling rates based on allowable stress limits, as well as the operating temperature limits of the CCWS. As the reactor coolant temperature decreases, the reactor coolant flow through the residual heat exchangers is increased by adjusting the control valve in each heat exchanger's tube side outlet line.

Assuming that only one heat exchanger and pump are in service and that the heat exchanger is supplied with component cooling water at design flow and at a temperature not exceeding 120°F, the coupled RHRS/CCWS/SWS system is capable of reducing the RCS temperature from 350°F at 6 hours after shutdown from an extended full power run at the current licensed RTP of 2900 MWt to 200°F within 30 hours from the beginning of the cooldown. The RHRS heat load during the transient includes the heat from one RCP, core decay heat, and the sensible heat of the RCS metal and fluid.

As cooldown continues, the pressurizer is filled with water and the RCS is operated in the water solid condition.

At this stage, pressure control is accomplished by regulating the charging flowrate and the rate of letdown from the RHRS to the CVCS.

After the reactor coolant pressure is reduced and the temperature is 140°F or lower, the RCS may be opened for refueling or maintenance once the remaining shutdown operations are considered complete.

5.5.7.2.2.4 Refueling

Both residual heat removal pumps are utilized during refueling to pump borated water from the refueling water storage tank to the refueling cavity. During this operation, the isolation valves in the inlet lines of the RHRS are closed, and the isolation valves from the refueling water storage tank are opened.

Station operating procedures include instructions for draining the RCS for vessel head removal prior to refueling operations. The instruction includes the installation of clear hose between one of the RCS loop drains and the pressurizer relief line vent to provide level indication after the pressurizer level indication is off scale. The procedure also states that after the RCS level has reached 4 to 12 inches below the reactor vessel flange, draining operations are secured. These actions ensure that air will not be introduced into the RHRS via the RCS during refueling operations.

The reactor vessel head is lifted. The refueling water is then pumped into the reactor vessel through the normal RHRS return lines and into the refueling cavity through the open reactor vessel. After the water level reaches the normal refueling level, the refueling water storage tank supply valves are closed, the inlet isolation valves are opened, and residual heat removal is resumed.

During refueling, the RHRS is maintained in service with the number of pumps and heat exchangers in operation as required by the heat load.

Following refueling, the residual heat removal pumps are used to drain the refueling cavity to the top of the reactor vessel flange by pumping water from the RCS to the refueling water storage tank.

5.5.7.3 Design Evaluation

5.5.7.3.1 System Availability and Reliability

General Design Criterion 34 requires that a system to remove residual heat be provided. The safety function of this system is to transfer fission product decay heat and other residual heat from the core at a rate sufficient to prevent fuel or pressure boundary design limits from being exceeded. Safety grade systems are provided in the plant design to perform this safety function. The NSSS safety grade systems which perform this function, for all plant conditions except a LOCA, are: the RCS and steam generators, which operate in conjunction with the Emergency Feedwater System, and the steam generator safety valves; and the RHRS which operates in conjunction with the reactor plant CCWS and the Service Water System. The BOP safety grade systems which perform this function, for all plant conditions except LOCA, are: the Emergency Feedwater System, the steam generator safety valves, which operate in conjunction with the RCS and the steam generators; and the reactor plant CCWS and Service Water Systems, which operate in conjunction with the RHRS. For LOCA conditions, the safety grade system which performs the function of removing residual heat from the reactor core is the ECCS, which operates in conjunction with the reactor plant CCWS and the Service Water System.

The Emergency Feedwater System, along with the steam generator safety valves, provides a completely separate, independent, and diverse means of performing the safety function of removing residual heat, which is normally performed by the RHRS when RCS temperature is less than 350°F. The Emergency Feedwater System is capable of performing this function for an extended period of time following plant shutdown.

The RHRS is provided with two residual heat removal pumps and two residual heat removal heat exchangers arranged in two separate, independent flow paths. To assure reliability, each residual heat removal pump is connected to a different vital bus. Each residual heat removal train is isolated from the RCS on the suction side by two motor operated valves in series. Each motor operated valve receives power via a separate motor control center and the two valves in series in each train receive their power from a different vital bus. Each suction isolation valve is also independently and diversely interlocked to one of two RCS wide range pressure instruments to prevent opening the valves when the RCS pressure is above 425 psig. Independence is

accomplished by aligning each RCS wide range pressure transmitter to a different vital bus. Diversity is accomplished through the use of two RCS wide range pressure instruments which employ different pressure sensing principles. Also, at strategically identified local high points, the RHRS is provided with indicating air-traps to ensure the RHRS remains void free (reference NRC GL 2008-01).

RHRS operation for normal conditions is accomplished from the control room. The redundancy in the RHRS design provides the system with the capability to maintain its cooling function even with major single failures, such as failure of an RHR pump, valve, or heat exchanger since the redundant train can be used for continued heat removal. See Table 5.5-15 for a single active failure analysis of the RHRS.

Although such major system failures are within the system design basis, there are other less significant failures which can prevent opening of the RHR suction isolation valves from the control room. Since these failures are of a minor nature, improbable to occur, and easily corrected outside the control room, with ample time to do so, they have been realistically excluded from the engineering design basis. Such failures are not likely to occur during the limited time period in which they can have any effect (i.e., when opening the suction isolation valves to initiate RHR operation); however, even if they should occur, they have no adverse safety impact and can be readily corrected. In such a situation, the Emergency Feedwater System and steam generator safety valves can be used to perform the safety function of removing residual heat and can be used to continue the plant cooldown below 350°F, until the RHRS is made available.

One failure which can prevent opening the RHR suction isolation valves from the control room is a failure of an electrical power train. Such a failure is extremely unlikely to occur during the few minutes per year operating time, during which it can have any consequence. If such an unlikely event should occur, several alternatives are available. The most realistic approach would be to obtain restoration of offsite power, which can be expected to occur in less than 1/2 hour. Other alternatives are to restore the emergency diesel generator to operation, to bring in an alternate power source, or to open the affected valves with their manual handwheels.

The only impact of either of the above types of failure is some delay in initiating RHR operation, while action is taken to open the RHR suction isolation valves. This delay has no adverse safety impact because of the capability of the Emergency Feedwater System and steam generator safety relief valves to continue to remove residual heat.

The safe shutdown design basis of the Virgil C. Summer Nuclear Station is hot standby, as it is for all other Westinghouse designed pressurized water reactors. Hot standby is a safe and stable plant condition which can be maintained for an extended period of time following any Condition II, III, or IV event. In the hot standby condition, residual heat removal, in compliance with GDC 34, is provided by the Emergency Feedwater System in conjunction with the steam generator safety valves. Cross connections from the Service Water System to the Emergency Feedwater System provide a long term (i.e., greater than 7 days) source of emergency feedwater.

In view of the above described capability, the RHRS is not required to fully comply with the single failure requirement of GDC 34. For most major single failures, the RHRS does fully

comply with the single failure criterion. The only situation where full compliance is not provided is for opening the RHR suction isolation valves (to initiate RHR cooling) in the event of the failure of one of the safeguards power trains. In the event of such a failure, sufficient time is available to either compensate for the single failure by manual actions inside (i.e., by opening a suction valve with its manual handwheel) or outside (by providing an alternate temporary power supply to a suction valve) the containment or to restore the failed safeguards power train to operation.

See Section 5.5.7.1.1 for compliance with BTP RSB 5-1.

The maximum cooldown rate which can result if both RHR flow control valves and both RHR bypass valves all simultaneously fail in such a manner as to permit maximum flow through the RHR heat exchangers (a low probability event considering the few hours a year when it could cause any effect) depends on several factors including the RHR flow rate, the CCWS flow rates and temperatures, and other heat loads on the CCWS. One of the key factors is the RCS temperature since the heat removal rate depends on the temperature differential between the RHR (RCS) flow and the component cooling water flow in the RHR heat exchanger. Typically, it is impossible to maintain a cooldown rate even as high as the design rate of 50°F/hr when the RCS temperature is less than 250°F, even with the maximum flow through the RHR heat exchangers.

Even if maximum flow through the RHR heat exchangers was experienced at the instant of initiating RHR operation and no operator action was taken, it is unlikely that the cooldown would exceed 100°F in the first hour. The cooldown rate in the subsequent hours would be much less than 100°F/hr. The maximum possible cooldown rate from 350°F to 250°F would not exceed 200°F/hr. Calculations have been done which show that, from a stress standpoint, a cooldown rate greater than 200°F/hr is acceptable for such a hypothetical cooldown from 350°F to 250°F even though, as discussed above, the actual maximum rate of cooldown at or below 250°F is not expected to exceed 50°F/hr.

Although such a hypothetical cooldown event is acceptable assuming no operator action, it should be noted that the operator can significantly limit the maximum possible cooldown rate by merely stopping one of the RHR pumps.

5.5.7.3.2 Leakage Provisions and Activity Release

In the event of a loss of coolant accident or during normal recirculation mode, radioactive fluid may be recirculated through part of the RHRS exterior to the reactor building. If the residual heat removal pump seal should fail, the water would spill out on a floor in a shielded compartment. Each residual heat removal pump compartment contains a sump which is equipped with an alarm system set to indicate leakage of greater than 45 gpm. The alarm system is annunciated in the control room so the operator can determine the location of the leak. Redundant sump pumps are capable of handling leakage flows up to 50 gpm each. In the case of failure of both sump pumps, each residual heat removal pump room has a water tight volume of at least 200 ft^3 to accommodate a 50 gpm leak for at least 30 minutes. This provides protection against pump flooding in the event of a 50 gpm leak. Any leakage, whether handled by the residual heat removal pump room sumps or the Auxiliary Building sump pumps, is directed to holdup tanks in

the liquid waste processing system. Residual heat removal piping and pumps in each cubicle can be remotely isolated by motor operated valves so they can be drained and flushed prior to being repaired.

The maximum discharge rate from a moderate energy pipe crack in the RHRS is approximately 714 gpm.

Since such a leak rate would have no effect on core cooling until it resulted in emptying the RCS loops, the time available to the operator to take action is at least 73 minutes.

The operator would be alerted to the leak by decreasing pressurizer level and the pressurizer low level alarm. Depending on the location of the crack, the operator could also be alerted by RHR pump compartment sump level alarms. The only action necessary to recover from the event is to close the suction isolation valve(s) of the affected RHR train and to initiate cooling on the other RHR train, if it is not already operating. Depending on the amount of water lost before isolating the leak, the operator may be required to makeup to the RCS.

5.5.7.3.3 Overpressurization Protection

Each inlet line to the RHRS is equipped with a pressure relief valve which protects the system from inadvertent overpressurization during plant cooldown or startup. Each valve has a relief flow capacity of 900 gpm at a set pressure of 450 psig. Analyses have been conducted to confirm the capability of the RHRS relief valve to prevent overpressurization of the RHRS. All credible events were examined for their potential to overpressurize the RHRS. These events included normal operating conditions, infrequent transients, and abnormal occurrences. The analyses confirmed that one relief valve has the capability to keep the RHRS maximum pressure within 10 CFR 50 Appendix G limits.

Each discharge line from the RHRS to the RCS is equipped with a pressure relief valve to relieve the maximum possible back-leakage through the valves separating the RHRS from the RCS. Each valve has a relief flow capacity of 20 gpm at a set pressure of 600 psig. These relief valves are located in the ECCS (see Figure 6.3-1).

The fluid discharged by the suction side relief valves is collected in the pressurizer relief tank. The fluid discharged by the discharge side relief valves is collected in the recycle holdup tanks of the boron recycle system.

5.5.7.3.4 Prevention of Exposure of the RHRS to Normal RCS Operating Pressure

The design of the RHRS includes two motor operated gate isolation valves in series on each inlet line between the high pressure RCS and the lower pressure RHRS. They are closed during normal operation and are only opened for residual heat removal and RCS cold overpressure protection during a plant cooldown after the RCS pressure is reduced to less than 425 psig and the RCS temperature is reduced to approximately 350°F. During a plant startup, the inlet isolation valves are shut after drawing a bubble in the pressurizer and prior to increasing RCS pressure above 425 psig. Power to the isolation valves is manually locked out during normal operation.

The two inlet isolation valves in each residual heat removal subsystem are independently and diversely interlocked with pressure signals to prevent their being opened whenever the RCS pressure is greater than approximately 425 psig. The autoclosure interlock of these valves has been removed as per WCAP-11835. An alarm has been added to alert the operator if the valves are not closed when the RCS pressure increases above the alarm setpoint of 520 psig.

The use of two independently powered motor operated valves in each of the twp inlet lines, along with an independent and diverse pressure interlock to prevent them from being opened, and a RCS pressure high with RHR suction valves not closed alarm assures a design which meets applicable single failure criteria. Not only more than one single failure, but also different failure mechanisms, must be postulated to defeat the function of preventing possible exposure of the RHR system to normal RCS operating pressure. This protective interlock design, in combination with alarm, administrative controls, and plant operating procedures, provides the means for accomplishing the protective function. For further information on the instrumentation and control features, see Section 7.6.2.

The RHR inlet isolation valves are provided with red-green position indicator lights on the main control board and a ESF monitor light for proper valve position. ESF monitor light is independent and diverse from valve position indication.

Isolation of the low pressure RHRS from the high pressure RCS is provided on the discharge side by two check valves in series. These check valves are located in the ECCS and their testing is described in Section 5.2.2.4.

5.5.7.3.5 Shared Function

The safety function performed by the RHRS is not compromised by its normal function which is normal plant cooldown. The valves associated with the RHRS are normally aligned to allow immediate use of this system in its engineered safety features mode of operation. The system has been designed in such a manner that two redundant flow circuits are available, assuring the availability of at least one train for safety purposes.

The normal plant cooldown function of the RHRS is accomplished through a suction line arrangement which is independent of any safety function. The cold leg cooldown return lines are arranged in parallel redundant circuits and are utilized also as the low head injection lines to the RCS. Utilization of the same return circuits for cold leg cool down lends assurance to the proper functioning of these lines for engineered safety features purposes.

5.5.7.3.6 Radiological Consideration

The highest radiation levels experienced by the RHRS are those which would result from a loss of coolant accident. Following a loss of coolant accident, the RHRS is used as part of the ECCS. During the recirculation phase of emergency core cooling, the RHRS is designed to operate for up to a year pumping water from the reactor building sump, cooling it, and returning it to the reactor building to cool the core.

Since, except for some valves and piping, the RHRS is located outside the reactor building, most of the system is not subjected to the high levels of radioactivity in the reactor building post accident environment.

The operation of the RHRS does not involve a radiation hazard for the operators since the system is controlled remotely from the control room. If maintenance of the system is necessary, the portion of the system requiring maintenance is isolated by remotely operated valves and/or manual valves with stem extensions which allow operation of the valves from a shielded location. The isolated piping is drained and flushed before maintenance is performed.

5.5.7.4 Tests and Inspections

Periodic visual inspections and preventive maintenance are conducted during plant operation according to normal industrial practice.

The instrumentation channels for the residual heat removal pump flow instrumentation devices are calibrated during each refueling operation if a check indicates that recalibration is necessary.

Due to the role the RHRS has in sharing components with the ECCS, the residual heat removal pumps are tested as a part of the ECCS testing program (see Section 6.3.4). Preoperational testing is discussed in Chapter 14.

5.5.8 Reactor Coolant Cleanup System

The CVCS provides reactor coolant cleanup and is discussed in Section 9.3.4. The radiological considerations are discussed in Chapter 11.

5.5.9 Main Steam Line and Feedwater Piping

Main steam line and feedwater piping are discussed in Sections 10.3 and 10.4.7, respectively.

5.5.10 Pressurizer

5.5.10.1 Design Bases

The general configuration of the pressurizer is shown in Figure 5.5-6. The design data of the pressurizer are given in Table 5.5-9. Codes and material requirements are provided in Section 5.2.

The pressurizer provides a point in the RCS where liquid and vapor can be maintained in equilibrium under saturated conditions for pressure and control purposes.

Stress analysis of the pressurizer components was performed at the plant conditions associated with steam generator replacement. While a slight increase in the fatigue usage for several of the pressurizer components was noted, the acceptance limits of Section III of the ASME Code were not exceeded. Therefore, the pressurizer components will not be overstressed or subject to fatigue usage during the remainder of the projected plant lifetime.

5.5.10.1.1 Pressurizer Surge Line

The surge line is sized to limit the pressure drop between the RCS and the safety valves with maximum allowable discharge flow from the safety valves. Overpressure of the RCS does not exceed 110% of the design pressure.

The surge line and thermal sleeve at the pressurizer end are designed to withstand the thermal stresses resulting from volume surges of relatively hotter or colder water which may occur during operation.

The pressurizer surge line nozzle diameter is given in Table 5.5-9 and the pressurizer surge line dimensions are shown in Figure 5.1-1, Sheet 2.

5.5.10.1.2 Pressurizer

The volume of the pressurizer is equal to or greater than the minimum volume of steam, water, or total of the two which satisfies the following requirements:

1. The combined saturated water volume and steam expansion volume is sufficient to provide the desired pressure response to system volume changes.
2. The water volume is sufficient to prevent the heaters from being uncovered during a 10% step load increase to full power.
3. The steam volume is large enough to accommodate the surge resulting from 50% reduction of full load with automatic reactor control and 40% steam dump without the water level reaching the high level reactor trip point.
4. The steam volume is large enough to prevent water relief through the safety valves following a loss of load with the high water level initiating a reactor trip, without reactor control or steam dump.
5. The pressurizer will not empty following reactor trip and turbine trip.
6. The emergency core cooling signal is not activated during reactor trip and turbine trip.

5.5.10.2 Design Description

5.5.10.2.1 Pressurizer Surge Line

The pressurizer surge line connects the pressurizer to one reactor hot leg. The line enables continuous coolant volume pressure adjustments between the RCS and the pressurizer.

5.5.10.2.2 Pressurizer

The pressurizer is a vertical, cylindrical vessel with hemispherical top and bottom heads constructed of carbon steel, with austenitic stainless steel cladding on all surfaces exposed to the reactor coolant. A stainless steel liner or tube is used in lieu of cladding in some nozzles.

The high strength welds joining the component parts of the pressurizer are the four girth welds joining the upper head, three shell barrels, and the lower head, and the three longitudinal welds joining the three sections of the shell barrels. The various weld and flux combinations used in these welds are listed in Table 5.5-18 along with the appropriate fracture toughness test information.

The surge line nozzle and removable electric heaters are installed in the bottom head. The heaters are removable for maintenance or replacement. A thermal sleeve is provided to minimize stresses in the surge line nozzle. A screen at the surge line nozzle and baffles in the lower section of the pressurizer prevent an insurge of cold water from flowing directly to the steam/water interface and assist mixing.

Spray line nozzles, relief, and safety valve connections are located in the top head of the vessel. Spray flow is modulated by automatically controlled air operated valves. The spray valves can also be operated manually in the control room.

A small continuous spray flow is provided through a manual bypass valve around the power operated spray valves to assure that the pressurizer liquid is homogeneous with the coolant and to prevent excessive cooling of the spray piping.

During an outsurge from the pressurizer, flashing of water to steam, and generating of steam by automatic actuation of the heaters, keep the pressure above the minimum allowable limit. During an insurge from the RCS, the spray system, which is fed from two cold legs, condenses steam in the vessel to prevent the pressurizer pressure from reaching the setpoint of the power operated relief valves for normal design transients. Heaters are energized on high water level during insurge to heat the subcooled surge water that enters the pressurizer from the reactor coolant loop.

SA533 Grade A Class 2 material was used in the Virgil C. Summer pressurizer. (SA533 Grade A Class 2 material was not used in primary side (RCPB) pressure retaining applications of the Virgil C. Summer steam generators.) The actual fracture toughness data for the SA533 Grade A Class 2 material in the pressurizer are tabulated in Table 5.5-17.

Material specifications are provided in Table 5.2-8 for the pressurizer, pressurizer relief tank, and the surge line. Design transients for the components of the RCS are discussed in Section 5.2.1.5. Additional details on the pressurizer design cycle analysis are given in Section 5.5.10.3.5.

The pressurizer nozzle weld overlays as noted in Section 5.5.3.3.4 identified that the overlay weld filler material used was alloy 52M. This high chromium weld filler metal is compatible with the carbon steel, stainless steel, and existing Inconel materials in the underlying components. This weld metal was applied utilizing a temperbead method to eliminate the need for pre and post weld heat treatment.

5.5.10.2.2.1 Pressurizer Support

The skirt type support is attached to the lower head and extends for a full 360 degrees around the vessel. The lower part of the skirt terminates in a bolting flange with bolt holes for securing the

vessel to its foundation. The skirt type support is provided with ventilation holes around its upper perimeter to assure free convection of ambient air past the heater plus connector ends for cooling.

5.5.10.2.2.2 Pressurizer Instrumentation

Refer to Chapter 7 and Section 5.6 for details of the instrumentation associated with pressurizer pressure, level, and temperature.

5.5.10.2.2.3 Spray Line Temperatures

Temperatures in the spray lines from two loops are measured and indicated. Alarms from these signals are actuated by low spray water temperature. Alarm conditions indicate insufficient flow in the spray lines.

5.5.10.2.2.4 Safety and Relief Valve Leakage Monitoring

Monitoring of the status of the pressurizer safety and relief valves is by the following methods:

a. Temperature detectors in the piping downstream of the valves. (An increase in discharge line temperature is an indication of leakage through the valve.)
b. Acoustical type monitors to detect safety valve leakage.
c. Pressure/temperature/level of the pressurizer relief tank.
d. Valve limit switches on the pressurizer power operated relief valves which indicate valve open/closed position.

All four methods for detecting leakage through the pressurizer safety and relief valves are monitored in the control room.

5.5.10.3 Design Evaluation

5.5.10.3.1 System Pressure

Whenever a steam bubble is present within the pressurizer, RCS pressure is maintained by the pressurizer. A safety limit has been set to ensure that the RCS pressure does not exceed the maximum transient value allowed under the ASME Code, Section III, and thereby assure continued integrity of the RCS components.

Evaluation of plant conditions of operation which follow indicates that this safety limit is not reached.

During startup and shutdown, the rate of temperature change is controlled by the operator. Heatup rate is controlled by pump energy and by the pressurizer electrical heating capacity. This heatup rate takes into account the continuous spray flow provided to the pressurizer. When the reactor core is shutdown, the heaters are de-energized.

When the pressurizer is filled with water (i.e., during initial system heatup) and near the end of the second phase of plant cooldown, RCS pressure is maintained by the letdown flowrate via the RHRS.

5.5.10.3.2 Pressurizer Performance

The normal operating water volume at full load conditions is 60% of the free internal vessel volume. Under part load conditions, the water volume in the vessel is reduced for proportional reductions in plant load to 25% of free vessel volume at zero power level. The various plant operating transients are analyzed and the design pressure is not exceeded with the pressurizer design parameters as given in Table 5.5-9.

5.5.10.3.3 Pressure Setpoints

The RCS design and operating pressure together with the safety, power relief and pressurizer spray valves setpoints, and the protection system setpoint pressures are listed in Table 5.2-7. The design pressure allows for operating transient pressure changes. The selected design margin considers core thermal lag, coolant transport times and pressure drops, instrumentation and control response characteristics, and system relief valve characteristics.

5.5.10.3.4 Pressurizer Spray

Two separate, automatically controlled spray valves with remote manual overrides are used to initiate pressurizer spray. In parallel with each spray valve is a manual throttle valve which permits a small continuous flow through both spray lines to reduce thermal stresses and thermal shock when the spray valves open and to help maintain uniform water chemistry and temperature in the pressurizer. Temperature sensors with low alarms are provided in each spray line to alert the operator to insufficient bypass flow. The layout of the common spray line piping to the pressurizer forms a water seal which prevents the steam buildup back to the control valves. The spray rate is selected to prevent the pressurizer pressure from reaching the operating setpoint of the power relief valves during a step reduction in power level of 10% of full load.

The pressurizer spray lines and valves are large enough to provide adequate spray using as the driving force the differential pressure between the surge line connection in the hot leg and the spray line connection in the cold leg. The spray line inlet connections extend into the cold leg piping in the form of a scoop so that the velocity head of the reactor coolant loop flow adds to the spray driving force. The spray valves and spray line connections are arranged so that the spray will operate when one reactor coolant pump is not operating. The line may also be used to assist in equalizing the boron concentration between the reactor coolant loops and the pressurizer.

A flow path from the CVCS to the pressurizer spray line is also provided. This additional facility provides auxiliary spray to the vapor space of the pressurizer during cooldown if the reactor coolant pumps are not operating. The thermal sleeves on the pressurizer spray connection and the spray piping are designed to withstand the thermal stresses resulting from the introduction of cold spray water.

5.5.10.3.5 Pressurizer Design Analysis

The occurrences for pressurizer design cycle analysis are defined as follows:

1. The temperature in the pressurizer vessel is always, for design purposes, assumed to equal saturation temperature for the existing RCS pressure, except in the pressurizer steam space subsequent to a pressure increase. In this case, the temperature of the steam space will exceed the saturation temperature since an isentropic compression of the steam is assumed.

   The only exception of the above occurs when the pressurizer is filled solid during plant startup and cooldown.

2. The temperature shock on the spray nozzle is assumed to equal the temperature of the nozzle minus the cold leg temperature. The temperature shock on the surge nozzle is assumed to equal the pressurizer water space temperature minus the hot leg temperature.
3. Pressurizer spray is assumed to be initiated instantaneously to its design value as soon as the RCS pressure increases 40 psi above the nominal operating pressure. Spray is assumed to be terminated as soon as the RCS pressure falls 40 psi below normal operating pressure.
4. Unless otherwise noted, pressurizer spray is assumed to be initiated once per occurrence of each transient condition. The pressurizer surge nozzle is also assumed to be subject to one temperature transient per transient condition, unless otherwise noted.
5. At the end of each transient, except the faulted conditions, the RCS is assumed to return to a load condition consistent with the plant heatup transient.
6. Temperature changes occurring as a result of pressurizer spray are assumed to be instantaneous. Temperature changes occurring on the surge nozzle are also assumed to be instantaneous.
7. Whenever spray is initiated in the pressurizer, the pressurizer water level is assumed to be at the no load level.

5.5.10.4 Tests and Inspections

The pressurizer is designed and constructed in accordance with the ASME Code, Section III.

To implement the requirements of the ASME Code, Section XI, the following welds are designed and constructed to present a smooth transition surface between the parent metal and the weld metal. The path is ground smooth for ultrasonic inspection.

1. Support skirt to the pressurizer lower head.
2. Surge nozzle to the lower head.
3. Nozzles to the safety, relief, and spray lines.
4. Nozzle to safe end attachment welds.

5. All girth and longitudinal full penetration welds.
6. Manway attachment welds.

The liner within the safe end nozzle region extends beyond the weld region to maintain a uniform geometry for ultrasonic inspection.

The pressurizer nozzles for the surge, spray, safety, and relief lines had full structural weld overlays applied during Refuel 17. These weld overlays were designed to ensure that a smooth surface was applied such that the ultrasonic inspection volumetric requirements are maintained. The result of the weld overlays resulted in 100% ultrasonic inspection volumetric coverage of the respective nozzles and underlying welds and components. A Performance Demonstration Initiative (PDI) linear phased array inspection technique was used to perform the post weld overlay inspections.

Peripheral support rings are furnished for the removable insulation modules.

The pressurizer quality assurance program is given in Table 5.5-10.

5.5.11 Pressurizer Relief Tank

5.5.11.1 Design Bases

Design data for the pressurizer relief tank are given in Table 5.5-11. Codes and materials of the tank are given in Section 5.2.

The tank design is based on the requirement to absorb a discharge of pressurizer steam equal to 110% of the volume above the full power pressurizer water level setpoint. The tank is not designed to accept a continuous discharge from the pressurizer.

The volume of water in the tank is capable of absorbing the heat from the assumed discharge, assuming an initial temperature of 120°F and increasing to a final temperature of 200°F. If the temperature in the tank rises above 120°F during plant operation, the tank is cooled by spraying in cool water and draining out the warm mixture to the waste processing system.

5.5.11.2 Design Description

The pressurizer relief tank condenses and cools the discharge from the pressurizer safety and relief valves. Discharge from smaller relief valves located inside the containment is also piped to the relief tank. In addition, in the event that the reactor vessel head vent system (RVHVS) is used, the pressurizer relief tank receives the discharge from the RCS. An itemized list identifying the discharges to the pressurizer relief tank is provided in Table 5.2-6. The tank normally contains water and a predominantly nitrogen atmosphere; however, provision is made to permit the gas in the tank to be periodically analyzed to monitor the concentration of hydrogen and/or oxygen.

By means of its connection to the waste processing system, the pressurizer relief tank provides a means for removing any noncondensable gases from the RCS which might collect in the pressurizer vessel.

Steam is discharged through a sparger pipe under the water level. This arrangement provides for condensing and cooling the steam by mixing it with water that is near ambient temperature. The tank is also equipped with an internal spray and a drain which are used to cool the tank following a discharge. A flanged nozzle is provided on the tank for the pressurizer discharge line connection to the sparger pipe.

5.5.11.2.1 Pressurizer Relief Tank Pressure

The pressurizer relief tank pressure transmitter provides an indication of pressure relief tank pressure. An alarm is provided to indicate high tank pressure.

5.5.11.2.2 Pressurizer Relief Tank Level

The pressurizer relief tank level transmitter supplies a signal for an indicator with high and low level alarms.

5.5.11.2.3 Pressurizer Relief Tank Water Temperature

The temperature of the water in the pressurizer relief tank is indicated, and an alarm actuated by high temperature informs the operator that cooling to the tank contents is required.

5.5.11.3 Design Evaluation

The volume of water in the tank is capable of absorbing a discharge of 110% of the pressurizer steam volume above the full power water level setpoint. Water temperature in the tank is maintained at the nominal containment temperature.

The rupture disks on the relief tank have a relief capacity equal to or greater than the combined capacity of the pressurizer safety valves. The tank design pressure is twice the calculated pressure resulting from the maximum design safety valve discharge described above. The tank and rupture disc holders are also designed for full vacuum to prevent tank collapse if the contents cool following a discharge without nitrogen being added.

The discharge piping from the safety and relief valves to the relief tank is sufficiently large to prevent backpressure of the safety valves from exceeding 20% of the setpoint pressure at full flow.

5.5.12 Valves

5.5.12.1 Design Bases

As noted in Section 5.2, all valves out to and including the second valve normally closed or capable of automatic or remote closure, larger than 3/4 inch, are Safety Class 1, and ASME III, Code Class 1 valves. All 3/4 inch or smaller valves in liquid filled lines connected to the RCS are Class 2 since the interface with the Class 1 piping is provided with suitable orificing for such valves. Pressurizer instrument root valves connected to the steam space above the normal water level have been upgraded to Safety Class 1 since failure of these valves could cause automatic operation of the ECCS systems. Design data for the RCS valves are given in Table 5.5-12.

To ensure that the valves meet the design objectives, the materials specified for construction must minimize corrosion/erosion and ensure compatibility with the environment. Leakage is minimized to the extent practicable by design and Class 1 stresses are maintained within the limits of the ASME Code, Section III and the limits specified in Section 5.5.1.

5.5.12.2 Design Description

Valves in the RCS which are in contact with the coolant are constructed primarily of stainless steel. Other materials in contact with the coolant, such as for hard surfacing and packing, are special materials.

Manual and motor operated valves of the RCS which are 3 inches and larger are provided with double-packed stuffing boxes and intermediate lantern ring leakoff connections. Throttling control valves, regardless of size, are provided with double-packed stuffing boxes and with stem leakoff connections. Leakoff connections on valves, normally operated in a radioactive fluid, are piped to a closed collection system. Leakage to the atmosphere is essentially zero for these valves.

Gate valves at the engineered safety features interface are wedge design and are essentially straight through. The wedges are flex-wedge or solid. All gate valves have backseats. Globe valves are "T" and "Y" style. Check valves are swing type for sizes 2-1/2 inches and larger. All check valves which contain radioactive fluid are stainless steel and do not have body penetrations other than the inlet, outlet, and bonnet. The check hinge is serviced through the bonnet.

The accumulator check valve is designed such that at the required flow the resulting pressure drop is within the specified limits. All operating parts are contained within the body. The disc has limited rotation to provide a change of seating surface and alignment after each valve opening.

5.5.12.3 Design Evaluation

The design/analysis requirements for Class 1 valves, as discussed in Section 5.2, limit stresses to levels which ensure the structural integrity of the valves. In addition, the testing programs described in Section 3.9.2.4 demonstrate the ability of the valves to operate as required during anticipated and postulated plant conditions.

Reactor coolant chemistry parameters are specified in the design specifications to assure the compatibility of valve construction materials with the reactor coolant.

5.5.12.4 Tests and Inspections

RCS valves are tested in accordance with the requirements of the ASME Code, Section III. The tests and inspections discussed in Section 3.9.2.4 are performed to ensure the operability of active valves. In-place operational testing is performed on valves as required by the Technical Specifications.

There are no full penetration welds within valve body walls. Valves are accessible for disassembly and internal visual inspection to the extent practical. Plant layout configurations determine the degree of inspectability. The valve quality assurance program is given in Table 5.5-13.

Inservice inspection is discussed in Section 5.2.8.

5.5.13 Safety and Relief Valves

5.5.13.1 Design Bases

The combined capacity of the pressurizer safety valves is designed to accommodate the maximum surge resulting from complete loss of load. This objective is met without reactor trip or any operator action by the opening of the steam safety valves when steam pressure reaches the steam side safety setting.

The pressurizer power operated relief valves are designed to limit pressurizer pressure to a value below the fixed high pressure reactor trip setpoint for most transients. Conservative analyses indicate that, for the 95% load rejection transient, the high pressure reactor trip setpoint would be reached. No credit is taken for automatic operation of these valves to mitigate the consequences of an accident. They are designed to fail to the closed position on loss of air supply.

5.5.13.2 Design Description

The pressurizer safety valves are totally enclosed pop type. The valves are spring loaded, self-actuated, and with backpressure compensation features.

The pipe connecting the pressurizer nozzles to their respective code safety valves are shaped in the form of a loop. The low point of the loops is drained continuously to the pressurizer liquid space to remove any condensation formed in the safety valve inlet pipes.

The pressurizer power operated relief valves are pneumatic actuated valves which respond to a signal from a pressure sensing system or to manual control. Remotely operated stop valves are provided to isolate the power operated relief valves if excessive leakage develops.

Pressurizer safety and relief valve leakage monitoring is discussed in Section 5.5.10.2.2.4. Refer to Section 5.2 for a discussion of discharge line supports.

Design parameters for the pressurizer spray control, safety, and power relief valves are given in Table 5.5-14.

5.5.13.3 Design Evaluation

The pressurizer safety valves prevent RCS pressure from exceeding 110% of system design pressure in compliance with the ASME Nuclear Power Plant Components Code.

The pressurizer power relief valves prevent actuation of the fixed reactor high pressure trip for all design transients except the design step load decreases with steam dump. For this event, peak pressure will exceed the trip setpoint but remains below the safety valve setpoint. The relief valves limit undesirable opening of the spring-loaded safety valves. Note that setpoint studies to date indicate that the pressure rise in a three-loop plant for the design step load decrease of 10% from full power is limited to 60 psi. These studies also indicate that the design step load decrease of 10% under N-1 loop operation is limited to approximately 50 psi. In both cases, the pressure rise is not sufficient to actuate the power operated relief valves and, thus, this design is conservative.

5.5.13.4 Tests and Inspections

All safety and relief valves are subjected to hydrostatic tests, seat leakage tests, operational tests, and inspections as required. For safety valves that are required to function during a faulted condition, additional tests are performed. These tests are described in Section 3.9.2.4.

There are no full penetration welds within the valve body walls. Valves are accessible for disassembly and internal visual inspection.

5.5.14 Component Supports

Component supports allow virtually unrestrained lateral thermal movement of the loops during plant operation and provide restraint to the loops and components during accident conditions. The loading combinations and design stress limits are discussed in Section 5.2.1.10. The design maintains the integrity of the RCS boundary for normal and accident conditions and satisfies the requirements of the piping code. Results of piping and supports stress evaluation will be presented in Section 5.2.1.10. The normal operating temperatures for the RCS supports are 50°F to 400°F.

5.5.14.1 Description

The support structures are of welded steel construction and are either linear type or plate and shell type. Vessel skirts and saddles are fabricated from plate and shell elements to accommodate a biaxial stress field. Linear supports are tension and compression struts, beams, and columns. Attachments are of integral and nonintegral types. Integral attachments are welded, cast, or forged to the pressure boundary component by lugs, shoes, rings, and skirts. Nonintegral attachments are bolted, pinned, or bear on the pressure boundary component.

The supports permit unrestrained thermal growth of the supported systems, but restrain vertical, lateral, and rotational movement resulting from seismic and pipe break loadings. This is accomplished using pin-ended columns for vertical support and girders, bumper pedestals, and tie rods for lateral support.

Shimming and grouting enable adjustment of all support elements during erection to achieve correct fit-up and alignment.

1. Vessel

   Supports for the reactor vessel (see Figure 5.5-7) are individual air cooled rectangular box structures beneath the vessel nozzles bolted to the primary shield wall concrete. Each box structure consists of a horizontal top plate that receives loads from the reactor vessel shoe, a horizontal bottom plate supported by and transferring loads to the primary shield wall concrete, and connecting vertical plates. The supports are air cooled to maintain the supporting concrete temperature within acceptable levels.

2. Steam Generator

   The lower supports for the steam generator (see Figure 5.5-8) consist of four vertical pin-ended columns bolted to the bottom of the steam generator support pads; and lateral support girders and pedestals that bear against horizontal bumper blocks bolted to the side of the generator support pads. The upper lateral steam generator support consists of a ring girder around the generator shell supported by struts. Loads are transferred from the equipment to the ring girder by means of a number of bumper blocks between the girder and generator shell.

3. Pump

   The reactor coolant pump supports (see Figure 5.5-9) consist of three pin-ended structural steel columns and three lateral tie bars. A large diameter bolt connects each column and tie rod to a pump support pad. The outer ends of all three tie rods have slotted pin holes to permit unrestrained lateral movement of the pump during plant heatup and cooldown but provide lateral restraint for accident loadings.

4. Pressurizer

   The pressurizer (see Figure 5.5-10) is supported at its base by bolting the flangering to the supporting concrete slab. In addition, upper lateral support is provided near the vessel center of gravity by four "V frames" or struts extending horizontally from the compartment walls and bearing against the vessel lugs.

5.5.14.2 Evaluation

Detailed evaluation ensures the design adequacy and structural integrity of the reactor coolant loop and the primary equipment supports system. This detailed evaluation is made by comparing

the analytical results with established criteria for acceptability. Structural analyses are performed to demonstrate design adequacy for safety and reliability of the plant in case of a large or small seismic disturbance and/or loss of coolant accident conditions. Loads that the system is designed to encounter, of 10 during its lifetime (thermal, weight, pressure, and operating basis earthquake [OBE]), are applied and stresses are compared to allowable values, as described in Section 5.2.1.10.

All RCS supports are designed for concurrent loadings from deadweight, pressure, postulated pipe ruptures in the RCS as identified in WCAP-8082 and WCAP-13206, and the SSE. As indicated in Section 3.6, postulated breaks in the reactor coolant loop piping, except for branch line connections, have been eliminated. Reactor coolant loop piping branch nozzle (i.e., accumulator connection, pressurizer surge line, residual heat removal, etc.) breaks are postulated. Additionally, steam line breaks, and safety and relief line breaks, are considered in the design of steam generator and pressurizer supports, respectively. Included under the considerations for pipe rupture loads are the effects of RCS hydraulic loads, jet impingement, thrust, and asymmetric pressures about the supported components.

The pipe rupture analysis which is performed for the reactor vessel support loads includes nonaxisymmetric pressure distributions on the internals.

A detailed dynamic model of the reactor vessel and internals includes the stiffnesses of the reactor vessel support and the attached piping. Hydraulic forces are developed in the internals for the postulated break; these forces are characterized by time dependent forcing functions on the vessel and core barrel. In the derivation of these forcing functions, the fluid-structure (or hydroelastic) interaction in the downcomer region between the barrel and the vessel is taken into account. As a result of the loop branch pipe breaks, loop mechanical loads are also applied to the vessel. The loads from these three sources, the internals reactions, reactor cavity pressure loads, and the loop mechanical forces, are applied simultaneously in a nonlinear elastic dynamic time history analysis on the model of the vessel, supports, and internals. The results of this analysis are the dynamic loads on the reactor vessel supports and vessel time history displacements. The maximum loads are combined with other applicable loads, such as seismic and deadweight, and applied statically to the vessel support structure.

Although considered in the design, it is expected on the basis of past experience that asymmetric pressure loadings on the major components will be negligible.

For public health and safety, the SSE and design basis loss of coolant accident, resulting in a rapid depressurization of the system, are required design conditions. For these loadings, the basic criteria ensure that the severity of the accident will not be increased, thus maintaining the system in a safe condition. The rupture of a reactor coolant loop pipe will not violate the integrity of the unbroken leg of the loop. To ensure the integrity and stability of the reactor coolant loop support system and a safe shutdown of the system under loss of coolant accident and the worst combined (Normal + SSE + LOCA) loadings, the stresses in the unbroken piping of a broken loop, the unbroken loop piping, and the supports system are analyzed. The results of design analysis are provided in Section 5.2.1.10.

5.5.14.3 Tests and Inspections

The design and fabrication are specified in accordance with the AISC Specifications for the "Design, Fabrication, and Erection of Structural Steel for Buildings," 1969 Edition and applicable portions of the ASME Boiler and Pressure Vessel Code. Welder qualifications, welding procedures, and inspection of welded joints are specified to be in accordance with Section IX of the ASME Code.

5.5.15 Reactor Vessel Head Vent System

5.5.15.1 Design Basis

The basic function of the RVHVS is to remove non-condensable gases or steam from the reactor vessel head. This system is designed to mitigate a possible condition of inadequate core cooling or impaired natural circulation resulting from the accumulation of noncondensable gases in the RCS. The design of the RVHVS is in accordance with the requirements of NUREG-0578 and subsequent definitions and clarifications (References 2 and 3).

5.5.15.2 Design Description and Evaluation

5.5.15.2.1 General Description

The RVHVS is designed to remove non-condensable gases or steam from the RCS via remote manual operations from the control room. The system discharges to the pressurizer relief tank. The RVHVS is designed to vent a volume of hydrogen, noncondensable gases, etc., at system design pressure and temperature approximately equivalent to 1/2 of the RCS volume in 1 hour.

An H_2 burn from a 100% zircaloy/H_2O reaction has been addressed and it has been determined that containment integrity would not be breached. Therefore, contained venting outside containment is not considered necessary.

The flow diagram of the RVHVS is shown in Figure 5.5-13. The RVHVS consists of two parallel flow paths with redundant isolation valves in each flow path. The venting operation uses only one of the flow paths at any time.

The physical layout of the RCS hot leg piping is such that its entire volume can be vented via the RVHVS.

The equipment design parameters are listed in Table 5.5-16.

As indicated above, normally the venting from the RVHVS is contained by the pressurizer relief tank. However, venting to containment could occur if the rupture disc ruptures. In that case, the location of the PRT is such that excellent gas communication exists within the secondary shield area that any gas that escapes from the PRT will be readily mixed with the containment atmosphere with additional mixing being promoted by the Reactor Building Ventilation System.

The active portion of the system consists of 4 two-inch motor operated isolation valves connected to the reactor vessel head vent pipe. The isolation valves in series in each flow path are powered by opposite vital power supplies. The isolation valves are fail as is, active valves. One normally closed isolation valve and one normally open valve are located in each flow path. Leakage past the vent valves during normal plant operation is detected by the pressurizer relief tank instrumentation. All of the isolation valves are qualified to IEEE - 323-1974, 344-1975, and 382-1972 and to the requirements of Regulatory Guide 1.48 as described in Appendix 3A.

If one single active failure prevents a venting operation through one flow path, the redundant path is available for venting. Similarly, the two isolation valves in each flow path provide a single failure method of isolating the venting system. With two valves in series, the failure of any one valve or power supply will not inadvertently open a vent path. Thus, the combination of safety grade train assignments and valve failure modes will not prevent vessel head venting nor venting isolation with any single active failure.

The RVHVS has two normally de-energized valves in series in each flow path. Power lockout capability to all four isolation valves is provided by administrative control at the motor control load center. This arrangement eliminates the possibility of a spuriously opened flow path.

The system is operated from the control room. The position indication from each valve is monitored in the control room by status lights. Position indication is unavailable in the control room when the motor control breaker is open.

The RVHVS is connected to the head vent pipe as shown on Figure 5.5-13. The system is orificed to limit the blowdown from a break downstream of the first orifice to within the capacity of one of the centrifugal charging pumps.

A break of the RVHVS line upstream of the first orifice would result in a small LOCA of not greater than one inch diameter. Such a break is similar to those analyzed in WCAP-9600 (Reference 4). Since a break in the head vent line would behave similarly to the hot leg break case presented in WCAP-9600, the results presented therein are applicable to a RVHVS line break. This postulated vent line break, therefore, results in no calculated core uncovery.

The Replacement Reactor Vessel Closure Head has changed the piping for the head vent. The new piping has an orifice approximately 6 feet from the head vent penetration. This permitted the movement of the Class 1 to Class 2 ASME Code boundary. The new Class 1 to Class 2 transition is at the first orifice. The piping analysis requirements remain the same since piping of NPS one inch or less which has been classified as Class 1 may be designed in accordance with the design requirements of ASME subsection NC (Class 2). The Class 2 piping is from the outlet of the first orifice to the second orifice. Piping and components downstream of the second orifice are non-nuclear safety but seismically supported up to the 12 inch pressurizer relief line.

The system provides for venting the reactor vessel head by using only safety grade equipment. The RVHVS satisfies applicable requirements and industry standards including ASME Code classification, safety classification, single-failure criteria, and environmental qualification.

5.5.15.2.2 Supports

The vent system piping is supported to ensure that the resulting loads and stresses on the piping and on the vent connection to the vessel head are acceptable.

The head vent piping supports were totally re-designed with the Replacement Reactor Vessel Closure Head and the Integrated Head Assembly (IHA). The head vent riser inside the IHA is attached to the support columns, Figure 5.5-14 shows the two types of piping supports. Clearance in the support allows for axial pipe movement/thermal growth.

The horizontal head vent piping is run above the IHA walkway with clamp type supports as shown on Figure 5.5-15. All of these supports are designed for axial pipe thermal movement and radial restraint.

All of these pipe supports are designed in accordance with ASME Section III NF Class 2 requirements.

5.5.15.3 Analytical Considerations

The analysis of the reactor vessel head vent piping is based on the following plant operation conditions defined in the ASME Code Section III:

1. Normal Condition:

   Pressure, deadweight, and thermal expansion analysis of the vent pipe during

   a. normal reactor operation with the two inboard vent isolation valves closed and
   b. post-refueling venting.

2. Upset Condition:

   Loads generated by the OBE response spectra.

3. Faulted Condition:

   Loads generated by the SSE and by valve thrust during venting. In accordance with ASME Code Section III, faulted conditions are not included in fatigue evaluations.

The Class I piping used for the reactor vessel head vent is one inch schedule 160 and, therefore, in accordance with ASME Code Section III, is analyzed following the procedures of NC-3600 for Class II piping.

For plant operating conditions listed above, the piping stresses are shown to meet the requirements of equations (8), (9), (10), or (11) of ASME III, Section NC-3600 with a design temperature of 650°F and a design pressure of 2485 psig.

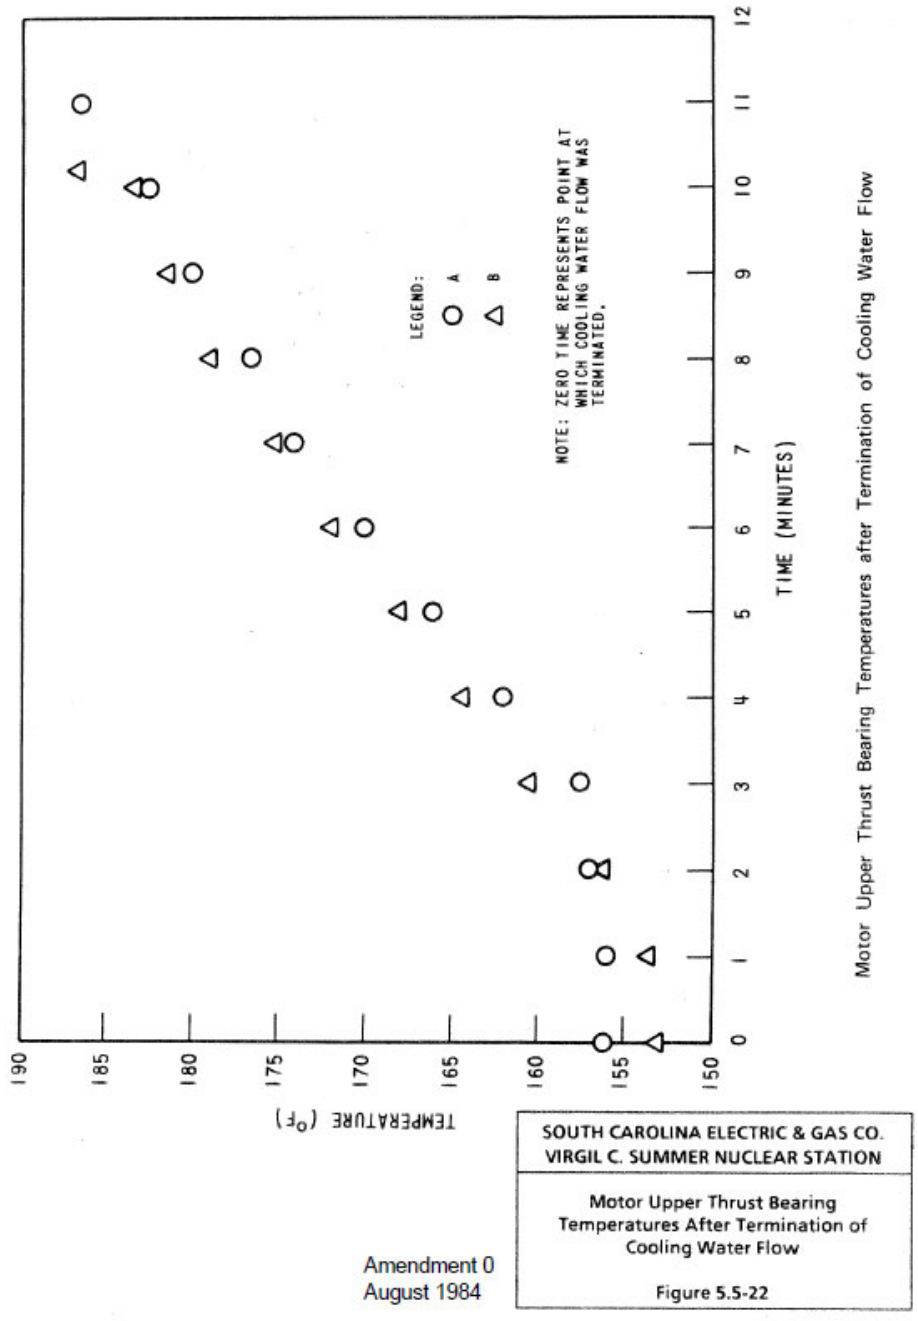
MOTOR UPPER THRUST BEARING TEMPERATURES AFTER TERMINATION OF COOLING WATER FLOW



5.6 Instrumentation Requirements

Process control instrumentation is provided for the purpose of acquiring data on the pressurizer and on a per loop basis for the key process parameters of the Reactor Coolant System (including the reactor coolant pump motors), as well as for the Residual Heat Removal System. The pick-off points for the Reactor Coolant System are shown in Figure 5.1-1 (Sheets 1 through 3); and for the Residual Heat Removal System in Figures 5.5-4 and 6.3-1, Sheet 3. In addition to providing input signals for the protection system and the plant control systems, the instrumentation sensors furnish input signals for monitoring and/or alarming purposes for the following parameters:

1. Temperatures
2. Flows
3. Pressures
4. Water levels
5. Valve position

In general, these input signals are used for the following purposes:

1. Provide input to the reactor trip system for reactor trips as follows:
    a. Overtemperature ΔT
    b. Overpower ΔT
    c. Low pressurizer pressure
    d. High pressurizer pressure
    e. High pressurizer water level
    f. Low primary coolant flow

It is noted that the following parameters, which are also sensed so as to generate an input to the reactor trip system, while not part of the Reactor Coolant System, are included here for purposes of completeness:

    g. Feedwater flow
    h. Multiple steam generator water level
    i. Turbine first stage pressure
2. Provide input to the Engineered Safety Features Actuation System as follows:
    a. Pressurizer low pressure

It is noted that the following parameters, which are also sensed so as to generate an input to the Engineered Safety Features Actuation System, while not part of the Reactor Coolant System, are included here for purposes of completeness:

b. High steamline differential pressure

c. High steamline flow coincident with lo-lo reactor coolant average temperature (T_{avg})

d. High containment pressure

e. Low steamline pressure

3. Furnish input signals to the non-safety-related systems, such as the plant control systems and surveillance circuits, so that:

a. T_{avg} is maintained within prescribed limits. The resistance temperature detector instrumentation is identified on Figure 5.1-1, Sheet 3.

b. Pressurizer level control, using T_{avg} to program the setpoint, maintains the coolant level within prescribed limits.

c. Pressurizer pressure is controlled within specified limits.

d. Steam dump control, using T_{avg} control, accommodates sudden loss of generator load.

e. Information is furnished to the control room operator and to local stations for monitoring.

The following is a functional description of the system instrumentation. Unless otherwise stated, all indicators, recorders, and alarm annunciators are located in the control room.

1. Temperature Monitoring Instrumentation

a. Narrow Range Hot and Cold Leg Temperature

The hot and cold loop temperature signals required for input to the protection and control functions are obtained using thermowell mounted RTDs installed in each reactor coolant loop.

The hot leg temperature measurement in each loop is accomplished using three fast response, narrow range, dual element RTDs mounted in thermowells. The hot leg thermowells are located within the three scoops previously used for the RTD bypass manifold at locations 120° apart in the cross sectional plane. The scoops were modified by drilling a flow hole in the top of the scoops so that water flows in through the existing holes in the leading edge of the scoop, past the RTD, and out through the new drilled hole.

Due to temperature streaming, the three fast response hot leg RTDs are electronically averaged to generate the hot leg temperature.

The cold leg temperature measurements in each loop are accomplished by one fast response, narrow range, dual element RTD. The existing cold leg RTD bypass penetration nozzle was modified to accept the thermowell and RTD. Temperature streaming in the cold leg is not a concern due to the mixing action of the reactor coolant pump

Signals from these instruments are used to compute the reactor coolant ΔT (temperature of the hot leg, T_{hot}, minus the temperature of the cold leg, T_{cold}) and the T_{avg}. These temperatures are indicated on the main control board for each loop. In addition, high T_{avg},

T_{ref} deviation, overtemperature setpoint, overpower setpoint, and ΔT setpoint, are recorded on the main control board.

b. Cold Leg and Hot Leg Temperatures

Temperature detectors, located in the thermometer wells in the cold and hot leg piping of each loop, supply signals to wide range temperature recorders and indicators for loops A and B on the main control board. This information is used by the operator to control coolant temperature during startup and shutdown.

c. Pressurizer Temperature

There are two temperature detectors in the pressurizer: one in the steam phase and one in the water phase. Both detectors supply signals to temperature indicators and high temperature alarms in the control room. The steam phase detector, located near the top of the vessel, is used during startup to determine water temperature when the pressurizer is completely filled with water. The water phase detector, located at an elevation near the center of the heaters, is used during cooldown when the steam phase detector response is slow due to poor heat transfer.

d. Surge Line Temperature

This detector supplies a signal for a temperature indicator and a low temperature alarm in the control room. Low temperature is an indication that the continuous spray rate is too small.

e. Safety and Relief Valve Discharge Temperatures

Temperatures in the pressurizer safety and relief valve discharge lines are measured and supply signals for a high temperature alarm and indicator in the control room. An increase in a discharge line temperature is an indication of leakage through the associated valve.

f. Spray Line Temperatures

Temperatures in the spray lines from two loops are measured and indicated on the main control board. Alarms from these signals are actuated by low spray water temperature. Alarm conditions indicate insufficient flow in the spray lines.

g. Pressurizer Relief Tank Water Temperature

The temperature of the water in the pressurizer relief tank is indicated on the main control board. An alarm actuated by high temperature informs the operator that cooling of the tank contents is required.

h. Reactor Vessel Flange Leakoff Temperature

The temperature in the leakoff line from the reactor vessel flange o-ring seal leakage monitor connections is indicated on the main control board. An increase in temperature above ambient is an indication of o-ring seal leakage. High temperature actuates an alarm.

i. Reactor Coolant Pump Motor Temperature Instrumentation

(1) Thrust Bearing Upper and Lower Shoes Temperature

Resistance temperature detectors are provided with one located in the shoe of the upper and one in the shoe of the lower thrust bearing. Monitoring of these detectors is provided by the plant computer which actuates a high temperature alarm at the computer.

(2) Stator Winding Temperature

The stator windings contain six resistance type detectors, two per phase, imbedded in the windings. A signal from one of these detectors is monitored by the plant computer which actuates a high temperature alarm at the computer.

(3) Upper and Lower Bearing Temperature

Resistance temperature detectors are located one in the upper and one in the lower radial bearings. Monitoring of these detectors is provided by the plant computer which actuates a high temperature alarm at the computer.

j. Reactor Head Vent Piping Temperature Instrumentation

(1) A temperature element is installed on the common line downstream of the motor operated valves to detect any potential leakage across the valve seats during Power Operation.

2. Flow Indication

a. Reactor Coolant Loop Flow

Flow in each reactor coolant loop is monitored by three differential pressure measuring detectors at a piping elbow tap in each reactor coolant loop and indicated on the main control board. These measurements on a two out of three coincidence circuit provide a low flow signal to actuate a reactor trip.

b. Safety Valve Flow

An acoustical type sensor is provided downstream of each safety valve to detect flow through the safety valves. The sensor activates an alarm in the control room when flow is detected. Control room indication is provided to enable the plant operator to determine which valve is open.

3. Pressure Indication

a. Pressurizer Pressure

Three pressurizer pressure transmitters provide signals for individual indicators in the control room for actuation of both a low pressure trip and a high pressure trip. One of the signals may be selected by the operator for indication on a pressure recorder. Three transmitters provide low pressure signals for safety injection initiation. Three transmitters provide signals for safety injection signal unblock during plant startup. An additional transmitter is used, along with a reference pressure signal, to develop a demand signal for a three-mode controller. The lower portion of the controller’s output range operates the

pressurizer heaters. For normal operation, a small group of heaters is controlled by variable power to maintain the pressurizer operating pressure. If the pressure error signal falls towards the bottom of the variable heater control range, all pressurizer heaters are turned on.

The upper portion of the controller's output range operates the pressurizer spray valves and one power relief valve. The spray valves are proportionally controlled in a range above normal operating pressure with spray flow increasing as pressure rises. If the pressure rises significantly above the proportional range of the spray valves, a power relief valve (interlocked with a separate transmitter so as to prevent spurious operation) is opened. A further increase in pressure will actuate a high pressure reactor trip. A separate transmitter (interlocked also with another transmitter to prevent spurious operation) provides power relief valve operation for two additional valves upon high pressurizer pressure. A signal interlock between transmitter is required to open (or keep open) the power relief valve.

b. This item deleted.

c. Reactor Coolant Loop Pressures

Two transmitting channels are provided. Both transmitters provide a recorder signal and an indication of reactor coolant pressure on two of the hot legs. These are wide range transmitters which provide pressure indication over the full operating range. The recorder, together with the indicators, serve as a guide to the operator for manual pressurizer heater and spray control and letdown to the Chemical and Volume Control System during plant startup and shutdown. An amplifier signal from the lower portion of the range of one of the channels is indicated on the main control board to provide improved legibility at the lower pressures.

The two wide range channels provide the permissive signals for the residual heat removal loop suction line isolation valve interlock circuit.

d. Pressurizer Relief Tank Pressure

The pressurizer relief tank pressure transmitter provides a signal to an indicator and a high pressure alarm in the control room.

e. Reactor Coolant Pump Motor Oil Pressure and Level

(1) Oil Pressure

Pressure switches are provided on the high pressure oil lift system. Low oil pressure actuates an alarm on the main control board. In addition, an interlock system prevents starting of the pump until the oil lift pump is started manually prior to starting the reactor coolant pump motor and actuates a status light to indicate adequate oil pressure. A local pressure gauge is also provided.

(2) Lower Oil Reservoir Liquid Level

A level switch is provided in the motor lower radial bearing oil reservoir. The switch actuates a high or low level alarm in the control room

(3) Upper Oil Reservoir Liquid Level

A level switch is provided in the motor upper radial bearing and thrust bearing oil reservoir. The switch actuates a high or low level alarm in the control room.

4. Liquid Level Indication

a. Pressurizer Water Level

Three pressurizer liquid level transmitters provide signals for use in the Reactor Control and Protection System, the Emergency Core Cooling System, and the Chemical and Volume Control System. Each transmitter provides an independent high water level signal that is used to actuate an alarm and a reactor trip. The transmitters also provide independent low water level signals that activate an alarm. Each transmitter also provides a signal for a level indicator that is located on the main control board.

In addition to the above, signals may be selected for specific functions as follows:

(1) Any one of the three level transmitter signals may be selected by the operator for display on a level recorder located on the main control board. This same recorder is used to display a pressurizer reference liquid level signal.

(2) Two of the three transmitters perform the following functions: (A selector switch allows the third transmitter to replace either of these two.)

(a) One transmitter provides a signal which actuates an alarm when the liquid level falls to a fixed level setpoint. The same signal trips the pressurizer heaters "off" and closes the letdown line isolation valves.

(b) One transmitter supplies a signal to the liquid level controller for charging flow control and initiation of a low flow (hi demand) alarm. This signal is compared to the reference level. If the actual level is lower than the reference level, a low alarm is actuated. If the actual level exceeds the reference level, a high level alarm and all pressurizer backup heaters are energized.

A fourth independent pressurizer level transmitter that is calibrated for low temperature conditions provides water level indication on the main control board during startup, shutdown, and refueling operations.

b. Pressurizer Relief Tank Level

The pressurizer relief tank level transmitter supplies a signal for an indicator on the main control board for high and low level alarms.

c. Reactor Vessel Level

The reactor vessel level system provides a direct reading of reactor vessel level on the main control board which can be used by the operator in conjunction with the core subcooling monitor to identify the possibility of inadequate core cooling conditions. Details of the reactor vessel level system are provided in Section 7.6.9.

5. Valve Position

   The pressurizer power operated relief valves are provided with limit switches for safety grade indication of valve open/closed position in the control room.

6. Core Subcooling Indication

   The core subcooling monitor provides continuous monitoring of the margin to saturation in the reactor core (i.e., the amount of subcooling) on the main control board. The core subcooling monitor utilizes inputs from the hot leg RTDs, Reactor Coolant System pressure sensors, and selected incore thermocouples. Details of the core subcooling monitor system are provided in Section 7.5.5.

   The Reactor Coolant System design and operating pressure together with the safety, power relief, and pressurizer spray valve setpoints, as well as the protection system setpoint pressures, are listed in Table 5.2-7.

   The design pressure allows for operating transient pressure changes. The selected design margin considers core thermal lag, coolant transport times and pressure drops instrumentation and control accuracy and response characteristics, and system relief valve characteristics.

   Process control instrumentation for the Residual Heat Removal System is provided for the following purposes:

   a. Furnish input signals for monitoring and/or alarming purposes for:
      (1) Temperature indications
      (2) Pressure indications
      (3) Flow indications
   b. Furnish input signals for control purposes of such processes as follows:
      (1) Control valve in the residual heat removal pump bypass line so that it opens at flows below a preset limit and closes at flows above a preset limit.
      (2) Residual heat removal inlet valves control circuitry. See Section 7.6 for the description of the interlocks and requirements for automatic closure.
      (3) Control valve in the residual heat removal heat exchanger bypass line to control temperature of reactor coolant returning to reactor coolant loops during plant cooldown.
      (4) Residual heat removal pump circuitry for starting residual heat removal pumps on "S" signal.

5.7 INSERVICE INSPECTION PROGRAM (INCLUDING PRESERVICE INSPECTION)

During the design phase of the Virgil C. Summer Nuclear Station, careful consideration has been given to access, where practical, for the performance of preservice and inservice examinations.

5.7.1 Applicable Codes and Standards

The inservice inspection program (including preservice inspection) is administered in accordance with the applicable codes and standards as addressed in 10 CFR 50.55a.

Deviations from Code requirements are allowed and/or prescribed by various means. These deviations may be permitted via NRC approved Relief Requests, Code Cases which are adopted by the NRC in various Regulatory Guides, Generic Letters, and exceptions described in 10 CFR 50.55a. Any deviations from the Code requirements will be documented in the inservice inspection program (i.e., ISI, IST, and Repair and Replacement).

5.7.1.1 Preservice Inspection

The initial preservice inspection for Class 1, 2, and 3 components was performed to the extent practical in accordance with IWB-2100, IWC-2100, and IWD-2100 of the ASME B&PV Code Section XI (1974 edition through Summer 1975 addenda).

5.7.1.2 First Inspection Interval - January 1, 1984 Through December 31, 1993

During the first 10 year inspection interval, for Class 1, 2, and 3 components (except as noted below), the preservice inspections for repairs, replacements, and inservice inspections were performed to the extent practical to the ASME B&PV Code Section XI (1977 edition through Summer 1978). Per 10 CFR 50.55a(b)(2)(iv), examination of Code Class 2 pipe welds in the Residual Heat Removal System, Emergency Core Cooling System, and Containment Heat Removal System shall be determined by the requirements of paragraph IWC-1220, Table IWC-2520 Category C-F and C-G, and paragraph IWC-2411 of the ASME B&PV Code Section XI (1974 edition through Summer 1975 addenda). For V. C. Summer, these systems are defined as Residual Heat Removal (RH), Safety Injection (SI), Service Water (SW), Reactor Building Spray (SP), and Component Cooling Water (CC). For ASME Class 1, 2, and 3 component supports, preservice inspections for repairs and replacements and inservice inspection are performed to the extent practical in accordance with the ASME B&PV Code Section XI (1977 edition through Summer 1978) and subsection IWF of the ASME B&PV Code Section XI (1980 edition through Winter 1981). Inservice testing of Class 1, 2, and 3 valves is performed to the extent practical in accordance with subsection IWV of the ASME B&PV Code Section XI (1977 edition through Summer 1978). Inservice testing of Class 1, 2, and 3 pumps is performed to the extent practical in accordance with the ASME B&PV Code Section XI (1980 edition).

5.7.1.3 Second Inspection Interval - January 1, 1994 Through December 31, 2003

The second 10 year interval was performed to the requirements of Section XI of the ASME B&PV Code as prescribed by 10 CFR 50.55a. The latest edition of Section XI approved for use on January 1, 1994 was the 1989 edition.

5.7.1.4 Third Inspection Interval - January 1, 2004 Through December 31, 2013

The third 10 year inservice inspection interval will meet the requirements of Section XI of the ASME B&PV Code as prescribed by 10 CFR 50.55a. The latest edition of Section XI approved for use on January 1, 2004 was the 1998 edition, with addenda through 2000. However, as later editions are incorporated into 10 CFR 50.55a, the provisions of the later Code may be incorporated, in part or in whole, as allowed by 10 CFR 50.55a during the interval. The inservice inspection plans will designate the applicable edition and addenda to the corresponding inspection items. The inservice testing program for ASME Class 1, 2, and 3 pumps and valves will be implemented in accordance with the ASME OM Code, 1998 edition, with addenda through 2000 as prescribed by 10 CFR 50.55a.

Note to 5.7.1.4:

During the third and subsequent 10 year inspection intervals, preservice inspections for repairs and replacements and inservice inspection will be performed to the extent practical to the ASME B&PV Code Section XI [edition and addenda to be determined by the latest edition and addenda incorporated by reference in 10 CFR 50.55a(a), 12 months prior to the start of the inspection interval as per 10 CFR 50.55a(g)(4)(ii)]. Per IWA-2430(b), "The inspection interval shall be determined by calendar years following placement of the power unit into commercial service" as determined by the regulation of the Federal Power Commission, Chapter I - Title 18, Code of Federal Regulations Part 191, paragraph 9.D. Sub paragraph IWA-2430(c) further states that, "Each inspection interval may be decreased or extended (but not cumulatively) by as much as 1 year." For the purpose of determining the beginning and end of future ten year inspection intervals, the plant began commercial operation on January 1, 1984.

5.7.1.5 Fourth Inspection Interval - January 1, 2014 Through December 31, 2023

The fourth 10 year inservice inspection interval will meet the requirements of Section XI of the ASME B&PV Code as prescribed by 10 CFR 50.55a. The latest edition of Section XI approved for use on January 1, 2014 was the 2007 edition, with addenda through 2008. However, as later editions are incorporated into 10 CFR 50.55a, the provisions of the later Code may be incorporated, in part or in whole, as allowed by 10 CFR 50.55a during the interval. The inservice inspection plans will designate the applicable edition and addenda to the corresponding inspection items. The inservice testing program for ASME Class 1, 2, and 3 pumps, valves, and snubbers will be implemented in accordance with the ASME OM Code, 2004 edition, with addenda through 2006 as prescribed by 10 CFR 50.55a.

5.7.2 Provisions for Access to Reactor Coolant Pressure Boundary

Provisions for adequate access have been verified by a review of all the drawings applicable to the layout and arrangement of the reactor coolant and associated auxiliary systems within the boundaries established in accordance with the requirements of IWB-1200 and IWC-1200.

Specific provisions made for inspection access in the design of the reactor vessel, system layout, and other major primary coolant components to ensure compliance with the requirements of IWA-1500 and IWB-2600 are as follows:

1. Reactor internals are completely removable. The tools and storage space required to permit reactor internals removal for these inspections are provided.
2. The reactor vessel shell in the core area is designed with a clean, uncluttered cylindrical inside surface to permit future positioning of test equipment without obstruction.
3. The reactor vessel cladding is improved in finish by the vessel manufacturer by grinding to the extent necessary to permit meaningful examination of the vessel welds and adjacent base metal in accordance with the Code.
4. The cladding to base metal interface is ultrasonically examined by the vessel manufacturer to assure satisfactory bonding to allow the volumetric inspection of the vessel welds and base metal from the vessel inside surface.
5. The reactor closure head is stored dry on the operating floor during refueling, allowing direct access for inspection.
6. The insulation on the vessel closure and lower heads is removable, allowing access for the visual and nondestructive examination of head welds.
7. Reactor vessel studs, nuts, and washers are removed for dry storage during refueling, allowing inspection in parallel with refueling operations.
8. Access holes in the core barrel flange allow access for remote visual examination of the clad surface of the vessel without removal of the lower internals assembly.
9. Access holes are provided in the primary shield, providing access for the surface and visual examination of the primary nozzle safe end welds.
10. Manways are provided in the steam generators to provide access for internal inspection.
11. A manway is provided in the pressurizer top head to allow access for internal inspection.
12. Where practical, the insulation covering component and piping welds and adjacent base metal are designed for ease of removal and replacement in areas where external inspection is planned.
13. Openings are provided in the operating floor concrete above the reactor coolant pumps to permit removal of the pump motor to provide internal inspection access to the pumps.

14. The primary loop compartments are designed to allow personnel entry during refueling operations to permit direct inspection access to the external portion of piping and components.

Provisions are made for inspection access in the design of Class 2 components to ensure compliance with the requirements of IWC-2600.

The use of conventional nondestructive volumetric test techniques can be applied to the inspection of all primary loop components except for the reactor vessel. The reactor vessel presents special problems because of the radiation levels and remote underwater accessibility to this component.

As indicated above, the only sophisticated remote inspection equipment currently required is for inspection of the reactor vessel. The baseline preservice inspection is performed onsite by Westinghouse utilizing a remote reactor vessel ultrasonic inspection tool which will perform the Code required inspection of the circumferential and longitudinal shell welds, the flange to vessel weld, the ligaments between the flange holes, the nozzle to vessel welds, and the nozzle to safe end to pipe welds.

5.7.3 Equipment for Inservice Inspections

The vessel inspection tool has two major structural components, the center column assembly which is supported and aligned from the vessel internals support flange by the head assembly. These two structures form the rigid base assembly from which the scanning arm and drive assemblies are mounted and operated. Two configurations of the tool can be arranged depending on the areas of the vessel to be examined. In Figure 5.7-1, the scanning arm and transducer array, necessary to examine the vessel shell welds, are mounted on the main carriage assembly. The main carriage assembly can traverse the full length of the vessel up and down the center column and also provide 360 degrees circumferential rotation around the inside of the vessel. In Figure 5.7-2, the nozzle scanning assembly is mounted beneath the main carriage and can be rotated for 360 degrees to provide alignment with any of the vessel nozzles. The tool, in this configuration, can be installed in the vessel without removal of the lower internals package. The scanning attachment for the examination of the vessel flange weld and ligaments can be installed on the tool in either of the two configurations described above. Figures 5.7-1 and 5.7-2 show the inspection tool in both these configurations.

5.7.4 Recording and Comparing Data

For reactor vessel scanning, a data acquisition system is used which combines simplicity with operational reliability and adaptability. It employs an electronic system with a receiver or data channel for each transducer unit. The signal received from the transducer is transmitted through an electronic distance amplitude correction device and, depending on the amplitude, gated through individual transigates to a printer. Simultaneously with the gated signal, information is received from the position indication encoder system which provides position coordinates. The resultant indication is printed on a recording device together with its position reference.

Following the completion of the scan of the areas scheduled for inspection, the tool operator(s) will, operating on manual control, return the transducer array to each of the indication position coordinates and evaluate the nature of the indication to sufficient extent to be able to determine the size, shape, and location. Special transducer arrays with variable angle search units are provided to assist in this activity.

For manual ultrasonic scanning, such as examination of a circumferential pipe weld, Westinghouse Nuclear Energy Systems has prepared a set of standard operator procedures to ensure that inspection results are recorded in a manner which will avoid any ambiguity in interpretation. The procedure specifies how any indication must be recorded with respect to scan direction and weld orientation, and how datum points, from which the location of indications are measured, are to be selected. Figure 5.7-3 shows a typical data sheet for recording instrument calibration settings for the volumetric examination of a circumferential pipe weld.

The data from the various baseline examinations, collected in accordance with the above procedures, were assembled into a comprehensive report tabulating the results.

The report describes the scope of the inspection, the procedures utilized, the equipment utilized, names and qualifications of the operators, and the examination results including instrument calibration criteria in sufficient detail to ensure repeatability for each examination.

5.7.5 Reactor Vessel Acceptance Standards

The reactor vessel acceptance standards to be used during preoperational mapping of the vessel by ultrasonic examination met the requirements of IWB-3000.

5.7.6 Coordination of Inspection Equipment with Access Provisions

The only area where it is expected that high radiation levels will prohibit the access of personnel for direct examination of component areas or systems is the reactor vessel. The special design provisions and tooling required to perform the Code required examinations in these areas have been discussed above. Westinghouse is carrying out a continuing program of radiation surveys during refueling programs in operating plants to ensure that possible future problem areas are detected at an early stage. Should additional experience in the maintenance and inspection of operating plants indicate that other areas exist where access will be either limited or impossible, steps will be taken to develop any remotely operated inspection equipment considered necessary to meet the commitments of examinations required by Section XI of the Code.

HISTORICAL DATA ONLY

The detailed inservice inspection program is presented in the Technical Specifications, Section 3/4.4.10. This program is based on Section XI of the ASME Code. It is anticipated that the results obtained from compliance with the Technical Specifications and the state of the art will be evaluated before establishing a long term inspection program. The data collected during the first five years of operation, along with the overall operating experiences, will be reviewed to determine the overall inspection program to be implemented for the lifetime of the facility.

5.7.7 Preservice and Inservice Inspection of Class 1, 2, and 3 Components

5.7.7.1 Component Subject to Examination or Inspection

All ASME Code, Section III, Class 1 components subject to examination or inspection will be examined or tested, as applicable, in accordance with the requirements of Article IWB-2000 ASME Code Section XI.

All ASME Code, Section III, Class 2 components subject to examination or inspection will be examined or tested, as applicable, in accordance with the requirements of Article IWC-2000 ASME Code Section XI. The Technical Specifications specify Code Class 2 components requiring weld examinations, including the type(s) of examination as specified by Article IWC-2000 ASME Code Section XI.

ASME Code, Section III, Class 3 components, if any, subject to examination or inspection will be examined or tested in accordance with Article IWD-2000 ASME Code Section XI and any additional requirements of the Technical Specifications.

Code Class 2 and 3 pumps will be inservice tested in accordance with the ASME Code of Record, prescribed under 10 CFR 50.55a.

Code Class 1, 2, and 3 valves will be inservice tested in accordance with the ASME Code of Record, prescribed under 10 CFR 50.55a.

5.7.7.2 Accessibility

The design and arrangement of Code Class components, where possible, provides suitable access to welds for nondestructive testing and visual inspections. Special platforms are provided at the circumferential welds on the steam generator shells. Weld preparation, spacing, and clearance for welds on Code Class 2 components that are to be nondestructively examined are in accordance with ASME Section XI.

In general, the plant piping and equipment arrangement is designed with consideration for maintenance and inspection. Should accessibility prevent a particular inspection or examination from being performed adequately, this condition will be resolved in accordance with ASME Section XI and/or 10 CFR 50.55a.

5.7.7.3 Examination Techniques and Procedures

The examination techniques and procedures utilized are in accordance with the applicable requirements of ASME Section XI. Nondestructive examinations and visual procedures are in accordance with the requirements of ASME Section XI Code and its applicable references.

5.7.7.4 Inspection Frequency

Class 1 components are inspected in accordance with a schedule which satisfies the requirements of Article IWB-2000 ASME Code Section XI.

Class 2 components are inspected in accordance with a schedule which satisfies the requirements of Article IWC-2000 ASME Code Section XI.

Class 3 components, if any, are inspected in accordance with a schedule which satisfies the requirements of Article IWD-2000 ASME Code Section XI.

5.7.7.5 Examination Categories and Requirements

The inspection categories and requirements for Class 1 components are in compliance with Article IWB-2000 ASME Code Section XI.

The inspection categories and requirements for Class 2 components are in compliance with Article IWC-2000 ASME Code Section XI.

The inspection categories and requirements for Class 3 components, if any, are in compliance with Article IWD-2000 ASME Code Section XI.

5.7.7.6 Evaluation of Examination Results

The evaluation of Class 1, 2, and 3 component examination results complies with the requirements of Articles IWA-3000 and IWB-3000, IWC-3000, or IWD-3000 of the ASME Code Section XI, as appropriate. The acceptance standard(s) for indications detected during the examination are those of ASME Code Section XI. When acceptance standards are not addressed in the ASME Code Section XI, those of the construction code, ASME Section III, are used. When specified, Section III edition and addenda are applied for the acceptance standard.

Repair procedures for flaws discovered during examination are developed in accordance with the requirements of Article IWA-4000 ASME Code Section XI and its applicable references for Class 1, 2, and 3 components.

5.7.7.7 System Pressure Tests

System pressure tests for Class 1 items comply with the testing and examination criteria of Articles IWA-5000 and IWB-5000, ASME Code Section XI.

System pressure tests for Class 2 items comply with the testing and examination criteria of Articles IWA-5000 and IWC-5000, ASME Code Section XI.

System pressure tests for Class 3 items, if any, comply with the testing and examination criteria of Articles IWA-5000 and IWD-5000, ASME Code Section XI.

5.7.8 Augmented Inservice Inspection to Protect Against Postulated Piping Failures

Design measures have been taken to ensure that the reactor vessel and essential equipment within or outside of the containment, including components of the reactor coolant pressure boundary and other safety-related components, have been adequately protected against the effects of blowdown jet, reactive forces, and pipe whip resulting from postulated rupture of piping located inside or outside of containment. These measures are discussed in Section 3.6. As explained earlier in this section, high energy fluid system piping is inspected in accordance with ASME XI. Augmented inspection of high energy fluid system piping between containment isolation valves is not deemed necessary.

CHAPTER 6 - ENGINEERED SAFETY FEATURES

The central safety objective in reactor plant design and operation is control of reactor fission products. The methods used to assure this objective are:

1. Design of the reactor core in conjunction with the reactor control and protection systems to preclude release of fission products from the fuel (Chapter 4 and 7).
2. Retention of fission products in the Reactor Coolant System (Chapters 5 and 6).
3. Retention of fission products by the containment for operational and accidental releases beyond the reactor coolant boundary (Sections 3.8 and 6.2).
4. Limiting or optimizing fission product dispersal to minimize population exposure for an accidental release beyond the containment (Chapter 2 and 11).

The engineered safety features are the provisions in the plant which embody methods 2 and 3 above to prevent the occurrence, or to ameliorate the effects, of serious accidents.

6.1 GENERAL

The engineered safety features are:

1. Containment

   The reactor building provides a virtually leaktight barrier to the escape of fission products. Detailed information on the containment is provided in Section 6.2.1.

2. Reactor Building Heat Removal Systems

   These systems serve to reduce reactor building pressure and temperature. These systems are discussed in detail in Section 6.2.2.

3. Reactor Building Air Purification and Cleanup Systems

   The function of these systems is to provide air purification and cleanup services to the Reactor Building. These systems are discussed in Section 6.2.3.

4. Containment Isolation System

   This system provides containment isolation capability for the various system lines penetrating the containment. Detailed discussions of this system are presented in Section 6.2.4.

5. Combustible Gas Control System

   This system acts to control the concentration of hydrogen, oxygen, and other combustible gas which may be released to the reactor building to assure containment integrity. This system is discussed in Section 6.2.5.

6. Containment Leakage Testing

   Containment leakage testing provisions are discussed in Section 6.2.6.

7. Emergency Core Cooling System

   This system delivers borated water to the reactor core to provide core cooling following postulated accidents. The boron, together with the control rods provides sufficient negative reactivity for safe shutdown following design basis accidents. The Emergency Core Cooling System is discussed in detail in Section 6.3.

8. Habitability Systems

   These systems provide the control room with adequate shielding, air purification, and climatic control. These systems are discussed in Section 6.4.

9. Fission Product Removal and Control Systems

   The fission product removal systems include the high efficiency particulate air filters in the Reactor Building cooling system and the control room emergency filter plenums. This equipment is discussed in Section 6.5.

6.2 CONTAINMENT SYSTEMS

6.2.1 Containment Functional Design

6.2.1.1 Design Bases

6.2.1.1.1 Reactor Building

The safety design basis for the Reactor Building is the requirement that the releases of radioactive material subsequent to a reactor accident do not result in doses which exceed the guideline values specified by 10 CFR 50.67. To satisfy this requirement, a design containment leak rate is specified in conjunction with performance requirements for the other engineered safety features. The containment must withstand the temperatures and pressures resulting from a spectrum of postulated loss of coolant (LOCA) and secondary system pipe break accidents without leakage in excess of the design leak rate of 0.2% per day. The radiological consequences of the most severe hypothetical LOCA are presented in Section 15.4

The Reactor Building design pressure of 57 psig is above the peak calculated pressure of 53.0 psig resulting from the postulated double ended guillotine rupture (DER) of a main steam line. The bounding case, the 1.40 ft^2 DER at 25% power, is conservatively analyzed assuming an electrical channel A (CH-A) failure resulting in loss of one diesel generator (DG) and failure to isolate Emergency Feedwater (EFW) to the faulted steam generator.

The peak calculated Reactor Building temperature is 372.7°F. This peak calculated temperature results from the postulated 1.4 ft^2 DER at 102% power, assuming failure of a main steam isolation valve (MSIV) to close and a safety injection pump to start.

General containment design information is presented in Table 6.2-1. Figures 6.2-68 through 6.2-81 provide additional information on the general arrangement of Reactor Building structures and components.

6.2.1.1.1.1 Spectrum of Postulated Accidents

Five (5) postulated Reactor Coolant System pipe ruptures and 25 main steam line breaks have been analyzed to determine the peak Reactor Building pressure and temperature following an accident. For analytical purposes, it was assumed that each accident was coincident with loss of offsite power and a failure of at least 1 engineered safety feature.

The 5 postulated Reactor Coolant System pipe ruptures analyzed are as follows:

1. A double-ended pump rupture of the reactor coolant pump suction (DEPS) with maximum safety injection and 2 operable trains of the Reactor Building Spray (SP) System.
2. A DEPS with maximum safety injection and failure of 1 train of SP.
3. A DEPS with maximum safety injection, 2 operable trains of SP, and failure of 1 train of Reactor Building Cooling Units (RBCU).

4. A DEPS with minimum safety injection and failure of 1 train of emergency diesel generator coincident with a loss of offsite power.
5. A double-ended hot leg guillotine break (DEHL).

The mass and energy release information used for these enveloping Reactor Coolant System accidents is discussed in Section 6.2.1.3.10.1. The CONTEMP LT containment analysis code is used for this analysis and its use is discussed in Section 6.2.1.3.3.1.

The main steam line breaks (MSLB) analyzed to determine both peak reactor building pressure and peak reactor building temperature are listed in Table 6.2-1. The mass and energy release data developed for these breaks is discussed in Section 6.2.1.3.10.3. The main steam line breaks are analyzed using the CONTEMPT LT/26 (Reference 27) containment analysis code discussed in Section 6.2.1.3.3.1.

Post accident pressure reduction is accomplished through the operation of the Reactor Building Spray System and Reactor Building cooling units and by the Reactor Building structures. The performance of the Reactor Building Spray System and Reactor Building cooling units is discussed in Section 6.2.1.3.4. Structural heat removal is also discussed in Section 6.2.1.3.4.

6.2.1.1.2 Subcompartments

The analysis of the pressures existing at any time in the reactor compartment and steam generator compartment is discussed in Section 6.2.1.3. This analysis is based upon mass and energy inputs described in Section 6.2.1.3.10. The compartment volumes and vent openings were obtained from design drawings and are consistent with the structural capacity of the walls discussed in Sections 3.8.1 and 3.8.3. All vent areas were calculated based upon “net” cross sectional flow areas through pertinent openings in compartment walls and slabs. Net flow area is defined as the gross opening area minus any obstructions (piping, insulation, etc.), which are located in the particular opening. No credit was taken for the movement of obstructions or insulation in the analyses.

6.2.1.2 System Design

The design features of the Reactor Building and internal structures, as well as general arrangement drawings, are presented in Sections 3.8.1 and 3.8.3.

The codes, standards, and guides applied to the design of the Reactor Building and internal structures are included in Sections 3.8.1.2. and 3.8.3.2.

6.2.1.2.1 Design Provisions For Missiles and Pipe Whip

Design provisions are incorporated to protect the Reactor Building structure and Engineered Safety Features Systems against loss of function from dynamic effects that could occur following postulated accidents. The integrity of containment is maintained and functional capability of Engineered Safety Feature Systems is not compromised following postulated accidents that involve pipe rupture with subsequent pipe whip and jet impingement, and postulated accidents that involve missile impact. Design provisions include the following:

1. Physical separation of the redundant portions of Engineered Safety Features System.
2. Pipe rupture restraints that limit pipe movement following postulated pipe rupture.
3. Physical barriers, such as walls, floors, backfill, etc., to separate and protect equipment, as required.
4. Jet impingement shields, located where required, to protect specific piping or components from jet impingement from a postulated pipe break.
5. Detailed stress analyses to determine specific cases where provision of a shield or barrier is not required. This occasionally occurs in the path of low energy jets where sufficient stress margin is available in the pipe or component design to tolerate the impact.

Detailed discussion of design provisions for protection against postulated pipe rupture is presented in Section 3.6.

Detailed discussion of design provisions for protection against the effects of postulated missiles, both internal and external, is presented in Section 3.5.

6.2.1.2.2 External Loading

Inadvertent operation of the Reactor Building Spray System can result in a negative differential pressure in the Reactor Building. The external design pressure of the Reactor Building is 3.5 psig. Analysis of inadvertent Reactor Building Spray System operation is discussed in Section 6.2.1.3.6.

The external design pressure for tornado pressure loading is discussed in Section 3.3.

1. Reactor Building Pressure Equalization

   A narrow range differential pressure transmitter provides signals for monitoring Reactor Building internal pressure. Control room alarms are actuated by this pressure channel when the differential pressure approaches the baseline positive or negative pressure. Administrative procedures are implemented following the alarm to adjust Reactor Building pressure to within the required baseline pressure limits.

2. Inadvertent Reactor Building Spray

   During normal operation, inadvertent Reactor Building spray can occur only when performing the periodic inservice testing of one spray loop. An inadvertent safety injection signal to the spray loop discharge valve during spray loop test is the worst single failure.

6.2.1.2.3 Reactor Building Heating, Ventilating, and Air Conditioning System Functional Capability

The following Reactor Building ventilation systems operate continuously during normal plant operation to maintain suitable Reactor Building ambient temperature, pressure and humidity:

1. Reactor Building cooling units.
2. Reactor Building reactor compartment cooling system.
3. Reactor Building secondary compartment cooling system.
4. Integrated Head Assembly CRDM Cooling Fans

The Reactor Building charcoal cleanup system may operate intermittently during normal plant operation to maintain suitable radiation levels inside the Reactor Building.

The 36 inch Reactor Building Purge System may be operated during cold shutdown and refueling to maintain suitable radiation levels inside the Reactor Building. During the other modes of plant operation (Modes 1-4), the valves are locked closed and operation of the system is not permitted.

The 6 inch alternate Reactor Building Purge System may be operated up to 1000 hours per year during modes 1-4, to maintain suitable moisture and radiation levels inside the Reactor Building.

Details of the operation of these systems are presented in Sections 6.2.2, 6.2.5, 6.5.1, and 9.4.8.

6.2.1.3 Design Evaluation

6.2.1.3.1 Reactor Building Peak Pressure and Temperature Analysis

In the event of a loss of coolant accident, much of the released reactor coolant will flash to steam. This release of mass and energy raises the temperature and pressure of the atmosphere within the Reactor Building. A rupture of a main steam pipe produces similar effects. The severity of the temperature and pressure peaks depends upon the nature, size, and location of the rupture.

A steam line break yields higher Reactor Building pressure than does a feedwater line break inside the Reactor Building. The same amount of water is added to the Reactor Building in each case. However, a steam line break causes the water to be added as superheated vapor, while a feedwater line break adds liquid with much lower enthalpy to the Reactor Building atmosphere. The feedwater line break is not considered to be as limiting as the main steam line break or primary system LOCA and, therefore, was not analyzed.

6.2.1.3.1.1 Peak Pressure Analysis

In order to identify the worst case, the spectrum of hypothetical main stream line break and LOCA events described in Section 6.2.1.1.1.1, based upon the initial conditions specified in Tables 6.2.2 and 6.2-33, respectively, has been analyzed using the CONTEMPT LT computer program discussed in Section 6.2.1.3.3.1.

The break resulting in the maximum calculated pressure in the Reactor Building is the 1.40 ft^2 DER at 25% power main steam line break assuming a CH A failure. The peak pressure in the Reactor Building is conservatively calculated to be 53.0 psig, at 1800 seconds following the break.

The following peak pressure analyses were performed:

1. Loss of Coolant Accident Analyses

   The loss of coolant accidents analyzed; information concerning break type, peak pressure, and temperature, and single active failure are presented in Table 6.2-3.

   Figure 6.2-1 presents the calculated pressure as a function of time for the DEPS break with minimum safety injection.

   Figure 6.2-2 presents the calculated pressure as a function of time for the spectrum of pump suction DEPS break with maximum safety injection.

   Figure 6.2-3 presents the calculated pressure as a function of time for the double ended guillotine hot leg break (DEHL). This case was only run until the time at which the peak containment pressure is achieved. The break results in the peak RB pressure (45.53 psig) for the spectrum of LOCAs that is less than the Technical Specification 6.8.4.g calculated peak pressure (Pa) of 46.0 psig, and accounts for the reactor vessel up-flow modification.

   Methods used, initial conditions, and single active failures assumed are discussed in Section 6.2.1.3.3.

   PAD5 implementation impacts the LOCA containment analyses for DEPS and DEHL due to an increase in core stored energy from 3.19 full power seconds (fps) to 3.45 fps. Evaluation of the DEPS and DEHL breaks resulted in an increase in containment pressure of +0.12 psig and RB peak pressure remains <Pa (i.e., DEHL peak pressure of 45.65 psig). The limiting Peak pressures shown in Figures 6.2-1 through 6.2-3 remain representative of LOCA containment pressure response.

2. Main Steam Line Break Analysis

   Figure 6.2-4 presents the calculated pressure versus time for the 1.40 ft^2 DER at 25% power main steam line break assuming a CH-A failure (the design basis accident).

   Methods used, initial conditions, and failures assumed for main steam line break analyses are discussed in Section 6.2.1.3.3.

   Table 6.2-3 presents a summary for each main steam line break analyzed.

   An evaluation of the impact of PAD5 implementation on the MSLB containment analysis determined that MSLB mass and energy (M&E) releases were not sensitive to the changes that result from PAD5 implementation. Therefore, the transient M&E releases inside or outside containment remain valid for use as input to the containment integrity analysis or the outside containment compartment temperature response analysis.

6.2.1.3.1.2 Peak Temperature Analysis

The spectrum of steam line breaks listed in Table 6.2-1a, based upon the initial conditions specified in Table 6.2-2, has been analyzed using the CONTEMPT LT/26 (Reference 27) computer program discussed in Section 6.2.1.3.3.

The steam line break resulting in the maximum calculated temperature in the Reactor Building is the 1.4 ft^2 DER at 102% power with MSIV and SI failures. The peak temperature in the Reactor Building is calculated to be 372.7° F, 19 seconds after the break.

The following peak temperature analyses were performed.

1. Main Steam Line Break Analyses

   The main steam line break accidents analyzed; information concerning break type, peak temperature, and pressure; times of peak temperature and pressure; and active failures assumed are presented in Table 6.2-3.

   Figure 6.2-5a illustrates calculated temperature versus time for the worst case (temperature) main steam line break (1.4 ft^2 DER at 102% power with MSIV and SI failures).

   Figure 6.2-5b illustrates the calculated temperature as a function of time for a spectrum of main steam line split ruptures.

   Figure 6.2-5c and Figure 6.2-5d illustrate the condensing steam heat transfer coefficient and the Reactor Building liner and interior concrete wall temperatures versus time for the worst case (temperature) main steam line break.

6.2.1.3.2 Long Term Reactor Building Performance

The long term system behavior during the design basis accident main steam line break and the worst case DEPS guillotine (minimum safety injection) LOCA have been evaluated to verify the ability of the ECCS and Reactor Building heat removal systems to maintain the Reactor Building pressure and temperature below design limits following a postulated high energy pipe rupture. This evaluation is based upon conservative predictions of the performance of these engineered safety features.

The primary system loss of coolant accident releases more energy into the Reactor Building over the course of the accident than the design basis accident main steam line break. The design basis accident mass and energy release is terminated after 1800 seconds. Since the plant operators are required to take action to terminate emergency feedwater flow to the faulted steam generator at 10 minutes, as discussed in Section 10.4.9.3, the analysis performed is conservative. Therefore, for long term Reactor Building performance, the LOCA is analyzed to 1440 hours and the design basis accident main steam line break is analyzed to 1800 seconds. The long term values of the Reactor Building parameters at 1440 hours for LOCA and 1800 seconds for the design basis accident main steam line break are presented in Table 6.2-4 and are shown graphically by Figures

6.2-1, 6.2-7 and Figures 6.2-4, 6.2-6, and 6.2-6a, respectively. The reactor vessel upflow modification has no impact on long-term Reactor Building parameters.

Figures 6.2-8 through 6.2-14 are presented to demonstrate the long term cooling capability of the Reactor Building. The following conservative assumptions were used in the analysis:

1. No leakage.
2. Reactor Building Spray System is operated for a period of up to 40 days.
3. Reactor Building Cooling Units are operated for a period of up to 40 days.
4. Boiling in the reactor vessel is suppressed after 40 days by aligning the ECCS to the RCS hot legs and cold legs simultaneously after 8 hours during the hot leg recirculation phase.

The following parameters are illustrated by the figures indicated:

1. Total energy absorbed by passive heat sinks:
   a. Design basis accident main steam line break, Figure 6.2-8.
   b. LOCA, DEPS, minimum safety injection, Figure 6.2-9.
2. Condensing film heat transfer coefficients:
   a. Design basis accident main steam line break, Figure 6.2-10.
   b. LOCA, DEPS, minimum safety injection, Figure 6.2-11.
3. Reactor Building cooling units heat removal rate:
   a. Design basis accident main steam line break, Figure 6.2-12.
   b. LOCA, DEPS, minimum safety injection,Figure 6.2-13.
4. Residual Heat Removal System heat rate, Figure 6.2-14 (LOCA).

The accident chronology for the design basis accident main steam line break is given in Table 6.2-5.

The accident chronology for the DEPS with minimum safety injection, DEPS with maximum injection, DEHL LOCA scenarios are given in Tables 6.2-6a, 6.2-6b. and 6.2-6c respectively.

6.2.1.3.3 Methods of Analyses

6.2.1.3.3.1 Description of Computer Code

Calculation of Reactor Building pressure and temperature transients were performed using the digital computer code, CONTEMPT LT. CONTEMPT LT will model up to 4 containment volumes, consisting of primary system, wetwell, drywell, or dual containment. Only the primary system and drywell options are used. Transient phenomena within the Reactor Coolant System

affect containment conditions by means of convective mass and energy transport through the pipe break. The containment drywell is separated into 2 regions. The first region consists of the air steam phase; the second, the water phase. Sufficient relationships to describe the transient are provided by the equations of conservation of mass and energy as applied to each region, together with appropriate boundary conditions.

Two (2) versions of the CONTEMPT-LT computer program are used for analysis of Reactor Building pressure and temperature transients. CONTEMPT-LT/26 was used for analysis of MSLB and LOCA transients for steam generator replacement. Subsequent revision of LOCA Reactor Building pressure and temperature analysis used CONTEMPT-LT/28, which is described in NUREG/CR-0255 (Reference 47). CONTEMPT-LT/28 is an update to version LT/26 described in this section. The analytical assumptions described in Section 6.2.1.3.3.2 apply to both versions of the program. No modifications to any models have been made CONTEMPT-LT/28 by SCE&G. The only significant modeling change resulting from the change to LT/28 from LT/26 is the use of the Uchida condensing heat transfer coefficient, rather than Tagami, for the condensing heat transfer to concrete and steel heat sinks during the LOCA transient, as described in Section 6.2.1.3.4.1. Containment pressure-temperature analysis for MSLB has not been revised since steam generator replacement and reflects the use of CONTEMPT-LT/26. Analysis of the double-ended hot leg rupture pressure and temperature transients has also not been revised since use of LT/28 was adopted.

The applicability of the CONTEMPT computer code to the containment pressure/temperature analyses can be verified by the Carolinas Virginia Tube Reactor (CVTR) experiments (Reference 24). An excerpt from Reference 24 states the following:

> "The CVTR DBA tests and analyses have demonstrated that the CONTEMPT containment response analytical model will predict reasonably accurately the containment atmosphere pressure-temperature response provided correct assignment of condensing steam heat transfer coefficients and other key parameters are made. But, when common assumptions currently used for the heat transfer coefficient (Tagami) or similar were employed, the CVTR DBA test results indicated that the peak pressure prediction obtained from CONTEMPT was conservative by about 45%. However, the magnitude of overprediction of pressure depends on the blowdown conditions and other factors such that for a large pipe rupture (or fast blowdown), underestimating the heat transfer coefficient probably has a lesser effect on the peak pressure predictions (15% or less)."

CONTEMPT is basically a 1 node containment code. The containment temperature stratification, as measured in the CVTR tests, cannot be predicted by a 1 volume model which necessarily uses average overall heat transfer coefficients, such as Uchida (Reference 5) or Tagami (Reference 4). However, the Uchida and Tagami correlation have been shown by the CVTR data and the work of Slaughterbeck (Reference 25) to be conservative for containment analysis.

6.2.1.3.3.2 Assumptions

The following are the major assumptions made in analysis:

1. Discharge mass and energy flow rates through the Reactor Coolant System break or main steam line break are established from the coolant blowdown and core thermal transient analysis described in Section 6.2.1.3.10
2. At the break point, the discharge water and corresponding energy are introduced into the vapor region. An energy balance is then made in 3 stages:
   a. Transfer of water and energy from the sump if the liquid region can boil.
   b. Determination of the masses of liquid and vapor in the atmosphere and the pressure and temperature of the atmosphere.
   c. Condensation of liquid from the vapor region to the liquid region and calculation of the liquid temperature.

   CONTEMPT LT/26 models condensate removal based upon the heat transferred to the containment heat sinks. For the main steam line break analysis, 92% of all condensate is assumed to be removed from the vapor region and added to the sump. For the LOCA analysis the isolated condensate model is not used. The use of the isolated condensate model results in a short term superheated temperature transient for dry steam blowdowns until containment sprays are actuated.

$$\dot{m} = F^{*} q (h_v - h_1)$$

Where:

$\dot{m}$	=	Rate of mass transfer of condensate from vapor region to pool region.
q	=	Heat transfer rate used to calculate condensate dropout rate.
h_v	=	Specific enthalpy of vapor in vapor region.
h_1	=	Specific enthalpy of liquid in vapor region.
F	=	Fraction of condensate formed on walls or cooling coils which is dropped into the pool region (F = 0.92).

3. Homogeneous mixing. The steam-air mixture has uniform properties, more specifically, thermal equilibrium between the air and steam.
4. Air is considered to be an ideal gas; water and steam tables are employed for thermodynamic properties.

During the transient, there is energy transfer from the steam-air and water regions to the internal structure and equipment within the Reactor Building shell. The temperature distribution through each of the heat conducting structures is determined by solving the 1 dimensional, multi-region heat conduction equation. Continuity of temperature and heat flow is assumed at composition interfaces. Boundary conditions are applied to the external surfaces of heat conducting structures as appropriate.

The following modifications have been made to CONTEMPT LT/26:

1. As originally programmed, CONTEMPT LT/26 used the Uchida heat transfer coefficient even if the heat structure were superheated; a heat transfer coefficient of 2.0 Btu/hr ft^2 °F (11.4w/m^2 °K) should be used. The following equations are now employed:

   $q_1 = h_u A (T_s - T_w)$
   $q_2 = h_s A (T_v - T_w)$

   Where:

q_1, q_2	=	Heat transfer rate.
h_u	=	Uchida heat transfer coefficient.
h_s	=	Superheated heat transfer coefficient.
	=	2.0 Btu/hr-ft^2-°F(11.4 w/m^2-°K).
T_s	=	Containment vapor saturation temperature.
T_w	=	heat structure wall temperature.
T_v	=	Containment vapor temperature.
A	=	Heat structure surface area ($ft^{2)}$.

2. The greater heat transfer rate is used: the Uchida transfer coefficient is used when the structure wall temperature is below saturation, while the superheated heat transfer coefficient is used when the structure surface is at, or above, saturation temperature.
3. Modifications have also been made to allow use of a tabular input for the condensing heat transfer coefficient and a constant forced convection heat transfer coefficient for each heat structure rather than using Uchida and natural convection coefficient of 2.0 Btu/hr-ft^2- °F.

4. These changes allow the isolated condensate model to be used in determining component temperature transients without restricting the heat transfer to the conservatively low values used in containment analysis.
5. A line change was also made to correct an error involving the driving potential for the structural heat sinks. This change corrected the energy imbalance that existed between heat removal from the vapor region and that absorbed by the passive heat sinks.

Provision is made in the computer analysis for the effects of several engineered safety features; including Reactor Building spray, Reactor Building cooling units and recirculation of sump water. Heat removal from the containment steam-air phase by Reactor Building spray is determined by allowing the spray water temperature to rise to the steam-air temperature.

6.2.1.3.3.3 Initial Conditions

The initial conditions used in the peak pressure main steam line break and LOCA analyses are presented in Tables 6.2-2 and 6.2-33, respectively. The net free volume used is conservatively calculated from design drawings when establishing the heat sinks used for the ECCS analysis.

Under all operating conditions, the Reactor Building Cooling Systems maintain the following range of temperature and relative humidity conditions:

1. Temperature, 50° F to 120° F.
2. Relative humidity, 30% to 100%.

Under all operating conditions, Reactor Building pressure is maintained below 1.5 psig, the design limit achieved by manually relieving Reactor Building pressure, when required, as discussed in Section 6.2.1.2.2.

The initial conditions used in the peak temperature main steam line break analyses are the same as those used for the peak pressure analyses with the exception that initial Reactor Building pressure is 0.0 psig. (Used for breaks with no entrainment.) This maximizes the time it takes to reach the containment pressure setpoints for main steam isolation and Reactor Building spray actuation. It also reduces the mass of air available to absorb energy, resulting in higher containment vapor temperatures.

The use of the maximum Reactor Building operating temperature and a nominal relative humidity of 30% results in the highest calculated Reactor Building pressures.

Reactor Building heat removal through passive heat sinks and by the Reactor Building Spray System and cooling units is discussed in Section 6.2.1.3.4.

6.2.1.3.3.4 Failure of Engineered Safety Features

For the LOCA analyses, the peak containment temperature and pressure occur in the short term, near the end of blowdown and thus are not extremely sensitive to single failures. Long term

pressures and temperatures are; however, maximized with the assumed failure of an emergency diesel resulting in the loss of 1 train of Reactor Building Spray, 1 Reactor Building cooling unit, and 1 train of ECCS.

For the DEPS guillotine breaks, the 4 cases analyzed are as follows:

1. A double-ended pump rupture of the reactor coolant pump suction (DEPS) with a maximum safety injection and 2 operable trains of Reactor Building Spray (SP) System.
2. A DEPS with maximum safety injection and failure of 1 train of SP.
3. A DEPS with maximum safety injection, 2 operable trains of SP, and failure of 1 train of Reactor Building Cooling Units (RBCU).
4. A DEPS with minimum safety injection and failure of 1 train of emergency diesel generator coincident with a loss of offsite power.

The main steam line break analyses conservatively assume one or more active failures. The active failures considered are as follows:

1. Electrical channel A (CH-A) failure, resulting in minimum Reactor Building heat removal from sprays and fan coolers and failure to isolate the flow to the broken loop steam generator, resulting in a 1000 gpm flow rate to that steam generator.
2. Main steam isolation valve (MSIV) on the broken loop steam generator fails to close, increasing the steam inventory released to the Reactor Building.
3. Main feedwater isolation valve fails (FWIV) to close, resulting in continued flow of feedwater.
4. Failure of a safety injection pump (SI) to operate.
5. Failure of 1 emergency diesel to start, resulting in minimum Reactor Building heat removal from sprays and fan coolers.
6. Failure of an emergency feedwater flow control valve to isolate flow to the faulted SG.

A summary of each main steam line break analyzed and its associated failures is shown in Table 6.2-1a.

The single active failure analysis of the systems relied upon to limit the mass and energy release and containment pressure/temperature response for the main steam line breaks are presented in the sections listed below:

1. Main steam, Section 10.3.3
2. Feedwater, Section 10.4.7.2.3
3. Emergency feedwater, Table 10.4-8
4. Reactor Building cooling, Tables 6.2-50 and 6.2-52

A summary of each main steam line break and LOCA analyzed is presented in Table 6.2-3.

6.2.1.3.4 Energy Sinks

6.2.1.3.4.1 Reactor Building Structures

Provision is made in the Reactor Building pressure transient analysis for heat storage in both interior and exterior walls. Every wall is divided into a large number of nodes. For each node, a conservation of energy equation expressed in finite difference form accounts for transient conduction into and out of the node and temperature rise of the node. Table 6.2-7 presents a detailed summary of the structural heat sinks. This summary includes the detailed information used in the ECCS analysis. For the Reactor Building peak pressure and long term analyses, the total amount of steel used was conservatively reduced from the values reported for the ECCS analysis.

The heat sinks were modeled for use in the CONTEMPT-LT computer code as shown by Table 6.2-8. The criteria used for mesh point spacing is based upon the work of Clausing (Reference 3).

1. Concrete
   a. Mesh point of 0.05 inches for the first 3 inches.
   b. Mesh point spacing greater than, or equal to, 0.5 inches through the remaining thickness.
2. Steel
   Mesh point spacing of 0.05 inches to 0.08 inches.

The modeling of the Reactor Building liner/air/concrete was done using a volume weighted average for the steel/air mixture in the gap between the liner and the concrete. To assure conservatism, the thermal conductivity and volumetric heat capacity were halved.

The containment liner surface temperature and interior concrete surface temperature, as calculated by CONTEMPT LT/26 for worst case temperature main steam line break, are given by Figure 6.2-5d.

The thermophysical properties used in the peak pressure analyses are shown in Table 6.2-9. These represent conservatively low thermal conductivity and volumetric heat capacity values found in the literature.

The protective coatings on surfaces such as the Reactor Building liner and internal concrete were not considered in the analysis. This exclusion is based upon the following assumption.

If it is assumed that these coatings do not affect the steam condensation film coefficient, which most probably is the case, then the inclusion of an extra heat transfer “resistor”, such as the coating, affects the overall heat transfer coefficient, U, by only 0.01%. This does not affect the Reactor Building pressure significantly.

Condensing film heat transfer coefficients are discussed in items 1 and 2, below:

1. Tagami

   During the blowdown period of a LOCA, heat transfer to steel heat sinks from the Reactor Building vapor region is based upon the Tagami (Reference 4) condensing heat transfer coefficient. Heat transfer to concrete heat sinks during blowdown is based on the Uchida correlation discussed later.

   The Tagami heat transfer coefficient increased parabolically to a peak value at the end of blowdown. Following the end of blowdown, the Uchida condensing heat transfer coefficient is used for both concrete and steel heat sinks.

   Tagami presents a plot of the maximum value of h as a function of "coolant energy transfer speed", defined as:

   $$\frac{\text{total coolant energy transferred into containment}}{\text{(containment vessel volume) (time interval to peak pressure)}}$$

From this equation, the maximum heat transfer coefficient, h, for steel is calculated as follows:

$$h_{max} = 75\left(\frac{E}{t_p V}\right)^{0.60}$$

Where:

h_{max}	=	Maximum value of h (Btu/hr-ft^2-°F).
t_p	=	Time from start of accident to end of blowdown (sec.).
V	=	Reactor Building volume (ft^3).
E	=	Initial coolant blowdown energy (Btu).

The parabolic increase from the steady-state value of 2.0 Btu/hr-ft^2 -°F is given by the following equation:

$$h_s = h_{max} \left(\frac{t}{t_p} \right)^{1/2} ; 0 < t \leq t_p$$

Where:

h_s	=	Heat transfer coefficient for steel (Btu/hr-ft^2-°F).
t	=	Time from the start of accident (sec.).

For concrete, the heat transfer coefficient is taken as 40% of the value calculated for steel.

The Tagami condensing film heat transfer coefficient used for the DEPS with minimum safety injection is given by Figure 6.2-11.

2. Uchida

The main steam line break analysis uses the Uchida (Reference 5) correlation, rather than Tagami, for the condensing steam heat transfer coefficient. LOCA analysis uses the Uchida correlation for condensing heat transfer to concrete heat sinks during blowdown and for both concrete and steel heat sinks after the end of blowdown.

The Uchida correlation results in a lower heat transfer coefficient and, is therefore, the more conservative of the 2 for the main steam line break analyses. Slaughterbeck (Reference 25) presents a discussion of the basis of heat transfer coefficients used for containment analysis.

Using the Tagami correlation with the peak heat transfer coefficient occurring when the main steam isolation valves close would result in higher heat transfer to the containment heat sinks. The Tagami correlation was not used due to the difficulty in defining the end of the turbulent portion of the blowdown.

The Uchida condensing film heat transfer coefficient is based primarily upon the mass ratio of air to steam in a nonturbulent environment. The Uchida correlation gives much lower heat transfer coefficients during the initial phase of the transient. The Uchida correlation, therefore, results in a conservative estimate of the heat removed from the vapor region during the main steam line blowdown.

The Uchida condensing steam heat transfer coefficients used during the worst case (pressure and temperature) main steam line breaks are presented by Figures 6.2-10 and Figure 6.2-5c, respectively.

6.2.1.3.4.2 Reactor Building Spray

When a spray drop enters the hot saturated steam-air environment, the vapor pressure of the water at its surface is much less than the partial pressure of the steam in the atmosphere. Hence, there will be diffusion of steam to the drop surface and condensation on the drop. This mass flow will carry energy to the drop. Simultaneously, the temperature difference between the atmosphere and the drop will cause a heat flow to the drop. Both of these mechanisms will cause the spray drop temperature and vapor pressure to rise. The vapor pressure of the drop will eventually become equal to the partial pressure of the steam and the condensation will cease. The temperature of the drop will be essentially equal to the temperature of the steam-air mixture.

The terminal velocity of the drop can be calculated using the formula given by Weinberg (Reference 6) where the drag coefficient, C_D, is a function of the Reynolds (Re) number:

$$V^2 = \frac{4Dg(\rho - \rho_m)}{3C_D\rho_m}$$

Assuming a 700 micron drop size from the Reactor Building spray nozzles, the terminal velocity is less than 7 ft/sec. For a 1000 micron drop, the velocity would be less than 10 ft/sec. The Nusselt number for heat transfer, Nu, and the Nusselt number for mass transfer, Nu′ (Sherwood Number), can be calculated from the empirical relations given by Ranz and Marshall (Reference 7):

$$Nu = 2 + 0.6\,(Re)^{1/2}\,(Pr)^{1/3}$$

$$Nu' = 2 + 0.6\,(Re)^{1/2}\,(Sc)^{1/3}$$

The Prandtl (Pr) number and the Schmidt (Sc) number for the conditions assumed are approximately 0.7 and 0.6, respectively. Both of these are sufficiently independent of pressure, temperature, and composition that they are assumed constant under containment conditions (Reference 8, and Reference 9). The coefficients of heat transfer (h_c) and mass transfer (k_G) are calculated from Nu and Nu′ respectively. The equations describing the temperature rise of a falling drop are as follows:

$$\frac{d}{dt}(Mu) = mh_g + q$$

$$\frac{d}{dt}(M) = m$$

Where:

$$q = h_c A\,(T_s - T)$$

$$m = k_G A\,(P_s - P_v)$$

These equations can be integrated numerically to find the internal energy and mass of the drop as a function of time as it falls through the atmosphere. Analysis shows that the liquid drop temperature rises to the steam-air temperature in less than 0.5 seconds. This temperature increase occurs before the drop has fallen 5 feet. These results demonstrate that the Reactor Building spray will be 100% effective in removing heat from the Reactor Building atmosphere.

The Reactor Building Spray System is actuated based upon Hi-3 containment pressure. For the full double ended rupture main steam line break and Reactor Coolant System LOCA analyses, the pressure setpoint is reached well before the 10 seconds required for diesel generator startup. Reactor Building spray is assumed to actuate at 52 seconds for the LOCA and 53.1 seconds for the large main steam line breaks following accident initiation. This is conservative based upon the following:

1.	Diesel Start Time	10 seconds
2.	Time for RB Spray Pump to reach full capacity	5 seconds
3.	Time required to fill RB Spray piping and ring headers	32 seconds
4.	Total Elapsed Time	47 seconds

Note: As a conservatism, filling of RB Spray piping is not credited during the 5 second pump acceleration phase.

Actuation timing calculations for the smaller main steam line breaks are presented in Table 6.2-47b.

6.2.1.3.4.3 Reactor Building Cooling Units

Heat removal by the Reactor Building cooling units is dependent upon the number of units operating, unit start and stop times, and the heat removal rate. The heat removal rate is dependent upon the Reactor Building atmosphere temperature and a number of thermal-physical cooler design parameters. The cooling coils of a Reactor Building cooling unit remove energy directly from the vapor region of the containment which results in reduced energy and pressure.

Heat removal due to Reactor Building cooling unit operation is simulated in the CONTEMPT code by specifying input values from a heat removal rate versus Reactor Building atmosphere temperature curve. The design values given on Figure 6.2-15, conservatively reduced to 60% to account for potential performance degradation, are used for MSLB analysis. LOCA analysis utilizes the RBCU performance curve corresponding to a conservative tubeside fouling factor of 0.0014 (Reference 46) shown on Figure 6.2-15. That curve is based on analytical results calculated by American Air Filter according to the methods described in Topical Report TR-7101A (Reference 16). That analysis assumes the following boundary conditions:

Cooling water inlet temperature:	95° F
Cooling water flow:	2000 gpm
Tubeside fouling factor:	0.0014

The resulting performance curve gives a higher heat removal rate than the 60% design performance curve used in MSLB analysis, but still conservative compared to the design curve. All three curves are shown together for comparison on Figure 6.2-15.

The Reactor Building cooling units are calculated to be fully operational within 86.5 seconds following loss of offsite power. A description of the timing involved is presented in Section 6.2.2.2.2.2. The time used in the analyses is 86.5 seconds for the large main steam line breaks and the LOCA analyses. Actuation timing calculations for the main steam line breaks are presented in Table 6.2-47b.

6.2.1.3.4.4 Sump Water Recirculation Heat Exchangers

During the post accident long term cooling period, safety injection pumps (charging pumps and RHR pumps) supply recirculated water from the Reactor Building recirculation sumps to the reactor vessel. The RHR heat exchangers are placed in operation during the recirculation phase to remove energy directly from the reactor vessel to the outside environment.

The RHR heat exchangers are of the shell and U-tube type. Physical and thermal characteristics of each heat exchanger are specified in Table 6.2-1, as are the coolant inlet temperatures and flow rates.

6.2.1.3.5 Systems for Protection Against Negative Pressure Inside the Reactor Building

A narrow range differential pressure transmitter provides signals for monitoring the Reactor Building internal pressure. Control room alarms are actuated by this pressure channel when the differential pressure approaches the baseline pressure. Administrative procedures are used following actuation of the alarm to adjust Reactor Building pressure to within the required baseline pressure limits.

During normal operation, inadvertent Reactor Building spray can occur when doing the periodic inservice testing on 1 spray loop. An inadvertent safety injection signal to the spray loop discharge valve during spray loop testing is the worst single failure.

6.2.1.3.6 Reactor Building Analysis, Negative Pressure

Inadvertent operation of the Reactor Building Spray System causes depressurization of the Reactor Building due to the cooling effect of the spray water. A theoretical maximum depressurization can be calculated by assuming that the temperature of the Reactor Building atmosphere ultimately reaches the spray water temperature. (The evaporative cooling phase is not controlling for this case. See Reference 10). Thus, the partial pressure of the air will simply change by a ratio of the absolute temperatures, while the vapor pressure will be equal to the saturation value at the spray water temperature. The theoretical maximum depressurization is:

$$P_d = P_o - \left[P_a \frac{T_{sp}}{T_o} + P_g(T_{sp}) \right]$$

Where:

P_d	=	Depressurization.
P_o	=	Initial pressure.
P_a	=	Initial air partial pressure.
$P_g (T_{sp})$	=	Water vapor partial pressure evaluated at T_{sp}.
T_{sp}	=	Spray water temperature.
T_o	=	Initial atmospheric temperature.

Using an initial temperature, pressure and relative humidity of 120°F, -0.1 psig, and 100%, respectively, for the Reactor Building atmosphere and a spray water temperature of 40° F, depressurization results in an external pressure of 3.5 psig. Therefore, the maximum external pressure does not exceed the design pressure given in Section 6.2.1.2.2.

6.2.1.3.7 Function Capability of the Normal Reactor Building Ventilation System

The normal ambient operating temperatures of the Reactor Building under various operating modes are indicted in Section 6.2.2.1.2. A single failure analysis is presented in Table 6.2-52. The maximum acceptable local compartment or area temperatures are described in Section 3.11.1.1. Instrumentation and alarms for the reactor building ventilation system are discussed in Section 9.4.8.

6.2.1.3.8 Accident Pressure and Temperature Monitoring

The Reactor Building pressure and temperature and Reactor Building recirculation sump temperature instrumentation (including recording capability) is discussed in Section 7.5. The qualification of this instrumentation (including recording capability) is discussed in Section 7.5. The qualification of this instrumentation for use in the post accident containment environment is discussed in Sections 3.10, 3.11, and 7.4. The recorders are located in the control room, thus assuring accessibility to control room personnel during a LOCA.

6.2.1.3.9 Reactor Building Subcompartment Pressurization

Reactor Building subcompartments (steam generator compartments, pressurizer compartment, reactor cavity area) have been analyzed with respect to the appropriate design basis break to determine the peak pressure differential for pipe rupture. Each compartment has been broken down into volumes and flow paths. The steam generator and reactor cavity compartments were analyzed using the RELAP4/MOD5 (Reference 30) code without air. The incompressible flow option without momentum flux was used for the momentum equation. Critical flow was predicted by the homogeneous equilibrium model, using the stagnation conditions of each node, consistent with the homogeneous equilibrium model critical flow table on RELAP4/MOD5. The transient pressure behavior of the pressurizer compartment has been calculated by the COMPARE-MOD 1 computer program (Reference 37). Results of these analyses have been used in the compartment structural design.

The Subcompartments have been analyzed for the largest break(s) possible in each compartment. A summary is given below:

1. Pressurizer compartment - spray line and surge line breaks (see Section 6.2.1.3.9.1)
2. Steam generator compartments - double ended hot leg and cold leg breaks (see Section 6.2.1.3.9.2)
3. Reactor cavity - cold leg break, 150 in^2 area (see Section 6.2.1.3.9.3).

The mass/energy release for each break used in subcompartment pressurization analyses is provided in Section 6.2.1.3.10.2.

The differential pressure on compartment walls is spatially varied for structural evaluation, where applicable. The vent parameters are realistically evaluated to provide a realistic pressure distribution following the accident.

The steam-water atmosphere was used to describe the initial conditions of Reactor Building subcompartments. The initial atmosphere within a subcompartment is modeled by a homogeneous water-steam mixture with an average density equivalent to the dry air model.

In addition, 100% entrainment has been assumed. The resulting calculated and design pressures are presented in Table 6.2-11. The analysis of each subcompartment is discussed separately in Sections 6.2.1.3.9.1 through 6.2.1.3.9.3.

The impact of the replacement steam generators and changes in plant operating parameters have been evaluated on the Reactor Building subcompartment analyses. Since the completion of the FSAR design analyses the Leak-Before-Break (LBB) Methodology has been applied in the plant design to the large primary piping. This eliminates the dynamic effects of postulated primary pipe ruptures from the design basis. Therefore, application of LBB means that the 150 in^2 cold leg break, DECL break and DEHL breaks need not be considered in the structural design basis. Continued use of these original bases results in a conservative design for the steam generator compartments and the reactor cavity which bounds any potential effects of the replacement steam generators and changes in the plant operating conditions.

For the pressurizer compartments, no reduction in break size is possible since the LBB methodology has only been applied to the large primary piping. Since the revised design power operating power parameters will allow for reduced Reactor Coolant System (RCS) temperatures, an increase in the pressurizer surge and spray line mass releases must be considered. The increase in the releases from previous analysis are conservatively bounded by increasing the surge and spray line mass releases by factors of 1.15 and 1.10, respectively. The corresponding enthalpies are conservatively bounding for the lower RCS temperature. The results of this analysis are shown in Section 6.2.1.3.9.1.

6.2.1.3.9.1 Pressurizer Compartment Analysis

The pressurizer and surge tank compartments have been analyzed for pressure response from spray line and surge line breaks, respectively, using the COMPARE-MOD 1 computer program (Reference 37). In each case, a 2 node model has been used. Figures 6.2-18 and 6.2-19 show the nodalization and appropriate parameters for the pressurizer compartment and surge tank compartment, respectively. Major relief areas for the pressurizer compartment include an opening at elevation 437’-6” and grating at elevation 488’-6”. For the surge tank compartment, the major relief area is directly to the steam generator compartment.

The mass/energy releases are discussed in Section 6.2.1.3.10.2. Mass/energy releases for the spray line rupture have been conservatively extended past the information provided by the NSSS vendor to permit calculation of the necessary transient differential pressure.

Figures 6.2-20 and 6.2-21 depict the pressure-time history for the pressurizer and surge tank compartments following the appropriate break. Differential pressures are also shown by these figures. Peak calculated and differential pressure are 41.9 psia (26.0 psid) and 45.0 psia (30.6 psid) for the pressurizer and surge tank compartments, respectively.

The peak calculated and design differential pressures for the pressurizer compartment are presented in Table 6.2-11.

The above mentioned calculated pressures are without margin. As shown by the valves in Table 6.2-11, the available margin between the calculated differential pressure and the structural design pressure is 59% for the pressurizer compartment and 68% for the surge tank compartment.

6.2.1.3.9.2 Steam Generator Compartment Analysis

The steam generator compartments were initially analyzed to determine the peak pressures on the compartment walls and the forces and moments acting upon the steam generator and reactor coolant pump supports. The general layout of the steam generator compartments is illustrated by Figure 6.2-22.

The analysis was performed using the RELAP4/MOD5 code (Reference 30). Flow paths between nodes were modeled using inertial flow bounded by the homogeneous equilibrium critical flow model where significant changes in area occurred. In addition, all flow paths out of the break nodes were limited by the homogeneous equilibrium critical flow model regardless of geometry.

Initially, each steam generator compartment was analyzed for both the double ended hot and cold leg breaks. Models were set up to include significant restrictions and changes in area where practical.

From results of the initial studies it was determined that the loop C steam generator compartment was the worst case. Both the overall lower compartment pressure and specific nodal pressures due to geometric considerations were higher in loop C.

The loop C steam generator compartment was then modeled to include more definition and to establish loadings on the reactor coolant pump and steam generator.

The impact of the replacement steam generators and changes in plant operating parameters have been evaluated on the Reactor Building subcomponent analyses. Since the completion of the FSAR design analyses, the Leak-Before-Break (LBB) Methodology has been applied in the plant design to the large primary piping. This eliminates the dynamic effects of postulated primary pipe rupture from the design basis. Therefore, application of LBB means that the 150 in^2 cold leg break, DECL break and DEHL breaks need not be considered in the structural design basis. Continued use of these original bases results in a conservative design for the steam generator compartments and the reactor cavity which bounds any potential effects of the replacement steam generators and changes in the plant operating conditions.

6.2.1.3.9.2.1 Initial Steam Generator Compartment Models

The initial models for each loop were similar. In general, these models were comprised of 2 nodes below the steam generator and reactor coolant pump, 5 or 6 nodes between elevations 426.5’ and 436’, one node between elevations 436’ and 459.5’ and one node between elevations 459.5’ and 475.4’. Elevation 436’ was chosen as a dividing line because the steam generator supports and inservice inspection platforms form a natural boundary. The boundary at elevation 426.5’ is not real but does provide vertical symmetry for the break nodes.

The nodal arrangements, analytical results and model descriptions for the initial models are summarized by Table 6.2-11a. Tables 6.2-12 through 6.2-14a present model descriptions and results. Figures 6.2-22a through 6.2-22k illustrate nodal arrangements and results.

6.2.1.3.9.2.2 Final Loop C Steam Generator Compartment Models

A 20 node loop C steam generator compartment model was analyzed to determine nodal sensitivity and loadings on the reactor coolant pump due to a cold leg break. The volume between elevations 436’ and 451’ (top of reactor coolant pump) was divided into 5 nodes. The increase nodalization did not result in increased pressure in the break nodes since flow out of these nodes chokes early in the transient.

A 25 node compartment model was analyzed to determine nodal sensitivity and loadings on the steam generator due to a hot leg break. This model was similar to the 20 node model previously described but included more nodes around the steam generator above elevation 459.5’. The resultant peak pressure in break node 7 increased by less than 6%. This result was expected since the peak in node 7 is an inertial peak.

Forces and moments on the reactor coolant pump and steam generator were determined using results from the 20 and 25 node model, respectively.

The nodal arrangements, analytical results, model descriptions, and forces and moments data are summarized by Table 6.2-15. Tables 6.2-15a through 6.2-15f present model descriptions, and forces, and moments data. Figures 6.2-23 through 6.2-26 illustrate nodal arrangements, results and forces, and moments data.

6.2.1.3.9.2.3 Discussion of Results

From the tables and figures noted in Sections 6.2.1.3.9.2.1 and 6.2.1.3.9.2.2 it can be seen that the overall pressure response of the lower steam generator compartments (23 psid) is well below the design pressure of 41.2 psid.

A peak pressure of 47.9 psid was calculated (Node 4, cold leg) around the reactor coolant pump near the refueling canal wall.

A short term inertial peak of 45.9 psid (Node 7, hot leg) between the steam generator and secondary shield wall was calculated.

To study the impact of the above calculated pressures on the structural design, a simplified model of the lower steam generator compartment was developed. An analysis was performed using this model to evaluate the effects of the calculated pressures. Analytical results were compared to the results of a similar analysis for design pressure. It was determined that the design forces and moments for the above calculated pressures are less than for the design pressure. This reduction is due to the decrease in overall pressure even though pressure is increased locally.

6.2.1.3.9.3 Reactor Cavity Analysis

The impact of the replacement steam generators and changes in plant operating parameters have been evaluated on the Reactor Building subcomponent analyses. Since the completion of The FSAR design analyses the Leak-Before-Break (LBB) Methodology has been applied in the plant

design to the large primary piping. This eliminates the dynamic effects of postulated primary pipe ruptures from the design basis. Therefore, application of LBB means that the 150 in^2 cold leg break, DECL break and DEHL breaks need not be considered in the structural design basis. Continued use of these original bases results in a conservative design for the steam generator compartments and the reactor cavity which bounds any potential effects of the replacement steam generators and changes in the plant operating conditions.

1. Analyses

   A pressurization analysis of the reactor cavity and penetration areas of the primary shield was performed using the RELAP4/MOD5 code (Reference 30) to predict pressures and forces and moments resulting from a postulated rupture. The analysis was performed by considering the maximum break size which could occur in the primary shield pipe penetrations. Cold leg and hot leg guillotine breaks are limited by restrictions imposed upon pipe movement by the penetration, supports, and loop geometry. Cold leg break geometry is illustrated by Figure 6.2-27. Due to the break geometry, the cold leg break area is larger than the hot leg break area. The maximum cold leg break area is limited to a value less than 150 in^2, the value used for mass/energy releases (see Section 6.2.1.3.10.2).

   The general layout of the reactor cavity area is illustrated by Figure 6.2-28. A break in the loop B cold leg was selected for analysis because of the small inspection port opening. Dimensions on Figure 6.2-28 represent cold conditions. Thermal expansion under hot conditions was included in the calculation of the various model parameters in the RELAP4/MOD5 code. Insulation was assumed to move against the reactor vessel and/or piping, as appropriate, instantaneously with not change in thickness. Further details are provided by Figures 6.2-65 through 6.2-67.

   A nodalization sensitivity study was performed for the forces and moments. Axes used in the orientation of the reactor vessel are illustrated by Figure 6.2-29. Forces in the x and z directions and the moment about y axis are the major components. These major components were considered in the acceptance of the nodalization sensitivity study.

   Three (3) reactor cavity modes, incorporating 22, 31, and 33 nodes, were analyzed. The 22 node model included 3 nodes in the cold leg penetration and 15 nodes in the reactor vessel annulus. The 31 node model also used 3 nodes in the penetration but used 24 nodes in the annulus. The 33 node model incorporated 5 nodes in the penetration and 24 nodes in the annulus.

   Information presented for the reactor cavity models include penetration, reactor vessel annulus, and overall models, as well as forces and moments. A cross reference between various models and appropriate tables and figures is presented by Table 6.2-16. Tables 6.2-16a through 6.2-16c address control volumes; Tables 6.2-17 through 6.2-17b, flow paths; and Tables 6.2-18 through 6.2-18b, force/moment areas. Figures 6.2-30 through 6.2-32a illustrate penetration nodes, reactor vessel annulus nodes, and overall model schematics.

2. Results

   The results from the 3 models are the pressures in each node and the resulting forces and moments. The peak differential pressure with respect to containment pressure is tabulated for each node and differential pressure transient for the break node and reactor vessel annulus nodes adjacent to the break are also shown. In addition, forces and moments are tabulated for each model. A cross reference is provided by Table 6.2-18c. Tables 6.2-16a through 6.2-16c present peak differential pressures. Tables 6.2-18d through 6.2-18f present forces and moments. Figures 6.2-33 through 6.2-33e illustrate transient differential pressures for selected nodes.

   The peak pressures listed in Table 6.2-16a through Table 6.2-16c are well below the design pressures in the penetration and reactor vessel annulus.

   Peak forces and moments of interest are presented by Table 6.2-18g for each of the 3 models. The results of the nodalization sensitivity study indicate reasonable agreement among the 3 models.

   Since the 33 node model is the most detailed, the numbers for this model are used for the design evaluation. A transient representation of forces and moments for the 33 node model is provided by Figures 6.2-34 through 6.2-35a.

6.2.1.3.10 Mass and Energy Releases

Rupture of any of the piping carrying pressurized high temperature reactor cooling water, termed a loss of cooling accident (LOCA), or rupture of a secondary system steam line within the containment will result in release of steam and water into the containment. This in turn will result in an increase in the containment pressure and temperature. In order to evaluate the response of the containment to such accidents, the rate of release as a function of time must be evaluated. Section 6.2.1.3.10.1 describes the long term releases following a LOCA in the primary cooling system. These results are used to evaluate the overall effect of such releases on the containment. Section 6.2.1.3.10.3 describes the releases resulting from rupture of a secondary system steam line located within the containment.

6.2.1.3.10.1 LOCA Mass and Energy Release

6.2.1.3.10.1.1 LOCA Release Rate Transient

The LOCA transient is typically divided into 4 phases:

1. Blowdown - which includes the period from accident initiation (when the reactor is at steady state operation) to the time that the RCS pressure reaches initial equilibrium with containment.
2. Refill - the period of time when the lower plenum is being filled by accumulator and safety injection water. At the end of blowdown, a large amount of water remains in the cold legs,

downcomer, and lower plenum; therefore to conservatively consider the refill period for the purpose of containment mass and energy releases, this water is instantaneously transferred to the lower plenum. This allows an uninterrupted release of mass and energy to containment. Thus the refill period is conservatively neglected in the mass and energy release calculation.

3. Reflood - begins when the water from the lower plenum enters the core and ends when the core is completely quenched.
4. Post-Reflood (Froth) - describes the period following the reflood transient. For the pump suction break, a two-phase mixture exits the core, passes through the hot legs, and is superheated in the steam generators. After the broken loop steam generator cools, the break flow becomes 2 phase.

Tables 6.2-19a-6.2-19b through 6.2-22, 6.2-25, and 6.2-26 provide the tabulations of the current long term mass and energy release rates versus time for all 4 phases over the spectrum of breaks analyzed.

6.2.1.3.10.1.2 Mass and Energy Release Analyses For Postulated Loss-of Coolant Accidents

The evaluation model used for the long term LOCA mass and energy release calculations used was the March 1979 model described in Reference 38. This evaluation model has been reviewed and approved by the NRC, and has been used in the analyses of other dry containment plants.

A discrepancy between volumetric heat capacities used in WCAP-10325-P-A (Reference 38) and those documented in more recent ASME Code documents was identified. This condition was addressed in PWROG-17034-P-A (Reference 49), where the NRC determined, with various generic methodology issues addressed, the continued use of WCAP-10325-P-A is acceptable for performing LOCA mass and energy release analysis for plants with large dry containments.

The analyses presented in this section have also been performed to evaluate any potential effects the reactor vessel upflow conversion had on the mass and energy releases. This design change was shown to have a negligible effect on the calculated LOCA mass and energy releases.

For the long term mass and energy release calculations, operating temperatures for the highest average coolant temperature at full power (see Table 5.1-1) were selected as the bounding analysis conditions. The RCS temperature conditions for the rerating analysis for the long term LOCA transients are also bounding for asymmetric loop flow considerations. The modeled core power level of 2958 MWt, adjusted for calorimetric error (+2% of power), was the basis in the analysis. The use of higher temperatures is conservative because the initial fluid energy is based on coolant temperatures which are at the maximum levels attained in steady state operation. Additionally, an allowance of +6.3° F is reflected in the temperatures in order to account for instrument error and deadband. The initial RCS pressure in this analysis is based in a nominal value of 2250 psia. Also included is an allowance of +54 psia, which accounts for the uncertainty on pressurizer pressure. The resulting limiting pressure of 2304 psia affects the blowdown phase results, since this represents the initial pressure of the RCS. The RCS rapidly depressurizes from this value until the point at which it equilibrates with containment pressure.

The rate at which the RCS blows down is initially more severe at the higher RCS pressure (2304 psia). Additionally, the RCS has a higher fluid density at 2304 psia (assuming a constant temperature) and subsequently has a higher RCS mass available for release. Thus, 2304 psia initial pressure was selected as the limiting case for the long term mass and energy release calculations. These assumptions conservatively maximize the mass and energy in the RCS.

The selection of fuel allowance for the long term mass and energy calculations and subsequent LOCA containment integrity calculation is based on the need to conservatively maximize the core stored energy. The margin in core stored energy is integral to the methodology and is based on a statistical combination of effects including fuel type, power level, manufacturing tolerances, and densification.

Margin in RCS volume of 3% (which is composed of 1.6% allowance for thermal expansion, and 1.4% for uncertainty) is modeled.

Regarding safety injection flow, the mass and energy calculation considers both minimum and maximum safety injection flow rates. Further details concerning these assumptions are contained in Section 6.2.1.3.10.1.9.

6.2.1.3.10.1.3 LOCA Break Size and Location

Generic studies have been performed with respect to the effect on LOCA mass and energy releases to postulated break size. The double-ended guillotine break has been found to be limiting due to larger mass flow rates during the blowdown phase of the transient. During the reflood and froth phases, the break size has little effect on the releases.

Three (3) distinct locations in the reactor coolant loop can be postulated for pipe rupture:

1. Hot leg (between vessel and steam generator)
2. Cold leg (between pump and vessel)
3. Pump suction (between steam generator and pump)

The break location analyzed and described herein is the double-ended pump suction guillotine break (10.48 ft^2). Pump suction break mass and energy releases have been calculated for the blowdown, reflood, and post-reflood phases of the LOCA.

The following information provides a discussion on each break location. The double-ended hot leg guillotine has been shown in previous studies to result in the highest blowdown mass and energy release rates. Although the core flooding rate would be highest for this break location, the amount of energy released from the steam generator secondary side is minimal because the majority of the fluid, which exists the core, bypasses the steam generators in venting to containment. As a result, the reflood mass and energy releases are reduced significantly as compared to either the pump suction or cold leg break locations where the core exit mixture must pass through the steam generators before venting through the break.

For the hot leg break, there is no reflood peak as determined by generic studies (i.e., from the end of the blowdown period the releases would continually decrease). Therefore, the reflood (and subsequent post reflood) releases are not calculated for a hot leg break. The mass and energy releases for the hot leg break blowdown phase have been included in the scope of this containment integrity analysis.

The cold leg break location has also been found in previous studies to be much less limiting in terms of the overall containment peak pressure. The cold leg blowdown is faster than that of the pump suction break and more mass is released into the containment. However, the core heat transfer is greatly reduced and this results in a considerably lower energy release into containment. Studies have determined that the blowdown transient for the cold leg is, in general, less limiting than that for the pump suction break. During reflood, the flooding rate is greatly reduced and the energy release rate into the containment is also reduced. Therefore, the cold leg break analysis is not usually performed.

The pump suction break combines the effects of the relatively high core flooding rate as in the hot leg break and the addition of the stored energy in the steam generators.

As a result, the pump suction break yields the highest energy flow rates during the post-blowdown period by including all of the available energy of the Reactor Coolant System in calculating the releases to containment. This break location has been determined to be the limiting break for typical dry containment plants. The choice of this break location, as the limiting break analyzed for the V. C. Summer plant, is consistent with other dry containment plants for the post-blowdown phase of the event.

In summary, the analysis of the limiting break location for a dry containment has been performed. The double-ended pump suction guillotine break has historically been considered to be the limiting break location for the post-blowdown phase of the event by virtue of its consideration of all energy sources present in the RCS. The analyses presented support the conclusions of the double-ended pump suction (DEPS) as the limiting break case for the post-blowdown period, considering both the minimum and maximum safety injection cases. This break location provides a mechanism for the release of the available energy in the Reactor Coolant System, including both the broken and intact loop steam generators.

6.2.1.3.10.1.4 LOCA Mass and Energy Release Data

The following items ensure that the mass and energy releases are conservatively calculated for maximum containment pressure:

1. Maximum expected operating temperature of the Reactor Coolant System.
2. Allowance in temperature for instrument error and deadband (+6.3°F).
3. Margin in volume of 3% (which is composed of 1.6% allowance for thermal expansion and 1.4% for uncertainty).
4. Nominal core power level of 2900 MWt.

5. Allowance for calorimetric error (+ 2% of power).
6. Conservative coefficients of heat transfer (i.e. steam generator primary/secondary heat transfer and Reactor Coolant System metal heat transfer).
7. Allowance in core stored energy that is based on a statistical combination of effects including fuel type, power level, manufacturing tolerances, and densification.
8. Allowance for RCS pressure uncertainty (+ 54 PSI).
9. A maximum containment backpressure equal to design pressure (57 psig)
10. Minimum RCS loop flow (92,600 gpm/loop)
11. SGTP leveling (0 percent uniform)

6.2.1.3.10.1.5 Blowdown Mass and Energy Release Data

The SATAN-VI code is used for computing the blowdown transient and is the same as that used for the ECCS calculation in Reference 39. The methodology for the use of this model is described in Reference 38.

Tables 6.2-19a, 6.2-19b, and 6.2-20 present calculated mass and energy releases or the blowdown phase of the break analyzed for the DEPS minimum ECCS, DEPS maximum ECCS, and DEHL breaks, respectively. Break flow time histories from each side of the guillotine break are tabulated, where Break Flow Path No. 1 represents the flow from the reactor vessel outlet side of the break and Break Flow Path No. 2 represents the flow from the reactor vessel inlet side of the break. The mass and energy release for the blowdown phase terminate in less than 20 seconds, after the initiation of the postulated accident.

6.2.1.3.10.1.6 Reflood Mass and Energy Release Data

The WREFLOOD code is used for computing the reflood transient, is a modified version of that used in the ECCS calculation in Reference 39. The methodology for the use of this model is described in Reference 38.

To clarify the mass and energy evaluation model described in Reference 38 steam/water mixing in the broken loop has been included in this analysis. This assumption is justified and is supported by test data, summarized as follows:

The model assumes a complete mixing condition (i.e., thermal equilibrium) for the steam/water interaction. The complete mixing process, however, is made up of 2 distinct physical processes. The first is a 2 phase interaction with condensation of steam by cold injection water. The second is a single phase mixing of condensate and injection water. Since the mass and energy of the steam released is the most important influence to the containment pressure transient, the steam condensation part of the mixing process is the only part that need be considered. (Any spillage directly heats only the sump.)

The most applicable steam/mixing test data has been reviewed for validation of the containment integrity reflood steam/water mixing model. This data is that generated in the 1/3 scale test (Reference 40), which are the largest scale data available and thus most closely simulates the flow regimes and gravitational effects that would occur in a PWR. These tests were designed specifically to study the steam/water interaction for PWR reflood conditions.

From the entire series of 1/3 scale tests, a group corresponds almost directly to containment integrity reflood conditions. The injection flow rates for this group cover all phases and mixing conditions calculated during the reflood transient. The data from these tests were reviewed and discussed in detail in Reference 38. For all these tests the data clearly indicates the occurrence of very effective mixing with rapid steam condensation. The mixing model used in containment integrity reflood calculation is therefore, wholly supported by the 1/3 scale steam/water mixing data.

Additionally, the following justification is also noted. The limiting break for the containment integrity peak pressure analysis during post-blowdown phase is the double-ended pump suction break. For this break, there are 2 flow paths available in the RCS by which mass and energy may be released to containment. One (1) is through the outlet of the steam generator, the other via reverse flow through the reactor coolant pump. Steam, which is not condensed by ECCS injection in the intact RCS loops passes around the downcomer and through the broken loop cold leg and pump in venting to containment. This steam also encounters ECCS injection water as it passes through the broken loop cold leg; complete mixing occurs and a portion of it is condensed. It is this portion of steam, which is condensed, that is taken credit for in this analysis. This assumption is justified based upon the postulated break location and the actual physical presence of the ECCS injection nozzle. A description of the test and test results is contained in References 38 and 40.

The methodology previously discussed and described in Reference 38 has been utilized and approved on Dockets for Catawba Units 1 and 2, Indian Point 2 and 3, McGuire Units 1 and 2, Sequoyah Units 1 and 2, Millstone 3, Shearon Harris Unit 1, and Beaver Valley Unit 2.

Tables 6.2-21 and 6.2-22 present the calculated mass and energy release for the reflood phase of the double-ended pump suction break with minimum and maximum safety injection respectively. Flow time histories from each side of the double-ended pump suction break are tabulated where Break Flow Path No. 1 represents the flow through the outlet of the steam generator and Break Flow Path No. 2 represents reverse flow through the reactor coolant pump. A significantly higher mass and energy release occurs during the period the accumulators are injecting (from 22.3 to 43.8 seconds for minimum and maximum safety injection as illustrated in Table 6.2-21 and Table 6.2-22). The transient of the principal parameters during reflood are given in Tables 6.2-23 and 6.2-24 for the minimum and maximum safety injection double-ended pump suction break case.

6.2.1.3.10.1.7 Post-Reflood Mass and Energy Release Data

The FROTH code is used for computing the post-reflood transient. The methodology for the use of this model is described in Reference 38. The mass and energy rates calculated by FROTH are used in the containment analysis until the time of containment depressurization.

After depressurization, the mass and energy release from decay heat is based on the 1979 ANSI/ANS Standard, Shown in Reference 41, and the following input:

1. Decay heat sources considered are fission product decay and heavy element decay of U-239 and Np-239.
2. Decay heat power from fissioning isotopes other than U-235 is assumed to be identical to that of U-235.
3. Fission rate is constant over the operating history of maximum power level.
4. The factor accounting for neutron capture in fission products was taken from Table 10 of Reference 41.
5. Operating time before shutdown is 3 years.
6. The total recoverable energy associated with 1 fission has been assumed to be 200 Mev/fission.
7. Two (2) sigma uncertainty (2 times the standard deviation) has been applied to the fission product decay.

Table 6.2-34 gives the core generated decay heat used in the long term mass and energy release calculation.

Tables 6.2-25 and 6.2-26 present the 2 phase (froth) mass and energy release data for the double-ended pump suction break minimum and maximum safety injection cases. Flow time histories from each side of the double-ended pump suction break are tabulated, where Break Flow Path No. 1 represents the flow through the outlet of the steam generator and Break Flow Path No. 2 represents reverse flow through the reactor coolant pump.

6.2.1.3.10.1.8 Mass and Energy Sources

The sources of mass considered in the LOCA mass and energy release analysis are given in Tables 6.2-27, 6.2-28, and 6.2-29. These sources are the Reactor Coolant System, accumulators, and pumped safety injection.

The energy inventories considered in the LOCA mass and energy release analysis are given in Tables 6.2-30, 6.2-31, and 6.2-32.

The components included in the mass and energy calculations are:

1. Reactor Coolant System water
2. Accumulator water
3. Pumped Injection water
4. Decay heat
5. Core stored energy

6. Reactor Coolant System metal
7. Steam generator metal
8. Steam generator secondary energy
9. Secondary transfer of energy (feedwater into and steam out of the steam generator secondary)

In the mass and energy release data presented, no Zirc-water reaction heat was considered because the clad temperature did not rise high enough for the energy released by this reaction to be of any significance.

System parameters needed to perform confirmatory analyses are provided in Table 6.2-33.

The consideration of the various energy sources in the mass and energy release analysis provides assurance that all available sources of energy has been included in this analysis. Thus, the review guidelines presented in the Standard Review Plan have been satisfied.

The mass and energy inventories are presented at the following times, as appropriate:

1. Time zero (initial conditions)
2. End of blowdown time
3. End of refill time
4. End of reflood time
5. Time of full depressurizations

The methods and assumptions used to release the various energy sources are given in Reference 38 except as noted in Section 6.2.1.3.10.1.6, which has been approved as a valid evaluation model by the Nuclear Regulatory Commission.

6.2.1.3.10.1.9 Application of Single Failure Criteria

An analysis of the effects of the single failure criteria has been performed on the mass and energy release rates for the (DEPS) break. For the DEPS results presented in this report an inherent assumption in the generation of the mass and energy release is that offsite power is lost. This results in the actuation of the emergency diesel generators, required to power the safety injection system. This is not an issue for the blowdown period, which is limited by the DEHL break.

Three (3) cases have been analyzed for the effects of a single failure. The double-ended pump suction case with both minimum and maximum safety injection for the 2900 MWt rerated conditions was analyzed. In the case of minimum safety injection, the single failure, postulated to occur, is the loss of an emergency diesel generator. This results in the loss of 1 pumped safety injection train, thereby, minimizing the safety injection flow and the loss of 1 train of RB spray and RBCU. For the case of maximum safety injection, two separate single failures are postulated to occur. One failure is the loss of 1 train of RB spray. The other is the loss of 1 train of RBCU.

The analysis of both minimum and maximum safety injection cases ensures that the effect of all credible single failures is bounded.

6.2.1.3.10.2 Short Term Mass and Energy Releases

The model used to perform the short term blowdown analysis is fully described in Reference 12. The release rates used for the reactor cavity, steam generator compartment, and pressurizer compartment analyses are listed in the following tables:

1. Reactor cavity blowdown for 150 in^2 cold leg break.
2. Cold leg DEG.
3. Hot leg DEG.
4. Double ended pressurizer surge line break, Table 6.2-44.
5. Pressurizer spray line break, Table 6.2-45.

As indicated in Section 3.6, postulated breaks in the reactor coolant loop piping, except for branch line connections, have been eliminated through the use of Leak-Before-Break (LBB) methodology. The mass and energy releases previously used are retained; however, as bounding values to serve as the basis for the Reactor Building subcompartment pressurization analyses described in Section 6.2.1.3.9. The RCS temperature conditions for the rerating analysis for the short term LOCA transients are also bounding for asymmetric loop flow considerations.

6.2.1.3.10.3 Mass And Energy Release Analyses (Containment Response) For Postulated Secondary System Pipe Ruptures Inside Containment

6.2.1.3.10.3.1 Method of Analysis

The analysis of the main steam line break (MSLB) inside containment includes a calculation of the mass and energy release from the blowdown and the corresponding containment response. The mass and energy releases following a steam line rupture are dependent upon the configuration of the plant steam system and containment design, as well as the plant operating conditions and size of the rupture. The cases examined in this study were chosen to determine a limiting case, in terms of containment temperature and pressure response.

The following items must be considered for a steam line rupture inside containment analysis:

- nuclear kinetics characteristics and power generation in the reactor core,
- stored energy in both the primary reactor system and the secondary steam plant,
- main and auxiliary feedwater systems operation,
- safety systems operation (e.g. reactor trip, steam line isolation, ECCS),
- break size and location, and
- blowdown characteristics.

The analyses utilize a steam line break mass and energy release methodology which considers all of these factors, such that conservative steam line break blowdown transients may be determined.

The methods described in Reference 28 were used to generate the mass and energy release information. These methods form the basis for the assumptions and models used in the calculation of the mass and energy releases resulting from a steam line rupture. Reference 28 presents an extensive analysis of the nature of the effluent releases following a postulated main steam line rupture, as well as a discussion of the methods and models and models used.

Transient mass and energy releases following a postulated secondary side pipe break are calculated using the LOFTRAN code (Reference 32). LOFTRAN is used for studies of the transient response of a PWR system to specified perturbations in process parameters. The code stimulates a multi-loop system including the reactor vessel, hot and cold leg piping, steam generator (shell and tube sides), and the pressurizer. A neutron point kinetics model is used and the reactivity effects of the moderator, fuel, boron, and rods are included. The secondary side of the steam generator is modeled as a homogeneous saturated mixture. Protection and control systems are simulated, as well as the Safety Injection System. The calculation of the secondary side break flow is based on the Moody critical flow correlation (Reference 42) with fl/D=0.

6.2.1.3.10.3.2 Definition of Cases

The postulated break area can have competing effects on blowdown results. Larger break areas result in larger break mass flow rates. However, larger breaks also result in earlier generation of protective trip signals following the break and a reduction of both the power reduction by the plant and amount of high energy fluid available to be released to the containment.

To determine the effects of plant power level and break area on the mass and energy releases from a ruptured steam line, a spectrum of cases have been evaluated. For plant power levels of 102%, 75%, 50%, 25%, and 0% of the Engineered Safeguards Design (ESD) rating, 4 break sizes have been defined.

1. A full double-end rupture (DER) of main steam line. Note that integral steam generator flow restrictors limit the maximum break size to 1.4 ft^2 in any 1 steam line.
2. A large DER having an area just larger than that at which water entrainment occurs.
3. A small DER having an area just smaller than that at which water entrainment occurs.
4. A small split rupture defined as the largest break size in which the isolation signals must be generated by high containment pressure signals and result in no water entrainment on the break effluent.

Table 6.2-47a shows the steam line break mass and energy release to containment cases which were analyzed. Note that, at full power, no entrainment was predicted in any of the DER cases. However, full power large and small DER break sizes were analyzed, both with no entrainment, to provide a sensitivity. For the steam line break mass and energy releases to containment cases analyzed, a number of failures have been considered either individually, or in combination with other failures. The failures considered are: failure of the emergency feedwater runout control

system to function, failure of a single train of the Safety Injection System, and failure of a main feedwater isolation valve to close.

Failure of a main steam isolation valve to close has not been explicitly considered as part of the mass and energy release calculation, but is included separately with the containment response portion of this analysis.

6.2.1.3.10.3.3 Mass And Energy Release Calculation Assumptions

The key assumptions made in the calculation of mass and energy releases for determination of the containment response analysis are discussed below.

6.2.1.3.10.3.3.1 Reactor Coolant System

Table 6.2-46b identifies the nominal plant design parameters considered in this analysis.

Initial Power Level

Steam line breaks can be postulated to occur with the plant in any operating condition ranging from zero to full power. Since steam generator mass decreases with increasing power level, breaks occurring at lower power levels will generally result in a greater total mass release to containment. However, because of increased stored energy in the primary plant, increased heat transfer in the steam generator, and additional heat generation in the fuel, the energy release to the containment from breaks postulated to occur while at power, may be greater than for breaks occurring with the plant at a zero power condition. Additionally, steam pressure and the dynamic conditions in the steam generators change with pressure and the dynamic conditions in the steam generators change with increasing power and have a significant influence on both the rate of blowdown and the amount of moisture entrained in the fluid leaving the break.

Because of the opposing effects (mass versus energy release) of changing power level on steam line break releases, no single power level can be singled out as a worst case initial condition for containment response following a steam line break. Therefore, several different power levels from zero to full power conditions were investigated.

In general, the plant initial conditions for each case are assumed to be at the nominal value, with appropriate uncertainties included. Table 6.2-46c identifies the values assumed for RCS flowrate, pressurizer pressure, RCS vessel average temperature, pressurizer water volume, steam generator water level, and feedwater enthalpy corresponding to each power level analyzed.

Core Decay Heat

Core residual heat generation assumed is based on the 1979 ANS Decay Heat + 2σ model.

Reactor Coolant Metal Heat Capacity

As the primary plant cools, the temperature of the primary coolant drops below the temperature of the reactor coolant piping, the reactor vessel, and the reactor coolant pumps. As this occurs, the heat stored in the metal is available to be transferred to the faulted steam generator. The effects of stored heat in the RCS metal mass are included in the results using conservative thick metal masses and heat transfer coefficients. However, stored heat does not have a major impact on the calculated mass and energy releases.

Core Reactivity Coefficients

Conservative core reactivity coefficients corresponding to end-of-cycle conditions were chosen to maximize the reactivity feedback effects resulting from the steam line break. Use of maximum reactivity feedback maximizes the potential for a post trip return to power, this conservatively maximizes heat transfer to the steam generator. The most reactive control rod assembly assumed to be stuck out of the core.

Rod Control

The rod control system was assumed to be in manual operation for all analyses.

6.2.1.3.10.3.3.2 Secondary System

Main Feedwater System

The rapid depressurization which occurs following a steam line rupture typically results in large amounts of water being added to the steam generators through the Main Feedwater System. Rapid closing feedwater control valves in the main feedwater lines limit this effect. The feedwater addition which occurs prior to closing of the feedwater line control valves influences the steam generator blowdown in several ways. First, the rapid addition increase the amount of entrained water in large break cases by lowering the bulk quality of the steam exiting the rupture. Secondly, because the water entering the steam generator is subcooled, it lowers the steam pressure thereby reducing the flow rate out of the break. As the steam generator pressure decreases, some of the fluid in the feedwater lines downstream of the control valves will flash into the steam generators providing additional secondary fluid which may exit out the rupture. Finally, the increased flow causes an increase in the heat transfer rate from the primary to secondary system resulting in greater energy being released out the break. Since these are competing effects on the total mass and energy release, no worst case feedwater transient can be defined for all plant conditions.

In the analysis, the worst effects of each variable have been assumed. For example, moisture entrainment for each break is calculated assuming conservatively small feedwater additions such that the entrained water is minimized. Determination of total steam generator inventory, however, is based on conservatively large feedwater additions as described below.

For double-ended-ruptures, main feedwater flow to the intact steam generators was modeled by assuming a constant feedwater flow until feedwater isolation. This minimizes the fluid inventory in the intact generators at the time of isolation, which reduces their cooling effect. This conservatively maximizes the energy which must be released through the break. The mass of

feedwater added to the affected steam generator prior to feedline isolation is based upon the conservative assumption that the feedwater flow is at pump runout for the full-time period from initiation of the break until feedline isolation is complete. Feedline isolation may be provided by either the feedwater isolation valve or closure of both the feedwater regulating valve and the feedwater bypass control valve. The total response time of 10 seconds includes a 1.5 second instrument response time and 8.5 second valve stroke time.

For the split breaks, feedwater flow to all generators was increased proportionally with the steam releases from the steam generators.

Following feedwater isolation, as the steam generator pressure decreases, some of the fluid in the feedwater lines downstream of the isolating valve may flash to steam if the feedwater temperature exceeds the saturation pressure. This unisolatable feedwater line volume is an additional source of high energy fluid that was assumed to be discharged out of the break and is conservatively maximized in this analysis.

Emergency Feedwater System

Generally, within the first 30 seconds following a steam line break, the Emergency Feedwater System will be initiated on any 1 of several protection system signals. Addition of emergency feedwater to the steam generators will increase the secondary mass available for release to containment as well as increase the heat transferred to the secondary fluid. The emergency feedwater flow rates were developed with the following conservatisms incorporated. The flow rates to the faulted loop were assumed to be conservatively high, maximizing the available mass for release to containment, and flow rates to the intact loops were assumed to be conservatively low, minimizing the available mass for secondary side heat removal.

The Emergency Feedwater System is designed to automatically isolate flow to the faulted steam generator and to limit flow to the faulted steam generator to less than 1000 gpm. With proper operation, emergency feedwater flow to the faulted generator is not more than 1000 gpm and generally automatically terminated within 48 seconds of detecting high flow to a depressurized SG. For conservatism, however, the emergency feedwater flow to the faulted generator was assumed to be 200 gpm until operator action is taken to terminate flow.

Steam Generator Fluid Mass

Conservative initial steam generator masses were used in all of the cases analyzed. The initial masses for the faulted steam generator were calculated as the mass corresponding to the programmed level + 5% of narrow range span. The initial masses for the intact steam generators were calculated as the mass corresponding to the programmed level -5% of narrow range span. Although the effect is not significant, this conservatively maximizes the secondary inventory available for release to containment, while minimizing the heat transfer capability of the intact steam generators.

Steam Generator Reverse Heat Transfer

Once steam line isolation is complete, those generators in the intact loops become sources of energy which can be transferred to the faulted steam generator. This energy transfer occurs via the primary coolant. As the primary plant cools, the temperature of the RCS coolant flowing in the steam generator tubes drops below the temperature of the secondary fluid in the intact steam generators resulting in energy being returned to the primary coolant. This energy is then available to be transferred to the steam generator with the broken steam line. The effects of reverse steam generator heat transfer are included in the results.

Break Flow Model

Piping discharge resistances were not included in the calculation of the releases from the steam line ruptures (Moody, Curve, Reference 42, for an fl/D = 0 was used).

6.2.1.3.10.3.3.3 Protection System

The protection systems available to mitigate the effects of a main steam line break accident inside containment are listed below along with the corresponding actuation signals modeled. The setpoints and delay times modeled in this analysis are provided in Tables 6.2-46d, 6.2-47a, and 6.2-47b.

Reactor Trip

The following reactor trip signals were modeled in this analysis:

- Low pressurizer pressure
- Safety Injection System actuation
- Overpower ΔT
- High-1 containment pressure

Safety Injection

The following safety injection signals (SIS) were modeled in the analysis:

- Low pressurize pressure
- Low steam line pressure
- High-1 containment pressure

Steam Line Isolation

Main steam isolation valve actuation was modeled following receipt of any of the following:

- Low steam line pressure
- High-2 containment pressure

Feedwater Isolation

The following feedwater system isolation signals were modeled in this analysis:

- Low pressurizer pressure
- Low steam line pressure
- High-1 containment pressure

6.2.1.3.10.3.3.4 Safety System Failure Considerations

To minimize the number of cases to be analyzed, multiple failures were assumed in many, but not all, of the steam line break mass and energy release to containment cases analyzed. The following failures in the mass and energy release calculations are postulated which may significantly affect the containment results. The failure of a main steam isolation valve has been considered separately in the containment response analysis.

Failure of One Train of the Safety Injection System

A minimum Safety Injection System (SI) flow rate corresponding to the failure of one safety injection train was assumed in this analysis. A minimum SI flow is conservative since the reduced boron addition maximizes a return to power resulting from the RCS cooldown. The higher power generation increases heat transfer to the secondary side, maximizing both mass and energy flow out of the break. The delay time to achieve full SI flow was assumed to be 27 seconds.

Failure of Feedwater Isolation Valve (FWIV) in Faulted Loop

If the FWIV in the feedwater line to the faulted steam generator is assumed to fail in the open position, main feedwater would continue from the condensate pumps until isolation is provided via closure of the feedwater regulating valve and feedwater bypass control valve. Also, the unisolatable feedwater line volume will increase by the volume of the feedwater line between the isolation valve and the feedwater regulating valve and bypass control valve. This additional inventory would then be available to be released to containment.

Failure to Automatically Isolate Emergency Feedwater

The Emergency Feedwater System is designed to isolate emergency feedwater flow to the faulted steam generator via closure of control valves. Failure to automatically close a control valve to the faulted generator results in the addition of up to 1000 gpm of emergency feedwater flow to the faulted generator until operator action is taken to terminate the flow. The increased emergency feedwater flow conservatively provides additional steam generator inventory, which is available to be released to the Reactor Building. Furthermore, the increased emergency feedwater flow serves to maintain a higher pressure in the faulted generator, thus providing additional driving force for the mass and energy release.

Failure of Emergency Diesel

Failure of an emergency diesel to start results in the loss of one motor driven emergency feedwater pump and one train of the SI within the mass and energy calculations. Within the containment response analysis, one train of RB cooling would also be lost.

Failure of Electrical Channel

A loss of an electrical channel (CH-A) is postulated at event initiation. Within the mass and energy calculations, this results in loss of power to the feedwater control valves, feedwater isolation valves, and the main steam isolation valves; prevents the startup of one emergency diesel thus resulting in the loss of one motor driven emergency feedwater pump and one train of the SI; and prevents automatic isolation of emergency feedwater to the faulted SG. Within the containment response analysis, one train of RB cooling would also be lost.

Failure of Main Steam Line Isolation Valve (MSIV)

Failure of the faulted loop MSIV delays isolation of the intact loops and results in a larger unisolatable steam line volume. Prior to steam line isolation, all loops are feeding the break. Steam line isolation terminates fluid discharge from the intact steam generators while the faulted steam generator continues to blowdown. After isolation, reverse flow continues until the unisolatable volume is depleted. This failure is not explicitly considered within the mass and energy release, but is considered separately in the containment response analysis.

6.2.1.3.10.3.4 Results

Table 6.2-47a provides a summary of the mass and energy cases analyzed for use in the MSLB containment analysis. For each case, the initial NSSS power level, break size, single failure(s) assumed (if any), and entrainment assumptions are identified. The time of reactor trip (along with the actuation signal), feedwater isolation, and steam line isolation are provided for each case. Note that for cases that credit High-1 containment pressure or High-2 containment pressure the actuation times were determined iteratively from preliminary LOFTRAN and containment response analyses and confirmed in the final analysis.

Furthermore, in order to reduce the number of iterations during this process, the time to reach the High-1 setpoint was delayed until the High-2 setpoint was reached for the purpose of safeguards actuation. This delays actuation of the Safety Injection System and feedwater isolation, as well as reactor trip.

Tables of mass and energy release rates for the limiting containment pressure case and limiting containment temperature case are provided on Tables 6.2-48a and 6.2-48b, respectively.

6.2.1.3.11 Minimum Containment Pressure Analysis for Performance Capability Studies of Emergency Core Cooling System

A conservatively low containment backpressure is calculated for each LOCA transient in the Large Break LOCA analysis, presented in Section 15.4.1. The containment backpressure for the transient that produced the analysis PCT result is provided in Figure 15.4-21. The containment backpressure is calculated using the methods and assumptions described in Section 15.4.1.1.4.2. Input parameters including the containment initial conditions, net free containment volume, and starting time and number of containment cooling systems used in the analysis are presented in Tables 15.4-1b and 15.4-1c. Passive heat sink material thickness and surface area are shown in Table 6.2-60.

6.2.1.4 Testing and Inspection

Containment leak rate testing is discussed in Section 6.2.6.

Testing and inservice inspection requirements for the Reactor Building are discussed in Section 3.8.1.7.

6.2.1.5 Instrumentation Requirements

The instrumentation to monitor containment conditions and perform the post accident monitoring function is discussed in Section 7.5. In addition, Reactor Building pressure instrumentation channels serve as inputs to both the Reactor Protection System and Engineered Safety Features Actuation System, discussed in Sections 7.2 and 7.3, respectively.

Qualification of safety related balance of plant instrumentation inside the Reactor Building is based upon the peak environmental conditions following the postulated design basis accident main steam line break and is discussed in Section 3.11.2.2.2. Qualification parameters are presents in Table 3.11-3.

Qualification of NSSS safety related instrumentation inside the Reactor Building is discussed in Section 3.11.2.2.1.

6.2.1.6 Materials

Safety-related coating systems are used for concrete and carbon steel surfaces. Both of these coating systems satisfy the quality assurance requirements of Reference 13. In addition, the selected coating manufactures have documented test results certifying compliance with References 14 and 15 requirements for coating materials used inside containment.

The estimated quantity of unqualified paint inside containment is covered in calculation DC03190-025.

The amount of exposed organic material exposed directly to the containment atmosphere is considered negligible.

Metallic material for engineered safety features equipment are discussed in Sections 6.2.3.6, 6.2.4.5 and 6.2.5.6.

6.2.2 Reactor Building Heat Removal Systems

Post accident Reactor Building heat removal is provided by 2 systems acting in concert. One (1) system is the Reactor Building Spray System and the other is the Reactor Building Cooling System. Each of these systems also performs other functions. The Reactor Building Spray System removes iodine, which may be released from the core following a loss of coolant accident (LOCA) (see Section 6.2.3). The Reactor Building Cooling System removes heat from the Reactor Building during normal operation. The reactor building cooling system is composed of four dual-speed fan and coil Reactor Building Cooling Units (RBCUs) arranged in two Groups, with a pair of RBCUs constituting each Group associated with a train. Under accident conditions, each fan in the RBCU is powered by a Class 1E emergency bus, and its associated coil is cooled by a Service Water system train. The accident analysis credits only one RBCU in only one Group operating at slow speed. This system also functions to remove particulate fission products from the post accident Reactor Building atmosphere as discussed in Section 6.5.1.

6.2.2.1 Design Bases

6.2.2.1.1 Post Accident Reactor Building Heat Removal Systems Design Bases

The design bases for the post accident Reactor Building heat removal systems are as follows:

1. The 2 systems, acting in concert, with the most disabling single failure as discussed in item 2 below, will limit the peak Reactor Building pressure to less than the Reactor Building design pressure of 57 psig. The heat sources considered in this analysis are discussed in Section 6.2.1.3.
2. The most disabling single failure is considered to be a loss of offsite power and failure of one onsite diesel generator to operate. This situation will result in the operation of one Reactor Building Spray Subsystem and one Reactor Building cooling unit. Other single failures will allow at least this amount of equipment to function.
3. Equipment inside the Reactor Building which is required to remove post accident heat is qualified to operate in the post accident Reactor Building environment.
4. Portions of these systems which are required to remove post accident heat are designed to withstand the most severe post accident pressure transient.
5. Portions of these systems which are required to remove post accident heat are qualified to experience the safe shutdown earthquake (SSE) without loss of function.
6. Portions of these systems which are required to remove post accident heat are protected from the dynamic effects of pipe rupture in accordance with the criteria presented in Section 3.6.
7. Reactor Building heat removal systems are designed for periodic testing and inspection.
8. Reactor Building heat removal systems are Seismic Category 1. The Reactor Building Spray System components are Safety Class 2a except the sodium hydroxide storage tank and

related discharge lines which are Safety Class 2b. The Reactor Building Cooling System components are Safety Class 2b.

9. The Reactor Building heat removal systems are designed to satisfy containment depressurization requirements discussed in Section 6.2.1.
10. At strategically identified local high points, the Reactor Building Spray System is provided with indicating air-traps and vented orifices to ensure the Reactor Building Spray System remains void free (reference NRC GL 2008-01).

6.2.2.1.2 Reactor Building Cooling System Design Bases for Normal Operation

Design bases for the Reactor Building Cooling System during normal operation are as follows:

1. Operation of any 3 Reactor Building cooling units during normal power operation maintains average Reactor Building ambient air temperature at, or below, 120°F.
2. Operation of any 2 Reactor Building cooling units under loss of offsite power conditions is sufficient to remove the residual heat to bring the plant into a hot or cold shutdown condition.
3. Operation of any 2 Reactor Building cooling units during containment leak rate tests maintains an average Reactor Building ambient temperature with minimum stratification.
4. The system duct arrangement results in general Reactor Building air circulation and provides for discharge of cooled air in close proximity to suction inlets of various subsystems. These subsystems are described in Section 9.4.
5. System instrumentation provides for continuous monitoring of equipment and sounding of alarms to alert the operator to high vibration, smoke, high temperature, abnormally high coil condensate rate, or motor trip.

6.2.2.2 System Design

6.2.2.2.1 Reactor Building Spray System

This section discusses the design of the Reactor Building Spray System with respect to Reactor Building heat removal and its functions in common with fission product removal. Features that relate solely to fission product removal are described in Section 6.2.3.

The system diagram for the Reactor Building Spray System is provided as Figure 6.2-46. The system consists of 2 independent and redundant subsystems, each consisting of a pump, 2 Reactor Building sump isolation valves, 1 refueling water storage tank (RWST) isolation valve, 1 sodium hydroxide storage tank isolation valve, 1 discharge isolation valve, 3 ring headers, 165 spray nozzles, and connecting piping, manual maintenance valves, and check valves. The items shared by the 2 subsystems are the injection water source, the RWST; sodium hydroxide storage tank; and the full flow test line to the RWST. There are no shared active components. This design ensures single failure protection. Reactor Building Spray System component data are presented in Table 6.2-49. A single failure analysis is provided by Table 6.2-50.

6.2.2.2.1.1 System Design Features

Three (3) spray header and nozzle assemblies are provided for each spray subsystem. The headers are stainless steel ring manifolds that uniformly distribute the water mixture to each spray nozzle. Each spray subassembly has 165 spray nozzles and provides full coverage. Five (5) nozzles are located on the inner header and 80 on each of the middle and outer headers. The nozzles are attached to the headers with screwed nipple connectors. Figure 6.2-47 shows the spray header arrangement and nozzle orientation. The sizes and locations of headers inside the Reactor Building are listed Table 6.2-51.

The location of the Reactor Building Spray System ring headers within the Reactor Building dome and the position of the spray nozzles in the ring headers provide for 100% spray coverage of the operating floor with both spray loops operating. For the case of minimum engineered safety features, i.e., only one spray loop available, 93% of the Reactor Building at the operating floor level is covered by the spray.

During both normal and post accident plant operation, the Reactor Building cooling units and associated discharged ductwork supply cooling air flow to the unsprayed regions below the operating floor. This cooling air flow establishes a connective flow path whereby air or air/steam mixtures from the unsprayed regions and from inside the secondary shield walls are directed upward into the suction areas of the Reactor Building cooling units. Thus, the Reactor Building cooling units provide, for the normal or accident case, the required mixing and recirculation of Reactor Building atmosphere for the volumes between and lowest elevation inside the Reactor Building and the elevation of the Reactor Building cooling units (approximately 67 feet above the operating floor).

The spray nozzles are one piece, stainless steel units that deliver water at a nominal rate 15.2 gpm with a pressure differential of 40 psi across the nozzle. Flow is delivered in a hollow cone pattern with an included angle of approximately 60 degrees.

Orifices are located in each individual spray header and the common header supply line to compensate for the differences in elevation of the different headers and to balance Reactor Building Spray System characteristics with pump characteristics.

In the event of LOCA, water from the spray nozzles and water spilled through the break in the Reactor Coolant System is collected in either the A or the B Reactor Building recirculation sumps. Each of these two sumps has a suction line to one residual heat removal (RHR) pump and a suction line to one Reactor Building spray pump. Each recirculation sump is irregular in shape as shown in Figures 1.2-3 and 1.2-4. The overall plan dimensions of each sump are approximately 17 feet by 28 feet. Each of the recirculation sumps is surrounded by a 6 inch high curb. One side of Sump B abuts directly against the adjacent secondary compartment wall and does not have the 6 inch curb. The basement floor of the Reactor Building is at elevation 412’. The floor level of the recirculation sump area is at elevation 408’. There are four individual deep sump pits for the RHR and spray pump suctions – one RHR and one spray deep pit located in each of Sump A and Sump B. The deep pits are 4 foot by 4 foot in plan extending down to elevation 400’. The centerline of the suction pipe within each deep pit is at elevation 402’.

A schematic vertical section through a typical deep sump pit is shown in Figure 6.2-48. A removable welded stainless steel bar grating walkway is provided over the sump for a personnel access walkway and to support maintenance in the area. The grating is designed to remain in place during plant operation. The top of the grating walkway cover over the sumps is at elevation 412'-9". A large opening is provided through the grating to ensure adequate flow to the pumps through the opening for the postulated worst case assuming full blockage of the grating by debris transported to the sump following the postulated pipe break.

Each of the four deep sump pits is protected by a strainer assembly against the entry of potential types and quantities of debris generated as the result of hypothetical, postulated LOCA pipe break events. The RHR and Spray strainer modules are interconnected by a cross-duct to allow water to flow from one module to the other conservatively assuming one of the strainer modules becomes heavily blocked by postulated debris.

Each strainer assembly is composed of a single square module, the header box, equipped with 44 hollow fins, 11 on each of the 4 sides of the strainer header box. The fins are connected laterally to the approximately 4.75 foot high sides of the header box located directly over each sump pit. The fins are of varied length designed to fit within the available space in the sump. Each vertically oriented strainer fin consists of 18 gauge stainless steel sheet, perforated with 1/16 inch diameter holes. The performance of the strainer is enhanced by the extremely low approach velocity to the perforated fins of less than 0.1 inch/second. The area ratio of holes is about 41 percent and the surfaces of the fins are corrugated to increase their surface area. As the water level rises in the strainer during filling, air can escape through the fins and through the vent holes provided at the top of the strainer header box. This design ensures that there is no risk of air ingestion due to trapped air pockets during filling.

The total strainer surface areas provided are:

Sump A:	A RHR	-	1404 sq ft	Total Sump A: 2938 sq ft
	A Spray	-	1534 sq ft	
		-		
Sump B:	B RHR	-	1251 sq ft	Total Sump B: 2380 sq ft
	B Spray	-	1129 sq ft	

The design of both the Sump A and Sump B strainers includes a closed cross duct connecting the RHR and Spray header boxes within the sump. The cross duct design consists of 1/4 inch thick stiffened stainless steel plates. The cross duct provides a flow area approximately 5 inches high by 30 inches wide for flow between the interior of the two header boxes. The cross duct connection to the header boxes is located on the side and near the top of the header boxes. The cross duct is designed and fabricated to the same criteria as the strainers. The cross duct serves to provide additional redundancy to the strainer design for both the Sump A and Sump B. For a postulated event where the fin strainers on either the RHR or Spray sides of the sump are assumed to be

blocked by debris generated by the postulated LOCA pipe break event, the flow into the unblocked strainer header box provides sufficient recirculation flow through the cross duct to satisfy the NPSH requirements for the pumps on both the RHR and Spray sides of that sump.

The header boxes, strainer fins, and cross ducts are designed, fabricated, and installed in accordance with ASME Code and Seismic Category 1 requirements. Each strainer fin bank consisting of 11 fins is supported as an integral unit by bolting each fin to a horizontal truss located along the top and also along the bottom of each fin bank. The trusses are bolted to the header box assemblies. Each fin is also securely pinned at the bottom and bolted at the top to the header box assembly. Adjustable vertical supports for each fin bank are provided beneath the horizontal truss at the bottom of the fin bank to the sump floor at elevation 408'. The top of each header box consists of 3/8 inch stainless steel plate with stiffeners. A solid 3/8 inch thick hinged hatch cover plate for personnel access down into the deep pit is secured to the top of each header box by bolting all four sides of the personnel access hatch plate to the welded flange assembly on the header box top plate.

The bottom surface of each hatch cover plate is designed and fabricated to fit tightly with no gap when secured with the bolts against the continuous bearing bar located around the perimeter of the opening beneath the hatch cover plate. The continuous tight metal to metal closure with no gap precludes any potential debris entry without the need for any gasket material under the hinged cover plate.

Vortex formation was investigated at the controlling locations including at the engineered opening through the grating walkways over the sumps and also above the strainers. The controlling location is at the engineered opening through the grating where the cross section area is smaller and flow rate larger. The grating is assumed to be fully blocked by debris and the combined RHR and Spray streams flow through the engineered opening.

At the start of recirculation, the water level is assumed to be at the controlling minimum elevation of 414.6 feet corresponding to a small break LOCA. This is conservative in that the debris assumed to be blocking flow through the walkway grating could not be generated by a postulated small break LOCA rather only by postulated large break LOCA. The calculated Froude number corresponding to the flow rate and associated velocity through the engineered opening for this conservative case is 0.241. The critical submergence 15.3 inches maximum at the engineered opening is less than the minimum submergence of 22.2 inches to the engineered opening for the small break LOCA. Therefore, no air ingestion down into the sump through vortexing will occur.

Sump design features that prevent the generation of flow irregularities include:

1. Perforated fin and header design. As the water level rises in the strainer during filling, air can escape through the fins and also through 3/8 inch diameter vent holes located close to the top of the strainer header box. As the sump pit fills, a small air pocket may form in the top of the strainer header box. To allow the air pocket to escape, each strainer assembly is designed with 24 vent holes of 3/8 inch diameter close to the top of the strainer header box. Vent holes are covered by perforated sheet having 1/16 inch diameter holes. The pumps are activated well after the strainers are fully submerged and any air pocket within the strainer assembly has been displaced by water. As a result, ingestion of an air pocket into the pump intake is not considered to be a credible scenario. Air ingestion through the vent holes is similarly considered an incredible scenario due to the submergence of the strainers at the holes being much greater than the critical submergence at the holes.
2. The generation of vortices within the 4 foot by 4 foot plan deep sump pit standpipe at the inlet to the Reactor Building Spray System suction piping is prevented by the following:
   a. An established fluid velocity within the standpipe of less than 1 foot per second.
   b. A minimum submergence from the suction piping inlet to the minimum water level at the start of recirculation of at least 12.6 feet.
3. Generator of flow disturbances at the suction piping inlet is minimized by the inclusion of a 24 inch by 12 inch reducer which provides for a gradual change in fluid velocity between the standpipe and suction piping.
4. The location of the Reactor Building spray pumps relative to the top of the recirculation sumps (35 feet, minimum elevation difference) provides the fluid system conditions that ensure dissipation of any flow irregularities that might be generated within the sumps. These positive fluid system conditions are as follows:
   a. A minimum elevation head of 35 feet of water at the pump suction nozzles.
   b. The significant lengths of piping (75 and 100 feet) from the sump outlets to the pump suction nozzles.

Design of the RWST includes an internal vortex baffle at the entrance to the 20 inch suction connection through which cooling water is supplied to the RHR, safety injection Reactor Building spray pumps during operation in the safety injection mode. This internal baffle consists of a 4 foot by 4 foot by 4 foot, stainless steel box with open sides, which directs cooling water flow into the 20 inch suction nozzle from 2 sides along the horizontal centerline of the baffle. This designed control of the flow path into the 20 inch suction nozzle prevents formation of vortices even under conditions of low fluid level in the RWST.

The recirculation water enters the strainer fins through the perforated steel sheet (1/16 inch diameter holes) and flows horizontally within the hollow fin corrugations into the header box. Due to the extremely low approach velocity to the perforated fins of less than 0.1 inches/second it is expected that most of the entrained particulate debris falls out of the flow stream to the sump floor. The top of the sump header box consists of stiffened 3/8 inch plate with a 3/8 inch plate

single leaf bolted personnel hatch cover plate to permit entry into the deep sumps for inspection. All material in the sump area, including liner plate, strainer assembly, deep pit access ladder, etc., is stainless steel to prevent corrosion degradation.

Debris which washes down to the sump and passes through the strainer is evaluated for both blockage and erosion of downstream systems and components. The size of the debris is limited by the 1/16 inch round holes in the perforated plate strainer. Systems and component downstream effects are analyzed based on the methodology in WCAP-16406, Rev. 1 (Reference 48). The analysis was completed as part of the response for Generic Letter 2004-02.

The potential for clogging the sump screens with debris is reduced by minimizing the use of non-metallic, high temperature insulation and by not using displaceable components, such as sand plugs, to provide vent area.

For a discussion of the potential for sump screen clogging, refer to Section 6.3.2.6.1.

Compliance with Regulatory Guide 1.82 is discussed in Appendix 3A.

High temperature insulation used inside the Reactor Building is generally stainless steel, reflective type insulation. Insulation encased in stainless steel is used on the sloping portion of the 6 reactor vessel nozzles and between the pipe restraint collars and Reactor Coolant System piping in the vicinity of the primary shield.

There are 2 independent pipe lines connecting the sump to the suction of the spray pumps. These lines are independent of the 2 lines for the Residual Heat Removal System. The lines from the sump can be isolated by remote, manually controlled, motor operated valves. These valves have relief valves installed to prevent pressure locking due to thermal expansion of fluid trapped between the double-disc gate following closure. Each line is enclosed in a concentric guard pipe which is connected to a protective chamber completely surrounding the isolation valve closest to the Reactor Building.

The guard pipe and protective chamber collect any leakage due to a passive failure of the sump line up to and including the first isolation valve and thus prevent draining the sump to the Auxiliary Building. Passive failures beyond the first isolation valve can be isolated by the first isolation valve The guard pipes and protective chambers are designed to a pressure of 57 psig at a temperature of 300° F.

All outdoor system piping is insulated and has heat tracing. The outdoor sodium hydroxide storage tank is neither insulated nor heat traced. This tank contains a 20 to 22% sodium hydroxide solution which is liquid at temperatures above 13° F.

6.2.2.2.1.2 System Operation

During normal plant operation, the Spray System is in standby condition with the suction aligned to receive water from the RWST. Operation of the system is initiated automatically following a LOCA or MSLB by signals from the Engineered Safety Features (ESF) Actuation System when

the Reactor Building pressure increases to the actuation set point. The Spray System can also be started manually from the control room by the operator. A description of the ESF actuation signals is presented in Section 7.3.

If there is a spray actuation signal, the Reactor Building spray pumps are loaded onto the onsite diesel generators following a loss of offsite power (see Chapter 8). The total time for RB Spray water to start being delivered through the spray nozzles to the RB atmosphere is 47 seconds following LOCA initiation. This includes a 10 second start time for EDGs, 5 seconds for the spray pump to reach full capacity (during this 5 second pump acceleration time, no filling of lines is assumed), and 32 seconds to fill the RB spray line up to the nozzles. For conservatism, it is assumed in the Reactor Building pressure analysis that spray starts 52 seconds after the LOCA occurs.

Each spray subsystem is started by separate ESF containment isolation Phase A and spray actuation signals. Normally, both subsystems operate; however, they are independent and can operate individually. The design basis for Reactor Building heat removal is one spray subsystem operating in conjunction with one Reactor Building cooling unit (with one RHR pump and one charging pump providing emergency core cooling water).

During the injection phase following a LOCA, the spray pumps receive fluid from the RWST and sodium hydroxide storage tank. The solutions are carried through the pump discharge lines to the spray headers and are then sprayed into the Reactor Building atmosphere through the spray nozzles. The spray is collected in the bottom of the Reactor Building with water from ECCS and the Reactor Coolant System in the Reactor Building recirculation sumps. During the recirculation phase, the spray pumps may take suction from the sumps, in the Reactor Building.

The spray droplets absorb heat as they fall through the steam-air atmosphere in the Reactor Building, thereby reducing Reactor Building atmosphere temperature.

A nominal spray flow of 2500 gpm is provided by each spray subsystem. When the system is receiving water from the RWST (injection phase) the flow nominally includes 50 gpm of a 20 to 22 weight percent solution of sodium hydroxide. This flow (nominal 2500 gpm) is delivered into the Reactor Building through 165 nozzles at a rate of 15.2 gpm per nozzle. The nozzles are arranged on ring headers in the top of the Reactor Building such that the spray from each subsystem covers essentially the same volume.

There are 4 significant operating combinations of Reactor Building spray pumps and Emergency Core Cooling System (ECCS) pumps:

1. Reactor Building Spray System design case: 1 Reactor Building spray pump; 1 residual heat removal (RHR) pump; and 1 charging pump operating (loss of offsite power and malfunction of one emergency diesel generator).
2. Normal case: 2 Reactor Building spray pumps; 2 RHR pumps; and 2 charging pumps (all ECCS pumps) operating.
3. One (1) Reactor Building spray pump inoperable, all ECCS pumps operating.

4. One (1) RHR pump operating, 2 charging pumps and 2 Reactor Building spray pumps operating

The sodium hydroxide solution is gravity fed into the Reactor Building spray pump suction lines. The system is so designed that the sodium hydroxide storage tank empties at approximately the same time as does the refueling water storage tank (RWST) (e.g., the rate of change, proportional to the initial level, of the 2 liquid levels is the same) for Cases 1 and 2, above. This provides nominally constant sodium hydroxide flow rates for these 2 cases. The design flow rates are approximately 50 gpm to the single operating spray pump for Case 1 and approximately 45 gpm/pump for Case 2.

In Case 3, the initial flow of sodium hydroxide to the single operating Reactor Building spray pump is approximately 55 gpm. However, at this rate of flow from the sodium hydroxide storage tank, the liquid level lags the drop in liquid level in the RWST, since the equilibrium sodium hydroxide flow rate for this case is 73 gpm. (The equilibrium flow rate is the flow rate at which the sodium hydroxide storage tank level drops at the same proportional rate as does the RWST liquid level. This is the stable operating condition for the Reactor Building Spray System. The sodium hydroxide flow rate is unstable under any other condition and the sodium hydroxide flow rate gradually changes toward the equilibrium rate.) As a result, pressure head differential begins building up on the sodium hydroxide side of the Reactor Building Spray System at the junction of the sodium hydroxide and RWST lines. However, as the total pressure head on the sodium hydroxide side must balance the total pressure head on the RWST side of the junction, the sodium hydroxide flow rate increases as necessary to create an additional flow loss to offset the differential pressure head. The flow rate continues to increase as the system adjusts toward a stable operating condition at the equilibrium flow rate.

The rate at which the sodium hydroxide flow increases depends upon the flow impedance of the sodium hydroxide circuit from the sodium hydroxide storage tank to the junction with the line from the RWST. If the impedance is very low, the flow rate increases very rapidly to the equilibrium rate. An increase in the impedance slows the rate of change of flow rate. Thus, the rate at which the sodium hydroxide flow rate increases from the initial rate can be controlled through discrete design of the impedance characteristics of the sodium hydroxide circuit. Flow characteristics of the circuit from the RWST must also be properly designed. Impedance elements must be limited to characteristics and locations that do not reduce the minimum available net positive suction head at the pump to less than the minimum required, or to zero, anywhere in the circuit from the RWST to the Reactor Building spray pumps.

Properly sized pressure loss inducing orifices are located in the common and individual sodium hydroxide lines (in conjunction with orifices in the individual spray pump lines from the RWST) to create sufficient and properly distributed flow impedance such that, in Case 3, flow increases to a maximum rate of 65 gpm at the end of the injection phase (“lo-lo” level in the RWST).

In the fourth case, the initial sodium hydroxide flow rate is approximately 42 gpm per Reactor Building spray pump. The equilibrium flow rate for this case is 34.5 gpm per pump. In this case, the liquid level in the sodium hydroxide storage tank drops at an increased rate compared to the liquid level in the RWST. The result is the reverse of the situation in Case 3. The sodium

hydroxide flow rate decreases from the initial rate toward the equilibrium rate as the injection phase continues.

Upon receipt of the RWST “lo-lo” level signal in conjunction with the safety injection signal, the Reactor Building recirculation sump isolation valves (3004A & B and 3005A & B) automatically open. (See Section 7.6.11 for a discussion of the switch over logic.)

A design evaluation of the Reactor Building Spray System has been performed to track the fluid levels in the refueling water storage tank and sodium hydroxide tank during emergency safeguards operation. Refer to Section 6.2.2.3.1.4.

Sump water temperature data shown by Figures 6.2-6 and 6.2-7 were obtained from results of the transient analyses performed for both the main steam line break and the LOCA. The conservative assumptions applicable to the generation of this data are listed in Section 6.2.1.3.2. One of these assumptions, used in determining the temperature data illustrated by Figure 6.2-7, is that the Reactor Building Spray System is operated for up to 40 days to provide Reactor Building cooling following the design basis LOCA.

During post recirculation operations, the Reactor Building recirculation sump water can be sampled with the normal and Post-Accident Sampling System to monitor the pH. If additional sodium hydroxide is required, the sodium hydroxide feed line valve(s) from the sodium hydroxide storage tank is (are) opened and the sodium hydroxide solution is gravity fed into the Reactor Building spray pump suction line(s). The sodium hydroxide solution will flow into the pump suction line only when the Reactor Building pressure is less than or equal to atmospheric pressure.

A flow test line connecting spray pump discharge lines to the RWST provides a return loop for use in conducting periodic operating tests.

6.2.2.2.2 Reactor Building Cooling System

The system diagram for the Reactor Building Cooling System is provided as Figure 6.2 49. Design and performance data are included on this figure. Plan and elevation drawings of the system ductwork are provided as Figures 6.2 50 and 6.2 51. A single failure analysis is provided by Table 6.2-52.

6.2.2.2.2.1 System Design Features

The system consists of 4 plenums arranged to discharge filtered and cooled air into a common air supply main. The cooling air is further distributed from the supply main to the upper portions of the Reactor Building through supply air outlets in the supply main and to the lower elevations of the Reactor Building through vertical supply ducts connected to the supply main. Non-engineered safety features systems are provided for normal ventilation, cooling and filtering of the Reactor Building atmosphere and for transfer of heat to the Industrial Cooling Water System. These systems are described in Section 9.4.

Each plenum includes moisture separators, high efficiency particulate air (HEPA) filters, filter bypass opening and dampers, cooling coils and an axial flow fan driven by separate high speed and slow speed motors. The moisture separators and HEPA filters are arranged in vertical banks in the plenum. Air enters the plenum through vertical openings in two of the plenum walls or through a bypass opening in the plenum roof if the bypass damper is open. Air entering through the bypass opening is not filtered and passes directly to the cooling coils.

The Reactor Building cooling unit fans operate at high speed during normal periods and at slow speeds during post LOCA periods and during Reactor Building leak rate testing. The units are serviced by cooling water from the Industrial Cooling System during normal periods and by service water during post LOCA or loss of offsite power conditions. For normal operation, 3 out of 4 fans operate. For LOCA, one fan in each train operates.

The plenums are arranged along the perimeter of the Reactor Building with the base of each at elevation 514'. Two (2) of the Reactor Building cooling units are supplied with electrical power from the A channel and the other two from the B channel of the Class 1E electric system.

A single supply and return cooling water main serves the two Reactor Building cooling units powered from the A channel of the Class 1E system. A separate, single supply and return main serves the two units powered from the B channel. These two sets of cooling water mains are separated from each other.

Each Reactor Building cooling unit is provided with lighted service platforms inside the plenums with access doors for inspection, maintenance and replacement of filters, motor and fans. Information on monitoring and control of these units is presented in Section 6.2.2.5.2.

The Reactor Building cooling units are designed and constructed in accordance with the following codes, standards, and guides:

1. Title 10, Code of Federal Regulation, Part 50, Appendices A and B.
2. *Health and Safety Information*, Atomic Energy Commission, Issue No. 306, March 31, 1971.
3. *Standard Test Code For Air Moving Devices*, Air Moving and Conditioning Association, Bulletin No. 210.
4. Boiler and Pressure Vessel Code, Sections III and IX, American Society of Mechanical Engineers, 1973.
5. *Standard Test Code for Sound Ratings, Air Moving Devices,* Air Moving and Conditioning Association, Bulletin No. 300.
6. *Structural Welding Code*, American Welding Society, AWS D1.1 72.
7. Military Specifications MI- F-51079 and MIL-STD-282.
8. *Type Test of Continuous Duty Class 1 Motors Installed Inside the Containment of Nuclear Power Generating Stations*, (Proposed Standard), Institute of Electrical and Electronic Engineers, IEEE 334-1971.

9. *High Efficiency Air Filter Units*, Underwriters Laboratories, Bulletin UL-586.
10. *Air Filter Units*, Underwriters Laboratories, Bulletin UL-900.
11. Regulatory guide 1.52 *Design,* T*esting and Maintenance Criteria for Atmospheric Cleanup System Air Filtration and Absorption Units of Light Water Cooled Nuclear Power Plants* (see Appendix 3A).

6.2.2.2.2.2 System Operation

The automatic change in operating mode from normal to emergency involves changing from motors operating at high speed to motors operating at slow speed, changing the unit cooling water from that supplied by the Industrial Cooling Water System to that from the Service Water System, and automatically closing the Reactor Building HEPA filter bypass damper. The active RBCU discharge valves will automatically align so that 2 of the 4 valves, one per train, will open when their associated RBCU fans are selected to run; the other two valves will close when their RBCU fans are not selected to run. The units, when operating in the normal mode, are tripped upon the receipt of a safety injection or loss of offsite power signal and are then automatically started at slow speed in accordance with the ESF actuation system and the ESF loading sequence of the related emergency diesel generator. A description of the ESF loading sequence is provided in Section 7.3.

In the following discussion, the times given for the occurrence of events are referenced to the time at which the ESF loading sequence gives a start signal to the first electrical load. See Section 7.3 for information on the relationship between this time and the time of occurrence of the input signal which initiates the ESF loading sequence.

The slow speed motors are energized at approximately 25 seconds after the referenced time. An additional 8 seconds are required after energizing the slow speed motor for air flow to reach operating values. Thus, the total “air-side” switchover from normal to emergency operation is completed approximately 33 seconds after the reference time. The safety injection or loss of offsite power signals also initiate closing of the industrial cooling water supply and return valves connected to piping serving the plenum cooling coils. Following receipt of either of these signals, the ESF loading sequence energizes the service water pumps 10 seconds after the reference time and energizes the service water booster pumps 35 seconds after the reference time. The service water booster pumps require approximately 5 seconds after the motor is energized to reach the operating value for water flow. The total “water-side” valve switchover from normal to emergency operation is completed approximately 86.5 seconds after the reference time.

The Reactor Building cooling units can be manually operated from the control room at either high or slow speed. Control room selector switches also determine which one of the 2 A and which 1 of the 2 B electrical power channel units starts in response to an ESF loading sequence signal. The plenum unit HEPA filter bypass damper is in the open position during normal operation and is automatically closed upon receipt of a safety injection signal. Additionally, this damper can be manually opened or closed from the control room during the normal mode of operation. The damper can also be manually closed from the control room during operation in the emergency

mode. The damper fails closed upon loss of electric power. The effects of the HEPA filter upon removal of fission products in the Reactor Building are discussed in Chapter 15.

6.2.2.3 Design Evaluation

An evaluation of the Reactor Building heat removal systems relative to their effect upon the Reactor Building pressure transient analysis is presented in Section 6.2.1.

6.2.2.3.1 Reactor Building Spray System

6.2.2.3.1.1 Net Positive Suction Head to Reactor Building Spray Pumps

It is important that the net positive suction head (NPSH) at the suction of the Reactor Building spray pumps be maintained at or above the minimum required value to assure the long term availability of the pumps. The NPSH available is a function of Reactor Building pressure, water temperature, static head of water, friction losses in the pump suction piping and pressure drop across the sump strainer as follows:

$$NPSH_a = P_c - P_s + \Delta H_z - \Delta H_f - \Delta H_s$$

Where:

$NPSH_a$	=	NPSH available at the pump suction.
P_c	=	Reactor Building pressure.
P_s	=	Saturation pressure of the pumped water.
ΔH_z	=	Elevation pressure due to the height of water above the pump nozzle.
ΔH_f	=	Pressure loss due to friction in the suction line.
ΔH_s	=	Pressure loss across the sump strainer.

The pressure in the Reactor Building (P_c) will always equal or exceed the vapor pressure of the water in the sump because water will evaporate from the sump to increase the vapor pressure of the atmosphere if P_c starts to decrease below P_s. Generally, the partial pressure of the air in the atmosphere will maintain P_c greater than P_s. For conservatism, no containment overpressure is assumed, i.e., $P_c = P_s$. This is consistent with the guidance provided in Regulatory Guide 1.1. The elevation of the pump shaft centerline is 377 feet. The minimum sump water elevation in the Reactor Building during recirculation is 414.6 feet for small break LOCA with water holdup in the reactor vessel cavity. Therefore, the minimum elevation head is:

(414.6 feet - 377 feet) = 37.6 feet

Friction losses are calculated using the runout flow (3300 gpm) rather than the design flow (2500 gpm). The minimum required NPSH at 3300 gpm is 17 feet based on vendor data. Head friction losses through the piping, fittings and valves have been determined and yield a calculated head loss of 5.96 feet for Pump A and 6.16 feet for Pump B (Reference 44). The pressure drop through the sump strainers was determined experimentally by small scale testing with chemical effects from aluminum corrosion precipitants. The maximum pressure drop through the strainer is 4.09 psid at 70° F for the maximum debris loading case.

A summary of the results is as follows:

	NPSH Available (ft)	NPSH Required (ft)	Margin (ft)
Pump A	22.1	17	5.1
Pump B	21.9	17	4.9

Design of the recirculation sumps prevents formation of vortices without the use of vortex suppressors. Plan and elevation drawings of the sump and piping to the Reactor Building spray pumps are provided by Figures 6.2-82 through 6.2-84. Preoperational testing established suction paths through the sump lines to the Reactor Building spray pumps for the purpose of determining the actual piping friction losses at full flow. The as-tested head loss for each train is 4.6 feet (Reference 45).

The potential effects of Reactor Building spray water and reactor blowdown liquid becoming trapped (also called holdup volume) in areas of the Reactor Building and unavailable for post accident recirculation are considered in sump level analysis. Spray flow entering the refueling cavity drains through an 8 inch line to elevation 412' for recirculation. (This drain line is temporarily flanged off during refueling and contains no valves.) Spray flow entering the southern portion of the refueling cavity may drain into the reactor cavity through the reactor cavity seal ring. This is a small gap, so water accumulation in the reactor cavity would be very slow. The spray water may also drain through the access openings for inservice inspection of the reactor vessel “safe-end- welds”. Most of the water flowing into these openings will drain out through pipe sleeves due to a unique baffle arrangement around each reactor vessel nozzle which prevents

drainage to the reactor cavity. Spray flow landing on the 463 ft operating deck drains to the 412' elevation through the equipment hatch and two stair wells. There is no curbing around the equipment hatch.

Leakage from breaks in the large Reactor Coolant System piping, including a “safe-end-weld” break, will drain to the recirculation sumps since leakage into the reactor cavity is prevented by the baffle arrangement previously mentioned. Flow exits the loop compartments by one of the three openings in the secondary shield wall and travels around the containment annulus to the recirculation sumps. After the water from the reactor coolant blowdown and Reactor Building spray collects above the Reactor Building floor to an elevation of 415 feet, it can enter the incore instrument pit through a ventilation opening in the shield wall that is part of the incore instrument chase. The volume of water collected in the incore instrument pit will vary, depending upon the height of the recirculation water above the Reactor Building floor.

The sump water elevation for the NPSH calculations assumed water fills the reactor cavity to the 430.75 ft elevation where it will spill out the loop openings in the primary shield wall. This is a conservative assumption which bounds any possible hold up concerns in the reactor vessel cavity. Holdup water volumes are also considered for droplet accumulation on vertical surfaces, steam in the containment free volume, water accumulation on the 463 ft and 436 ft floors, as well as transit water volumes in the spray and spill flows.

6.2.2.3.1.2 Spray Nozzles

Reactor Building spray nozzles are discussed in Section 6.2.3.2.

6.2.2.3.1.3 Leakage Considerations

Following a postulated LOCA the Residual Heat Removal System and the Reactor Building Spray System are operational. During the recirculation phase, leakage could occur through component flanges, pump shaft seals, valve flanges, and valve stems. Although leakage rates have been assumed for these sources, maintenance and periodic system testing will preclude all but a small percentage of the assumed leakage. Values for the expected maximum leakage through such components are listed in Table 6.2-52b for Reactor Building Spray System components and Table 6.3-4 for Residual Heat Removal System components. The radiological assessment of this operational leakage is discussed in Section 15.4.1.3. Radioactivity release rates are listed in Table 15.4 10.

6.2.2.3.1.4 Drawdown Analysis

A design evaluation analysis has been performed to track fluid levels in the refueling water storage tank (RWST) and sodium hydroxide storage tank (SHST) during each of the 4 operating combinations outlined in Section 6.2.2.2.1.2. The analysis involves modeling all pumps and associated piping that take suction from the RWST and SHST as input to the PIPF computer program. This computer program then performs a steady state pressure balance on the piping network. The PIPF Computer Code (Reference 29) was approved by the NRC on March 29, 1978, for use in hydraulic analyses, providing 3 criteria were satisfied:

1. Fluid is low temperature and incompressible.
2. Energy conservation can be omitted.
3. For transient calculations, flow rate changes are slow and smooth.

In this analysis, the fluid is water at 70 F in solution with boric acid or sodium hydroxide. Energy is neither added to nor removed from the fluid, except through the pumps. The pumps are modeled to maintain a uniform flow rate throughout the transient. Models of the Reactor Building Spray System and Emergency Core Cooling System for each of the 4 operating combinations are shown by Figures 6.2-51a through 6.2-51d.

The drawdown transient is modeled by determining the steady state flow from the tanks at the initial levels. The volume of fluid drawn from the tanks during a 5 minute interval (or smaller, if desired) is calculated from the above flow. Tank levels are then adjusted and another steady state balance is performed. The procedure is repeated until the RWST reaches a predetermined level, at which time drawdown is terminated.

Since sodium hydroxide concentrations range between 20 and 22% by weight and initial tank levels for both the RWST and SHST range between min-max values, 2 separate modes of analysis were considered. First, a minimum pH mode was analyzed in which the sodium hydroxide fluid concentration and initial tank level were at minimum values, while the RWST was a maximum value. Secondly, a maximum pH mode, in which the initial conditions were reversed, was considered. All 4 operating combinations were analyzed for each pH mode.

Input parameters used in the analysis are given in Tables 6.2-52c through 6.2-52f. Table 6.2-52c is a compilation of system branch data. Table 6.2-52d lists pump head data. Table 6.2-52e gives tank parameters. Table 6.2-52f lists specific volume and viscosity for the minimum and maximum concentrations of sodium hydroxide solution.

Drawdown transients for each of the 4 cases at both minimum and maximum sodium hydroxide initial conditions are plotted on Figures 6.2-51e through 6.2-51l. Summary tables for each initial sodium hydroxide condition are provided as Tables 6.2-52g and 6.2-52h. The analysis shows that the RWST and SHST drawdown uniformly.

The pH values of the spray solution, as a function of time during the injection and recirculation phases, for the 4 operating combinations of Reactor Building spray pumps and ECCS pumps are

shown by Figures 6.2-51m through 6.2-51bb . Supplemental analyses have been performed to support a larger RCS volume, due to steam generator replacement, with RCS boron levels ranging from 0-2000 ppm. These analyses show a small increase (0.2 to 0.3) in the sump and spray pH values during the recirculation phase of the accident.

6.2.2.3.1.5 Preoperational Water Test

The model used to predict the results of chemical drawdown outlined in Section 6.2.2.3.1.4 has been verified by comparison to a site preoperational water test. The test involved filling the refueling water storage tank and sodium hydroxide storage tank with grade A water and conducting one complete drawdown using each of the 4 operating combinations of the Reactor Building spray pumps and ECCS pumps for a portion of the transient. A comparison of the site test results to the analytical predictions is shown for each pump configuration in Figures 6.2-51cc, 6.2-51dd, 6.2-51ee, and 6.2-51ff.

The good correlation between site test results and analytical prediction confirms the validity of the model used in the chemical drawdown analysis of Section 6.2.2.3.1.4.

6.2.2.3.2 Reactor Building Cooling System

The Reactor Building cooling units are sufficiently separated to confine the effects of pipe whip, jet impingement of external missiles to one unit. The 2 units powered from the A channel of the Class 1E electric system are located on the opposite side of the Reactor Building from the 2 units supplied from the B channel. Also the cooling water supply and return mains to these units are physically separated as is the A and B channel wiring.

Each unit can operate independently of the others and the discharge from each unit is isolated from the common air supply main by gravity operated dampers.

Reactor Building Cooling System components that must remain intact following a LOCA include: the 4 plenums and all internal components, plenum discharge ducts, common air supply main, and the 6 vertical supply ducts from the common air supply main to the lower elevation of the Reactor Building.

Design considerations employed to assure that components noted above will remain intact following a LOCA include:

1. Qualification of the plenum and components as described in American Air Filter (AAF) Topical Report, AAF-TR-7101 (Reference 16).
2. Testing and qualification of the fan motor assembly in accordance with IEEE-334 (Reference 17) as indicated in Reliance Electric Test Report NUC-9 (Reference 18).
3. Testing and qualification of the HEPA filter bypass damper.
4. A seismic analysis for the duct systems and HEPA filter bypass dampers.

5. Design of the Reactor Building cooling unit plenum housing suitable for a 2 pound pressure differential and provision of plenum housing relief valves so that this differential is not exceeded during the LOCA pressure transient.
6. Design of duct systems suitable for a 2 pound pressure differential and provision of duct relief valves so that this differential is not exceeded during the LOCA pressure transient.

6.2.2.3.3 Heat Removal Rate

The Reactor Building Spray System utilizes 165 spray nozzles on each loop. The spray nozzles are Spray Engineering Company (SPRACO) Model 1713A and have a hollow cone spray pattern with an average droplet size of 230 microns at a differential pressure of 40 psi across the nozzles.

At a discharge flow rate of 2500 gpm, each subsystem absorbs 2×10^8 BTU/hr at a Reactor Building atmosphere temperature of 260° F. The spray droplets in this analysis reach thermal equilibrium with the Reactor Building atmospheres in less than 0.5 seconds.

The Reactor Building cooling units reject heat to the Service Water System following a LOCA. Four (4) Reactor Building cooling units are furnished, 2 piped and wired to the A loop and A channel, respectively, and the other 2 to the B loop and B channel, respectively. The system design anticipates simultaneous use of one Reactor Building cooling unit from each loop. The design heat removal rate for each unit following a LOCA is as follows: 125×10^6 BTU/hr with saturated air entering the cooling unit at 283° F, 69.39 psia, density of 0.182 lb/ft^3, with 2000 gpm of cooling service water entering at 95°F. In order to allow for degraded performance, containment pressure and temperature analysis for LOCA transients use the more conservative performance curve corresponding to a tubeside fouling factor of 0.0014, as shown on Figure 6.2-15. Analysis of MSLB transients use the design performance curve on Figure 6.2-15 times 60%.

6.2.2.4 Tests and Inspections

6.2.2.4.1 Reactor Building Spray System

In addition to the checkout tests performed prior to initial plant startup and following maintenance, system and component tests are performed periodically in accordance with the ASME Code, prescribed under 10CFR50.55a, to verify continued operability of the Reactor Building Spray System. Also, those elements of the Reactor Building Spray System that perform a containment isolation function must be leak tested periodically in accordance with the requirements of Appendix J to 10CFR50.

Prior to plant startup, flow tests were performed to verify that the various orifices are properly sized to provide the correct mixture of sodium hydroxide solution and RWST water during operation of the Reactor Building Spray System.

6.2.2.4.1.1 System Actuation Tests

Reactor Building Spray System actuation tests verify that the system will operate properly and as designed in the event of an accident. These tests are performed as a part of an overall test of the ESF actuation system. This procedure involves testing of analog and logic circuitry and the actuation of the ESF components (except those whose actuation is not acceptable while the plant is in operation).

The procedures followed in testing actuation of the Reactor Building Spray System components prevent introduction of spray into the Reactor Building or introduction of sodium hydroxide solution into the pump suction lines. Actuation of the header isolation valve and the spray pump in a spray subsystem are tested separately. By following this procedure during testing, pump operation with an open header isolation valve will not occur.

Actuation of the valves in the line from the sodium hydroxide storage tank is blocked during testing when the plant is operating. These valves are tested only during shutdown and then only with the manual shutoff valve in the sodium hydroxide storage tank outlet line closed.

The test line is opened (only to the subsystem being tested) for testing of the pump. This allows the pump to be operated without spray flow into the Reactor Building. In conjunction with testing the actuation of the pump, an evaluation of the pump performance is made to ensure that performance is satisfactory. The opening signal to the valve (normally open) in the suction line from the RWST is tested simultaneously with the actuation of the Reactor Building spray pumps by a simulated High-3 Reactor Building pressure signal. The RWST discharge valves are not closed except during testing of the valves themselves or testing of the sump isolation valves. Testing pump actuation with the RWST discharge valves closed is not considered necessary.

Testing is performed on one spray subsystem at a time. The other subsystem remains in its normal condition for plant operation.

6.2.2.4.1.2 Component Tests

Sump isolation valves are tested by manual operator action with the shutoff valves in the suction lines from the RWST closed. The sump isolation valves are tested in one line at a time. One valve in the line is actuated open and closed, followed by actuation of the other valve in that line. One valve in the line is fully closed at all times. The response of the valves is monitored and evaluated to verify proper operation. The header isolation valves and RWST discharge valves are tested with the Reactor Building spray pumps off.

When Reactor Building Spray Nozzles are required to be verified to be unobstructed, an evaluation, based on the specific situation, will determine the appropriate method (e.g., visual inspection, air or smoke or equivalent flow test, or by draining and flushing the filled portions of the system inside containment) to verify no nozzle obstruction.

6.2.2.4.1.3 Leak Tests of Containment Isolation Elements

Containment isolation is provided on each pump discharge line by a check valve located inside the Reactor Building and a motor operated gate valve located outside. Isolation is provided on each suction line from the Reactor Building sump by a motor operated gate valve located outside the Reactor Building combined with a concentric guard pipe and protective chamber enclosing the line from the sump to and including the gate valve. Test connections are provided for leak testing these isolation elements.

To leak test the check valves, it is necessary to replace the system balance orifice in the pump discharge line, located on the spray header side of the check valve, with a blank orifice plate. The orifice blank is provided with the orifice as a one piece unit. This provides a direct visual means of verifying that the orifice blank has been removed and the orifice replaced.

6.2.2.4.2 Reactor Building Cooling System

Various components of the Reactor Building cooling unit plenums have been tested and qualified for emergency conditions as reported in AAF-TR-7101 (Reference 16), approved by the USAEC, DRL in November, 1972. The components tested included moisture separators, cooling coils, HEPA filter banks, and plenum housing relief valves. The fan and motor assembly has been tested and qualified by the Joy Manufacturing Company in a simulated environmental test in accordance with the procedure outlined in IEEE-334 (Reference 17).

6.2.2.4.2.1 Preoperational and Periodic Tests

Prior to plant startup, check and balance tests are performed on the “air-side” and “water-side” of the Reactor Building Cooling System to adjust and verify that system components can develop the required design air and water flow rates. In addition to the tests performed prior to initial plant startup, system and component tests are performed periodically to verify continued operability of the Reactor Building cooling units in both normal and emergency modes.

6.2.2.4.2.2 System Actuation Tests

Reactor Building Cooling System actuation tests verify that the operating components of the system shift to the emergency mode. Actuation tests are performed to verify the following “air-side” and “water-side” functions:

1. “Air-Side” Actuation Tests

   a. Tripping of the Reactor Building cooling unit while operating at normal speed upon receipt of safety injection or loss of offsite power signals.

   b. Automatic start at low speed in accordance with the ESF actuation system.

   c. Closing of the bypass damper following receipt of safety injection signal.

2. "Water-Side" Actuation Tests

   a. Closing of the industrial cooling supply and return valves upon receipt of safety injection or loss of offsite power signals.

   b. Automatic starting of the service water pumps and service water booster pumps in accordance with the ESF actuation system.

   c. Automatic opening of the service water supply XVG-3106, 3108 and return XVB-3107 valves as the service water booster pumps start.

   d. Automatic opening of one of the service water Reactor Building cooling unit discharge XVG-3109 valves and automatic closure of the other XVG-3109 Reactor Building cooling unit discharge valve.

"Air-side" and "water-side" testing is performed on one of the 2 redundant subsystems at a time. The other subsystem continues normal operation during the tests. The manual shutoff valve downstream of the service water booster pumps is closed prior to the tests to prevent unnecessary contamination of the cooling coils with service water.

6.2.2.4.2.3 Component Inspections and Tests

The cooling plenum structure, cooling coils, fans, motors, and filters are inspected during refueling periods for signs of corrosion, metal fatigue, leakage, deterioration of gaskets or painted surfaces, loosening of instrumentation, and for adequate lubrication. The filter plenums are tested during each refueling period with dioctyl phthalate (DOP) in accordance with the requirements of ANSI N510-1975 (Reference 20).

6.2.2.5 Instrumentation Requirements

6.2.2.5.1 Reactor Building Spray System

Reactor Building Spray System instrumentation provides for system performance and status monitoring during normal plant operation, during system tests, and during system operation following a LOCA. The Spray System instrumentation does not have an active function in the actuation or operation of the system. The data displayed and controls located in the control room are adequate for assessing malfunctions and accidents and performing necessary actions for recovery.

6.2.2.5.1.1 Flow Instrumentation

Flow instrumentation loops utilize orifices and electronic transmitters for measuring the flow rate in the discharge of each pump. Each transmitter supplies a signal to a flow indicator on the main control board (in the control room) and to a bistable mounted in the instrumentation panel in the Control Building relay room. The bistable has adjustable setpoints for the high and low flow alarm inputs to the main control board annunciator system. Flow alarms are defeated until the associated pump breaker has been closed for a time interval greater than the setpoint of a time

delay relay. This alarm alerts the operator to an abnormality in the Reactor Building Spray System. Flow rate is also displayed locally at the transmitter and is monitored by the computer.

6.2.2.5.1.2 Level Instrumentation

Redundant liquid level measuring loops are provided on the sodium hydroxide storage tank. In each of the 2 measuring loops an electronic pressure differential transmitter is used to detect the fluid level in the tank. Fluid level is displayed on the main control board and is monitored by the computer. The level signal is also supplied to a bistable mounted on the instrumentation panel in the Control Building relay room. The bistable has adjustable setpoints for Hi and Lo alarm inputs to the main control board annunciator system. A site glass also provides visible indication of level in the sodium hydroxide storage tank. The site glass is isolated and drained after each reading and remains valved out until another reading is required.

An empty alarm is not used on the sodium hydroxide storage tank. Should the tank be emptied before the RWST is emptied, the liquid interface recedes into the tank discharge lines but the lines to not completely empty because of the pressure maintained at the junction with the RWST lines by the head of liquid in the RWST. Introduction of air into the pumps from vortex effects in the sodium hydroxide storage tank has no significant effect on pump operation because of the low flow velocity in the tank outlet line and the fact that the flow from the sodium hydroxide storage tank comprises only about 2% of the total pump flow.

Level instrumentation in the Reactor Building recirculation sumps permits verification that adequate water has been collected in the bottom of the Reactor Building to maintain sufficient flow and NPSH for the spray pumps in the recirculation mode.

The RWST is not a part of the Reactor Building Spray System but has level instrumentation relevant to the Reactor Building Spray System. An alarm is sounded if the water level drops to a “lo” level during startup or normal plant operations. Level instrumentation also initiates alarms in the Control Room on “Hi”, “lo-lo” and “empty” RWST level. Upon receipt of the RWST “lo-lo” level signal in conjunction with the safety injection signal, the Reactor Building sump isolation valves open automatically and the operator closes the valves in the line from the RWST. The operator will not terminate the Reactor Building Spray System operation until after the required operating period of 2 hours for a design basis LOCA.

6.2.2.5.1.3 Pressure Instrumentation

Local pressure gages are located in the suction lines and the discharge lines of each spray pump. A pressure gage is also located on the nitrogen gas supply line to the sodium hydroxide storage tank. The gages are used for system and component evaluation during testing. The latter gages are also used for monitoring and controlling the nitrogen cover gas pressure in the sodium hydroxide storage tank.

An electronic pressure transmitter is located on the discharge of each spray pump. These transmitters supply a signal to a pressure indicator on the main control board. Pressure data are also monitored by the computer.

Orifices are located in the individual lines from the sodium hydroxide storage tank. The purpose of these orifices is to create a specific flow impedance in the sodium hydroxide lines from the tank to the junctions with the lines from the RWST. However, test connections are provided to which test gages can be attached for measurement of flow through these lines.

Flow tests, performed prior to plant startup define the flow characteristics of the Reactor Building Spray System from the RWST and sodium hydroxide storage tank through the line junctions. These test data are utilized to verify that the system delivers the proper flow of sodium hydroxide solution or to resize the orifices to obtain correct system characteristics.

6.2.2.5.1.4 Temperature Instrumentation

A temperature loop provides local indication of the temperature of the liquid in the sodium hydroxide storage tank. Temperature loops (2) provide local indication of the temperature of the liquid at the spray pump suctions.

6.2.2.5.1.5 Valve Position Indication

Valve position indication for all 10 motor operated valves in this system is provided on the main control board by status lights.

6.2.2.5.1.6 Control

Actuation of the Reactor Building Spray System results from a safety injection and spray actuation signals or from manual action at the main control board. Four (4) manual spray actuation switches are provided. Manual actuation of the Spray System requires simultaneous operation of one of the pairs of the 4 switches. The safety injection signal and spray actuation signals are generated by the ESF Actuation System. Upon receipt of a phase “A” containment isolation signal, the valves in the discharge headers (XVG-3003A and B) and in the sodium hydroxide storage tank discharge lines (XVG-3002A and B) open. The spray actuation signals result from the Reactor Building “Hi-3” pressure instrumentation (2 out of 4 instrument channels tripped). A separate actuation signal is supplied to each spray subsystem. Upon receipt of this signal, the spray pump starts and the valve (XVG-3001A or B) in the suction line from the RWST is opened (if closed). The spray pump and each valve have individual switches on the main control board for manual operation of each component. Switches are also provided on the main control board for normal operation of the valves (XVG-3004A and B, and XVG-3005A and B) in the suction lines from the Reactor Building sumps. The spray pumps are automatically aligned to the Reactor Building sumps in response to signals from the RWST level instrumentation at the “lo-lo” level. The pumps can be restarted individually by switches located on the main control board. The operator will not terminate Reactor Building Spray System operation prior to the required 2 hour operating period.

Operator action from the control room is required to accomplish the following:

1. Shutdown of the Reactor Building Spray System.

2. Manual activation of a Reactor Building spray subsystem.
3. Reactor Building Spray System operation in the recirculation mode.

6.2.2.5.2 Reactor Building Cooling System

Reactor Building Cooling System instrumentation provides for performance and status monitoring of the system during normal operation, during system tests and, for certain components, during system operation following a LOCA. Some instrumentation components provide for control and interlock functions in the operation of the system. Instrumentation relevant to the "waterside" of the Reactor Building cooling system is further described in Sections 9.2.1.5 and 9.4.7.2.5.

6.2.2.5.2.1 Flow Instrumentation

Flow rate in the supply and return service water piping serving the plenum coils is displayed and alarms are provided in the control room. Main control board indication of these flow signals permits verification that adequate cooling water flow is established in the Reactor Building cooling unit coils for post accident Reactor Building heat removal. Refer to Section 9.2.1.5 for further information on this service water flow instrumentation.

6.2.2.5.2.2 Temperature Instrumentation

Redundant resistance temperature detectors are located inside the Reactor Building to measure Reactor Building ambient temperature. Each detector supplies a signal to a temperature indicator on the main control board and one detector, through an isolation device, supplies a signal to an indicator on the control room evacuation panel.

A temperature switch is located in the discharge duct of each Reactor Building cooling unit and provides a control room alarm upon occurrence of high discharge temperature during normal operation.

6.2.2.5.2.3 Pressure Instrumentation

A differential pressure switch and a direct reading differential pressure gage are installed across the moisture separator and across the HEPA filter bank of each Reactor Building cooling unit.

The pressure switches provide control room annunciation of high filter pressure drop.

The gages are used for component evaluation and inspection.

6.2.2.5.2.4 Vibration Instrumentation

A velomitor is mounted on each Reactor Building cooling unit fan. These switches provide signals to trip the fan motors from high speed and to annunciate the condition in the control room if high fan vibration exists for a period greater than approximately 10 seconds. The velomitor

signal is not a part of the fan control circuit for emergency (slow) speed operation and, therefore, has no effect upon this mode of fan operation.

6.2.2.5.2.5 Smoke Detection Instrumentation

An ionization type smoke detector is located in the discharge duct of each Reactor Building cooling unit. Each detector provides a control room alarm upon detection of smoke in the duct. Note that these duct detectors are maintained by the plant, but are not credited because other means exist to detect a fire in the Reactor Building. Their purpose is to aid plant operators in their decision making process.

6.2.2.5.2.6 Motor Current Instrumentation

Current transformers, located at the motor controllers, supply signals to ammeters on the main control board for indication of fan motor current. One ammeter is provided for each motor (high speed and slow speed) of each of the 4 cooling units (a total of 8 ammeters). Thus, fan motor current is continuously indicated for all operating modes and provides information on cooling unit status.

6.2.2.5.2.7 Damper Position Indication

Position indication for each HEPA filter bypass damper is provided on the main control board by status lights on the damper control switch assembly.

Additionally, the status of each damper is independently indicated by means of ESF monitor lights on the main control board.

6.2.2.5.2.8 Special Instrumentation

The main control board ESF monitor lights (see Section 7.5 for more detailed explanation) provide an easily recognizable indication of the status of essential components and equipment. Included among the monitor lights for this system are status indication (actuated or not actuated) of the Reactor Building cooling unit slow speed fan motors and of the HEPA filter bypass dampers. See Section 9.2.1.5 for a description of similar status monitoring of the Service Water System components required for Reactor Building heat removal.

An audible and visual alarm is annunciated on the main control board if manual action by the operator deliberately bypasses the operation of the Reactor Building Cooling System.

Also, an alarm annunciation of motor trip is provided on the main control board for each Reactor Building cooling unit fan.

6.2.2.5.2.9 Control

Actuation of the Reactor Building Cooling System results from a safety injection signal, a loss of offsite power signal, or manual action in the control room. Automatic actuation of the system

follows the sequence outlined in Section 6.2.2.2.2.2. A separate actuation signal is supplied to each subsystem. Control switches, located at the main control board, allow the operators to manually operate each component required for heat removal.

For each Reactor Building cooling unit, main control board switches are provided for the following components:

1. High speed fan motor.
2. Slow speed fan motor.
3. HEPA filter bypass damper.

Manual actuation of the Reactor Building Cooling System (air-side) is accomplished with these switches.

For automatic initiation of the system (air-side) operation, the position of main control board selector switches determines which 1 of the 2 A and which 1 of the 2 B power train units starts in response to the ESF loading sequence signal for that train. One (1) two-position selector switch per electrical power train is utilized for this purpose.

Actuation of the water-side of the Reactor Building cooling units is described in Sections 9.2.1.5 and 9.4.7.2.5.

Operator action from the control room is required to accomplish the following:

1. Shutdown of the Reactor Building Cooling System.
2. Manual actuation of a Reactor Building cooling subsystem.

6.2.3 Reactor Building Air Purification and Cleanup System

The Reactor Building Spray System has 2 functions. One is to remove heat from the Reactor Building atmosphere after a LOCA and the other is to remove fission products from the post LOCA atmosphere to reduce the dose to personnel offsite. The heat removal function is described and evaluated in Section 6.2.2. Additionally, the Reactor Building Cooling System HEPA filters aid in Reactor Building air purification. These filters are discussed in Section 6.5.

6.2.3.1 Design Bases

The Reactor Building Spray System is designed to reduce the concentration of radioactive iodine in the post LOCA Reactor Building atmosphere. In accordance with Regulatory Guide 1.183, it is assumed that of the radioiodine activity released from the core, 95% is in the form of cesium iodide (Csl), 4.85% in the form of elemental iodine and 0.15% in the form of organic iodine.

6.2.3.2 System Design (For Fission Product Removal)

The design of the Reactor Building Spray System is described in Section 6.2.2.2.1 for the overall system. The system diagram is included as Figure 6.2 46. This section discusses the design features related solely to the fission product removal function of the system.

6.2.3.2.1 System Design Features

The sodium hydroxide (NaOH) storage tank is designed and located to permit gravity draining into the spray pump suction line from the RWST. For the design case (one spray subsystem, one RHR pump, and one charging pump operating) it empties at approximately the same time as does the RWST. Orifices in RWST suction lines and the NaOH lines provide sufficient impedance to the system to maintain NaOH flow within the limits necessary for satisfactory spray pH level.

The 3300 gallon nominal capacity tank (3050 gallon minimum required usable volume) is 45-1/2 inches in diameter (OD), 40 feet-10 inches high, and is filled with NaOH solution at a minimum concentration of 20% by weight and a maximum concentration of 22% by weight. During injection, NaOH drains into each pump suction line at a junction at the 399' 6" elevation level at a nominal rate of 50 gpm.

A cover gas of nitrogen is maintained in the vapor space over the liquid to preclude precipitation or tank corrosion that could occur with air present. The tank is equipped with 2 pressure relief valves set to limit nitrogen overpressure to 3 psig. Redundant vacuum relief valves are sized to relieve vacuum in the tank as it is drained during spray operation. An orifice in the nitrogen supply line limits the flow of nitrogen to the relief capacity of one relief valve. This prevents any inadvertent overpressurization of the tank during pressurization operations.

A common discharge line from the NaOH storage tank is subsequently branched to provide flow to each pump suction line. In addition, nitrogen supply, vent, demineralized water supply, and liquid sample connections are provided on the tank. Redundant instrumentation is provided for measuring the liquid level and alarms in the control room. A temperature instrument is also provided.

The NaOH storage tank is provided with a recirculation loop attached at the fill and drain tank nozzles. The recirculation loop is provided with a recirculation pump and associated valves and instrumentation. The recirculation loop was added after initial plant operation under MRF 20168 to address concerns with NaOH tank stratification particularly when adding water to dilute the more dense NaOH solution and to provide a consistent NaOH concentration throughout the tank. To address industrial safety concerns related to handling NaOH, a feed pump and feed tank with a mixer are also provided, tying in to the recirculation loop. The feed is isolated from the recirculation loop by a check valve. The recirculation loop is normally isolated by locked closed valves as shown in Figure 6.2-46. The recirculation loop is non-safety related, but is seismically supported.

The NaOH storage tank is located outside in the Auxiliary Building tank pit at elevation 412'. For a concentration range between 20% and 22%, the maximum temperature at which freezing or separation of solids occurs is - 13°F. Therefore, a heat tracing system is not required.

The Reactor Building Spray System includes a total of 330 spray nozzles. These nozzles are ramp type, hollow cone nozzles. With a 40 psi pressure drop across the nozzle, the drop size distribution is a log normal distribution with a number mean diameter of 230 microns. The mass median diameter is approximately 680 microns. For conservatism, a mass mean diameter of 1300 microns is used in calculating iodine removal effectiveness (see Section 6.2.3.3.1). The spray nozzles are located on 6 rings as described in Section 6.2.2.2.1.1. A plan view of the spray nozzle locations is shown in Figure 6.2 47. The arrangement of the spray rings within the Reactor Building is such that essentially all of the free volume above the operating floor, elevation 463', is exposed to the spray. Below the operating floor elevation, areas outside the secondary shield walls are shielded from the spray. However, the atmosphere in this area is mixed with the rest of the volume inside the secondary shield walls. The volume inside the secondary shield walls with the exception of the pressurizer compartment, is open to the spray.

6.2.3.2.2 System Operation

The operation of the Reactor Building Spray System is presented in Section 6.2.2.2.1.2.

6.2.3.3 Design Evaluation

6.2.3.3.1 Fission Product Removal Effectiveness Calculations

The fission product removal capabilities of the Reactor Building Spray System under post accident conditions have been the subject of much research of government laboratories as well as NSSS vendors.

The effectiveness of this system is estimated by considering the chemical and physical processes that could occur under postulated accident conditions. Iodine is the primary fission product to be considered for removal by the Reactor Building Spray System, post accident. The principal forms of iodine that are of concern in the post accident environment are: elemental, aerosol particulates, and organic iodides.

The removal of elemental iodine from the Reactor Building atmosphere is considered a first order removal process which is mathematically represented by time dependent removal coefficients (λ) due to the action of the spray system (λ_S) and by wall deposition (λ_W). These removal coefficients are summed to obtain the total removal coefficient for elemental iodine.

Experimental results, References 33, 34, and 35 have shown that an important factor determining effectiveness of sprays in removing elemental iodine vapor is the concentration of iodine in the spray solution. Fresh sprays having no dissolved iodine were observed to be quite effective in the scrubbing of elemental iodine even at a pH as low as 5, References 34 and 35. Sump solutions with dissolved iodine that recirculate post accident may revolatilize iodine if the solution is acidic, Reference 36. Section 6.2.2.3.1.4 details the spray solution pH during the conditions of injection

and sump recirculation under the extremes of system operating conditions. In all configurations analyzed, the spray/sump solution pH remains greater than 7.

Chemical additives in the spray solution have no significant effect upon aerosol particle removal since this process is principally mechanical.

1. Elemental Iodine

During injection, the removal of elemental iodine by wall deposition is calculated by using the following equation:

$$\lambda_w = K_W A/V$$

where:

K_W	=	mass transfer coefficient = 4.9 m/hr.
A	=	wetted surface area = 3457 m^2.
V	=	Reactor Building net free volume = 1.84 x 10^6 ft^3.
λ_w	=	removal coefficient by wall deposition = 0.325 hr^{-1}.

Based upon the well-mixed droplet model, the effectiveness of the spray in removing elemental iodine vapor is chiefly determined by the rate at which fresh solution area is introduced into the atmosphere. This can be estimated by the relationship (6F/VD) where F is the volume flow rate of the spray, V is the building net free volume, and D is the mass mean diameter of the spray drops. The first order spray removal coefficient is calculated using the following relationship:

$$\lambda_s = 6K_gTF/VD$$

where:

K_g	=	gas-phase mass transfer coefficient = 180 m/hr.
T	=	fall time of the drops = ratio of the average fall height (h) to the terminal velocity (U) where h = 114 ft and U = 410 cm/sec.
F	=	Flow rate = 2500 gpm.
V	=	Reactor Building volume - 1.84 x 10^6 ft^3.
D	=	drop diameter = 1300μ
λ_s	=	20.0hr^{-1}
λ_s	=	$\lambda_s + \lambda_w = 20.0 + 0.325 = 20.325 hr^{-1}$

2. Organic Iodides

It is conservatively assumed that organic iodides are not removed by the action of the sprays or wall deposition.

3. Particulate Iodine

The removal coefficient for particulate iodine by sprays is given by the following equation:

$\lambda_p = 3hFE/2VD$

where:

h	=	fall height of the droplets = 114 ft.
F	=	spray flow rate = 2500 gpm.
V	=	Reactor Building volume = 1.84×10^6 ft^3.
E/D	=	ratio of the dimensionless collection efficiency, (E), to the drop diameter, (D). E/D is assumed equal to 10 m^{-1} for a period of time until the aerosol mass has been depleted by a factor of 50. Thereafter, E/D is reduced by a factor of 10 to 1 m^{-1} (i.e. 98% of the suspended mass is 10 times more readily removed than the remaining 2%).
λ_p	=	5.68 hr^{-1} (0 - 98% removal).
λ_p	=	0.568 hr^{-1}(98 - 100% removal).

6.2.3.4 Tests and Inspections

Tests and inspections of the Reactor Building Spray System are described in Section 6.2.2.4.1.

6.2.3.5 Instrumentation Requirements

Instrumentation requirements of the Reactor Building Spray Systems are described in Section 6.2.2.5.1.

6.2.3.6 Materials

Spray system materials are compatible with the reactor coolant and the alkaline (NaOH) solution. The major components of the system are constructed of stainless steel, except the sodium hydroxide storage tank which is of carbon steel. Minor parts, such as pump seals, utilize other corrosion resistant materials.

6.2.4 Containment Isolation System

The objective of the containment isolation system is to allow the passage of fluids through the containment boundary under normal and accident conditions, while preserving the integrity of the containment boundary, when required to prevent or limit the escape of fission products as a result of a postulated LOCA.

The containment isolation system is not an independent system. Rather, the system is comprised of specific provisions included in each piping system that penetrates the Reactor Building. Actuation of containment isolation is accomplished through the Engineered Safety Features Actuation System (ESFAS). A detailed discussion of the ESFAS system is provided in Section 7.3.

6.2.4.1 Design Basis

In the unlikely event of a LOCA, the containment isolation system is designed to limit leakage of radioactive materials through lines penetrating the Reactor Building so that the site boundary dose guidelines specified in 10 CFR 50.67 are not exceeded.

Lines for which isolation is required are provided with 2 barriers, such that no single failure can prevent isolation. Each of these barriers is adequate to limit leakage of radioactivity within acceptable values over the entire range of normal and accident conditions. The selection of fast action automatically operated valves that receive isolation signals is based upon the safety analysis requirements described in Chapter 15.

An “isolation barrier” is either an isolation valve, blind flange, or a closed system. A closed system is defined as a fluid system which is not part of the Reactor Coolant System and which does not communicate with the Reactor Building atmosphere.

Fluid systems, including instrument lines, penetrating the Reactor Building satisfy the following specific design bases:

1. The design of isolation barriers for lines penetrating the Reactor Building follows the requirements of General Design Criteria 54 through 57 of 10CFR50, Appendix A.
2. The containment isolation system is protected against the effects of missiles and postulated pipe ruptures. See Sections 3.5 and 3.6.
3. The containment isolation system is designed to Safety Class 2a, Seismic Category 1 requirements. Regulatory Guides 1.26 and 1.29 are discussed in Appendix 3A.
4. The containment isolation system is designed with redundancy in accordance with General Design Criterion 54 so that no single active failure can result in loss of containment integrity.
5. The containment isolation system is designed to withstand accident environmental conditions (see Section 3.11).

6. Provisions are made for periodically testing the operability and leak tightness of the containment isolation valves to the extent necessary to ensure that the system satisfies performance requirements in the event of an accident.

6.2.4.2 System Design

A list of Reactor Building penetrations showing the means of containment isolation is included as Table 6.2-53. Containment isolation valves are listed by penetration number in Table 6.2-54. Each listing indicates valve number, size, methods of actuation and positions under various plant conditions. Figure 6.2-52 schematically shows the various valve arrangements used to isolate the fluid system penetrations.

6.2.4.2.1 Lines Penetrating the Reactor Building that Connect to the Reactor Coolant Pressure Boundary (General Design Criterion 55)

This category includes the process lines passing through penetrations numbered 221, 222, 223, 226, 227, 229, 314, 316, 318, 322, 325, 405, 408, 409, 410, 412, 415 and 426. Of these, 221, 222, 227, 229, 322, 325, 408, 409, 412, 415 and 426 have one or more check valves in parallel as the inside isolation valves and one or more power-operated valves in parallel as the outside isolation valves. Penetrations 223, 314, 318 and 405 have one or more power-operated valves in parallel as the inside isolation valves and one power-operated valve as the outside isolation valve.

Penetration 410 has a power-operated valve and check valve in parallel as the inside isolation device and power-operated valve as the outside isolation device. These arrangements all comply with the literal requirements of General Design Criterion 55.

Penetrations 226 and 316 do not have outside isolation valves. The closed Residual Heat Removal (RHR) System boundary is used as the outside containment device. These lines connect to the safety injection recirculation loops which are filled with sump water and at least one of which is in operation following an accident. Should a leak occur in the short length of pipe inside the Reactor Building between the valve and Reactor Building wall, the Reactor Building atmosphere would pass only as far as the fluid filled system containing sump water. This would prevent gas release to the outside. The design basis for these penetrations is that isolation valves outside the Reactor Building on the RHR suction lines are unnecessary and that inclusion of any such additional valves does not enhance plant safety.

The power-operated valves for penetrations 223, 314, 318, 405, 409, and 410 are automatically closed upon receipt of either a safety injection signal or containment isolation, Phase A signal, as noted in Table 6.2-54. The power-operated valves for penetration 426 are automatically opened by the safety injection signal to permit boron injection.

Valves in lines required to perform a safety function following an accident must be opened or must remain open for the Engineered Safety Features (ESF) Systems to operate. Automatic closing of these valves would defeat their intended purpose. Therefore, these valves are designed for remote manual operation from the control room. Lines in this category include low pressure

safety injection lines and high pressure safety injection lines. Penetrations in this category are 222, 227, 322, 325, 412, and 415.

The seal injection lines to the reactor coolant pumps pass through penetrations 221, 229, and 408. Due to the sensitive nature of the pump seals, it is highly desirable to provide seal cooling flow at all times. Since the charging pumps are used for safety injection, the high pressure in-flow through the seal injection lines eliminates any need for automatic closure of the valves in these lines. Remote manual closure from the control room is available.

6.2.4.2.2 Lines Penetrating the Reactor Building That are Open to the Reactor Building Atmosphere (General Design Criterion 56)

This category includes the process lines passing through penetrations numbered 101, 103, 105A, 105B, 107, 201, 210, 211, 212, 216, 217, 231, 301A, 301B, 302, 303, 310, 311, 313, 317, 319, 320, 321, 324, 327, 328, 329, 401, 402, 404, 406B, 407A, 407B, 417D, 418, 419, 420, 421, 422, 423, 424, 425, 427, 500, 505, 600, 602, and 703. Of these, 101, 103, 105A, 105B, 302, 303, 311, 317, 319, 320, 321, 401, 402, 407A, 407B, 417D, 418, 420, 422, 423, 424, and 427 have one power-operated valve outside and one power-operated or check valve inside. Penetration 301A has 2 power operated valves in parallel as the inside isolation and one power operated valve as the outside isolation. Penetration 301B has one power operated valve as the inside isolation and 2 power operated valves as the outside isolation. Penetrations 231, 310, 313, 324, 404, 419, and 421 have a locked closed manual valve outside and check valve or a locked closed manual valve inside. The process pipes through penetrations 201, 210, 211, 212, 216, 505, 600, and 602 are sealed with blind flanges inside and outside during operation. These modes of isolation are in literal compliance with General Design Criterion 56, considering that a blind flange is the equivalent of a locked closed valve.

Penetration 107, the fuel transfer tube, is sealed with a blind flange on the inside end. This flange has a double O-ring seal to provide a double barrier. Although there is a manual gate valve on the outside end of the tube, it is not considered a containment isolation barrier since the blind flange, when in place, is the containment boundary.

Penetrations 217, 406B, 500, and 703 are for the Reactor Building pressure sensing lines. Reactor Building pressure is sensed by 4 physically separated differential pressure transmitters mounted on Seismic Category 1 supports outside the Reactor Building. These devices are connected to the 1/2 inch stainless steel Reactor Building penetration by a length of 1/4 inch outside diameter, high pressure, stainless steel tubing. Bellows are connected to the ends of the tubes inside the Reactor Building. The capillary tubing between the bellows and the transmitter is fluid filled. The distance from penetration to transmitter is minimized and separation is maintained. This arrangement, together with the pressure sensors outside the Reactor Building, forms a double barrier. For a discussion of Regulatory Guide 1.11, see Appendix 3A.

The lines from the Reactor Building recirculation sumps to the suctions of the redundant, low head safety injection recirculation (residual heat removal) pumps and Reactor Building spray pumps are each provided with a single motor-operated gate valve outside the Reactor Building. These valves are enclosed in containers which are leaktight at the Reactor Building design

pressure. Piping from the sump to the valve containers is enclosed in a concentric guard pipe, also leaktight at the Reactor Building design conditions. The structural configuration is such that neither a valve contained nor the guard pipe is connected directly to the sump or to the Reactor Building atmosphere.

At the beginning of the safety injection recirculation phase the sump is full of water, the sump line valves are opened, and the line from the refueling water storage tank is closed. Since the sump is always submerged during recirculation following an accident and no Reactor Building atmosphere can impinge upon the valve, this valve is not a containment isolation valve in the usual sense. The valve does provide a barrier outside the Reactor Building to prevent loss of sump water should a leak develop in a recirculation loop. (This valve is capable of remote manual closure from the control room to accomplish this.) Should a leak develop in the valve body or in the pipe between the sump and the valve, the sump fluid is contained by the leaktight container and guard pipe arrangement. Since the sump line connection to the sump is always submerged during the recirculation phase, there is no need for a valve inside the Reactor Building to prevent escape of the Reactor Building atmosphere.

No single failure of either an active or passive component of this system will prevent recirculation of core cooling water nor will such a failure adversely affect the integrity of the Reactor Building. This arrangement satisfies safety requirements and no additional valves are necessary for containment isolation with respect to penetrations 327, 328, 329, and 425.

The power operated valves associated with penetrations 311, 317, 319, 320, 321, 407A, 407B, 417D, 418, 420, 422, 423, 424, and 427 are automatically closed by the containment isolation, Phase A signal. The hydrogen analyzer isolation valves associated with penetrations 105A, 105B, 301A, and 301B do not receive a closure signal because these valves are normally closed and will be opened post LOCA. The portion of penetration 301B shared with a Reactor Building pressure transmitter does isolate on a Phase A signal. The power operated valves associated with penetrations 101, 103, 302, and 402 are automatically closed by a containment ventilation isolation signal or high radiation in the Reactor Building purge exhaust vent (A train valves) or containment atmosphere high radiation (B train valves). The valves on penetrations 303 and 401, the Reactor Building spray supply lines, are automatically opened by a containment Phase A isolation signal.

6.2.4.2.3 Lines Penetrating Reactor Building That Do Not Connect With Either the Reactor Coolant Pressure Boundary or the Reactor Building Atmosphere (General Design Criterion 57)

The category includes the process lines passing through penetrations numbered 102, 202, 203, 204, 205, 206, 207, 213, 219, 220, 224, 225, 230A, 230B, 230C, 304, 305, 306, 308, 312, 323, 326, 330, 403, 411, 417A, 417B, 417C, and 428. Of these 102, 204, 304, 305, 312, 323, 330, and 403 have automatically actuated power operated valves outside the Reactor Building. These lines are in literal compliance with General Design Criterion 57.

6.2.4.3 Design Evaluation

The process piping through the penetrations and the isolation valves are designated as Safety Class 2a. They are designed in accordance with the ASME Code, Section III, Class 2.

Where power-operated valves are supplied inside and outside the Reactor Building, the inside valve and the outside valve are actuated by different trains of the actuation system. The train that actuates any isolation valve is indicated in the “Signal” column of Table 6.2-54.

Valves which may be required to operate in the post LOCA Reactor Building atmosphere to serve their safety function are qualified as described in Section 3.11.

The containment isolation system design complies with the recommendations of SRP 6.2.4; i.e., that there be diversity in the parameters sensed for the initiation of containment isolation. The containment isolation signals are given in Table 6.2-54.

Careful reconsideration as required by NUREG-0578, item 2.1.4, to the definition of essential and non-essential systems has been given. The basis of selection is that the essential systems are those which are required immediately to mitigate the consequences of an accident. All other systems are considered non-essential. The systems which penetrate containment and their classification are listed in Tables 6.2-53 and 6.2-54a. During the re-evaluation none of the systems were changed from nonessential to essential.

All non-essential systems, except those which have a blind flange or a locked closed manual valve, are automatically isolated by the containment isolation signals.

The design of control systems for automatic containment isolation valves is such that resetting the isolation signal will not result in the automatic reopening of containment isolation valves, with the exception of the letdown orifice isolation valves if the transfer switch on the Control Room Evacuation Panel is set for local operation and the control switch is in the open position. Reopening of containment isolation valves requires deliberate operator action. System operating procedures detail specific valves to operate during post accident recovery operations and valve operations for complete Safety Injection - Containment Isolation Recovery operations.

6.2.4.4 Test and Inspection

Leakage tests and containment isolation valve operability tests are discussed in Section 6.2.6.3. An isolation valve seal system is not employed.

6.2.4.5 Materials

The materials used in the components of the containment isolation system are selected so that the system can perform its engineered safety function throughout the life of the plant under all anticipated environmental situations. Criteria considered are as follows:

1. Materials selected for components of the containment isolation system inside the Reactor Building will withstand an integrated radiation dose of 10^8 rads without significant degradation of material properties.
2. All materials used in the containment isolation system that come in contact with the Reactor Building spray solution (alkaline solution of sodium hydroxide and boric acid) are resistant to corrosion by this solution. Nuclear steam supply systems that are normally wetted by borated water are made of austenitic stainless steel. Other containment isolation valves inside the Reactor Building are of carbon steel.
3. Materials used for containment isolation system components which contain zinc or aluminum are kept to a minimum.

6.2.4.6 Special Instrumentation

The main control board ESF monitor lights (see Section 7.5 for more detailed explanation) provide an easily recognizable indication of the status of essential components and equipment. Included among the monitor lights are status (position) indication of the containment isolation valves.

6.2.5 Combustible Gas Control in Reactor Building

Following a design basis accident, hydrogen gas may be generated inside the Reactor Building by reactions such as zirconium metal with water, corrosion of materials of construction, and core and sump water radiolysis. The following section is presented to describe the basis for the sizing of the combustible gas control system. To ensure that the hydrogen recombiners and an alternate Reactor Building purge system are provided.

To minimize hydrogen generation as a result of corrosion of containment metals, the use of exposed zinc and aluminum inside the Reactor Building is tracked and logged. In addition, the amount of hydrogen generated in the post accident environment is limited by maintaining a Reactor Building spray pH of 10.5 or less and a recirculation solution pH of less than 9.0.

6.2.5.1 Design Bases

6.2.5.1.1 Electric Hydrogen Recombiners

1. The recombiners are designed to sustain all normal loads as well as accident loads including safe shutdown earthquake and pressure transients from a design basis loss of coolant accident.
2. The recombiners are designed for a lifetime of 40 years, consistent with that of the plant. (Aging management will extend recombiner life for the duration of the plant life.)
3. All materials used in the recombiners are selected to be compatible with the environmental conditions inside the Reactor Building during normal operation or during accident conditions.

4. Process capacity is such that the Reactor Building hydrogen concentration will not exceed 4 volume percent based on the NRC TID-14844 release model as indicated in Regulatory Guide 1.7.
5. Each recombiner is provided with a separate power panel and control panel. Each recombiner is powered from a separate ESF bus.

6.2.5.1.2 Alternate Reactor Building Purge System

Supply and exhaust flow lines connected to pressure blowers are provided as a backup system to purge the Reactor Building for combustible gas control and to aid in cleanup of the Reactor Building atmosphere.

6.2.5.1.3 Hydrogen Concentration Monitor

The following design bases apply to the equipment provided to monitor hydrogen in the Reactor Building.

1. Redundant hydrogen concentration analyzers are provided to confirm that the electric hydrogen recombiners are functioning property following an accident. The analyzers are not required to initiate operation of the electric hydrogen recombiners since the recombiners will be started 24 hours after a LOCA and the ability of these recombiners to remove hydrogen from the Reactor Building atmosphere has been accepted by the NRC (Reference 22). During normal plant operating conditions, one hydrogen analyzer is in standby. The redundant hydrogen analyzers will be started after a LOCA.
2. Dedicated sampling points for each monitor, capable of withstanding the SSE without loss of function, are provided.
3. The system is capable of remaining operable under both positive and negative pressure assuming a single failure.
4. The hydrogen monitoring system is class 1E and seismic Category 1.
5. Semi-automatic sampling capability to permit laboratory analysis as backup to the hydrogen analyzer is provided. This system is also capable of determining noble gases and iodine concentrations.
6. During a loss of coolant accident, Reactor Building hydrogen concentration is monitored and hydrogen recombiners are placed in service to minimize hydrogen buildup in the Reactor Building. Adequate shielding is provided to prevent personnel overexposure during hydrogen recombiner operation at local panels.

6.2.5.2 System Design

The system is designed for control of combustible H_2 concentrations in the Reactor Building following a loss of coolant accident. This system consists of a sampling system that provides Reactor Building atmosphere samples with electric hydrogen recombiners as the primary means

of reducing H_2 Reactor Building concentrations and a purge system which is used as a backup system to the recombiners.

6.2.5.2.1 Electric Hydrogen Recombiners

Redundant electrical recombiners, as shown on Figure 6.2-53 are located inside the Reactor Building. The recombiner units are located in the Reactor Building such that they process a flow of Reactor Building air containing hydrogen at a concentration which is generally typical of the average concentration throughout the Reactor Building. Since the recombiner units are located in the Reactor Building, dedicated containment penetrations for hydrogen control are not required. In addition, the capability to install a recombiner unit outside the Reactor Building is not required.

To meet the requirements for redundancy and independence, 2 recombiners are provided, and each recombiner is provided with a separate power panel and control panel, and each is powered from a separate class 1E bus.

Reactor Building atmosphere is circulated through the recombiner by natural circulation where hydrogen is removed by heating to a temperature sufficient to cause recombination with the Reactor Building oxygen.

The recombiner consists of a thermally insulated vertical metal duct with electric resistance metal sheathed heaters provided to heat a continuous flow of Reactor Building air (containing hydrogen) up to a temperature which is sufficient to cause a reaction between hydrogen and oxygen. The recombiner is provided with an outer enclosure to keep out Reactor Building spray water. The recombiner consists of an inlet preheater section, a heater-recombination section, and a discharge mixing chamber that lowers the exist temperature of the air.

The unit is manufactured with corrosion resistant, high temperature materials except for the base which is carbon steel. The electric hydrogen recombiner uses commercial type electric resistance heaters sheathed with Incoloy-800 which is an excellent corrosion resistant material for this service.

Air drawn into the recombiner by natural convection and passes first through the preheater section. This section consists of a shroud placed around the center heater section to take advantage of heat conduction through the walls to preheat the incoming air. This accomplishes the dual functions of reducing heat losses from the recombiner and of preheating the air.

The warmed air passes through a flow orifice and then enters the electric heater section where it is heated to approximately 1150° F to 1400° F causing recombination to occur. Tests have verified that the recombination is not a catalytic surface effect associated with the heaters but occurs due to the increased temperature of the process gases. Since the phenomenon is not a catalytic effect, saturating of the unit by fission products will not occur. The heater section consists of 5 assemblies of electric heaters stacked vertically. Each assembly contains individual heating elements. Table 6.2-55 gives the recombiner design parameters.

The recombiner, power supply panel, and control panel are shown schematically in Figure 6.2-54. The power panel for the recombiner contains an isolation transformer plus a semiconductor controlled rectifier controller to regulate power into the recombiner. This equipment is not exposed to the post LOCA environment. To control the recombination process, the correct power input which will bring the recombiner above the threshold temperature for recombination will be set on the controller. The correct power required for recombination depends upon Reactor Building atmosphere conditions and will be determined when a recombiner operation is required. For equipment test and periodic checkout, a thermocouple readout instrument is also provided in the control panel for monitoring temperatures in the recombiner.

Reference 22 provides a description of the testing of a full scale prototype electric hydrogen recombiner.

6.2.5.2.2 Alternate Reactor Building Purge System

The alternate purge lines, which serve as backup to the hydrogen recombiners may be used in the unlikely event of failure of both hydrogen recombiners to operate following a LOCA. For this case, the supply pressure blower is operated to pressurize the Reactor Building to 3 psig with a clean supply of outside air (at approximately 600 scfm). This procedure is initiated when the H_2 concentration approaches 3 volume percent after a loss of coolant accident (approximately 2 1/2 days) and reduces the H_2 concentration to approximately 2.5 volume percent. As the H_2 concentration again approaches 3 volume percent, the backup purge isolation valves are opened and the Reactor Building atmosphere is released and throttled at a rate of 100 scfm through the charcoal and HEPA filters of the purge exhaust plenum while pressure returns to 0 psig. This operation is repeated each time H_2 concentration approaches 3 volume percent subsequent to initial accumulation. The alternate purge lines contain the required safety-related isolation valves as specified by Regulatory Guide 1.7. These components are designed for remote-manual operation from the control room, as required following a LOCA.

6.2.5.2.3 Hydrogen Concentration Monitor

Figure 6.2-58 schematically shows the provisions for monitoring the Reactor Building atmosphere.

The capability for obtaining samples near each electric hydrogen recombiner and near the Reactor Building cooling units at approximately 530 foot elevation is provided. The redundant analyzers are operated post accident to continuously monitor the Reactor Building atmosphere. The plant operator can operate each analyzer from the control room. Two (2) sampling panels are provided for taking samples from connections in each hydrogen analyzer system. Each redundant sampling system and its associated control panel are accessible following an accident.

Seismic and environmental qualifications of the containment isolation valves for the sample lines and the hydrogen analyzers are discussed in Sections 3.10 and 3.11, respectively. The hydrogen analyzers are located outside the Reactor Building and are not subjected to extreme environmental conditions.

6.2.5.3 Design Evaluation

6.2.5.3.1 Electric Hydrogen Recombiners

Prediction of hydrogen generation following a LOCA (refer to Figures 15.4-71 through 15.4-73), shows that although hydrogen production rate decreases with time after the accident, total hydrogen accumulation could exceed 4 volume percent. The hydrogen recombiners limit hydrogen accumulation. Figure 15.4-71 shows the rate of hydrogen production from various sources with no recombiner operating after a LOCA. Figure 15.4-72 depicts the corresponding hydrogen accumulation in the containment.

For the purpose of showing that the electric recombiner is capable of maintaining safe hydrogen concentrations, an analysis was performed using the Regulatory Guide 1.7 model. The results for the Reactor Building volume are shown in Figure 15.4-73. The model is based upon assuming a fission product activity release specified in TID-14844 and the values for post accident hydrogen generation specified in Regulatory Guide 1.7. The results, using no recombiner, are also shown on this figure.

Each electric recombiner is capable of continually processing a minimum of 100 scfm of Reactor Building atmosphere. The hydrogen contained in the processed atmosphere is converted to steam, which then exists to the Reactor Building atmosphere, thus reducing the overall Reactor Building hydrogen concentration. The hydrogen concentration in the Reactor Building was calculated for the models described above based on a recombiner capability of processing 100 scfm of Reactor Building atmosphere. This calculation shows that the maximum hydrogen concentration will be much less than 4 volume percent if the recombiner is started one day following the accident. Therefore one of these recombiners meets the design criterion of maintaining a safe hydrogen concentration with considerable margin, and the second unit provides the redundance of a system of equal capability on a redundant power supply.

The peak hydrogen concentration occurs at the time when the amount of hydrogen being generated is equal to the amount of hydrogen being processed. Once this peak has been reached, the recombiner will be processing hydrogen at a faster rate than it is being produced. This will result in an overall reduction of the hydrogen concentration inside the Reactor Building. Thus, once the peak has been reached, the electric recombiner provides a continually increasing margin between the Reactor Building hydrogen concentration and the 4 volume percent limit.

The recombiner is designed to sustain all normal loads as well as accident loads such as seismic loads and temperature and pressure transients from a LOCA.

The Westinghouse electrical hydrogen recombiner, as described in topical report WCAP 7709-L (Proprietary) with Supplements 1 to 4 and in WCAP 7820 (non-proprietary) is considered by the Virgil C. Summer Nuclear Station to be the principal component used for combustible gas control. Whereas, bypass and inoperable status monitoring may be needed to provide information that certain protection equipment and systems that are normally operating are actually inoperative, such monitoring is not necessary for the electrical hydrogen recombiner because it is normally not operating and is not armed for automatic actuation. As described in WCAP 7709, the system is

operated only during periodic testing and after the postulated Loss-of-Coolant Accident. Operation is initiated by operator action from the control station. Following an accident, the elapsed time prior to the needed start of the equipment is in terms of hours or days, and this elapsed time is evaluated in WCAP 7709. The design and environmental and seismic qualification of the Westinghouse electrical hydrogen recombiner was found acceptable for the prototype and production models by NRC, as reported in NRC's letter of May 1, 1975, from D. B. Vassallo to C. Eicheldinger, Manager of Westinghouse Nuclear Safety Department.

For further information on hydrogen production and accumulation see Section 15.4.1.2.

6.2.5.3.2 Alternate Reactor Building Purge System

If required, purging of the Reactor Building atmosphere following a LOCA is limited to a flow rate of 100 scfm by the alternate purge system. This flow rate is consistent with the minimum rated capacity of 100 scfm for one hydrogen recombiner.

6.2.5.3.3 Reactor Building Atmospheric Sampling System

Redundant sample systems have been designed to collect samples of the containment atmosphere. These samples are then analyzed in the radiochemistry laboratory for hydrogen, noble gases, and iodine. Radiation exposure and shielding considerations are discussed in FSAR Appendix 12A. Heat tracing is provided to prevent condensation of water vapor within the system.

6.2.5.4 Tests and Inspections

6.2.5.4.1 Electric Hydrogen Recombiners

The electric hydrogen recombiners have undergone extensive testing in the Westinghouse development program. These tests encompassed the initial analytical studies, laboratory proof-of-principal tests, and full scale prototype testing. The full scale prototype tests included the effects of:

1. Varying hydrogen concentrations.
2. Alkaline spray atmosphere.
3. Steam effects.
4. Convection currents.
5. Seismic.

A detailed discussion of these tests is given in Reference 22. Post operational tests and inspections will be performed in accordance with Technical Specification requirements. Inspections will be performed to assure the capability of the recombiner to perform its function. Testing will be performed to verify operation of the control system to verify functional performance of the heaters to the required temperature level.

Seismic and environmental qualifications are discussed in Sections 3.10 and 3.11.

6.2.5.4.2 Alternate Reactor Building Purge System

The active components of the alternate purge lines, which are the containment isolation valves, are periodically tested in accordance with the requirements of Section 6.2.6, Containment Leakage Testing.

6.2.5.4.3 Sample Panels

The sample panels will be used on a periodic basis to maintain operator proficiency with system operation.

6.2.5.5 Instrumentation Requirements

6.2.5.5.1 Electric Hydrogen Recombiners

The recombiners do not require any instrumentation inside the Reactor Building for proper operation after a LOCA. The recombiners will be started manually after a LOCA. The sampling system will be used in obtaining Reactor Building atmosphere samples to verify proper operation of the recombiners or to indicate when the purge system should be actuated. This sample can be taken from any of 3 well ventilated locations within the Reactor Building.

6.2.5.5.2 Alternate Reactor Building Purge System

The powered components of the alternate Reactor Building purge line are designed for remote manual operation from the control room, as required following a LOCA.

6.2.5.5.3 Hydrogen Concentration Monitors

Manual action is required to start the redundant hydrogen analyzers. Since these analyzers provide only confirmation of proper operation of the redundant electric hydrogen recombiners, no automatic action is required.

The hydrogen analyzers have 0-10% and 0-20% range of H_2 in air (by volume) and an accuracy of ± 2% of range. This provides adequate confirmation of electric hydrogen recombiner operation. Hydrogen concentration in the Reactor Building is indicated in the control room.

6.2.5.5.4 Reactor Building Atmospheric Sampling System

Manual action is required to align the sampling system valves with the hydrogen analyzer supply and return lines. Once in service, the operational sequence is controlled remotely. The system is purged with nitrogen to containment following sampling completion. Following purge, the system is returned to the non-sampling mode manually, if required.

6.2.5.6 Materials

6.2.5.6.1 Electric Hydrogen Recombiners

The materials of construction for the electric recombiner are selected for their compatibility with the post LOCA environment.

The major structural components are manufactured from 300-Series stainless steel except for the base which is carbon steel. Incoloy-800 is used for the heater sheaths and Inconel-600 for other parts, such as the heat duct, which operate at high temperature.

There are no radiolytic or pyrolytic decomposition products from these materials. The carbon steel base of the recombiner unit is coated with a paint that satisfies the requirements of ANSI 101.2 (1972), “Protective Coating (Paints) for Light Water Nuclear Reactor Containment Facilities.”

6.2.6 Containment Leakage Testing

The Virgil C. Summer Nuclear Station containment and associated systems are designed to permit leakage testing in accordance with 10CFR50, Appendix J.

6.2.6.1 Containment Integrated Leakage Rate Test

The containment integrated leakage rate test is a Type A test as defined by 10CFR50, Appendix J. Integrated leakage rate testing is performed in accordance with a detailed, written, and approved procedure prepared in accordance with 10CFR50, Appendix J, which satisfies the requirements of General Design Criteria 52, 53, and 54 (see Chapter 14).

6.2.6.1.1 Preoperational Type B and C Testing

Preoperational Type B and C leak testing is employed to detect leaks which may affect the integrity of the containment and the results of the initial integrated leakage rate test. These tests are performed at a pressure of not less than 45.8 psig.

The following areas are subjected to preoperational Type B or C tests, as applicable:

1. Containment penetrations (mechanical and electrical).
2. Equipment and personnel access hatches.
3. Fuel transfer tube.
4. Isolation valves in lines penetrating the containment boundary.

Any leaks detected are repaired as required.

6.2.6.1.2 Preoperational Testing - Integrated

An initial integrated leakage rate test of the Reactor Building is performed in accordance with 10CFR50, Appendix J, following completion of building construction, installation of all systems penetrating the containment boundary and after completion of Reactor Building inspection and structural integrity testing. This initial test is performed at the calculated peak containment internal pressure, P_a (47.1 psig). The absolute pressure-temperature method of measuring leakage from the Reactor Building, as described in ANSI N45.4-1972, Appendix B is employed during both of these leakage rate tests. The objectives of the tests are as follows:

1. To establish the measured integrated leakage rate, $L_{am.}$
2. To obtain a leakage rate history and leakage characteristic of the containment system.

The leakage rate is determined by measuring the leakage from the Reactor Building over a period of at least 24 hours after Reactor Building temperature and pressure have been stable for a minimum of 4 hours. To ensure equal temperature distribution, throughout the building interior, fans are provided to circulate the air in the Reactor Building during the test. Verification of the leakage rate is obtained by supplemental testing as described in ANSI N45.4-1972, Appendix B. By measuring leakage from the Reactor Building while a known leakage rate is superimposed on the normal building leakage rate, the difference between the total leakage and the superimposed known leakage results in the actual leakage rate. This leakage rate (difference) is compared with the original leakage rate as a check of its accuracy.

High accuracy instrumentation is provided to assure that building atmospheric temperature, pressure, and dewpoints are measured accurately.

Acceptance Criteria for this test are as follows:

1. The total measured containment leakage rate, L_{am}, at pressure, P_a, may not exceed O.75 L_a, the containment design basis leakage rate. L_a is 0.2% by weight of the contained atmosphere in 24 hours. If local leakage measurements are taken following repairs made to satisfy acceptance criteria, these measurements shall be taken at a test pressure, P_a.

In the event of failure of preoperational integrated testing to satisfy the acceptance outlined above, repairs and/or adjustments to equipment shall be made and a Type A test plus a supplemental test shall be performed. All repairs, adjustments to equipment, and test results shall be reported to the NRC as required by Section III.A.1.a of Appendix J to 10CFR50.

6.2.6.1.3 Periodic Testing - Integrated

Prior to December 1, 1996, Integrated Leakage Rate Testing was conducted in accordance with 10CFR50 Appendix J, Option A and ANSI N45.4 - 1972. Commencing with the implementation of Technical Specification Amendment 135, Integrated Leakage Rate Testing will be conducted in accordance with 10CFR50 Appendix J, Option B as delineated in the Containment Leakage Rate Testing Program (CLRTP).

The performance of Type A tests shall be limited to periods when the plant is nonoperational and secured in the shutdown condition under the administrative control and in accordance with the safety procedure defined in the license.

6.2.6.1.4 Special Conditions During Testing

All containment penetrations except those in systems which are required to remain filled during and following a LOCA (i.e., Residual Heat Removal, Reactor Building Spray and Safety Injection Systems) will be tested in accordance with the Type A test requirements as described in the CLRTP.

6.2.6.1.5 Leakage Rate Test System Description

ECR 50504 removes existing leak rate components and installs a spool piece to provide a tie-in for vendor supplied equipment. The as-built system is a combination of vendor supplied and permanent plant components. The schematic system diagram is shown by Figure 6.2-59 and locations of temperature and humidity elements are shown by Figure 6.2-60.

The leakage rate test system consists of the applicable components, valves, instrumentation, controls, and associated piping required to accomplish the following:

1. Pressurize the Reactor Building with dry, compressed air.
2. Control the pressurization and blowdown of the Reactor Building.
3. Remove moisture and other impurities from the compressed air.
4. Protect against overpressurization.
5. Measure pressure, temperature and humidity of the Reactor Building atmosphere.
6. Superimpose a known leakage rate on the measured containment leakage rate.

Instruments to monitor the pressure, temperature and dewpoint temperature of the contained air are mounted on a test panel located outside the Reactor Building. Sensors for these instruments are mounted in selected locations within the Reactor Building. Two (2) flow meters are also mounted on the test panel. These flow meters are used to superimpose a known leakage rate on the previously measured Reactor Building leakage rate. Additional temporary instrumentation may be installed to enhance the measurement of test parameters.

Two (2) 8 inch Reactor Building blowdown lines are provided for depressurization upon completion of the leakage rate tests. Associated piping, valves, instrumentation and controls are also provided.

Permanent components of the system are rated at 150 psig and 250° F. Piping penetrations and blind flanges are fabricated in accordance with the ASME Code, Section III (Reference 23), Class 2.

6.2.6.2 Containment Penetration Leakage Rate Test

Components which penetrate and seal the containment boundary with seals, gaskets or sealant compounds which are resilient; or piping penetrations fitted with an expansion bellows as the only barrier to leakage from containment are leak tested (Type B test) at periodic intervals in accordance the CLRTP during the lifetime of the plant to ensure their continuing integrity.

6.2.6.2.1 Applicability

This section discusses the various types of penetrations used in the Virgil C. Summer Nuclear Station and identifies which types are leakage tested and which do not require leakage testing.

6.2.6.2.1.1 Piping Penetrations and Spares

Table 6.2-53 is a listing of piping penetrations and spares. There are basically 4 types of penetration: spares, cold penetrations, hot penetrations, and specialty penetrations.

Spare penetrations are sealed by welding pipe caps to each end of the penetration sleeve. Since no resilient or flexible seals are used, these penetrations do not require Type B leakage tests.

Cold penetrations are sealed by a flat plate, of 1/2 inch or greater thickness, welded to both the sleeve and the process pipe at each end of the penetration sleeve. Since no resilient or flexible seals are used, these penetrations do not require Type B leakage tests.

Hot penetrations are sealed on the inside of containment by a flat plate in a manner similar to cold penetrations. On the outside, they are sealed by a single bellows, one end of which is attached to the penetration sleeve and the other to the process pipe. Since the containment barrier does not utilize a resilient or flexible seal, these penetrations do not require Type B leakage tests.

The specialty penetrations are No. 107, the fuel transfer tube; No. 309, is used to house an abandoned radiation detector and check source assembly originally assigned to RM-G7. Figure 6.2-60a illustrates details of this penetration. Nos. 327, 328, 329, and 425 are used for the recirculation sump line penetrations. The fuel transfer tube is sealed inside containment by a flat plate welded to both the penetration sleeve and to the fuel transfer tube. The fuel transfer tube closure design provides a double barrier and, therefore, constitutes the containment boundary and is tested. This penetration has a bellows seal in the refueling cavity, this bellows seal retains water within the cavity and is not a containment isolation seal. Similarly, a bellows seal is used in the transfer canal to retain water. Since no resilient or flexible seal is used for containment, this bellows seal does not require a Type B leakage test. The lines from the recirculation sumps are sealed by a 1/2 inch thick flat plate welded to both the penetration sleeve and the process pipe. Since no resilient or flexible seal is used for containment isolation, no Type B leakage test is required. The outer end of the sleeve is attached to sump isolation valve containers which are leakage tested. The pipe to containment liner seal is leakage tested with the container.

For the reasons listed above, no piping penetrations are required to be subjected to Type B leakage tests. However, all piping penetrations, including those with a single bellows, have a design

capability for Type B leakage testing. Other spare penetrations are as identified in Section 3.8.1.1.2.2.

6.2.6.2.1.2 Electrical Penetrations

The electrical penetrations are of the header plate type. The seal between the individual wires and the header plate is glass. This seal is neither resilient nor flexible. Therefore, no Type B leakage test is required. The header plate is bolted to the nozzle. The seal is formed by double O-ring gaskets. This type of seal is subjected to Type B leakage tests.

6.2.6.2.1.3 Personnel Airlocks and Equipment Hatch

There are 2 personnel airlocks and one equipment hatch that penetrate the containment boundary. There is a 16 foot diameter equipment hatch, a 9 foot diameter personnel airlock, and a 5 foot diameter personnel emergency airlock. In the case of these penetrations, the barrel is solidly welded to the Reactor Building liner. The cover door on the equipment hatch is sealed to the barrel assembly with a double O-ring seal. Both the inside and outside doors of both personnel airlocks are sealed with double O-ring seals. The personnel airlocks also have operating shafts which penetrate the inner and outer barriers of these penetrations. These barrier penetrations are also sealed with double O-ring seals. The double O-ring seals are subjected to Type B leakage tests.

The personnel airlock and emergency airlock are shown by Figures 3.8-19 through 3.8-20b. All mechanical and electrical penetrations through the atmosphere and containment bulkheads of each airlock are shown by these figures.

Each airlock design provides test connections on the atmosphere side of the atmosphere bulkhead for use in leak testing the entire airlock interspace at design pressure, P_a.

Clamps have been provided for the containment bulkhead door of each airlock. These clamps are installed from within the airlock and must be in place when testing the airlock interspace to P_a as defined in the CLRTP. The clamps are installed by sliding them from the stored position into the clamping position. For testing the personnel and emergency airlocks at P_a, test clamp bolts will be torqued in accordance with the manufacturer’s recommendations as specified in surveillance procedures.

Sufficient clamps have been provided around the door perimeter to assure uniform door sealing. The design has accounted for the bolt forces generated from torquing as well as the design pressure, P_a, multiplied by 1.15.

For local leak testing, a test panel is located on the atmosphere side of the atmosphere bulkhead of each airlock. Separate test connections are provided on each test panel for individual pressurization between the double seals for all handwheel shafts and between the double seals for each door.

Handwheel shaft seals are pressurized and leak tested at a pressure greater than or equal to 8 psig, for at least 3 minutes.

Double door seals are pressurized and leak tested at a pressure greater than or equal to 8 psig, for at least 3 minutes.

The door seals for each airlock have been designed for leak testing between the double seals at a maximum pressure of 10 psig when using only the normal door latching mechanism.

Testing the airlocks at a minimum of 8 psig will verify proper latching of the doors and seating of the double seals, as well as indicating any seal degradation detrimental to leak tightness.

6.2.6.2.2 Procedures

This section discusses the procedures for conducting Type B leakage tests, including test pressure and acceptance criteria.

6.2.6.2.2.1 Piping Penetrations and Spares

As discussed in Section 6.2.6.2.1.1, the only pressure testing of the piping penetrations is testing of the sump isolation valve containers and the process piping that is isolated by gasketed, blind flanges.

The sump isolation valve containers are tested by pressurizing the containers and guard pipes with compressed air through a test connection outside the Reactor Building and monitoring pressure decay.

The blind flange that seals the fuel transfer tube has a double gasketed seal. The collar on the transfer tube that mates with the flange is drilled with passageways that allow pressurization between the gaskets. Because of the small volume between the gaskets, the pressure decay method is impracticable. The test is performed by measuring makeup flow into the test connection.

The leakage rate test system piping is sealed inside and outside the Reactor Building with blind flanges. The gaskets on these flanges are tested by pressurizing the piping between the flanges through test connections on the piping and measuring makeup flow into the test connection.

6.2.6.2.2.2 Electrical Penetrations

As discussed in Section 6.2.6.2.1.2, only the O-ring seals in the mechanical joints on some of the electrical penetrations are subjected to Type B leakage testing. These seals are tested by pressurizing the space between the O-rings and either performing a pressure drop test or by measuring the makeup flow into the test connection.

6.2.6.2.2.3 Personnel Airlock and Equipment Hatch

Type B leakage tests are performed on these 3 penetrations by pressurizing the space between the double resilient seals and measuring the makeup flow into the test connection.

6.2.6.2.3 Test Pressure

Type B leakage tests are conducted using a pressure not less than P_a as defined in the CLRTP.

6.2.6.2.4 Acceptance Criteria

The combined leakage rate for all penetrations and valves subjected to Type B and C tests shall be in accordance with the CLRTP.

6.2.6.3 Containment Isolation Valve Leakage Rate Test

Periodic tests (Type C tests) are conducted in accordance with the CLRTP, to determine the operability and leakage rate characteristics of valves serving an isolation function in the testable fluid systems lines penetrating the Reactor Building.

The Engineered Safety Features Actuation System test circuitry provides the means for testing isolation valve operability.

6.2.6.3.1 Applicability

A list of all piping penetrations is included as Table 6.2-53. A column of this table indicates which penetrations are subjected to Type B leakage tests. Table 6.2-53a indicates containment isolation valves subject to Type C leakage tests. The containment isolation valves associated with the secondary isolation side are not tested.

The boundary or barrier against leakage of containment atmosphere to the environment is the inside of the steam generator tubes, the outside of the steam generator shell, and the outside of all lines connected to the steam generator shell side. After a loss of coolant accident, these components form the actual barrier against release of the containment atmosphere to the environment.

Lines which emanate from the steam generator shell side will not be damaged during a loss of coolant accident. The design of these components is at least equivalent to, or better than, the Reactor Building liner with respect to quality assurance, pressure, temperature, testing, missile protection, etc. Thus, after a loss of coolant accident, components will be available and can be relied upon to limit release of radioactivity in the same manner as the Reactor Building liner.

In the event that the plant has been operating with steam generator tube leaks at the time of a loss of coolant accident, the barrier against release is as previously described. For large breaks, when an orderly shutdown cannot be executed, a plant trip will occur and the Emergency Core Cooling System will be started. Reactor Coolant System pressure will decrease at a rate dependent upon

break size. Some time after the incident, containment atmosphere will enter the steam generator tube bundle through the pipe break. During this initial period (approximately 1/2 to 6 hours after the incident) the steam generator shell side is pressurized. Also, after the short term, the barrier is maintained by a head of water above the tube bundle.

Before, during, and after the initial relief of steam through the safety valves, radioactivity leakage is restricted by the barrier at the steam generator tubes, shell, steam lines, blowdown lines, and sample lines inside the Reactor Building.

In general, test connections are provided to permit pressurization of piping inside the inside isolation valve and a test vent is provided outside of the outside isolation valve to measure leakage through the valves. The test is conducted by connecting the pressure source to a test connection, aligning the valves so that there is only one closed valve between the test connection and test vent and measuring the leakage flow. In those cases where the inside isolation valve is a check valve, a second test connection is provided between the isolation valves to permit pressurizing the outside isolation valve. Where required, the test connection is attached to a blind flange which is attached to the piping inside the Reactor Building (e.g., Reactor Building purge valves).

The selection of the number and location of test connections and vents for each isolation valve to be subjected to Type C leakage testing is based upon satisfying the requirement that the test pressure be applied in the same direction as the pressure existing when the valve is performing its safety function, unless it can be determined that the results for a pressure applied in a different direction will provide equivalent or more conservative results. These valves are listed in Table 6.2-53a. The test media for XVG-08889-SI is directed between the disc. This method is identified per ANS 56.8 as an equivalent and conservative method of leak rate testing.

As previously discussed, test connections and vents have been incorporated into the design of piping penetrations that contain isolation valves. These connections, which permit testing of those isolation valves subject to Type C leakage testing, are shown schematically on the appropriate system flow diagrams. Leakage testing will be performed in such a manner that measurement of leakage past the valve seat will be from inside to outside containment except as listed in Table 6.2-53a.

6.2.6.3.2 Test Pressure

Type C leakage tests are conducted at a pressure not less than P_a as defined in the CLRTP.

6.2.6.3.3 Acceptance Criteria

See Section 6.2.6.2.4.

6.2.6.4 Scheduling and Reporting of Periodic Tests

6.2.6.4.1 Test Frequencies

6.2.6.4.1.1 Type A Tests

Test frequency shall be as established by the CLRTP.

6.2.6.4.1.2 Type B Tests

Test frequency shall be as established by the CLRTP.

6.2.6.4.1.3 Type C Tests

Test frequency shall be as established by the CLRTP.

6.2.6.4.2 Reports

The preoperational test summary technical report was submitted to the NRC approximately 3 months after the performance of the Type A test.

The report of the preoperational test included a schematic arrangement of the leakage rate measurement system, the instrumentation used and the test program selected as applicable to the preoperational test and subsequent periodic tests. The report contained an analysis and interpretation of the leakage rate test data for the Type A test results to the extent necessary for demonstration of the acceptability of the containment leakage rate in satisfying the acceptance criteria.

Periodic test results are documented and available for review in accordance with the CLRTP.

6.2.6.5 Special Testing Requirements

Leakage rate testing subsequent to containment modification is performed in accordance with the CLRTP.

Virgil C. Summer Nuclear Station does not utilize a subatmospheric containment, secondary containment, or pressure seal system.

Table 6.2-1
General Containment Design and Evaluation Parameters

General Design Information		
Maximum Internal Design Pressure, psig		57
Maximum External Design Pressure, psig		3.5 psig
Design temperature, °F		283(1)
Free Volume, ft^3		1.84×10^6
Design Leak Rate, max. allowable, %/day		0.2
Engineered Safety Features	Full Capacity	Value Used for Analysis
Passive Safety Injection		
Number of Accumulators	3	2 or 3
Pressure Setpoint, Psig	600	600
Active Safety Injection		
Residual Heat Removal Flow Rate, lb/sec	990.4	460.2 or 990.4
Reactor Building Spray System		
Number of Lines	2	1 or 2
Number of Pumps	2	1 or 2
Number of Headers	6	3 or 6
Design Flow, gpm	5,000	2,500 to 5,000
Reactor Building Cooling Units		
Number	4	1 or 2
Air Side Flow Rate, cfm/unit	60,270(3)	54,200(3)
Heat Removal Rate at 283°F, Btu/hr/unit	125×10^6	90.7×10^6(2)
Residual Heat Removal System Heat Exchangers		
Number	2	1
UA, BTU/hr-°F/unit	1.519×10^6(4)	1.519×10^6(4)

Table 6.2-1 (CONTINUED)
General Containment Design and Evaluation Parameters

Flow Rate		
Shell Side, gpm	5,600	5,600
Tube Side, gpm	3,750	3,750

(1) Peak reactor building temperature is 373.7 °F as described in Section 6.2.1.1.1

(2) Maximum analysis value assumed was an energy removal rate of 90.7 x 10^6 Btu/Hr, at 283°F.

(3) This parameter is used only in the Chapter 15 Radiological Consequence Analysis for particulate iodine removal post-LOCA. This parameter is not used in the Chapter 6 pressure/temperature analyses.

(4) Based on the maximum component cooling water shell-side inlet temperature of 120° F (Reference 47).

Table 6.2-1a
Main Steam Line Breaks Analyzed

Double Ended Ruptures[1] (No Entrainment) to Assess Impact of Single Failures

Area/Power	Failures Assumed[2]
1.4 ft^2/ 102%	MSIV[3]
1.4 ft^2/ 102%	FWIV[4]
1.4 ft^2/ 102%	EFW FCV[5]
1.4 ft^2/ 102%	Diesel[6]
1.4 ft^2/ 102%	CH-A[7]

Double Ended Ruptures (with Entrainment) to Assess Impact of Power Level

Area/Power	Failures Assumed[2]
1.4 ft^2/ 75%	CH-A
1.4 ft^2/ 50%	CH-A
1.4 ft^2/ 25%	CH-A
1.4 ft^2/ 25%	FWIV[4]
1.4 ft^2/ 0%	CH-A

Double Ended Ruptures (No Entrainment) to Assess Impact of Break Size

Area/Power	Failures Assumed[2]
1.2 ft^2/ 102%	FWIV, MSIV, EFW FCV, Diesel
1.2 ft^2/ 102%	FWIV, MSIV, EFW FCV, Diesel

Small Double Ended Ruptures (With Entrainment)

Area/Power	Failures Assumed[2]
1.1 ft^2/ 75%	FWIV, MSIV, EFW FCV, Diesel
0.8 ft^2/ 50%	FWIV, MSIV, EFW FCV, Diesel
0.6 ft^2/ 25%	FWIV, MSIV, EFW FCV, Diesel
0.2 ft^2/ 0%	FWIV, MSIV, EFW FCV, Diesel

Table 6.2-1a (continued)
Main Steam Line Breaks Analyzed

Small Double Ended Ruptures (No Entrainment)

Area/Power	Failures Assumed(2)
1.0 ft^2/ 75%	FWIV, MSIV, EFW FCV, Diesel
0.7 ft^2/ 50%	FWIV, MSIV, EFW FCV, Diesel
0.5 ft^2/ 25%	FWIV, MSIV, EFW FCV, Diesel
0.1 ft^2/ 0%	FWIV, MSIV, EFW FCV, Diesel

Split Ruptures (No Entrainment)

Area/Power	Failures Assumed(2)
0.878 ft^2/ 102%	
0.871 ft^2/ 75%	FWIV, EFW FCV, Diesel
0.863 ft^2/ 50%	FWIV, EFW FCV, Diesel
0.849 ft^2/ 25%	FWIV, EFW FCV, Diesel
0.772 ft^2/ 0%	FWIV, EFW FCV, Diesel

(1) Effective break area for broken loop is 1.4 ft^2.
(2) Failure of one Chg/SI pump is assumed in all analyses.
(3) MSIV = Main steam isolation valve fails to close.
(4) FWIV = Main feedwater isolation valve fails to close.
(5) EFW FCV = EFW control valve which terminates flow to the faulted SG fails to close.
(6) Diesel = One emergency diesel fails to start.
(7) CH-A = Failure of Electrical Channel A.

(2) DEHL = Double-Ended Hot Leg
(3) Includes a PAD5 penalty of 0.12 psig

Table 6.2-4
Long Term Values of Reactor Building Parameters For Loss of Coolant Accident and Main Steam Line Break

	Design Basis [1] Accident Main Steam Line Break	LOCA [1] DEPS with Minimum Safety Injection
Reactor Building Pressure, psig	38.3	2.1
Reactor Building Vapor Temperature, °F	257	111.1
Reactor Building Sump Temperature, °F	270	136.2

(1) Long-term MSLB = 1800 Seconds
Long-term LOCA = 1440 Hours

Table 6.2-5
Chronology of Events For the Design Basis Accident
Main Stream Line Break[1]

	Time (Sec.)
1. Break occurs, which blows down all three steam generators, coincident with Electrical Channel A Failure [2]	0.0
2. Reactor building pressure reaches the safety injection setpoint.	1.0
3. Feedwater pumps tripped (not assumed in analysis)	N/A
4. Main steam isolation valves close (blowdown limited to one steam generator)	7.0
5. Reactor building spray initiated	53.1
6. Reactor building cooling units fully operational	86.5
7. Peak pressure of 53.0 psig is reached	1800
8. Emergency feedwater flow manually terminated	1800
9. End of Analysis for DBA	1800.0

(1) 1.4 ft^2 DE Rupture from 25% power.
(2) Electrical Channel A Failure results in loss of power to the feedwater control and isolation valves, main steam isolation valves, prevents startup of an emergency diesel generator, and prevents automatic isolation of emergency feedwater to the faulted SG.

(1) Material thickness, where not indicated specifically, is in feet.
(2) A 5 percent (plus), margin (for ECCS analysis) is included in the calculated weights of reactor building liner, liner anchors and fuel transfer canal liner.
(3) The Area column shows a conservatively high surface area (for ECCS analysis) for one side (plus ends if significant) of the heat sink.
(4) The Exposure column indicates if both sides are exposed to the reactor building atmosphere (or one side to the outside).
(5) Carbon Steel plate (1/4 in.) lines interior surface. Theoretically, zero surface are is exposed directly to reactor building atmosphere.
(6) Uncertainty margin of 5 percent included.
(7) Heat sink modeled at ambient temperature of 120°F, weighted average temperature
(8) Not used for peak pressure analysis, only for ECCS analysis.
(9) Conservatively not used for peak pressure analysis.
(10) IHA Carbon and Stainless Steel Summaries - See DC00020-002, Table 12.

33 Node Reactor Cavity Model Control Volumes

Control Volume No.	Description	Height (ft)	Volume (ft^3)	Volume Flow Area (ft^2)	Bottom Elev. (ft)	Initial Conditions: Temp. (°F)	Initial Conditions: Pressure (psia)	Initial Conditions: Quality	Calc. Peak Diff. Press.(1) (psi)	Design Diff. Press (2) (psi)	Design Margin (%)

(1) With respect to containment.
(2) The following notes 3 and 4 are applicable to the design of the reactor baffle system.
(3) These values are for 150 sq. inch break and apply to original design of the baffles before the design details were changed in 1978 to accommodate a revised construction sequence. These loads were increased by a dynamic load factor of 1.5 for structural design.
(4) For Nodes 28, 29 and 32 the peak differential pressures were also evaluated for a break size of 100 sq. inches in 1978 and 127 sq. inches in 1988. The 127 sq. inch break values were obtained by interpolation of the pressure/temperature analyses for the 100 sq. inch and 150 sq. inch breaks. The calculated peak and design differential pressures (with respect to annulus) shown are for the 127 sq. inch break which is the maximum expected break size that can occur. These values were increased by a dynamic load factor of 1.2 for structural design.0

Table 6.2-49
Reactor Building Spray System Component Data

Reactor Building Spray Pumps	
Number	2
Rated Capacity, gpm	2500
Rated Head, ft	450
Material	Stainless steel (wetted parts) or equivalent corrosion resistant material
Design Pressure, psig	300
Design Temperature, °F	250
Code	ASME III, Class 2
Safety Class	2a
Sodium Hydroxide Storage Tank	
Number	1
Nominal Capacity, gal (minimum required usable volume)	3300 (3050)
Material	Carbon steel
Design Pressure, ft	Static Head + 3 psig
Code	ASME III, Class 3
Safety Class	2b
Valves Exposed to Recirculated Coolant and Valves in the Refueling Water Storage Tank Discharge Line	
Material	Stainless steel
Code	ASME III, Class 2
Safety Class	2a
Valves in the Sodium Hydroxide Storage Tank Discharge Line	
Material	Stainless steel

Table 6.2-49 (continued)
Reactor Building Spray System Component Data

Code	ASME III, Class 3
Safety Class	2b

Piping in Sodium Hydroxide Storage Tank Discharge Line

Material	Stainless steel
Code	ASME III, Class 3
Safety Class	2b

Other Piping, exposed to water recirculated from the Reactor Building Sump and water from the RWST

Material	Stainless steel
Code	ASME III, Class 2
Safety Class	2a

Spray Nozzles

Number	330
Material	Stainless steel
Type	Hollow cone
Flow, gpm/nozzle	15.2
Pressure Drop, psi	40

Table 6.2-50
Single Failure Analysis - Reactor Building Spray System

	Component	Malfunction	Comments
1.	Reactor building spray pump	Fails to start.	Since each of the two subsystems of the reactor building spray system is equally sized, the remaining subsystem provides heat removal capability at a reduced rate. In combination with the reactor building emergency cooling system, heat removal capability in excess of the requirements is provided. Elemental iodine removal is adequate with one subsystem operating.
2.	Reactor building isolation valve.	Fails to open.	(Same as above.)
3.	Check valve in suction line.	Fails to open.	(Same as above.)
4.	Sodium hydroxide tank discharge valve.	Fails to open.	The redundant discharge valve admits adequate sodium hydroxide to the other subsystem to provide the required iodine removal.

Table 6.2-51
Reactor Building Spray System Header Locations and Sizes

Subsystem A

Header	Ring Diameter (ft)	Pipe Size (in)	Elevation (ft-in)
Outer header	98	6	578-10
Middle header	58	6	590-4
Inner header	16	3	595-7

Subsystem B

Header	Ring Diameter (ft)	Pipe Size (in)	Elevation (ft-in)
Outer header	102	6	577-0
Middle header	62	6	589-6
Inner header	20	3	595-0

Table 6.2-52
Single Failure Analysis - Reactor Building
Heat Removal and Filtering System

	Component	Malfunction	Comments
1.	Air Handling Unit Fan Motor	Fails to start or fails to start at low speed.	Cooling continues from the remaining operating unit with supplemental cooling from the spray system.
2.	Cooling Coils	Rupture	The coils are designed for hydrostatic testing at 200 psig which is in excess of the design service water pressure. However, if rupture occurs, cooling continues as noted under item 1 above.
3.	Plenum and Ductwork	Rupture	The plenums and connected ductwork are designed to withstand the post accident pressure transient and the systems are sufficiently separated so that the effects of a pipe break or missile are confined to a single unit. Thus, rupture of a portion of the system or a single component does not prevent continued cooling as noted under item 1 above.
4.	Cooling Water Piping	Rupture	The piping for two of the units is physically separated from that of the remaining two units and is designed as Seismic Category I. Thus, rupture of a portion of the system does not affect all units and does not prevent cooling as noted under item 1 above.
5.	Water Control Valves	Fail to operate.	The valves are used for switching from the normal cooling water supply to the service water supply during a post accident period. The valves are redundant and are periodically tested. Failure of a single valve does not prevent cooling as noted under item 1 above.
6.	HEPA Filter Bypass Duct	Fails to operate.	Failure of the dampers in the normal position results in loss of filtering ability but not in loss of cooling for the affected units.

Table 6.2-53(Continued)
Isolation Summary

1 System abbreviations are as follows:

AH	-	Air Handling System
BD	-	Steam Generator Blowdown System
CC	-	Component Cooling Water System
CS	-	Chemical and Volume Control System
DN	-	Demineralized Water, Nuclear Services System
EF	-	Emergency Feedwater
FS	-	Fire Service System
FW	-	Feedwater System
HR	-	Post Accident Hydrogen Removal System
IA	-	Instrument Air System
LR	-	Leak Rate Test System
MS	-	Main Steam System
ND	-	Reactor Building and Auxiliary Building Sump Pumps System
NG	-	Nitrogen Blanketing System
RC	-	Reactor Coolant System
RM	-	Radiation Monitoring System
SA	-	Service Air System
SF	-	Spent Fuel Cooling System
SI	-	Safety Injection System
SP	-	Reactor Building Spray System
SS	-	Nuclear Sampling System
SW	-	Service Water System
WL	-	Liquid Waste Processing System

Table 6.2-53(Continued)
Isolation Summary

NOTES TO TABLE 6.2-53 (Continued)

2 "Yes" indicates that the penetration serves a system which is essential for safe shutdown or accident mitigation. Penetrations which may provide some post-accident services (e.g., sampling) are not indicated as essential.

3 This is the distance, along the pipe, from the outer edge of the concrete of the reactor building to the nearest edge of the outside containment isolation valve. Where there are one or more branches from the pipe, the distance is to the largest valve to the farthest of more than one equal size valves.

4 "No" indicates that these penetrations are sealed inside containment by a flat plate of 1/2 inch thickness or thicker, welded to both the penetration sleeve and process pipe. Since this isolation barrier does not utilize a resilient or flexible seal, these penetrations do not require Type B leakage tests.

5 This distance is measured as in Note 3 but it should be noted that the valve is within the valve compartment discussed in Section 6.2.4.2.2.

6 Isolation valve arrangement and pipe length to valve are not applicable since penetration is sealed inside containment by a welded cap.

Table 6.2-53a
Summary of Valves Subjected to Type C Leakage Tests

Penetration Number	Service	System	Type C Leakage Test [1] Inside Containment	Type C Leakage Test [1] Outside Containment
101	Reactor Building Purge Exhaust	AH	Yes [6]	Yes

Table 6.2-53a (Continued)
Summary of Valves Subjected To Type C Leakage Tests

NOTES:

1 N/A - not applicable.

2 These piping penetrations, which utilize blind flanges as isolation barriers, are subject to Type B leakage testing as indicated in Table 6.2-53.

3 Isolation valves located in secondary side piping that penetrates containment are exempt from Type C leakage testing since the requirements of Appendix J to 10CFR 50 for leak testing of these valves applies only to direct cycle boiling water power reactors. These valves are called Containment Boundary Valves (CBV) on the system flow diagrams.

4 Deleted RN 03-035, 10-21-2003

5 These check valves are not testable due to their location and orientation within their systems.

6 These valves are tested in the reverse direction due to system design and their orientation.,

7 In operation during Integrated Leak Rate Test or during LOCA.

8 Meets 10CFR50 Appendix J Type C leak test requirements by Type C air leak test or by taking credit for 30 day water seal capability upon passing a water leak test.

9 XVG08889-SI is equipped with a bonnet relief system that allows the test medium to be introduced between the valves disc. This allows the leakage to be measured in both directions.

10 Per ANS/ANSI-56.8, the associated valve is exempt from Type C leakage testing since the boundary does not constitute a potential primary containment atmospheric pathway during or following a LOCA. This valve is a Containment Isolation Valve as indicated on the system flow diagram.

Table 6.2-54(Continued)
Isolation Valve Summary

General - This table does not include small manual valves on test connections or test vents used for Type C leak tests.

1 Method of Actuation

EMO	-	Electric motor operated
AO/FC	-	Air pressure to open; spring return, fail close on loss of air
AO/FO	-	Air pressure to close; spring return, fail open on loss of air
PO/FC	-	Process pressure to open; spring return, fail close on loss of process pressure
HW	-	Hand wheel, manual operation
EO	-	Energize solenoid coil to open
AO/AC	-	Air to open; and air to close, fail closed on loss of electric signal

2 Actuation Signal and Channel

S - Safety Injection Signal

(1) Low pressurizer pressure (2/3), or

(2) High containment pressure (2/3), or

(3) Differential steam line pressure (2/3 on two loops), or

(4) Low steam line pressure (2/3), or

(5) Manual (1/2).

T - Containment Isolation Signal (Phase A)

(1) Safety injection signal or

(2) Manual (1/2)

C - Main Steam Isolation Signal

(1) High reactor building pressure (2/3) (note, different from S(2), above), or

(2) High steam flow (2/3) in coincidence with or low-low T_{avg} (2/3), or

(3) Low Steam pressure (2/3), or

(4) Manual (1/2)

Table 6.2-54(Continued)
Isolation Valve Summary

NOTES TO TABLE 6.2-54 (Continued)

D - Feedwater Isolation Signal

(1) Safety injection signal, or

(2) Steam generator "hi-hi" level (2/3), or

(3) Low T_{avg} coincident with reactor trip

P - Containment Isolation (Phase B)

(1) High-high reactor building pressure (2/4), or

(2) Manual (2/2)

F - Steam Generator Blowdown Isolation Signal

(1) Containment isolation (Phase A), or

(2) Start of emergency feedwater system.

G - Valve opens on pump start signal (ESF Loading sequence)

H - Reactor Building purge supply and exhaust isolation

(1) Containment ventilation isolation signal, or

(2) High radiation in reactor building purge exhaust vent
(A train valves) or
containment atmosphere high radiation (B train valves), or

(3) Manual

I - Engineered safety features load sequencer (ESFLS)

(1) Safety injection signal, or

(2) Blackout, or

(3) Manual

J - Remote Manual

K - Reactor Building 6 inch purge supply and exhaust vent

(1) Containment isolation (Phase A), or

(2) High radiation in reactor building purge exhaust
vent (A train valves) or containment atmosphere high radiation (B train valves), or

(3) Manual

Table 6.2-54(Continued)
Isolation Valve Summary

NOTES TO TABLE 6.2-54 (Continued)

L - (Intentionally left Blank by Amendment 96-03).

M - Feedwater isolation valve isolation signal

(1) Feedwater isolation (comprised of D above, Train A only), or

(2) (Intentionally left blank by Amendment 02-01)

(3) (Intentionally left blank by Amendment 96-03)

(4) High-high intermediate sump level (2 of 3), or

(5) (Intentionally left blank by Amendment 02-01)

(6) Manual

A - Automatic actuation from refueling water storage tank Lo-Lo level coincident with safety injection signal.

CHANNEL

(A) Signal is from the A channel of the actuation system.

(B) Signal is from the B channel of the actuation system

(A/B) Signal is from both channels of the actuation system (e.g., dual solenoid valves for an air operated valve – one from channel A, the other from channel B)

3 "Yes" indicates remote position indication

4 "Shutdown" means normal shutdown on residual heat removal system. It does not include testing or refueling operations.

5 Power Source:

IA-A - Valve is operated by the non safety-related instrument air system. The associated solenoid valve is supplied from safety-related battery A.

IA-B - Valve is operated by the non safety-related instrument air system. The associated solenoid valve is supplied from safety-related battery B.

EP-A - Valve is supplied from the safety-related emergency power bus A.

EP-B - Valve is supplied from the safety-related emergency power bus B.

Table 6.2-54(Continued)
Isolation Valve Summary

NOTES TO TABLE 6.2-54 (Continued)

6 Closure time is only for electric motor operated valves and air operated valves larger than 2-1/2 inches. Stroke times listed are not necessarily representative of actual stroke times. Tabulated stroke times reflect Technical Specifications, accident analysis assumptions, and design specified values.

7 Valve closure times are verified during preoperational testing.

8 Valve is controlled by non-class 1E control signal or loss of Class 1E power to the Train A and B Solenoid valves.

9 This is the maximum closure time originally supplied by Technical Specification, Table 3.6-1, for satisfying system isolation requirements. Tech. Spec. Table 3.6-1 has since been deleted by Amendment No. 110 in accordance with Generic Letter 91-08.

10 This is maximum stroke time assumed in Accident Analysis.

11 Technical Specification 3.6.1 listed NA for maximum stroke time of these valves. Tech. Spec. Table 3.6.1 has since been deleted by Amendment No. 110 in accordance with Generic Letter 91-08.

12 For more information about FIV stroke time see FSAR Section 6.2.1.3.10.3.1 and Technical Specification 4.7.1.6 and Bases.

13 The stroke time for XVG3003A/B-SP is greater than 30 seconds as a result of re-gearing the actuators per MRF-21745 (40 seconds). This increased stroke time is acceptable on the basis that 100% flow is achieved at 75% of the valve’s stroke time. Therefore the 30 seconds required stroke is maintained (.75 x 40 second = 30 seconds)

14 During normal or shutdown operation, either one letdown isolation valve (8149B or C) or any combination of two letdown isolation valves inside containment may be open. During shutdown operation, all three letdown isolation valves may be open when RCS pressure is less than normal.

(1) Cable Bill of Material is the same both inside and outside containment, unless otherwise noted.
(2) Field to install spare pigtails (through nozzle side only) and tag with pin and plug assignment. (See Note 9)
(3) For convenience spare pigtail cable B/M number is called out in B/M number column of field cable. Should spares be used in the future, information will be added.
(4) Spare plug pin position on junction box side of penetration flange to have blinding pins per vendor instructions. (See Note 9)
(5) The individual conductors coming from the plug shall be identified by wire marks as to which pin in the plug it comes from. When making the splice in the splice box, the field cable shall be spliced to the plug cable using the field cable term sheet to show which pin (plug conductor) it goes to.
(6) Field installed junction box.
(7) Spare cables should be coiled and put in a field mounted junction box or a suitable cable tray, on XRP0043,44,45, and 46. The spare cable should be coiled in the penetration junction box.
(8) All spare cables to use binding pins as specified c32c2103-pin #. (See Note 9)
(9) As required to facilitate construction/maintenance, the field shall replace all blinding pins on the junction box side. At the option of SCE&G or whenever the contractor enters a j-box side plug, all spare pins shall be wired out with 25’ long pigtails of the type cable specified. Tag all spare pigtails, per Note 5.

6.3 EMERGENCY CORE COOLING SYSTEM

6.3.1 Design Bases

6.3.1.1 Range of Coolant Ruptures and Leaks

The emergency core cooling system (ECCS) is designed to cool the reactor core as well as to provide additional shutdown capability following initiation of the following accident conditions:

1. Pipe breaks in the reactor coolant system (RCS) which cause a discharge larger than that which can be made up by the normal makeup system, up to and including the instantaneous circumferential rupture of the largest pipe in the RCS.
2. Rupture of a control rod drive mechanism causing a rod cluster control assembly ejection accident.
3. Pipe breaks in the steam system, up to and including the instantaneous circumferential rupture of the largest pipe in the steam system.
4. A steam generator tube rupture.

The acceptance criteria for the consequences of each of these accidents are described in Chapter 15 in the respective accident analyses sections.

6.3.1.2 Fission Product Decay Heat

The primary function of the ECCS following a loss of coolant accident is to remove the stored and fission product decay heat from the reactor core such that fuel rod damage, to the extent that it would impair effective cooling of the core, is prevented. The acceptance criteria for the accidents, as well as analyses of the accidents are provided in Chapter 15.

6.3.1.3 Reactivity Required for Cold Shutdown

The ECCS provides shutdown capability following the accidents listed in Section 6.3.1.1 by means of injecting borated water. The most critical accident for shutdown capability, relative to this system, is the steam line break and for this the ECCS meets the criteria defined in Chapter 15.

6.3.1.4 Capability to Meet Functional Requirements

To ensure that the ECCS will perform its desired function during the accidents listed in Section 6.3.1.1, it is designed to tolerate a single active failure during the short term immediately following an accident, or to tolerate a single active or passive failure during the long term following an accident. This subject is detailed in Sections 3.1 and 6.3.2.11.

6.3.1.5 Loss of Offsite Power

The ECCS is designed to meet its minimum required level of functional performance with onsite electrical power system operation (assuming offsite power is not available) or with offsite

electrical power system operation for any of the above abnormal occurrences assuming a single failure as defined above.

6.3.1.6 Seismic Requirements

The ECCS is designed to perform its function of ensuring core cooling and providing shutdown capability following an accident under simultaneous safe shutdown earthquake (SSE) loading. The seismic requirements are defined in Chapter 3.

6.3.2 System Design

The ECCS components are designed such that a minimum of two accumulators, one charging pump and one residual heat removal pump together with their associated valves and piping will assure adequate core cooling in the event of a Design Basis Accident. The redundant onsite emergency diesels assure adequate emergency power to all electrically operated components in the event that a loss of offsite power occurs simultaneously with a loss of coolant accident, even assuming a single failure in the emergency power system such as the failure of one diesel to start. Also, at strategically identified local high points, the ECCS is provided with indicating air-traps to ensure the ECCS remains void free (reference NRC GL 2008-01).

6.3.2.1 Schematic Piping and Instrumentation Diagrams

Schematic piping and instrumentation and process flow diagrams of the ECCS are shown in Figure 6.3-1 (Sheets 1 through 3) and Figure 6.3-2, respectively. Pertinent design and operating parameters for the components of the ECCS are given in Table designed are listed in Table 3.2-1.

6.3.2.2 Equipment and Component Descriptions

The component design and operating conditions are specified as the most severe conditions to which each respective component is exposed. For each component, these conditions are considered in relation to the Code to which it is designed. By designing the components in accordance with applicable codes, and with due consideration for the design and operating conditions, the fundamental assurance of integrity of the ECCS components is maintained. Components of the ECCS are designed to withstand the appropriate seismic loadings in accordance with their safety class as given in Table 3.2-1.

The major mechanical components of the ECCS are discussed in Sections 6.3.2.2.1 through 6.3.2.2.6.

6.3.2.2.1 Accumulators

The accumulators are pressure vessels partially filled with borated water and pressurized with nitrogen gas. During normal operation each accumulator is isolated from the RCS by two check valves in series. Should the RCS pressure fall below the Accumulator pressure, the check valves open and borated water is forced into the RCS. One accumulator is attached to each of the cold

legs of the RCS. Mechanical operation of the swing-disc check valves is the only action required to open the injection path from the accumulators to the core via the cold leg.

Connections are provided for remotely adjusting the level and boron concentration of the borated water in each accumulator during normal operation as required. Accumulator water level may be adjusted either by draining to the refueling water storage tank or by pumping borated water from the refueling water storage tank to the accumulator. Samples of the solution in the accumulators are taken periodically for checks of boron concentration.

Accumulator pressure is provided by a supply of nitrogen gas, and can be adjusted as required during normal plant operation; however, the accumulators are normally isolated from this nitrogen supply. Gas relief valves on the accumulators protect them from pressures in excess of design pressure.

The accumulators are located within the reactor building but outside of the secondary shield wall which protects them from missiles. Since the accumulators are located within the reactor building, a release of the nitrogen gas in the accumulators would cause an increase in normal containment pressure. Containment pressure increase following release of the gas from all accumulators has been calculated and is well below the containment pressure setpoint for ECCS actuation.

Release of accumulator gas is indicated by the accumulator pressure indicators and alarms. Thus, the operator takes action promptly as required to maintain plant operation within the requirements of the Technical Specification covering accumulator operability.

6.3.2.2.2 Boron Injection Tank

Deleted by Amendment 3.

6.3.2.2.3 Boron Injection Surge Tank

Deleted by Amendment 3.

6.3.2.2.4 Pumps

6.3.2.2.4.1 Residual Heat Removal Pumps

In the event of a loss of coolant accident the residual heat removal pumps are started automatically on receipt of a safety injection signal. The residual heat removal pumps deliver water to the RCS from the refueling water storage tank during the injection phase and from the reactor building sump during the recirculation phase. Each residual heat removal pump is a single stage, vertical position, centrifugal pump. It has an integral motor-pump shaft driven by an induction motor. The unit has a self-contained mechanical seal cooled by component cooling water.

A minimum flow bypass line is provided for the pumps to recirculate and return the pump discharge fluid to the pump suction should the pumps be started with their normal flow paths

blocked. Once flow is established to the RCS, the bypass line is automatically closed. This line prevents deadheading of the pumps and permits pump testing during normal operation.

The residual heat removal pumps are discussed further in Section 5.5.7. A pump performance curve is given in Figure 6.3-3.

6.3.2.2.4.2 Centrifugal Charging Pumps

In the event of an accident. the two operable charging pumps are started automatically on receipt of a safety injection signal and are automatically aligned to take suction from the refueling water storage tank during injection. During recirculation, suction is provided by the residual heat removal pumps.

These pumps deliver flow to the RCS at the prevailing RCS pressure. Each centrifugal charging pump is a multistage diffuser design, barrel-type casing with vertical suction and discharge nozzles. The pump is driven through a speed increaser connected to an induction motor. The unit has a self-contained lubrication system which is cooled by component cooling water and a self-contained mechanical seal cooling system.

A minimum flow bypass line is provided on each pump discharge to recirculate flow to the volume control tank after cooling via the seal water heat exchanger during normal plant operation. Each minimum flow bypass line contains a valve which may be closed during the switchover from injection to recirculation. The common minimum flow bypass line also contains a valve which may be closed during the switchover to recirculation. A safety injection signal closes the valves to isolate the normal charging line and volume control tank and opens the charging pump/refueling water storage tank suction valves to align the high head portion of the ECCS for injection. During normal plant operation, at least one charging pump is continuously in service. The second pump is a non-running pump on the inactive loop and the third, if available, is designated as a spare and its breaker(s) are racked out. The other charging pumps may be tested during power operation via the minimum flow bypass lines.

Pump performance curves are given in Figures 6.3-4a, 6.3-4b, and 6.3-4c.

6.3.2.2.4.3 Boron Injection Recirculation Pumps

Deleted by Amendment 3.

6.3.2.2.4.4 Positive Displacement Hydrostatic Test Pump

This pump serves two functions, neither of which is safety-related. Permanent connections are provided to the accumulators to allow addition of borated water from the refueling water storage tank. Temporary connections permit the use of this pump in hydro-testing the plant piping systems and leak testing check valves as described in Section 5.2.2.4.

6.3.2.2.5 Residual Heat Exchangers

The residual heat exchangers are conventional shell and U-tube type units. The tubes are seal welded to the tubesheet. During normal cooldown operation, the residual heat removal pumps circulate reactor coolant through the tube side while component cooling water flows through the shell side. During emergency core cooling recirculation operation, water from the reactor building sump flows through the tube side.

A further discussion of the residual heat exchangers is found in Section 5.5.7.

6.3.2.2.6 Valves

Design parameters for all types of valves used in the ECCS are given in Table 6.3-1. Operability requirements are discussed in Section 3.9.

Design features employed to minimize valve leakage include:

1. Where possible, packless valves are used.
2. Other valves which are normally open, except check valves and those which perform a control function, are provided with backseats to limit stem leakage.
3. Normally closed globe valves are installed with recirculation fluid pressure under the seat to prevent stem leakage of recirculated (radioactive) water.
4. Relief valves are enclosed, i.e., they are provided with closed bonnet.

6.3.2.2.6.1 Motor Operated Valves

The seating design of all motor operated gate valves is of the Crane flexible wedge design. These designs release the mechanical holding force during the first increment of travel so that the motor operator works only against the frictional component of the hydraulic unbalance on the disc and the packing box friction. The discs are guided throughout the full disc travel to prevent chattering and to provide ease of gate movement. The seating surfaces are hard faced to prevent galling and to reduce wear. The discs for the SI/RHR sump recirc valves, XVG08811A(B)-SI and XVG08812A(B)-SI have been drilled with a 1/8 inch hole to provide assurance against pressure locking. This hole provides a drain path from the bonnet to the bearing block void space then through the hole to one side of the disc. A bonnet relief system has been installed on the bonnet of XVG08889-SI to eliminate postulated pressure locking conditions.

Where a gasket is employed for the body to bonnet joint, it is either a fully trapped, controlled compression, spiral wound gasket with provisions for seal welding, or it is of the pressure seal design with provisions for seal welding. The valve stuffing boxes are designed with a lantern ring leakoff connection with a minimum of a full set of packing below the lantern ring and a minimum of one-half of a set of packing above the lantern ring. A full set of packing is defined as a depth of packing equal to 1-1/2 times the stem diameter. The motor operator incorporates a “hammer blow” feature that allows the motor to impact the discs away from the seat upon opening or backseat upon closing. This “hammer blow” feature not only impacts the disc but allows the

motor to attain its operational speed prior to impact. Valves which must function against system pressure are designed such that they function with a pressure drop equal to full system pressure across the valve disc.

Each of the three centrifugal charging pump minimum flow bypass lines is equipped with a motor operated globe valve. The valves are of the bolted bonnet design utilizing a spiral wound asbestos gasket with provisions for seal welding. The seating surfaces are hard faced to prevent galling and reduce wear. The valve stuffing box contains six rings of packing. During normal operation with the valves open, fluid pressure at the packing glands is 40 psig due to the presence of restricting orifices upstream of the valves. Installation of the valves is such that the charging pump discharge pressure is under the valve seat to prevent stem leakage when the valve is closed.

6.3.2.2.6.2 Manual Globe, Gate, and Check Valves

Gate valves are either wedge design or parallel disc and are straight through. The wedge is either split or solid. All gate valves have backseat and outside screw and yoke.

Globe valves, “T” and “Y” style are full ported with outside screw and yoke construction.

Check valves are spring loaded lift piston types for sizes 2 inches and smaller, and swing type for sizes greater than 2 inches. Stainless steel check valves have no penetration welds other than the inlet, outlet, and bonnet. The check hinge is serviced through the bonnet.

The stem packing and gasket of the stainless steel manual globe and gate valves are similar to those described above for motor operated valves. Carbon steel manual valves are employed to pass nonradioactive fluids only and therefore do not contain the double packing and seal weld provisions.

The High Head Safety Injection Throttle valve(s) is a 2-inch y-pattern globe valve that does contain valve packing. The valve design provides the required stem travel for allowing sump debris to pass through.

6.3.2.2.6.3 Accumulator Check Valves (Swing-disc)

The accumulator check valve is designed with a low pressure drop configuration with all operating parts contained within the body.

Design considerations and analyses which assure that leakage across the check valves located in each accumulator injection line does not impair accumulator availability are as follows:

1. During normal operation the check valves are in the closed position with a nominal differential pressure across the disc of approximately 1650 psi. Since the valves remain in this position except for testing or when called upon to open following an accident, and are therefore not subject to the abuse of flowing operation or impact loads caused by sudden

flow reversal and seating, they do not experience significant wear of the moving parts, and are expected to function with minimal backleakage. This backleakage can be checked via the test connection as described in Section 6.3.4.

2. When the RCS is being pressurized during the normal plant heatup operation, the check valves are tested for leakage as soon as reactor system pressure reaches about 2000 psi. This test confirms the seating of the disc and whether or not there has been an increase in the leakage since the last test. When this test is completed the accumulator discharge line motor operated isolation valves are re-opened. There should be no increase in leakage from this point on since increasing reactor coolant pressure increases the seating force and decreases the leakage.
3. The experience derived from the check valves employed in the emergency injection systems indicate that the system is reliable and workable; check valve leakage has not been a problem. This is substantiated by the satisfactory experience obtained from operation of the Robert Emmett Ginna Station and subsequent plants where the usage of check valves is identical to this application.
4. The accumulators can accept some inleakage from the RCS without affecting availability. Inleakage would require, however, that the accumulator water volume be adjusted in accordance with Technical Specification requirements.

6.3.2.2.6.4 Relief Valves

Relief valves are installed in various sections of the ECCS to protect lines which have a lower design pressure than the RCS. Valves that are, or potentially could be, in contact with borated water are constructed with stainless steel bodies. The bonnets of valves equipped with a balancing bellows are carbon steel. Bonnets of valves which are not equipped with a balancing bellows are stainless steel. The accumulator nitrogen supply relief valve does not have a potential to contact borated water, and the body and bonnet are constructed of carbon steel. Table 6.3-2 lists the systems relief valves with their capacities and setpoints.

6.3.2.2.6.5 Butterfly Valves

Each main residual heat removal line has an air operated butterfly valve which is normally open and is designed to fail in the open position. The actuator is arranged such that air pressure on the diaphragm overcomes the spring force, causing the linkage to move the butterfly to the closed position. Upon loss of air pressure, the spring returns the butterfly to the open position. These valves are left in the full open position during normal operation to maximize flow from this system to the RCS during the injection mode of the ECCS operation. These valves are used during normal residual heat removal system (RHRS) operation to control cooldown flowrate.

Each residual heat removal heat exchanger bypass line has an air operated butterfly valve which is normally closed and is designed to fail closed. These valves are used during normal cooldown to avoid thermal shock to the residual heat exchanger.

Monitor lights on the control board and alarms via the Bypass Inoperable Status Indication (BISI) CRT displays in the Control Room provide indication that the valves are and remain in the correct (open) position.

6.3.2.2.7 System Operation

The operation of the ECCS, following a loss of coolant accident, can be divided into two distinct modes:

1. The injection mode in which any reactivity increase following the postulated accident is terminated; initial cooling of the core is accomplished; and coolant lost from the primary system is replenished, and
2. The recirculation mode in which long term core cooling is provided during the accident recovery period.

A discussion of these modes follows.

The principal mechanical components of the ECCS which provide core cooling immediately following a loss of coolant accident are the accumulators, the centrifugal charging pumps, and the residual heat removal pumps.

For large pipe ruptures, the RCS is depressurized and voided of coolant rapidly, and a high flowrate of emergency coolant is required to quickly cover the exposed fuel rods and limit possible core damage. This high flow is provided by the passive accumulators, followed by the charging pumps and the residual heat removal pumps discharging into the cold legs of the RCS.

Emergency cooling is provided for small ruptures primarily by high head Injection.(1) Small ruptures are those which do not immediately depressurize the RCS below the accumulator discharge pressure. The centrifugal charging pumps deliver borated water at the prevailing RCS pressure to the cold legs of the RCS. During the injection mode, the charging pumps take suction from the refueling water storage tank. Evaluation of these small ruptures is also discussed in Sections 3.6.1.1.3 and 15.3.1.

The residual heat removal pumps take suction from the refueling water storage tank and deliver borated water to the RCS. These pumps begin to deliver water to the RCS only after the pressure has fallen below the pump shutoff head.

(1) The centrifugal charging pumps are commonly referred to as “high head pumps” and the residual heat removal pumps as “low head pumps.” Likewise, the term “high head injection” is used to denote charging pump injection and “low head injection” refers to residual heat removal pump injection.

Core protection is afforded with the minimum engineered safety feature equipment. The minimum engineered safety feature equipment is defined by consideration of the single failure criteria as discussed in Sections 3.1, 6.3.1.4, and 6.3.2.11. The minimum design case will ensure the entire break spectrum is accounted for and core cooling design bases of Section 6.3.1 are met. The analyses for this case are presented in Sections 15.3 and 15.4.

The Technical Specifications permit various pumps of the ECCS to be inoperable during power operation and for an additional time period while the reactor is at hot shutdown, provided that the remaining pump has been demonstrated to be operable prior to the repair. With regard to these repair times:

1. In most cases, repairs will be completed within the allowable time period.
2. If it is determined that this time period is not adequate to restore the component to the operable condition, putting the reactor in the hot shutdown condition significantly reduces the cooling requirements following a postulated loss of coolant accident.
3. Failure to complete repairs within the designated time interval after going to hot shutdown is considered indicative of a requirement for major maintenance and therefore the reactor is put in the cold shutdown condition.

The injection mode of emergency core cooling is initiated by the safety injection signal. This signal is actuated by any of the following:

1. Low pressurizer pressure
2. High Reactor Building pressure
3. High differential pressure between any two steam lines
4. Low Steam line pressure
5. Manual actuation

Operation of the ECCS during the injection mode is completely automatic. The safety injection signal automatically initiates the following actions:

1. Starts the emergency diesel generators, which if all other sources of power are lost, supplies the engineered safety feature buses.
2. Starts the charging pumps and the residual heat removal pumps.
3. Aligns the charging pumps for injection by:
   a. Closing the valves in the charging pump discharge line to the normal charging line.
   b. Opening the high head injection isolation valves.
   c. Opening the valves in the charging pumps suction line from the refueling water storage tank.

d. Closing the valves in the charging pump normal suction line from the volume control tank.

Remotely operated valves for the injection mode which are under manual control (i.e., valves which normally are in their ready position and do not require a safety injection signal) have their positions indicated on a common portion of the control board. If a component is out of its proper position, its monitor light will indicate this on the control board. At any time during operation when one of these valves is not in the ready position for injection, this condition is alarmed and shown visually on the board.

Process instrumentation available to the operator in the control room to provide him with appropriate and useful information during the automatic injection mode of operation are listed in Section 7.5.

The injection mode continues until the residual heat removal pumps have been realigned to the recirculation mode. During the injection mode all pumps take suction from the refueling water storage tank until a lo-lo level signal from the refueling water storage tank aligns the residual heat removal pumps to take suction from the reactor building sump. This signal also actuates an alarm to alert the operator to complete the realignment of the ECCS to the recirculation mode. The switchover procedure that must be performed by the operator is given in Table 6.3-3.

After the injection operation, water collected in the reactor building sump is cooled and returned to the RCS via the low/high head recirculation flow paths. The residual heat removal pumps are aligned to take suction from the reactor building sump and to deliver directly to the RCS and to supply suction to the charging pumps. The charging pumps deliver flow directly to the RCS cold legs. This latter mode of operation assures flow in the event of a small rupture where the depressurization proceeds more slowly such that the RCS pressure is still in excess of the shutoff head of the residual heat removal pumps at the onset of recirculation.

The maximum predicted water level elevation inside the Reactor Building following a postulated large break LOCA is elevation 419.229 feet. This height was calculated based upon the following:

1. The total amount of water available to flood the bottom of the Reactor Building is conservatively assumed to include:
   a. Water in the refueling water storage tank (RWST) from the maximum full level to the empty level alarm.
   b. The entire water inventory of the safety injection accumulators.
   c. The entire water inventory of the sodium hydroxide storage tank.
   d. The inventory of the reactor coolant system above the level of the reactor vessel nozzles.
2. The effective height of the Reactor Building basement floor was determined by weighing the heights of the various portions of the floor by the area of each portion.
3. The volume of all significant structures and equipment that reduces the free volume above the basement floor is explicitly accounted for in the calculations.

4. The volumes of the sumps and the incore instrumentation pit, which would fill with water following a LOCA and, thus reduce the volume of the water above the basement floor, are explicitly accounted for in the calculations.

As part of a Cycle 12 specific evaluation, an additional flood elevation was determined for LOCA with no single failures. The Reactor Building flood elevation was recalculated at 418.883' (418' 10.956") for this case. This flood level was calculated using operator time lines for swap-over. This no single failure case is also analyzed with the RWST filled to the overflow as an initial condition.

A calculation was also performed for a double ended main steam line break which resulted in a predicted flood level below the LOCA level. This calculation was performed using the same methodology and assumptions used for the LOCA calculation described above, except that the inventory of the safety injection accumulators and the inventory of the reactor coolant system above the reactor vessel nozzles was not included.

The location of equipment inside the Reactor Building has been reviewed to identify safety grade and associated non-safety grade equipment that would be submerged as a result of an accident.

The review resulted in the identification of valves and instrumentation that would be below a design value for the flood level of 420'0". Submerged instrumentation identified as a result of the review is in one of the following categories:

1. Instrumentation is non-safety grade but is associated with safety grade equipment. Fuses and/or circuit breakers provide sufficient protection to prevent adverse consequences to the safety grade equipment. Instruments in this category include level, pressure, and temperature monitoring devices that are used for normal control purposes and do not have any protection system functions.
2. The instrumentation is safety grade and is submerged while required to operate. Instrumentation in this category has been qualified as discussed in revised Section 3.11.1.2. Instruments in this category include post accident monitoring instrumentation associated with the reactor building RHR pump sumps and reactor building spray pump sumps (recirculation sumps).

Flooding outside the Reactor Building as a result of an accident will not affect safety grade equipment since protection is provided as follows:

1. Curbs are located at entrances to cubicles housing safety grade equipment.
2. Leakage detection systems, described in Section 7.6.5, are provided.

For a discussion of flooding outside the Reactor Building as a result of site flooding, see Section 3.4.

The location of valves inside the Reactor Building has been reviewed to identify safety grade and associated nonsafety grade valves flooded as a result of an accident. The review resulted in

identification of the valves discussed below which have some portion of the electrical circuits associated with the valve operators below the design flood level. Features that preclude adverse safety consequences or adverse consequences follows:

1. Valve, Tag No. HCV00137

   This valve, which is associated nonsafety grade equipment, is used for letdown flow control. Fuses provide sufficient protection to prevent adverse consequences to safety grade equipment. The electrical circuitry associated with this valve consists of a 4 to 20 ma signal transmitted from a Westinghouse Remote/Manual Setpoint Station which is connected to a 45 volt d-c power supply. This 45 volt d-c power is protected by a 1/2 ampere fuse on the load side of the power supply. The circuitry is not “protection grade” and serves only a “control function.” Loss of this circuit does not jeopardize plant safety.

2. Valve, Tag No. LCV01003

   This valve, which is associated with nonsafety grade equipment, is used for level control in the reactor coolant drain tank. It is provided with a positioning signal from the waste processing panel. The electrical circuitry associated with this valve is not “protection grade” and serves only a “control function.” Loss of this circuit does not jeopardize plant safety.

3. Valve, Tag No. XVM08143

   This valve, which is associated with nonsafety grade equipment, is used to direct excess letdown flow to either the volume control tank or the reactor coolant drain tank. Fuses provide sufficient protection to prevent adverse consequences to safety grade equipment. Electrical circuits for this valve are illustrated by GAI Drawing B-208-021, Sheet CS79, submitted as part of the Wiring and Schematic Package (see also Section 1.7).

4. Valves, Tag Nos. XVT08153 and 8154

   These valves, which are located in series, are used for redundant isolation of the reactor coolant system from the excess letdown heat exchangers. These valves are closed during normal plant operation, except as an alternate Letdown Flow path if normal Letdown has been isolated. These valves are open only during startup. Fuses provide sufficient protection to prevent spurious operation after flooding since limit switches are not used for seal-in or interlock functions. Electrical circuits for these valves are illustrated by GAI Drawings B-208-021, Sheet CS87 (valve 8153) and Sheet CS88 (valve 8154) submitted as part of the Wiring and Schematic Package (see also Section 1.7).

5. Valve, Tag No. XVG08701A

   Safety functions of this valve are isolation of residual heat removal system from the reactor coolant system, containment isolation, and interlock of external limit switch to valve 8706A. Performance of these isolation functions are assured by the institution of administrative controls to close the valve, and open the circuit breaker at the motor control center during power operation. The external limit switch, which is interlocked to valve 8706A, is above the design flood level.

6. Valve, Tag No. XVG08701B

   Safety function of this valve are isolation of residual heat removal system from the reactor coolant system, containment isolation, and interlock of external limit switch to valve 8706B. Performance of the isolation functions are assured by the institution of administrative controls to close the valve and open the circuit breaker at the motor control center during power operation. The external limit switch, which is interlocked to valve 8706B, is above the design flood level.

7. Valve, Tag No. XVG08702A

   Safety functions of this valve are isolation of residual heat removal to reactor coolant system and interlock of external limit switch to valve 8706A. Performance of the isolation function is assured by the institution of administrative controls to close the valve and open the circuit breaker at the motor control center during power operation. The external limit switch, which is interlocked to valve 8706A, is moved above the design flood level.

8. Valve, Tag No. XVG08702B

   Safety functions of this valve are isolation of residual heat removal system from the reactor coolant system and interlock of external limit switch to valve 8706B. Performance of the isolation function is assured by the institution of administrative controls to close the valve and open the circuit breaker at the motor control center during power operation. The external limit switch, which is interlocked to valve 8706B, is above the design flood level.

9. Valves, Tag No. LCV00459 and 460

   These valves, which are located in series, are used for redundant isolation of the reactor coolant system letdown. These valves are open during normal plant operation. They do not get an automatic closure signal from the reactor protection system and are not required to close in an accident condition. They are fail closed valves and are not required to function in accident conditions. Isolation of the RCS is provided by the Letdown Isolation valves, XVT08149A, B, and C and XVT08152. Fuses provide sufficient protection to prevent the valves' controls from adversely affecting any other components.

Within 8 hours following the loss of coolant accident, simultaneous hot leg and cold leg recirculation will be initiated to avoid boron precipitation in the core and to terminate boiling.

Core cooling during recirculation can be maintained by the flow from one residual heat removal pump if RCS pressure is low. If RCS pressure remains high, one charging pump operating in series with one residual heat removal pump provides sufficient additional head.

Initially the recirculated water is at a slightly subcooled condition. The residual heat removal pumps deliver this sump water to the RCS via the residual heat exchangers which subcool the water further. When the water is delivered to the reactor vessel, the majority of the subcooled water spills back to the sump through the broken RCS loop. The system pressure at the time recirculation is initiated is dependent on the initiating break size. Heat removal is accomplished from the recirculated sump water by operation of one or both of the residual heat exchangers.

The ECCS recirculation loop piping and components external to the Reactor Building are surrounded by shielding. This shielding is designed to permit access for maintenance to a component such as a pump while the redundant component is recirculating sump fluid.

Pressure relieving devices, from portions of the ECCS located outside the Reactor Building which might contain radioactivity, discharge to the recycle holdup tanks.

An analysis has been performed to evaluate the radiological effects of recirculation loop leakage. A discussion of the analysis and releases is provided in Section 15.4.1.4.2. A loop is assumed to include a centrifugal charging pump, a residual heat removal pump, a residual heat exchanger, and the associated piping. Thus, two separate loops are provided, each of which is adequate for core cooling.

Since redundant flow paths are provided during recirculation, a leaking component in one of the flow paths may be isolated. This action curtails any further leakage and renders the component available for corrective maintenance. Maximum potential external recirculation loop leakage is given in Table 6.3-4.

During recirculation, significant margin exists between the design and operating conditions (in terms of pressure and temperature) of the ECCS components.

6.3.2.3 Applicable Codes and Classifications

The codes and standards to which the individual components of the ECCS are designed are listed in Table 3.2-1.

6.3.2.4 Materials Specifications and Compatibility

Materials employed for components of the ECCS are given in Table 6.3-5. Materials are selected to meet the applicable material requirements of the codes in Table 3.2-1 and the following additional requirements:

1. All parts of components in contact with borated water are fabricated of or clad with austenitic stainless steel or equivalent corrosion resistant material.

2. All parts of components in contact (internal) with sump solution during recirculation are fabricated of austenitic stainless steel or equivalent corrosion resistant material. A soft seat material that is approved for system chemistry and design requirements is used in selected manual valves to minimize potential leakage.
3. Valve seating surfaces are hard faced with Stellite Number 6 or equivalent to prevent galling and to reduce wear.
4. Valve stem materials are selected for their corrosion resistance, high tensile properties, and resistance to surface scoring by the packing.

No cold worked austenitic stainless steel having a yield strength greater than 90,000 psi is used in the ECCS.

The elevated temperature of the sump solution during recirculation is well within the design temperature of all ECCS components. In addition, consideration has been given to the potential for corrosion of various types of metals exposed to the fluid conditions prevalent immediately after the accident or during long term recirculation operations.

Environmental testing of ECCS equipment inside the Reactor Building, which is required to operate following a loss of coolant accident, is discussed in Section 3.11. These components were qualified to function following exposure to a chemical spray solution equivalent to the Post LOCA spray described in Section 3.11.5.1.2. The environmental qualification test results of the engineered safety feature equipment indicate that this equipment will operate satisfactorily during and following exposure to the combined Reactor Building post accident environments of temperature, pressure, chemistry and radiation.

In addition to environmental testing of ECCS equipment, discussed in Section 3.11, the integrity of the materials of construction of engineered safety features equipment when exposed to post-design basis accident (DBA) conditions has been evaluated. Post-DBA conditions were conservatively represented by test conditions. The test program (Reference 2) performed by Westinghouse considered spray and core cooling solutions of the design chemical compositions, as well as the design chemical compositions contaminated with corrosion and deterioration products which may be transferred to the solution during recirculation. The effects of sodium (free caustic), chlorine (chloride), and fluorine (fluoride) on austenitic stainless steels were considered. Based on the results of this investigation, as well as testing by Oak Ridge National Laboratory (ORNL) and others, the behavior of austenitic stainless steels in the post-DBA environment will be acceptable. No cracking is anticipated on any equipment even in the presence of postulated levels of contaminants, provided the core cooling and spray solution pH is maintained at an adequate level. The inhibitive properties of alkalinity (hydroxyl ion) against chloride cracking and the inhibitive characteristic of boric acid on fluoride cracking have been demonstrated.

6.3.2.5 Design Pressures and Temperatures

The component design pressure and temperature conditions are given in Table 6.3-1. These pressure and temperature conditions are specified as the most severe conditions to which each

respective component (including the piping) is exposed. For each component, these conditions are considered in relation to the code to which it is designed. By designing the components in accordance with applicable codes (see Section 3.2) and with due consideration for the design and operation conditions, the fundamental assurance of structural integrity of the ECCS components is maintained.

6.3.2.6 Coolant Quantity

A minimum volume is required to be stored in the refueling water storage tank (see Table 6.3-6) to ensure that after RCS pipe ruptures, sufficient water will be injected to satisfy LOCA requirements and then be available within the Reactor Building to permit recirculation of cooling flow to the core, and to meet the net positive suction head requirements of the charging, residual heat removal pumps, and RB spray pumps. Also, sufficient water must be available for the prevention of RWST vortex formation, especially during the transition from cold leg injection to cold leg recirculation.

The sizing design bases for the refueling water storage tank (RWST) include the following design allowances:

a. A minimum volume of water (350,000 gallons) is maintained above the nominal lo-lo level semi-automatic switchover setpoint. This amount is more than sufficient to satisfy the injection requirements for LOCA. The RWST is designed to be kept at the “normal full” level during normal power operation. The volume of water in the RWST between the nominal “normal full” level and the nominal “lo-lo” level semi-automatic switchover setpoint is 387,245 gallons. This provides a margin of 37,245 gallons as compared to the 350,000 gallons.
b. The normal and accident errors for the RWST level instrumentation are accounted for in the time line for completing the transition from the injection phase to the recirculation phase.
c. For normal working allowance, the operator has at least 4,627 gallons between the maximum full level and the minimum full level (lo level), with normal instrument error conservatively combined.
d. The RWST level accounts for the “lo-lo” level setpoint error.
e. No-failure and various single failures that hinder the automatic actions of the transfer are considered for manual operator action timing to complete the transition.
f. The unusable volume in the RWST, from the tank bottom to the critical vortex level is 38,671 gallons. However, 10,266 gallons of the 38,671 gallons are above the top of the outlet nozzle.

In addition to the design allowances outlined above, the design of RWST includes an anti-vortex baffle assembly (see Figure 6.3-7) which consists of a horizontal plate supported over the outlet nozzle. Welded to the end of the horizontal plate is a vertical plate extending downward to the tank bottom. The water must enter the two open sides of the “box” formed by the two plates and

the tank, and make a 90-degree turn before exiting into the outlet pipe. The baffle assembly greatly reduces the tank level where air-inducing vortices begin to form. To show the effectiveness of the baffle, tests were performed on a ¼ scale model of the RWST. The results of the tests show that critical vortex levels are a linear function with total RWST outflow. At the maximum RWST outflow of 14,575 gpm, the critical vortex level is 5% RWST level, which is ~ 1 foot above the top of the outlet pipe and is coincident with the top of the baffle assembly.

Maximum total RWST outflow during injection mode operation, for LBLOCA, is 14,575 gpm and, for SBLOCA is 6975 gpm (975 gpm for two CHG pumps and 3000 gpm/pump for two RB Spray pumps). Given the minimum volume of 350,000 gallons above the lo-lo setpoint, the shortest times from LOCA initiation to receipt of the lo-lo semi-automatic switchover signal are approximately 24 minutes and 50 minutes for LB and SBLOCA respectively.

The switchover portion of the ECCS system features a semi-automatic scheme. The “lo-lo” level semi-automatic switchover signal in the RWST, coincident with a safety injection signal causes the RHR and Reactor Building spray suction valves from the Reactor Building recirculation sumps to automatically open (valves 3004A(B), 3005A(B), 8811A(B), and 8812A(B)). The RWST suction isolation valves (8809A(B) and 3001A(B) auto close on full open signals from the corresponding recirculation sump suction valves. To ensure that ECCS pumps and RB spray pumps have a suction source, the operator must complete actions to accomplish the transition from injection to recirculation mode prior to the depletion of the transfer allowance. The required operator actions are detailed in Table 6.3-3. The time available for switchover is dependent upon the flow rate out of the RWST as the switchover actions are performed. In order to provide conservative time allowances for the completion of these actions, the following are assumed:

1. The RWST volume available for switchover is defined as the transfer allowance.
2. The operator will secure all pumps taking suction from the RWST at 10% RWST indicated level.
3. Containment and RCS pressures for large break conditions are assumed to be 0 psig. Thus, no credit is taken for the reduction in RWST outflow that will result with higher containment and RCS pressures following a large break.

   The same conservative assumption is made for the small break conditions (except that RCS pressure is assumed to be greater than RHR pump shutoff head resulting in no RHR pump flow to the RCS for small break conditions). Because the RHR pump is deadheaded during the small break, backflow from the RWST to the sump will occur when the RHR sump suction valves open at the lo-lo semi-automatic switchover setpoint when 0 psig RB pressure is assumed. This effect is considered in the timeline development.
4. Flow out of the RWST during switchover includes allowances for both pumped flow to the RCS and containment and backflow to the Reactor Building recirculation sumps based upon the 0 psig containment pressure assumption. Pump flow rates are assumed to be constant during switchover and include the following conservative flow rates:
   a. Charging pump - 975 gpm for two pumps and 688 gpm for one pump
   b. RHR pump - 7600 gpm for two pumps and 4500 gpm for one pump

c. Reactor Building Spray Pump – 3000 gpm per pump

Backflow to the Reactor Building recirculation sumps will occur during ECCS switchover based upon the 0 psig containment pressure assumption if the RWST suction and Sump suction valves are both open and the corresponding RHR or RB Spray pump is secured (or RHR pump is deadheaded in a SBLOCA). Backflow will vary as the switchover proceeds, depending upon ECCS alignment and postulated failures.

5. Flow rates out of the RWST for both the no failure condition and the worst single failure condition vary as the switchover proceeds. The RWST outflow vs. time is calculated and used to determine limiting allowed timelines for the completion of switchover before the transfer allowance is depleted.

The large break cases are limiting with respect to the targeted timelines. The timelines presented provide sufficient time for the operator to successfully complete the switchover. It may be necessary to secure pump(s) when it is determined that the suction(s) cannot be transferred from the RWST. This conserves RWST water for the completion of the switchover in the event of a failure.

6.3.2.6.1 Containment Sump and its Effect on Long Term Cooling Following a LOCA

The Virgil C. Summer Nuclear Station Technical Specifications require that each Emergency Core Cooling System (ECCS) subsystem be demonstrated operable by a visual inspection. This visual inspection verifies that no loose debris is present in the Reactor Building which could be transported to the RHR and RB Spray sumps to cause restriction of their pump suctions. This inspection is performed immediately:

1. For all accessible areas of the Reactor Building prior to establishing CONTAINMENT INTEGRITY, and
2. In the areas affected within the Reactor Building at the completion of each Reactor Building entry when CONTAINMENT INTEGRITY is established.

Station Surveillance Test Procedures cover these requirements.

The Virgil C. Summer Nuclear Station Technical Specifications require a visual inspection of each containment sump and subsystem suction inlet at least once every 18 months. Station Surveillance Test Procedures have been written to satisfy these requirements. The suction inlets and sump components are inspected to ensure that debris is not present and that no evidence exists of structural distress or abnormal corrosion.

An instruction dealing with possible ECCS sump blockage is contained in the Virgil C. Summer Nuclear Station Emergency Operating Procedures (EOP-2.2). This procedure addressed long term cooling and requires the operator to monitor pump discharge pressure and motor amps when in the sump recirculation mode. It also cautions the operator that if pump discharge pressure or amps decrease, the cause may be sump blockage. If there is an indication of sump blockage, the

operator is instructed to close the associated bypass valve and throttle the outlet valve to stabilize pump amps. If suction is completely lost, the operator is instructed to stop the affected pump. If at least one flow path from RHR sumps to RCS can not be established or maintained, the operator is directed to EOP-2.4 Loss of Emergency Coolant Recirculation.

Two separate redundant ECCS Sumps, Sump A and Sump B, are provided for the Virgil C. Summer Nuclear Station. Sump A and Sump B each includes a separate deep sump pit for RHR and for RB spray. The strainer assemblies located over each deep sump pit and the cross duct between the RHR and RB Spray header boxes within each sump are described in Section 6.2.2.2.1.1. FSAR Figure 1.2-4 shows the physical separation between these sumps and the Reactor Building drain sump. The Reactor Building drainage system as well as the Refueling Canal drain are located such that this drainage water flow does not directly impinge in the sump areas. There are no high energy lines in the areas which will subject the sumps to postulated pipe whip or jet impingement loads and cause subsequent damage.

There is also a 6 inch high toe plate around the perimeter of the mezzanine and operating floors that prevents water from cascading down through the space between the floor perimeter and the containment wall to the sumps below. Water on the operating floor at 463’ will tend to go down through the stair wells for Stairways A and B. At the Stairway A on mezzanine floor at 436’, a 6 inch high toe plate incorporated into a hinged gate is located across the head of Stairway A. The gate is in the closed position during operation and the toe plate on the bottom of the gate diverts water flowing across the elevation 436’ floor from entering Stairway A and falling near Sump A at the 412’ basement floor level. Water flowing across the 436’ floor falls to the sump level at the 412’ floor either through the Stairway B or through two 8 foot long openings provided through the floor perimeter toe plate and which are located around the containment perimeter away from the ECCS Sumps A and B.

Sump A is surrounded on four sides and Sump B on three sides by a continuous 6 inch high curb at the basement floor level 412’. The fourth side of Sump B is bounded by a concrete secondary compartment wall. The floor level within the sumps is at elevation 408’. The sump strainer assemblies located at the 408’ level preclude debris entry down into the deep sump pits and into the recirculation piping. The LOCA condition water level when recirculation begins is approximately 6 to 7 feet above the general sump floor at elevation 408’. A horizontal grating with top elevation 412’-9” is provided over the sumps. The 6 inch curb and grating serve to limit debris and trash from transport down to the sump strainers. An engineered opening is provided through the grating to provide sufficient flow into the sumps assuming a postulated worst case where the horizontal grating surface is covered by debris following a postulated LOCA. The suction strainer assembly design is described in Section 6.2.2.2.1.1. The strainer openings are limited to 1/16 inch diameter holes to limit the size and quantity of debris permitted to pass through the strainers. The strainer fins and header box are designed with openings (maximum 1/16 inch hole size) that provide venting for air in the system as the sump fills. A hinged and bolted hatch cover is provided on the top of each of the four sump strainer header boxes located over the deep sump pits to permit personnel entry to the deep sump pit for inspection purposes. Components of the ECCS sumps are seismically designed for Seismic Category 1 conditions and are constructed of stainless steel.

In addition to the curbing around the sumps and grating over the sumps which serve to limit trash and debris transport to the sump strainers at the 408’ level, two partitions with integral gates consisting of welded stainless steel bars are provided at the 412’ floor level, one on either side of the area in which Sump A and Sump B are located. These partitions have bar spacing approximately 8 inches by 8 inches maximum and serve to stop postulated large trash items inadvertently left in the Reactor Building following a refueling outage from transporting to the sump strainers. The partitions are a minimum of approximately 7 feet high and span across the perimeter circumferential corridor between the secondary compartment concrete wall and the Reactor Building inside surface. A separation space is provided between the partitions and the Reactor Building inside surface to ensure no interaction under design base conditions including seismic. The welded stainless steel bar gates and partitions are designed for Seismic Category 1 conditions. The gates are maintained in the closed position when the plant is in operation.

Analysis and testing have been completed to evaluate sump strainer blockage and head loss in response to Generic Letter 2004-02. The analysis is comprised of five steps:

1. Debris Generation covers LOCA jet impact on insulation and Level 1 coatings, latent debris (dust and dirt on containment surfaces), coatings, labeling and placards which may disbond during design basis events and containment Foreign Material Exclusion which are identified during containment closeout inspection.
2. Debris Transport determines the fraction of debris (based on type, size and location) that may transport to the sump strainer. The analysis uses Computational Fluid Dynamics (CFD) modeling to determine post-LOCA sump flow velocities and experimental data on debris transport velocities.
3. Debris Accumulation combines the Generation and Transport analysis to develop debris loading cases for the strainer which includes type and quantity of debris.
4. Chemical Effects analysis which determines the quantity and time-line for aluminum corrosion precipitant entering the sump fluid and adding to the debris load.
5. Debris Headloss determines the pressure drop across the strainer screen using the strainer surface area, debris load and expected fluid velocity. For V. C. Summer Nuclear Station (VCSNS) the head loss is based on small scale chemical effects testing covered in Technical Report TR04560-004 (Reference 3).

Three (3) types of insulation are used inside the Reactor Building: all stainless steel reflective insulation, encapsulated Marinite XL, and TempMat. The Marinite XL and TempMat are used in limited applications and are encased in stainless steel.

The stainless steel reflective insulation is used on most piping and major components within the Reactor Building such as the steam generators, pressurizer and reactor vessel. If impacted by a LOCA jet, the stainless steel insulation cassettes may detach and break apart when the cassette hits the floor. If a cassette breaks open, the inner stainless foil is released. The foil and cassette body sink to the bottom of the containment pool. Testing and analysis have demonstrated that the stainless steel insulation debris does not readily transport (tumble along the floor) for the recirculation flow velocities calculated at VCSNS. Only a small amount is conservatively

predicted to reach the sump pit and would not present a sump blockage concern. Large scale testing of the sump strainer was also completed with the test strainer assembly completely covered in stainless steel insulation debris. The strainer head loss was well within acceptable limits and did not provide a design limiting sump strainer blockage case.

The Marinite XL is a mass type insulation used only around the reactor pressure vessel loop nozzles and portions of the reactor coolant pipe that penetrate the primary shield wall. The Marinite XL insulation cassettes around the nozzles serve a dual purpose for the VCSNS design. The first is thermal insulation. The second is a robust barrier around the nozzle to limit LOCA jet expansion into the reactor vessel cavity and pressurization of the primary shield wall. The insulation cassettes are Marinite XL machined to fit the nozzle taper and encased in 1/4 inch stainless steel. The cassettes are specifically designed to withstand the LOCA jet forces from a double ended guillotine break at the reactor vessel nozzle safe end. Due to this robust design, Marinite XL around the reactor vessel nozzles is not postulated to become LOCA generated debris.

A 1 inch thickness of Marinite XL is also used around the primary loop piping as it passes through the primary shield wall. For a break within the primary shield wall, the Marinite XL insulation is assumed to be fully particulated by the LOCA jet and mechanical damage from pipe whip within the wall. In particulate form the Marinite XL is 100 percent transportable to the sump strainer. Only the Marinite XL insulation around one pipe is postulated to become debris since each pipe is physically separated within the primary shield wall. The limiting break location for Marinite XL debris load is the loop C cold leg nozzle which has the largest volume of Marinite XL.

TempMat fibrous insulation is used on pressurizer ventilation ducts and steam generator level instrument lines in the loop A and loop C compartments. The TempMat insulating material is encased with stainless steel in each location. The three locations are in separate rooms such that only one location can be impacted by a LOCA jet. Debris Generation and Debris Transport calculations determine the limiting TempMat debris load is from the A loop compartment with a break at the steam generator outlet on the 31 inch cross-over leg.

In response to an NRC RAI, the limiting debris load cases for Marinite XL and for TempMat were tested to determine the limiting debris load for strainer head loss. Tests were carried out on a small scale test loop and demonstrated that the Marinite XL debris load is limiting by a substantial margin.

Other postulated debris sources include:

1. Rubber boots for reactor nozzle and support feet ventilation (six total).
2. Fifteen (15) fibrous reinforced silicon rubber enclosures which provide forced air cooling of equipment inside the pressurizer cubicle.
3. Rubber expansion joints in the ring header duct.
4. Kaowool wrapping (with stainless steel encasement sealed on edges with an elastomer sealant) for electrical conduit to meet separation criteria of electrical circuits for fire protection.

5. M-Board (with stainless steel encasement sealed on edges with an elastomer sealant) for electrical conduit and cable trays to meet separation criteria of electrical circuits for fire protection.
6. Unqualified labels and placards.
7. Failed and Unqualified coatings.
8. Latent Debris.

Two rubber boots on the reactor nozzle and support feet ventilation are located in each of the three loop compartments. The boots are bolted to the primary shield wall and clamped to the primary loop piping. The sump strainer analysis assumes two of the boots are dislodged by the LOCA jet and transported (100 percent) to the sump strainer. The analysis models the rubber boot debris load as a loss of surface area of the strainer. The rubber enclosures in the pressurizer cubicle are within the pressurizer cubicle and not subject to LOCA jet impingement from a loop compartment. The surface area of the rubber enclosures in the pressurizer compartment are bounded by the two rubber boots within a loop compartment, so the pressurizer rubber boots are not a limiting debris source. The ductwork expansion joints are located high in the Reactor Building along the perimeter. These are not subject to LOCA jet impingement and are not a sump strainer debris source.

The Kaowool is totally enclosed by a stainless steel corrugated tube which is split along the axial direction and installed over the Kaowool. The split tube is held in place by half inch wide banding straps. Strap spacing is 4 inches in the axial direction except at conduit supports. The ends of the encasement are sealed by an elastomer sealant to preclude entrance of any spray fluid into the encasement. The encasement assembly will also withstand seismic inputs to the installation without loss of structural integrity or sealing function. All Kaowool is located outside the Secondary Shield wall and are not subject to LOCA jet impingement. Kaowool does not enter the sump debris pool.

The M-Board installations are designed with total encasement of each M-Board by stainless steel sheets with the edges sealed by overlap of the sheets or angle clamps to preclude entrance of spray fluid. The assemblies of the various M-Board shapes are joined by angles and channels by bolting for structural strength and rigidity. The various sections which make up particular fire barrier are seismically qualified to remain in place. All of the M-Board installations are above post-LOCA sump fluid levels. One M-Board installation is located within the secondary shield wall, directly under the pressurizer. This location is only subject to LOCA jet impingement from a pressurizer surge line break. The M-Board fire barrier at this location is relative small and bounded by the Marinite XL debris load case.

A small amount of unqualified labels and placards were identified in response to Generic Letter 2004-02. These include items such as fire zone floor labeling, communication device labeling and similar material not qualified for design basis LOCA conditions. This material is assumed to disbond and transport to the sump strainer. The material is modeled as a loss of sump strainer surface area.

Failed coating assumptions for debris loading were made to provide operating margin for the Level 1 coating program. Unqualified coatings (non-Level 1 coatings) were also identified as a part of the Generic Letter 2004-02 response. All particulate is assumed to be 100 percent transportable to the sump strainer. Paint chips were a part of the Debris Transport calculation. Paint chips that arrived at the sump strainer were modeled as a loss of strainer surface area in the analysis.

Latent debris (dust and dirt) is based on containment housekeeping. Walk downs and sampling were completed in response to Generic Letter 2004-02 to develop a latent debris load. This debris is 100 percent transportable to the containment sump strainer.

Debris which washes down to the sump and passes through the strainer is evaluated for both blockage and erosion of downstream systems and components. The size of debris is limited by the 1/16 inch round holes in the perforated plate strainer. System and component downstream effects are analyzed based on methodology in WCAP-16406, Rev. 1 (Reference 4). The downstream effect on potential core blockage is a continuing industry effort with Virgil C. Summer Nuclear Station resolution plans specifically identified to the NRC in SCE&G letter RC-13-0006 from T. D. Gatlin to the Document Control Desk, Virgil C. Summer Nuclear Station (VCSNS) Unit 1, Path Forward for Resolution of Generic Safety Issue (GSI)-191.

The design basis head loss through the sump strainers was determined via testing on the small scale chemical effects test loops by the strainer vendor, Atomic Energy of Canada, Ltd. The test featured small scale corregated fins representative of those installed, debris addition tank and chemical additions. The test report is presented in Technical Report TR04650-004.

The analysis and testing was summarized and submitted to the NRC for review and approval. The submittals, NRC response and Request for Additional Information (RAI) are documented in the following correspondence:

RHR and RB Spray pump flow beyond rated runout is another condition which requires evaluation. Due to the different known and unknown conditions of operation, this evaluation is more important for the RHR system. Therefore, full scale tests of the RHR pumps were performed at the Virgil C. Summer Nuclear Station for the different modes of injection and recirculation. As a result of these tests, flow restricting orifices have been installed at the outlet of each heat exchanger. A retest of the RHR system will be performed to insure the adequacy of these orifices.

A full scale test of the RB Spray discharge ring headers and spray nozzles is not feasible. However, this system is only subjected to two worst case operating conditions, injection and recirculation, as its design basis. Full scale tests have been performed using the suction and recirculation test returns to the RWST. Test data on the suction piping has been compared to the results of the design calculations as a measure of their accuracy. A detailed analysis was then performed of the Reactor Building Spray System’s calculations to ensure that flow rates beyond runout are not possible with subsequent pump damage.

6.3.2.7 Pump Characteristics

Design parameters for the ECCS pumps are given in Table 6.3-1. Pump characteristic curves are shown in Figures 6.3-3 and 6.3-4a to 6.3-4c, see Section 5.5.7 for residual heat removal component data.

6.3.2.8 Heat Exchanger Characteristics

The design basis for the residual heat exchanger is discussed in Section 5.5.7. Design parameters appear in Table 5.5-8. The design is based on a normal cooldown rather than the recirculation phase of ECCS operation following a loss of coolant accident. This is due to the relatively small ΔT that exists on the tube side of the heat exchanger during the latter part of normal cooldown. Moreover, no credit is taken for the residual heat removal heat exchanger with respect to core cooling.

6.3.2.9 Emergency Core Cooling System Flow Diagrams

Piping and instrumentation and process flow diagrams of the ECCS are given in Figure 6.3-1 (Sheets 1 through 3) and Figure 6.3-2, respectively.

6.3.2.10 Relief Valves

The ECCS relief valves, their capacities, and settings are given in Table 6.3-2.

6.3.2.11 System Reliability

1. Definitions of Terms

   a. Period of Recovery

      The time necessary to bring the plant to a cold shutdown and regain access to faulted equipment. The recovery period is the sum of the short and long term periods defined below.

   b. Incident

      Any natural or accidental event of infrequent occurrence and its related consequences which affect the plant operation and require the use of engineered safeguards systems. Such events, which are analyzed independently and are not assumed to occur simultaneously, include the loss of coolant accident, steam line ruptures, steam generator tube ruptures, etc. A loss of offsite power may be an isolated occurrence or may be concurrent with any event requiring engineered safeguards systems use.

   c. Short Term

      The time immediately following the incident during which automatic actions are performed, system responses are checked, type of incident is identified, and preparations for long term recovery operation are made. The short term is the injection phase for loss of coolant accidents and is the first 24 hours following initiation of the event for all others.

   d. Long Term

      The remainder of the recovery period following the short term. In comparison with the short term where the main concern is to prevent or limit site release, the long term period of operation involves bringing the plant to cold shutdown conditions where access to the Reactor Building can be gained and repair effected.

e. Active Failure

The failure of a powered component such as a piece of mechanical equipment, component of the electrical supply system or instrumentation and control equipment to act on command to perform its design function. Examples include the failure of a motor operated valve to move to its correct position, the failure of an electrical breaker or relay to respond, the failure of a pump, fan or diesel generator to start, etc.

f. Passive Failure

The structural failure of a static component which limits the component's effectiveness in carrying out its design function. When applied to a fluid system, this means a break in the pressure boundary resulting in abnormal leakage not exceeding 50 gpm for 30 minutes. Such leak rates are consistent with limited cracks in pipes, sprung flanges, valve packing leaks, or pump seal failures.

2. Active Failure Criteria

The ECCS is designed to accept a single failure following the incident without loss of its protective function. The system is designed to tolerate the failure of any single active component in the ECCS itself or in the necessary associated service systems at any time during the period of required system operations following the incident.

A single active failure analysis is presented inTable 6.3-7, and demonstrates that the ECCS can sustain the failure of any single active component in either the short or long term and still meet the level of performance for core cooling.

Since the operation of the active components of the ECCS following a steam line rupture is identical to that following a loss of coolant accident, the same analysis is applicable and the ECCS can sustain the failure of any single active component and still meet the level of performance for the addition of shutdown reactivity.

3. Passive Failure Criteria

The following philosophy provides for necessary redundancy in component and system arrangement to meet the intent of the General Design Criteria on single failure as it specifically applies to failure of passive components in the ECCS. Thus, for the long term, the system design is based on accepting either a passive or an active failure, assuming no failures in the short term.

6.3.2.11.1 Redundancy of Flow Paths and Components for Long Term Emergency Core Cooling

In design of the ECCS, Westinghouse utilizes the following criteria.

1. During the long term cooling period following a loss of coolant, the emergency core cooling flow paths shall be separable into two subsystems, either of which can provide minimum core cooling functions and return spilled water from the floor of the Reactor Building back to the RCS.
2. Either of the two subsystems can be isolated and removed from service in the event of a leak outside the Reactor Building.
3. Adequate redundancy of check valves is provided to tolerate failure of a check valve during the long term as a passive component.
4. Should one of these two subsystems be isolated in this long term period, the other subsystem remains operable.
5. Provisions are also made in the design to detect leakage from components outside the Reactor Building, collect this leakage, and to provide for maintenance of the affected equipment. Level switches are located in alarm drain sumps and certain floor drain sumps. Excessive leakage actuates an alarm in the control room, alerting the operator to take action to isolate the leak.

Thus, for the long term emergency core cooling function, adequate core cooling capacity exists with one flow path removed from service.

6.3.2.11.2 Leakage from Engineered Safety Features Systems Outside Containment

Leakage from the engineered safety feature systems is collected by the Auxiliary Building drain system. Excessive leakage is detected by level switches located in pump room sumps and specially provided alarm drains. These alarm drains are strategically located in areas housing ECCS and reactor building spray system equipment. Leakage source identification is facilitated by zoning of the alarm drains with respect to ECCS and reactor building spray system equipment trains.

When leakage exceeds a flowrate of 25 gpm for the floor drains or 45 gpm for the sump drains, an alarm is activated in the Control Room. Alarm response time for leakage in excess of the maximum expected ranges from a few seconds for the alarm drains to less than four (4) minutes for the Residual Heat Removal pump room B sump. Upon actuation of this alarm, the operator can determine which level switch caused the alarm and, thus, identify which area housing ECCS or reactor building spray system equipment is affected. The operator then takes the required action to isolate the leak.

Components of the leakage detection system are seismically qualified, redundant, and can be tested during any phase of plant operation.

The largest sudden leak potential would be the sudden failure of an RHR pump shaft seal with a conservatively calculated leakage rate of 7.5 gpm. The results of an evaluation to determine RHR pump shaft leak rates are shown by Figure 6.3-5. Figure 6.3-6 illustrates the leakage rates after severe operation.

A single passive failure analysis is presented by Table 6.3-8. This analysis demonstrates that the ECCS can sustain a single passive failure during the long term phase and still retain an intact flow path to the core to supply sufficient flow to maintain the core covered and effect the removal of decay heat. The procedure followed to establish the alternate flow path also isolates the component which failed.

6.3.2.11.3 Integrity of Systems Outside Containment Likely to Contain Radioactive Materials

The design of systems that normally contain radioactive fluids includes a number of features for minimizing leakage paths from these systems to the surrounding environment. These features are outlined as follows:

1. Minimize the Use of Flanged Connections

   As standard practice for the V. C. Summer Project, piping system connections are socket-welded for 2" and smaller piping, and butt-welded for 2-1/2” and larger piping.

2. Use of Valve Leakoff Connections

   All 2-1/2” or greater air-operated or motor-operated valves in radioactive fluid systems, incorporate lantern-ring leakoff connections which are hard-piped to waste liquid holdup tanks. Therefore, leakage by the valve packings is directed to holdup tanks to prevent contamination of the area around the valves.

3. Use of “Zero-Leakage” Valves

   Manually-operated valves in systems that contain radioactive fluids are “zero-leakage” type valves, i.e., designed to prevent leakage within the environment of the valves. These valves include, but are not limited to, bellows-stem-seal type, metal-diaphragm seal, and diaphragm valves. An example of the metal-diaphragm seal type is the Rockwell-Edward’s “Hermavalve” (hermetically-sealed). Drain and vent valves are discussed as a separate feature.

4. Dual Barrier Design for Drain and Vent Valve Connections

   Drain and vent connections in radioactive fluid systems are provided with either (a) two (2) normally-closed isolation valves or (b) one (1) normally-closed isolation valve with a pipe or tube extension that is capped or incorporated a fluid flange. These schemes provide a dual barrier against potential leakage paths from radioactive fluid systems.

5. Use of Mechanical Shaft Seals for Critical Pumps

   The use of mechanical shaft seals for critical pumps limits the amount of radioactive fluid leakage for both normal and adverse operating conditions. For further discussion of pump shaft seals, see FSAR Section 6.3.2.11.2.

6. Use of “Alarm Drains” for Monitoring Leakage from the ECCS Systems

   The “Alarm Drains” are strategically located to monitor and alarm leakage from the ECCS Systems during the injection and recirculation modes of operation following a LOCA. For further discussion of the Alarm Drain System, See FSAR Section 6.3.2.11.2.

A single passive failure analysis is presented in Table 6.3-8. This analysis is discussed in Section 6.3.2.11.2.

Those systems and components outside the containment whose function may be required during serious transient or accident conditions which could or would contain highly radioactive fluids have been identified. In addition, these systems and component interfaces with other systems and components which would not be required to function to achieve cold stable conditions following an accident have been identified.

These systems and components are incorporated into leak reduction programs including, but not limited to, Inservice Inspection Hydrostatic and Leak Detection Testing, Preventative Maintenance Programs, Integrated System Leakage Testing as provided for by Technical Specification Surveillance Requirements, and existing Leak Detection systems.

6.3.2.12 Protection Provisions

The provisions taken to protect the system from damage that might result from dynamic effects are discussed in Section 3.6. The provisions taken to protect the system from missiles are discussed in Section 3.5. The provisions to protect the system from seismic damage are discussed in Sections 3.7, 3.9, and 3.10. The provisions to maintain the refueling water storage tank at or above 40°F and for freeze protection of outdoor piping connected to the tank are discussed in Sections 9.1.3.2 and 9.1.3.5.5. Thermal stresses on the RCS are discussed in Section 5.2.

6.3.2.13 Provisions for Performance Testing

The provisions incorporated to facilitate performance testing are discussed in Section 6.3.4.

6.3.2.14 Pump Net Positive Suction Head

The ECCS is designed so that adequate net positive suction head (NPSH) is provided to system pumps. The NPSH available is a function of Reactor Building pressure, water temperature, static head of water, friction losses in the pump suction piping and pressure drop across the sump strainer as follows:

$$NPSH_a = P_c \quad P_s + \Delta H_z - \Delta H_f - \Delta H_s$$

Where:

$NPSH_a$ = NPSH available at the pump suction.

P_c = Reactor Building pressure.

P_s = Saturation pressure of the pumped water.

ΔH_z = Elevation pressure due to the height of water above the pump nozzle.

ΔH_f = Pressure loss due to friction in the suction line.

ΔH_s = Pressure loss across the sump strainer (in the recirculation mode).

In the recirculation mode of operation, the pressure in the Reactor Building (P_c) will always equal or exceed the vapor pressure of the water in the sump because water will evaporate from the sump to increase the vapor pressure of the atmosphere if P_c starts to decrease below P_s. Generally, the partial pressure of the air in the atmosphere will maintain P_c greater than P_s. For conservatism, no containment overpressure is assumed so $P_c = P_s$. This is consistent with the guidance provided in Regulatory Guide 1.1.

Adequate net positive suction head is shown to be available for all pumps as follows:

1. Residual Heat Removal Pumps

   The net positive suction head of the residual heat removal pumps is evaluated for normal plant cooldown operation, and for both the injection and recirculation modes of operation for the Design Basis Accident. Recirculation operation gives the limiting net positive suction head requirement, and the net positive suction head available is determined from the Reactor Building sump level relative to the pump elevation and the pressure drop in the suction piping from the sump to the pumps. The net positive suction head evaluation is based on one residual heat removal pump delivering to three RCS loops and the suction of one charging pump.

A summary of the results for the RHR pump in the recirculation mode is as follows:

	Flow (gpm)	NPSH Available (ft)	NPSH Required (ft)	Margin (ft)
Pump A	4300	20.2	17	3.2
Pump B	4200	20.8	16	4.8

2. Centrifugal Charging Pumps

   The net positive suction head for the centrifugal charging pumps is evaluated for both the injection and recirculation modes of operation for the Design Basis Accident. The end of the injection mode of operation gives the limiting net positive suction head available. The net positive suction head available is determined from the elevation head and vapor pressure of the water in the refueling water storage tank, which is at atmospheric pressure, and the pressure drop in the suction piping from the tank to the pumps. When a predetermined low refueling water storage tank level is reached the charging pumps are manually aligned to take suction from the residual heat removal pump discharge headers. The net positive suction head requirements of these pumps are therefore satisfied by the discharge head of the residual heat removal pumps.

6.3.2.15 Accumulator Motor Operated Valve Controls

As part of the plant shutdown administrative procedures, the operator is required to close these valves. This prevents a loss of accumulator water inventory to the RCS and is done shortly after the RCS has been depressurized to between 900 and 950 psig. The redundant pressure and level alarms on each accumulator would remind the operator to close these valves, if any were inadvertently left open. Power is disconnected after the valves are closed.

During plant startup, the operator is instructed via procedures to energize and open these valves before the RCS pressure is between 900 and 950 psig. Monitor lights in conjunction with an audible alarm will alert the operator should any of these valves be left inadvertently closed once the RCS pressure increases above the safety injection block setpoint (P-11).

For each accumulator isolation valve (8808A, 8808B, or 8808C) position indicating design provisions include the following:

1. Visual indicating in the main control room by means of an ESF monitor light that will be “bright” when the valve is not open. Section 7.5.4 provides a more detailed explanation of the operation of the ESF monitor lights. An alarm will be annunciated via a common monitor light alarm if an accumulator valve is not open. This grouping highlights a valve not properly lined up. This light is energized from an ESF monitor light supply different from the valve control power and actuated by a valve motor operator switch. In addition to this visual position information, there are also red (open) and green (closed) position indicating lights at

the control switch for each valve. These lights are actuated by valve motor operator limit switches and are powered by valve control power which is distributed through the same accumulator valve breaker that feeds power to the motor operator.

2. Audible and visual alarm annunciator points will be activated by both a valve motor operator limit switch and by a valve position limit switch activated by stem travel whenever an accumulator valve is not fully open for any reason with the system at pressure (the pressure at which the safety injection block is unblocked). The alarm activated by the motor operator limit switch will be recycled by a timer at approximately 60 minute intervals to remind the operator of the improper valve line up. Both the alarm reflash annunciator point and the timer will be energized separately from the valve control power.

The accumulator isolation valves are considered to be “operating bypasses” in the context of IEEE 279-1971, which requires that bypasses of protective functions be removed automatically whenever permissive conditions are not met. The automatic unblock is derived from P-11 (1985 psig) which is the Safety Injection setpoint.

In that these valves are required by Technical Specifications to be open and incapable of being closed during power operation and do not act as active valves during any accident condition, the requirements of IEEE 279-1971 are not applicable for this situation in that an operating bypass function is not required for these valves. For a discussion of limiting conditions for operation and surveillance requirements of these valves, refer to the Technical Specifications.

The accumulator isolation valves receive a safety injection signal to ensure that they are open in the event of an accident which initiates safety injection.

For further discussions of the instrumentation associated with these valves refer to Sections 6.3.5, 7.3.1.1.2, and 7.6.4.

6.3.2.16 Motor Operated Valves and Controls

Remotely operated valves for the injection mode which are under manual control (i.e., valves which normally are in their ready position and do not require a safety injection signal) have their positions indicated on a common portion of the control board. If a component is out of its proper position, its monitor light will indicate this on the control panel. At any time during operation when one of these valves is not in the ready position for injection, this condition is shown visually on the board, and an audible alarm is sounded in the control room.

6.3.2.17 Manual Actions

No manual actions are required of the operator for proper operation of the ECCS during the injection mode of operation. Only limited manual actions are required by the operator to complete realignment of the system for the cold leg recirculation mode of operation, and, within 8 hours after event initiation, for the simultaneous hot leg and cold leg recirculation mode of operation. See Table 6.3-3 for the cold and hot leg recirculation switchover procedures.

6.3.2.18 Process Instrumentation

Process instrumentation available to the operator in the control room to assist in assessing post loss of coolant accident conditions are tabulated in Section 7.5.

6.3.2.19 Materials

Materials employed for components of the ECCS are given in Table 6.3-5. These materials are chosen based upon their ability to resist radiolytic and pyrolytic decomposition (see Section 6.3.2.4).

6.3.2.20 Power Lockout of Manually Controlled Electrically Operated Valves

Manually controlled electrically operated valves in the ECCS which require power lockout in accordance with Branch Technical Position EICSB 18 are 8808A, B, and C (accumulator isolation valves); 8884 and 8886 (high head safety injection hot leg injection isolation valves); 8888A and B (low head, safety injection cold leg isolation valves); 8889 (low head safety injection hot leg injection isolation valve); and 8133A and B (high head safety injection discharge cross-connect valves).

Power is locked out to accumulator isolation valves 8808A, B, and C (see Technical Specification 3/4.5.1 and to reactor head vent system isolation valves 8095A, B and 8096A, B by padlocking the breaker operating mechanism of the motor control center.

The power, control, and indication circuits for motor operated valves 8884, 8886, 8888A and B, 8889, and 8133A and B will satisfy the main control board “removal and restoration” requirements identified below:

1. Removal and restoration of electrical power for the valve power circuit will be accomplished from the main control board. A power contactor will be installed in XMCIDA2Y and wired in series to reversing starters for valves 8884, 8888A and 8889. When the contactor is open, it will break power to the starters. A similar situation exists in XMCIDB2X for valves 8886 and 8888B. Power lockouts are also installed in XMC1DA2Y for valve 8133A and XMC1DB2Y for valve 8133B. Before the valve position can be changed, the power lockout contactor must be closed from the main control board to provide power to the starters. Then, using a separate switch on the main control board, the starter must be actuated to open or close the valve. Using these normally de-energized power lockout contactors in series with the starters, no single electrical fault could cause valve motion.
2. Valve position indications, not defeated by the control circuit electrical power removal and restoration, are provided at the main control board. Valve position sensing for these position indicators is provided by the cam operated switch within the motor operator. AC Power for the indicators is supplied from the power lockout contactor control transformer in the motor control center (MCC).

3. Redundant valve position indicators, powered from the DC train opposite to the valve motive power train, are provided at the main control board. Valve position sensing for these position indicators is by separate, stem mounted limit switches.

6.3.3 Performance Evaluation

6.3.3.1 Evaluation Model

The following analyses are performed to ensure that the limits on core behavior following a pipe rupture are met by the ECCS operating with minimum design equipment:

1. Large pipe rupture analysis
2. Small pipe rupture analysis
3. Steam line rupture analysis

The performance characteristic is derived from the performance characteristic for each pump with system piping resistance, based upon final piping layouts.

The pump performance characteristics utilized in the accident analyses includes a 3.5% head reduction for the high head pumps and a 7% head reduction for the low head pumps for margin. The loss of coolant accident analysis is also based on the spilling of one injection line through the postulated break. This accounts for the case where the initiating incident is assumed to be the severance of an injection line.

6.3.3.2 Emergency Core Cooling System Performance

The large pipe rupture analysis is used to evaluate the initial thermal transient for a spectrum of pipe ruptures up to and including the instantaneous, double ended, circumferential rupture of the largest pipe in the RCS. The results of this analysis are presented in Section 15.4.

The flow delivered to the RCS by the ECCS as a function of the RCS pressure is also shown in Section 15.4. This flowrate is based on one injection path spilling out the postulated break, the loss of offsite power, and the assumed single failure of an onsite emergency diesel generator to start; leaving two accumulators, one charging pump, and one residual heat removal pump available for core cooling, with the injection path of least resistance assumed to be spilling.

RCS loop-to-loop flow imbalance of 5% is considered, to incorporate the effects of the RCS Flow Asymmetry, per Westinghouse Nuclear Safety Advisory Letter (NSAL) 00-008.

Initial core cooling is provided by the passive accumulators. Injection flow from the ECCS pumps is required subsequent to accumulator injection to complete vessel refill, reflood the core, and eventually return the core to a subcooled state. The results of the analysis presented in Section 15.4 indicate the peak clad temperature attained at any point in the core is such that the limits on core behavior as specified in Section 15.4 are met.

During shutdown the following operator actions pertain to the isolation of ECCS equipment and would affect a LOCA during the time accumulator isolation valves are closed with power locked out. (Startup is not addressed since shutdown is more limiting due to the higher core decay heat generation):

1. The operator is instructed to manually block the pressurizer safety injection signal when pressurizer pressure has decreased below 1985 psig and the steamline safety injection signal when T_{avg} decreases below 552 °F. All other safety injection signals including containment high pressure and high steam line differential pressure are armed and will actuate safety injection if their setpoints are exceeded. Manual safety injection actuation is also available.
2. With the RCS pressure maintained between 900 and 950 psig, the operator closes and locks out the safety injection accumulator isolation valves. At this time, two residual heat removal pumps (low head safety injection) would be available from either automatic or manual safety injection actuation.
3. At less than 425 psig and 350 °F, the operator aligns the suction of both trains of RHRS to the RCS. The valves in the line from the refueling water storage tank (RWST) are closed. Prior to dropping below 300 °F, the operator also locks out all but one high head charging pump.

The significance of these actions on the mitigation of a LOCA when power is locked out to the isolation valves is that:

1. Between 950 psig and 425 psig, a portion of the ECCS may be actuated automatically on containment high pressure or high steam line differential pressure signals or manually by the operator. The equipment that can be energized are two residual heat removal and one high head charging pumps. Subsequently, the operator would reinstitute power at the motor control centers to the other high head charging pump as necessary to maintain water level in the reactor vessel.
2. Below 425 psig and 350° F, the system is in the residual heat removal mode with both trains of RHRS aligned to the RCS and only one train in service until Mode 5. The opposite train is protected such that in the event of a LOCA, it is capable of performing its Mode 4 ECCS function. If required, the operator would manually realign the protected train per abnormal operating procedure for mitigation of a LOCA. In addition, the procedures direct the operator to start additional SI pumps, as necessary, to maintain water level in the reactor vessel.

6.3.3.3 Alternate Methods of Analysis

6.3.3.3.1 Small Pipe Break

The small pipe break analysis is used to evaluate the initial core thermal transient for a spectrum of pipe ruptures greater than 3/8 inches in diameter. For a rupture 3/8 inches in diameter or smaller, the charging system can maintain the pressurizer level. The ECCS would not be required and would not be automatically actuated in the short term, although it is actuated by low pressurizer pressure. A range of reactor coolant system small pipe breaks have been evaluated, as discussed in Section 15.3.1 and Section 15.4.1. The results of the small break analysis indicate that the limits on core behavior are adequately met as shown in Section 15.3 and Section 15.4.

6.3.3.3.2 Steam Line Rupture

Following a steam line rupture the ECCS is automatically actuated to deliver borated water to the RCS. The response of the ECCS following a steam line break is identical to its response during the injection mode of operation following a loss of coolant accident.

The safety injection signal initiates identical actions as described for the injection mode of the loss of coolant accident, even though not all of these actions are required following a steam line rupture, e.g., the residual heat removal pumps are not required since the RCS pressure will remain above their shutoff head.

The charging pumps deliver borated water from the refueling water storage tank, until enough water has been added to the RCS to make up for the shrinkage due to cooldown. After pressurizer water level has been restored, the injection is manually terminated.

The sequence of events following a postulated steam line break is described in Section 15.4.

6.3.3.4 Fuel Rod Perforation

Discussions of peak clad temperatures and metal-water reactions appear in Sections 15.3.1 and 15.4.1. Analyses of the radiological consequences of a fission product release due to the rupture of a pipe in the RCS are presented in Section 15.4.

6.3.3.5 Not applicable to Pressurized Water Reactors.

6.3.3.6 Not applicable to Pressurized Water Reactors.

6.3.3.7 Not applicable to Pressurized Water Reactors.

6.3.3.8 Not applicable to Pressurized Water Reactors.

6.3.3.9 Not applicable to Pressurized Water Reactors.

6.3.3.10 Not applicable to Pressurized Water Reactors.

6.3.3.11 Effects of ECCS Operation on the Core

The effects of ECCS operation on the reactor core are presented in Sections 15.3 and 15.4.

6.3.3.12 Use of Dual Function Components

The ECCS contains components which have no other operating function as well as components which are shared with other systems. Components in each category are as follows:

1. Components of the ECCS which perform no other function are:

a. One accumulator for each loop which discharges borated water into its respective cold leg of the reactor coolant loop piping.

b. Piping, valves and instrumentation associated with the accumulators or high head injection.

c. Valves and piping associated with RB sump recirculation.

2. Components which also have a normal operating function are as follows:

a. The residual heat removal pumps and the residual heat exchangers are normally used during the latter stages of normal reactor cooldown and when the reactor is held at cold shutdown for core decay heat removal. However, during all other plant operating periods, they are aligned to perform the low head injection function.

b. The centrifugal charging pumps are normally aligned for charging service. As a part of the chemical and volume control system, the normal operation of these pumps is discussed in Chapter 9.

c. The refueling water storage tank is used to fill the refueling canal for refueling operations. However, during other plant operating periods it is aligned to the suction of the residual heat removal pumps. The charging pumps are automatically aligned to the suction of the refueling water storage tank upon receipt of the safety injection signal.

An evaluation of all components required for operation of the ECCS demonstrates that either:

1. The component is not shared with other systems, or
2. If the component is shared with other systems, it is aligned during normal plant operation to perform its accident function; or if not aligned to its accident function, two valves in parallel are provided to align the system for injection, and two valves in series are provided to isolate portions of the system not utilized for injection. These valves are automatically actuated by the safety injection signal. During the recirculation mode of operation, manual valve alignments are required. (Reference 6.3.2.2.7)

Table 6.3-9 indicates the alignment of components during normal operation, and the realignment required to perform the accident function.

6.3.3.13 Lag Times

The minimum active components will be capable of delivering full rated flow within a specified time interval after process parameters reach the setpoints for the safety injection signal. Response of the system is automatic, with appropriate allowances for delays in actuation of circuitry and active components. The active portions of the system are actuated by the safety injection signal. In analyses of system performance, delays in reaching the programmed trip points and in actuation of components are established on the basis that only emergency onsite power is available.

In the loss of coolant accident analyses presented in Sections 15.3 and 15.4, no credit is assumed for partial flow prior to the establishment of full flow and no credit is assumed for the availability

of normal offsite power sources. After the initiation parameter achieves the setpoint, a delay is assumed for signal transmission, diesel startup, load sequencing, and pump startup, as discussed in Sections 15.4.1.1.3 and 15.4.1.1.4 and Table 15.4-1a.

For smaller loss of coolant accidents, there is some additional delay before the process variables reach their respective programmed trip setpoints since this is a function of the severity of the transient imposed by the accident. This is allowed for in the analyses of the range of loss of coolant accidents.

Accumulator injection occurs immediately when RCS pressure has decreased below the operating pressure of the accumulator.

6.3.3.14 Thermal Shock Considerations

Thermal shock considerations are discussed in Section 5.2.

6.3.3.15 Limits on System Parameters

The analyses show that the Performance characteristic of the ECCS is adequate to meet the requirements for core cooling following a loss of coolant accident with the minimum engineered safety feature equipment operating. In order to ensure this capability in the event of the simultaneous failure to operate any single active component, Technical Specifications are established for reactor operation.

Normal operating status of ECCS components is given in Table 6.3-6.

The ECCS components are available whenever the coolant energy is high and the reactor is critical. During low temperature physics tests there is a negligible amount of stored energy in the coolant and low decay heat; therefore, an accident comparable in severity to accidents occurring at operating conditions is not possible and ECCS components are not required.

A comprehensive testing program has been undertaken to demonstrate that ECCS components and associated instrumentation and electrical equipment which are located inside the Reactor Building will operate for the time period required in the combined post loss of coolant accident conditions of temperature, pressure, humidity, radiation, chemistry, and seismic phenomena (see Section 3.11).

Components such as remote motor operated valves have been shown capable of operating for the required post accident periods, when exposed to post loss of coolant environmental conditions. All other ECCS components are located outside of the Reactor Building.

The specification of individual parameters as given in Table 6.3-1 considers allowances for margin over and above the required performance value (e.g., pump flow and net positive suction head), and the most severe conditions to which the component could be subjected (e.g., pressure, temperature, and flow).

This consideration ensures that the ECCS is capable of meeting its minimum required level of functional performance.

6.3.4 Tests and Inspections

To demonstrate the readiness and operability of the ECCS, the components are subjected to periodic tests and inspections. Performance tests of the components are performed in the manufacturer's shop. An initial system flow test is performed to demonstrate the proper functioning of the components.

6.3.4.1 Quality Control

Tests and inspections are carried out during fabrication of each of the ECCS components. These tests are conducted and documented in accordance with the Quality Assurance Program discussed in Chapter 17.

6.3.4.2 Preoperational Tests

These tests are intended to evaluate the hydraulic and mechanical performance of the passive and active components involved in the injection mode by demonstrating that they have been installed and adjusted so they will operate in accordance with the design intent. These tests are divided into three individual sections that may be performed as plant conditions allow without compromising the integrity of the tests.

One of these individual sections consists of system actuation tests to verify: the operability of ECCS valves initiated by the safety injection signal (S), the phase A containment isolation signal (T), and the phase B containment isolation signal (P); the operability of safeguard pump circuitry down through the pump breaker control circuits; and the proper operation of valve interlocks.

Another of the individual sections is the accumulator injection test. The objective of this section is to check the accumulator injection line to verify that the lines are free from obstructions and that the accumulator check valves operate correctly. The test objectives will be met by a low pressure blowdown of each accumulator. The test will be performed with the reactor head and internals removed.

The last of the individual sections consists of operational tests of the major pumps (i.e., the charging pumps and the residual heat removal pumps). The purpose of these tests is to evaluate the hydraulic and mechanical performance of the pumps delivering through the flow paths required for emergency core cooling. These tests will be divided into two parts: pump operation under minimum flow conditions and pump operation at full flow conditions.

The predicted system resistance will be verified by measuring the flow in various piping branches, as each pump delivers from the refueling water storage tank to the open reactor vessel, and adjustments made where necessary to assure that no one branch has an unacceptably low or high resistance. During this flow test, the system will also be checked to assure there is sufficient total line resistance to prevent excessive runout of the pump. At the completion of the flow test,

the total pump flow and relative flow between the branch lines will be compared with the performance characteristics used in the accident analysis of Chapter 15.

The systems are accepted only after demonstration of proper actuation of components and after demonstration of flow delivery of components within design requirements.

6.3.4.3 Periodic Component Testing

Routine periodic testing of the ECCS components and necessary support systems at power is planned. Valves which operate after a loss of coolant accident are operated through a complete cycle, and pumps are operated individually. The testing is conducted on minimum flow and at full flow for the charging pumps and at full flow for the RHR pumps. If such testing indicates a need for corrective maintenance, the redundancy of equipment in these systems permits such maintenance, to be performed without shutting down or reducing load under certain conditions. These conditions include considerations such as the period within which the component should be restored to service and the capability of the remaining equipment to provide the minimum required level of performance during such a period.

The condition of the remote stop valve and the check valve in each accumulator tank discharge line may be tested by opening the remote test line valves just downstream of the stop valve and check valve respectively. Flow through the test line can be observed on instruments and the opening and closing of the discharge line stop valve can be sensed on this instrumentation.

Where series pairs of check valves form the high pressure to low pressure isolation barrier between the RCS and ECCS piping outside the Reactor Building, testing of these check valves must be performed to provide assurance that certain postulated failure modes will not result in a loss of coolant from the low pressure system outside the Reactor Building with a simultaneous loss of safety injection pumping capacity. The tests performed verify that each of the series check valves can independently sustain differential pressure across its disc, and also verify that the valve is in its closed position. The required periodic tests are to be performed after refuelings, on a performance-based frequency just prior to plant startup, after the RCS has been pressurized.

Lines in which the series check valves are to be tested are the residual heat removal pump cold leg and hot leg injection lines.

To implement the periodic component testing requirements, Technical Specifications are established. During periodic system testing, a visual inspection of pump seals, valve packings, flanged connections, and relief valves is made to detect leakage. Inservice inspection provides further confirmation that no significant deterioration is occurring in the ECCS fluid boundary.

Design measures have been taken to assure that the following testing can be performed:

1. Active components are tested periodically for operability (e.g., pumps, certain valves, etc.).
2. An integrated system test (1) can be performed when the plant is cooled down and the RHRS is in operation. This test does not introduce flow into the RCS but does demonstrate the operation of the valves, pump circuit breakers, and automatic circuitry including diesel starting and the automatic loading of ECCS components on the diesels (by simultaneously simulating a loss of offsite power).
3. An initial flow test of the full operational sequence can be performed.

The design features which assure this test capability are specifically:

1. Power sources are provided to permit individual actuation of each active pump and valve component of the ECCS.
2. The residual heat removal pumps are used every time the RHRS is put into operation. They can also be tested periodically when the plant is at power.
3. The centrifugal charging pumps are either normally in use for charging service or can be tested periodically on minimum flow, or full flow during plant shutdown.
4. Remote operated valves can be exercised during routing plant maintenance. These valves are tested both quarterly and/or during plant shutdowns based on operating and test requirements.
5. Level and pressure instrumentation is provided for each accumulator tank, for continuous monitoring of these parameters during plant operation.
6. Flow from each accumulator discharge tank can be directed at any time through a test line to determine check valve leakage.
7. Flow indicators are provided in the charging pump headers and in the residual heat removal pump headers. Pressure instrumentation is also provided in the residual heat removal pump headers and in the charging pump headers.

6.3.4.4 Inservice Tests and Inspections

The ECCS components are designed and fabricated to permit inspection and inservice tests in accordance with the ASME Code, prescribed under 10CFR50.55a. Inservice inspection is discussed in Section 5.7.

(1) Details of the testing of the sensors and logic circuits associated with the generation of a safety injection signal together with the application of this signal to the operation of each active component are given in Section 7.2.

6.3.5 Instrumentation Requirements

Instrumentation and associated analog and logic channels employed for initiation of ECCS operation is discussed in Section 7.3 This section describes the instrumentation employed for monitoring ECCS components during normal plant operation and also ECCS post accident operation. Alarms are annunciated in the control room.

6.3.5.1 Temperature Instrumentation

6.3.5.1.1 Boron Injection Tank Temperature

Deleted by Amendment 3.

6.3.5.1.2 Residual Heat Exchanger Inlet and Outlet Temperature

The fluid temperature at the inlet and outlet of each residual heat exchanger is recorded in the control room.

6.3.5.1.3 Boron Injection Surge Tank Temperature

Deleted by Amendment 3.

6.3.5.2 Pressure Instrumentation

6.3.5.2.1 High Head Injection Pressure

High head injection pressure is indicated in the control room. A high pressure alarm is provided.

6.3.5.2.2 Accumulator Pressure

Duplicate pressure channels are installed on each accumulator. Pressure indication in the control room and high and low pressure alarms are provided by each channel.

6.3.5.2.3 Hydrotest Pump Discharge Pressure

This instrument provides local indication of hydrotest pump discharge pressure.

6.3.5.2.4 Test Line Pressure

A local pressure indicator used to check for proper seating of the accumulator check valves is installed on the leakage test line.

6.3.5.2.5 Residual Heat Removal Pump Discharge Pressure

Residual heat removal discharge pressure for each pump is indicated in the control room. A high pressure alarm is actuated by each channel.

6.3.5.3 Flow Instrumentation

6.3.5.3.1 Boric Acid Recirculation Flow

Deleted by Amendment 3.

6.3.5.3.2 Charging Pump Injection Flow

These flow transmitters located in the hot leg and cold leg injection headers provide flow indication in the control room.

6.3.5.3.3 Residual Heat Removal Pump Injection Flow

Flow through each residual heat removal pump header is indicated in the control room. A low flow alarm is provided.

6.3.5.3.4 Test Line Flow

Local indication of the leakage test line flow is provided to check for proper seating of the accumulator check valves between the injection lines and the RCS.

6.3.5.3.5 Residual Heat Removal Pump Minimum Flow

A flowmeter installed in each residual heat removal pump discharge header provides control for the valve located in the pump minimum flow line.

6.3.5.4 Level Instrumentation

6.3.5.4.1 Refueling Water Storage Tank Level

Four independent refueling water storage tank level channels are provided for automatic actuation of the residual heat removal pump valves to initiate recirculation upon receipt of two out of four (2/4) lo-lo level signals coincident with the receipt of a safety injection signal (the residual heat removal pumps continue in the operating mode).

The refueling water storage tank water level is indicated in the control room. Two of the four channels also provide a high, low, and an empty level alarm. The high level (maximum fill) alarm is provided to protect against possible overflow of the refueling water storage tank. The low level (minimum fill) alarm is provided to assure that a sufficient volume of water is always available in the refueling water storage tank in conformance with the Technical Specifications.

6.3.5.4.2 Accumulator Water Level

Duplicate water level channels are provided for each accumulator. Both channels provide indication in the control room and actuate high and low water level alarms.

6.3.5.4.3 Boron Injection Surge Tank Level

Deleted by Amendment 3.

6.3.5.5 Valve Position Indication

Valve positions for those valves provided with engineered safety features monitoring lights (see Section 7.5) are indicated on the control board by a “bright-dim” system; i.e., should the valve not be in its proper position, a bright white light will be lit and thus give a highly visible indication to the operator. Valve position for remote manual ECCS valves is also indicated on the control board by red and green indicator lights.

The accumulator motor operated valves are provided with red (open) and green (closed) position indicating lights located at the control switch for each valve. These lights are powered by valve control power and actuated by valve motor operator limit switches.

A monitor light that is bright when the valve is not fully open (i.e., mispositioned) is provided in an array of monitor lights that are all dim when their respective valves are in proper position enabling engineered safety features operation. This light is energized from a separate monitor light supply and actuated by a valve motor operated limit switch.

An alarm annunciator point is activated by both a valve motor operator limit switch and by a valve position limit switch activated by stem travel whenever an accumulator valve is not fully open for any reason with the system at pressure (the pressure at which the safety injection block is unblocked approximately 1900 psig). A separate annunciator point is used for each accumulator valve.

The manual valve (XVG-6700-SF) in the common header from the refueling water storage tank is provided with a limit switch which alarms the main control room if the valve is not full open.

Table 6.3-2
Emergency Core Cooling System Relief Valve Data

Description	Fluid Discharged	Fluid Inlet Temperature Normal	Set Pressure Psig	Back Pressure Constant	Psig Buildup	Capacity
N_2 Supply to Accumulators (See Note)	N_2	120	700	0	0	1500 scfm
Residual Heat Removal Pump Safety Injection Lines	Water	350	600	3	50	20 gpm
Accumulator to Reactor Building	N_2 Gas	120	700	0	0	1500 scfm
Hydrotest Pump Discharge (See Note)	Water	120	800	0	0	30 gpm
Safety Injection Pumps Suction Lines	Water	115	220	3	50	25 gpm

Note: The N2 supply header and hydrostatic test pump relief valves are included in the SI system but are outside the boundary of the ECCS. The N_2 supply relief valve protects the N_2 supply line from overpressurization due to failure of the pressure regulator. The hydrostatic test pump relief valve protects the pump discharge piping during accumulator makeup operations.

Table 6.3-3
Sequence of Switchover Operation
From Injection to Recirculation

The following manual operator actions are required to complete the switchover operation from the injection mode to the recirculation mode in accordance with the provisions of Branch Technical Position (BTP) EICSB20. During the injection mode, the operator verifies that all ECCS pumps (not including the spare or out of service charging pump) are operating and monitors the RWST and reactor building recirculation sump levels in anticipation of switchover. The operator opens, or verifies open, the component cooling water inlet isolation valves to the residual heat removal heat exchanger prior to switchover initiation. Upon receipt of the RWST "lo-lo" level signal in conjunction with the safety injection signal, the reactor building recirculation sump isolation valves (3004A & B, 3005A & B, 8811A & B, and 8812A & B) automatically open. Following these automatic actions, the operator is required to initiate the following manual actions to complete switchover.

The following manual actions must be completed in a timely manner following switchover initiation to align the charging pumps suction to the residual heat removal pumps discharge.

1. Verify that the reactor building recirculation sump isolation valves (3004A & B, 3005A & B, 8811A & B, and 8812A & B) are open, the residual heat removal pump suction valves (8809A & B) and the reactor building spray pump suction valves (3001A & B) from the refueling water storage tank are closed.
2. Close the valves (8887A & B) in the crossover line downstream of the residual heat removal heat exchanger.
3. Close the valves (8106, 8109A, B, & C) in the charging pump miniflow lines.
4. Open residual heat removal pump discharge valves (8706A & B) to the suction of the charging pumps.

Note that the four basic steps above are followed even if a single failure occurs; however, it may be necessary to secure pump(s) when it is determined that the suction(s) cannot be transferred from the RWST to conserve RWST water for the completion of the switchover.

All ECCS pumps are now aligned with suction flow from the reactor building recirculation sumps. The operator verifies proper operation and alignment of all ECCS components and proceeds to complete the following manual actions to align the ECCS in redundant flow paths for long term recirculation operation:

1. Close charging pump suction valves (LCV-115B & D) from the refueling water storage tank.
2. Close valves (8130A & B or 8131A & B) (depending on operating charging pumps) in the suction headers to establish two separate high head recirculation suction systems.

Table 6.3-3 (continued)
Sequence of Switchover Operation
From Injection to Recirculation

3. Open valve (8885) in the alternate high head cold leg recirculation line.
4. Close valves (8132A & B or 8133A & B) (depending on operating charging pumps) in the discharge header to establish two separate high head recirculation discharge systems.

SEQUENCE OF SWITCHOVER OPERATION
FROM COLD LEG TO HOT LEG RECIRCULATION
(Procedure is executed one train at a time)

The following manual operator actions are required to perform the changeover operation from the cold leg recirculation mode to the hot leg and cold leg recirculation mode.

1. Stop charging pump no. 1.
2. Close the alternate high head cold leg header isolation valve (8885) and open the corresponding high head hot leg header isolation valve (8884).
3. Restart charging pump no. 1.
4. Stop charging pump no. 2.
5. Close the high head injection isolation valves (8801A/B) and open the corresponding high head hot leg header isolation valve (8886).
6. Restart charging pump no. 2.

Single Active Failure Analysis for Emergency
Core Cooling System Components Injection Mode

Recirculation Mode

Component Valves	Malfunction	Comments
1. Residual heat removal pumps suction line to refueling water storage tank	Fails to close	Two parallel lines; each with a gate and check valve. Operation of a gate or check in each line is required.
2. Centrifugal Charging Pump		
a. Suction line from refueling water storage tank	Fails to close	Check valve in series with two parallel gate valves. Operation of either the check valve or the gate valves required.
b. Minimum flow bypass line	Fails to close	One valve in each of three parallel lines backed up by one valve in common line. Only three parallel valves or one common valve required to close
3. Residual heat removal pumps suction line from reactor building sump	Fails to open	Two parallel lines, with two valves in series in each line, one pair of valves in either line is required to open.
4. Centrifugal charging/high head pump suction line at discharge of residual heat exchanger	Fails to open	One line provided from discharge of each residual heat removal pump, valve in only one required to open.
5. Residual heat removal cross-connect line	Fails to close	Two valves in series; operation of one required.

Table 6.3-7 (continued)
Single Active Failure Analysis for Emergency
Core Cooling System Components Injection Mode

Component	Malfunction	Comments
6. Residual heat removal cross-connect line	Fails to open	Two valves provided: Hot leg recirculation flow from one RHR pump via one valve adequate.
7. Charging/high head safety injection pump suction header and discharge header cross-connect isolation valves	Fails to close	Two valves in series. One required to close.
8. High head cold leg recirculation header isolation valves	Fails to open	Header containing redundant parallel valves open during safety injection. Other header is redundant and contains one valve that opens. One header required.
9. High head hot leg recirculation header isolation valves	Fails to open	Redundant headers in parallel with one valve in each header. One header required.
10. RHR cold leg recirculation/injection isolation valves	Fails to close	One cold leg RHR recirculation isolation valve provided per RHR pump. Hot leg recirculation flow from one pump adequate.
11. RHR hot leg recirculation isolation valve	Fails to open	Sufficient hot leg recirculation flow provided via two charging high head pumps.
12. High head cold leg recirculation header isolation valves	Fails to close	Two headers; one header contains redundant parallel valves that close during hot leg recirculation, the other header contains one valve that closes. One header is required to be isolated.

Figure 6.3-2

EMERGENCY CORE COOLING SYSTEM
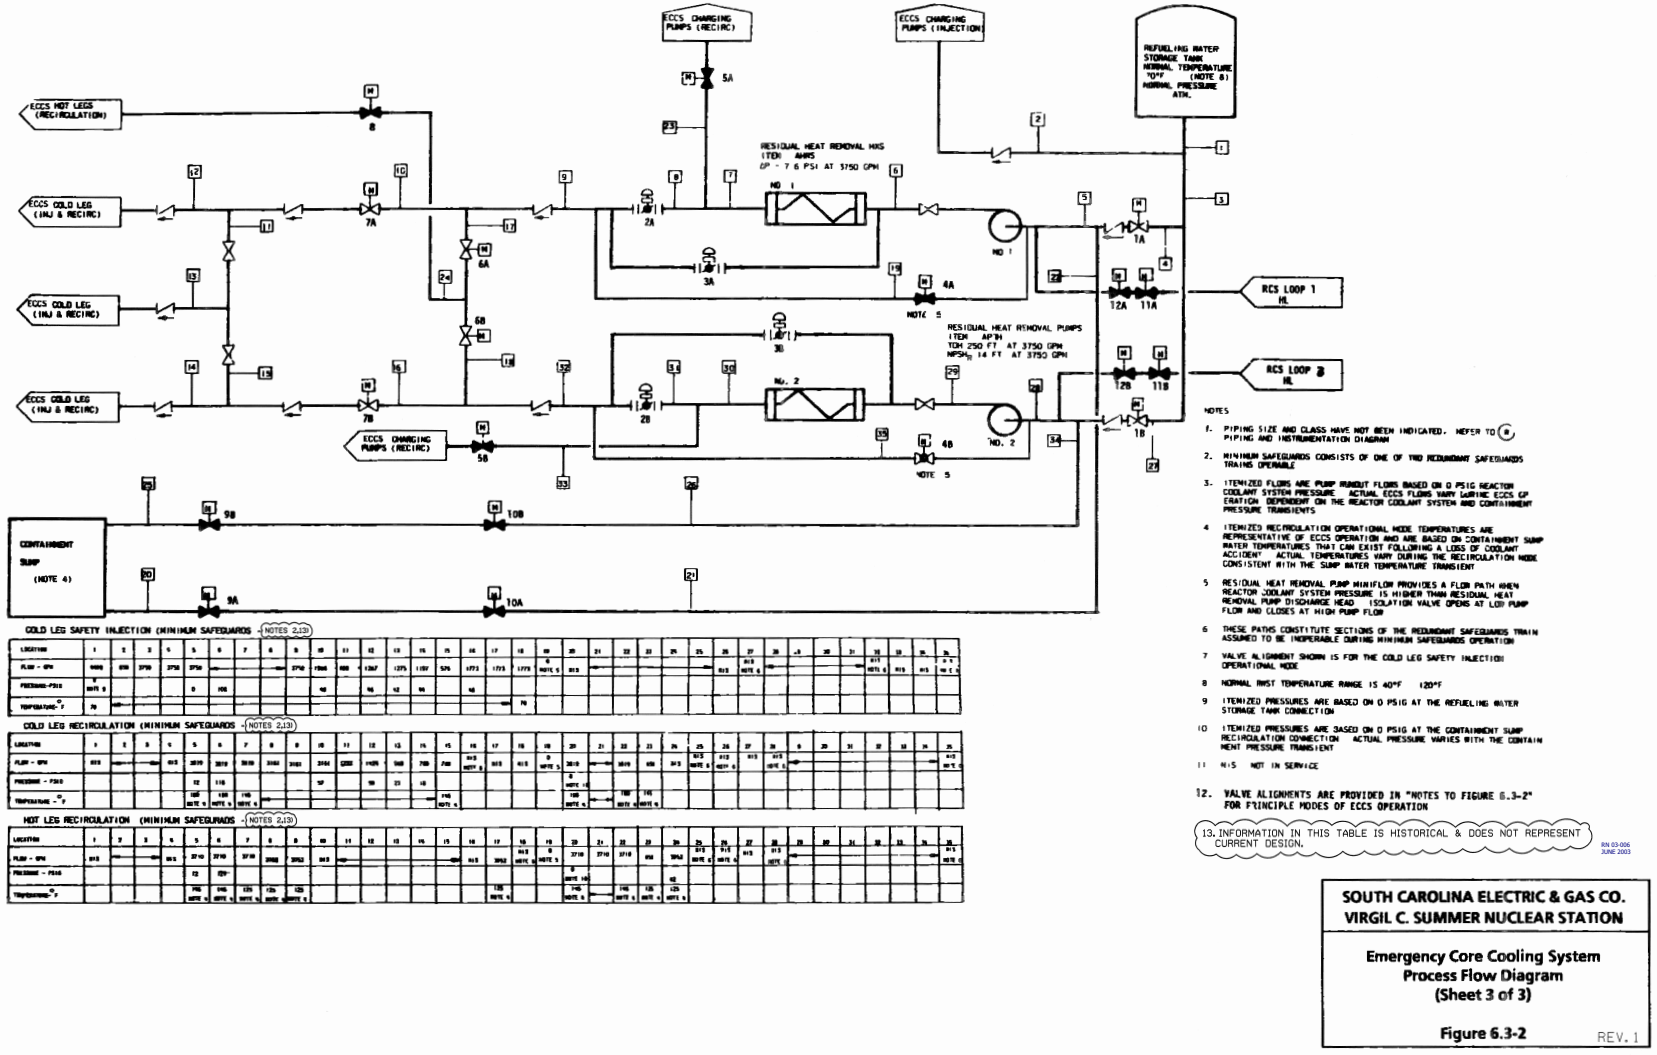
PROCESS FLOW DIAGRAM (SHEET 3 OF 3)



NOTES TO FIGURE 6.3-2 (Sheet 1 of 4)

1. Westinghouse process flow diagrams are provided for illustrative purposes only and are not intended to represent the flow rates used by Westinghouse in various accident analyses. Flow rates to the RCS are provided in Chapter 15, where appropriate. The process flow diagrams are developed to provide representative best estimate system performance data based on minimum safeguards systems alignment. The flow rates in the FSAR accident analyses are developed based on pump test curves degraded by 5 - 7 percent (see Section 6.3.3.1) and worst case assumptions pertaining to spilling line system resistances (e.g., maximum allowable resistances in lines connected to unbroken loops and minimum allowable resistances in the line connected to the broken loop) and RCS pressures.
2. The minimum safeguards alignments are for Train A components only. Minimum alignments assume a loss of power to Train B at the beginning of the event.
3. Charging pump suction and discharge valves are listed as Closed during the recirculation mode. In actuality, two suction and two discharge header valves will be open, depending on which charging pumps are in operation to establish two separate high head recirculation discharge flowpaths. (Reference Table 6.3-3)
4. RHR minimum recirculation valves are controlled automatically. During periods of low RHR injection flow rates, these valves open to maintain pump minimum flow requirements. (Reference Section 6.3.2.2.4.1)
5. In order to minimize procedure complexity, the preferred lineup for hot leg recirculation is to align the Charging SI pumps to the RCS cold legs and the RHR SI pumps to the hot legs. Adequate core cooling is ensured with either the preferred lineup or by aligning Charging SI pumps to the hot legs and the RHR SI pumps to the cold legs.

6.4 HABITABILITY SYSTEMS

Control room systems are designed in accordance with the design bases described in Section 6.4.1 so that habitability of the control room can be maintained under normal and accident conditions. The general guidance contained in Regulatory Guide 1.78 and the specific guidance contained in Regulatory Guide 1.95 is reflected throughout this section.

6.4.1 Habitability Systems Functional Design

6.4.1.1 Design Bases

The design bases for control room habitability systems are as follows:

1. Control Room Envelope

   The control room envelope includes most areas located on the 448’ and 463’ elevations of the Control Building. Housed within this control room envelope are the monitoring equipment, instrumentation, and control panels required for safe operation and shutdown of the plant. The control room envelope is provided with fire protection equipment, adequate lighting, communications equipment and kitchen, sanitary, administrative and storage facilities, and spaces necessary for normal plant operation and required to maintain the plant in a safe condition following an accident. The control room envelope ambient atmosphere is normally maintained at 75°F ± 2°F, drybulb and 50 percent relative humidity.

2. Period of Habitability

   The control room envelope is equipped to sustain seven people for a period of seven days following an accident.

3. Capacity

   The normal occupancy level of the control room is six people.

4. Food, Water, Medical Supplies, and Sanitary Facilities

   First aid equipment, food, and water are provided to sustain seven people for seven days following an accident. Chemical toilet facilities are provided for use in the event that normal sanitary facilities become inoperative.

5. Radiation Protection

   Radiation protection, as required by 10 CFR 50, Appendix A, Criterion 19, is provided by shield walls on the four exposures, shield slabs at floor and ceiling, radiation monitoring equipment, and emergency filtering systems. The control room atmosphere is monitored for radiation. When required, the control room atmosphere can be recirculated through the emergency filter system to remove contaminants. This filter system consists of roughing, high efficiency particulate air (HEPA), and charcoal filters. Assumptions and analyses regarding sources and amounts of radioactivity which may surround or leak into the control room and related shielding requirements are discussed in Chapters 12 and 15. The Radiation Monitoring System is discussed in Sections 11.4, 12.1.4 and 12.2.4.

6. Noxious Gas Protection

   Smoke detectors located in the control room air supply duct and in the emergency filter system discharge duct actuate alarms to indicate the presence of smoke in these locations. Additionally, the control room can be purged with outside air if required. Regulatory Guides 1.78 and 1.95 are discussed in Appendix 3A.

7. Respiratory, Eye, and Facial Protection for Emergencies

   Self-contained breathing apparatus are provided for control room occupants.

8. Habitability System Operation during Emergencies

   Operation of the habitability system during emergencies is discussed in Section 9.4.1.2.1.

9. Emergency Monitors and Control Equipment

   Emergency monitors and control equipment are discussed in Section 13.3.

6.4.1.2 System Design

6.4.1.2.1 Definition of Control Room Envelope

The areas to which the control room operator could require access during an emergency are the following:

1. Control room main control board and monitoring panel area - continuous occupancy required.
2. Chart and storage room - infrequent access required.
3. Shift Manager’s office - infrequent access required.
4. Kitchen facility - infrequent access required.
5. Toilet room - infrequent access required.

The equipment to which the control room operator could require access during an emergency is listed in Table 6.4-1.

6.4.1.2.2 Ventilation System Design

Normal and emergency ventilation of the control room are discussed in Section 9.4.1.2.1. The system diagram, Figure 9.4-1, indicates major components, ducts, dampers, instrumentation, and normal and emergency air flows.

System isolation dampers are pneumatically operated, spring opposed. Damper leakage does not exceed 20 cfm/ft^2 of damper area against a static pressure of 4 inches, water gage. Outside air inlet valves are 14 inch butterfly valves which have negligible leakage. Table 6.4-2 provides a summary of system isolation damper/valve data.

Components, essential instrumentation, ducting and outside air intake, and relief vents of the Control Building Ventilation System are designed in accordance with Seismic Category I requirements.

The components are not subject to the effects of floods, catastrophic weather, internal or external missiles, pipe whip, or jet impingement.

Figures 1.2-15 and 1.2-16 present layout drawings of the control room indicating doors, corridors, stairwells, shielded walls, ventilation equipment, and the location of outside air intakes.

The location of potential radioactive gas releases and their effect upon control room operation and the monitoring instrumentation and controls located therein are discussed in Chapter 15.

A description of the emergency filter system and a discussion of Regulatory Guide 1.52 is presented in Section 6.5.1 and Appendix 3A.

6.4.1.2.3 Leak Tightness

The control room system is designed so that, when operating in a normal or an emergency mode (admitting outside air), positive differential pressure is maintained between the control room and adjacent spaces. In the emergency mode, outside air is filtered by the emergency filter system and is used to pressurize the control room.

The potential paths of air leakage into the control room include: outside air valves in the non-operating redundant system and relief air dampers; openings around supply and return ducts in the control room walls and in duct chase floors; openings for electrical conduit and cables in the control room and chase walls and floors; doors; and piping. A review of these paths, as summarized below, indicates that air leakage through these paths during the emergency mode is minimal:

1. In the non-operating redundant system, the outside air is sealed from the control room by two 14 inch butterfly valves in series. Both valves are the low leakage type and fail closed upon loss of control air or power. The maximum leakage through a single closed 14 inch butterfly valve is negligible.
2. The relief dampers are two 36 inch by 36 inch dampers, one in each train. Both dampers are gasketed and blanked closed, except during control room purge, to ensure negligible air leakage.
3. The purge dampers are two 42 inch by 42 inch dampers in series. The inlet plenum to these dampers is gasketed and blanked closed, except during control room purge to ensure negligible air leakage. These dampers are fixed in the full open position.
4. Openings around supply and return ducts in the walls and floors of the control room and chases are sealed with air tight expanded silicone foam with a fire resistance rating of three hours. Negligible air leakage is present in these openings.
5. Openings for electrical conduit and cables in the walls and floors of the control room and chases are sealed in the same manner as the openings noted in item 4, above.
6. Doors from the control room to the chase area are three hour fire rated doors with closures. The maximum anticipated total air gap around each door is 0.21 ft^2. The doors leading from the turbine building to the control room are gasketed, pressure tight doors.
7. Piping to plumbing fixtures, drains, and potable water leaving the control room are sealed in the manner noted in item 4, above.

None of the control room doors lead directly to the outside. Doors lead to closed chase spaces, stairwells, or corridor spaces. Thus, neither outside wind conditions or other ventilation system cause infiltration or leakage into the control room.

6.4.1.2.4 Interaction With Other Zones and Pressure Containing Equipment

The Control Room Ventilation System is not interconnected with other building areas where potential for radioactivity exists. The system interconnects with cable spreading areas and with chase spaces through closed fire doors. There are no pressure containing pipes or equipment containing hazardous materials in the control room, cable spreading areas or duct chases.

The Turbine Building contains sources of carbon dioxide and steam but releases of these substances are diluted by the large Turbine Building volume and would be unlikely to reach the control room in any significant quantity since entry is protected by a pressure retaining door, a corridor, and a second door.

The normal and emergency operating modes of the Control Room Ventilation System maintain a positive pressure differential between the control room and adjacent spaces. Thus, the likelihood of infiltration is reduced. A radiation monitor sensing control room atmospheric radioactivity immediately causes the ventilation system to shift into the emergency mode upon detection of high gaseous activity. Thus, the potential for entry of outside airborne material into the control room is minimal. The Control Room Ventilation System can also be manually controlled to purge

the control room with outside air. The outside air purge rate is variable up to 100 percent of the system flow rate.

6.4.1.2.5 Shielding Design

The control room shielding design is discussed in Section 12.1.

6.4.1.3 Design Evaluation

Each of the operating systems which ensures control room habitability is discussed in detail in other sections. These systems and the FSAR section in which they are discussed are as follows:

1. Control Room Ventilation System, 9.4.1.
2. Fire Protection System, 9.5.1.
3. Communications System, 9.5.2.
4. Lighting System, 9.5.3.
5. Offsite power system, 8.2.
6. Onsite power system, 8.3.
7. Radiation Monitoring System, 11.4, 12.1.4, 12.2.4.

A summary evaluation of control room habitability based upon selected considerations is presented in Sections 6.4.1.3.1 through 6.4.1.3.6.

6.4.1.3.1 Radiological Protection

The evaluation of radiological exposures to control room operators for postulated accident conditions is presented in Section 15.4.

6.4.1.3.2 Toxic Gas Protection

While chlorine is not permanently stored on-site, it would be the primary hazardous chemical in sufficient quantities which may under accidental release approach toxicity limits in the control room should the use of chlorine be re-implemented.

In accordance with the recommendations of Item C2 of Regulatory Guide 1.95 chlorine, if stored on-site, would be in containers having a single container inventory of 150 pounds or less. Chlorine would be stored in the chlorine shed adjacent to the Water Treatment Building which is greater than 150 meters from the control room intake. Indication of a chlorine leak is provided by a chlorine leak detector located in the chlorine shed which annunciates an alarm locally and in the control room. Capability for manual isolation of the Control Room Ventilation System is described in Section 9.4.1. For discussion of postulated off-site hazardous chemical releases see Section 2.2.

In the absence of chlorine, ammonium hydroxide would be the primary hazardous chemical on-site. In sufficient quantities it may, under accidental release, approach toxicity limits in the control room.

One 7,000-gallon storage tank, XTK-105, containing between 1,000 and 4,000 gallons of aqueous ammonia (ammonium hydroxide) is located outside of the northeast corner of the water treatment building. The tank supplies aqueous ammonia to the auxiliary boiler chemical injection system and is filled by a two-inch liquid connection line.

A weir around the tank contains small liquid spills while large spills drain by gravity into a trough to the waste neutralizing basin. The worst-case situation for an accidental release of gas from the tank would be a catastrophic failure of the tank during a time of wind drift directly toward a Control Building air intake. In the unlikely event of such a failure, ammonia gas would be released from the tank's vapor space and the evaporation of the liquid pooled on the ground could result in ammonia gas leaking into the Control Room.

Analysis of the tank failure shows that the operators would detect the gas and have enough time to don protective equipment before reaching the exposure limit of 2 minutes at 100 ppm described in Regulatory Guide 1.78.

6.4.1.3.3 Control Room Filtering System

The general arrangement and control of the Control Room Filtering Systems are as described in Section 9.4.1.

6.4.1.3.4 Control of the Control Room Thermal Environment

The Control Room Air Handling System operates during normal and emergency periods to maintain an environment suitable for personnel and equipment. The conditions maintained and general system description are presented in Section 9.4.1.

6.4.1.3.5 Fire Protection

Evaluation of the Fire Protection System is presented in Section 9.5.1.

6.4.1.3.6 Food, Water and Sanitation

A seven day supply of food is provided in the control room for emergency use. If the emergency requires confinement for periods longer than seven days, additional food will be brought onsite in protected containers. Site accessibility will be determined by the plant Health Physicist.

Potable water is normally available from the Potable Water System described in Section 9.2.4. Should this system become unavailable during an emergency period, stored, bottled water is available in an area immediately adjacent to the control room. Additional bottled water could be brought into the control room if required.

Normal sanitation facilities are available as described in Section 9.2.4. Chemical toilets are also available in these areas for use in the event that the normal facilities become inoperative following an emergency.

6.4.1.4 Testing and Inspection

The equipment which maintains control room habitability includes the Emergency Filter System, the Control Room Air Handling System, and the Chilled Water System.

The testing and inspection is further described in Section 9.4.1.4.

6.4.1.5 Instrumentation Requirements

Habitability systems instrumentation and control equipment provides for control and monitoring of performance and status during system operation and testing. The instrumentation and control provisions for each of the systems used to ensure control room habitability are discussed in other sections of the FSAR. A list of these systems and the sections in which they are discussed is presented in Section 6.4.1.3.

6.4.2 System Operational Procedures

The normal and emergency operating modes of normal and emergency control room habitability equipment, instrumentation, and the associated controls are described in Section 9.4.1.2.1.

Table 6.4-1
Equipment to Which the Control Room Operator
Could Require Access During an Emergency

Item or Equipment	Location Within Control Room Envelope

6.5 FISSION PRODUCT REMOVAL AND CONTROL SYSTEMS

6.5.1 Engineered Safety Feature Filter Systems

The engineered safety features (ESF) filter systems include:

1. The high efficiency particulate air (HEPA) filters in the Reactor Building Cooling System.
2. The control room emergency filter plenums.
3. The Fuel Handling Building charcoal exhaust system.

6.5.1.1 Design Bases

The ESF filter systems are designed and sized to perform the following functions. Non ESF filter systems are discussed in Section 9.4.

1. Satisfy the radiation control requirements of 10 CFR 20.
2. Satisfy requirements of General Design Criteria 19, 41, 42 and 43.
3. Remove particulate fission products from the post accident Reactor Building atmosphere (Reactor Building Cooling System only).
4. Remove gaseous and particulate fission products from the spent fuel pool surface and from general areas of the Fuel Handling Building.

6.5.1.2 System Design

Descriptive information concerning the ESF filter systems is presented in the following sections:

1. Reactor Building cooling system HEPA filters:
   a. Design bases - Sections 6.5.1.1 through 6.5.1.3
   b. General description - Section 6.2.2.2.2
   c. System design features - Section 6.2.2.2.2.1
2. Control room emergency filter plenums:
   a. Design bases - Section 9.4.1.1
   b. General description - Section 9.4.1.2
   c. System design features - Section 9.4.1.2.1
3. Fuel Handling Building charcoal exhaust system.
   a. Design bases - Section 9.4.3.1
   b. General description - Section 9.4.3.2
   c. System design features - Section 9.4.3.2.1

Table 6.5-1 provides a comparison of the emergency filter systems with the requirements of Regulatory Guide 1.52. General compliance with Regulatory Guide 1.52 is discussed in Appendix 3A.

6.5.1.3 Design Evaluation

The general arrangement and control of the ESF filter systems are described in Sections 6.2.2, 9.4.1, and 9.4.3. System components are separated, redundant, powered by Class 1E electric systems, and are housed in Seismic Category 1 structures. The control room system is not subject to jet impingement, pipe whip or flooding. The HEPA filter systems in the Reactor Building are physically separated so that no more than 1 unit is subject to these occurrences. The Fuel Handling Building charcoal exhaust system plenums are housed in shielded and separated cubicles. The exhaust fans of this system are adjacent to each other. Neither the exhaust fans nor the filter plenums are subject to jet impingement, pipe whip or flooding. The ESF filter systems can sustain a single component failure without impairing their full functional capability. Additionally, provision is made for suitable maintenance and change-out space and adequate instrumentation and lighting, all of which reduce personnel exposure by reducing time exposure.

The control room emergency filter system is required in the event of radioactive leakage from the outside into the Control Building following a LOCA. Post LOCA operation of the control room filter systems is ensured by automatic actuation as a result of a safety injection signal or high radiation in the control room signal from the radiation monitor (RM-A1).

The Reactor Building cooling system and control room emergency filter trains provide a minimum of 99.97 percent removal efficiency for particulates. The control room emergency filters also provide a minimum of 95 percent removal efficiency for methyl iodine at 85 percent relative humidity and 70°F (see Reference 1).

6.5.1.4 Tests and Inspections

Details of the tests and inspections for the ESF filter systems are provided in the following sections:

6.2.2.4.2 - Reactor Building Cooling System HEPA Filters
9.4.1.4 - Control Room Emergency Filters
9.4.3.4 - Fuel Handling Building Charcoal Exhaust System

Laboratory tests, inplace tests, and test acceptance criteria are in accordance with the requirements of Regulatory Guide 1.52 (see Table 6.5-1).

6.5.1.5 Instrumentation Requirements

Each of the ESF filter systems include instrumentation for system performance and status monitoring during normal plant operation, system tests, and system operation following a design basis accident. The instrumentation and control features of the ESF filter systems are described in Sections 6.5.1.5.1 and 6.5.1.5.2.

6.5.1.5.1 Reactor Building Cooling System HEPA Filter Instrumentation

Activation of this filtering system is initiated automatically by a safety injection signal (from the ESF actuation system) or by manual action at the main control board. A separate automatic initiation signal is supplied to each redundant train. Under accident conditions, the filter bypass dampers of both trains (4 units) receive a signal to automatically close, 1 preselected cooling unit in each train is automatically started in low speed.

Main control board switches are provided for each fan motor (high and low) and for the filter bypass damper of each reactor building cooling unit.

Instrumentation used for monitoring the performance of this filter system including bypass damper position indication, is described in Section 6.2.2.5.2.

6.5.1.5.2 Control Room Emergency Filter Instrumentation

Activation of the control room emergency filter system is initiated automatically by a safety injection signal, a high control room radiation signal (RM-A1), (see Section 12.2.4) or by manual action at the HVAC control board in the control room. Other elements of the control room ventilation system are operated in conjunction with this emergency filter system to carry out the air cleaning function. In particular, the relief dampers and outside air supply dampers of the control room ventilation system are automatically tripped closed by the signals listed above. HVAC control board switches are provided for each emergency filtering fan. The fan inlet and discharge dampers operate in conjunction with their respective fans.

The overall operation of the control room ventilation system is described in Section 9.4.1. Instrumentation used for monitoring the performance of this filter system, including fan and damper status indication, is described in Section 9.4.1.2.1.

6.5.1.5.3 Fuel Handling Building Charcoal Exhaust System Instrumentation

The Fuel Handling Building charcoal exhaust system components (2 filter plenums, one exhaust fan) are in continuous operation during normal, shutdown and refueling periods. The ESF function of the fuel building charcoal exhaust system is only required during the movement of fuel in the spent fuel pool or during crane operation with loads over the pool. Instrumentation used for monitoring system performance, including fan and damper status indication, is described in Section 9.4.3.2.1.

6.5.1.6 Materials

Filter materials employed in the ESF filter systems are discussed in Section 6.5.1.6.1 and 6.5.1.6.2.

6.5.1.6.1 Reactor Building Cooling System HEPA Filter Materials

Each of four Reactor Building cooling system filter plenums includes 120 HEPA cells. Cells are nominally 24 inches square by 12 inches deep. Cells include media of high strength, waterproof glass fiber without separators, high temperature silicon adhesive, metal cell sides and silicon rubber closed cell sponge gasketing.

6.5.1.6.2 Control Room Emergency Filter and Fuel Handling Building Charcoal Exhaust System Filter Materials

Both of the control room emergency filter plenums contain 1 prefilter bank, each with 15 prefilter cells. Each of the 3 Fuel Handling Building charcoal exhaust system filter plenums contains 1 prefilter bank, each with 12 prefilter cells. The prefilters satisfy the requirements of and are marked for Underwriters Standard UL-900 (Reference 2), Class I; and therefore, the radiolytic or pyrolytic decomposition products will not interfere with safe ESF operation.

Both of the control room emergency filter plenums contain 2 banks of HEPA filters with 15 HEPA filters per bank. Each of the Fuel Handling Building charcoal exhaust system filter plenums includes 2 banks of HEPA filters with 12 HEPA filters per bank. Each filter is 24 inches square by 12 inches deep and includes glass media. The HEPA filters satisfy the requirements of MIL-C-51068C, MIL-F-51079 and are qualified to Underwriters Standard UL-586 (Reference 3); and therefore, the radiolytic or pyrolytic decomposition products will not interfere with safe ESF operation.

The 2 control room emergency filter plenums and the 3 Fuel Handling Building charcoal exhaust system filter plenums are of the vertical bed design. The control room plenums contain 11 sections and the Fuel Handling Building charcoal exhaust system plenums contain 8 sections. Media is impregnated, activated coconut shell charcoal which meets the requirements of Regulatory Guide 1.52, Revision 2.

Table 6.5-1
Comparison of Engineered Safety Features Filter Systems
With Regulatory Guide 1.52 (Revision 1, 7/76) Requirements

1. Reactor Building Cooling System HEPA Filters

Regulatory Guide 1.52 Item	
1-a	The system complies with this requirement.
1-b,c	The filters comply with the integrated radiation dose criteria as required by items 1-b, c.
1-d	The system complies with this requirement.
1-e	Not applicable.
2-a	Filter plenums include only demisters and HEPA filters. Systems are redundant. Charcoal adsorbers are not included since the reactor building spray system serves this function.
2-b	The system complies with this requirement.
2-c	The system complies with this requirement.
2-d	The system complies with this requirement.
2-e	The system complies with this requirement.
2-f	The capacity of each plenum is 120,000 cfm. The plenum is arranged as three filter modules, each four filters high and ten filters wide. Space limitations make use of multiple 30,000 cfm plenums for this system physically impractical.
2-g	The system is instrumented to indicate differential pressure drop across demisters and HEPA filters by means of alarms in the control room and to indicate filter damper position. Since the filters are used only following a LOCA or during test, the additional instrumentation specified would provide minimum benefit and, therefore, was not added.
2-h	See Chapters 7.0 and 8.0 for IEEE compliance.

Table 6.5-1 (continued)
Comparison of Engineered Safety Features Filter Systems
With Regulatory Guide 1.52 (Revision 1, 7/76) Requirements

1. Reactor Building Cooling System HEPA Filters (Continued)

Regulatory Guide 1.52 Item	
2-i	The system complies with Regulatory Guide 8.8 through provision of service platforms and arrangement of HEPA filters for "bagging" during the changing procedure. As noted for item 2-f, above, capacity of the unit made change as a single unit physically impractical. Also, high radiation deposits are not expected to accumulate on these filters from normal operation. Therefore, filter replacement as a single unit loses importance.
2-j	Not applicable
2-k	Duct and housing leakage is not of primary importance since this system is a recirculation type system housed inside the reactor building
3-a	The system complies with this requirement.
3-b	Not applicable.
3-c	The system complies with this requirement.
3-d	The system complies with this requirement, except that filter tests were performed by the manufacturer.
3-e	The system complies with this requirement.
3-f	The system complies with this requirement.
3-g	The system complies with this requirement.
3-h	Not applicable since there is no fire spray system to this plenum.
3-i	Not applicable since there are no adsorption filters in this system.
3-j	Not applicable since there are no adsorption filters in this system.
3-k	Not applicable since there are no adsorption filters in this system.

Table 6.5-1 (continued)
Comparison of Engineered Safety Features Filter Systems
With Regulatory Guide 1.52 (Revision 1, 7/76) Requirements

1. Reactor Building Cooling System HEPA Filters (Continued)

Regulatory Guide 1.52 Item	
3-l	The system complies with this requirement.
3-m	The system complies with this requirement.
3-n	The system complies with this requirement.
3-o	The system complies with this requirement.
4-a	The system complies with this requirement.
4-b	The system complies with this requirement.
4-c	The capacity of this system makes this requirement physically impractical.
4-d	External connections have been provided for field insertion of test probes and manifolds.
4-e	Operating procedures satisfy this request.
4-f	System procedures comply with this request.
5-a	Startup and test and operating procedures comply with this requirement except testing will be performed every 18 months in lieu of once per operating cycle and after 720 hours of system operation. The visual test will be performed before each in place air flow distribution test, or DOP test (Note 1).
5-b	Filter plenum testing procedures comply with this requirement.
5-c	Operating procedures and filter plenum testing procedures comply with this requirement except testing will be performed every 18 months in lieu of once per operating cycle and after 720 hours of system operation. (Note 1).
5-d	Not applicable since there are no adsorption filters in this system.
6-a	Not applicable since there are no adsorption filters in this system.
6-b	Not applicable since there are no adsorption filters in this system.

Table 6.5-1 (continued)
Comparison of Engineered Safety Features Filter Systems
With Regulatory Guide 1.52 (Revision 1, 7/76) Requirements

2. Control Room Emergency Filter

Regulatory Guide 1.52 Item	
1-a	The listed criteria, except radiation dose rate, relative to this system are not affected by the DBA. The dose rate following DBA was considered in the filter design.
1-b	The filters comply with the integrated radiation dose criteria as required by items 1-b, c.
1-d	Not applicable.
1-3	Not applicable.
2-a	Filter plenums include all sequential components listed, except demisters and heating/cooling coils. Demisters are not included because there is no source of water spray coincident with continuing filter operation. Heating/cooling coils are not included because relative humidity is not expected to exceed 50 percent. Systems are redundant.
2-b	The system complies with this requirement.
2-c	The system complies with this requirement.
2-d	Not applicable since filter plenums are not in an area where pressure surges could occur.
2-e	The system complies with this requirement.
2-f	The system complies with this requirement.
2-g	The system complies with this requirement through provision of control room indication of isolation damper position, high temperature and smoke. Recorders are not considered pertinent since this system is operated only for test or under accident conditions. Provisions have been made for local indication of pressure drop across filter sections.
2-h	See Chapters 7.0 and 8.0 for IEEE compliance.
2-i	The system complies with this requirement.

Table 6.5-1 (continued)
Comparison of Engineered Safety Features Filter Systems
With Regulatory Guide 1.52 (Revision 1, 7/76) Requirements

2. Control Room Emergency Filter (Continued)

Regulatory Guide 1.52 Item	
2-j	Not applicable.
2-k	Ducts were specified to satisfy leakage testing requirements of SMACNA, Chapter 8, 1967. Plenums were specified to indicate no leakage through soap bubble testing with ducts at 2 psig. Neither the plenum nor the attached ducts are in any contaminated area between the plenum equipment area and the control room.
3-a	Not applicable since this system will not be exposed to a water spray.
3-b	No heaters are included in the design. The filters process room return air and room relative humidity should not exceed 50 percent. Therefore, heaters are not required.
3-c	The system complies with this requirement.
3-d	The system complies with this requirement.
3-e	The system complies with this requirement.
3-f	The system complies with this requirement.
3-g	The system complies with this requirement.
3-h	The system complies with this requirement.
3-i	The system complies with this requirement. New activated carbon meets the physical property specifications given in Table 5.1 of ANSI N509-1976. (Note 1) New and used activated carbon meet the laboratory testing criteria of ASTM D3803-1989, at a relative humidity of 70% and a temperature of 30° C (86° F) with a methyl iodide penetration of less than 2.5%.
3-j	The system complies with this requirement.
3-k	The system complies with this requirement.
3-l	The system complies with this requirement.
3-m	The system complies with this requirement.
3-n	The system complies with this requirement.

Table 6.5-1 (continued)
Comparison of Engineered Safety Features Filter Systems
With Regulatory Guide 1.52 (Revision 1, 7/76) Requirements

2. Control Room Emergency Filter (Continued)

Regulatory Guide 1.52 Item	
3-o	The system complies with this requirement.
4-a	The system complies with this requirement.
4-b	The system complies with this requirement.
4-c	The system complies with this requirement.
4-d	External connections have been provided for field insertion of test probes and manifolds.
4-e	Operating procedures satisfy this request.
4-f	System procedures comply with this request.
5-a	Startup and test and operating procedures comply with this requirement except testing will be performed every 18 months in lieu of once per generating cycle and after 720 hours of system operation. The visual test will be performed before each in place air flow distribution test, DOP test or activated carbon adsorber section leak test. (Note 1)
5-b	Filter plenum testing procedures comply with this requirement.
5-c	Operating procedures and filter plenum testing procedures comply with this requirement except testing will be performed every 18 months in lieu of once per operating cycle and after 720 hours of system operation. (Note 1)
5-d	Filter plenum testing procedures comply with this requirement except adsorber testing will be done with then DOP test is performed and following removal of an adsorber sample for laboratory testing if the integrity of the adsorber section is affected. (Note 1)
6-a	The system analysis complies with this requirement. New activated carbon meets the physical property specifications given in Table 5.1 of ANSI N 509-1976 (Note 1)

Table 6.5-1 (continued)
Comparison of Engineered Safety Features Filter Systems
With Regulatory Guide 1.52 (Revision 1, 7/76) Requirements

2. Control Room Emergency Filter (Continued)

Regulatory Guide 1.52 Item	
6-b	The system analysis complies with this requirement except laboratory tests will be performed every 18 months in lieu of once per operating cycle. New unused activated carbon meeting the physical requirements of Table 5.1 of ANSI N 509-1976 will be used if (1) Testing is in accordance with footnote c of Table 3 (except as noted above) results in a representative sample failing to pass the applicable test in Table 3 or (2) no representative sample is available for testing. (Note 1) New and used activated carbon meet the laboratory testing criteria of ASTM D3803-1989, at a relative humidity of 70% and a temperature of 30° C (86° F) with a methyl iodide penetration of less than 2.5%.

3. Fuel Handling Building Charcoal Exhaust System

Regulatory Guide 1.52 Item	
1-a	The system complies with this requirement.
1-b, c	The filter plenums comply with the integrated radiation dose criteria as required by items 1-b, c.
1-d	The system complies with this requirement.
1-e	Not applicable.
2-a	Filter plenums include all sequential components listed, except demisters and heating/cooling coils. Demisters are not included because there is no source of water spray coincident with continuing filter operation. Heating/cooling coils are not provided because the relative humidity is not expected to exceed 70 percent. Plenums and fans are redundant.
2-b	The plenums are physically separated. The fans are adjacent to each other but are not in an area exposed to missiles.

Table 6.5-1 (continued)
Comparison of Engineered Safety Features Filter Systems
With Regulatory Guide 1.52 (Revision 1, 7/76) Requirements

3. Fuel Handling Building Charcoal Exhaust System (Continued)

Regulatory Guide 1.52 Item	
2-c	The system complies with this requirement.
2-d	Not applicable since the filter plenums are not in an area where pressure surges could occur.
2-e	The system complies with this requirement.
2-f	The system complies with this requirement.
2-g	Temperature of the charcoal filter sections of the plenums is recorded in the control room and detection of high temperature actuates alarms in the control room. Fan operation and isolation damper position are indicated in the control room. Filter bank pressure drop is indicated locally.
2-h	See Chapters 7.0 and 8.0 for IEEE compliance.
2-i	The system complies with this requirement.
2-j	Not applicable.
2-k	Ducts were specified to satisfy leakage testing requirements of SMACNA Chapter 8, 1967. Plenums were specified to indicate no leakage through soap bubble testing with ducts at 2 psig.
3-a	Not applicable since this system will not be exposed to a water spray.
3-b	No heaters are included in the design. The filters process room air and room relative humidity should not exceed 70 percent. Therefore, a heater is not required.
3-c	The system complies with this requirement.
3-d	The system complies with this requirement.
3-e	The system complies with this requirement.
3-f	The system complies with this requirement.
3-g	The system complies with this requirement.
3-h	The system complies with this requirement.

Table 6.5-1 (continued)
Comparison of Engineered Safety Features Filter Systems
With Regulatory Guide 1.52 (Revision 1, 7/76) Requirements

3. Fuel Handling Building Charcoal Exhaust System (Continued)

Regulatory Guide 1.52 Item	
3-i	The system complies with this requirement. New activated carbon meets the physical property specifications given in Table 5.1 of ANSI N509-1976. (Note 1) New and used activated carbon meet the laboratory testing criteria of ASTM D3803-1989, at a test media temperature of 30° C (86° F).
3-j	The system complies with this requirement.
3-k	The system complies with this requirement.
3-l	The system complies with this requirement.
3-m	The system complies with this requirement.
3-n	The system complies with this requirement.
3-o	The system complies with this requirement.
4-a	The system complies with this requirement.
4-b	The system complies with this requirement.
4-c	The system complies with this requirement.
4-d	External connections have been provided for field insertion of test probes and manifolds.
4-e	Operating procedures comply with this request.
4-f	System procedures comply with this request.
5-a	Startup and test and operating procedures comply with this requirement except testing will be performed every 18 months in lieu of once per operating cycle and after 720 hours of system operation. The visual test will be performed before each in place air flow distribution test, DOP test or activated carbon adsorber leak test. (Note 1)
5-b	Filter plenum testing procedures comply with this requirement.

Table 6.5-1 (continued)
Comparison of Engineered Safety Features Filter Systems
With Regulatory Guide 1.52 (Revision 1, 7/76) Requirements

3. Fuel Handling Building Charcoal Exhaust System (Continued)

Regulatory Guide 1.52 Item	
5-c	Operating procedures and filter plenum testing procedures comply with this requirement except testing will be performed every 18 months in lieu of once per operating cycle and after 720 hours of system operation. (Note 1)
5-d	Filter plenum testing procedures comply with this requirement except adsorber testing will be done when the DOP test is performed and following removal of an adsorber sample for laboratory testing if the integrity of the adsorber section is affected. (Note 1)
6-a	The system analysis complies with this requirement. New activated carbon meets the physical property specifications given in Table 5-1 of ANSI N 509-1976. (Note 1)
6-b	The system complies with this requirement except laboratory tests will be performed every 18 months in lieu of once per operating cycle (Note 1) and every 720 hours (since units run continuously) during the period of time there is fuel or crane movement with loads over the pool. New unused activated carbon meets the physical requirements of Table 5.1 of ANSI N 509-1976 will be used if (1) testing is in accordance with footnote C of Table 3 (except as noted above) results in a representative sample failing to pass the applicable test in Table 3 or (2) no representative sample is available for testing. (Note 1) New and used activated carbon meet the laboratory testing criteria of ASTM D3803-1989, at a media temperature of 30° C (86° F).

Note 1 - Exceptions and clarifications are consistent with revisions made to these sections in Revision 2 of Regulatory Guide 1.52.

V.C. Summer Power Station
Safety Analysis Report

Instrumentation and Controls

Chapter 7

Revision 26--06/25/26

The Revision summary replaces the List of Effective pages of the VC Summer FSAR, effective June 30, 2021. It will appear in Chapter 00 of the VC Summer FSAR and is the best history available of all the changes made to the original VC Summer FSAR.

CHAPTER 7 - INSTRUMENTATION AND CONTROLS

7.0 INSTRUMENTATION AND CONTROLS

7.1 INTRODUCTION

This chapter presents the various plant instrumentation and control systems by relating the functional performance requirements, design bases, system descriptions, design evaluations, and tests and inspections for each. The information provided in this chapter emphasizes those instruments and associated equipment which constitute the protection system as defined in IEEE Standard 279-1971 "IEEE Standard: Criteria for Protection Systems for Nuclear Power Generating Stations," (Reference 1).

The primary purpose of the instrumentation and control systems is to provide automatic protection and exercise proper control against unsafe and improper reactor operation during steady-state and transient power operations (ANS Conditions I, II, III) and to provide initiating signals to mitigate the consequences of faulted conditions (ANS Condition IV). ANS conditions are discussed in Chapter 15. Consequently, the information presented in this chapter emphasizes those instrumentation and control systems which are central to assuring that the reactor can be operated to produce power in a manner that ensures no undue risk to the health and safety of the public.

It is shown that the applicable criteria and codes, such as General Design Criteria and IEEE Standards, concerned with the safe generation of nuclear power are met by these systems. See Table 7.1-1 for a listing of applicable criteria.

Terminology used in this chapter is based on the definitions given in IEEE Standard 279-1971 which is listed in Table 7.1-1. In addition, the following definitions apply:

1. Degree of Redundancy

   The difference between the number of channels monitoring a variable and the number of channels which when tripped, will cause an automatic system trip.

2. Minimum Degree of Redundancy

   The degree of redundancy below which operation is prohibited, or otherwise restricted by the Technical Specifications.

3. Cold Shutdown Condition

   When the reactor is subcritical by at least 1 percent $\Delta k/k$ and T_{avg} is $\leq$ 200 °F.

4. Hot Shutdown Condition

   When the reactor is subcritical, by an amount greater than or equal to the margin specified in the applicable Technical Specification and T_{avg} is in the range specified in the applicable Technical Specification.

5. Phase A Containment Isolation

   Closure of all nonessential process lines which penetrate the Reactor Building, except engineered safety features lines, component cooling lines and steam lines into and out of the Reactor Building, initiated by the safety injection signal, or manually.

6. Phase B Containment Isolation

   Closure of remaining process lines, initiated by Reactor Building Hi-3 pressure signal or manually (process lines do not include engineered safety features lines). Steam lines will previously have been closed by Reactor Building Hi-2 pressure signal.

7. System Response Times

   a. Reactor Trip System Response Time

      The Reactor Trip System response time shall be the time interval from when the monitored parameter exceeds its trip setpoint at the channel sensor until loss of stationary gripper coil voltage.

   b. Engineered Safety Features Actuation System Response Time

      The Engineered Safety Features Actuation System response time shall be that time interval from when the monitored parameter exceeds its engineered safety features actuation setpoint at the channel sensor until the engineered safety features equipment is capable of performing its safety function (i.e., the valves travel to their required positions, pump discharge pressures reach their required values, etc.). Times shall include diesel generator starting and sequence loading delays where applicable.

8. Reproducibility

   This definition is taken from Scientific Apparatus Manufactures Association (SAMA) Standard PMC-20.2-1973, Process Measurement and Control Terminology: "the closeness of agreement among repeated measurements of the output for the same value of input, under normal operating conditions over a period of time, approaching from both directions." It includes drift due to environmental effects, hysteresis, long term drift, and repeatability. Long term drift (aging of components, etc.) is not an important factor in accuracy requirements since, in general, the drift is not significant with respect to the time elapsed between testing. Therefore, long term drift may be eliminated from this definition. Reproducibility, in most cases, is a part of the definition of accuracy (see item 9).

9. Accuracy

   This definition is derived from Scientific Apparatus Manufactures Association (SAMA) Standard PMC-20.2-1973, Process Measurement and Control Terminology. An accuracy statement for a device falls under Note 2 of the Scientific Apparatus Manufactures Association definition of accuracy, which means reference accuracy or the accuracy of that device at reference operating conditions: "Reference accuracy includes conformity, hysteresis and repeatability." To adequately define the accuracy of a system, the term reproducibility is useful as it covers normal operating conditions. The following terms, "trip accuracy" and "indicated accuracy," etc., will then include conformity and reproducibility under normal operating conditions. Where the final result does not have to conform to an actual process variable but is related to another value established by testing, conformity may be eliminated, and the term reproducibility may be substituted for accuracy.

10. Normal Operating Conditions

    Normal operating conditions include normal process temperature and pressure changes, and ambient temperature changes around the transmitter and racks. The normal operating conditions exclude those parameters experienced under post accident conditions.

11. Readout Devices

    For consistency the final device of a complete channel is considered a readout device. This includes indicators, recorders, and controllers.

12. Channel Accuracy

    This definition includes accuracy of primary element, transmitter and rack modules. It does not include readout devices or rack environmental effects, but does include process and environmental effects on field mounted hardware. Rack environmental effects are included in the next 2 definitions to avoid duplication due to dual inputs.

13. Indicated and/or Recorded Accuracy

    This definition includes channel accuracy, accuracy of readout devices and rack environmental effects.

14. Trip Accuracy

    This definition includes comparator accuracy, channel accuracy, for each input, and rack environmental effects. This is the tolerance expressed in process terms (or percent or span) within which the complete channel must perform its intended trip function. This includes all instrument errors but no process effects such as streaming. The term "actuation accuracy" may be used where the word "trip" might cause confusion (for example, when starting pumps and other equipment).

15. Control Accuracy

    This definition includes channel accuracy, accuracy of readout devices (isolator, controller), and rack environmental effects. Where an isolator separates control and protection signals, the isolator accuracy is added to the channel accuracy to determine control accuracy, but credit is taken for tuning beyond this point; i.e., the accuracy of these modules (excluding controllers) is included in the original channel accuracy. It is simply defined as the accuracy of the control signal in percent of the span of that signal. This will then include gain changes where the control span is different from the span of the measured variable. Where controllers are involved, the control span is the input span of the controller. No error is included for the time in which the system is in a non-steady-state condition.

7.1.1 Identification of Safety-Related Systems

7.1.1.1 Safety-Related Systems

The Nuclear Steam Supply System (NSSS) instrumentation discussed in Chapter 7 that is required to function to achieve the system responses assumed in the safety evaluations, and those needed to shutdown the plant safely are given in this section. Table 7.1-2 identifies safety related instrumentation and control systems.

7.1.1.1.1 Reactor Trip System

The Reactor Trip System is a functionally defined system described in Section 7.2. The equipment which provides the trip functions is identified and discussed in Section 7.2. Design bases for the Reactor Trip System are given in Section 7.1.2.1. Figure 7.1-1 includes a single line diagram of this system. Additional background information on the Reactor Trip System is contained in Reference 2.

7.1.1.1.2 Engineered Safety Features Actuation System

The Engineered Safety Features Actuation System is a functionally defined system described in Section 7.3. The equipment which provides the actuation functions is identified and discussed in Section 7.3. Design bases for the Engineered Safety Features Actuation System are given in Section 7.1.2.1.

7.1.1.1.3 Instrumentation and Control Power Supply System

Design bases for the Instrumentation and Control Power Supply System are given in Section 7.1.2.1. Further description of this system is provided in Section 7.6.1.

7.1.1.2 Safety-Related Display Instrumentation

Display instrumentation provides the operator with information to enable him to monitor the results of engineered safety features actions following a Condition II, III, or IV event. Section 7.5

describes the instrumentation required to maintain the plant in a hot shutdown condition or to proceed to cold shutdown.

7.1.1.3 Instrumentation and Control System Designers

Systems discussed in Chapter 7 have definitive functional requirements developed on the basis of the Westinghouse Nuclear Steam Supply System design. Figure 7.2-1 defines scope interface. Regardless of the supplier, the functional requirements necessary to assure plant safety and proper control are clearly delineated.

7.1.1.4 Plant Comparison

System functions for all systems discussed in Chapter 7 are similar to those of the Joseph M. Farley Nuclear Plant. A comparison table is provided in Section 1.3.

7.1.2 Identification of Safety Criteria

Section 7.1.2.1 gives design bases for the systems given in Section 7.1.1.1. Design bases for non-safety related systems are provided in the sections which describe the systems. Conservative considerations for instrument errors are included in the accident analyses presented in Chapter 15. Functional requirements, developed on the basis of the results of the accident analyses, which have utilized conservative assumptions and parameters are used in designing these systems and a preoperational testing program verifies the adequacy of the design. Accuracies are given in Sections 7.2, 7.3, and 7.5.

The documents listed in Table 7.1-1 were considered in the design of the systems given in Section 7.1.1. In general, the scope of these documents is given in the document itself. This determines the systems or parts of systems to which the document is applicable. A discussion of compliance with each document for systems in its scope is provided in the referenced sections given in Table 7.1-1 for each criterion. Because some documents were issued after design and testing had been completed, the equipment documentation may not meet the format requirements of some standards. Justification for any exceptions taken to each document for systems in its scope is provided in the referenced sections.

Table 7.1-2 outlines the design criteria that have been implemented in the design of safety related instrument and control systems.

7.1.2.1 Design Bases

7.1.2.1.1 Reactor Trip System

The Reactor Trip System acts to limit the consequences of Condition II events (faults of moderate frequency), such as loss of feedwater flow, by, at most, a shutdown of the reactor and turbine, with the plant capable of returning to operation after corrective action. The Reactor Trip System features impose a limiting boundary region to plant operation which ensures that the reactor safety limits are not exceeded during Condition II events and that these events can be

accommodated without developing into more severe conditions. Reactor trip setpoints are given in the Technical Specifications.

The design requirements for the Reactor Trip System are derived by analyses of plant operating and fault conditions where automatic rapid control rod insertion is necessary in order to prevent or limit core or reactor coolant boundary damage. The design bases addressed in IEEE Standard 279-1971 are discussed in Section 7.2.1. The design limits specified by Westinghouse for the Reactor Trip System are:

1. There shall be at least a 95% probability (at a 95% confidence level) that departure from nucleate boiling (DNB) will not occur as a result of any anticipated transient or malfunction (Condition II faults).
2. Power density shall not exceed the rated linear power density for Condition II faults. See Chapter 4 for fuel design limits.
3. The stress limit of the Reactor Coolant System for the various conditions shall be as specified in Chapter 5.
4. Release of radioactive material shall not be sufficient to interrupt or restrict public use of those areas beyond the exclusion radius as a result of any Condition III fault.
5. For any Condition IV fault, release of radioactive material shall not result in an undue risk to public health and safety.

7.1.2.1.2 Engineered Safety Features Actuation System

The Engineered Safety Features Actuation System acts to limit the consequences of Condition III events (infrequent faults such as primary coolant spillage from a small rupture which exceeds normal charging system makeup and requires actuation of the Safety Injection System). The Engineered Safety Features Actuation System acts to mitigate Condition IV events (limiting faults, which include the potential for significant release of radioactive material).

The design bases for the Engineered Safety Features Actuation System are derived from the design bases given in Chapter 6 for the engineered safety features. Design bases requirements of IEEE Standard 279-1971 are addressed in Section 7.3.1.2. General design requirements are given below:

1. Automatic Actuation Requirements

   The primary requirement of the Engineered Safety Features Actuation System is to receive input signals (information) from the various on-going processes within the reactor plant and containment and automatically provide, as output, timely and effective signals to actuate the various components and subsystems comprising the Engineered Safety Features System.

2. Manual Actuation Requirements

   The Engineered Safety Features Actuation System must have provisions in the control room for manually initiating the functions of the Engineered Safety Features System.

7.1.2.1.3 Instrumentation and Control Power Supply System

The Instrumentation and Control Power Supply System provides continuous, reliable, regulated single phase a-c power to all instrumentation and control equipment required for plant safety. Details of this system are provided in Section 7.6. The design bases are given below:

1. The inverter shall have the capacity and regulation required for the a-c output for proper operation of the equipment supplied.
2. Redundant loads shall be assigned to different distribution panels which are supplied from different inverters.
3. Auxiliary devices that are required to operate dependent equipment shall be supplied from the same distribution panel to prevent the loss of electric power in one protection set from causing the loss of equipment in another protection set. No single failure shall cause a loss of power supply to more than one distribution panel.
4. Each of the distribution panels shall have access only to its respective inverter supply and a standby power supply.
5. The system shall comply with IEEE Standard 308-1971, paragraph 5.4.

7.1.2.1.4 Emergency Power

Design bases and system description for the emergency power supply are provided in Chapter 8.

7.1.2.1.5 Interlocks

Interlocks are discussed in Sections 7.2, 7.3, 7.6, and 7.7. The Reactor Trip and Engineered Safety Features Actuation System protection (P) interlocks are given on Tables 7.2-2 and 7.3-3. The safety analyses demonstrate that even under conservative critical conditions for either postulated or hypothetical accidents, the protective systems ensures that the Nuclear Steam Supply System will be put into and maintained in a safe state following an ANS Condition II, III, or IV accident commensurate with applicable Technical Specifications and pertinent ANS Criteria. Therefore, the protective systems have been designed to meet IEEE Standard 279-1971 and are entirely redundant and separate, including all permissives and blocks. All blocks of a protective function are automatically cleared whenever the protective function would be required to function in accordance with General Design Criteria 20, 21, and 22 and paragraphs 4.11, 4.12 and 4.13 of IEEE Standard 279-1971. Control interlocks (C) are identified on Table 7.7-1. Because control interlocks are not safety-related, they have not been specifically designed to meet the requirements of IEEE Protection System Standards.

7.1.2.1.6 Bypasses

Bypasses of protective functions are designed to meet the requirements of IEEE Standard 279-1971, paragraphs 4.11, 4.12, 4.13, and 4.14. A discussion of bypasses provided is given in Sections 7.2 and 7.3.

7.1.2.1.7 Equipment Protection

The criteria for equipment protection are given in Chapter 3. Equipment related to safe operation of the plant is designed, constructed and installed to protect it from damage. This is accomplished by working to accepted standards and criteria aimed at providing reliable instrumentation which is available under varying conditions. As an example, certain equipment is seismically qualified in accordance with IEEE Standard 344-1971. During construction, independence and separation is achieved, as required by IEEE Standard 279-1971 and IEEE Standard 384-1974, either by barriers, physical separation or demonstration by test. This serves to protect against complete destruction of a system by fires, missiles or other natural hazards.

7.1.2.1.8 Diversity

Functional diversity has been designed into the system. Functional diversity is discussed in Reference 3. The extent of diverse system variables has been evaluated for a wide variety of postulated accidents. Generally, 2 or more diverse protection functions would automatically occur to mitigate the consequences of an accident.

For example, there are automatic reactor trips based upon neutron flux measurements, reactor coolant loop temperature and flow measurements, steam generation level measurements, pressurizer pressure and level measurements, feedwater flow measurements, and reactor coolant pump underfrequency and undervoltage measurements, as well as manually, and by initiation of a safety injection signal or turbine trip.

Regarding the Engineered Safety Features Actuation System for a loss of coolant accident, a safety injection signal can be obtained manually or by automatic initiation from any one of the following diverse parameter measurements:

1. Low pressurizer pressure.
2. High Reactor Building pressure (Hi-1).

For a steam break accident, safety injection signal actuation is provided by:

1. Low steam line pressure.
2. High steam line differential pressure.
3. For a steam break inside Reactor Building, high Reactor Building pressure (Hi-1) provides an additional parameter for generation of the signal.

All of the above sets of signals are redundant and physically separated and meet the requirements of IEEE Standard 279-1971.

7.1.2.1.9 Bistable Trip Setpoints

Westinghouse specifies 3 setpoints applicable to reactor trip and engineered safety features actuation:

1. Safety limit setpoint.
2. Limiting setpoint.
3. Nominal setpoint.

The safety limit is the value assumed in the accident analysis and is the least conservative value.

The limiting setpoint is the Technical Specification value and is obtained by subtracting a safety margin from the safety limit. The safety margin accounts for instrument error, process uncertainties such as flow stratification and transport factor effects, etc.

The nominal setpoint is the value set into the equipment and is obtained by subtracting allowances for instrument drift and calibration uncertainty from the limiting setpoint. The nominal setpoint allows for the normal expected instrument setpoint drifts such that the Technical Specification limits will not be exceeded under normal operation.

The setpoints that require trip action are given in the Technical Specifications. A further discussion on setpoints is found in Section 7.2.2.2.1.

The trip setpoint is determined by factors other than the most accurate portion of the instrument's range. The safety limit setpoint is determined only by the accident analysis. As described above, allowance is then made for process uncertainties, instrument error, instrument drift, and calibration uncertainty to obtain the nominal setpoint value which is actually set into the equipment. The only requirement on the instrument's accuracy value is that over the instrument span, the error must always be less than or equal to the error value allowed in the accident analysis. The instrument does not need to be the most accurate at the setpoint value as long as it meets the minimum accuracy requirement. The accident analysis accounts for the expected errors at the actual setpoint.

Range selection for the instrumentation covers the expected range of the process variable being monitored consistent with its application. The design of the Reactor Protection and Engineered Safety Features Systems is such that the bistable trip setpoints do not require process transmitters to operate within 5% of the high and low end of their calibrated span or range. Functional requirements established for every channel in the Reactor Protection and Engineered Safety Features Systems stipulate the maximum allowable errors on accuracy, linearity, and reproducibility. The protection channels have the capability for, and are tested to ascertain that the characteristics throughout the entire span in all aspects are acceptable and meet functional

requirement specifications. As a result, no protection channel actuates within 5% of the limits of its specified span (activation setpoints are located between 5 – 95% of span).

In this regard, it should be noted that the specific functional requirements for response time, setpoint, and operating span was finalized based on the results and evaluation of safety studies carried out using data pertinent to the plant. Emphasis is placed on establishing adequate performance requirements under both normal and faulted conditions. This includes consideration of process transmitters margins such that even under a highly improbable situation of full power operation at the limits of the operating map (as defined by the high and low pressure reactor trip, ΔT overpower and overtemperature trip lines (departure from nucleate boiling protection) and the steam generator safety valve pressure setpoint) that adequate instrument response is available to ensure plant safety.

7.1.2.1.10 Engineered Safety Features Motor Specifications

Engineered safety features motor specifications are described in Section 8.3.1.1.4.

7.1.2.2 Independence of Redundant Safety-Related Systems

The safety related systems in Section 7.1.1.1 are designed to meet the independence and separation requirements of Criterion 22 of the 1971 General Design Criteria and paragraph 4.6 of IEEE Standard 279-1971.

The electrical power supply, instrumentation, and control conductors for redundant circuits of a nuclear plant have physical separation to preserve the redundancy and to ensure that no single credible event will prevent operation of the associated function due to electrical conductor damage. Critical circuits and functions include power, control and analog instrumentation associated with the operation of the Reactor Trip System or Engineered Safety Features Actuation System. Credible events shall include, but not be limited to, the effects of short circuits, pipe rupture, missiles, fire, etc., and are considered in the basic plant design.

7.1.2.2.1 General

Specifications for field wiring of redundant circuitry are discussed in Section 8.3.1.4.

The physical separation criteria for redundant safety related system sensors, sensing lines, wireways, cables, and components on control boards/racks within Westinghouse scope meet recommendations contained in Regulatory Guide 1.75 and Westinghouse letter NS-CE-604 of March 31, 1975 from C. Eicheldinger to the Secretary of the Commission.

7.1.2.2.2 Specific Systems

Independence is maintained throughout the system, extending from the sensor through to the devices actuating the protective function. Physical separation is used to achieve separation of redundant transmitters. Separation of wiring is achieved using separate wireways, cable trays, conduit runs and Reactor Building penetrations for each redundant protection channel set.

Redundant analog equipment is separated by locating modules in different protection rack sets. Each redundant channel set is energized from a separate a-c power feed.

There are 4 separate process analog sets. Separation of redundant analog channels begins at the process sensors and is maintained in the field wiring, Reactor Building penetrations, and analog protection cabinets to the redundant trains in the logic racks. Redundant analog channels are separated by locating modules in different cabinets.

Since all equipment within any cabinet is associated with a single protection set, there is no requirement for separation of wiring and components within the cabinet.

In the Nuclear Instrumentation System, Process Systems, and Solid-State Protection System input cabinets where redundant channel instrumentation are physically adjacent, there are no wireways, or cable penetrations which would permit, for example, a fire resulting from electrical failure in one channel to propagate into redundant channels in the logic racks. Redundant analog channels are separated by locating modules in different cabinets. Since all equipment within any cabinet is associated with a single protection set, there is no requirement for separation of wiring and components within the cabinet. Nevertheless, concerns relative to wiring of isolation devices within protection cabinets prompted Westinghouse programs aimed at alleviating them. A discussion is given in Section 7.2.2.2.3.7.

Two (2) reactor trip breakers are actuated by 2 separate logic matrices which interrupt power to the control rod drive mechanisms. The breaker main contacts are connected in series with the power supply so that opening either breaker interrupts power to all full length control rod drive mechanisms, permitting the rods to free fall into the core.

1. Reactor Trip System

   a. Separate routing shall be maintained for the 4 basic Reactor Trip System channel sets analog sensing signals, bistable output signals and power supplies for such systems. The separation of these 4 channel sets shall be maintained from sensors to instrument cabinets to logic system input cabinets.

   b. Separate routing of the redundant reactor trip signals from the redundant logic system cabinets shall be maintained, and in addition, they shall be separated by spatial separation or by provision of barriers or by separate cable trays or wireways from the 4 analog channel sets.

2. Engineered Safety Features Actuation System

   a. Separate routing shall be maintained for the 4 basic sets of Engineered Safety Features Actuation System analog sensing signals, bistable output signals and power supplies for such systems. The separation of these 4 channel sets shall be maintained from sensors to instrument cabinets to logic system input cabinets.

   b. Separate routing of the engineered safety features actuation signals from the redundant logic system cabinets shall be maintained. In addition, they shall be separated by spatial separation or by provisions of barriers or by separate cable trays or wireways from the 4 analog channel sets.

c. Separate routing of control and power circuits associated with the operation of engineered safety features equipment is required to retain redundancies provided in the system design and power supplies.

3. Instrumentation and Control Power Supply System

The separation criteria presented also apply to the power supplies for the load centers and buses distributing power to redundant components and to the control of these power supplies.

4. Control Board

A majority of the control board switches and associated lights are furnished in modules. These modules provide a high degree of physical protection for the switches, associated lights, and wiring. Control board switches and associated lights which are not located in modules and other devices within the control boards are located such that a minimum of 6 inches air separation is maintained between devices and wiring associated with different trains. Where this 6 inches of air space in all directions cannot be maintained, barriers are provided or an analysis of the installation is performed. This analysis is based on tests performed to determine the flame retardant characteristics of the wiring material, equipment, and other materials internal to the panel.

Where necessary to maintain separation, cabling from devices on the front of the control board to the horizontal metal wireways (gutters) within the control board is routed in flexible conduit or metallic braid. The redundant cables are then routed through separate gutters to the termination cabinets located beneath the control room via vertical metal wireways (risers). The termination cabinets are arranged to maintain the separated routing of the control board cables through the termination cabinets to the field wiring tray systems. In addition, separate metal wireways and termination cabinets are used for the various low-level analog channels and for the various control-level channels.

Relay subpanels located in or associated with the control boards contain Class 1E devices such as fuses, relays, and relay type isolation devices. Mutually redundant safety related devices are located on separate subpanels. Separate metal wireways provide separation for Class 1E wiring and non-Class 1E wiring departing the subpanels. Where relay panels contain relay type isolation devices, the separation of the wiring from the input and output terminals to the separate wireways may be less than 6 inches provided it is not less than the 1 inch distance between input and output terminals of the isolation device.

Flame resistant cable is used for internal module wiring and multi-conductor cables within the control board. Flame resistant single conductor cable with 30 MIL insulation is used for intraboard jumpers. Sizing of copper conductors is based upon conservative current carrying capacities set forth by the National Electric Code.

Inherent flame-retardant characteristics and properties were an important consideration in the selection, design, and fabrication of components and materials used in the control board; therefore, a postulated fire cannot propagate.

In order to maintain separation between wiring associated with different trains, mutually redundant safety train wiring is not terminated on a single device. Backup manual actuation switches link the separate trains by mechanical means to provide greater reliability of operator action for the manual reactor trip function and manual engineered safety features actuations. The linked switches are themselves redundant so that operation of either set of linked switches will actuate safety trains “A” and “B” simultaneously. This is shown in Figure 7.2-3. The design of the manual reactor trip function and manual engineered safety features actuations comply with Regulatory Guide 1.62 (see also Figure 7.3.2.2.7).

Manual actuation from the control room of each Reactor Protection or Engineered Safety Features System is provided by 2 functionally redundant, physically separate and independent switches meeting the requirements of IEEE-279-1971. In order to prevent inadvertent manual actuation of reactor building spray, a pair of switches must be operated simultaneously. A second pair of switches is provided for manual actuation so a single failure will not prevent manual actuation of the reactor building spray. Redundant switches are provided for the manual control of steam line isolation.

Control switches are provided on the control board for all components that are actuated by manual engineered safety features function initiation switches.

Manual controls for the reactor protection and engineered safety features are listed in Tables 7.2-1, 7.3-1, and 7.3-2.

Transmitted signals (flow, pressure, temperature, etc.) which cause actuation of the engineered safety features are either indicated or recorded. Redundant channels of post accident monitoring indicators are separated by barriers and/or air separation.

7.1.2.2.3 Fire Protection

Electrical equipment is supplied with noncombustible or fire retardant material. Materials which may ignite or explode from an electrical spark, flame, or from heating are not used. Current carrying capacities of instrument cabinet wiring preclude electrical fires resulting from excessive overcurrent (I^2R) losses. For example, wiring used for instrument cabinet construction has teflon or tefzel insulation and is adequately sized based on current carrying capacities set forth by the National Electric Code. In addition, fire retardant (intumescent) paint is used to prevent fire or heat propagation from rack to rack. The application of paint to interiors and/or exteriors of nuclear safety related electrical equipment located outside the Reactor Building containment is a non-nuclear safety related activity. Braided sheathed material is noncombustible.

For early warning and protection against propagation of electrical fires, smoke or other high sensitivity detectors are provided for fire detection, alarm and extinguishing systems in remote wireways or other unattended areas where large concentrations of cables are installed (see Section 8.3.3.2).

Details of the fire protection system are provided in Section 9.5.1.

7.1.2.3 Physical Identification of Safety-Related Equipment

There are 4 separate protection sets identifiable with process equipment associated with the Reactor Trip and Engineered Safety Features Actuation Systems. A protection set may be comprised of more than a single process equipment cabinet. The color coding of each process equipment rack nameplate coincides with the color code established for the protection set of which it is a part. Redundant channels are separated by locating them in different equipment cabinets. Separation of redundant channels begins at the process sensors and is maintained in the field wiring, Reactor Building penetrations and equipment cabinets to the redundant trains in the logic racks. The Solid-State Protection System input cabinets are divided into 4 isolated compartments, each service 1 of the 4 redundant input channels. Horizontal 1/8 inch thick solid steel barriers, coated with fire retardant paint, separate the compartments. Four (4), 1/8 inch thick solid steel, wireways coated with fire retardant paint enter the input cabinets vertically, even in its own quadrant. The wireway for a particular compartment is open only into that compartment so that flame could not propagate to affect other channels. At the logic racks the protection set color coding for redundant channels is clearly maintained until the channel loses its identity in the redundant logic trains. The color coded nameplates described below provide identification of equipment associated with protective functions and their channel set association:

PROTECTION SET	COLOR CODING
I	RED with BLACK lettering
II	ORANGE with BLACK lettering
III	BLUE with BLACK lettering
IV	YELLOW with BLACK lettering

Noncabinet mounted protective equipment and components are provided with an identification tag or nameplate. Small electrical components such as relays have nameplates on the enclosure which houses them. There are also identification nameplates on the input panels of the Solid-State Logic Protection System. The identification of cables, cable trays, conduits and electrical equipment is discussed in Section 8.3.1.5.

7.1.2.4 Conformance to Criteria

A listing of applicable criteria and the sections where conformance is discussed is given in Tables 7.1-1 and 7.1-2.

7.1.2.5 Conformance to Regulatory Guide 1.22

Periodic testing of the Reactor Trip and Engineered Safety Features Actuation Systems, as described in Sections 7.2.2 and 7.3.2, complies with Regulatory Guide 1.22, "Periodic Testing of Protection System Actuation Functions."

Where the ability of a system to respond to a bona fide accident signal is intentionally bypassed for the purpose of performing a test during reactor operation, each bypass condition is automatically indicated to the reactor operator in the Main Control Room by a separate annunciator for the train in test. Test circuitry does not allow 2 trains to be tested at the same time so that extension of the bypass condition to the redundant system is prevented.

The actuation logic for the Reactor Trip and Engineered Safety Features Actuation System is tested as described in Sections 7.2 and 7.3. As recommended by Regulatory Guide 1.22, where actuated equipment is not tested during reactor operation it has been determined that:

1. There is no practicable system design that would permit operation of the equipment without adversely affecting the safety or operability of the plant;
2. The probability that the protection system will fail to initiate the operation of the equipment is, and can be maintained, acceptably low without testing the equipment during reactor operation; and
3. The equipment can routinely be tested when the reactor is shutdown.

The list of equipment that cannot be tested at full power so as not to damage equipment or upset plant operation is:

1. Manual actuation switches.
2. Reactor coolant pump breakers.
3. Turbine.
4. Main steam line isolation valves (complete closure).
5. Main feedwater isolation valves (close).
6. Feedwater control valves and feedwater bypass control valves (close).
7. Main feedwater pump trip solenoids.
8. Reactor coolant pump component cooling water isolation valves (close).
9. Reactor coolant pump seal water return valves (close).
10. Instrument air supply to reactor building isolation valves (close).
11. Engineered safety features loading sequencer input buffer and output relays.

The justifications for not testing the above items at full power are discussed below:

1. Manual Actuation Switches

   These would cause initiation of their protection system function at power causing plant upset and/or reactor trip. The analog signals, from which the automatic safety injection signal is derived, is tested at power in the same manner as the other analog signals and as described in Section 7.2.2.2.3. The processing of these signals in the Solid-State Protection System wherein their channel orientation converts to a logic train orientation is tested at power by the built-in semiautomatic test provisions of the Solid-State Protection System. The reactor trip breakers are tested at power as discussed in Section 7.2.2.2.3.

2. Reactor Coolant Pump Breakers

   No credit is taken in the accident analyses for a reactor coolant pump breaker opening causing a reactor trip. Since testing them at power would cause plant upset, the reactor coolant pump breakers do not need to be tested at power.

3. Turbine

   Testing of main turbine trip signals during normal operation would result in a reactor trip. Although the EHC control system turbine trip logic is not qualified as a safety related system, it is a highly reliable system that consists of redundant (2-of-3 per train) trip actuation logic (as functionally shown on Figure 7.2-1, Sheet 15). The turbine trip logic allows for an “Online ETD Test” method which temporarily cycles applicable components, for the Electronic Trip Device (ETD) undergoing test, into its tripped state; the corresponding exercised components include Primary Trip Relay (PTR) logic output, one ETD solenoid, one ETD dump valve, and its dump valve position indication. This test method systematically verifies the functionality of each 1-of-3 ETD solenoid/dump valve in each of the two ETD trains, without actually tripping the Turbine. (Note that 2-of-3 Emergency Trip Relay (ETR) logic outputs (also shown on Figure 7.2-1, Sheet 15) are functionally verified only during offline testing, given its application as backup protection.)

   The interface between the Engineered Safety Features (ESF) System and the EHC control system is also shown functionally on Figure 7.2-1, Sheet 15. Trip signals received from these ESF System interfaces (or from other Turbine protection trip signals) will be processed by EHC control system trip actuation logic circuitry, which include PTRs (or the backup ETRs, where applicable). Receipt of 2-of-3 actuations via either PTRs or ETRs (in either train) will result in de-energized ETD solenoids and tripped-open ETD dump valves. The outcome of either train’s 2-of-3 dump valve actuation is ETS hydraulic fluid loss (dump), closure of Turbine Stop and Control Valves, and a Turbine Trip condition. This 2-of-3 Turbine Trip actuation can also result from a complete loss of both non-safety related power supply feeders to the EHC control system cabinet (including the loss of a dedicated EHC battery-backed uninterruptible power supply, in the alternate feeder circuit).

Given the identified problem (turbine trip initiation) incurred with periodic testing during power operation of the entire 2-of-3 turbine trip actuation logic, the proposed resolution (using the "Online ETD Test" method) meets the intent of Regulatory Guide 1.22, Section D.4 guidelines (see Appendix 3A). The "Online ETD Test" method provides for periodic testing of individual components within a practical system design, without adversely affecting the plant safety or operability. Use of the "Online ETD Test" method is further justified since: the probability of protection system failure to trip the Turbine is acceptably low, given trip system redundancy and power fail safe design features; and the complete turbine trip logic is routinely tested during refueling outages.

4. Main Steam Line Isolation Valves (Complete Closure)

   Main steam line isolation valves are routinely tested during refueling outages. Testing of the main steam line isolation valves to full closure at power is not practical. As the plant power is increased, the core average temperature is programmed to increase. If the valves are fully closed under these elevated temperature conditions, the steam pressure transient would unnecessarily operate the steam generator relief valves and possibly the steam generator safety valves. The steam pressure transient produced would cause shrinkage in the steam generator level, which would cause the reactor to trip on low-low steam generator water level. Testing during operation will decrease the operating life of the valve.

   Based on the above identified problems incurred with periodic testing of the main steam line isolation valves at power and since, 1) no practical system design will permit operation of the valves without adversely affecting the safety or operability of the plant, 2) the probability that the protection system will fail to initiate the actuated equipment is acceptably low due to test up to final actuation, 3) these valves will be routinely tested during refueling outages, and 4) these valves are tested during plant operation by partial closure (90 to 95 percent open) by actuating a test solenoid valve which does not inhibit an engineered safety feature automatic closure, the proposed resolution meets the guidelines of Section D.4 of Regulatory Guide 1.22.

5. Main Feedwater Isolation Valves (Close)

   The main feedwater isolation valves are routinely tested during refueling outages. Periodic testing of these feedwater isolation valves, closing them completely, or partially, at power would induce steam generator water level transients and oscillations which would trip the reactor. These transient conditions would be caused by perturbing the feedwater flow and pressure conditions necessary for proper operation of the variable-speed feedwater pump control system and the steam generator water level control system. An operation which induces perturbations in the main feedwater flow, whether deliberate or otherwise, may lead to a reactor trip and should be avoided.

Based on these identified problems incurred with periodic testing of the backup feedwater valves at power and since, 1) no practical system design will permit operation of these valves without adversely affecting the safety or operability of the plant, 2) the probability that the protection system will fail to initiate the activated equipment is acceptably low due to testing up to final actuation, and 3) these valves will be routinely tested during refueling outages, the proposed resolution meets the guidelines of Section D.4 of Regulatory Guide 1.22.

6. Feedwater Control Valves (Close)

   These valves are routinely tested during refueling outages. To close them at power would adversely affect the operability of the plant. The verification of operability of feedwater control valves at power is assured by confirmation of proper operation of the Steam Generator Water Level System. The actual actuation function of the solenoids, which provides the closing function is periodically tested at power as discussed in Section 7.3.2.2.5. The operability of the slave relay which actuates the solenoid, which is the actuating device, is verified during this test. Although the actual closing of these control valves is blocked when the slave relay is tested, all functions are tested to assure that no electrical malfunctions have occurred which could defeat the protective function. It is noted that the solenoids work on the de-energize-to-actuate principle, so that the feedwater control valves will fail close upon either the loss of electrical power to the solenoids or loss of air pressure.

   Based on the above, the testing of the isolating function of feedwater control valves meets the guidelines of Section D.4 of Regulatory Guide 1.22.

7. Main Feedwater Pump Trip Solenoids

   The containment integrity analysis assumes the feedwater isolation valves and/or feedwater control valves isolate feedwater flow and therefore the feedwater pump trip solenoids require no periodic testing.

   However, these trip solenoids are routinely tested during refueling outages. To close them at full power would adversely affect the operability of the plant. The actual actuation function of the solenoids, which provides the closing function is periodically tested at power as discussed in Section 7.3.2.2.5. The operability of the slave relay which actuates the solenoid, which is the actuating device, is verified during this test. Although the actual closing of these trip solenoids is blocked when the slave relay is tested, all functions are tested to assure that no electrical malfunctions have occurred which could defeat the function of the solenoids.

8. Reactor Coolant Pump Component Cooling Water Isolation

   Valves (Close)

Component cooling water supply and return containment isolation valves are routinely tested during refueling outages. Testing of these valves while the reactor coolant pumps are operating introduces an unnecessary risk of costly damage to all the reactor coolant pumps. Loss of component cooling water to these pumps is of economic consideration only, as the reactor coolant pumps are not required to perform any safety-related function.

The reactor coolant pumps will not seize due to complete loss of component cooling. Information from the pump manufacturer indicates that the bearing babbitt would eventually break down but not so rapidly as to overcome the inertia of the flywheel. If the pumps are not stopped within 3 to 10 minutes after component cooling water is isolated, pump damage could be incurred.

Also, since the component cooling water flowrates and temperatures are about equal during both plant power operation and plant refueling, periodic tests of these valves during a refueling outage would duplicate accident conditions. Additionally, possibility of failure of containment isolation is remote because an additional failure of the low pressure fluid system in addition to failure of both isolation valves would have to occur to open a path through the containment.

Based on the above described potential reactor coolant pump damage incurred with periodic testing of the component cooling water containment isolation valves at power, the duplication of at-power operating conditions during refueling outages, and since, 1) no practical system design will permit operation of these valves without adversely affecting the safety or operability of the plant, 2) the probability that the protection system will fail to initiate the activated equipment is acceptably low due to testing up to final actuation, and 3) these valves will be routinely tested during refueling outages when the reactor coolant pumps are not operating, the proposed resolution meets the guidelines of Section D.4 of Regulatory Guide 1.22.

9. Reactor Coolant Pump Seal Water Return Valves (Close)

   Seal return line isolation valves are routinely tested during refueling outages. Closure of these valves during operation would cause the safety valve to lift, with the possibility of valve chatter. Valve chatter would damage this relief valve. Testing of these valves at power would cause equipment damage. Therefore, these valves will be tested during scheduled refueling outages. As above, additional containment penetrations and isolation valves introduce additional unnecessary potential pathways for radioactive release following a postulated accident. Thus, the guidelines of Section D.4 of Regulatory Guide 1.22 are met.

10. Instrument Air Supply to Reactor Building Isolation Valves (Close)

    The Reactor Building instrument air isolation valves are routinely tested during refueling outages. Closing the valves completely at power would result in loss of instrument air supply inside containment, causing an upset to normal operation which could cause a reactor trip.

    Based on the above identified problem incurred with periodic testing of the Reactor Building instrument air isolation valves at power and since, 1) no practical system design will permit operation of the valves without adversely affecting the safety or operability of the plant, 2) the probability that the protection system will fail to initiate the actuated equipment is acceptably low due to test up to final actuation, and 3) these valves will be routinely tested during refueling outages, the proposed resolution meets the guidelines of Section D.4 of Regulatory Guide 1.22.

11. Engineered Safety Feature Loading Sequencer Input Buffer and Output Relays

    The Engineered Safety Feature Loading Sequencer output and input buffer relays are routinely tested during refueling outages. Testing the output relays will actuate plant equipment and requires extensive system and breaker alignments to perform the entire output relay test. Due to the intensity required for testing, plant operability and safety could be jeopardized. The Engineered Safety Feature Loading Sequencer is not designed to test the output relays by continuity of the electrical circuitry associated with the relays as a check in lieu of actual operation; therefore, the only test is by actuation. A reliability study showed that the probability of the output relays to fail when required to initiate the operation of equipment is, and can be, maintained acceptably low without periodic testing of the actuated equipment during reactor operation. The 18 month test frequency is acceptable. The Engineered Safety Feature Loading Sequencer is not designed to test the input buffer relays on line without actually initiating Safety Injection or Blackout sequence. The total testing by actuation of undervoltage relays and Safety Injection signals to final equipment actuation is performed every 18 months while plant is shutdown. The inputs and logic up through the output relay drivers are tested with the reactor operational is a continuous automatic test mode.

    Based on the above, the testing of the ESFLS meets the guidelines of Section D.4 of Regulatory Guide 1.22.

7.1.2.6 Conformance to Regulatory Guide 1.47

The principles described in Regulatory Guide 1.47 have been used to design the bypassed and inoperable status indication for the Engineered Safety Features Systems. System level indication is provided on the Control Room bypass and inoperable status indication CRT to display the operable status of each of the redundant portions of the Emergency Core Cooling System, the Reactor Building Cooling System, and the Reactor Building Spray System, and supporting systems: Engineered Safety Features Power System, Chilled Water System, Service Water System and Component Cooling Water System.

Inoperable indication occurs automatically when equipment vital to the operation of the system has been removed from service and a contact is available from the equipment to signify this condition (e.g., control switch in the "pull to lock" position, switchgear circuit breaker withdrawn from the operating position, safety system bypassed for logic testing). Inoperable indication also occurs when the operator, by administrative procedures, removes essential equipment from service and at the same time manually inputs the status into the Technical Support Center Computer. When automatic equipment inoperable indication occurs, it will be accompanied by an audible alarm.

The following criteria are utilized in providing contacts for automatic indication of inoperable status.

1. The bypass or inoperable condition effects one of the Emergency Core Cooling Systems, Reactor Building Cooling Systems, or Reactor Building Spray Systems, and/or the Auxiliary Support Systems for these systems are required to perform automatically a function important to the safety of the public.
2. The bypass or inoperable condition can reasonably be expected to occur more frequently than once per year.
3. The bypass or inoperable condition is expected to occur when the effected safety system is required to be operable.

7.1.2.7 Conformance to Regulatory Guide 1.53 and IEEE Standard 379-1972

The principles described in IEEE Standard 379-1972 were used in the design of the Westinghouse protection system. The system complies with the intent of this standard and the additional guidance of Regulatory Guide 1.53, although the formal analyses have not been documented exactly as outlined. Westinghouse has gone beyond the required analyses and has performed a fault tree analysis, Reference 3.

The referenced topical report provides details of the analyses of the protection systems previously made to show conformance with the single failure criterion set forth in paragraph 4.2 of IEEE Standard 279-1971. The interpretation of the single failure criterion provided by IEEE Standard 379-1972 does not indicate substantial differences with the Westinghouse interpretation of the criterion except in the methods used to confirm design reliability. Established design criteria in conjunction with sound engineering practices form the bases for the Westinghouse protection

systems. The Reactor Trip and Engineered Safety Features Actuation Systems are each redundant safety systems. The required periodic testing of these systems will disclose any failures or loss of redundancy which could have occurred in the interval between tests, thus ensuring the availability of these systems.

Chapters 6.0, 8.0, 9.0, and 10.0 discuss the single failure criteria for safety systems and auxiliary support systems within the balance of plant scope. Section 7.3.2.2 outlines the degree of conformance for the Engineered Safety Features loading sequence control panels. The degree of conformance for the undervoltage/underfrequency relay panels is addressed in Section 8.3.1.1.1.

Table 7.1-3 outlines, in detail, how the specific principles described by Regulatory Guide 1.53 and IEEE 379-1972, have been used in the design of balance of plant safety related instrumentation and control systems.

7.1.2.8 Conformance to Regulatory Guide 1.63

Regulatory Guide 1.63 is discussed in Appendix 3A.

7.1.2.9 Conformance to IEEE Standard 317-1972

Electrical penetrations are designed and fabricated in accordance with the requirements of IEEE Standard 317-1972.

7.1.2.10 Conformance to IEEE Standard 336-1971

Conformance with the scope of IEEE Standard 336-1971 for installation, inspection, and testing of instrumentation and electrical equipment during construction and startup is covered in Chapters 14 and 17.

7.1.2.11 Conformance to IEEE Standard 338-1971

The periodic testing of the Reactor Trip System and Engineered Safety Features Actuation System conforms to the requirements of IEEE Standard 338-1971 with the following comments:

1. The surveillance requirements of the Technical Specifications for the protection system ensure that the system functional operability is maintained comparable to the original design standards. Periodic tests at frequent intervals demonstrate this capability for the system, excluding sensors.

   Overall protection systems response times shall be demonstrated by test or verification. Sensors within Westinghouse scope will be demonstrated adequate for this design by vendor testing, in-site tests in operating plants with appropriately similar design, or by suitable type testing. The Nuclear Instrumentation System detectors are excluded since they exhibit response time characteristics such that delays attributable to them are negligible in the overall channel response time required for safety.

A periodic verification test program for sensors within Westinghouse scope, for determining any deterioration of installed sensor's response time, is currently being performed by on-site Surveillance Test Procedures (STP). Should sensor fail criteria outlined in the STP, the sensor is either replaced or repaired.

Each test shall include at least 1 logic train such that both logic trains are tested at least 1 per 36 months and 1 channel per function such that all channels are tested at least once every (N times 18 months), where N is the total number of redundant channels in a specific protective function.

The measurement of response time at the specified time intervals provides assurance that the protective and engineered safety features action function associated with each channel is completed within the time limit assumed in the accident analyses.

As an alternative to periodic measurement of instrument channel response time, Amendment 146 permits a verification of the channel response time by summation of allocated sensor, signal processing and actuation logic response times with actual response time tests performed on the remainder of the channel. The methodology is provided in References 4 and 5 and is only applicable to such equipment as was reviewed and approved by the NRC.

The response time may be verified for components that replace the components that were previously evaluated in References 4, 5, or 6 provided that the components have been evaluated in accordance with the NRC approved methodology as discussed in Attachment 1 to TSTF-569, "Methodology to Eliminate Pressure Sensor and Protection Channel (for Westinghouse Plants only) Response Time Testing," which was adopted by Amendment 221 (Reference 7 and 8).

The allocated times must be verified as bounding prior to placing a component in service and re-verified following any work that may adversely affect the component response time.

2. Surveillance test failures are trended and evaluated through various programs to ensure equipment reliability specified in the IEEE Standard 338-1971.
3. The periodic time interval discussed in paragraph 4.3 of IEEE Standard 338-1971, and specified in the Technical Specifications, is conservatively selected to assure that equipment associated with protection functions has not drifted beyond its minimum performance requirements. If any protection channel appears to be marginal or requires more frequent adjustments due to plant condition changes, the time interval will be decreased to accommodate the situation until the marginal performance is resolved.
4. The test interval discussed in paragraph 5.2 of IEEE Standard 338-1971, is developed primarily on past operating experience and modified if necessary to assure that system and subsystem protection is reliably provided. Analytic methods for determining reliability are not used to determine test interval.

Based on the scope definition given in IEEE Standard 338-1971, no other systems described in Chapter 7 are required to comply with this standard.

– IS DEFINED AS MEANING THE REFERENCED CRITERIA IS NOT APPLICABLE TO THE INSTRUMENT AND CONTROL SYSTEM AND COMPONENTS

Reformatted Per Amendment 00-01

00-01

NOTES TO TABLE 7.1-2

1. See Section 7.7 for a list of control systems typical of those not required for safety.
2. Although credit is not taken for the turbine trip inputs from the pressure sensors and turbine stop valves (as described in Section 7.2.1.1.2, Item 6) the circuits are classified as Associated with Class 1E, are seismically supported, and are separated in accordance with plant design criteria as described in Appendix 3A (RG 1.75) when located in Seismic Category 1 structures. Safety criteria apply only to the input devices and do not include the mechanical portions of the turbine generator.
3. Safety criteria apply only to those portions of the system that are part of containment.
4. Safety criteria apply only to those portions of HVAC systems that are safety related.
5. Safety criteria denoted as applicable for this input include only the main steam isolation valves, steam generator power operated relief valves, and valves that admit steam to the turbine driven emergency feedwater pump.
6. Applicability is limited to a chemical and volume control system function rather than a safety injection system function.
7. Instrumentation and associated wiring applies.
8. Design satisfies Branch Technical Position APCSB 9.5-1, Appendix A, to the extent outlined in the FPER.
9. Complies for those portions (components) of the system that are part of the protection system, i.e., inputs, logic, actuation device inputs, etc.
10. See Section 7.5.1 for discussion of compliance.
11. See Section 7.6.2 for discussion.
12. See Appendix 3A (RG 1.75) and Sections 7.1.2.2.1, 8.3.1.4, and 8.3.1.5 for discussion of compliance.
13. See Section 3.1.2 for discussion of compliance.

NOTES TO TABLE 7.1-2 (Continued)

14. See Section 3.1 for discussion of GDC 25. The analyses which are discussed in Chapter 15.0 are categorized as Condition II, III, and IV occurrences. These analyses show that the acceptance criteria for these categories are satisfied.
15. See Section 3.1 for discussion of GDC 26.
16. See Section 3.1 for discussion of GDC 27.
17. See Section 3.1 for discussion of GDC 28.
18. As noted in Section 7.4, nonaccident conditions are assumed.
19. See Sections 5.5.7, 6.3, and 7.6.5 for discussion of compliance.
20. See Sections 3.1.2, 6.3, and 7.6.5 for discussion of compliance.
21. 21. The general philosophy of IEEE-279 is met by addressing redundancy and independence on a redundant subsystem basis, i.e., A loop/train and B loop/train basis. Testing can be performed on a loop basis consistent with the requirements of Sections 4.9 and 4.10 of IEEE-279.
22. For Westinghouse scope it is noted that:
    a. IEEE-279-1971 is not required as a design basis for systems, equipment, or components to which this note is applicable.
    b. The scope of IEEE-279-1971 is limited to the protection system from sensors to actuation devices inputs.
23. See Section 7.5.1 for discussion of post-accident monitoring.
24. See Section 7.6.2.2 for discussion of residual heat removal system interlocks.
25. Deleted (RNs 99-015 and 99-114)
26. Non-Class 1E components fed from Class 1E power source.
27. See Section 3.11 and Appendix 3A for discussion of compliance.
28. Applicable only to reactor building cooling unit fan motors.
29. See Section 7.1.2.11 for description of details of conformance to IEEE-338-1971.

NOTES TO TABLE 7.1-2 (Continued)

30. See Section 6.3.4.3 for description of safety injection system testing.
31. See Section 3.10 and Appendix 3A (RG 1.100) for discussion of compliance.
32. See Section 7.6.5 for description of leakage detection system.
33. Complies as outlined in Section 7.1.2.7, Table 7.1-3, and Table 7.3-6.
34. See Sections 6.2.5 and 7.3.3 for discussion of hydrogen recombiner.
35. See Section 6.3.2.9 for discussion of safety injection.
36. Boric acid transfer pump power and control circuits are classified as Associated with Class 1E.
37. See Appendix 3A (RG 1.7), Section 6.2.5 and the response to NRC Question 031.56 for discussion of compliance.
38. See Appendix 3A for discussion of compliance.
39. See Appendix 3A (RG 1.11) and Section 6.2.6 for discussion of compliance.
40. Complies, see Section 3.7.4 and Appendix 3A (RG 1.12) for details.
41. Complies, for the protection system actuated devices, except as noted in Section 7.1.2.5.
42. See Appendix 3A (RG 1.45) and Section 5.2.7 for discussion of compliance.
43. Complies, as applicable to specific system components. Details are discussed in the response to NRC Question 031.49.
44. Complies, see Appendix 3A (RG 1.95).
45. See Appendix 3A (RG 1.97) and Sections 6.2.5 and 7.5 for discussion of compliance.
46. Reasons for non-applicability are outlined in Appendix 3A.
47. See Section 7.6.4 for discussion.

NOTES TO TABLE 7.1-2 (Continued)

48. See Section 7.2.2.2.3.10 for discussion. Also, see Chapter 16.0 (Technical Specifications), Table 4.3-1.
49. See Technical Specifications, Table 4.3-1.
50. See Technical Specifications, Section 3/4.4.1.
51. The results of analysis of a single rod cluster control assembly at full power are described in Section 15.3.
52. Accident analysis, as described in Sections 15.2.9 and 15.3.4, does not take credit for reactor coolant pump trip. Offsite electric system stability is described in Section 8.2.2.2.
53. BTP EICSB 18 applies to valves XVG8808A,B,C, XVG8884, XVG8885, XVG8886, XVG8888A,B, XVG8889, XVG8106, and XVG8133A,B in the Safety Injection System. See Chapter 16.0 (Technical Specifications), Section 3/4.5.1 and the responses to NRC Questions 040.18, 211.31, 211.32 and 211.37 for additional details.
54. See Section 6.3.2.7.
55. See Section 7.1.2.11 and Chapter 16.0 (Technical Specifications), Section 3/4.3.
56. See Appendix 3A (RG 1.106) for discussion of thermal overloads for electric motor operated valves.
57. See Section 9.1.4.1 (Item 6) and 9.1.4.3.1.2 (Item 5) and Tables 3.2-1, 3.2-2, and 3.2-3.

Table 7.1-3
Conformance With Regulatory Guide 1.53 and IEEE 379-1972, for
Balance of Plant Safety Related Instrumentation Control Systems

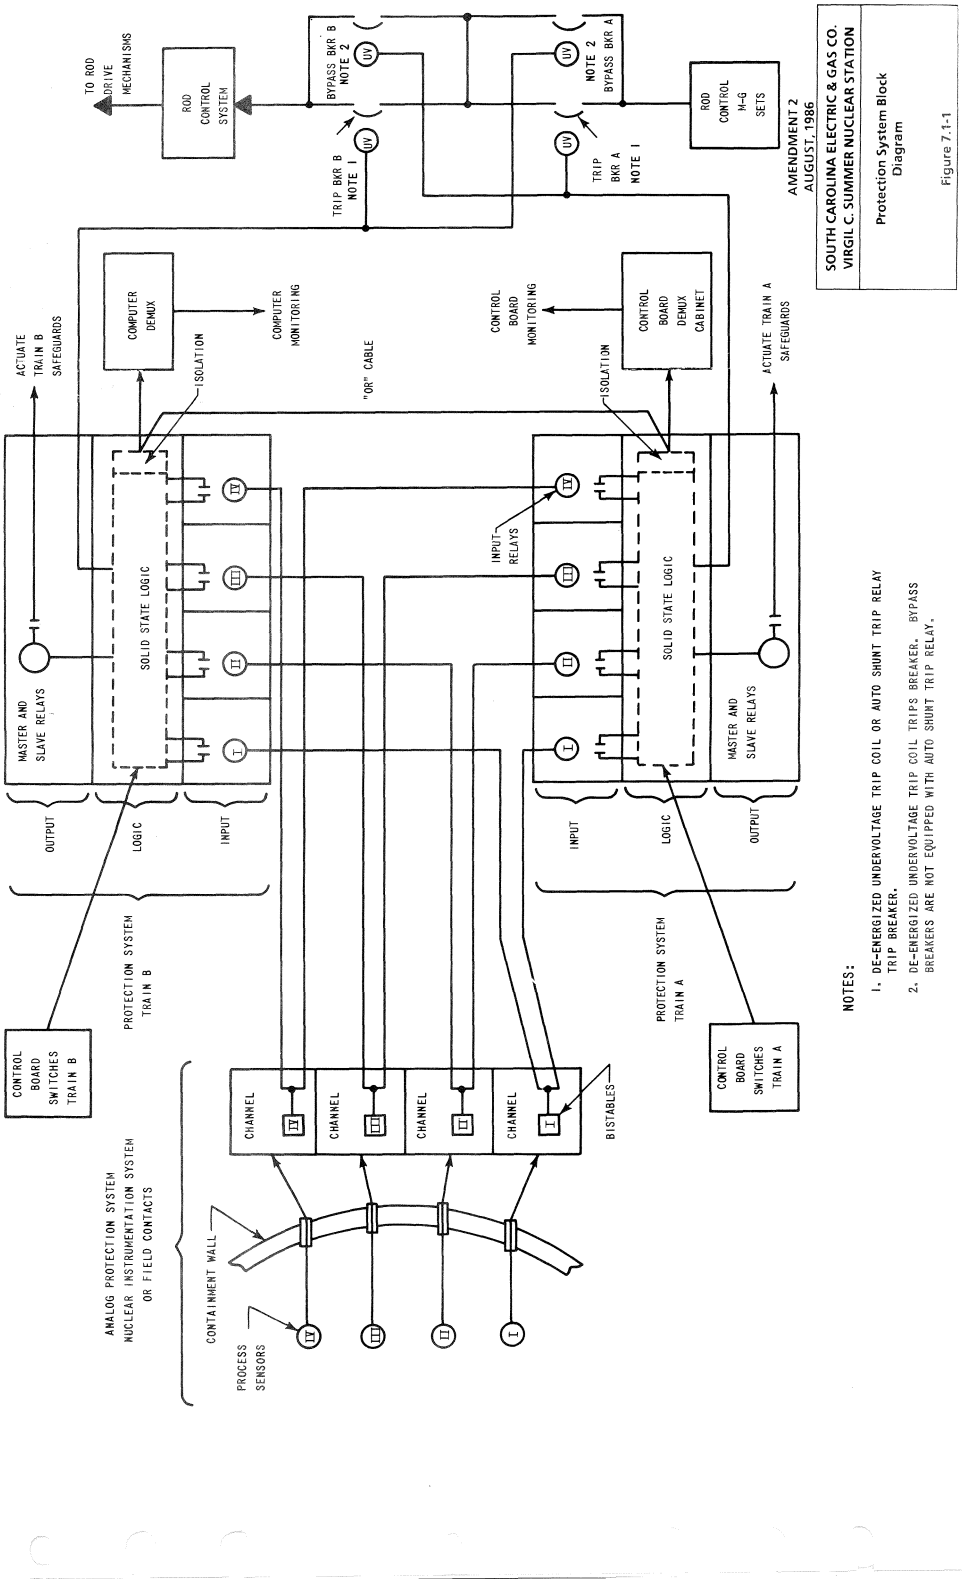
Criterion	Degree of Compliance
REGULATORY GUIDE 1.53	
C.1 IEEE 379-1972	See IEEE 379-1972, comparison, below.
C.2 Continuity Checks	Except as outlined by Sections 7.1.2.5 and 7.3.2.2.5, components are designed to allow operation while being tested during reactor operation.
C.3 Interconnections	Channel separation is maintained and integrity is assured through use of isolating devices where interconnections may occur or suitable barriers are employed.
C.4 Protection System Logic and Actuator System	Actuator circuits are designed to prevent a single failure from causing loss of a protective function.
IEEE 379-1972	
3(1) Redundancy	Redundancy is used and maintained to prevent a single failure in a channel or component from preventing operation of the redundant counterpart.
3(2) Detectability	Control room indication and alarms are provided and are used in conjunction with periodic testing.
3(3) Nondetectability	Not applicable, see Note 1.
3(4) Multiple Faults	Not applicable, see Note 1.
3(5) Completing Protective Functions	Systems are designed to prevent a single failure from resulting in noncompletion of the system protective function.
3(6) DBE and Single Failure	Concurrent occurrence of a design basis event and a single failure was considered in the design. System protective function will not be lost under such circumstances.
3(7) Operational Reliability	Not applicable, but included in the design concept.
5.1 Classification	Not applicable, but included in the design concept.

Table 7.1-3 (continued)
Conformance With Regulatory Guide 1.53 and IEEE 379-1972, for
Balance of Plant Safety Related Instrumentation Control Systems

Criterion	Degree of Compliance
5.2 Undetectable Failures	Not applicable, see Note 1. Also, see Regulatory Guide 1.53, Regulatory Position C.2, above.
5.3 Common Mode Failures	Concept was considered during design. Equipment qualification was used significantly in designing against common mode failures. Sections 3.10 and 3.11 outline qualification in more details.
6.1 General	See Note 1.
6.2 Channels	See Regulatory Guide 1.53, Regulatory Position C.3, above.
6.3 Protection System Logic	See Regulatory Guide 1.53, Regulatory Position C.3, above.
6.4 Actuator Circuit	See Regulatory Guide 1.53, Regulatory Position C.3, above.
Type 2 and 3 Single Failure Analysis	Equipment qualification was used significantly in designing against common mode failures. Sections 3.10 and 3.11 outline qualification in more detail.
6.6 Overall System - Failure Analysis	Concepts addressed were used during system design.

(1) Each applicable FSAR section presents a safety evaluation which addresses the single failure criteria.

Figure 7.1-1
PROTECTION SYSTEM BLOCK DIAGRAM



7.2 REACTOR TRIP SYSTEM

7.2.1 Description

7.2.1.1 System Description

The reactor trip system automatically keeps the reactor operating within a safe region by shutting down the reactor whenever the limits of the region are approached. The safe operating region is defined by several considerations such as mechanical/hydraulic limitations on equipment, and heat transfer phenomena. Therefore, the reactor trip system keeps surveillance on process variables which are directly related to equipment mechanical limitations, such as pressure, pressurizer water level (to prevent water discharge through safety valves, and uncovering heaters) and also on variables which directly affect the heat transfer capability of the reactor (e.g., flow and reactor coolant temperatures). Still other parameters utilized in the reactor trip system are calculated from various process variables. In any event, whenever a direct process or calculated variable reaches a setpoint the reactor will be shutdown in order to protect against either gross damage to fuel cladding or loss of system integrity which could lead to release of radioactive fission products into the containment.

The following systems make up the reactor trip system. Refer to References 1, 2, and 3 for additional background information.

1. Process Instrumentation and Control System.
2. Nuclear Instrumentation System.
3. Solid-State Logic Protection System.
4. Reactor Trip Switchgear.
5. Manual Actuation Circuit.

The reactor trip system consists of sensors which, when connected with analog circuitry consisting of 2 to 4 redundant channels, monitor various plant parameters and digital circuitry, consisting of 2 redundant logic trains, which receive inputs from the analog protection channels to complete the logic necessary to automatically open the reactor trip breakers.

Each of the two trains, A and B, is capable of opening a separate and independent reactor trip breaker, RTA and RTB, respectively and a bypass breaker, BYB and BYA, respectively. The 2 trip breakers in series connect three-phase a-c power from the rod drive motor generator sets to the rod drive power cabinets, as shown on Figure 7.2-1, Sheet 2. During plant power operation, a d-c undervoltage coil on each reactor trip breaker holds a trip plunger out against its spring, allowing the power to be available at the rod control power supply cabinets. For reactor trip, a loss of d-c voltage to the undervoltage coil, as well as energization of the shunt trip coil, trips open the breaker.

When either of the trip breakers opens, power is interrupted to the rod drive power supply, and the control rods fall, by gravity, into the core. The rods cannot be withdrawn until the trip breakers are

manually reset. The trip breakers cannot be reset until the abnormal condition which initiated the trip is corrected. Bypass breakers BYA and BYB are provided to permit testing of the trip breakers, as discussed in Figure 7.2.2.2.3.

7.2.1.1.1 Functional Performance Requirements

The reactor trip system automatically initiates reactor trip:

1. Whenever necessary to prevent fuel damage for an anticipated operational transient (Condition II).
2. To limit core damage for infrequent faults (Condition III).
3. So that the energy generated in the core is compatible with the design provisions to protect the reactor coolant pressure boundary for limiting fault conditions (Condition IV).

The reactor trip system initiates a turbine trip signal whenever reactor trip is initiated to prevent the reactivity insertion that would otherwise result from excessive reactor system cooldown. The turbine trip avoids unnecessary actuation of the engineered safety features actuation system.

The reactor trip system provides for manual initiation of reactor trip by operator action.

7.2.1.1.2 Reactor Trips

The various reactor trip circuits automatically open the reactor trip breakers whenever a condition monitored by the reactor trip system reaches a preset level. To ensure a reliable system, high quality design, components, manufacturing, quality control and testing is used. In addition to redundant channels and trains, the design approach provides a reactor trip system which monitors numerous system variables, therefore providing protection system functional diversity. The extent of this diversity has been evaluated for a wide variety of postulated accidents.

Table 7.2-1 provides a list of reactor trips which are described below.

1. Nuclear Overpower Trips

   The specific trip functions generated are as follows:

   a. Power range high neutron flux trip

      The power range high neutron flux trip circuit trips the reactor when 2 of the 4 power range channels reach the trip setpoint.

There are 2 bistables (for each of the 4 power range channels), each with its own trip setting used for a high and a low range trip setting. The high trip setting provides protection during normal power operation and is always active. The low trip setting, which provides protection during startup, can be manually bypassed when 2 out of the 4 power range channels read above approximately 10% power (P-10). Three (3) out of the 4 channels below 10% automatically reinstates the trip function. Refer to Table 7.2-2 for a listing of all protection system interlocks.

b. Intermediate range high neutron flux trip

The intermediate range high neutron flux trip circuit trips the reactor when 1 out of the 2 intermediate range channels reaches the trip setpoint. This trip, which provides protection during reactor startup, can be manually blocked if 2 out of 4 power range channels are above approximately 10% power (P-10). Three (3) out of the 4 power range channels below this value automatically reinstates the intermediate range high neutron flux trip. The intermediate range channels (including detectors) are separate from the power range channels. The intermediate range channels can be individually bypassed at the nuclear instrumentation racks to permit channel testing. This bypass action is annunciated on the control board.

c. Source range high neutron flux trip

The source range high neutron flux trip circuit trips the reactor when 1 of the 2 source range channels exceeds the trip setpoint. This trip, which provides protection during reactor startup and plant shutdown, can be manually bypassed when 1 of the 2 intermediate range channels reads above the P-6 setpoint value and is automatically reinstated when both intermediate range channels decrease below the P-6 setpoint value. This trip is also automatically bypassed by 2 out of 4 logic from the power range protection interlock (P-10). This trip function can also be reinstated below P-10 by an administrative action requiring manual actuation of 2 control board mounted switches. Each switch will reinstate the trip function in 1 of the 2 protection logic trains. The source range trip point is set between the P-6 setpoint (source range cutoff power level) and the maximum source range power level. The channels can be individually bypassed at the nuclear instrumentation racks to permit channel testing during plant shutdown or prior to startup. This bypass action is annunciated on the control board.

d. Power range high positive neutron flux rate trip

This circuit trips the reactor when a sudden abnormal increase in nuclear power occurs in 2 out of 4 power range channels.

This trip provides DNB protection against rod ejection accidents of low worthfrom mid-power and is always active.

Table 7.2-1, Sheet 3, shows the logic for all of the nuclear overpower and rate trips.

2. Core Thermal Overpower Trips

The specific trip functions generated are as follows:

a. Overtemperature ΔT trip

This trip protects the core against low DNBR and trips the reactor on coincidence as listed in Table 7.2-1 with 1 set of temperature measurements per loop. The setpoint for this trip is continuously calculated by analog circuitry for each loop by solving the following equation:

$$\Delta T_{setpoint} = \Delta T_O \left[K_1 - K_2 \left(\frac{1+\tau_1 S}{1+\tau_2 S} \right) \left(T_{avg} - T_{Oavg} \right) + K_3 (P - 2235) - f(\Delta\phi) \right]$$

Where:

ΔT_O	=	Indicated ΔT at rated thermal power
T_{avg}	=	Average reactor coolant temperature (°F)
T_{Oavg}	=	Indicated T_{avg} at rated thermal power
P	=	Pressurizer pressure (psig)
K_1	=	Preset bias
K_2	=	Preset gain which compensates for the temperature on the DNB limits
K_3	=	Preset gain which compensates for the effect of pressure on the DNB limits
τ_1, τ_2	=	Preset constants which compensate for piping and instrument time delay
s	=	Laplace transform operator (seconds^{-1})
$f(\Delta\phi)$	=	A function of the neutron flux difference between upper and lower long ion chambers (refer to Figure 7.2-2)

A separate long ion chamber unit supplies the flux signal for each overtemperature ΔT trip channel.

Increases in $\Delta\phi$ beyond a predefined deadband result in a decrease in trip setpoint. Refer to Figure 7.2-2.

The required 1 pressurizer pressure parameter per loop is obtained from separate sensors connected to 3 separate pressure taps at the top of the pressurizer. Refer to Section 7.2.2.3.3 for an analysis of this arrangement.

Figure 7.2-1, Sheet 5, shows the logic for overtemperature ΔT trip function.

b. Overpower ΔT trip

This trip protects against excessive power (fuel rod rating protection) and trips the reactor on coincidence as listed in Table 7.2-1, with 1 set of temperature measurements per loop. The setpoint for each channel is continuously calculated using the following equation:

$$\Delta T_{setpoint} = \Delta T_O \left[K_4 - K_5 \left(\frac{\tau_3 S}{1+\tau_3 S} \right) T_{avg} - K_6 \left(T_{avg} - T_{Oavg} \right) \right]$$

Where:

ΔT_O	=	Indicated ΔT at rated thermal power
K_4	=	A preset bias
K_5	=	A constant which compensates for piping and instrument time delay
K_6	=	A constant which compensates for the change in density flow and heat capacity of the water with temperature.
T_{Oavg}	=	Indicated T_{avg} at rated thermal power
T_{avg}	=	Average reactor coolant temperature (°F)
τ_3	=	Preset time constant (seconds)
s	=	Laplace transform operator ($seconds^{-1}$)

The source of temperature and flux information is identical to that of the overtemperature ΔT trip and the resultant ΔT setpoint is compared to the same ΔT. Figure 7.2-1, Sheet 5, shows the logic for this trip function.

3. Reactor Coolant System Pressurizer Pressure and Water Level Trips

The specific trip functions generated are as follows:

a. Pressurizer low pressure trip

The purpose of this trip is to protect against low pressure which could lead to DNB. The parameter being sensed is reactor coolant pressure as measured in the pressurizer. Above P-7 the reactor is tripped when the pressurizer measurements fall below preset limits. This trip is blocked below P-7 to permit startup. The trip logic and interlocks are given in Table 7.2-1.

The trip logic is shown on Figure 7.2-1, Sheet 6.

b. Pressurizer high pressure trip

The purpose of this trip is to protect the Reactor Coolant System against system overpressure.

The same sensors and transmitters used for the pressurizer low pressure trip are used for the high pressure trip except that separate bistables are used for trip. These bistables trip when uncompensated pressurizer pressure signals exceed preset limits on coincidence as listed in Table 7.2-1. There are no interlocks or permissives associated with this trip function.

The logic for this trip is shown on Table 7.2-1, Sheet 6.

c. Pressurizer high water level trip

This trip is provided as a backup to the high pressurizer pressure trip and serves to prevent water relief through the pressurizer safety valves. This trip is blocked below P-7 to permit startup. The coincidence logic and interlocks of pressurizer high water level signals are given in Table 7.2-1.

The trip logic for this function is shown on Figure 7.2-1, Sheet 6.

4. Reactor Coolant System Low Flow Trips

These trips protect the core from DNB in the event of a loss of coolant flow situation. Figure 7.2-1, Sheet 5 shows the logic for these trips. The means of sensing the loss of coolant flow are as follows:

a. Low reactor coolant flow

The parameter sensed is reactor coolant flow. Four (4) elbow taps in each coolant loop are used as a flow device that indicates the status of reactor coolant flow. The basic function of this device is to provide information as to whether or not a reduction in flow has occurred. An output signal from 2 out of the 3 bistables in a loop would indicate a low flow in that loop.

The coincidence logic and interlocks are given in Table 7.2-1.

b. Reactor coolant pump undervoltage trip

This trip is required in order to protect against low flow which can result from loss of voltage to more than 1 reactor coolant pump motor (e.g., from loss of offsite power or reactor coolant pump breakers opening).

There are 3 undervoltage sensing relays connected for each pump (1 for each phase) at the motor side of each reactor coolant pump breaker. These relays provide an output signal when the pump voltage goes below approximately 70% of rated voltage. Signals from these relays are time delayed to prevent spurious trips caused by short term voltage perturbations. The coincidence logic and interlocks are given in Table 7.2-1.

c. Reactor coolant pump underfrequency trip

This trip protects against low flow resulting from pump underfrequency, for example a major power grid frequency disturbance. The function of this trip is to trip the reactor for an underfrequency condition greater than 2.5 Hz. The setpoint of the underfrequency relays is adjustable between 54.00 and 60.98 Hz (nominal).

There is 1 underfrequency sensing relay for each reactor coolant pump motor. Signals from relays for any 2 of the pump motors (time delayed up to approximately 0.1 seconds to prevent spurious trips caused by short term frequency perturbations) will trip the reactor if the power level is above P-7.

5. Steam Generator Trips

The specific trip functions generated are as follows:

a. Low feedwater flow trip

This trip protects the reactor from a sudden loss of heat sink. The trip is actuated by steam/feedwater flow mismatch (1 out of 2) in coincidence with low water level (1 out of 2) in any steam generator.

Figure 7.2-1, Sheet 7, shows the logic for this trip function.

There are no interlocks associated with this trip.

b. Low-Low steam generator water level trip

This trip protects the reactor from loss of heat sink in the event of a sustained steam/feedwater flow mismatch of insufficient magnitude to cause a low feedwater flow reactor trip. This trip is actuated on 2 out of 3 low-low water level signals occurring in any steam generator.

The logic is shown on Figure 7.2-1, Sheet 7.

6. Reactor Trip on a Turbine Trip (anticipatory)

The reactor trip on a turbine trip is actuated by 2 out of 3 logic from trip fluid pressure signals or by all closed signals from the turbine steam stop valves. A turbine trip causes a direct reactor trip above P-9. The reactor trip on turbine trip provides additional protection and conservatism beyond that required for the health and safety of the public. This trip is included as part of good engineering practice and prudent design. No credit is taken in any of the safety analyses (Chapter 15) for this trip.

The turbine provides anticipatory trips to the reactor protection system from contacts which change position when the turbine stop valves close or when the turbine emergency trip fluid pressure goes below its setpoint.

One of the design bases considered in the protection system is the possibility of an earthquake. With respect to these contacts, their functioning is unrelated to a seismic event in that they are anticipatory to other diverse parameters which cause reactor trip. The contacts are shut during plant operation and open to cause reactor trip when the turbine is tripped. No power is provided to the protection system from the contacts; they merely serve to interrupt power to cause reactor trip. This design functions in a de-energize-to-trip fashion to cause a plant trip if power is interrupted in the trip circuitry. This ensures that the protection system will in no way be degraded by this anticipatory trip because seismic design considerations do not form part of the design bases for anticipatory trip sensors. (The reactor protection system cabinets which receive the inputs from the anticipatory trip sensors are, of course, seismically qualified as discussed in Section 3.10.) The anticipatory trips thus meet IEEE Standard 279-1971, including redundancy, single failure, etc.

Prior to spring 2011 (RF-19), variations in the separation criteria (which still met the intent of IEEE 279 per previous FSAR discussion) existed with the turbine stop valve limit switches and the turbine electro-hydraulic control cabinet (EHC). This previously justified plant design configuration was eliminated by the digital EHC upgrade during RF-19, based upon the following:

- Turbine stop valve limit switches are now independent from non-safety EHC valve position sensors, safety-related limit switch cabling from each stop valve terminal box is separated from non-safety position sensor cabling, and safety related limit switch wiring is separated (from non-safety EHC position sensors) to the extent practical due to space limitations within each stop valve terminal box.
- Train-oriented reactor protection system reactor trip output signal contacts wired as EHC (turbine trip system) system inputs are isolated in train-oriented reactor protection system cabinets, prior to being routed in a common raceway system immediately upstream of the EHC cabinet. (It should be further noted that this circuit application differs as the exact opposite purpose of the subject of this subsection; i.e., reactor trip signal to turbine trip system input, versus turbine trip signal to an anticipatory reactor trip function.) Therefore, there is no concern with any lack of wire separation between these two isolated reactor trip signals (either upstream or within the EHC cabinet), since MSIV closure will cause turbine shutdown, and since manual operator verification of a turbine trip subsequent to a reactor trip is always performed.

The logic for this trip is functionally shown on Figure 7.2-1, Sheet 15.

7. Safety Injection Signal Actuation Trip

A reactor trip occurs when the safety injection system is actuated. The means of actuating the safety injection system are described in Section 7.3. This trip protects the core against a loss of reactor coolant or steam.

Figure 7.2-1, Sheet 8, shows the logic for this trip.

8. Manual Trip

The manual trip consists of 2 switches with 2 outputs on each switch. One (1) output is used to actuate the train A trip breaker and the train B bypass breaker; the other output actuates the train B trip breaker and the train A bypass breaker. Operating a manual trip switch removes the voltage from the undervoltage trip coil and energizes the shunt trip coil.

There are no interlocks which can block this trip. Figure 7.2-1, Sheet 3, shows the manual trip logic. The design conforms to Regulatory Guide 1.62 as shown in Figure 7.2-3.

7.2.1.1.3 Reactor Trip System Interlocks

1. Power Escalation Permissives

The overpower protection provided by the out of core nuclear instrumentation consists of 3 discrete, but overlapping, ranges. Continuation of startup operation or power increase requires a permissive signal from the higher range instrumentation channels before the lower range level trips can be manually blocked by the operator.

A 1 of 2 intermediate range permissive signal (P-6) is required prior to source range trip blocking. Source range trips are automatically reactivated when both intermediate range channels are below the permissive (P-6) setpoint. There are 2 manual reset switches for administratively reactivating the source range trip when between the permissive P-6 and P-10 setpoints, if required. Source range trip block is always maintained when above the permissive P-10 setpoint.

The intermediate range trip and power range (low setpoint) trip can only be blocked after satisfactory operation and permissive information are obtained from 2 of 4 power range channels. Four (4) individual blocking switches are provided so that the low range power range trip and intermediate range trip can be independently blocked (1 switch for each train). These trips are automatically reactivated when any 3 of the 4 power range channels are below the permissive (P-10) setpoint, thus ensuring automatic activation to more restrictive trip protection.

The development of permissives P-6 and P-10 is shown on Figure 7.2-1, Sheet 4. All of the permissives are digital; they are derived from analog signals in the nuclear power range and intermediate range channels.

Separation of circuits is maintained throughout the system where practical. An exception is in the wiring between the turbine stop valve limit switch junction box and the valve limit switches and where external circuits terminate within the junction box. However, wiring within the junction box is separated as far as is practical.

See Table 7.2-2 for the list of protection system interlocks.

2. Blocks at Reactor Trips at Low Power

   Interlock P-7 blocks a reactor trip at lower power (below approximately 10% of full power) on a low reactor coolant flow in more than 1 loop, reactor coolant pump undervoltage, reactor coolant pump underfrequency, pressurizer low pressure, or pressurizer high water level. See Figure 7.2-1, Sheets 5 and 6 for permissive applications. The low power signal is derived from 3 out of 4 power range neutron flux signals below the setpoint in coincidence with 2 out of 2 turbine first stage pressure signals below the setpoint (low plant load). See Figure 7.2-1, Sheets 4 and 15, for the derivation of P-7.

   The P-8 interlock blocks a reactor trip when the plant is below approximately 50% of full power, on a low reactor coolant flow in any 1 loop. The block action (absence of the P-8 interlock signal) occurs when 3 out of 4 neutron flux power range signals are below the setpoint. Thus, below the P-8 setpoint, the reactor will be allowed to operate with 1 inactive loop and trip will not occur until 2 loops are indicating low flow. See Figure 7.2-1, Sheet 4, for derivation of P-8, and Sheet 5 for applicable logic.

   Interlock P-9 blocks a reactor trip following a turbine trip below 50% power. See Figure 7.2-1 Sheet 15, for the implementation of the P-9 interlock. See Figure 7.2-1, Sheet 4, for the derivation of P-9.

   See Table 7.2-2 for the list of protection system blocks.

7.2.1.1.4 Coolant Temperature Sensor Arrangement

Narrow Range Hot and Cold Leg Temperature

The hot and cold loop temperature signals are required for input to the protection and control functions are obtained using thermowell mounted RTDs installed in each reactor coolant loop.

The hot leg temperature measurement in each loop is accomplished using 3 fast response narrow range dual element RTDs mounted in thermowells. The hot leg thermowells are located within the 3 scoops previously used for the RTD bypass manifold as locations 120° apart in the cross sectional sleeve. The scoops were modified by drilling a flow hole in the top of the scoops so that water flows in through the existing holes in the leading edge of the scoop, past the RTD and out through the new drilled hole.

Due to temperatures streaming, the 3 fast response hot leg RTDs are electronically averaged to generate the hot leg temperature.

The cold leg temperature measurements in each loop are accomplished by 1 fast response narrow range dual element RTD. The existing cold leg RTD bypass penetration nozzle was modified to accept the thermowell and RTD. Temperature streaming in the cold leg is not a concern due to the mixing action of the reactor coolant pump.

7.2.1.1.5 Pressurizer Water Level Reference Leg Arrangement

The design of the pressurizer water level instrumentation employs the usual tank level arrangement using differential pressure between an upper and a lower tap on a column of water. A reference leg connected to the upper tap is kept full of water by condensation of steam at the top of the leg.

7.2.1.1.6 Analog System

The analog system consists of two instrumentation systems; the process instrumentation system and the Nuclear Instrumentation System.

Process instrumentation includes those devices (and their interconnection into systems) which measure temperature, pressure, fluid flow, fluid level as in tanks or vessels, and occasionally physiochemical parameters such as fluid conductivity or chemical concentration. Process instrumentation specifically excludes nuclear and radiation measurements. The process instrumentation includes the process measuring devices, power supplies, indicators, recorders, alarm actuating devices, controllers, signal conditioning devices, etc., which are necessary for day-to-day operation of the nuclear steam supply system as well as for monitoring the plant and providing initiation of protective functions upon approach to unsafe plant conditions.

The primary function of nuclear instrumentation is to protect the reactor by monitoring the neutron flux and generating appropriate trips and alarms for various phases of reactor operating and shutdown conditions. It also provides a secondary control function and indicates reactor status during startup and power operation. The nuclear instrumentation system uses information from 3 separate types of instrumentation channels to provide 3 discrete protection levels. Each range of instrumentation (source, intermediate, and power) provides the necessary overpower reactor trip protection required during operation in that range. The overlap of instrument ranges provides reliable continuous protection beginning with source level through the intermediate and low power level. As the reactor power increases, the overpower protection level is increased by administrative procedures after satisfactory higher range instrumentation operation is obtained. Automatic reset to more restrictive trip protection is provided when reducing power.

Various types of neutron detectors, with appropriate solid-state electronic circuitry, are used to monitor the leakage neutron flux from a completely shutdown condition to 120% of full power. The power range channels are capable of recording overpower excursions up to 200% of full power. The neutron flux covers a wide range between these extremes. Therefore, monitoring with several ranges of instrumentation is necessary. The lowest range (“source” range) covers 6 decades of leakage neutron flux. The lowest observed count rate depends on the strength of the neutron sources in the core and the core multiplication associated with the shutdown reactivity. This is generally greater than 2 counts per second. The next range (“intermediate” range) covers ten plus decades. Detectors and instrumentation are chosen to provide overlap between the higher portion of the source range and the lower portion of the intermediate range. The highest range of instrumentation (“power” range) covers approximately 2 decades of the total instrumentation range. This is a linear range that overlaps with the higher portion of the intermediate range.

The system described above provides control room indication and recording of signals proportional to reactor neutron flux during core loading, shutdown, startup and power operation, as well as during subsequent refueling. Startup rate indication for the source and intermediate range channels is provided at the control board. Reactor trip, rod stop, control and alarm signals are transmitted to the reactor control and protection system for automatic plant control. Equipment failures and test status information are annunciated in the control room.

See References 1 and 2 for additional background information on the process and nuclear instrumentation systems.

7.2.1.1.7 Solid-State Logic Protection System

The solid-state logic protection system takes binary inputs (voltage/no voltage) from the process and nuclear instrument channels corresponding to conditions (normal/abnormal) of plant parameters. The system combines these signals in the required logic combination and generates a trip signal (no voltage) to the undervoltage trip attachment and shunt trip auxiliary relay coils of the reactor trip circuit breakers when the necessary combination of signals occur. The system also provides annunciator, status light and computer input signals which indicate the condition of bistable input signals, partial trip and full trip functions and the status of the various blocking, permissive and actuation functions. In addition the system includes means for semi-automatic testing of the logic circuits. Refer to Reference 3 for background information.

7.2.1.1.8 Isolation Amplifiers

Westinghouse considers it advantageous to employ control signals derived from individual protection channels through isolation amplifiers contained in the protection channel, as permitted by IEEE Standard 279-1971.

Analog signals derived from protection channels for nonprotective functions are obtained through isolation amplifiers located in the analog protection racks. By definition, nonprotective functions include those signals used for control, remote process indication, and computer monitoring.

7.2.1.1.9 Energy Supply and Environmental Variations

The energy supply for the reactor trip system, including the voltage and frequency variations, is described in Section 7.6 and Chapter 8. The environmental variations, throughout which the system will perform, is given in Section 3.11 and Chapter 8.

7.2.1.1.10 Setpoints

The setpoints that require trip action are given in the Technical Specifications. A detailed discussion on setpoints is found in Section 7.1.2.1.9.

7.2.1.1.11 Seismic Design

The seismic design considerations for the reactor trip system are given in Section 3.10. This design meets the requirements of Criterion 2 of the 1971 General Design Criteria (GDC).

7.2.1.2 Design Bases Information

The information given below presents the design bases information requested by Section 3 of IEEE Standard 279-1971. Functional logic diagrams are presented in Figure 7.2-1.

7.2.1.2.1 Generating Station Conditions

The following are the generating station conditions requiring reactor trip:

1. DNBR approaching the safety limit.
2. Power density (kilowatts per foot) approaching rated value for Condition II faults (see Chapter 4 for fuel design limits).
3. Reactor Coolant System overpressure creating stresses approaching the limits specified in Chapter 5.

7.2.1.2.2 Generating Station Variables

The following are the variables required to be monitored in order to provide reactor trips (see Table 7.2-1).

1. Neutron flux.
2. Reactor coolant temperature.
3. Reactor coolant system pressure (pressurizer pressure).
4. Pressurizer water level.
5. Reactor coolant flow.
6. Reactor coolant pump operational status (voltage and frequency).
7. Steam generator feedwater flow.
8. Steam generator water level.
9. Turbine generator operational status (trip fluid pressure and stop valve position).
10. Steam flow

7.2.1.2.3 Spatially Dependent Variables

The following variable is spatially dependent:

1. Reactor coolant temperature (see Section 7.3.1.2 for a discussion of this variable spatial dependence).

7.2.1.2.4 Limits, Margins and Setpoints

The parameter values that will require reactor trip are given in the Technical Specifications, and in Chapter 15, Accident Analyses. Chapter 15 proves that the setpoints used in Chapter 16 are conservative.

The setpoints for the various functions in the reactor trip system have been analytically determined such that the operational limits so prescribed will prevent fuel rod clad damage and loss of integrity of the reactor coolant system as a result of any ANS Condition II incident (anticipated malfunction). As such, during any ANS Condition II incident, the reactor trip system limits the following parameters to:

1. Minimum DNBR ≥ safety limit.
2. Maximum system pressure ≤. 2750 psia
3. Fuel rod maximum linear power for determination of protection setpoints ≤ 18.0 kW/foot

The accident analyses described in Section 15.2 demonstrate that the functional requirements as specified for the reactor trip system are adequate to meet the above considerations, even assuming, for conservatism, adverse combinations of instrument errors (refer to Table 15.1-2). A discussion of the safety limits associated with the reactor core and reactor coolant system, plus the limiting safety system setpoints, are presented in the Technical Specifications.

7.2.1.2.5 Abnormal Events

The malfunctions, accidents or other unusual events which could physically damage reactor trip system components or could cause environmental changes are as follows:

1. Earthquakes (see Chapters 2 and 3).
2. Fire (see Section 9.5).
3. Missiles (see Section 3.5).
4. Flood (see Chapters 2 and 3).
5. Wind and Tornadoes (see Section 3.3).

The reactor trip system fulfills the requirements of IEEE Standard 279-1971 to provide automatic protection and to provide initiating signals to mitigate the consequences of faulted conditions.

7.2.1.2.6 Minimum Performance Requirements

1. Reactor trip system response times

Reactor trip system response time is defined in Section 7.1. Typical maximum allowable time delays in generating the reactor trip signal are tabulated in Table 7.2-3. (See Section 7.1.2.11 for a discussion of periodic response time verification

2. Reactor trip accuracies

   Accuracy is defined in Section 7.1. Reactor trip accuracies are tabulated in Table 7.2-3. An additional discussion on accuracy is found in Table 7.1.2.1.9.

3. Protection system ranges

   Typical protection system ranges are tabulated in Table 7.2.3. Range selection for the instrumentation covers the expected range of the process variable being monitored during power operation. Limiting setpoints are at least 5% from the end of the instrument span.

7.2.1.3 Final Systems Drawings

Functional block diagrams, electrical elementaries and other drawings required to assure electrical separation and perform a safety review are provided in the safety-related drawing package as discussed in Section 1.7.

7.2.2 Analysis

7.2.2.1 Failure Mode and Effects Analyses

An analysis of the reactor trip system has been performed. Results of this study and a fault tree analysis are presented in Reference 4.

7.2.2.2 Evaluation of Design Limits

While most setpoints used in the reactor protection system are fixed, there are variable setpoints, most notably the overtemperature ΔT and overpower ΔT setpoints. All setpoints in the reactor trip system have been selected on the basis of engineering design or safety studies. The capability of the reactor trip system to prevent loss of integrity of the fuel cladding and/or Reactor Coolant System pressure boundary during Condition II and III transients is demonstrated in Chapter 15. These accident analyses are carried out using those setpoints determined from results of the engineering design studies. Setpoint limits are presented in the Technical Specifications. A discussion of the intent for each of the various reactor trips and the accident analyses (where appropriate) which utilize this trip is presented below. It should be noted that the selection trip setpoints all provide for margin before protection action is actually required to allow for uncertainties and instrument errors. The design meets the requirements of Criteria 10 and 20 of the 1971 GDC.

7.2.2.2.1 Trip Setpoint Discussion

The accident analysis shows that below the DNBR safety limit, a potential for local fuel cladding failure exists. The DNBR existing at any point in the core for a given core design can be determined as a function of the core inlet temperature, power output, operating pressure and flow. Consequently, core safety limits in terms of a DNBR equal to the safety limit for the hot channel can be developed as a function of core ΔT, T_{avg} and pressure for a specified flow as illustrated by the solid lines in Figure 15.1-1. Also shown as solid lines in Figure 15.1-1 are the loci of conditions equivalent to 118% of power as a function of ΔT and T_{avg} representing the overpower (kW/ft) limit on the fuel. The dashed lines indicate the maximum permissible setpoint (ΔT) as a function of T_{avg} and pressure for the overtemperature and overpower reactor trip. Actual setpoint constants in the equation representing the dashed lines are as given in the Technical Specifications. These values are conservative to allow for instrument errors. The design meets the requirements of Criteria 10, 15, 20, and 29 of the 1971 GDC.

DNBR is not a directly measurable quantity; however, the process variables that determine DNBR are sensed and evaluated. Small isolated changes in various process variables may not individually result in violation of a core safety limit; whereas the combined variations, over sufficient time, may cause the overpower or overtemperature safety limit to be exceeded. The design concept of the reactor trip system takes cognizance of this situation by providing reactor trips associated with individual process variables in addition to the overpower/overtemperature safety limit trips. Process variable trips prevent reactor operation whenever a change in the monitored value is such that a core or system safety limit is in danger of being exceeded should operation continue. Basically, the high pressure, low pressure and overpower/overtemperature ΔT trips provide sufficient protection for slow transients as opposed to such trips as low flow or high flux which will trip the reactor for rapid changes in flow or flux, respectively, that would result in fuel damage before actuation of the slower responding ΔT trips could be effected.

Therefore, the reactor trip system has been designed to provide protection for fuel cladding and Reactor Coolant System pressure boundary integrity where: 1) a rapid change in a single variable or factor which will quickly result in exceeding a core or a system safety limit, and 2) a slow change in 1 or more variables will have an integrated effect which will cause safety limits to be exceeded. Overall, the reactor trip system offers diverse and comprehensive protection against fuel cladding failure and/or loss of reactor coolant system integrity for Condition II and III accidents. This is demonstrated by Table 7.2-4 which lists the various trips of the reactor trip system, the corresponding Technical Specification on safety limits and safety system settings and the appropriate accident discussed in the safety analyses in which the trip could be utilized.

The design meets the requirements of Criterion 21 of the 1971 GDC.

Preoperational testing is performed on reactor trip system components and systems to determine equipment readiness for startup. This testing serves as a further evaluation of the system design.

Analyses of the results of Condition I, II, III, and IV events, including considerations of instrumentation installed to mitigate their consequences are presented in Chapter 15. The

instrumentation installed to mitigate the consequences of load rejection and turbine trip is given in Section 7.4.

7.2.2.2.2 Reactor Coolant Flow Measurement

The elbow taps used on each loop in the primary coolant system are instrument devices that indicate the status of the reactor coolant flow. The basic function of this device is to provide information as to whether or not a reduction in flow has occurred. The correlation between flow and elbow tap signal is given by the following equation:

$$\frac{\Delta P}{\Delta P_O} = \left(\frac{W}{W_O} \right)^2$$

where ΔP_0 is the pressure differential at the reference flow, w_0, and ΔP is the pressure differential at the corresponding flow, w. The full flow reference point is established during initial plant startup. The low flow trip point is then established by extrapolating along the correlation curve. The expected absolute accuracy of the channel is within ± 10% of full flow and field results have shown the repeatability of the trip point to be within ± 1%.

7.2.2.2.3 Evaluation of Compliance to Applicable Codes and Standards

The reactor trip system meets the criteria of the General Design Criteria as indicated. The reactor trip system meets the requirements of Section 4 of IEEE Standard 279-1971 as indicated below.

7.2.2.2.3.1 General Functional Requirement

The protection system automatically initiates appropriate protective action whenever a condition monitored by the system reaches a preset level. Functional performance requirements are given in Section 7.2.1.1.1. Section 7.2.1.2.4 presents a discussion of limits, margins and setpoints; Section 7.2.1.2.5 discusses unusual (abnormal) events; and Section 7.2.1.2.6 presents minimum performance requirements.

7.2.2.2.3.2 Single Failure Criterion

The protection system is designed to provide 2, 3, or 4 instrumentation channels for each protective function and 2 logic train circuits. These redundant channels and trainsare electrically isolated and physically separated. Thus, any single failure within a channel or train will not prevent protective action at the system level when required. Loss of input power to a channel or logic train will result in a signal calling for a trip. This design meets the requirements of Criterion 23 of the 1971 GDC.

To prevent the occurrence of common mode failures, such additional measures as functional diversity, physical separation, and testing as well as administrative control during design,

production, installation and operation are employed. The design meets the requirements of Criteria 21 and 22 of the 1971 GDC.

7.2.2.2.3.3 Quality of Components and Modules

For a discussion on the quality of the components and modules used in the reactor trip system, refer to Chapter 17. The quality assurance applied conforms to Criterion 1 of the 1971 GDC.

7.2.2.2.3.4 Equipment Qualification

For a discussion of the type tests made to verify the performance requirements, refer to Section 3.11. The test results demonstrate that the design meets the requirements of Criterion 4 of the 1971 GDC.

7.2.2.2.3.5 Channel Integrity

Protection system channels required to operate in accident conditions maintain necessary functional capability under extremes of conditions relating to environment, energy supply, malfunctions, and accidents. The energy supply for the reactor trip system is described in Section 7.6 and Chapter 8. The environmental variations, throughout which the system will perform is given in Section 3.11.

7.2.2.2.3.6 Independence

Channel independence is carried throughout the system, extending from the sensor through to the devices actuating the protective function. Physical separation is used to achieve separation of redundant transmitters. Separation of wiring is achieved using separate wireways, cable trays, conduit runs and containment penetrations for each redundant channel. Redundant analog equipment is separated by locating modules in different protection cabinets. Each redundant protection channel set is energized from a separate a-c power feed. This design meets the requirements of Criterion 21 of the 1971 GDC.

Two (2) reactor trip breakers are actuated by 2 separate logic matrices which interrupt power to the control rod drive mechanisms. The breaker main contacts are connected in series with the power supply so that opening either breaker interrupts power to all full length control rod drive mechanisms, permitting the rods to free fall into the core (see Figure 7.1-1).

The design philosophy is to make maximum use of a wide variety of measurements. The protection system continuously monitors numerous diverse system variables. Generally, 2 or more diverse protection functions would terminate an accident before intolerable consequences could occur. This design meets the requirements of Criterion 22 of the 1971 GDC.

7.2.2.2.3.7 Control and Protection System Interaction

The protection system is designed to be independent of the control system. In certain applications the control signals and other nonprotective functions are derived from individual protective

channels through isolation amplifiers. The isolation amplifiers are classified as part of the protection system and are located in the analog protective racks. Nonprotective functions include those signals used for control, remote process indication, and computer monitoring. The isolation amplifiers are designed such that a short circuit, open circuit, or the application of credible fault voltages from within the cabinets on the isolated output portion of the circuit (i.e., the nonprotective side of the circuit) will not affect the input (protective) side of the circuit. The signals obtained through the isolation amplifiers are never returned to the protective racks. This design meets the requirements of Criterion 24 of the 1971 GDC and paragraph 4.7 of IEEE Standard 279-1971.

Moreover, Westinghouse programs in the period of late 1973 to mid 1976 have demonstrated by tests that credible faults or interference on cables associated with protection system racks cannot degrade system performance. The nuclear instrumentation and solid state protection systems tests are reported in the “Westinghouse Protection System Noise Tests” which were accepted by the NRC in support of the Diablo Canyon Application (Docket Numbers 50-275 and 50-323). The tests on the 7300 Series Process Control System are reported in Reference 5, a topical report accepted by the NRC.

In the Virgil C. Summer Nuclear Station, cables leaving the protection system racks are not routed with cables carrying potentials greater than those to which the systems were subjected in the Westinghouse test programs. Consequently these test programs are applicable to the Virgil C. Summer Nuclear Station and demonstrate that protection system performance cannot be degraded even if subjected to abnormal electrical conditions which far exceed those which can be reasonably postulated.

The results of applying various malfunction conditions on the output portion of the isolation amplifiers show that no significant disturbance to the isolation amplifier input signal occurred.

7.2.2.2.3.8 Derivation of System Inputs

To the extent feasible and practical, protection system inputs are derived from signals which are direct measures of the desired variables. Variables monitored for the various reactor trips are listed in Section 7.2.1.2.2.

7.2.2.2.3.9 Capability for Sensor Checks

The operational availability of each system input sensor during reactor operation is accomplished by cross checking between channels that bear a known relationship to each other and that have readouts available. Channel checks are discussed in Technical Specification 3/4.3 and Table 4.3-1 of the Technical Specifications.

7.2.2.2.3.10 Capability for Testing

The reactor trip system is capable of being tested during power operation. Where only parts of the system are tested at any one time, the testing sequence provides the necessary overlap between the parts to assure complete system operation. The testing capabilities are in conformance with Regulatory Guide 1.22 as discussed in Section 7.1.2.5.

The protection system is designed to permit periodic testing of the analog channel portion of the reactor trip system during reactor power operation without initiating a protective action unless a trip condition actually exists. This is because of the coincidence logic required for the reactor trip. These tests may be performed at any plant power from cold shutdown to full power. Before starting any of these tests with the plant at power, all redundant reactor trip channels associated with the function to be tested must be in the normal (unstripped) mode in order to avoid spurious trips. Setpoints are referenced in the precautions, limitations and setpoints portion of the plant technical manual.

1. Analog Channel Tests

   Analog channel testing is performed at the analog instrumentation rack set by individually introducing dummy input signals into the instrumentation channels and observing the tripping of the appropriate output bistables. Process analog output to the logic circuitry is interrupted during individual channel test by a test switch which, when thrown, de-energizes the associated logic input and inserts a proving lamp in the bistable output. Interruption of the bistable output to the logic circuitry for any cause (test, maintenance purposes, or removed from service) will cause that portion of the logic to be actuated (partial trip) accompanied by a partial trip alarm and channel status light actuation in the control room. Each channel contains those switches, test points, etc. necessary to test the channel. See Reference 1 for additional background information.

   The following periodic tests of the analog channels of the protection circuits are performed:

   a. T_{avg} and ΔT protection channel testing.
   b. Pressurizer pressure protection channel testing.
   c. Pressurizer water level protection channel testing.
   d. Steam/feedwater flow protection channel testing.
   e. Steam generator water level protection channel testing.
   f. Reactor coolant low flow, underfrequency, and undervoltage protection channels.
   g. Turbine first stage pressure channel testing.

2. Nuclear Instrumentation Channel Tests

The power range channels of the Nuclear Instrumentation System are tested by superimposing a test signal on the actual detector signal being received by the channel at the time of testing. The output of the bistable is not placed in a tripped condition prior to testing. Also, since the power range channel logic is 2 out of 4, bypass of this reactor trip function is not required.

To test a power range channel, a "TEST-OPERATE" switch is provided to require deliberate operator action and operation of which will initiate the "CHANNEL TEST" annunciator in the control room. Bistable operation is tested by increasing the test signal to its trip setpoint and verifying bistable relay operation by control board annunciator and trip status lights.

It should be noted that a valid trip signal would cause the channel under test to trip at a lower actual reactor power level. A reactor trip would occur when a second bistable trips. No provision has been made in the channel test circuit for reducing the channel signal level below that signal being received from the Nuclear Instrumentation System detector.

A Nuclear Instrumentation System channel which can cause a reactor trip through 1 of 2 protection logic (source or intermediate range) is provided with a bypass function which prevents the initiation of a reactor trip from that particular channel during the short period that it is undergoing test. These bypasses are annunciated in the control room.

The following periodic tests of the Nuclear Instrumentation System are performed:

a. Testing at plant shutdown

   (1) Source range testing.

   (2) Intermediate range testing.

   (3) Power range testing.

b. Testing below P-6 permissive power level

   (1) Source range testing.

c. Testing below P-10 permissive power level

   (1) Intermediate range testing.

   (2) Power range, low setpoint testing.

d. Testing above P-10 permissive power level

   (1) Power range testing.

Any deviations noted during the performance of these tests are investigated and corrected in accordance with the established calibration and troubleshooting procedures provided in the plant technical manual for the Nuclear Instrumentation System. Control and protection trip settings are indicated in the plant technical manual under precautions, limitations, and setpoints.

For additional background information on the Nuclear Instrumentation System see Reference 2.

3. Solid-State Logic Testing

The reactor logic trains of the reactor trip system are designed to be capable of complete testing at power. After the individual channel analog testing is complete, the logic matrices are tested from the train A and train B logic rack test panels. This step provides overlap between the analog and logic portions of the test program. During this test, all of the logic inputs are actuated automatically in all combinations of trip and nontrip logic. Trip logic is not maintained sufficiently long enough to permit opening of the reactor trip breakers. The reactor trip undervoltage coils are "pulsed" in order to check continuity. During logic testing of 1 train, the other train can initiate any required protective functions. Annunciation is provided in the control room to indicate when a train is in test (train output bypassed) and when a reactor trip breaker is bypassed. Logic testing can be performed in less than 30 minutes.

A direct reactor trip resulting from undervoltage or underfrequency on the reactor coolant pump buses is provided as discussed in Section 7.2.1 and shown on Figure 7.2-1. The logic for these trips is capable of being tested during power operation. When parts of the trip are being tested, the sequence is such that an overlap is provided between parts so that a complete logic test is provided. Thus complete testing of Westinghouse equipment is possible.

This design complies with the testing requirements of IEEE Standard 279-1971 and IEEE Standard 338-1971 discussed in Section 7.1.2.11.

The permissive and block interlocks associated with the reactor trip system and engineered safety features actuation system are given on Tables 7.2-2 and 7.3-3 and designated protection or "P" interlocks. As a part of the protection system, these interlocks are designed to meet the testing requirements of IEEE Standards 279-1971 and 338-1971.

Testing of all protection system interlocks is provided by the logic testing and semi-automatic testing capabilities of the solid-state protection system. In the solid-state protection system the undervoltage trip attachment and shunt trip auxiliary relay coils (reactor trip) and master relays (engineered safeguards actuation) are pulsed for all combinations of trip or actuation logic with and without the interlock signals. For example, reactor trip on low flow (2 out of 3 loops showing 2 out of 3 low flow) is tested to verify operability of the trip above P-7 and nontrip below P-7 (see Figure 7.2-1, Sheet 5). Interlock testing may be performed at power.

Testing of the logic trains of the reactor trip system includes a check of the input relays and a logic matrix check. The following sequence is used to test the system:

a. Check of input relays

During testing of the process instrumentation system and Nuclear Instrumentation System channels, each channel bistable is placed in a trip mode causing one input relay in train A and one in train B to de-energize. A contact of each relay is connected to a universal logic printed circuit card. This card performs both the reactor trip and monitoring functions. Reactor trip inputs cause status lamps and annunciators on the control board to operate as shown in Figure 7.2-1. Either the Train A or Train B input relay operation will light the status lamp and annunciator.

Each train contains a multiplexing test switch. At the start of a process or Nuclear Instrumentation System test, this switch (in either train) is placed in the A + B position. The A + B position alternately allows information to be transmitted from the 2 trains to the control board. A steady status lamp and annunciator indicates that input relays in both trains have been de-energized. A flashing lamp means that the input relays in the 2 trains did not both de-energize. Contact inputs to the logic protection system, such as reactor coolant pump bus underfrequency relays, operate input relays which are tested by operating the remote contacts as described above and using the same type of indications as those provided for bistable input relays.

Actuation of the input relays provides the overlap between the testing of the logic protection system and the testing of those systems supplying the inputs to the logic protection system. Test indications are status lamps and annunciators on the control board. Inputs to the logic protection system are checked 1 channel at a time, leaving the other channels in service. For example, a function that trips the reactor when 2 out of 4 channels trip becomes a 1 out of 3 trip when 1 channel is placed in the trip mode. Both trains of the logic protection system remain in service during this portion of the test.

b. Check of logic matrices

Logic matrices are checked 1 train at a time. Input relays are not operated during this portion of the test. Reactor trips from the train being tested are inhibited with the use of the input error inhibit switch on the semi-automatic test panel in the train. At the completion of the logic matrix tests, one bistable in each channel of process instrumentation or nuclear instrumentation is tripped to check closure of the input error inhibit switch contacts.

The logic test scheme uses pulse techniques to check the coincidence logic. All possible trip and nontrip combinations are checked. Pulses from the tester are applied to the inputs of the universal logic card at the same terminals that connect to the input relay contacts. Thus there is an overlap between the input relay check and the logic matrix check. Pulses are fed back from the reactor trip breaker undervoltage trip attachment and shunt trip auxiliary relay coils to the tester. The pulses are of such short duration that the reactor trip breaker undervoltage coil armature cannot respond mechanically.

Test indications that are provided are an annunciator in the control room indicating that reactor trips from the train have been blocked and that the train is being tested, and green and red lamps on the semi-automatic tester to indicate a good or bad logic matrix test. Protection capability provided during this portion of the test is from the train not being tested.

The testing capability meets the requirements of Criterion 21 of the 1971 GDC.

4. Testing of Reactor Trip Breakers

Normally, reactor trip breakers 52/RTA and 52/RTB (see Figure 7.2-1, Sheet 2) are in service, and bypass breakers 52/BYA and 52/BYB are withdrawn (out of service). The following procedure describes the method used for testing the trip breakers:

a. With bypass breaker 52/BYA racked out, manually close and trip it to verify its operation.
b. Rack in and close 52/BYA. Manually trip 52/RTA through a protection system logic matrix while at the same time operating the “Auto Shunt Trip Block” pushbutton on the automatic shunt trip panel. This verifies operation of the Undervoltage Trip Attachment (UVTA) when the breaker trips. After reclosing RTA, trip it again by operation of the “Auto Shunt Trip Test” pushbutton on the automatic shunt trip panel. This is to verify tripping of the breaker through the shunt trip device.
c. Reset 52/RTA.
d. Trip and rack out 52/BYA.
e. Repeat above steps to test trip breaker 52/RTB using bypass breaker 52/BYB.

Auxiliary contacts of the bypass breakers are connected into the alarm system of their respective trains such that if either train is placed in test while the bypass breaker of the other train is closed, both reactor trip breakers and both bypass breakers will automatically trip.

Auxiliary contacts of the bypass breakers are also connected in such a way that if an attempt is made to close the bypass breaker in 1 train while the bypass breaker of the other train is already closed, both bypass breakers will automatically trip.

The train A and train B alarm systems operate separate annunciators in the control room. The 2 bypass breakers also operate an annunciator in the control room. Bypassing of a protection train with either the bypass breaker or with the test switches will result in audible and visual indications.

The complete reactor trip system is normally required to be in service. However, to permit online testing of the various protection channels or to permit continued operation in the event of a subsystem instrumentation channel failure, a Technical Specification, 3/4.3, defining the minimum number of operable channels has been formulated. This Technical Specification also defines the required restriction to operation in the event that the channel operability requirements cannot be met.

7.2.2.2.3.11 Channel Bypass or Removal from Operation

The protection system is designed to permit periodic testing of the analog channel portion of the reactor trip system during reactor power operation without initiating a protective action unless a trip condition actually exists. This is because of the coincidence logic required for reactor trip. Additional information is given in Section 7.3.2.2.5.

7.2.2.2.3.12 Operating Bypasses

Where operating requirements necessitate automatic or manual bypass of a protective function, the design is such that the bypass is removed automatically whenever permissive conditions are not met. Devices used to achieve automatic removal of the bypass of a protective function are considered part of the protective system and are designed in accordance with the criteria of this section. Indication is provided in the control room if some part of the system has been administratively bypassed or taken out of service.

7.2.2.2.3.13 Indication of Bypasses

Bypass indication is discussed in Section 7.1.2.6 and Appendix 3A.

7.2.2.2.3.14 Access to Means for Bypassing

The design provides for administrative control of access to the means for manually bypassing channels or protective functions.

7.2.2.2.3.15 Multiple Setpoints

For monitoring neutron flux, multiple setpoints are used. When a more restrictive trip setting becomes necessary to provide adequate protection for a particular mode of operation or set of operating conditions, the protective system circuits are designed to provide positive means or administrative control to assure that the more restrictive trip setpoint is used. The devices used to prevent improper use of less restrictive trip settings are considered part of the protective system and are designed in accordance with the criteria of this section.

7.2.2.2.3.16 Completion of Protective Action

The protection system is so designed that, once initiated, a protective action goes to completion. Return to normal operation requires action by the operator.

7.2.2.2.3.17 Manual Initiation

Switches are provided on the control board for manual initiation of protective action. Failure in the automatic system does not prevent the manual actuation of the protective functions. Manual actuation relies on the operation of a minimum of equipment.

7.2.2.2.3.18 Access

The design provides for administrative control of access to all setpoint adjustments, module calibration adjustments, and test points.

7.2.2.2.3.19 Identification of Protective Actions

Protective channel identification is discussed in Section 7.1.2.3. Indication is discussed in Section 7.2.2.2.3.20.

7.2.2.2.3.20 Information Read Out

The protective system provides the operator with complete information pertinent to system status and safety. All transmitted signals (flow, pressure, temperature, etc.) which can cause a reactor trip will be either indicated or recorded for every channel, including all neutron flux power range currents (top detector, bottom detector, algebraic difference and average of bottom and top detector currents).

Any reactor trip will actuate an alarm and an annunciator. Such protective actions are indicated and identified down to the channel level.

Alarms and annunciators are also used to alert the operator of deviations from normal operating conditions so that he may take appropriate corrective action to avoid a reactor trip. Actuation of any rod stop or trip of any reactor trip channel will actuate an alarm.

7.2.2.2.3.21 System Repair

The system is designed to facilitate the recognition, location, replacement, and repair of malfunctioning components or modules. Refer to the discussion in Section 7.2.2.2.3.10.

7.2.2.3 Specific Control and Protection Interactions

7.2.2.3.1 Neutron Flux

Four (4) power range neutron flux channels are provided for overpower protection. An isolated auctioneered high signal is derived by auctioneering of the 4 channels for automatic rod control. If any channel fails in such a way as to produce a low output, that channel is incapable of proper overpower protection but will not cause control rod movement because of the auctioneer. Two (2) out of 4 overpower trip logic will ensure an overpower trip if needed even with an independent failure in another channel.

In addition, channel deviation signals in the control system will give an alarm if any neutron flux channel deviates significantly from the average of the flux signals. Also, the control system will respond only to rapid changes in indicated neutron flux; slow changes or drifts are compensated by the temperature control signals. Finally, an overpower signal from any nuclear power range

channel will block manual and automatic rod withdrawal. The setpoint for this rod stop is below the reactor trip setpoint.

7.2.2.3.2 Coolant Temperature

The accuracy of the resistance temperature detector temperature measurements is demonstrated during plant startup. Tests compare with each other as well as with the temperature measurements obtained from cold leg piping of each loop. The comparisons are done with the Reactor Coolant System in an isothermal condition. The linearity of the ΔT detectors as a function of plant power is also checked during plant startup as far as reactor protection is concerned. Reactor trip system setpoints are based upon percentages of the indicated ΔT at nominal full power rather than on absolute values of ΔT. This is done to account for loop differences which are inherent. Therefore, the percent ΔT scheme is relative, not absolute, and therefore provides better protective action without the expense of accuracy. For this reason, the linearity of the ΔT signals as a function of power is of importance rather than the absolute values of the ΔT. As part of the plant startup tests, the resistance temperature detector signals will be compared with the core exit thermocouple signals.

The input signals to the reactor control systems are obtained from electronically isolated protection T_{avg} and Delta-T signals, (one per loop). A Median Signal Selector (MSS) is implemented in the reactor control system, one for T_{avg} and one for Delta-T. The MSS receives three signals as input and selects the median signal for input to the appropriate control system. Any single failure (high or low) in a calculated temperature will not result in adverse control system behavior since the failed high or low temperature signal will be rejected by the MSS.

Hence, the implementation of a MSS in the reactor coolant systems in conjunction with the 2 out of 3 protection logic satisfies the requirements of IEEE 279-1971, Section 4.7, “Control and Protection System Interaction.”

In addition, channel deviation signals in the control system will give an alarm if any temperature channel deviates significantly from the median value. Automatic rod withdrawal blocks and turbine runback (power demand reduction) will also occur if any 2 of the 3 overtemperature or overpower ΔT channels indicate an adverse condition.

7.2.2.3.3 Pressurizer Pressure

The pressurizer pressure protection channel signals are used for high and low pressure protection and as inputs to the overtemperature ΔT trip protection function. Pressurizer pressure is sensed by fast response pressure transmitters. Control signals are not derived from protection channels.

A spurious high pressure signal from one control channel can cause decreasing pressure by actuation of either spray or relief valves. Protection is provided in the low pressurizer pressure reactor trip and in the logic for safety injection to ensure low pressure protection.

Overpressure protection is based upon the positive surge of the reactor coolant produced as a result of turbine trip under full load, assuming the core continues to produce full power. The self-

actuated safety valves are sized on the basis of steam flow from the pressurizer to accommodate this surge at a setpoint of 2500 psia and an accumulation of 3%. Note that no credit is taken for the relief capability provided by the power operated relief valves during this surge.

In addition, operation of any 1 of the power operated relief valves can maintain pressure below the high pressure trip point for most transients. The rate of pressure rise achievable with heaters is slow, and ample time and pressure alarms are available to alert the operator of the need for appropriate action.

One (1) tap on the pressurizer is shared for 1 each protection level and pressure transmitter, 2 control pressure transmitters and 1 wide range level transmitter. Redundancy is not compromised by having a shared tap since the logic for this trip is 2 out of 3. If the shared tap is plugged, the affected channels will remain static. If the impulse line bursts, the indicated pressure will drop to 0. In either case the fault is easily detectable, and the protective function remains operable.

7.2.2.3.4 Pressurizer Water Level

Three (3) pressurizer water level channels are used for reactor trip. Isolated signals from these channels are used for pressurizer water level control. A failure in the level control system could fill or empty the pressurizer at a slow rate (on the order of 30 minutes or more).

The high water level trip setpoint provides sufficient margin such that the undesirable condition of discharging liquid coolant through the safety valves is avoided. Even at full power conditions, which would produce the worst thermal expansion rates, a failure of the water level control would not lead to any liquid discharge through the safety valves. This is due to the automatic high pressurizer pressure reactor trip actuating at a pressure sufficiently below the safety valve setpoint.

For control failures which tend to empty the pressurizer, 2 out of 3 logic for safety injection action on low pressure ensures that the protection system can withstand an independent failure in another channel. In addition, ample time and alarms exist to alert the operator of the need for appropriate action.

7.2.2.3.5 Steam Generator Water Level and Feedwater Flow

The basic function of the reactor protection circuits associated with low steam generator water level and low feedwater flow is to preserve the steam generator heat sink for removal of long term residual heat. Should a complete loss of feedwater occur, the reactor would be tripped on coincidence of steam/feedwater flow mismatch and low steam generator water level or on low-low steam generator water level. In addition, redundant emergency feedwater pumps are provided to supply feedwater in order to maintain residual heat removal after trip. These reactor trips act before the steam generators are dry to reduce the required capacity and increase the starting time requirements of these emergency feedwater pumps and to minimize the thermal transient on the reactor coolant system and steam generators. Therefore, the following reactor trip circuits are provided for each steam generator to ensure that sufficient initial thermal capacity is available in the steam generator at the start of the transient:

1. A mismatch in steam and feedwater flow coincident with low steam generator water level;
2. A low-low steam generator water level regardless of steam/feedwater flowmismatch;

It is desirable to minimize thermal transients on a steam generator for credible loss of feedwater accidents. Hence, it should be noted that controller malfunctions caused by a protection system failure affect only 1 steam generator; the steam generator level signal used in the feedwater control originates separately from that used in the low feedwater reactor trip.

A spurious high signal from the feedwater flow channel being used for control would cause a reduction in feedwater flow preventing that channel from ultimately tripping. However, the mismatch between steam demand and feedwater flow produced by this spurious signal will actuate alarms to alert the operator of this situation in time for manual correction. If the condition is allowed to continue and the mismatch is not sufficient to trip the reactor, reactor trip will occur on a low-low water level signal independent of indicated feedwater flow.

A spurious low signal from the feedwater flow channel being used for control would cause an increase in feedwater flow. The mismatch between steam flow and feedwater flow produced by the spurious signal would actuate alarms to alert the operator of the situation in time for manual correction. If the condition continues, a 2 out of 3 high-high steam generator water level signal in any loop, independent of the indicated feedwater flow, will cause feedwater isolation and trip the turbine. The turbine trip will result in a subsequent reactor trip if power is above the P-9 setpoint. The high-high steam generator water level trip is an equipment protective trip preventing excessive moisture carryover which could damage the turbine blading.

In addition, the 3 element feedwater controller incorporates reset action on the level error signal, such that with expected controller settings a rapid increase or decrease in the flow signal would cause only a small change in level before the controller would compensate for the level error. A slow change in the feedwater signal would have no effect at all. A spurious low or high steam flow signal would have the same effect as high or low feedwater signal, discussed above.

A spurious high steam generator water level signal from the protection channel used for control will tend to close the feedwater valve. However, before a reactor trip would occur, 2 out of 3 channels for a steam generator would have to indicate a high water level. A spurious low steam generator water level signal will tend to open the feedwater valve. Again, before a reactor trip would occur, 2 out of 3 channels in a loop would have to indicate a low water level. Any slow drift in the water level signal will permit the operator to respond to the level alarms and take corrective action. Automatic protection is provided in case the spurious high level reduces feedwater flow sufficiently to cause low level in the steam generator. The reactor will trip either on a mismatch on steam and feedwater flow coincident with low water level or, ultimately, on low-low steam generator water level. Automatic protection is also provided in case the spurious low level signal increases feedwater flow sufficiently to cause high level in the steam generator. A turbine trip and feedwater isolation would occur on 2 out of 3 high-high steam generator water level in any loop.

7.2.2.4 Additional Postulated Accidents

Loss of plant instrument air or loss of component cooling water is discussed in Section 7.3.2. Load rejection and turbine trip are discussed in further detail in Section 7.7.

The control interlocks, called rod stops, that are provided to prevent abnormal power conditions which could result from excessive control rod withdrawal are discussed in Section 7.7.1.4.1 and listed on Table 7.7-1. Excessively high power operation (which is prevented by blocking of automatic rod withdrawal), if allowed to continue, might lead to a safety limit (as given in the Technical Specifications) being reached. Before such a limit is reached, protection will be available from the reactor trip system. At the power levels of the rod block setpoints, safety limits have not been reached; and therefore these rod withdrawal stops do not come under the scope of safety-related systems, and are considered as control systems.

7.2.3 Tests and Inspections

The reactor trip system meets the testing requirements of IEEE Standard 338-1971 as discussed in Section 7.1.2.11. The testability of the system is discussed in Section 7.2.2.2.3. The initial test intervals are specified in the Technical Specifications. Written test procedures and documentation, conforming to the requirements of IEEE Standard 338-1971, will be available for audit by responsible personnel. Periodic testing complies with Regulatory Guide 1.22 as discussed in Sections 7.1.2.5 and 7.2.2.2.3.

Table 7.2-1
List of Reactor Trips

	Reactor Trip	Coincidence Logic	Interlocks	Comments
1.	High neutron flux (Power Range)	2/4	Manual block of low setting permitted by P-10	High and low setting; manual block and automatic reset of low setting by P-10
2.	Intermediate range neutron flux	1/2	Manual block permitted by P-10	Manual block and automatic reset
3.	Source range neutron flux	1/2	Manual block permitted by P-6, interlocked with P-10	Manual block and automatic reset. Automatic block above P-10
4.	Power range high positive neutron flux rate	2/4	No interlocks	
5.	Overtemperature ΔT	2/3	No interlocks	
6.	Overpower ΔT	2/3	No interlocks	
7.	Pressurizer low pressure	2/3	Interlocked with P-7	Blocked below P-7
8.	Pressurizer high pressure	2/3	No interlocks	
9.	Pressurizer high water level	2/3	Interlocked with P-7	Blocked below P-7
10.	Low reactor coolant flow	a. 2/3 in 2/3 loops	Interlocked with P-7	Low flow in one loop will cause a reactor trip when above P-8 and a low flow in two loops will cause a reactor trip when above P-7; blocked below P-7
		b. 2/3 in any loop	Interlocked with P-8

List of Reactor Trips

	Reactor Trip	Coincidence Logic	Interlocks	Comments
11.	Reactor coolant pump undervoltage	2/3	Interlocked with P-7	
12.	Reactor coolant pump underfrequency	2/3	Interlocked with P-7	Underfrequency on 2 motors will trip all reactor coolant pump breakers and cause reactor trip; blocked below P-7
13.	Low feedwater flow	1/2 in any loop(1)	No interlocks	
14.	Low-Low Steam Generator Water Level	2/3 in any loop	No interlocks	
15.	Safety injection signal	Coincident with actuation of safety injection	No interlocks	(See Section 7.3 for engineered safety features actuation conditions)
16.	Turbine trip (anticipatory)			
	a. Trip fluid pressure	2/3	Interlocked with P-9	Blocked below P-9
	b. Turbine stop valve close	4/4	Interlocked with P-9	Blocked below P-9
17.	Manual	1/2	No interlocks	

(1) 1/2 steam/feedwater flow mismatch in coincidence with 1/2 low steam generator water level.

Table 7.2-2
Protection System Interlocks

I. POWER ESCALATION PERMISSIVES

Designation	Derivation	Function
P-6	Presence of P-6: 1/2 neutron flux (intermediate range) above setpoint	Allows manual block of source range reactor trip
	Absence of P-6: 2/2 neutron flux (intermediate range) below setpoint	Defeats the block of source range reactor trip
P-10	Presence of P-10: 2/4 neutron flux (power range) above setpoint	Allows manual block of power range (low setpoint) reactor trip
		Allows manual block of intermediate range reactor trip and intermediate range rod stops (C-1)
		Blocks source range reactor trip (backup for P-6)
	Absence of P-10: 3/4 neutron flux (power range) below setpoint	Defeats the block of power range (low setpoint) reactor trip
		Defeats the block of intermediate range reactor trip and intermediate range rod stops (C-1)
		Input to P-7

Table 7.2-2 (continued)
Protection System Interlocks

II. BLOCKS OF REACTOR TRIPS

Designation	Derivation	Function
P-7	Absence of P-7: 3/4 neutron flux (power range) below setpoint (from P-10)	Blocks reactor trip on: Low reactor coolant flow in more than one loop, undervoltage, underfrequency, pressurizer low pressure, and pressurizer high level
	and	
	2/2 turbine first stage pressure below setpoint (from P-13)	
P-8	Absence of P-8: 3/4 neutron flux (power range) below setpoint	Blocks reactor trip on low reactor coolant flow in a single loop
P-9	Absence of P-9: 3/4 neutron flux (power range) below setpoint	Blocks reactor trip on turbine trip
P-13	2/2 turbine first stage pressure below setpoint	Input to P-7

7.3 ENGINEERED SAFETY FEATURES ACTUATION SYSTEM

In addition to the requirements for a reactor trip for anticipated abnormal transients, the facility is provided with adequate instrumentation and controls to sense accident situations and initiate the operation of necessary engineered safety features. The occurrence of a limiting fault, such as a loss of coolant accident or a steam line break, requires a reactor trip plus actuation of one or more of the engineered safety features in order to prevent or mitigate damage to the core and Reactor Coolant System components, and ensure containment integrity.

In order to accomplish these design objectives the Engineered Safety Features System has proper and timely initiating signals which are to be supplied by the sensors, transmitters and logic components making up the various instrumentation channels of the Engineered Safety Features Actuation System.

7.3.1 Description

The Engineered Safety Features Actuation System uses selected plant parameters, determines whether or not predetermined safety limits are being exceeded and, if they are, combines the signals into logic matrices sensitive to combinations indicative of primary or secondary system boundary ruptures (Condition III or IV faults). Once the required logic combination is completed, the system sends actuation signals to the appropriate engineered safety features components. The Engineered Safety Features Actuation System meets the requirements of Criteria 13, 20, 27, 28, and 38 of the 1971 General Design Criteria (GDC).

7.3.1.1 System Description

The Engineered Safety Features Actuation System is a functionally defined system described in this section. The equipment which provides the actuation functions identified in Section 7.3.1.1.1 is listed below and discussed in this section and the references.

1. Process Instrumentation and Control System (Reference 1).
2. Solid-State Logic Protection System (Reference 2).
3. Engineered safety features test cabinet (Reference 3).
4. Engineered safety features loading sequence control panels.
5. Manual actuation circuits.

The Engineered Safety Features Actuation System consists of 2 discrete portions of circuitry: 1) An analog portion consisting of 3 to 4 redundant channels per parameter or variable to monitor various plant parameters such as the Reactor Coolant System and steam system pressures, temperatures and flows and Reactor Building pressures; and 2) a digital portion consisting of 2 redundant logic trains which receive inputs from the analog protection channels and perform the logic needed to actuate the engineered safety features. Each digital train is capable of actuating the engineered safety features equipment required. The intent is that any single failure within the Engineered Safety Features Actuation System shall not prevent system action when required.

The redundant concept is applied to both the analog and logic portions of the system. Separation of redundant analog channels begins at the process sensors and is maintained in the field wiring, containment penetrations and analog protection racks terminating at the redundant safeguards logic racks. The design meets the requirements of Criteria 20, 21, 22, 23, and 24 of the 1971 GDC.

The variables are sensed by the analog circuitry as discussed in Reference 1 and in Section 7.2. The outputs from the analog channels are combined into actuation logic as shown on Figure 7.2-1, Sheets 5, 6, 7, and 8. Tables 7.3-1 and 7.3-2 give additional information pertaining to logic and function.

The interlocks associated with the Engineered Safety Features Actuation System are outlined in Table 7.3-3. These interlocks satisfy the functional requirements discussed in Section 7.1.2.

Manual actuation from the control board of both trains of containment isolation Phase A is provided by operation of either one of the redundant momentary containment isolation Phase A controls. Also on the control board is manual actuation of safety injection by one of the redundant controls and a manual activation of containment isolation Phase B by either of 2 sets of controls. Each set consists of 2 switches which also actuate reactor building spray.

Manual controls are also provided to supplement the semi-automatic switchover from the injection to the recirculation phase after a loss of coolant accident.

7.3.1.1.1 Function Initiation

The specific functions which rely on the Engineered Safety Features Actuation System for initiation are:

1. A reactor trip, provided one has not already been generated by the Reactor Trip System.
2. Cold leg injection isolation valves which are opened for injection of borated water by charging pumps into the cold legs of the Reactor Coolant System.
3. Charging pumps and associated valving which provide emergency makeup water to the cold legs of the Reactor Coolant System following a loss of coolant accident.
4. Phase A containment isolation, whose function is to prevent fission product release. (Isolation of all lines not essential to reactor protection.)
5. Steam line isolation to prevent the continuous, uncontrolled blowdown of more than one steam generator and thereby uncontrolled Reactor Coolant System cooldown.
6. Main feedwater line isolation to prevent or mitigate the effect of excessive cooldown.
7. Start the emergency diesels to assure backup supply of power to emergency and supporting systems components.
8. Isolate the control room intake ducts to meet control room occupancy requirements following a loss of coolant accident.

9. Reactor building spray actuation which performs the following functions:
    a. Initiates reactor building spray to reduce reactor building pressure and temperature following a loss of coolant or steam line break accident inside the Reactor Building. Iodine removal benefits are also obtained from reactor building spray following a loss of coolant accident.
    b. Initiates Phase B containment isolation which isolates the Reactor Building following a loss of reactor coolant accident, or a steam or feedwater line break within the Reactor Building to limit radioactive releases. (Phase B isolation together with Phase A isolation results in isolation of all but engineered safety features lines penetrating the Reactor Building.)
10. Initiates the engineered safety features loading sequence (ESFLS) which provides timing in order to load the buses at predetermined intervals, avoiding overload conditions on the associated bus. In addition, the engineered safety features loading sequence provides for tripping and blocking of loads. The engineered safety features loading sequence initiates the following functions:
    a. Those pumps which serve as part of the heat sink for Reactor Building cooling (i.e., service water) and associated supporting systems, such as component cooling water pumps and chilled water pumps.
    b. Motor driven emergency feedwater pumps.
    c. Residual heat removal pumps.
    d. Reactor building cooling units (recirculation fans and filtration system) which cool the Reactor Building and limit the potential for release of fission products from the Reactor Building by reducing pressure following an accident.
    e. Trip and lockout of non-engineered safety features loads.

7.3.1.1.2 Analog Circuitry

The process analog sensors and racks for the Engineered Safety Features Actuation System are covered in Reference 1. Discussed in this report are the parameters to be measured including pressures, flows, tank and vessel water levels, and temperatures as well as the measurement and signal transmission considerations. These latter considerations include the transmitters, orifices and flow elements, resistance temperature detectors, as well as automatic calculations, signal conditioning and location and mounting of the devices.

The sensors monitoring the primary system are located as shown on the piping flow diagrams in Chapter 5. The secondary system sensor locations are shown on the steam system flow diagrams given in Chapter 10.

Reactor Building pressure is sensed by 4 physically separated differential pressure transmitters mounted and supported outside of the Reactor Building. These transmitters, meeting Class 1E seismic criteria regarding mounting, are connected to the Reactor Building atmosphere by a filled transmission system. The distance from penetration to transmitter is kept to a minimum, and

separation is maintained. This arrangement, together with the pressure sensors external to the Reactor Building, meets the double barrier requirements of General Design Criteria-56 and Regulatory Guide 1.11.

Pumps and valves which are an integral part of, or associated with the engineered safeguards (used for injection, reactor building spray and recirculation) will have an operation/position status light.

Engineered safety features remote operated valves have position indication on the control board in 2 places to show proper positioning of the valves. Red and green indicator lights are located next to the manual control station showing open and closed positions. The engineered safety features (safety injection) positions of these valves are displayed by an energized bright light on the monitor light panels, which consist of an array of white lights which are dim when the valves are in their normal or required positions for power operations. The monitor lights for automatically actuated valves are energized when the valve is in the automatically actuated position. These monitor lights thus enable the operator to quickly assess the status of the Engineered Safety Features Systems. These indications are derived from contacts integral to the valve operators. The circuits for the engineered safety features monitor lights and red/green lights are classified as associated circuits and have electrical and physical separation. In the cases of the accumulator isolation valves, redundancy of position indication is provided by valve stem mounted limit switches which actuate annunciators on the control board when the valves are not correctly positioned for engineered safety features actuation. The stem mounted switches for the accumulator isolation valves are independent of the limit switches in the motor operators.

7.3.1.1.3 Digital Circuitry

The engineered safety features logic racks are discussed in detail in Reference 2. The description includes the considerations and provisions for physical and electrical separation as well as details of the circuitry. Reference 2 also covers certain aspects of online test provisions, provisions for test points, considerations for the instrument power source, considerations for accomplishing physical separation. The outputs from the analog channels are combined into actuation logic as shown on Sheets 5, 6, 7, 8, and 14 of Figure 7.2-1.

To facilitate engineered safety features actuation testing, 2 test cabinets (1 per train) are provided which enable operation, to the maximum practical extent, of safety features loads on a group by group basis until actuation of all devices has been checked (see Reference 3). Final actuation testing is discussed in detail in Section 7.3.2.

Separation and redundancy requirements are satisfied for the engineered safety features loading sequence by the provision of 2 independent engineered safety features load sequencer control panels. These physically separate control panels, located in the relay room, each consist of a logic output relay cabinet.

7.3.1.1.4 Final Actuation Circuitry

The outputs of the Solid-State Logic Protection System (the slave relays) are energized to actuate. These devices are listed as follows:

1. Safety Injection System pump and valve actuators. See Chapter 6 for flow diagrams and additional information.
2. Containment isolation (Phase A - “T” signal isolates all nonessential process lines on receipt of safety injection signal; Phase B - “P” signal isolates remaining process lines (which do not include engineered safety features lines) on receipt of 2/4 Hi-3 containment pressure signal). For further information, see Section 6.2.4.
3. Diesel start (see Chapter 8).
4. Feedwater isolation (see Chapter 10).
5. Ventilation isolation valve and damper actuators (see Chapter 6).
6. Steam line isolation valve actuators (see Chapter 10).
7. Reactor Building spray pump and valve actuators (see Chapter 6).
8. Engineered safety features loading sequence (see Section 7.3.1.1.5).

If an accident is assumed to occur coincident with a loss of offsite power, the engineered safety features loads must be sequenced onto the diesel generators to prevent overloading them. This sequence is discussed in Chapter 8. The design meets the requirements of Criterion 35 of the 1971 General Design Criteria.

7.3.1.1.5 Engineered Safety Features Loading Sequence Control Panels

The ESFLS automatically loads engineered safety features components to the ESF buses under the following conditions:

a. Loss of offsite power or degradation of voltage. Safety injection.
b. Safety injection.
c. Safety injection coincident with loss of offsite power or degradation of voltage.

The loss of offsite power or degradation of voltage considered here is related to the engineered safety features buses (7.2 V buses 1DA and/or 1DB). Loss of voltage is detected on either bus by 3/3 loss of voltage relays. Degraded voltage is detected on either bus by 3/3 degraded voltage relays. The safety injection signal is generated by the Solid-State Protection System. To assure component operation under the various initiating conditions, 2 initiating sequences are provided. These sequences are a “blackout sequence,” which loads the components needed to shut down the plant in the event of a loss of power or degraded voltage, and a “safety injection sequence,” which loads the components needed to mitigate the consequences of design bases accidents occurring coincident with a loss of offsite power or degradation of voltage.

The initiation of engineered safety features loads following safety injection with engineered safety features bus power available utilizes the same “safety injection sequence” identified above. Use of the loading sequencer during conditions when ESF bus power is available provides the following benefits:

1. Enhanced reliability due to a simplified logic for component actuation.
2. Improved online testing capability.

As discussed in Section 8.3, each 7.2 kV engineered safety features bus is fed from both the normal (offsite) and emergency (onsite) supplies and each engineered safety features bus is provided with loss of voltage and degraded voltage relays. This arrangement enables operation of the engineered safety features logic sequence independent of the source (offsite or onsite) of power.

When initiated, the sequencer provides timing to load the buses at 5 second intervals. Order of loading is determined by system requirements, design capabilities of the diesel and the type of incident or accident, as evaluated by the engineered safety features logic sequence logic circuitry (see Figure 7.3-1 and Section 8.3). In addition, the sequencer provides for tripping and blocking of loads. The engineered safety features logic sequence is located in the relay room and indication is provided on the main control board. It provides the operator with information on the progress of the loading sequence and consists of internal logic circuits and output relays (the relays are located in a cabinet in the relay room). The output of these relays actuates the required safety-related equipment.

Each engineered safety features loading sequence consists of the following components:

1. Logic circuits, located in the logic section of the control cabinet.
2. Indication, located on the monitor section of the control cabinet and on section XCP-6117 of the main control board. The indication on the main control board provides the operator with information necessary for evaluation of progress of the loading sequence.
3. Output relays, located in the relay cabinet, to provide multiple contacts for the various functions.

7.3.1.1.6 Support Systems

The following systems are required for support of the engineered safety features:

1. Service Water - Heat Removal (see Chapter 9).
2. Component Cooling Water Systems - Heat Removal (see Chapter 9).
3. Chilled Water System - Heat Removal (see Chapter 9).
4. Class 1E Electrical Power Distribution Systems (see Chapter 8).
5. Other Heating, Ventilating and Air Conditioning Systems (see Section 9.4.5).

7.3.1.2 Design Bases Information

The functional diagrams presented in Figure 7.2-1, Sheets 5, 6, 7, and 8 provide a graphic outline of the functional logic associated with requirements for the Engineered Safety Features Actuation System. Requirements for the Engineered Safety Features System are given in Chapter 6. Given below is the design bases information required in IEEE Standard 279-1971, Reference 4.

7.3.1.2.1 Generating Station Conditions

The following is a summary of those generating station conditions requiring protective action:

1. Primary System
   a. Rupture in small pipes or cracks in large pipes.
   b. Rupture of a reactor coolant pipe (loss of coolant accident).
   c. Steam generator tube rupture.
2. Secondary System
   a. Minor secondary system pipe breaks resulting in steam release rates equivalent to a single dump, relief, or safety valve.
   b. Rupture of a major steam pipe.

7.3.1.2.2 Generating Station Variables

The following list summarizes the generating station variables required to be monitored for the automatic initiation of safety injection during each accident identified in the preceding section. Post accident monitoring requirements are described in the VCSNS Environmental Qualification/Reg. Guide 1.97 Design Basis Document.

1. Primary System Accidents
   a. Pressurizer pressure.
   b. Reactor Building pressure (not required for steam generator tube rupture).
2. Secondary System Accidents
   a. Pressurizer pressure.
   b. Steam line pressures.
   c. Reactor Building pressure (steam or feedwater line break inside reactor building).
   d. Steam line differential pressure.

7.3.1.2.3 Spatially Dependent Variables

The only variable sensed by the Engineered Safety Features Actuation System which has spatial dependence is reactor coolant temperature. The effect on the measurement is negated by taking

multiple samples from the reactor coolant hot leg and averaging these samples by mixing in the resistance temperature detector bypass loop.

7.3.1.2.4 Limits, Margins, and Levels

Prudent operational limits, available margins, and setpoints before onset of unsafe conditions requiring protective action are discussed in Chapter 15 and the Technical Specifications.

7.3.1.2.5 Abnormal Events

The malfunctions, accidents, or other unusual events which could physically damage protection system components or could cause environmental changes are as follows:

1. Loss of coolant accident (see Sections 15.3 and 15.4).
2. Steam line breaks (see Sections 15.3 and 15.4).
3. Earthquakes (see Chapters 2 and 3).
4. Fire (see Section 9.5.1).
5. Explosion (Hydrogen buildup inside the Reactor Building) (see Section 15.4).
6. Missiles (see Section 3.5).
7. Flood (see Chapters 2 and 3).

7.3.1.2.6 Minimum Performance Requirements

Minimum performance requirements are as follows:

1. System Response Times

   The Engineered Safety Features Actuation System response time is defined as the interval required for the engineered safety features sequence to be initiated subsequent to the point in time that the appropriate variable(s) exceed setpoints. The response time includes sensor/process (analog) and logic (digital) delay plus, the time delay associated with tripping open the reactor trip breakers and control and latching mechanisms. The values listed herein are maximum allowable times consistent with the safety analyses and are systematically verified during plant preoperational startup tests. These maximum delay times thus include all compensation and therefore require that any such network be aligned and operating during verification testing.

   The Engineered Safety Features Actuation System is always capable of having response time tests performed using the same methods as those tests performed during the preoperational test program or following significant component changes.

   System response times for loss of coolant protection are:

a. Pressurizer pressure -1.0 second

b. Reactor building pressure - 1.5 seconds

Maximum allowable time delays in generating the actuation signal for steam break protection are given in Table 7.3-4.

2. System Accuracies

Accuracies required for generating the required actuation signals for loss of coolant protection are given in Table 7.3-5.

3. Ranges of sensed variables to be accommodated until conclusion of protective action is assured are given in Table 7.3-5.

7.3.1.3 Final System Drawings

The schematic diagrams for the systems discussed in this section are discussed in Section 1.7.

7.3.2 Analysis

7.3.2.1 Failure Mode and Effects Analyses

Failure mode and effects analyses have been performed on Engineered Safety Features Systems (ESFS) equipment within the scope of Westinghouse. The results verify that these systems meet protection single failure criteria as required by IEEE Standard 279-1971 and the Virgil C. Summer Nuclear Station (Engineered Safety Features Systems) equipment is designed to equivalent safety design criteria. The actuation of the Virgil C. Summer Nuclear Station Engineered Safety Features Systems is functionally the same as the systems studied in these analyses.

The failure mode and effects analysis (FMEA) which was performed on engineered safety features engineered safety features equipment within the scope of Westinghouse was for a typical Westinghouse Engineered Safety Features Actuation System (ESFAS). (See Reference [5]). The analysis has generic application to all Westinghouse Engineered Safety Features Actuation Systems of the Virgil C. Summer Nuclear Station vintage. The conclusion is that the analysis (1) qualitatively demonstrates the reliability of the Engineered Safety Features Actuation System to perform its intended function and (2) shows that the Engineered Safety Features Actuation System does comply with the single failure criterion, because no single failure was found which could prevent the Engineered Safety Features Actuation System from generating the proper actuation signal on demand for an engineered safety feature. Random single failures are either in a safe direction or a redundant channel or train ensures the necessary actuation capability.

The basis of a failure mode and effects analysis is principally that single failures are detectable, identifiable, and random. They are not systematic (common mode). The systematic failure considerations applied to equipment hardware, as well as actuation functions, are addressed elsewhere in the final safety analysis report, such as:

1. Seismic qualification of Seismic Category 1 instrumentation and electrical equipment (Section 3.10). This conforms to Section 4.7.4.2 of IEEE 279-1971.
2. Environmental design of mechanical and electrical equipment (Section 3.11). This conforms to Section 4.7.4.2 of IEEE 279-1971.
3. The Nuclear Instrumentation System, the Solid State Protection System, and the 7300 Series Process Control System noise tests (See Section 7.2.2.2.3.7 and Reference 5 in Section 7.2.4).
4. Manual initiation of protective actions (See Section 7.3.2.2.7).

7.3.2.2 Compliance With Standards and Design Criteria

Discussion of the General Design Criteria (GDC) is provided in various sections of Chapter 7 where a particular General Design Criteria is applicable. Applicable General Design Criteria include Criteria 13, 20, 21, 22, 23, 24, 25, 27, 28, 35, 37, 38, 40, 43, and 46 of the 1971 General Design Criteria. Compliance with certain IEEE Standards is presented in Sections 7.1.2.7, 7.1.2.9, 7.1.2.10, and 7.1.2.11. The discussion given below shows that the Engineered Safety Features Actuation System complies with IEEE Standard 279-1971, Reference 4. For the list of references to the discussions of conformance to applicable criteria, see Table 7.1-1.

Table 7.3-6 outlines the degree of conformance of the engineered safety features loading sequence control panels to Regulatory Guide 1.53 and IEEE Standard 379-1972, Reference 5.

7.3.2.2.1 Single Failure Criteria

The discussion presented in Section 7.2.2.2.3 is applicable to the Engineered Safety Features Actuation System, with the following exception.

In the engineered safety features, a loss of instrument power will call for actuation of engineered safety features equipment controlled by the specific bistable that lost power (Reactor Building spray excepted). The actuated equipment must have power to comply. The power supply for the protection systems is discussed in Section 7.6 and in Chapter 8. For Reactor Building spray, the final bistables are energized to trip to avoid spurious actuation. In addition, manual Reactor Building spray requires a simultaneous actuation of 2 manual controls. This is considered acceptable because spray actuation on Hi-3 Reactor Building pressure signal provides automatic initiation of the system via protection channels meeting the criteria in Reference 4. Moreover, 2 sets (2 switches per set) of Reactor Building spray manual initiation switches are provided to meet the requirements of IEEE Standard 279-1971. Also it is possible for all engineered safety features equipment (valves, pumps, etc.) to be individually manually actuated from the control board. Hence, a third mode of Reactor Building spray initiation is available. The design meets the requirements of Criteria 21 and 23 of the 1971 General Design Criteria.

7.3.2.2.2 Equipment Qualification

Equipment qualifications are discussed in Sections 3.10 and 3.11.

7.3.2.2.3 Channel Independence

The discussion presented in Section 7.2.2.2.3 is applicable. The engineered safety features slave relay outputs from the solid-state logic protection cabinets are redundant, and the actuations associated with each train are energized up to and including the final actuators by the separate a-c power supplies which power the logic trains.

7.3.2.2.4 Control and Protection System Interaction

The discussions presented in Section 7.2.2.2.3 are applicable.

7.3.2.2.5 Capability for Sensor Checks and Equipment Test and Calibration

The discussions of system testability in Section 7.2.2.2.3 are applicable to the sensors, analog circuitry, and logic trains of the Engineered Safety Features Actuation System.

The following discussions cover those areas in which the testing provisions differ from those for the Reactor Trip System.

7.3.2.2.5.1 Testing of Engineered Safety Features Actuation Systems

The Engineered Safety Features Systems are tested to provide assurance that the systems will operate as designed and will be available to function properly in the unlikely event of an accident. The testing program meets the requirements of Criteria 21, 37, 40, and 43 of the 1971 General Design Criteria and requirements on testing of the Emergency Core Cooling System as stated in General Design Criteria-37 except for the operation of those components that will cause an adverse effect to the safety or operability of the plant per Regulatory Guide 1.22 as discussed in Section 7.1.2.5. The tests described in Section 7.2.2.2.3 and further discussed in Section 6.3.4 meet the actual safety injection. The test, as described, demonstrates the performance of the full operational sequence that brings the system into operation, the transfer between normal and emergency power sources and the operation of associated cooling water systems. The charging pumps and residual heat removal pumps are started and operated and their performance verified in a separate test discussed in Section 6.3.4. When the pump tests are considered in conjunction with the Emergency Core Cooling System test, the requirements of General Design Criteria-37 on testing of the Emergency Core Cooling System are met as close as possible without causing an actual safety injection.

Testing as described in Sections 6.3.4, 7.2.2.2.3, and 7.3.2.2.5 provides complete periodic testability during reactor operation of all logic and components associated with the Emergency Core Cooling System.

This design meets the requirements of Regulatory Guide 1.22 as discussed in the above sections. The program is as follows:

1. Prior to initial plant operations, Engineered Safety Features System tests will be conducted.

2. Subsequent to initial startup, Engineered Safety Features System tests will be conducted during each regularly scheduled refueling outage.
3. During online operation of the reactor, engineered safety features analog and logic circuitry will be fully tested. In addition, essentially all of the engineered safety features final actuators will be fully tested. The remaining few final actuators whose operation is not compatible with continued online plant operation will be checked by means of continuity testing.

7.3.2.2.5.2 Performance Test Acceptability Standard for the “S” (Safety Injection Signal) and for the “P” (the Automatic Demand Signal for Reactor Building Spray Actuation) Actuation Signals Generation

During reactor operation the basis for Engineered Safety Features Actuation Systems acceptability will be the successful completion of the overlapping tests performed on the initiating system and the Engineered Safety Features Actuation System, see Figure 7.3-2. Checks of process indications verify operability of the sensors. Analog checks and tests verify the operability of the analog circuitry from the input of these circuits through to and including the logic input relays except for the input relays associated with the Reactor Building spray function which are tested during the solid-state logic testing. Solid-State logic testing also checks the digital signal path from and including logic input relay contacts through the logic matrices and master relays and performs continuity tests on the coils of the output slave relays; final actuator testing operates the output slave relays and verifies operability of those devices which require safeguards actuation and which can be tested without causing plant upset. A continuity check is performed on the actuators of the untestable devices. Operation of the final devices is confirmed by control board indication and visual observation that the appropriate pump breakers close and automatic valves shall have completed their travel.

The basis for acceptability for the engineered safety features interlocks will be control board indication of proper receipt of the signal upon introducing the required input at the appropriate setpoint.

Routine periodic inspections of the ESF equipment and performance acceptability testing of the “S” (Safety Injection Signal) and of the “P” (Automatic Demand Signal for Reactor Building Spray Actuation) are consistent with inspections and tests of the NSSS Electrical Equipment Section 3.11.2.2.1 and the Technical Specifications.

7.3.2.2.5.3 Frequency of Performance of Engineered Safety Features Actuation Tests

During reactor operation, complete system testing (excluding sensors or those devices whose operation would cause plant upset) is performed on a periodic basis. Testing, including the sensors, is also performed during scheduled plant shutdown for refueling.

7.3.2.2.5.4 Engineered Safety Features Actuation Test Description

The following sections describe the testing circuitry and procedures for the online portion of the testing program. The guidelines used in developing the circuitry and procedures are:

1. The test procedures must not involve the potential for damage to any plant equipment.
2. The test procedures must minimize the potential for accidental tripping.
3. The provisions for online testing must minimize complication of engineered safety features actuation circuits so that their reliability is not degraded.

7.3.2.2.5.5 Description of Initiation Circuitry

Several systems comprise the total Engineered Safety Features System, the majority of which may be initiated by different process conditions and be reset independently of each other.

The remaining functions (listed in Section 7.3.1.1.1) are initiated by a common signal (safety injection) which in turn may be generated by different process conditions.

In addition, operation of all other vital auxiliary support systems, such as Emergency Feedwater, Component Cooling Water, Service Water, and Heating, Ventilating and Air Conditioning Systems listed in Section 9.4.5, is initiated by the safety injection signal.

Each function is actuated by a logic circuit which is duplicated for each of the 2 redundant trains of engineered safety features initiation circuits.

The output of each of the initiation circuits consists of a master relay which drives slave relays for contact multiplication as required. The logic, master, and slave relays are mounted in the solid-state logic protection cabinets designated Train A, and Train B, respectively, for the redundant counterparts. The master and slave relay circuits operate various pump and fan circuit breakers or starters, motor operated valve contactors, solenoid operated valves, emergency generator starting, etc.

7.3.2.2.5.6 Analog Testing

Analog testing is identical to that used for reactor trip circuitry and is described in Section 7.2.2.2.3.

An exception to this is Reactor Building spray, which is energized to actuate 2/4 and reverts to 2/3 when 1 channel is in test.

7.3.2.2.5.7 Solid-State Logic Testing

Except for Reactor Building spray channels; solid-state logic testing is the same as that discussed in Section 7.2.2.2.3. During logic testing of 1 train, the other train can initiate the required engineered safety features function. For additional details, see Reference 2.

7.3.2.2.5.8 Actuator Testing

At this point, testing of the initiation circuits through operation of the master relay and its contacts to the coils of the slave relays has been accomplished. Slave relays (K601, K602, etc.) do not operate because of reduced voltage.

The Engineered Safety Features Actuation System final actuation device or actuated equipment testing shall be performed from the engineered safety features test cabinets. These cabinets are normally located near the Solid-State Logic Protection System equipment. There is 1 test cabinet provided for each of the 2 protection Trains “A” and “B”. Each cabinet contains individual test switches necessary to actuate the slave relays. To prevent accidental actuation, test switches are of the type that must be rotated and then depressed to operate the slave relays. Assignments of contacts of the slave relays for actuation of various final devices or actuators have been made such that groups of devices or actuated equipment, can be operated individually during plant operation without causing plant upset or equipment damage. In the unlikely event that a safety injection signal is initiated during the test of the final device that is actuated by this test, the device will already be in its engineered safety feature position.

During this last procedure, close communication between the Control Room operator and the operator at the test panel is required. Prior to the energizing of a slave relay, the operator in the Control Room assures that plant conditions will permit operation of the equipment that will be actuated by the relay. After the tester has energized the slave relay, the Control Room operator observes that all equipment has operated as indicated by appropriate indicating lamps, monitor lamps and annunciators on the control board and, using a prepared check list, records all operations. After proper operation is verified, the test switch is reset at the test panel and each device is returned to its desired mode from the control board.

By means of the procedures outlined above, all engineered safety features devices actuated by engineered safety features actuation systems initiation circuits, with the exceptions noted in Section 7.1.2.5 under a discussion of Regulatory Guide 1.22 are operated by the automatic circuitry.

7.3.2.2.5.9 Actuator Blocking and Continuity Test Circuits

Those few final actuation devices that cannot be designed to be actuated during plant operation (discussed in Section 7.1.2.5) have been assigned to slave relays for which additional test circuitry has been provided to individually block actuation of a final device upon operation of the associated slave relay during testing. Operation of these slave relays, including contact operations, and continuity of the electrical circuits associated with the final devices’ control are checked in lieu of actual operation. The circuits provide for monitoring of the slave relay contacts, the devices’ control circuit cabling, control voltage and the devices’ actuation relay coils, solenoids, etc. Interlocking prevents blocking the output from more than 1 output relay in a protection train at a time. Interlocking between trains is also provided to prevent continuity testing in both trains simultaneously, therefore the redundant device associated with the protection train not under test will be available in the event protection action is required. If an accident occurs during testing, the automatic actuation circuitry will override testing as noted above. One (1)

exception to this is that if the accident occurs while testing a slave relay whose output must be blocked, those few final actuation devices associated with this slave relay will not be overridden; however, the redundant devices in the other train would be operational and would perform the required safety function. Actuation devices to be blocked are identified in Section 7.1.2.5.

The continuity test circuits for these components that cannot be actuated online are verified by proving lights on the engineered safety features test racks.

The typical schemes for blocking operation of selected engineered safety features function actuator circuits are shown in Figure 7.3-3 as details A and B. The schemes operate as explained below and are duplicated for each engineered safety features train.

Detail A shows the circuit for contact closure for protection function actuation. Under normal plant operation, and equipment not under test, the test lamps “DS *” for the various circuits will be energized. Typical circuit path will be through the normally closed test relay contact “K *” and through test lamp connections 1 to 3. Coils “X1” and “X” will be capable of being energized for protection function actuation upon closure of solid-state logic output relay contacts “K *”. Coil “X1” or “X” is typical for a breaker closing auxiliary coil, motor starter master coil, coil of a solenoid valve, auxiliary relay, etc. When the contacts “K *” are opened to block energizing of coil “X1” and “X2”, the white lamp is de-energized, and the slave relay “K *” may be energized to perform continuity testing. To verify operability of the blocking relay in both blocking and restoring normal service, open the blocking relay contact in series with lamp connections - the test lamp should be de-energized; close the blocking relay contact in series with the lamp connections - the test lamp should now be energized, which verifies that the circuit is now in its normal, i.e., operable condition.

Detail B shows the circuit for contact opening for protection function actuation. Under normal plant operation, and equipment not under test, and white test lamps “DS *” for the various circuits will be energized, and green test lamp “DS *” will be de-energized. Typical circuit path for white lamp “DS *” will be through the normally closed solid-state logic output relay contact “K *” and through test lamp connections 1 to 3. Coils “Y1” and “Y2” will be capable of being de-energized for protection function actuation upon opening of solid-state logic output relay contacts “K *”. Coil “Y2” is typical for a solenoid valve coil, auxiliary relay, etc. When the contacts “K8 *” are closed to block de-energizing of coils “Y1” and “Y2”, the green test lamp is energized, and the slave relay “K *” may be energized to verify operation (opening of its contacts). To verify operability of the blocking relay in both blocking and restoring normal service, close the blocking relay contact to the green lamp - the green test lamp should now be energized also; open this blocking relay contact - the green test lamp should be de-energized, which verifies that the circuit is now in its normal, i.e., operable condition.

7.3.2.2.5.10

The testing provisions of the engineered safety features loading sequence control panels differ from the Engineered Safety Features Actuation System. Each engineered safety features loading sequence control panel is designed to combine automatic testing with manual testing. Continuous and periodic test features are provided to test for equipment faults (e.g., open circuits, short

circuits, inoperative timers). All system accuracy and functional requirements are maintained when automatic testing is implemented. These features are provided in accordance with IEEE-420, Section 4.7 and the following:

1. Automatic Test

   The Automatic Test Feature has 3 operating modes: Continuous, Fast, and Slow. During these modes, the Automatic Test Feature monitors the engineered safety features loading sequence and upon occurrence of an improper response will display the step number of the failed test and energize a fault relay for remote annunciator. The Continuous mode provides on-line surveillance of the engineered safety features loading sequence operation by repeatedly cycling the Automatic Test circuits through their test states and monitoring the various system outputs for appropriate responses. Operation is check from the logic input signals through the logic and counter stages and up to and including the relay driven outputs. The surveillance will not interface with system requirements nor cause an undesired relay actuation during normal system operation. The Fast mode operates in the same manner as the Continuous mode except that only 1 test cycle is performed for each operation initiated test.

   The Slow mode allows manual stepping of the Automatic Test circuits through a test cycle to observe the system response via the cabinet control panel indicators. Operation is checked from the logic input signals through the logic and counter stages, the relay driver outputs, and output relays. The Slow mode actuates the output relays thereby starting or tripping plant equipment.

   Fault detection and annunciation, local and remote, are automatic in the Continuous and Fast mode while operation interpretation of the system response is required in the Slow mode. Additionally, automatic resetting of the Automatic Test circuits, in response to a True input signal, is provided in the Continuous and Fast modes. Manual reset is required in the Slow mode.

2. Manual Test

   The Manual Test Features provide the means to verify all engineered safety features loading sequence functions locally at the cabinet control panel. Input test switches enable simulation of all inputs, including operation of the input buffer relays, in any combination or time sequence. Output test switches enable actuation of each step or output individually, including operating of the final associated solid state driver stage. Blocking switches, which allow active testing of Output 1 and Output 4 without effecting associated external loads, are also provided. Indicator lamps associated with each input, system, startup, each step and each output allow the operation to visually observe the results of all tests.

7.3.2.2.5.11 Time Required for Testing

It is estimated that analog testing can be performed at a rate of several channels per hour. Logic testing of both Trains A and B can be performed in less than 30 minutes. Testing of actuated components (including those which can only be partially tested) will be a function of control

room operator availability. It is expected to require several shifts to accomplish these tests. During this procedure automatic actuation circuitry will override testing, except for those few devices associated with a single slave relay whose outputs must be blocked and then only while blocked. It is anticipated that continuity testing associated with a blocked slave relay could take several minutes. During this time the redundant devices in the other train would be functional.

7.3.2.2.5.12 Summary of Online Testing Capabilities

The procedures described provide capability for checking completely from the process signal to the logic cabinets and from there to the individual pump and fan circuit breakers or starters, valve contactors, pilot solenoid valves, etc., including all field cabling actually used in the circuitry called upon to operate for an accident condition. For those few devices whose operation could adversely affect plant or equipment operation, the same procedure provides for checking from the process signal to the logic rack. To check the final actuation device, a continuity test of the individual control circuits is performed.

The procedures require testing at various locations.

1. Analog testing and verification of bistable setpoint are accomplished at process analog racks. Verification of bistable relay operation is done at the control board status lights.
2. Logic testing through operation of the master relays and low voltage application to slave relays is done at the logic rack test panel.
3. Testing of pumps, fans and valves is done at a test panel located in the vicinity of the logic racks in combination with the control room operator.
4. Continuity testing from those circuits that cannot be operated is done at the same test panel mentioned in item 3 above.

The reactor coolant pump essential service isolation valves consist of the isolation valves on the component cooling water and the seal water return header.

The main reason for not testing these valves periodically is that the reactor coolant pumps may be damaged. Although pump damage from this type of test would not result in a situation which endangers the health and safety of the public, it could result in unnecessary shutdown of the reactor for an extended period of time while the reactor coolant pump or certain of its parts were replaced. This would place a great economic burden on South Carolina Electric and Gas Company.

Reactor Building Spray System pump tests will be performed periodically. The pump tests will be performed with the isolation valves in the spray pump discharge lines at the Reactor Building blocked closed; the Sodium Hydroxide Storage Tank valves are also blocked closed.

7.3.2.2.5.13 Testing During Shutdown

Emergency Core Cooling System tests will be performed at each major fuel reloading with the Reactor Coolant System isolated from the Emergency Core Cooling System by closing the

appropriate valves. A test safety injection signal will then be applied to initiate operation of active components (pumps and valves) of the Emergency Core Cooling System. This is in compliance with Criterion 37 of the 1971 General Design Criteria.

7.3.2.2.5.14 Periodic Maintenance Inspection

The maintenance procedures which follow may be accomplished in any order. The frequency will depend on the operating conditions and requirements of the reactor power plant. If any degradation of equipment operation is noted, either mechanically or electrically, remedial action is taken to repair, replace, or readjust the equipment.

Typical maintenance procedures include the following:

1. Check cleanliness of all exterior and interior surfaces.
2. Inspect for loose or broken control knobs and burned-out indicator lamps.
3. Inspect for moisture and condition of cables and wiring.
4. Visually or mechanically check connectors and terminal boards for looseness, poor connection, or corrosion.
5. Inspect the components of each assembly for signs of overheating or component deterioration.
6. Perform complete system operating check.

The balance of the requirements listed in Reference 4 (paragraphs 4.11 through 4.22) are discussed inSection 7.2.2.2.3. Paragraph 4.20 receives special attention in Section 7.5.4.

7.3.2.2.6 Manual Resets and Blocking Features

The manual reset feature associated with reactor building spray actuation is provided in the standard design of the Westinghouse Solid-State Protection System design for 2 basic purposes: First, the feature permits the operator to start an interruption procedure of automatic reactor building spray in the event of false initiation of an actuation signal. Second, although spray system performance is automatic, the reset feature enables the operator to start a manual takeover of the system to handle unexpected events which can be better dealt with by operator appraisal of changing conditions following an accident.

It is most important to note that manual control of the Spray System does not occur, once actuation has begun, by just resetting the associated log devices alone. Components will seal in (latch) so that removal of the actuation signal, in itself, will neither cancel or prevent completion of protective action or provide the operator with manual override of the automatic system by this single action. In order to take complete control of the system to interrupt its automatic performance, the operator must deliberately unlatch relays which have “sealed in” the initial actuation signals in the associated motor control center, in addition to tripping the pump motor circuit breakers, if stopping the pumps is desirable or necessary.

The manual reset feature associated with reactor building spray, therefore, does not perform a bypass function. It is merely the first of several manual operations required to take control from the automatic system or interrupt its completion should such an action be considered necessary.

In event that the operator anticipates system actuation and erroneously concludes that it is undesirable or unnecessary and imposes a standing reset condition in 1 train (by operating and holding the corresponding reset switch at the time the initiate signal is transmitted) the other train will automatically carry the protective action to completion. In the event that the reset condition is imposed simultaneously in both trains at the time the initiate signals are generated, the automatic sequential completion of system action is interrupted and control has been taken by the operator. Manual takeover will be maintained, even though the reset switches are released, if the original initiate signal exists. Should the initiate signal then clear and return again, automatic system actuation will repeat.

Note also that any time delays imposed on the system action are to be applied after the initiating signals are latched. Delay of actuation signals for fluid systems lineup, load sequencing, etc., does not provide the operator time to interrupt automatic completion, with manual reset alone, as would be the case if time delay were imposed prior to sealing of the initial actuation signal.

The manual block features associated with pressurizer and steam line safety injection signals provide the operator with the means to block initiation of safety injection during plant startup. These block features meet the requirements of paragraph 4.12 of IEEE Standard 279-1971 in that automatic removal of the block occurs when plant conditions require the protection system to be functional.

Safety injection actuation on low pressurizer pressure may be manually blocked when the primary pressure falls below the P-11 setpoint. Safety injection and steamline isolation actuation on low steamline pressure may also be manually blocked below the P-12 setpoint (low-low T_{avg}). Safety injection cannot be blocked on high steam line differential pressure or high-1 containment pressure, and steam line isolation cannot be blocked on either high steam line flow coincident with low-low T_{avg} or high-2 containment pressure. Thus these signals would always be available to automatically terminate a steam line rupture during cooldown or startup.

Furthermore, during heatup and cooldown and while safety injection is blocked, the operator will be in full manual control of the plant. He will be cognizant of the plant operating conditions and the expected changes in these parameters. If a serious steam line break should occur during this time, it should be apparent to the operator so that he can take the necessary action to prevent any adverse consequences in a timely fashion.

The types of instrumentation available to the operator which would indicate that a steam line break has occurred consists of alarms and indicated values. Alarms could occur on high steam flow, low steam line pressure (SI actuation, Steamline Isolation), low-low steam generator level (reactor trip), low steam generator level, high steam line differential pressure (SI actuation), high source range nuclear flux (reactor trip), and containment pressure high-1 (SI actuation) and high-2 (steam line isolation).

The instrumentation which would be indicated on the control board consists of the above channels plus T_{avg}, pressurizer level and pressurizer pressure. Since the shutdown margin during cooldown or startup is greater than that for the case analyzed in the FSAR, there will be more time for manual action to terminate the transient. Furthermore, the steam line pressure during cooldown and startup would be such that the consequences of the steam generator blowdown would be less severe than for the hot zero power case analyzed in the Final Safety Analysis Report.

Therefore, either the protection system will automatically terminate the transient or the operator will determine soon after the incident begins that a break has occurred and will take the necessary action.

7.3.2.2.7 Manual Initiation of Protective Actions (Regulatory Guide 1.62)

There are 3 individual main steam isolation valve momentary control switches (1 per loop) mounted on the control board. Each switch when actuated, will isolate its main steam line. In addition, an independent momentary control switch, mounted on the control board, will isolate all 3 main steam lines when actuated.

Manual initiation of semi-automatic switchover to recirculation following a loss of primary coolant accident is in compliance with paragraph 4.17 of IEEE Standard 279-1971 with the following comments:

1. The manual operations that are involved in this switchover are described in Section 6.3.
2. Once safety injection is initiated following a loss of primary coolant accident, the Reactor Building sump isolation valves in the Residual Heat Removal System pump suction lines will open automatically upon receipt of a lo-lo level signal from the refueling water storage tank level instrumentation.
3. Manual initiation of either 1 of 2 redundant safety injection actuation main control board mounted switches not only provides for actuation of the components required for reactor protection and mitigation of adverse consequences of the postulated accident prior to the recirculation mode associated with a loss of primary coolant accident, but also enables the Reactor Building sump isolation valves to automatically open when the lo-lo level setpoint on the refueling water storage tank is reached.

Manual operation of other components or manual verification of proper position as part of emergency procedures is not precluded nor otherwise in conflict with the above described compliance to paragraph 4.17 of IEEE Standard 279-1971.

No exception to the requirements of IEEE Standard 279-1971 has been taken in the manual initiation circuit of safety injection. Although paragraph 4.17 of IEEE Standard 279-1971 requires that a single failure within common portions of the protective system shall not defeat the protective action by manual or automatic means, the standard does not specifically preclude the sharing of initiated circuitry logic between automatic and manual functions. It is true that the manual safety injection initiation functions associated with 1 actuation train (e.g., Train A) shares portions of the automatic initiation circuitry logic of the same logic train; however, a single failure

in shared functions does not defeat the protective action of the redundant actuation train (e.g., Train B). A single failure in shared functions does not defeat the protective action of the safety functions. It is further noted that the sharing of the logic by manual and automatic initiation is consistent with the system level action requirements of IEEE Standard 279-1971, paragraph 4.17 and consistent with the minimization of complexity.

7.3.2.3 Further Considerations

In addition to the considerations given above, a loss of instrument air or loss of component cooling water to vital equipment has been considered. Neither the loss of instrument air nor the loss of component cooling water (assuming no other accident conditions) can cause safety limits as given in the Technical Specifications to be exceeded. Likewise, loss of either 1 of the 2 will not adversely affect the core or the Reactor Coolant System nor will it prevent an orderly shutdown if this is necessary. Furthermore, all pneumatically operated valves and controls will assume a preferred operating position upon loss of instrument air. It is also noted that, for conservatism during the accident analyses (Chapter 15), credit is not taken for the instrument air systems nor for any control system benefit.

In its present design, Westinghouse does not provide any circuitry which will directly trip the reactor coolant pumps on a loss of component cooling water. Normally, indication in the control room is provided whenever component cooling water is lost. The reactor coolant pumps can run about 10 minutes after a loss of component cooling water. This provides adequate time for the operator to correct the problem or trip the plant if necessary.

In regards to the Emergency Feedwater System, there are 2 motor driven pumps and one turbine driven pump. The motor driven pumps are initiated automatically by the following signals:

1. Safety injection, through the engineered safety features load sequencer.
2. Low-low level (2/3) in any steam generator (derived from the Solid-State Protection System output cabinets).
3. Manual start.
4. Trip of all main feed pumps.
5. Undervoltage on the diesel bus.

The turbine driven pump as well as the closing of blowdown and sample valves are initiated automatically by:

1. Low-low level (2/3) in 2/3 steam generators (derived from the Solid-State Protection System output cabinets).
2. Manual start.
3. Undervoltage on both diesel buses.

To assure auto-start of the component cooling water and service water pumps on the inactive loop and to prevent diesel generator overloading on a SI/LOOP signal, the circuit breaker(s) for the out of service or spare pump/chiller for systems with swing components will be racked out.

7.3.2.4 Summary

The effectiveness of the Engineered Safety Features Actuation System is evaluated in Chapter 15, based on the ability of the system to contain the effects of Condition III and IV faults, including loss of reactor coolant and steam break accidents. The Engineered Safety Features Actuation System parameters are based upon the component performance specifications which are given by the manufacturer or verified by test for each component. Appropriate factors to account for uncertainties in the data are factored into the constants characterizing the system.

The Engineered Safety Features Actuation System must detect Condition III and IV faults and generate signals which actuate the engineered safety features. The system must sense the accident condition and generate the signal actuating the protection function reliably and within a time determined by and consistent with the accident analyses in Chapter 15.

Much longer times are associated with the actuation of the mechanical and fluid system equipment associated with engineered safety features. This includes the time required for switching, bringing pumps and other equipment to speed and the time required for them to take load.

Operating procedures require that the complete Engineered Safety Features Actuation System normally be operable. However, redundancy of system components is such that the system operability assumed for the safety analyses can still be met with certain instrumentation channels out of service. Channels that are out of service are to be placed in the tripped mode, or bypass mode in the case of Reactor Building spray.

7.3.2.4.1 Loss of Coolant Protection

By analysis of loss of coolant accident and in system tests it has been verified that (except for very small coolant system breaks, which can be protected against by the charging pumps followed by an orderly shutdown), the effects of various loss of coolant accidents are reliably detected by the low pressurizer pressure signal.

For large coolant system breaks the passive accumulators inject first, because of the rapid pressure drop. This protects the reactor during the unavoidable delay associated with actuating the active Emergency Core Cooling System phase.

High Reactor Building pressure also actuates the Emergency Core Cooling System. Therefore, emergency core cooling actuation can be brought about by sensing this other direct consequence of a primary system break; that is the Engineered Safety Features Actuation System detects the leakage of the coolant into the Reactor Building. The generation time of the actuation signal of about 1.5 seconds, after detection of the consequences of the accident, is adequate.

Reactor Building spray will provide additional emergency cooling of the Reactor Building and also limit fission product release upon sensing elevated Reactor Building pressure (Hi-3) to mitigate the effects of a loss of coolant accident.

The delay time between detection of the accident condition and the generation of the actuation signal for these systems is assumed to be about 1.0 second; well within the capability of the protection system equipment. However, this time is short compared to that required for startup of the fluid systems.

The analyses in Chapter 15 show that the diverse methods of detecting the accident condition and the time for generation of the signals by the protection systems are adequate to provide reliable and timely protection against the effects of loss of coolant.

7.3.2.4.2 Steam Line Break Protection

The Emergency Core Cooling System is also actuated in order to protect against a steam line break. Table 7.3.4 gives the time between sensing high steam line differential pressure or low steam line pressure and generation of the actuation signal. Analysis of steam line break accidents, assuming this delay for signal generation, shows that safety injection is actuated for a steam line break in time to limit or prevent further core damage for steam break cases. There is a reactor trip and the core reactivity is further reduced by the borated water injected by the Emergency Core Cooling System.

Additional protection against the effects of steam line break is provided by feedwater isolation which occurs upon actuation of the Emergency Core Cooling System. Feedwater isolation is initiated in order to prevent excessive cooldown of the reactor vessel and thus protect the Reactor Coolant System boundary.

Additional protection against a steam line break accident is provided by closure of all steam line isolation valves in order to prevent uncontrolled blowdown of all steam generators. The time for generation of the protection system signal (about 2.0 seconds) is again short compared to the time to trip the fast acting steam line isolation valves which are designed to close in less than approximately 5 seconds.

In addition to actuation of the engineered safety features, the effect of a steam line break accident also generates a signal resulting in a reactor trip on overpower or following Emergency Core Cooling System actuation. The core activity is further reduced by the Emergency Core Cooling System.

The analyses in Chapter 15 of the steam line break accidents and an evaluation of the protection system instrumentation and channel design shows that the Engineered Safety Features Actuation Systems are effective in preventing or mitigating the effects of a steam line break accident.

7.3.3 Electric Hydrogen Recombiner-Description of Instrumentation

The Electric Hydrogen Recombiner System is discussed in Section 6.2.5. Two (2) redundant recombiners, which are located inside the Reactor Building, do not require any instrumentation inside the Reactor Building for proper operation after a loss of coolant accident (LOCA). Thermocouples are provided for convenience in test and periodic checkout of the recombiner; however, they are not considered necessary to assure proper operation of the recombiner.

There are provided for each recombiner a control panel and a power supply panel which are located outside the Reactor Building, as shown on Figure 6.2.54 and Figure 6.2-58. The power supply panel contains an isolation transformer plus a controller to regulate power into the recombiners. The manually operated potentiometer for this controller is on the control panel. For equipment test and periodic checkout, a thermocouple readout instrument is also provided on the control panel for monitoring temperatures in the recombiner. To control the recombination process, the correct power input which will bring the recombiner above the threshold temperature for recombination will be set on the controller. Setting of the controller is accomplished at the local control panel and power input monitored by a wattmeter, which is also mounted on the control panel. This predetermined power setting will cover variations in Reactor Building pressure and hydrogen concentration in the post-loss of coolant accident environment. The manually operated switch for energizing a recombiner is on the control panel.

7.3.3.1 Initiating Circuits

The Hydrogen Recombiner System would be operated only during periodic testing and after a loss-of-coolant accident. Operation is initiated manually from the control station, so as to allow the heating elements within the unit to be energized. A 2 position switch is provided on the control panel for this purpose.

7.3.3.2 Logic

All operation of the electric hydrogen recombiner is by operator action; there are no automatic logic functions required. A post accident hydrogen analyzer will be used to indicate when the recombiners or the venting system should be actuated.

7.3.3.3 Bypasses

The electric hydrogen recombiners are normally not operating and are not armed for automatic actuation. Following an accident the elapsed time prior to the needed start of the equipment is in terms of hours or days. The recombiners are also operated during periodic testing. Other than these times they are in a standby mode. This standby mode is not a bypass mode, which refers to the inoperative status of systems that are normally operating.

7.3.3.4 Interlocks

There are no functional interlocks associated with the electric hydrogen recombiner.

7.3.3.5 Sequence

Each electric hydrogen recombiner is capable of being supplied from an independent onsite diesel generator. Loading on the emergency electric bus is by manual means, not by sequencers.

7.3.3.6 Redundancy

To meet the requirements for redundancy and independence, 2 electric hydrogen recombiners are provided, and each recombiner is provided with a separate power panel and control panel and each is powered from a separate Class 1E bus. The operation of a single unit is intended to provide the required hydrogen removal capability.

7.3.3.7 Diversity

Diversity between the redundant portions of the Electric Hydrogen Recombiner System is not required to protect against systematic failures, such as, multiple failures resulting from a credible single event. The design and environmental and seismic qualification of the Westinghouse electric hydrogen recombiner, as reported on in topical report WCAP-7709-L (Proprietary) with Supplements 1 to 7 and WCAP-7820 (Non-Proprietary), was found acceptable for the prototype and production models by the NRC. This acceptance was reported in NRC's letters of May 1, 1975 from D. B. Vassalo to C. Eicheldinger, Manager of W Nuclear Safety Department and of June 22, 1978 from John Stolz to T. M. Anderson regarding supplements 5, 6, and 7.

7.3.3.8 Actuated Devices

A manually operated switch on the control panel is used to initiate operation of an electric hydrogen recombiner. This switch energizes a contactor in the power supply panel which applies the 3-phase electric power source to the transformer, also in the power supply panel. Electric power input to the recombiner is controlled by a controller in the power supply panel, by means of a manually operated potentiometer and a wattmeter on the control panel. Electric power is fed to the recombiner's electric resistance heaters which are used to heat a continuous flow of Reactor Building atmosphere to the hydrogen-oxygen reaction temperature. This causes hydrogen to combine with the oxygen which is in the Reactor Building.

7.3.4 Cross References

Table 7.3-7 provides cross references outlining appropriate sections that supply descriptions of initiating circuitry, logic, bypasses, interlocks, sequencing, redundancy, diversity and actuated devices for ESF and ESF supporting systems.

(1) FSAR figure numbers refer to figures in the FSAR; drawing numbers refer to drawings in the Wiring Schematic Package (see Section 1.7)
(2) Not sequenced
(3) Not diverse
(4) Solenoid valve is the actuation device
(5) Motor Control Center is actuation device
(6) No Interlocks or Bypasses are provided which would inhibit ESF actuation.
(7) The containment leakage testing system is not an Engineered Safety Features System or an essential Auxiliary Supporting System. The system includes only that equipment and instrumentation required to perform the initial and periodic containment leakage testing during plant shutdown. All penetrations through containment are capped during normal plant operation.

August 1984

7.4 SYSTEMS REQUIRED FOR SAFE SHUTDOWN

The functions necessary for safe shutdown are available from instrumentation channels that are associated with the major systems in both the primary and secondary of the Nuclear Steam Supply System. These channels are normally aligned to serve a variety of operational functions, including startup and shutdown as well as protective functions. There are no identifiable safe shutdown systems per se. However, prescribed procedures for securing and maintaining the plant in a safe condition can be instituted by appropriate alignment of selected systems in the Nuclear Steam Supply System. The discussion of these systems together with the applicable codes, criteria and guidelines is found in other sections of this Final Safety Analysis Report. In addition, the alignment of shutdown functions associated with the engineered safety features which are invoked under postulated limiting fault situations is discussed in Chapter 6 and Section 7.3.

The instrumentation and control functions which are required to be aligned for maintaining safe shutdown of the reactor that are discussed in this section are the minimum number under nonaccident conditions. These functions will permit the necessary operations that will:

1. Prevent the reactor from achieving criticality in violation of the Technical Specifications and
2. Provide an adequate heat sink such that design and safety limits are not exceeded.

7.4.1 Description

The designation of systems that can be used for safe shutdown depends on identifying those systems which provide the following capabilities for maintaining a safe shutdown:

1. Boration (see Section 9.3.4, “Chemical and Volume Control System”).
2. Adequate supply for emergency feedwater (see Section 10.4.9, “Emergency Feedwater System”).
3. Residual heat removal (see Section 5.5.7, “Residual Heat Removal System”).

These systems are identified in the following lists together with the associated instrumentation and controls provisions. The identification of the monitoring indicators (Section 7.4.1.1) and controls (Section 7.4.1.2) are those necessary for maintaining a hot shutdown. The equipment and services available for a cold shutdown are identified in Section 7.4.1.4.

7.4.1.1 Monitoring Indicators

Safety related display instrumentation, as described in Section 7.5, is provided outside as well as inside the Control Room. The necessary indicators for maintaining a hot shutdown are as follows:

1. Water level indicator for each steam generator (1).
2. Pressure indicator for each steam generator (1).
3. Pressurizer water level indicator (1).
4. Pressurizer pressure indicator (1).

In addition, the following indicators are also provided:

1. Reactor Building temperature (1).
2. Volume control tank level (1).
3. Charging pressure and flow (1).
4. Emergency boration flow (1).
5. Condensate storage tank level (1).
6. Letdown flow (1).

7.4.1.2 Controls

7.4.1.2.1 General Considerations

1. The turbine is tripped. (Note that this can be accomplished at the turbine as well as in the Control Room.)
2. The reactor is tripped. (Note that this can be accomplished at the reactor trip switchgear as well as in the Control Room.)
3. All automatic systems continued functioning. (Discussed in Sections 7.2 and 7.7.)

(1) Indication is physically located on the Control Room Evacuation Panel (CREP).

4. For certain equipment having motor controls outside the Control Room (which duplicate the functions inside the Control Room) the controls are provided with a selector switch at the local station which transfers control of the switchgear from the Control Room to the local station(s). Placing the local selector switch in the local operating position will give an annunciating alarm in the Control Room. The transfer switches are designed so that after the transfer switch is in the local position, a failure in the Control Room or Cable Spreading Room does not cause a failure in the local control. Also, a failure in the local control circuit beyond the transfer switch does not cause a failure in the remote control circuit when the control is transferred there. The following equipment is provided with transfer switches:

   a. Pressurizer heater backup group 1 (4) (see Section 5.5.10, “Pressurizer”).

   b. Pressurizer heater backup group 2 (4) (see Section 5.5.10, “Pressurizer”).

   c. Charging flow controller (setpoint station) (see Section 9.3.4, “Chemical and Volume Control System”).

   d. Emergency borate valve (see Section 9.3.4, “Chemical and Volume Control System”).

   e. Turbine driven emergency feedwater pump flow control valves (see Section 10.4.9, “Emergency Feedwater System”).

   f. Motor driven emergency feedwater pump flow control valves (see Section 10.4.9, “Emergency Feedwater System).

   g. Letdown line isolation valves (see Section 9.3.4, “Chemical and Volume Control System”).

   h. Letdown orifice A, B, and C isolation valves (see Section 9.3.4, “Chemical and Volume Control System”).

   i. Steam supply valve to emergency feedwater pump turbine (see Section 10.4.9, “Emergency Feedwater System”).

   j. NOT USED.

   k. Service water pumps A and B (see Section 9.2.1, “Service Water System”).

   l. Service water pump C (as part of A train and as part of B train) (see Section 9.2.1, “Service Water System”).

   m. Boric acid transfer pump B (see Section 9.3.4, “Chemical and Volume Control System”).

   n. Pressurizer power operated relief valves PCV445A and PCV444B (see Section 5.5.13, “Safety and Relief Valves”).

   The backup heater groups are designed to be available during plant operations required to maintain hot shutdown or bring the plant to cold shutdown. However, this availability is not a mandatory requirement for maintaining hot shutdown or for bringing the plant to cold shutdown.

   These switches are shown by Figures 7.4-1 through 7.4-2.

Use of the transfer switch removes the automatic actuation capability for the following components (such as motors):

a. Pressurizer heater backup group 1 (see Section 5.5.10, “Pressurizer”).

b. Pressurizer heater backup group 2 (see Section 5.5.10, “Pressurizer”).

c. Service water pumps (see Section 9.2.1, “Service Water System”).

d. Boric acid transfer pump B (see Section 9.3.4, “Chemical and Volume Control System”).

e. Pressurizer power operated relief valves PCV445A and PCV444B (see Section 5.5.13, “Safety and Relief Valves”).

Removal of this automatic actuation capability does not jeopardize plant safety, since no accident is postulated to occur concurrent with the need for this transfer.

5. Certain motor operated valves, such as for service water backup water supply to the Emergency Feedwater System (see Section 10.4.9, “Emergency Feedwater System”) will have their electrical operators disconnected and the valves will be positioned manually by disconnecting the main circuit breaker at the motor control center and operating the valve by means of the handwheel after depressing a lever n the direction marked “Manual Control”.

6. Certain pumps will be controlled from their motor switchgear mechanical switches. The ability to perform the shutdown function is not jeopardized by a failure in the Control Room or Cable Spreading Room since redundant equipment could be used. In the unlikely event that a failure in the Control Room or Cable Spreading Room short circuits the switchgear trip circuit, local operation of the switchgear (without control power) would isolate this fault. Such operation can be accomplished as follows:

   a. Remove both the closing and trip fuses to isolate d-c control voltage.

   b. Manually close the circuit breaker utilizing operating mechanism located on the breaker.

   c. Manually trip the circuit breaker utilizing operating mechanism located on the breaker.

7. Certain redundant equipment (air compressors, see Section 9.3.1, “Compressed Air Systems”); heating, ventilating and air conditioning chillers (see Section 9.4.7, “Miscellaneous Building Ventilation and Cooling Systems”); and diesel generators (see Sections 8.3.1.1.2, “Onsite Standby Power Supply,” and 9.5, “Other Auxiliary Systems”) have comprehensive local control cabinets with functionally parallel start/stop controls extended to the Control Room. The ability to perform the shutdown function is not jeopardized by a failure in the Control Room or Cable Spreading Room since redundant equipment could be used. In the unlikely event that a failure in the Control Room or Cable Spreading Room prevents local control of this equipment, isolation of the fault in parallel control circuits would require removal of the external control wires at the local control cabinets.

7.4.1.2.2 Pumps and Fans

1. Emergency feedwater pumps

   In the event of a trip of all main feedwater pumps (see Section 10.4.7, “Condensate and Feedwater Systems”), feedwater pumps (see Section 10.4.9, “Emergency Feedwater System”) start automatically or can be started manually. Start/stop motor controls located locally (as well as being inside the Control Room) are provided as well as handwheel control for the valves.

2. Charging and boric acid transfer pumps

   Start/stop control for both boric acid pumps is located in the Control Room. In addition, control for one pump is located at CREP.

   The start/stop control for 3 charging pumps is located in the Control Room. In addition, controls for “B” pump and “C” pump aligned to “B” train are located at their respective switchgear. Also, all circuit breakers for the 3 pumps can be closed or tripped utilizing the operating mechanisms located on their respective breakers.

3. Service water pumps (2) (see Section 9.2.1, “Service Water System”).

   Start/stop motor controls are located outside as well as inside the Control Room.

4. Component cooling water pumps (see Section 9.2.2, “Component Cooling Water System”). The circuit breakers can be closed or tripped from operating mechanisms located on their respective breakers.
5. Instrument air compressors (see Section 9.3.1, “Compressed Air Systems”). These compressors start automatically on low air pressure.
6. Reactor building cooling units (see Section 6.2.2, “Reactor Building Heat Removal Systems”). Start/stop motor controls with a selector switch are provided for the fan motors. The controls are located outside as well as inside the Control Room.

7.4.1.2.3 Diesel Generators (see Section 8.3.1.1.2, “Onsite Standby Power Supply,” and 9.5, “Other Auxiliary Systems”)

These units start automatically following a loss of voltage on their respective buses. However, manual controls for diesel startup are also provided locally at the diesel generators (as well as inside the Control Room).

(2) Control and indication are physically located on the CREP

7.4.1.2.4 Valves and Heaters

1. Charging flow control valves[(2)] (see Section 9.3.4, “Chemical and Volume Control System”)

   Remote manual control with a selector switch for the charging line flow control valves is provided outside, as well as inside, Control Room. These controls duplicate functions that are available inside the Control Room.

2. Letdown orifice isolation valves[(2)] (see Section 9.3.4, “Chemical and Volume Control System”).

   Open/close controls with a selector switch for the letdown orifice isolation valves are grouped with the controls for the charging flow control valve. These controls duplicate functions that are inside the Control Room.

3. Emergency feedwater control valves[(2)] (see Section 10.4.9, “Emergency Feedwater System”)

   Controls for these valves are located outside as well as inside the Control Room.

4. Condenser steam dump and atmospheric steam relief valves (see Section 10.4.4, “Turbine Bypass System”)

   The condenser steam dump and atmospheric relief valves are automatically controlled. Manual control is provided locally as well as inside the Control Room for the atmospheric relief valves. Steam dump to the condenser is blocked on high condenser pressure.

5. Pressurizer heater control [(2)] (see Section 7.7.1.5, “Pressurizer Pressure Control”)

   On/off control with selector switch is provided for 2 backup heater groups. The heater groups are connected to separate buses, such that each can be connected to separate diesels in the event of loss of outside power. The controls are grouped with the charging flow controls and duplicate functions that are available inside the Control Room.

(2) Control and indication are physically located on the CREP

7.4.1.3 Control Room Evacuation

The instrumentation and controls listed in Sections 7.4.1 and 7.4.1.2 that are used to achieve and maintain a safe shutdown are available in the event an evacuation of the Control Room is required. These controls and instrumentation channels together with the equipment identified in Section 7.4.1.4 identify the potential capability for cold shutdown of the reactor subsequent to a Control Room evacuation through the use of suitable procedures. Table 7.4-1 and Figures 7.4-1 through 7.4-2 address the local control stations and the relative locations of these control stations in the plant. The design basis for Control Room evacuation does not consider a concurrent Condition II, III, or IV event, nor a single failure.

Control Room evacuation resulting from a fire in the control complex and the ability to achieve safe shutdown concurrent with the fire is demonstrated in the Fire Protection (FP) DBD.

7.4.1.4 Equipment and Systems Available for Cold Shutdown

1. Reactor coolant pumps (see Section 5.5.1, “Reactor Coolant Pumps”).
2. Emergency feedwater pumps (see Section 10.4.9, “Emergency Feedwater System”).
3. Boric acid transfer pumps (see Section 9.3.4, “Chemical and Volume Control System”).
4. Charging pumps (see Section 9.3.4, “Chemical and Volume Control System”).
5. Service water pumps (see Section 9.2.1, “Service Water System”).
6. Reactor building fans (see Section 6.2.2, “Reactor Building Heat Removal Systems,” and Section 9.4.8, “Reactor Building Cooling and Filtering Systems”).
7. Component cooling water pumps (see Section 9.2.2, “Component Cooling Water System”).
8. Residual heat removal pumps (see Section 5.5.7, “Residual Heat Removal System)[3].
9. Certain motor control center and switchgear Sections (see Section 8.3, “Onsite Power Systems”).
10. Controlled steam release and feedwater supply (see Sections 7.7.1.8, “Steam Dump Control” and 10.4.4, “Turbine Bypass System”).
11. Boration capability (see Section 9.3.4, “Chemical and Volume Control System”).

---

(3) Instrumentation and controls for these systems may require some modification in order that their functions may be performed from outside the Control Room. Note that the reactor plant design does not preclude attaining the cold shutdown condition from outside the Control Room. An assessment of plant conditions can be made on the long term basis (a week or more) to establish procedures for making the necessary physical modifications to instrumentation and control equipment in order to attain cold shutdown. During such time the plant could be safely maintained at hot shutdown condition.
Detailed procedures to be followed in effecting cold shutdown from outside the Control Room are best determined by plant personnel at the time of the postulated incident.

12. Nuclear Instrumentation System source and intermediate ranges (both ranges are provided remote from the Control Room, but only source range is independent of the Control Room). (See Sections 7.2, “Reactor Trip System,” and 7.7, “Control Systems Not Required for Safety”).
13. Reactor coolant inventory control (charging and letdown) (see Section 9.3.4, “Chemical and Volume Control System”).
14. Pressurizer pressure control including opening control for pressurizer relief valves (heaters and spray) (see Section 7.7.1.5, “Pressurizer Pressure Control”). (3)

In addition, the safety injection signal trip circuit must be defeated and the accumulator isolation valves closed (3) (see Sections 6.3, “Emergency Core Cooling System,” and 7.3, “Engineered Safety Features Actuation System”).

The Fire Protection (FP) DBD identifies Virgil Summer Nuclear Station’s compliance used to achieve cold shutdown in the event of a fire in the plant.

7.4.2 Analysis

Hot shutdown is a stable plant condition, automatically reached following a plant shutdown. The hot shutdown condition can be maintained safely for an extended period of time. In the unlikely event that access to the Control Room is restricted, the plant can be safely kept at a hot shutdown until the Control Room can be re-entered by the use of the monitoring indicators and the controls listed in Sections 7.4.1.1 and 7.4.1.2. These indicators and controls are provided outside as well as inside the Control Room.

---

(3) Instrumentation and controls for these systems may require some modification in order that their functions may be performed from outside the Control Room. Note that the reactor plant design does not preclude attaining the cold shutdown condition from outside the Control Room. An assessment of plant conditions can be made on the long term basis (a week or more) to establish procedures for making the necessary physical modifications to instrumentation and control equipment in order to attain cold shutdown. During such time the plant could be safely maintained at hot shutdown condition.
Detailed procedures to be followed in effecting cold shutdown from outside the Control Room are best determined by plant personnel at the time of the postulated incident.

The safety evaluation of the maintenance of a shutdown with these systems and associated instrumentation and controls has included consideration of the accident consequences that might jeopardize safe shutdown conditions. The accident consequences that are germane are those that would tend to degrade the capabilities for boration, adequate supply for emergency feedwater, and residual heat removal.

The results of the accident analysis are presented in Chapter 15. Of these the following produce the most severe consequences that are pertinent:

1. Uncontrolled Boron Dilution.
2. Loss of Normal Feedwater.
3. Loss of External Electrical Load and/or Turbine Trip.
4. Loss of Offsite Power to the Station Auxiliaries.

It is shown by these analyses that safety is not adversely affected by these incidents with the associated assumptions being that the instrumentation and controls indicated in Sections 7.4.1.1 and 7.4.1.2 are available to control and/or monitor shutdown. These available systems will allow a maintenance of hot shutdown even under the accident conditions listed above which would tend toward a return to criticality or a loss of heat sink.

The results of the analysis which determined the applicability to the Nuclear Steam Supply System safe shutdown systems of the NRC General Design Criteria, IEEE Standard 279-1971, applicable NRC Regulatory Guides and other industry standards are presented in Table 7.1-1. The functions considered and listed below include both safety-related and nonsafety-related equipment.

1. Reactor Trip System (see Section 7.2, “Reactor Trip System”).
2. Engineered Safety Features Actuation System (see Section 7.3, “Engineered Safety Features Actuation System”).
3. Safety-related display instrumentation for post accident monitoring (see Section 7.5, “Safety-Related Display Instrumentation”).
4. Main control board (see Section 7.0, “Instrumentation and Controls”).
5. Control room evacuation panel (see Sections 7.4.1.1, “Monitoring Indicators,” and 7.4.1.2, “Controls).
6. Residual heat removal (see Section 5.5.7, “Residual Heat Removal System”).
7. Instrument power supply (see Section 8.3, “Onsite Power Systems”).
8. Control systems (see Section 7.0, “Instrumentation and Controls”).

For the discussions addressing how these requirements are satisfied, the column in Table 7.1-1 entitled “Conformance Discussed In” provides the appropriate reference.

An analysis demonstrating the ability to achieve safe shutdown in the event of a fire is presented in the Fire Protection (FP) DBD.

7.4.2.1 Conformance to General Design Criterion 19

As noted in Section 7.4.1.3, equipment is provided outside the Control Room with a design capability for prompt hot shutdown of the reactor and for maintaining the unit in a safe condition during hot shutdown and with a potential capability for subsequent cold shutdown through the use of suitable procedures. For criteria relative to the control board in the Main Control Room, see Section 7.1.2.2.2.

7.4.2.2 Conformance to IEEE Standard 279-1971

The design basis information requested by Section 3 of IEEE Standard 279-1971 for protective action and pertaining to the signals for actuation of reactor trip are presented in Section 7.2.1.2. The analyses for compliance to the criteria of IEEE Standard 279-1971 for the reactor trip are addressed in Section 7.2.2. The design basis information for protective action for the Engineered Safety Features Actuation system (ESFAS) is presented Section 7.3.1.2 and the analyses for ESFAS are addressed in Section 7.3.2. For the list of references to the discussions of conformance to applicable criteria, see Tables 7.1-1 and 7.1-2.

7.4.3 Cross References

Table 7.4-2 provides cross references outlining appropriate sections that supply descriptions of initiating circuitry, logic, bypasses, interlocks, redundancy, diversity and actuated devices for systems required for safe shutdown.

7.5 SAFETY RELATED DISPLAY INSTRUMENTATION

7.5.1 Description

Regulatory Guide 1.97, “Instrumentation for Light-Water-Cooled Nuclear Power Plants to Assess Plant and Environs Conditions During and Following an Accident”, provides guidance for selection of readouts to monitor plant variables and systems during and following a design basis event. For VCSNS, the post-accident monitoring instrumentation provides readouts to the operator to enable him to perform manual safety functions and to determine the effect of manual actions taken following a reactor trip due to a Condition II, III, or IV event, as defined in Chapter 15. Regulatory Guide 1.97 instrumentation includes the readouts required to maintain the plant in a hot shutdown condition or to proceed to cold shutdown within the limits of the Technical Specifications. Reactivity control after Condition II and III faults will be maintained by administrative sampling of the reactor coolant for boron to ensure that the concentration is sufficient to maintain the reactor subcritical. Additional details are provided in Reference 1.

Table 7.5-2 lists the information available to the operator in addition to Regulatory Guide 1.97 instrumentation for monitoring conditions in the reactor, the Reactor Coolant System, and in the Reactor Building and process systems throughout all normal operating conditions of the plant, including anticipated operational occurrences.

7.5.2 Analysis

This section deleted by Amendment No. 94-08 in October, 1994.

7.5.3 Design Criteria

This section deleted by Amendment No. 94-08 in October, 1994.

7.5.4 ESF Monitor Lights

Certain pumps and valves, which are an integral part of or which are associated with the engineered safety features systems (used for safety injection, Reactor Building spray, and recirculation) are equipped with ESF monitor lights. These “bright/dim” lights are displayed on the main control board within easy view of the operator. When the plant is in normal full power operation, the ESF monitor lights should generally be “dim.” These lights change to the “bright” condition when the component monitored changes to an off normal operating mode. In addition to the ESF monitor lights, certain valves have an annunciator which indicates a change to an off-normal operating mode and actuates an alarm.

The ESF monitor lights are arranged on the main control board as shown by Figures 7.5-1 through 7.5-6 to permit the operator to discover easily a component that is in an off-normal operating mode. These figures also outline the components monitored. Elementary diagrams (GAI Dwg. B-208-066), submitted separately in the “Wiring Schematic Package” and listed in Table 1.7-1, outline the specific components included.

The ESF monitor lights provide supplemental information with regard to the status of ESF components.

7.5.5 Inadequate Core Cooling

The inadequate core cooling instrumentation includes the Incore Temperature Monitoring System, the core subcooling monitors, and the Reactor Vessel Level Instrumentation System (RVLIS). These systems meet the requirements of NUREG-0737 item II.F.2 for inadequate core cooling instrumentation. They are also used to provide Post Accident Monitoring Information in compliance with Regulatory Guide 1.97, Rev. 3. See Section 7.5.1.

The Incore Temperature Monitoring system is designed to provide rapid monitoring of fuel assembly outlet temperatures and to verify that the core is being adequately cooled during and after an accident. The Incore Temperature Monitoring System consists of 51 thermocouples positioned in the reactor vessel above the core to measure reactor coolant temperature at the fuel assembly outlets. After the thermocouple leads exit the reactor vessel head the circuits are divided into two electrical trains and separately routed out of the containment, through separate thermocouple penetrations, to two separate thermocouple transmitter/isolator cabinets. Outputs from the cabinets are connected to the plant computer system and Technical Support Center computer and core subcooling monitoring system. Plant computer system displays and SPDS displays, via the Technical Support Center computer, of core exit thermocouple readings are provided in the Control Room.

The core subcooling monitoring system is designed to provide information to plant personnel concerning the status of reactor core heat removal capability. This information includes a continuous display of the saturation margin to provide an early warning that core conditions are approaching saturation. Two separate core subcooling monitoring system microprocessors calculate the RCS saturation margin based on independent wide range RCS pressure input and RCS temperature inputs and display the results on four main control board analog indicators (two per channel). Temperature inputs are from both hot and cold leg wide range RTDs and Incore Temperature Monitoring System thermocouples (two per core quadrant). Only the two indicators utilizing incore thermocouple inputs are used for Post-Accident Regulatory Guide 1.97 monitoring functions.

RVLIS provides an indication of the water level in the reactor vessel when the reactor coolant pumps are not running and the relative void content of the reactor coolant when one or more of the reactor coolant pumps is running. RVLIS provides an anticipatory and unambiguous indication of an inadequate core cooling situation. The system consists of two redundant trains of instrumentation to provide three main control board indications of reactor vessel level. The indicated levels are: 1) reactor vessel upper range (water level above the penetration top of the hot leg pipe when no reactor coolant pumps are running); 2) reactor vessel full range (level from the bottom to the top of the reactor vessel when no reactor coolant pumps are operating); and 3) reactor vessel dynamic range (a measurement of the reactor core and internals pressure drop when reactor coolant pumps are operating which provides means to estimate the relative void content of the circulating fluid).

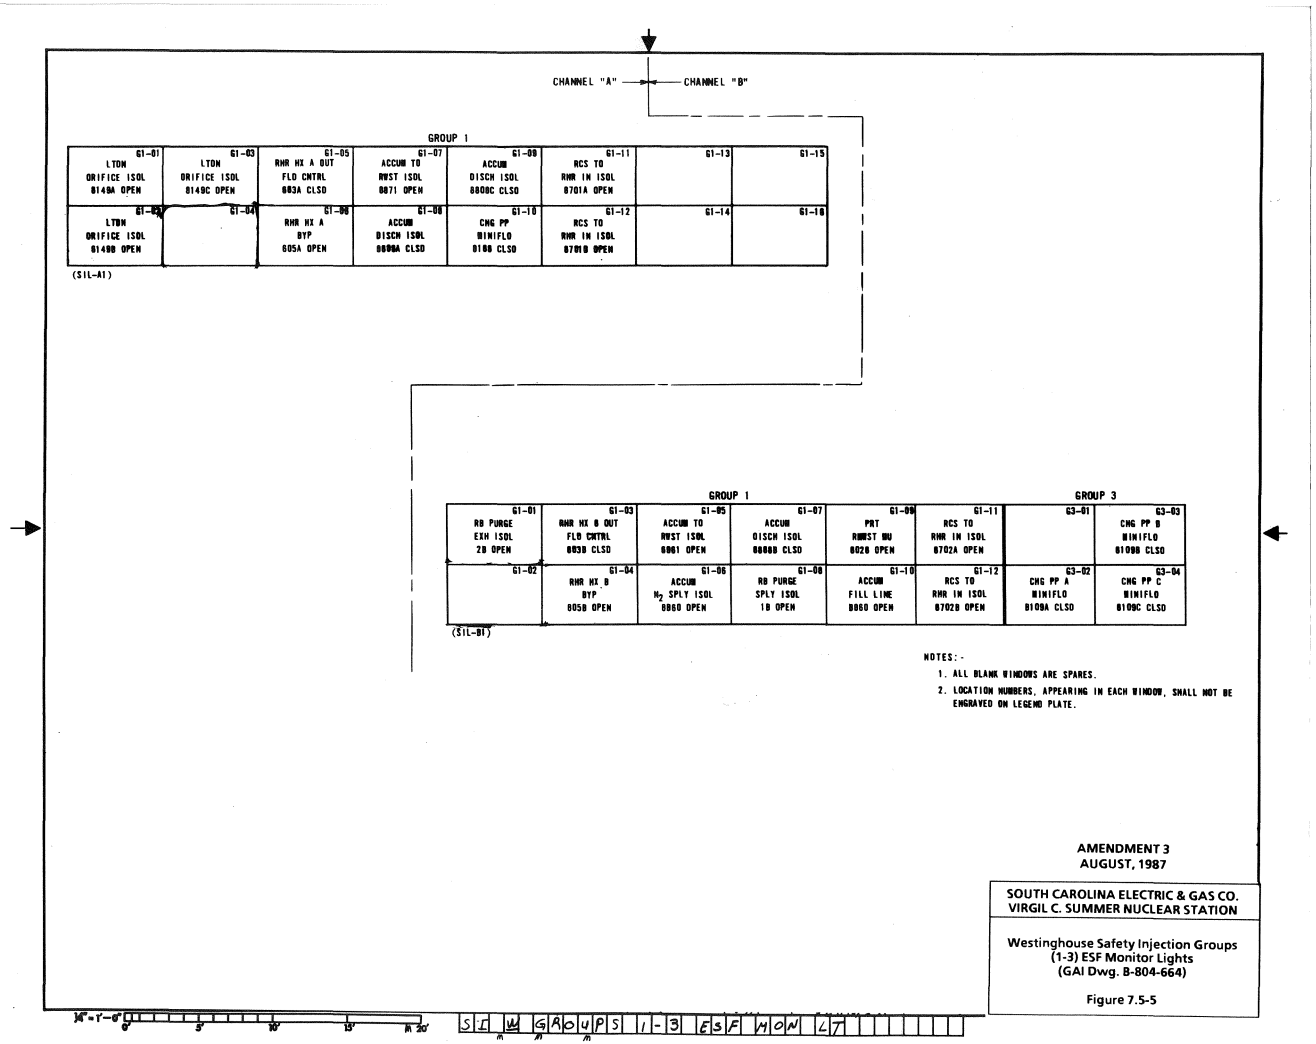
WESTINGHOUSE SAFETY INJECTION GROUPS
(1-3) ESF MONITOR LIGHTS
(GAI DWG. B-804-664)



7.6 ALL OTHER SYSTEMS REQUIRED FOR SAFETY

7.6.1 Instrumentation and Control Power Supply System

7.6.1.1 Description

The following is a description of the Instrumentation and Control Power Supply System:

1. Refer to Figures 8.3-1, 8.3-2, 8.3-2aa, and 8.3-2ab for a single line diagram of the Instrumentation and Control Power Supply System.
2. There are 4 inverters and 6 distribution panels. Four (4) normally operating inverters are connected to 4 distribution panels. The remaining 2 panels are branch loads of the same channelized distribution panel.
3. The inverters provide a source of 120 volt 60 Hz power for the operation of the Nuclear Steam Supply System instrumentation. This power is derived from the 480 volt a-c, 3ø, 60 Hz distribution system Class 1E power supply, or the station batteries which assure continued operation of instrumentation systems in the event of loss of offsite power.
4. Each of the 4 distribution panels fed from the 4 normally operating inverters may be connected to a backup regulated source of 120 volt Class 1E a-c power. The tie is through an automatic static transfer switch or through a manual bypass switch such that the distribution panel cannot be connected to both sources simultaneously.

7.6.1.2 Analysis

There are 2 independent 480 volt a-c power sources, each serving 2 inverters. Therefore, loss of either of the two 480 volt a-c power sources affects only 2 of the 4 inverters.

There are 2 independent Class 1E batteries and battery chargers. Each battery is attached to a bus serving 2 inverters.

There is a third battery charger provided, which serves as a standby charger. This charger is provided for use during maintenance of, and backup to the normal battery chargers. The standby charger has mechanically interlocked circuit breakers on the a-c input and d-c output such that only the 2 circuit breakers associated with Channel A or the 2 circuit breakers associated with Channel B can close at one time.

Since not more than 2 inverters are connected to the same bus, a loss of a single bus can only affect 2 of the 4 inverters.

Since each of the 4 instrument channels is supplied power by independently connected inverters, the loss of an inverter cannot affect more than 1 of the 4 instrument channels.

Each distribution panel can receive power from the 120 volt Class 1E a-c backup regulated source through an automatic static transfer switch or through a manual bypass switch. The inverter power

source and the backup source are aligned such that the distribution panels cannot be connected to both sources at the same time.

Therefore no single failure in the Instrumentation and Control Power Supply System or its associated power supplies can cause a loss of power to more than one of the redundant loads.

The inverters are designed to maintain their outputs within acceptable limits. The loss of the a-c or d-c inputs is alarmed in the Control Room, as is the loss of an inverter's output. There are no inverter breaker controls on the control board, as no manual transfers are necessary in the event of loss of the 480 volt a-c preferred power source. The a-c and d-c inputs are diode isolated in the UPS.

Physical separation and provisions to protect against fire are discussed in Chapter 8.

Based on the scope definitions presented in References 1 through 3, the criteria which are applicable to the Instrumentation and Control Power Supply System are listed in IEEE Standard 308-1971. The design is in compliance with IEEE Standard 308-1971 and Regulatory Guide 1.6. Availability of this system is continuously indicated by the operational status of the systems it serves (see Figures 8.3-1 and 8.3-2) and is verified by periodic testing performed on the served systems. The inverters have been seismically qualified as discussed in Section 3.10 and shown in Table 3.10-2.

7.6.2 Residual Heat Removal Isolation Valves

7.6.2.1 Description

There are 2 motor operated gate valves in series in each of 2 inlet lines from the Reactor Coolant System to the Residual Heat Removal System. They are normally closed and are only opened for residual heat removal and Reactor Coolant System overpressure protection after system pressure is reduced below approximately 425 psig and system temperature has been reduced to approximately 350°F (see Chapter 5). They are the same type of valve and motor operator as those used for accumulator isolation (refer to Section 7.6.4), but they differ in their controls indications in the following respect (see Figures 7.6-1, 7.6-1a., and 7.6-1b):

1. Pressure interlocks are provided to prevent opening of the isolation valves whenever the Reactor Coolant System pressure is greater than approximately 425 psig. This interlock is derived from Class 1E process instrumentation channel for the isolation valves closest to the Reactor Coolant System (XVG8702A and XVG8702B) and from another independent process instrumentation channel for the 2 isolation valves closest to the Residual Heat Removal System (XVG8701A and XVG8701B). Interlock diversity is provided through the use of pressure transmitters from different manufacturers employing different measurement principles for the 2 channels of process instrumentation.
2. In addition to the open interlock, an alarm is located in the Control Room which will alert the operator if these valves are not fully closed when the Reactor Coolant System pressure increases above the 520 psig alarm setpoint.

7.6.2.2 Analyses

Based on the scope definitions presented in References 2 and 3, these criteria do not apply to the residual heat removal isolation valve interlocks; however, in order to meet NRC requirements and because of the possible severity of the consequences of loss of function, the requirements of IEEE Standard 279-1971 will be applied with the following comments:

1. For the purpose of applying IEEE Standard 279-1971, to this circuit, the following definitions will be used.

   a. Protection System

      The 2 valves in series in each line and all components of their interlocks that prevent opening of the isolation valves whenever the Reactor Coolant System pressure is greater than 425 psig.

   b. Protective Action

      The maintenance of Residual Heat Removal System isolation from the Reactor Coolant System when Reactor Coolant System pressures are above the preset value.

2. IEEE Standard 279-1971, paragraph 4.10: The above mentioned pressure interlock signals and logic will be tested on line to the maximum extent possible without adversely affecting safety. This test will include the analog signal through to the train signal which activates the relays that provide the interlocks into the valve control circuit. This is done in the best interests of safety since defeat of the interlock to permit opening the valve could potentially leave only 1 remaining valve to isolate the low pressure Residual Heat Removal System from the Reactor Coolant System.

   It is noted that the valve position lights operated from the motor operated valve limit switch on the operator are similar to the position lights (red for open and green for closed) for the accumulator isolation valves described in Section 7.6.4.

3. IEEE Standard 279-1971, paragraph 4.15: This requirement does not apply, as the setpoints are independent of mode of operation and are not changed.

Environmental qualification of the valves and wiring is discussed in Section 3.11.

7.6.3 Refueling Interlocks

Electrical interlocks (i.e., limit switches) as discussed in Section 9.1.4 are provided for minimizing the possibility of damage to the fuel during fuel handling operations.

7.6.4 Accumulator Motor Operated Valves

The design of the interconnection of signals to open the accumulator isolation valves meets the following criteria established in previous NRC positions on this matter:

1. Automatic opening of the accumulator valves when a) the primary coolant system pressure exceeds a preselected value (specified in the Technical Specifications) or b) as a safety injection signal has been initiated. Both signals shall be provided to the valves.
2. Utilization of a safety injection signal to automatically remove (override) any bypass features that are provided to allow an isolation valve to be closed for short periods of time when the Reactor Coolant System is at pressure (in accordance with the provisions of the Technical Specifications). As a result of the confirmatory "S" signal, isolation of an accumulator with the Reactor Coolant System at pressure is acceptable.

The control circuit for these valves is shown on Figure 7.6-2. The valves and control circuits are further discussed in Sections 6.3.2.15 and 6.3.5.

The Safety Injection System accumulator discharge isolation valves are motor operated normally open valves which are controlled from the main control board. These valves are interlocked such that:

1. They open automatically on receipt of an "S" signal with the main control board switch in either the "AUTO" or "CLOSE" position.
2. They open automatically whenever the Reactor Coolant System pressure is above the safety injection unblock pressure (P-11) specified in the Technical Specifications only when the main control board switch is in the "AUTO" position.
3. They cannot be closed as long as an "S" signal is present.

The main control board switches for these valves are 3 position switches which provide a "spring return to auto" from the open position and a "maintain position" from the closed position.

The "maintain closed" position is required to provide an administratively controlled manual block of the automatic opening of the valve at pressure above the safety injection unblock pressure (P-11). The manual block or "maintain closed" position is required when performing periodic check valve leakage tests when Reactor Coolant System is at pressure. The maximum permissible time that an accumulator valve can be closed when the Reactor Coolant System is at pressure is specified in the Technical Specifications.

Administrative control is required to ensure that any accumulator valve, which has been closed at pressures above the safety injection unblock pressure, is returned to the "AUTO" position. Verification that the valve automatically returns to its normal full open position would also be required.

During plant shutdown, the accumulator valves are in a closed position. To prevent an inadvertent opening of these valves during that period the accumulator valve breakers should be opened or removed. Administrative control is again required to ensure that these valve breakers are closed during the prestartup procedures.

7.6.5 Leakage Detection Systems

7.6.5.1 Description

Leakage detection is provided for the following areas and systems:

1. Reactor coolant pressure boundary (see Section 5.2.7 for a detailed description).
2. Engineered safety features systems (i.e., Reactor Building Spray, Residual Heat Removal, Safety Injection systems) in the Auxiliary Building.
3. Feedwater system (intermediate building flood protection).

7.6.5.1.1 Engineered Safety Features Systems in the Auxiliary Building

1. Level

   Undetected leaks from the Engineered Safety Features Systems in the Auxiliary Building (Reactor Building Spray, Residual Heat Removal, Safety Injection) could have adverse effects upon the safety functions of these systems. For this reason, means for detecting leakage are provided.

   Level switches are located in specifically provided alarm drains and in the building drain sumps. When leakage exceeds a flowrate of 25 gpm for the floor drains or 45 gpm the sump drains, an alarm is activated in the Control Room. Upon receipt of such an alarm, the operator takes action to isolate the leak.

   Figures 9.3-6 and 9.3-7 schematically depict the locations of alarm drains and building sumps.

2. Temperature

   Undetected leakage from the Chemical and Volume Control System letdown lines or the Auxiliary Steam System could cause the ambient temperature in the Auxiliary Building to rise. This high temperature could possibly prohibit personnel access to the area and limit the capability of equipment to function. Pipe rupture analysis has indicated the location of the most probable break areas in the system. Temperature sensors located in these break areas actuate alarms in the Control Room. Locations of these sensors are illustrated by Figures 7.6-3a through 7.6-8.

7.6.5.1.2 Feedwater System

Safety equipment and systems in the Intermediate Building are protected from flooding due to postulated pipe break or component failure resulting in leakage from the Feedwater System.

The sump level system incorporates a level switch located in each of the 3 Intermediate Building sumps. Should a high level occur in any sump, it is annunciated in the Control Room to alert the

operator to the need for investigation of the source of leakage and, if necessary, to take manual action to isolate the leak. The high-high sump level detectors are set to detect flooding which occurs at a rate which exceeds the capacity of the sump pumps. When 2 out of 3 redundant high-high sump level switches are energized, the A channel closes the feedwater pump discharge valves and the B channel trips the feedwater pumps and closes the feedwater pump suction valves. The A channel closes the feedwater isolation valves to the steam generators.

7.6.5.1.3 Leak Detection Methods Inside the Control Room

Table 7.6-1 provides a tabulation of leak detection methods inside the Control Room.

7.6.5.2 Analysis

Leak detection instrumentation is seismically qualified. These instruments are located throughout the Auxiliary Building in areas where engineered safety features equipment and piping are located. Physical separation and separate electrical power sources are used for 2 sets of redundant instruments. Calibration of the Leak Detection System instrumentation can be performed during plant operation. The instrumentation can be functionally checked by testing at any time.

7.6.6 Interlocks for RCS Pressure Control During Low Temperature Operation

This Section deleted by Amendment 1 in August, 1985.

7.6.7 Switchover From Injection to Recirculation

The details of achieving cold leg recirculation following safety injection and a postulated LOCA are given in Section 6.3.2.2.7 and on Table 6.3-3.

7.6.7.1 Description of Instrumentation Used for Switchover

As noted in Table 6.3-3, protection logic is provided to automatically open the 4 Safety Injection System (SIS), Reactor Building recirculation sump isolation valves (8811A and 8812A in Train A and 8811B and 8812B in Train B) when 2 of 4 (2/4) Refueling Water Storage Tank (RWST) level transmitters sense the Lo-Lo level setpoint in conjunction with the initiation of the engineered safety features actuation signal ("S" signal). The "S" signal is initiated by the contact of a slave relay in the Solid State Protection System output cabinet that closes on Safety Injection and remains closed until manually reset from the control board. This reset switch is separate from the main safety injection reset switch which is not associated with this circuit. The purpose of the sump valve automatic open circuit reset switch is to permit the operator to remove the actuation signal in the event the corresponding sump isolation valve must be closed and retained in a closed position following a LOCA, such as for maintenance purposes.

7.6.7.2 Initiating Circuit

The 2/4 Lo-Lo RWST level is the trip signal, which in coincidence with the "S" signal, provides the initiation function which would align the 2 residual heat removal pumps to take suction from the Reactor Building sumps and deliver directly to the RCS.

7.6.7.3 Logic

The logic function derived from the RWST level sensors and the "S" signal are depicted in Figure 7.6-9.

7.6.7.4 Bypass

The manual reset logic function is shown in Figure 7.6-10 and its purpose and action are described in Section 7.6.7.1. As noted, the "S" signal is retained by sealing it in (i.e., it is latched). This signal is not removed by action of the main safety injection reset that is used by the operator per emergency procedures to block the "S" signal to certain other equipment prior to realignment for switchover to the recirculation mode following a postulated loss of coolant accident.

7.6.7.5 Interlocks

The Trip Signal logic consists of 4 Refueling Water Storage Tank water level transmitters, each of which provides a level signal to 1 of the 4 Refueling Water Storage Tank level channel bistables. The Refueling Water Storage Tank level channel bistables are:

1. Normally de-energized
2. De-energized on loss of power
3. Energized on Lo-Lo setpoint

Each level channel bistable is assigned to a separate instrumentation and control power supply. A Trip Signal is provided from both Train A and Train B Solid State Protection System cabinets to the corresponding Reactor Building recirculation sump isolation valves logic, should 2 of the 4 water level channel bistables receive an RWST level signal lower than the Lo-Lo level setpoint, following the generation of an "S" signal.

7.6.7.6 Sequence

This circuit is energized directly from the Solid State Protection System output cabinet and is not sequenced following an accident that requires its functioning.

7.6.7.7 Redundancy

The function of this semi-automatic switchover is available from both Train A and Train B down to the actuated equipment. The function including the actuated equipment is, therefore, redundant and train separation and independence are maintained from sensor to actuated equipment.

7.6.7.8 Diversity

Diversity of components and equipment between the redundant Trains is not required to protect against systematic failures, such as multiple failures resulting from a credible single event. The associated components are environmentally and seismically qualified in accordance with the procedures described in Sections 3.10 and 3.11. It is noted that there is functional diversity provided in that manual operation is available as a backup to the semi-automatic mode.

7.6.7.9 Actuated Devices

The actuated devices are the 4 motor control center starters, 1 for each of the Motor Operated Sump Valves, 8811 A&B, and 8812 A&B.

7.6.7.10 Channel Bypass Indication

Indication is provided on the main control board to alert the operator that a Refueling Water Storage Tank water level channel is in the bypass mode and is unavailable. The indication is by status light and alarm window as shown on Figure 7.6-10.

7.6.11 Switchover From Spray to Recirculation

The details of the Reactor Building Spray System operation following a postulated loss of coolant accident are given in Section 6.2.2.2.1.2.

7.6.11.1 Description of Instrumentation Used for Switchover

As noted in Section 6.2.2.2.1.2 logic is provided to automatically open the 4 Reactor Building Spray System, Reactor Building recirculation sump isolation valves (3004A and 3005A in Train A and 3004B and 3005B in Train B) when 2 of 4 (2/4) Refueling Water Storage Tank (RWST) level transmitters sense the Lo-Lo level setpoint in conjunction with the initiation of the engineered safety features actuation signal ("S" signal). The "S" signal is initiated by the contact of a slave relay in the Solid State Protection System output cabinet that closes on safety injection and remains closed until manually reset from the control board. This reset switch is separate from the main safety injection reset switch which is not associated with this circuit. The purpose of the sump valve automatic open circuit reset switch is to permit the operator to remove the actuation signal in the event the corresponding sump isolation valve must be closed and retained in a closed position following a loss of coolant accident, such as for maintenance purposes.

7.6.11.2 Initiation Circuit

The 2/4 Lo-Lo Refueling Water Storage Tank level is the trip signal, which in coincidence with the "S" signal, provides the initiation function which would automatically align the 2 Reactor Building spray pumps to take suction from the Reactor Building recirculation sumps and deliver directly to the Reactor Building spray nozzles.

7.6.11.3 Logic

The logic function derived from the Refueling Water Storage Tank level sensors and the "S" signal are depicted in Figures 7.6-9 and 7.6-10.

7.6.11.4 Bypass

The manual reset logic function is shown in Figure 7.6-9 and its purpose and action are described inSection 7.6.11.1. As noted, the "S" signal is retained by sealing it in (i.e., it is latched). This signal is not removed by action of the main safety injection reset that is used by the operator per emergency procedures to block the "S" signal to certain other equipment prior to realignment for switchover to the recirculation mode following a postulated loss of coolant accident.

7.6.11.5 Interlocks

The Trip Signal logic consists of 4 Refueling Water Storage Tank water level transmitters, each of which provides a level signal to 1 of the 4 Refueling Water Storage Tank level channel bistables. The Refueling Water Storage Tank level channel bistables are:

1. Normally de-energized
2. De-energized on loss of power
3. Energized on Lo-Lo setpoint

Each level channel bistable is assigned to a separate instrumentation and control power supply. A Trip Signal is provided from both Train A and Train B Solid State Protection System cabinets to the corresponding Reactor Building recirculation sump isolation valves logic, should 2 of the 4 water level channel bistables receive an Refueling Water Storage Tank level signal lower than the Lo-Lo level setpoint, following the generation of an "S" signal.

7.6.11.6 Sequence

This circuit is energized directly from the Solid State Protection System output cabinet and is not sequenced following an accident that requires its functioning.

7.6.11.7 Redundancy

The function of this switchover is available from both Train A and Train B down to the actuated equipment. The function including the actuated equipment is, therefore, redundant and train separation and independence are maintained from sensor to actuated equipment.

7.6.11.8 Diversity

Diversity of components and equipment between the redundant Trains is not required to protect against systematic failures, such as multiple failures resulting from a credible single event. The associated components are environmentally and seismically qualified in accordance with the procedures described in Sections 3.10 and 3.11. It is noted that there is functional diversity provided in that manual operation is available as a backup to the semi-automatic mode.

7.6.11.9 Actuated Devices

The actuated devices are the 4 motor control center starters, 1 for each of the Motor Operated Sump Valves, 3004 A&B and 3005 A&B.

7.6.11.10 Channel Bypass Indication

Indication is provided on the main control board to alert the operator that a Refueling Water Storage Tank water level channel is in the bypass mode and is unavailable. The indication is by status light and alarm window as shown on Figure 7.6-10.

7.7 CONTROL SYSTEMS NOT REQUIRED FOR SAFETY

The general design objectives of the plant control systems are:

1. To establish and maintain power equilibrium between primary and secondary system during steady-state unit operation;
2. To constrain operational transients so as to preclude unit trip and re-establish steady-state unit operation;
3. To provide the reactor operator with monitoring instrumentation that indicates required input and output control parameters of the systems and provides the operator the capability of assuming manual control of the system.

7.7.1 Description

The plant control systems described in this section perform the following functions:

1. Reactor Control System
   a. Enables the nuclear plant to accept a step load increase or decrease of 10% and a ramp increase or decrease of 5% per minute within the load range of 15% to 100% without reactor trip, steam dump, or pressurizer relief actuation, subject to possible xenon limitations.
   b. Maintains reactor coolant average temperature (T_{avg}) within prescribed limits by creating the bank demand signals for moving groups of full length rod cluster control assemblies during normal operation and operational transients. The T_{avg} control also supplies a signal to pressurizer water level control, and steam dump control.
2. Rod Control System
   a. Provides for reactor power modulation by manual or automatic control of full length control rod banks in a preselected sequence and for manual operation of individual banks.
   b. Systems for Monitoring and Indicating
      (1) Provide alarms to alert the operator if the required core reactivity shutdown margin is not available due to excessive control rod insertion.
      (2) Display control rod position.
      (3) Provide alarms to alert the operator in the event of control rod deviation exceeding a preset limit.
3. Plant Control System Interlocks
   a. Prevent further withdrawal of the control banks when signal limits are approached that predict the approach of a departure from nucleate boiling ratio (DNBR) limit or linear power (kW/ft) limit.
   b. Inhibit automatic turbine load change as required by the Nuclear Steam Supply System.

4. Pressurizer Pressure Control

   a. Maintains or restores the pressurizer pressure to the design pressure ± 50 psi (which is well within reactor trip and relief and safety valve actuation setpoint limits) following normal operational transients that induce pressure changes by control (manual or automatic) of heaters and spray in the pressurizer. Provides steam relief by controlling the power relief valves.

5. Pressurizer Water Level Control

   a. Establishes, maintains, and restores pressurizer water level within specified limits as a function of the average coolant temperature. Changes in level are caused by coolant density changes induced by loading, operational, and unloading transients. Level changes are controlled by means of charging flow control (manual or automatic) as well as by manual selection of letdown orifices. Maintaining coolant level in the pressurizer within prescribed limits by actuating the charging and letdown system thus provides control of the reactor coolant water inventory.

6. Steam Generator Water Level Control

   a. Establishes and maintains the steam generator water level to within predetermined physical limits during normal operating transients.

   b. Restores the steam generator water level to within predetermined limits at unit trip conditions. Regulates the feedwater flowrate such that under operational transients the heat sink for the reactor coolant system does not decrease below a minimum. Steam generator water inventory control is manual or automatic through the use of feedwater control valves.

7. Steam Dump Control

   a. Permits the nuclear plant to accept a sudden loss of load without incurring reactor trip. Steam is dumped to the condenser and/or the atmosphere as necessary to accommodate excess power generation in the reactor during turbine load reduction transients.

   b. Ensures that stored energy and residual heat are removed following a reactor trip to bring the plant to equilibrium no load conditions without actuation of the steam generator safety valves.

   c. Maintains the plant at no load conditions and permits a manually controlled cooldown of the plant.

7.7.1.1 Reactor Control System

The Reactor Control System enables the nuclear plant to follow load changes automatically including the acceptance of step load increase or decreases of 10% and ramp increases or decreases of 5% per minute within the load range of 15% to 100% without reactor trip, steam dump, or pressure relief (subject to possible xenon limitations). The system is also capable of restoring coolant average temperature to within the programmed temperature deadband following a change in load. Manual control rod operation may be performed at any time.

The Reactor Control System controls the reactor coolant average temperature by regulation of control rod bank position. The reactor coolant loop average temperatures are determined from hot leg and cold leg measurements in each reactor coolant loop. There is an average coolant temperature (T_{avg}) computed for each loop, where:

$$T_{avg} = \frac{T_{hot-avg} + T_{cold}}{2}$$

The error between the programmed reference temperature (based on turbine first stage pressure) and the median of the T_{avg} measured temperatures (which is processed through a lead/lag compensation unit) from each of the reactor coolant loops constitutes the primary control signal as shown in general on Figure 7.7-1 and in more detail on the functional diagrams shown in Figure 7.2-1, Sheet 9. The system is capable of restoring coolant average temperature to the programmed value following a change in load. The programmed coolant temperature increases linearly with turbine load from zero power to the full power condition. The T_{avg} also supplies a signal to pressurizer level control and steam dump control and rod insertion limit monitoring.

The temperature channels needed to derive the temperature input signals for the Reactor Control System are fed from protection channels via isolation amplifiers.

An additional control input signal is derived from the reactor power versus turbine load mismatch signal. This additional control input signal improves system performance by enhancing response and reducing transient peaks.

7.7.1.2 Rod Control System

7.7.1.2.1 Full Length Rod Control System

The full length rod control system receives rod speed and direction signals from the T_{avg} control system. The rod speed signal by design may vary over the corresponding range of 5 to 45 inches per minute (6 to 72 steps/minute) depending on the magnitude of the input signal. Manual control is provided to move a control bank in or out at a prescribed fixed speed.

When the turbine load reaches approximately 15% of rated load, the operator may select the “AUTOMATIC” mode, and rod motion is then controlled by the Reactor Control Systems. A permissive interlock C-5 (see Table 7.7-1) derived from the measurements of turbine first stage pressure prevents automatic control when the turbine load is below 15%. In the “AUTOMATIC” mode, the rods are again withdrawn (or inserted) in a predetermined programmed sequence by the automatic programming with the control interlocks (see Table 7.7-1).

The shutdown banks are always in the fully withdrawn position during normal operation, and are moved to this position at a constant speed by manual control prior to criticality. A reactor trip signal causes them to fall by gravity into the core. There are 2 shutdown banks.

The control banks are the only rods that can be manipulated under automatic control. Each control bank is divided into 2 groups to obtain smaller incremental reactivity changes per step. All rod control cluster assemblies in a group are electrically paralleled to move simultaneously. There is individual position indication for each rod cluster control assembly.

Power to rod drive mechanisms is supplied by 2 motor generator sets operating from 2 separate 480 volt, 3-phase buses. Each generator is the synchronous type and is driven by a 200 Hp induction motor. The a-c power is distributed to the rod control power cabinets through the 2 series connected reactor trip breakers.

The variable speed rod drive programmer affords the ability to insert small amounts of reactivity at low speed to accomplish fine control of reactor coolant average temperature about a small temperature deadband, as well as furnishing control at high speed. A summary of the rod cluster control assembly sequencing characteristics is given below:

1. Two (2) groups within the same bank are stepped such that the relative position of the groups will not differ by more than 1 step.
2. The control banks are programmed such that withdrawal of the banks is sequenced in the following order; control bank A, control bank B, control bank C, and control bank D. The programmed insertion sequence is the opposite of the withdrawal sequence, i.e., the last control bank withdrawn (bank D) is the first control bank inserted.
3. The control bank withdrawals are programmed such that when the first bank reaches a preset position, the second bank begins to move out simultaneously with the first bank. When the first bank reaches the top of the core, it stops, while the second bank continues to move toward its fully withdrawn position. When the second bank reaches a preset position, the third bank begins to move out, and so on. This withdrawal sequence continues until the unit reaches the desired power level. The control bank insertion sequence is the opposite.
4. Overlap between successive control banks is adjustable between 0 to 50% (0 to 115 steps), with an accuracy of ± 1 step.
5. Rod speeds for either the shutdown banks or manual operation of the control banks are capable of being controlled between a minimum of 8 steps per minute and a maximum of 72 (+ 0 steps per minute, - 10 steps per minute) steps per minute.

7.7.1.2.2 Part Length Rod Control System

The part length control rods have been deleted.

7.7.1.3 Plant Control Signals for Monitoring and Indicating

7.7.1.3.1 Monitoring Functions Provided by the Nuclear Instrumentation System

The power range channels are important because of their use in monitoring power distribution in the core within specified safe limits. They are used to measure power level, axial power imbalance, and radial power imbalance. The channels are capable of recording overpower

excursions up to 200% of full power. Suitable alarms are derived from these signals as described below.

Basic power range signals are:

1. Total current from a power range detector (4 such signals from separate detectors); these detectors are vertical and have a total active length of 10 feet.
2. Current from the upper half of each power range detector (4 such signals).
3. Current from the lower half of each power range detector (4 such signals).

Derived from these basic signals are the following (including standard signal processing for calibration).

4. Indicated nuclear power (4 such signals).
5. Indicated axial flux imbalance, derived from upper half flux minus lower half flux (4 such signals).

Alarm functions derived are as follows:

6. Deviation (maximum minus minimum of 4) in indicated nuclear power.
7. Upper radial tilt (maximum to average of 4) on upper-half currents.
8. Lower radial tilt (maximum to average of 4) on lower-half currents.

Provision is made to continuously record, on the control board, the 8 ion chamber signals, i.e., upper and lower signals for each detector. Nuclear power and axial unbalance is selectable for recording as well.

The axial flux difference imbalance deviation $\Delta\Phi$ alarms are derived from the plant process computer which determines the one minute averages of the excore detector outputs to monitor $\Delta\Phi$ in the reactor core and alerts the operator where $\Delta\Phi$ alarm conditions exist. Two (2) types of alarm messages are output. Above a preset (90%) power level, an alarm message is output immediately upon determining a delta flux exceeding a preset band (usually $\pm$ 5%) about a target delta flux value. Below this preset power level, an alarm message is output if the $\Delta\Phi$ exceeded its allowable limits for a preset cumulative (usually 1 hour) amount of time in the past 24 hours.

Additional background information on the Nuclear Instrumentation System can be found in Reference 1.

7.7.1.3.2 Rod Position Monitoring of Full and Part Length Rods

Two (2) separate systems are provided to sense and display control rod position as described below:

1. Digital Rod Position Indication System

   The Digital Rod Position Indication System displays full length position. Part length rods and control are not used at V. C. Summer Nuclear Station. The Digital Rod Position Indication System senses the actual position of each full length rod using a detector which consists of discrete coils mounted concentrically with the rod drive pressure housing. The coils are located axially along the pressure housing and magnetically sense the entry and presence of the rod drive shaft through its center line. For each detector, the coils are interlaced into 2 data channels, and are connected to the containment electronics (Data A and B) by separate multi-conductor cables. By employing 2 separate channels of information, the Digital Rod Position Indication System can continue to function (at reduced accuracy) when 1 channel fails. Multiplexing is then used to transmit the digital position signals from the containment electronics to the control board display unit.

   The control board display consists of two flat panel monitors that display the control rod position in a graphical and digital format. Each rod in the control and shutdown banks has its position displayed to ±4 steps throughout its range of travel when the system is operating at full accuracy.

   Included in the system is a rod at bottom signal for each rod that operates a local alarm. Also a control room annunciator is actuated when any shutdown rod or control bank A rod is at bottom.

2. Demand Position System - The Demand Position System counts pulses generated in the Rod Drive Control System to provide a digital readout of the demanded bank position.

   The Demand Position and Digital Rod Position Indication Systems are separate systems, but safety criteria were not involved in the separation, which was a result only of operational requirements. Operating procedures require the reactor operator to compare the demand and indicated (actual) readings from the Rod Position Indication System so as to verify operation of the Rod Control System.

7.7.1.3.3 Control Bank Rod Insertion Monitoring

When the reactor is critical, the normal indication of reactivity status in the core is the position of the control bank in relation to reactor power (as indicated by the Reactor Coolant System loop ΔT) and coolant average temperature. These parameters are used to calculate insertion limits for the control banks. Two (2) alarms are provided for each control bank:

1. The “low” alarm alerts the operator of an approach to the rod insertion limits requiring boron addition by following normal procedures with the Chemical and Volume Control System.

2. The “low-low” alarm alerts the operator to take immediate action to add boron to the Reactor Coolant System by any one of several alternate methods.

The purpose of the control bank rod insertion monitor is to give warning to the operator of excessive rod insertion. The insertion limit maintains sufficient core reactivity shutdown margin following reactor trip and provides a limit on the maximum inserted rod worth in the unlikely event of a hypothetical rod ejection, and limits rod insertion such that acceptable nuclear peaking factors are maintained. Since the amount of shutdown reactivity required for the design shutdown margin following a reactor trip increases with increasing power, the allowable rod insertion limits must be decreased (the rods must be withdrawn further) with increasing power. Two (2) parameters which are proportional to power are used as inputs to the insertion monitor. These are the ΔT between the hot leg and the cold leg, which is a direct function of reactor power, and T_{avg}, which is programmed as a function of power. The rod insertion monitor uses parameters for each control rod bank as follows:

$$Z_{LL} = A(\Delta T)_{median} + B(T_{avg})_{median} + C$$

where:

Z_{LL} = Maximum permissible insertion limit for affected control bank.

$(\Delta T)_{median}$ = Median ΔT of all loops.

$T_{avg})_{median}$ = Median T_{avg} of all loops.

A,B,C= Constants chosen to maintain $Z_{LL} \geq$ actual limit based on physics calculations.

The control rod bank demand position (Z) is compared to ZLL as follows:

If $Z - Z_{LL} \leq D$ a low alarm is actuated.
If $Z - Z_{LL} \leq E$ a low-low alarm is actuated.

Actuation of the low alarm alerts the operator of an approach to a reduced shutdown reactivity situation. Administrative procedures require the operator to add boron through the Chemical and Volume Control System. Actuation of the low-low alarm requires the operator to initiate emergency boration procedures. The value for “E” is chosen such that the low-low alarm would normally be actuated before the insertion limit is reached. The value for “D” is chosen to allow the operator to follow normal boration procedures. Figure 7.7-2 shows a block diagram representation of the control rod bank insertion monitor. The monitor is shown in more detail on the functional diagrams shown in Figure 7.2-1, Sheet 9. In addition to the rod insertion monitor for the control banks, the plant computer, which monitors individual rod positions, provides an alarm that is associated with the rod deviation alarm discussed in Section 7.7.1.3.4 is provided to warn the operator if any shutdown rod cluster control assembly leaves the fully withdrawn position.

Rod insertion limits are established by:

1. Establishing the allowed rod reactivity insertion at full power consistent with the purposes given above.
2. Establishing the differential reactivity worth of the control rods when moved in normal sequence.
3. Establishing the change in reactivity with power level by relating power level to rod position.
4. Linearizing the resultant limit curve. All key nuclear parameters in this procedure are measured as part of the initial and periodic physics testing program.

Any unexpected change in the position of the control bank under automatic control, or a change in coolant temperature under manual control, provides a direct and immediate indication of a change in the reactivity status of the reactor. In addition, samples are taken periodically of coolant boron concentration. Variations in concentration during core life provide an additional check on the reactivity status of the reactor, including core depletion.

7.7.1.3.4 Rod Deviation Alarm

The demanded and measured rod position signals are also monitored by the plant computer which provides a visual printout and an audible alarm whenever an individual rod position signal deviates from the other rods in the bank by a preset limit. The alarm can be set with appropriate allowance for instrument error and within sufficiently narrow limits to preclude exceeding core design hot channel factors.

Figure 7.7-3 is a block diagram of the rod deviation comparator and alarm system implemented by the plant computer.

7.7.1.3.5 Rod Bottom Alarms

A rod bottom signal for the full length rods in the Digital Rod Position System is used to operate control relays, which generate the “Rod Bottom” alarms.

7.7.1.4 Plant Control System Interlocks

The listing of the Plant Control System interlocks, along with the description of their derivations and functions, is presented in Table 7.7-1. It is noted that the designation numbers for these interlocks are preceded by “C”. The development of these logic functions is shown in the functional diagrams (Figure 7.2-1, Sheets 9 to 15).

7.7.1.4.1 Rod Stops

Rod stops are provided to prevent abnormal power conditions which could result from excessive control rod withdrawal initiated by either a Control System malfunction or operator violation of administrative procedures.

Rod stops are the C_1, C_2, C_3, C_4, and C_5 control interlocks identified in Table 7.7-1. The C_3 rod stop derived from overtemperature ΔT and the C_4 rod stop, derived from overpower ΔT are also used for turbine runback, which is discussed below.

7.7.1.4.2 Automatic Turbine Load Runback

Automatic turbine load runback is initiated by an approach to an overpower or overtemperature condition. This will prevent high power operation that might lead to an undesirable condition, which, if reached, will be protected by reactor trip.

Turbine load reference reduction is initiated by either an overtemperature or overpower ΔT signal. Two (2) out of 3 coincidence logic is used. A rod stop and turbine runback are initiated when:

$$\Delta T > \Delta T_{\text{rod stop}}$$

for both the overtemperature and the overpower condition.

For either condition in general:

$$\Delta T_{\text{rod stop}} = \Delta T_{\text{setpoint}} - B_p$$

where:

B_p = a setpoint bias.

Where $\Delta T_{\text{setpoint}}$ refers to the overtemperature ΔT reactor trip value and the overpower ΔT reactor trip value for the 2 conditions.

The turbine runback is continued until ΔT is equal to or less than $\Delta T_{\text{rod stop}}$. This function serves to maintain an essentially constant margin to trip.

7.7.1.5 Pressurizer Pressure Control

The Reactor Coolant System pressure is controlled by using either the heaters (in the water region) or the spray (in the steam region) of the pressurizer plus steam relief for large transients. The electrical immersion heaters are located near the bottom of the pressurizer. A portion of the heater group is proportionally controlled to correct small pressure variations. These variations are due to heat losses, including heat losses due to a small continuous spray. The remaining (backup) heaters are turned on automatically or manually to control pressure in conjunction with the control heaters and spray.

The spray nozzles are located on the top of the pressurizer. Spray is initiated when the pressure controller spray demand signal is above a given setpoint. The spray rate increases proportionally with increasing spray demand signal until it reaches a maximum value.

Steam condensed by the spray reduces the pressurizer pressure. A small continuous spray is normally maintained to reduce thermal stresses and thermal shock and to help maintain uniform water chemistry and temperature in the pressurizer.

Power relief valves limit system pressure for large positive pressure transients. In the event of a large load reduction, not exceeding the design plant load rejection capability, the pressurizer power operated relief valves might be actuated for the most adverse conditions, e.g., the most negative Doppler coefficient, and the maximum incremental rod worth.

Diagrams of the pressurizer pressure control system are shown on Figures 7.7-4 and 7.2-1 Sheets 11 and 12.

7.7.1.6 Pressurizer Water Level Control

The pressurizer operates by maintaining a steam cushion over the reactor coolant. As the density of the reactor coolant adjusts to the various temperatures, the steam water interface moves to absorb the variations with relatively small pressure disturbances.

The water inventory in the Reactor Coolant System is maintained by the Chemical and Volume Control System. During normal plant operation, the charging flow varies to produce the flow demanded by the pressurizer water level controller. The pressurizer water level is programmed as a function of coolant average temperature, with the highest average temperature (auctioneered) being used. The pressurizer water level decreases as the load is reduced from full load. This is a result of coolant contraction following programmed coolant temperature reduction from full power to low power. The programmed level is designed to match as nearly as possible the level changes resulting from the coolant temperature changes.

To control pressurizer water level during startup and shutdown operations, the charging flow is manually regulated from the Main Control Room.

A block diagram of the Pressurizer Water Level Control System is shown on Figure 7.7-5.

7.7.1.7 Steam Generator Water Level Control

Each steam generator is equipped with a 3 element feedwater flow controller which maintains a programmed water level which is a function of reactor flux. The 3 element feedwater controller regulates the feedwater valve by continuously comparing the feedwater flow signal, the steam generator water level signal, the programmed level and the pressure compensated steam flow signal. In addition, the feedwater pump speed is varied to maintain a programmed pressure differential between the steam header and the feed pump discharge header. The speed controller continuously compares the actual ΔP with a programmed ΔP_{ref} which is a linear function of steam flow. Continued delivery of feedwater to the steam generators is required as a sink for the heat stored and generated in the reactor following a reactor trip and turbine trip. An override signal closes the feedwater valves when the average coolant temperature is below a given temperature and the reactor has tripped. Manual override of the feedwater control system is available at all times. The Instrument Air system for each main feedwater control valve is equipped with the

necessary hardware to allow for local, manual control and locking of the main feedwater control valves in position with air pressure (air-gag), while maintaining the trip closed feature of the feedwater control valves.

When the plant is operating at very low power levels (as during startup), the steam and feedwater flow signals will not be usable for control. Therefore, a secondary automatic control system is provided for operation at low power. This system uses the steam generator water level and nuclear power signals in a feed forward control scheme to position a bypass valve which is in parallel with the main feedwater regulating valve. Switchover from the Bypass Feedwater Control System (low power) to the Main Feedwater Control System is initiated by the operator at approximately 25% power.

A block diagram of the Steam Generator Water Level Control System is shown in Figure 7.7-6 and 7.7-7.

7.7.1.8 Steam Dump Control

The Main Steam Supply System was originally designed to follow a full load rejection, defined as a reduction from 100% of rated turbine generator load to plant auxiliary load, without reactor trip through actuation of the steam dump to the condenser and atmosphere. With the transition to longer fuel cycles and less negative moderator temperature coefficients at the beginning of the fuel cycle, a full load rejection can no longer be sustained without a reactor trip for all times in core life and all allowable values of full power, average coolant temperature within the Reactor Coolant System.

The Automatic Steam Dump System is able to accommodate this abnormal load rejection and to reduce the effects of the transient imposed upon the Reactor Coolant System. By bypassing main steam directly to the condenser and/or the atmosphere, an artificial load is thereby maintained on the primary system. The Rod Control System can then reduce the reactor temperature to a new equilibrium value without causing a reactor trip for most allowed operating conditions (See Section 10.3.2.1). The steam dump system flow capacity was designed to be at least 85% of full load steam flow at full load steam pressure. The actual capacity is ~ 93.6%, (See Table 10.4-2).

If the difference between the reference T_{avg} (T_{ref}) based on turbine first stage pressure and the lead/lag compensated median T_{avg} exceeds a predetermined amount, and the interlock mentioned below is satisfied, a demand signal will actuate the steam dump to maintain the Reactor Coolant System temperature within control range until a new equilibrium condition is reached.

A lead/lag compensation to this T_{ref} signal is provided to improve steam dump response and provide a stable steam dump control. This allows for reducing T_{hot}, thereby opening the steam dumps at a lower temperature error.

To prevent actuation of steam dump on small load perturbations, an independent load rejection sensing circuit is provided. This circuit senses the rate of decrease in the turbine load as detected by the turbine first stage pressure. It is provided to unblock the dump valves when the rate of load

rejection exceeds a preset value corresponding to a 10% step load decrease or a sustained ramp load decrease of 5%/minute. Additional interlocks for steam dump are described in Table 7.3-3, designation P-12, and Table 7.7-1, designations C-7, C-8, C-9, C-15, and C-16.

Block diagrams of the Steam Dump Control System are shown on Figure 7.2-1, Sheet 10, and Figure 7.7-8.

7.7.1.8.1 Load Rejection Steam Dump Controller

This circuit prevents large increase in reactor coolant temperature following a large, sudden load decrease. The error signal is a difference between the lead/lag compensated median T_{avg} and the reference T_{avg} is based on turbine first stage pressure.

The T_{avg} signal is the same as that used in the Reactor Coolant System. The lead/lag compensation for the T_{avg} signal is to compensate for lags in the plant thermal response and in valve positioning. Following a sudden load decrease, T_{ref} is immediately decreased and T_{avg} tends to increase, thus generating an immediate demand signal for steam dump. Since control rods are available, in this situation steam dump terminates as the error comes within the maneuvering capability of the control rods.

7.7.1.8.2 Turbine Trip Steam Dump Controller

Following a turbine trip, as monitored by the turbine trip signal, the load rejection steam dump controller is defeated and the turbine trip steam dump controller becomes active. Since control rods are not available in this situation, the demand signal is the error signal between the lead/lag compensated median T_{avg} and the no load reference T_{avg}. When the error signal exceeds a predetermined setpoint the dump valves are tripped open in a prescribed sequence. As the error signal reduces in magnitude indicating that the Reactor Coolant System T_{avg} is being reduced toward the reference no load value, the dump valves are modulated by the plant trip controller to regulate the rate of decay heat removal and thus gradually establish the equilibrium hot shutdown condition.

Following a turbine trip only sufficient steam dump capacity is necessary to maintain steam pressure below the steam generator relief valve setpoint (approximately 40% capacity to the condenser); therefore, only the first 2 groups of valves are opened. The error signal determines whether a group is to be tripped open or modulated open. The valves are modulated when the error is below the trip-open setpoints.

7.7.1.8.3 Steam Header Pressure Controller

Residual heat removal is maintained by the steam generator pressure controller (manually selected) which controls the amount of steam flow to the condensers. This controller operates a portion of the same steam dump valves to the condensers which are used during the initial transient following a turbine and reactor trip.

7.7.1.9 Incore Instrumentation

The Incore Instrumentation System consists of Chrome-Alum-el thermocouples at fixed core outlet positions and movable miniature neutron detectors which can be positioned at the center of selected fuel assemblies, anywhere along the length of the fuel assembly vertical axis. The basic system for insertion of these detectors is shown in Figure 7.7-9.

7.7.1.9.1 Thermocouples

This section deleted by Amendment 1, August 1985.

7.7.1.9.2 Movable Neutron Flux Detector Drive System

Miniature fission chamber detectors can be remotely positioned in retractable guide thimbles to provide flux mapping of the core. The stainless steel detector shell is welded to the leading end of helical wrap drive cable and to stainless steel sheathed coaxial cable. The retractable thimbles, into which the miniature detectors are driven, are pushed into the reactor core through conduits which extend from the bottom of the reactor vessel down through the concrete shield area and then up to a thimble seal table. Their distribution over the core is nearly uniform with about the same number of thimbles located in each quadrant.

The thimbles are closed at the leading ends, are dry inside, and serve as the pressure barrier between the Reactor Coolant System and the atmosphere. Mechanical seals between the retractable thimbles and the conduits are provided at the seal line. During reactor operation, the retractable thimbles are stationary. They are extracted downward from the core during refueling to avoid interference within the core. A space above the seal line is provided for the retraction operation.

The Drive System for the insertion of the miniature detectors consists basically of drive assemblies, 5 path rotary transfer assemblies, and 10 path rotary transfer assemblies, as shown in Figure 7.7-9. The Drive System pushes hollow helical wrap drive cables into the core with the miniature detectors attached to the leading ends of the cables and small diameter sheathed coaxial cables threaded through the hollow centers back to the ends of the drive cables. Each drive assembly consists of a gear motor which pushes a helical wrap drive cable and detector through a selective thimble path by means of a special drive box and includes a storage device that accommodates the total drive cable length.

Manual isolation valves (1 for each thimble) are provided for closing the thimbles. When closed, the valves form a 2500 psig barrier. The manual isolation valves are not designed to isolate a thimble while a detector/drive cable is inserted into the thimble. The detector/drive cable must be retracted to a position above the isolation valve prior to closing the valve.

A small leak would probably not prevent access to the isolation valves and thus a leaking thimble could be isolated during a hot shutdown. A large leak might require cold shutdown for access to the isolation valve.

7.7.1.9.3 Control and Readout Description

The Control and Readout System provides means for inserting the miniature neutron detectors into the reactor core and withdrawing the detectors while plotting neutron flux versus detector position. The Control System is located in the Control Room. Limit switches in each transfer device provide feedback of path selection operation. Each gear box drives an encoder for position feedback. One (1) 5 path operation selector is provided for each drive unit to insert the detector in one of 5 functional modes of operation. One (1) 10 path operation selector is also provided for each drive unit that is used to route a detector into any 1 of up to 10 selectable paths. A common path is provided to permit cross calibration of the detectors.

The Control Room contains the necessary equipment for control, position indication, and flux recording for each detector.

A “flux-mapping” consists, briefly, of selecting (by panel switches) flux thimbles in given fuel assemblies at various core quadrant locations. The detectors are driven to the top of the core and stopped automatically. An x-y plot (position versus flux level) is initiated with the slow withdrawal of the detectors through the core from top to a point below the bottom. In a similar manner other core locations are selected and plotted. Each detector provides axial flux distribution data along the center of a fuel assembly.

Various radial positions of detectors are then compared to obtain a flux map for a region of the core.

The number and location of these thimbles have been chosen to permit measurement of local to average peaking factors to an accuracy of ± 5% (95% confidence). Measured nuclear peaking factors will be increased by 5% to allow for this accuracy. If the measured power peaking is larger than acceptable, reduced power capability will be indicated.

Operating plant experience has demonstrated the adequacy of the incore instrumentation in meeting the design bases stated.

7.7.1.9.4 Power Distribution Monitoring System

An alternative to the Movable Incore Detector System for developing full core flux maps while above 25% power, is the BEACON Power Distribution Monitoring System (Reference 3). This system obtains data from the plant computer and processes the data into a 3-dimensional core model. The inputs into this system are core exit thermocouples, control rod bank position, Tcold, Reactor power level, and the nuclear instrumentation Power Range section signals. Per Technical Specifications, there is a minimum number of each type of input necessary to consider the system operable.

7.7.2 Analysis

The plant control systems are designed to assure high reliability in any anticipated operational occurrences. Equipment used in these systems is designed and constructed with a high level of reliability.

Proper positioning of the control rods is monitored in the Control Room by bank arrangements of the individual position columns for each rod cluster control assembly. A rod deviation alarm alerts the operator of a deviation of 1 rod cluster control assembly from the other rack in that bank position. There are also insertion limit monitors with visual and audible annunciation. A rod bottom alarm signal is provided to the Control Room for each full length rod cluster control assembly. Four (4) excore long ion chambers also detect asymmetrical flux distribution indicative of rod misalignment.

Overall reactivity control is achieved by the combination of soluble boron and rod cluster control assemblies. Long term regulation of core reactivity is accomplished by adjusting the concentration of boric acid in the reactor coolant. Short term reactivity control for power changes is accomplished by the Plant Control System which automatically moves rod cluster control assemblies. This system uses input signals including neutron flux, coolant temperature, and turbine load.

The Plant Control Systems will prevent an undesirable condition in the operation of the plant that, if reached, will be protected by reactor trip. The description and analysis of this protection is covered in Section 7.2. Worst case failure modes of the Plant Control Systems are postulated in the analysis of off-design operational transients and accidents covered in Chapter 15, such as, the following:

1. Uncontrolled rod cluster control assembly withdrawal from a subcritical condition.
2. Uncontrolled rod cluster control assembly withdrawal at power.
3. Rod cluster control assembly misalignment.
4. Loss of external electrical load and/or turbine trip.
5. Loss of all a-c power to the station auxiliaries.
6. Excessive heat removal due to Feedwater System malfunctions.
7. Excessive load increase incident.
8. Accidental depressurization of the Reactor Coolant System.

These analyses show that a reactor trip setpoint is reached in time to protect the health and safety of the public under those postulated incidents and that the resulting coolant temperatures produce a departure from nucleate boiling (DNBR) well above the limiting value of 1.30. Thus, there will be no cladding damage and no release of fission products to the Reactor Coolant System under the assumption of these postulated worst case failure modes of the plant control system.

7.7.2.1 Separation of Protection and Control System

In some cases, it is advantageous to employ control signals derived from individual protection channels through isolation amplifiers contained in the protection channel. As such, a failure in the control circuitry does not adversely affect the protection channel. Test results have shown that a short circuit or the application (credible fault voltage from within the cabinets) of 120 volt a-c ± 1% or 140 volt d-c on the isolated output portion of the circuit (nonprotection side of the circuit) will not affect the input (protection) side of the circuit.

Where a single random failure can cause a control system action that results in a generating station condition requiring protective action and can also prevent proper action of a protection system channel designed to protect against the condition, the remaining redundant protection channels are capable of providing the protective action even when degraded by a second random failure. The loop T_{avg} and Delta-T channel required inputs to the Steam Dump System, Reactor Control System, the Control Rod Insertion Monitor and the Pressurizer Level Control System are electrically isolated prior to being routed to the control cabinets. A median signal is then calculated for T_{avg} and Delta-T in the control cabinets utilizing a Median Signal Selection (MSS) for input to the appropriate control systems. This meets the applicable requirements of Section 4.7 of IEEE Standard 279-1971.

The pressurizer pressure channels needed to derive the control signals are electrically isolated from protection.

7.7.2.2 Response Considerations of Reactivity

Reactor shutdown with control rods is completely independent of the control functions since the trip breakers interrupt power to the full length rod drive mechanisms regardless of existing control signals. The design is such that the system can withstand accidental withdrawal of control groups or unplanned dilution of soluble boron without exceeding acceptable fuel design limits. The design meets the requirements of the 1971 General Design Criteria 25.

No single electrical or mechanical failure in the Rod Control System could cause the accidental withdrawal of a single rod cluster control assembly from the partially inserted bank at full power operation. The operator could deliberately withdraw a single rod cluster control assembly in the control bank; this feature is necessary in order to retrieve a rod, should one be accidentally dropped. In the extremely unlikely event of simultaneous electrical failures which could result in a single rod cluster control assembly withdrawal, rod deviation would be displayed on the plant annunciator, and the individual rod position readouts would indicate the relative positions of the rods in the bank. Withdrawal of a single rod cluster control assembly by operator action, whether deliberate or by a combination of errors, would result in activation of the same alarm and the same visual indications.

Each bank of control and shutdown rods in the system is divided into 2 groups (group 1 and group 2) of 4 mechanisms each. The rods comprising a group operate in parallel through multiplexing thyristors. The 2 groups in a bank move sequentially such that the first group is always within 1 step of the second group in the bank. The group 1 and group 2 power circuits are installed in

different cabinets as shown in Figure 7.7-15, which also shows that 1 group is always within 1 step (5/8 inch) of the other group. A definite schedule of actuation or deactuation of the stationary gripper, moveable gripper, and lift coils of a mechanism is required to withdraw the rod cluster control assembly attached to the mechanism. Since the 4 stationary gripper, moveable gripper, and lift coils associated with the rod cluster control assemblies of a rod group are driven in parallel, any single failure which could cause rod withdrawal would affect a minimum of 1 group of rod cluster control assemblies. Mechanical failures are in the direction of insertion, or immobility.

Figure 7.7-15 is provided for a discussion of design features that assure that no single electrical failure could cause the accidental withdrawal of a single rod cluster control assembly from the partially inserted bank at full power operation.

The Figure 7.7-15 shows the typical parallel connections on the lift, movable and stationary coils for a group of rods. Since single failures in the stationary or movable circuits will result in dropping or preventing rod (or rods) motion, the discussion of single failure will be addressed to the lift coil circuits. 1) Due to the method of wiring the pulse transformers which fire the lift coil multiplex thyristors, 3 of the 4 thyristors in a rod group could remain turned off when required to fire, if for example the gate signal lead failed open at point $\chi 1$. Upon “up” demand, 1 rod in group 1 and 4 rods in group 2 would withdraw. A second failure at point $\chi 2$ in group 2 circuit is required to withdraw 1 rod cluster control assembly; 2) Timing circuit failures will affect the 4 mechanisms of a group or the 8 mechanisms of the bank and will not cause a single rod withdrawal; 3) More than 2 simultaneous component failures are required (other than the open wire failures) to allow withdrawal of a single rod.

The identified multiple failure involving the least number of components consists of open circuit failure of the proper 2 out of 16 wires connected to the gate of the lift coil thyristors. The probability of open wire (or terminal) failure is 0.016×10^{-6} per hour by MIL-HDB217A. These wire failures would have to be accompanied by failure, or disregard, of the indications mentioned above. The probability of this occurrence is therefore too low to have any significance.

Concerning the human element, to erroneously withdraw a single rod cluster control assembly, the operator would have to improperly set the blank selector switch, the lift coil disconnect switches, and the in hold out switch. In addition, the indications would have to be disregarded or ineffective. Such series of errors would require a complete lack of understanding and administrative control. A probability number cannot be assigned to a series of errors such as these.

The Rod Position Indication System provides direct visual displays of each control rod assembly position. The plant computer alarms for deviation of rods from their banks. In addition a rod insertion limit monitor provides an audible and visual alarm to warn the operator of an approach to an abnormal condition due to dilution. The low-low insertion limit alarm alerts the operator to follow emergency boration procedures. The facility reactivity control systems are such that acceptable fuel damage limits will not be exceeded even in the event of a single malfunction of either system.

An important feature of the Control Rod System is that insertion is provided by gravity fall of the rods.

In all analyses involving reactor trip, the single, highest worth rod cluster control assembly is postulated to remain untripped in its full out position.

One means of detecting a stuck control rod assembly is available from the actual rod position information displayed on the control board. There is a control board rod position readout with one for each full length rod, to provide the plant operator actual position of the rod in steps. The indications are grouped by banks (e.g., control bank A, control bank B, etc.) to indicate to the operator the deviation of one rod with respect to other rods in a bank. This serves as a means to identify rod deviation.

The plant computer monitors the actual position of all rods. Should a rod be misaligned from the other rods in that bank by more than 15 inches, the rod deviation alarm is actuated.

Misaligned rod cluster control assemblies are also detected and alarmed in the Control Room via the Flux Tilt Monitoring System which is independent of the plant computer. Isolated signals derived from the Nuclear Instrumentation System are compared with one another to determine if a preset amount of deviation of average power level has occurred. Should such a deviation occur the comparator output will operate a bistable unit to actuate a control board annunciator. This alarm will alert the operator to a power imbalance caused by a misaligned rod. By use of individual rod position readouts, the operator can determine the deviating control rod and take corrective action. The design of the Plant Control Systems meets the requirements of the 1971 General Design Criteria 23.

Refer to Section 4.3.2.1 for additional information on response considerations due to reactivity.

7.7.2.3 Step Load Changes Without Steam Dump

The Plant Control System restores equilibrium conditions, without a trip, following a plus or minus 10% step change in load demand, over the 15 to 100% power range for automatic control. Steam dump is blocked for load decrease less than or equal to 10%. A load demand greater than full power is prohibited by the turbine control load limit devices.

The Plant Control System minimizes the reactor coolant average temperature deviation during the transient within a given value and restores average temperature to the programmed setpoint. Excessive pressurizer pressure variations are prevented by using spray and heaters and power relief valves in the pressurizer.

The control system must limit nuclear power overshoot to acceptable values following a 10% increase in load to 100%.

7.7.2.4 Loading and Unloading

Ramp loading and unloading of 5% per minute can be accepted over the 15 to 100% power range under automatic control without tripping the plant. The function of the control system is to maintain the coolant average temperature as a function of turbine generator load.

The coolant average temperature increases during loading and causes a continuous insurge to the pressurizer as a result of coolant expansion. The sprays limit the resulting pressure increase. Conversely, as the coolant average temperature is decreasing during unloading, there is a continuous outsurge from the pressurizer resulting from coolant contraction. The pressurizer heaters limit the resulting system pressure decrease. The pressurizer water level is programmed such that the water level is above the setpoint for heater cut out during the loading and unloading transients. The primary concern during loading is to limit the overshoot in nuclear power and to provide sufficient margin in the overtemperature ΔT setpoint.

The automatic load controls are designed to adjust the unit generation to match load requirements within the limits of the unit capability and licensed rating.

7.7.2.5 Load Rejection Furnished by Steam Dump System

When a load rejection occurs, if the difference between the required temperature setpoint of the Reactor Coolant System and the actual average temperature exceeds a predetermined amount, a signal will actuate the steam dump to maintain the Reactor Coolant System temperature within control range until a new equilibrium condition is reached.

The reactor power is reduced at a rate consistent with the capability of the Rod Control System. Reduction of the reactor power is automatic. The steam dump flow reduction is as fast as rod cluster control assemblies are capable of inserting negative reactivity.

The Rod Control System can then reduce the reactor temperature to a new equilibrium value without causing a reactor trip for most allowed operating conditions (See Section 10.3.2.1). The steam dump system flow capacity was designed to be at least 85% of full load steam flow at full load steam pressure. The actual capacity is ~ 93.6%, (See Table 10.4-2).

The steam dump flow reduces proportionally as the control rods act to reduce the average coolant temperature. The artificial load is therefore removed as the coolant average temperature is restored to its programmed equilibrium value.

The dump valves are modulated by the reactor coolant average temperature signal. The required number of steam dump valves can be tripped quickly to stroke full open or modulate, depending upon the magnitude of the temperature error signal resulting from loss of load.

7.7.2.6 Turbine Generator Trip with Reactor Trip

Whenever the turbine generator unit trips at an operating power level above 50% power, the reactor also trips. The unit is operated with a programmed average temperature as a function of

load, with the full load average temperature significantly greater than the equivalent saturation pressure of the steam generator safety valve setpoint. The thermal capacity of the Reactor Coolant System is greater than that of the Secondary System, and because the full load average temperature is greater than the no load temperature, a heat sink is required to remove heat stored in the reactor coolant to prevent actuation of steam generator safety valves for a trip from full power. This heat sink is provided by the combination of controlled release of steam to the condenser and by makeup of feedwater to the steam generators.

The Steam Dump System is controlled from the reactor coolant average temperature signal whose setpoint values are programmed as a function of turbine load. Actuation of the steam dump is rapid to prevent actuation of the steam generator safety valves. With the dump valves open, the average coolant temperature starts to reduce quickly to the no load setpoint. A direct feedback of temperature acts to proportionally close the valves to minimize the total amount of steam which is by-passed.

Following the turbine trip, the feedwater flow is cut off when the average coolant temperature decreases below a given temperature or when the steam generator water level reaches a given high level.

Additional feedwater makeup is then controlled manually to restore and maintain steam generator water level while assuring that the reactor coolant temperature is at the desired value. Residual heat removal is controlled by the steam (manually selected) which controls the amount of steam flow to the condensers. This controller operates a portion of the same steam dump valves to the condensers which are used during the initial transient following turbine and reactor trip.

The pressurizer pressure and level fall rapidly during the transient because of coolant contraction. The pressurizer water level is programmed so that the level following the turbine and reactor trip is above the heaters. However, if the heaters become uncovered following the trip, the Chemical and Volume Control System will provide a full charging flow to restore water level in the pressurizer. Heaters are then turned on to restore pressurizer pressure to normal.

The Steam Dump and Feedwater Control Systems are designed to prevent the average coolant temperature from falling below the programmed no load temperature following the trip to ensure adequate reactivity shutdown margin.

7.7.3 Technical Support Complex (TSC)

7.7.3.1 Description

In response to the recommendations issued post-TMI (e.g., NUREG-0578, NUREG-0585), South Carolina Electric & Gas will incorporate into the Virgil C. Summer Nuclear Power Plant a Technical Support Complex (TSC). This complex will improve the information available to operating and technical personnel. The 3 elements of the Technical Support Complex are:

1. ON-SITE Technical Support Center (OSTS).

2. Bypass and Inoperable Status Indication (BISI)
3. Safety Parameter Display System (SPDS)

The ON-SITE Technical Support Center is at a location adjacent to but separate from the Control Room. Key plant information can be displayed in and transmitted from the ON-SITE Technical Support Center to those technical personnel who are responsible for engineering support during post accident recovery. The center has the capability to receive, process, and display analog and digital signals from both the Nuclear Steam Supply System and balance of plant parts of the plant.

Bypass and Inoperable Status Indication provides the operator with a clear indication of the availability of plant safety systems. It provides the operator and OTSC personnel with a continuous systems level indication of bypasses or inoperable status of the systems comprising the Engineered Safety Features.

The purpose of the safety parameter display system (SPDS) is to assist operating personnel in evaluating the safety status of the plant. The safety parameter display system provides a continuous indication of plant parameters or derived variables which are representative of the safety status of the plant during both normal and emergency use except in the case that a seismic event results in the loss of the Integrated Plant Computer System (IPCS). The primary function of the SPDS is to aid in the rapid detection of abnormal operating conditions. Secondary functions include analyzing and diagnosing the abnormality, and providing an informational basis for corrective action execution.

The Technical Support Complex is located in the Control Building, elevation 463’0”, separate from but next to, the Control Room and is capable of accommodating a minimum of 25 persons (see Figure 1.2-15). Access to the Control Room is available through connecting doors between the Technical Support Complex and the Control Room. Print storage and plant information will be available in the Technical Support Center. The Technical Support Complex contains the following areas:

1. Data Display Room - This contains the communications and monitoring equipment necessary to provide the engineering and management support functions during an accident condition. The Communications, monitoring, and display equipment in this area includes:
   a. Communications Network including plant telephones, dedicated lines to external parties, and radio systems.
2. SCE&G Co. Technical Area - Office and communications facilities for SCE&G assigned personnel.
3. NRC Office - Office and communications for 5 NRC assigned personnel.
4. Operations Conference Room - Conference Room facilities.
5. Westinghouse Office - Office and communications facilities for plant personnel to communicate with Westinghouse.
6. GAI Office - Office and communications facilities for plant personnel to communicate with GAI.

7. Emergency Monitoring Team Office - Office facilities for the SCE&G Co. emergency monitoring team.

The Technical Support Complex is habitable to the same environmental conditions as the Control Room for postulated accident conditions. (The Technical Support Complex has the same air supply and exhaust system as the Control Room, see Section 9.4.1.2.1).

Installed radiation monitors (RM-G1 and RM-A1) will detect direct radiation and airborne radioactive contaminants for both the Control Room and the Technical Support Complex. The monitors will alarm when high radiation levels are being approached. SCE&G Co. has established in the plant's emergency procedures the necessary precautionary protective measures to be taken for high levels of radiation.

7.7.3.2 Analysis

1. The Technical Support Complex is located on elevation 463'0" of the Control Building, which is a Seismic Category I structure.
2. The environmental conditions within the Technical Support Complex are the same as those in the Control Room.
3. Installed radiation monitors (RM-G1 and RM-A1) will detect direct radiation and airborne radioactive contaminants for both the Control Room and the TSC. The monitors will alarm when high radiation levels are being approached.
4. Equipment within the Technical Support Complex is designed to assure reliability in the recovery of data.
5. The Technical Support Complex and equipment located in the Technical Support Complex are not required to initiate actuation of safety related systems. Loss of the Technical Support Complex or any equipment within the TSC will not prevent safe shutdown of the plant.

7.7.4 Critical Systems Leak Monitoring System

7.7.4.1 Description

An acoustical type leak monitoring system is provided to detect through the wall and valve seat leakage downstream of the pressurizer safety valves.

The sensors and preamps for the system are located inside the Reactor Building, with all other conditioning components located outside.

A leak through a valve seat generates metal borne acoustic waves which are detected by acoustic transducers mounted on the piping adjacent to the valves. The transducers convert the acoustic waves into electrical signals which are amplified and then transmitted to the Leak Detection System.

The Control Room is provided with indication which relates to the size of the leak and an alarm which alerts the operator of the occurrence of a leak. The system is provided with multiple sensors to enable the plant operator to determine which pressurizer safety valve is open.

7.7.4.2 Analysis

The Critical Systems Leak Monitoring System is powered from a vital instrument bus. The system will be qualified to IEEE 323-1971 and IEEE 344-1975. Seismic and environmental qualification is discussed in Section 3.10 and 3.11, respectively.

7.7.5 Reactor Vessel Level Instrumentation System

This section deleted by Amendment 4.

7.8 ATWS MITIGATION SYSTEM ACTUATION CIRCUITRY (AMSAC)

7.8.1 Description

7.8.1.1 System Description

The ATWS (Anticipated Transient Without Scram) Mitigation System Actuation Circuitry (AMSAC) provides a backup to the Reactor Trip System (RTS) and Engineered Safety Features Actuation System (ESFAS) for initiating turbine trip and emergency feedwater flow in the event an anticipated transient results (e.g., in the complete loss of main feedwater). The AMSAC is independent of and diverse from the Reactor Trip System and the Engineered Safety Features Actuation System with the exception of the final actuation devices and is classified as quality related equipment. It is a highly-reliable, microprocessor-based, single train system powered by a non-Class 1E source with battery backup.

The AMSAC continuously monitors level in the steam generators, which is an anticipatory indication of a loss of heat sink, and initiates certain functions when the level drops below a predetermined setpoint for at least a preselected time and for 2 of the 3 steam generator levels. These initiated functions are the tripping of the turbine, the initiation of emergency feedwater, and isolation of the steam generator blowdown and sample lines.

The AMSAC is designed to be highly reliable, resistant to inadvertent actuation, and easily maintained. Reliability is assured through the use of internal redundancy and continual self-testing by the system. Inadvertent actuations are minimized through the use of internal redundancy and majority voting at the output stage of the system. The time delay on low steam generator level and the coincidence logic used also minimize inadvertent actuations.

The AMSAC automatically performs its actuations when above a preselected power level, determined using turbine impulse chamber pressure, and remains armed sufficiently long after that pressure drops below the setpoint to ensure that its function will be performed in the event of a turbine trip.

7.8.1.2 Equipment Description

The AMSAC consists of a single train of equipment located in a seismically qualified cabinet.

The design of the AMSAC is based on the industry standard Intel multibus format, which permits the use of various readily available, widely used microprocessor cards on a common data bus for various functions.

The AMSAC consists of the following:

1. Steam Generator Level Sensing

   SG level is measured with 3 existing differential pressure-type level transmitters, for each of the main steam generators.

2. Turbine Impulse Pressure

   Turbine Impulse Pressure is measured with 2 existing pressure transmitters located in the steam supply line near the turbine.

3. System Hardware

   The system hardware consists of 2 primary systems: the Actuation Logic System (ALS) and the Test/Maintenance System (T/MS).

   Actuation Logic System

   The Actuation Logic System monitors the analog and digital inputs, performs the functional logic required, provides actuation outputs to trip the turbine and initiate emergency feedwater flow, and provides status information to the Test/Maintenance System. The Actuation Logic System consists of 3 groups of input/output (I/O) modules, 3 actuation logic processors (ALPs), 2 majority voting modules, and 2 output relay panels. The I/O modules provide signal conditioning, isolation, and test features for interfacing the Actuation Logic System and Test/Maintenance System. Conditioned signals are sent to 3 identical actuation logic processors for analog-to-digital conversion, setpoint comparison, and coincidence logic performance. Each of the actuation logic processors perform identical logic calculations using the same inputs and derive component actuation demands, which are then sent to the majority voting modules. The majority voting modules perform a 2 out of 3 vote on the actuation logic processor demand signals. These modules drive the relays providing outputs to the existing turbine trip and emergency feedwater initiation circuits. A simplified block diagram of the AMSAC Actuation Logic System architecture is presented in Figure 7.8-1.

   Test/Maintenance System

   The Test/Maintenance System provides the AMSAC with automated and manual testing as well as a maintenance mode. Automated testing is the continuously performed self-checking done by the system during normal operation. Actuation Logic System status is monitored by the T/MS and sent to the plant computer and the main control board. Manual testing of the system by the maintenance staff can be performed on-line to provide assurance that the Actuation Logic System is fully operational. The maintenance mode permits the maintenance staff, under administrative control, to modify channel setpoints, channel status and timer values, and initiate channel calibration.

   The Test/Maintenance System consists of a test/maintenance processor, a digital-to-analog conversion board, a memory board, expansion boards, a self-health board, digital output modules, a test/maintenance panel, and a portable terminal/printer.

4. Equipment Actuation

   The output relay panels provide component actuation signals through isolation relays, which then drive the final actuation circuitry for initiation of emergency feedwater and for turbine trip. Existing actuation devices of the component are used.

7.8.1.3 Functional Performance Requirements

The AMSAC automatically initiates emergency feedwater, trips the turbine, and isolates steam generator blowdown and sampling lines. Analyses have shown that the most limiting Anticipated Transient Without Scram event is a loss of feedwater event without a reactor trip. Therefore, the AMSAC performs its mitigative actuations:

1. In order to ensure a secondary heat sink following an anticipated transient (ANS Condition II) without a reactor trip.
2. In order to limit core damage following an anticipated transient without a reactor trip, and
3. To ensure that the energy generated in the core is compatible with the design limits to protect the reactor coolant pressure boundary by maintaining the reactor coolant pressure to within ASME Stress Level C.

7.8.1.4 AMSAC Interlocks

A single interlock, designated as C-20, is provided to allow for the automatic arming and blocking of the AMSAC system. The system is blocked below 40% turbine power when the actions taken by the AMSAC following an Anticipated Transient Without Scram need not be automatically initiated. Turbine impulse chamber pressure in a 2-out-of-2 logic scheme is used for this permissive. Turbine impulse chamber pressure above the setpoint will automatically defeat any block, i.e., will arm the AMSAC system. Dropping below this setpoint will automatically block the AMSAC system. Removal of the C-20 permissive is automatically delayed for a predetermined time. The operating status of the AMSAC is displayed on the main control board.

7.8.1.5 Steam Generator Level Sensor Arrangement

Steam generator level is determined by a differential pressure transmitter, measuring the level drop in the steam generator. These steam generator level signals are used as input to the AMSAC and are isolated signals from the Process Protection Cabinets.

7.8.1.6 Turbine Impulse Chamber Pressure Arrangement

Turbine impulse chamber pressure is determined by a differential pressure transmitter, measuring the pressure rise in the turbine. These pressure signals are used as input into AMSAC and are isolated signals from the Process Protection Cabinets.

7.8.1.7 Trip System

The differential pressure that is measured in the steam generator is used by the AMSAC to determine trip demand. Signal conditioning is performed on the transmitter output and used by each of the actuation logic processors to derive a component actuation demand. If 2 of the 3 steam generators have a low level at a power level greater than the C-20 permissive, then a trip demand signal is generated. This signal drives output relays for performing the necessary mitigative actions.

7.8.1.8 Isolation Devices

AMSAC is independent of the Reactor Trip and Engineered Safety Features Actuation Systems. The AMSAC inputs for measuring turbine impulse chamber pressure and narrow range steam generator water level are derived from existing transmitters and channels within the process protection system. Connections to these channels are made downstream of Class 1E isolation devices which are located within the process protection cabinets. These isolation devices ensure that the existing protection system continues to meet all applicable safety criteria by providing isolation. Buffering of the AMSAC outputs from the safety related final actuation device circuits is achieved through qualified relays. A credible fault occurring in the non-safety-related AMSAC will not propagate through and degrade the RTS and ESFAS.

7.8.1.9 AMSAC Diversity from the Reactor Protection Systems

Equipment diverse from the Reactor Trip System and Engineered Safety Features Actuation System is used in the AMSAC to prevent common mode failures that might affect the AMSAC and the Reactor Trip System or Engineered Safety Features Actuation System. The AMSAC is a digital, microprocessor-based system with the exception of the analog steam generator level and turbine impulse pressure transmitter inputs, whereas the Reactor Trip System utilizes an analog based protection system. Also where similar components are utilized for the same function in both AMSAC and the Reactor Trip System, the components used in AMSAC are provided from a different manufacturer.

Common mode failure of identical components in the analog portion of the Reactor Trip System that results in the inability to generate a reactor trip signal will not impact the ability of the digital AMSAC to generate the necessary mitigative actuations. Similarly, a postulated common mode failure affecting analog components in Engineered Safety Features Actuation System, affecting its ability to initiate emergency feedwater, will not impact the ability of the digital based AMSAC to automatically initiate emergency feedwater.

7.8.1.10 Power Supply

The AMSAC power supply is a non-Class 1E vital bus, which is independent from the RTS power supplies, and is backed by batteries which are independent from the existing batteries which supply the RTS.

7.8.1.11 Environmental Variations

AMSAC equipment is not designed as safety related equipment; therefore, it is not required to be qualified as safety related equipment. The AMSAC equipment is located in a controlled environment such that variations in the ambient conditions are minimized. No AMSAC equipment is located inside containment. The transmitters (steam generator level and turbine impulse chamber pressure) that supply the input into AMSAC are located inside containment and the Turbine Building, respectively.

7.8.1.12 Setpoints

The AMSAC makes use of 2 setpoints in the coincidence logic in order to determine if mitigative functions are required. Water level in each steam generator is sensed to determine if a loss of secondary heat sink is imminent. The low level setpoint is selected in such a manner that a true lowering of the level will be detected by the system. The normal small variations in steam generator level will not result in a spurious AMSAC signal.

The C-20 permissive setpoint is selected in order to be consistent with Anticipated Transient Without Scram investigations showing that the mitigative actions performed by the AMSAC need not be automatically actuated below a certain power level. The maximum allowable value of the C-20 permissive setpoint is defined by these investigations.

To avoid inadvertent AMSAC actuation on the loss of 1 main feedwater pump, AMSAC actuation is delayed by a defined amount of time. This will ensure the Reactor Protection System will provide the first trip signal.

To ensure that the AMSAC remains armed sufficiently long to permit its function in the event of a turbine trip, the C-20 permissive is maintained for a preset time delay after the turbine impulse chamber pressure drops below the setpoint.

The setpoints and the capability for their modification in the AMSAC are under administrative control.

7.8.2 Analysis

7.8.2.1 Safety Classification/Safety-Related Interface

The AMSAC is not safety related and therefore need not meet the requirements of IEEE 279-1971. The AMSAC has been implemented such that the Reactor Trip System and the Engineered Safety Features Actuation System continue to meet all applicable safety-related criteria. The AMSAC is independent of the Reactor Trip System and Engineered Safety Features Actuation System. The isolation provided between the Reactor Trip System and the AMSAC and between the Engineered Safety Features Actuation System and the AMSAC by the isolator modules and the isolation relays ensures that the applicable safety-related criteria are met for the Reactor Trip System and the Engineered Safety Features Actuation System.

7.8.2.2 Redundancy

System redundancy has not been provided. Since AMSAC is a backup non-safety related system to the redundant Reactor Trip System, redundancy is not required. To ensure high system reliability, portions of the AMSAC have been implemented as internally redundant, such that a single failure of an input channel or Actuation Logic Processor will neither actuate nor prevent actuation of the AMSAC.

7.8.2.3 Diversity from the Existing Trip System

Diverse equipment has been selected in order that common cause failures affecting both the Reactor Trip System and the AMSAC or both the Engineered Safety Features Actuation System and the AMSAC will not render these systems inoperable simultaneously. A more detailed discussion of the diversity between the Reactor Trip System and the AMSAC and between the Engineered Safety Features Actuation System and the AMSAC is presented in Section 7.8.1.9.

7.8.2.4 Electrical Independence

The AMSAC is electrically independent of the Reactor Trip System and Engineered Safety Features Actuation System from the sensor output up to the final actuation devices. Isolation devices are provided to isolate the non-safety AMSAC circuitry from the safety-related actuation circuits of the Emergency Feedwater System.

7.8.2.5 Physical Separation from the Reactor Trip System and Engineered Safety Features Actuation System

AMSAC needs to be and is physically separated from the existing protection system hardware. The AMSAC outputs are provided from separate relay panels within the cabinets. The 2 trains are separated within the AMSAC cabinet by a combination of metal barriers, conduit and distance.

7.8.2.6 Environmental Qualification

Equipment related to the AMSAC is qualified to operate under conditions resulting from anticipated operational occurrences for the respective equipment location. The AMSAC equipment, with the exception of the isolation devices, located outside containment in a mild environment follows the same design standard that currently exists for non-Class 1E control grade equipment.

7.8.2.7 Seismic Qualification

It is required that only the isolation devices comply with seismic qualification. The AMSAC output isolation device is qualified in accordance with a program that was developed to implement the requirements of IEEE Standard 344-1975, “IEEE Standard for Seismic Qualification of Class 1E Electrical Equipment for Nuclear Power Generating Stations.”

7.8.2.8 Test, Maintenance, and Surveillance Quality Assurance

NRC Generic Letter 85-06, “Quality Assurance Guidance for Anticipated Transient Without Scram Equipment that is not Safety Related,” requires quality assurance procedures commensurate with the quality related classification of the AMSAC. The quality controls for the AMSAC are, at a minimum, consistent with existing plant procedures or practices for non-safety-related equipment.

Design of the AMSAC followed procedures relating to equipment procurement, document control, and specification of system components, materials and services. In addition, specifications also define quality assurance practices for inspections, examinations, storage, shipping and tests as appropriate to a specific item or service.

A computer software verification program and a firmware validation program have been implemented commensurate with the quality related classification of the AMSAC to ensure that the system design requirements implemented with the use of software have been properly implemented and to ensure compliance with the system functional, performance and interface requirements.

System testing is completed prior to installation and operation of the AMSAC, as part of the normal factory acceptance testing and the validation program. Periodic testing is performed both automatically through use of the system automatic self-checking capability, and manually, under administrative control via the AMSAC test/maintenance panel.

7.8.2.9 Power Supply

Power to the AMSAC is from a battery-backed, non-Class 1E vital bus independent of the power supplies for the Reactor Trip System and Engineered Safety Features Actuation System. The station battery supplying power to the AMSAC is independent of those used for the Reactor Trip System and Engineered Safety Features Actuation System. The AMSAC is an energize-to-actuate system capable of performing its mitigative functions with a loss of offsite power.

7.8.2.10 Testability at Power

The AMSAC is testable at power. This testing is done via the system test/maintenance panel. The capability of the AMSAC to perform its mitigative actuations is bypassed at a system level while in the test mode. Total system testing is performed as a set of 3 sequential, partial, overlapping tests. The first of the tests checks the analog input portions of the AMSAC in order to verify accuracy. Each of the analog input modules is checked separately. The second test checks each of the actuation logic processors to verify that the appropriate coincidence logic is sent to the majority voter. Each actuation logic processor is tested separately. The last test exercises the majority voter and the integrity of the associated output relays. The majority voter and associated output relays are tested by exercising all possible input combinations to the majority voter. The integrity of each of the output relays is checked by confirming continuity of the relay coils without operating the relays. The capability to individually operate the output relays, confirm

integrity of the associated field wiring, and operate the corresponding isolation relays and final actuation devices at plant shutdown is provided.

7.8.2.11 Inadvertent Actuation

The AMSAC has been designed such that the frequency of inadvertent actuations is minimized. This high reliability is ensured through use of 3 redundant Actuation Logic Processors and a majority voting module. A single failure in any of these modules will not result in a spurious AMSAC actuation. In addition, a 2 out of 3 low steam generator level coincidence logic and a time delay have been selected to further minimize the potential for inadvertent actuations.

7.8.2.12 Maintenance Bypasses

The AMSAC is blocked at the system level during maintenance, repair, calibration or test. While the system is blocked, the bypass condition is continuously indicated in the Main Control Room.

7.8.2.13 Operating Bypasses

The AMSAC has been designed to allow for operational bypasses with the inclusion of the C-20 permissive. Above the C-20 setpoint, the AMSAC is automatically unblocked (i.e., armed); below the setpoint, the system is automatically blocked. The operating status of the AMSAC is continuously indicated in the Main Control Room via a status light.

7.8.2.14 Indication of Bypasses

Whenever the mitigative capabilities of the AMSAC are bypassed or deliberately rendered inoperable, this condition is continuously indicated in the Main Control Room. In addition to the operating bypass, any manual maintenance bypass is indicated via the AMSAC general warning sent to the Main Control Room.

7.8.2.15 Means for Bypassing

A permanently installed system bypass selector switch is provided to bypass the system. This is a 2-position selector switch with “NORMAL” and “BYPASS” positions. At no time is it necessary to use any temporary means, such as installing jumpers or pulling fuses, to bypass the system.

7.8.2.16 Completion of Mitigative Actions Once Initiated

The AMSAC mitigative actions go to completion as long as the coincidence logic is satisfied and the time delay requirements are met. If the flow in the feedwater lines is re-initiated before the timer expires and the steam generator water level increases to above the low setpoint, then the coincidence logic will no longer be satisfied and the actuation signal disappears. If the coincidence logic conditions are maintained for the duration of the time delay, then the mitigative actions go to completion. The emergency feedwater initiation signal is latched in at the component actuating devices and the turbine trip is latched in at the turbine electro-hydraulic control system. Deliberate operator action is then necessary to terminate emergency feedwater

flow, clear the turbine trip signal using the main control board turbine master reset, and proceed with the reopening of the turbine stop valves.

7.8.2.17 Manual Initiation

Manual initiation of the AMSAC is not provided. The capability to initiate the AMSAC mitigative functions manually, i.e., initiate emergency feedwater, trip the turbine, and isolate steam generator blowdown and sampling lines, exists at the main control board.

7.8.2.18 Information Readout

The AMSAC has been designed such that the operating and maintenance staffs have accurate, complete and timely information pertinent to the status of the AMSAC. A system level general warning alarm is indicated in the Control Room. Diagnostic capability exists from the test/maintenance panel to determine the cause of any unanticipated interoperability or deviation.

7.8.3 Compliance With Standards and Design Criteria

The AMSAC meets the applicable requirements of Part 50.62 of Title 10 of the Code of Federal Regulations and the quality assurance requirements of NRC Generic Letter 85-06. No other standards currently apply to the AMSAC.

CHAPTER 8 - ELECTRIC POWER

8.0 ELECTRIC POWER

8.1 INTRODUCTION

The Licensee's transmission system, along with points of interconnection with neighboring utilities, is shown in Figure 8.1-1. The Licensee is a member utility of the Virginia-Carolinas (VACAR) Subregion Reliability Agreement which is a part of the Southeastern Reliability Council. As a member of such a group, the Licensee can supply power to, or consume power from other members, as its system allows or demands. Transmission system ties to other utilities are as listed in Table 8.1-1. The specific interface between the transmission grid and the Virgil C. Summer Nuclear Station is discussed in Section 8.2.

The Virgil C. Summer Nuclear Station 230 kV switchyard has a single bus, single breaker arrangement, with three main bus sections. The center section is designated bus section 3, the east section designated bus section 1 and the west section designated bus section 2. A tap from bus section 2 provides a subsection of this bus with two bay positions for the Fairfield No. 1 and No. 2 lines.

The Parr 115 kV engineered safety features (ESF) line terminates in a bay in bus section 3, crosses over bus section 3 with rigid bus construction, and continues to the Virgil C. Summer Nuclear Station.

There is an Alternate AC (AAC) source of power installed that is fed from an underground 13.8kV cable to the Parr Hydro Power Station (Separate from Parr Generating Complex). This line feeds a 13.2/7.2kV weather event hardened transformer located in the VCS Substation that is connected on the low side to a non-safeguards bus in the turbine building. This source of power was designed to the requirements of NUMARC 87-00 App B and can power one entire safeguards train of equipment.

The onsite power network consists of three non-Class 1E distribution networks and two independent, redundant Class 1E distribution networks. The voltage levels of each network are 7200 volts, 480 volts and 120 volt a-c and 125 volt d-c.

The main source of power for the non-Class 1E networks is the unit auxiliary transformer which is connected to the output of the main generator between the generator circuit breaker and the low voltage bushings of the main power transformer (see Figure 8.2-3).

The emergency auxiliary transformers provide an emergency source of power for the non-Class 1E distribution network.

The normal source of power for the two independent Class 1E distribution networks are the ESF transformers and a winding of the emergency auxiliary transformers. These two sources of power also serve as an alternate source of power to each other (see Figures 8.2-3 and 8.2-4).

Two diesel generators are provided, one for each of the Class 1E buses to serve as an emergency source of power. The safety-related loads their safety functions and power requirements, supplied by the two emergency diesel generators are listed in Table 8.3-3. The ESF battery buses, inverter buses and associated loads are shown by Figures 8.3-1 and 8.3-2.

The Class 1E power network provides an adequate and reliable source of electric power for safe reactor shutdown following any design basis event, including loss of offsite power and for all normal modes of station operation.

The Virgil C. Summer Nuclear Station electrical systems are designed to comply with the scope of IEEE-308 (Reference 1) as specified in Section 1 of IEEE-308. Onsite power systems are designed to satisfy the applicable criteria of (Reference 1), as well as the criteria of Regulatory Guides 1.6 and 1.9 (see Appendix 3A).

Implementation of IEEE Standards and the extent to which any alternative approaches are used is itemized in Table 8.1-2. Applicable criteria, including: General Design Criteria, Appendix A to 10 CFR 50; Regulatory Guides; and Branch Technical Positions are listed in Table 8.1-3 with references to appropriate sections of this FSAR. Implementation of Regulatory Guides is discussed in Appendix 3A.

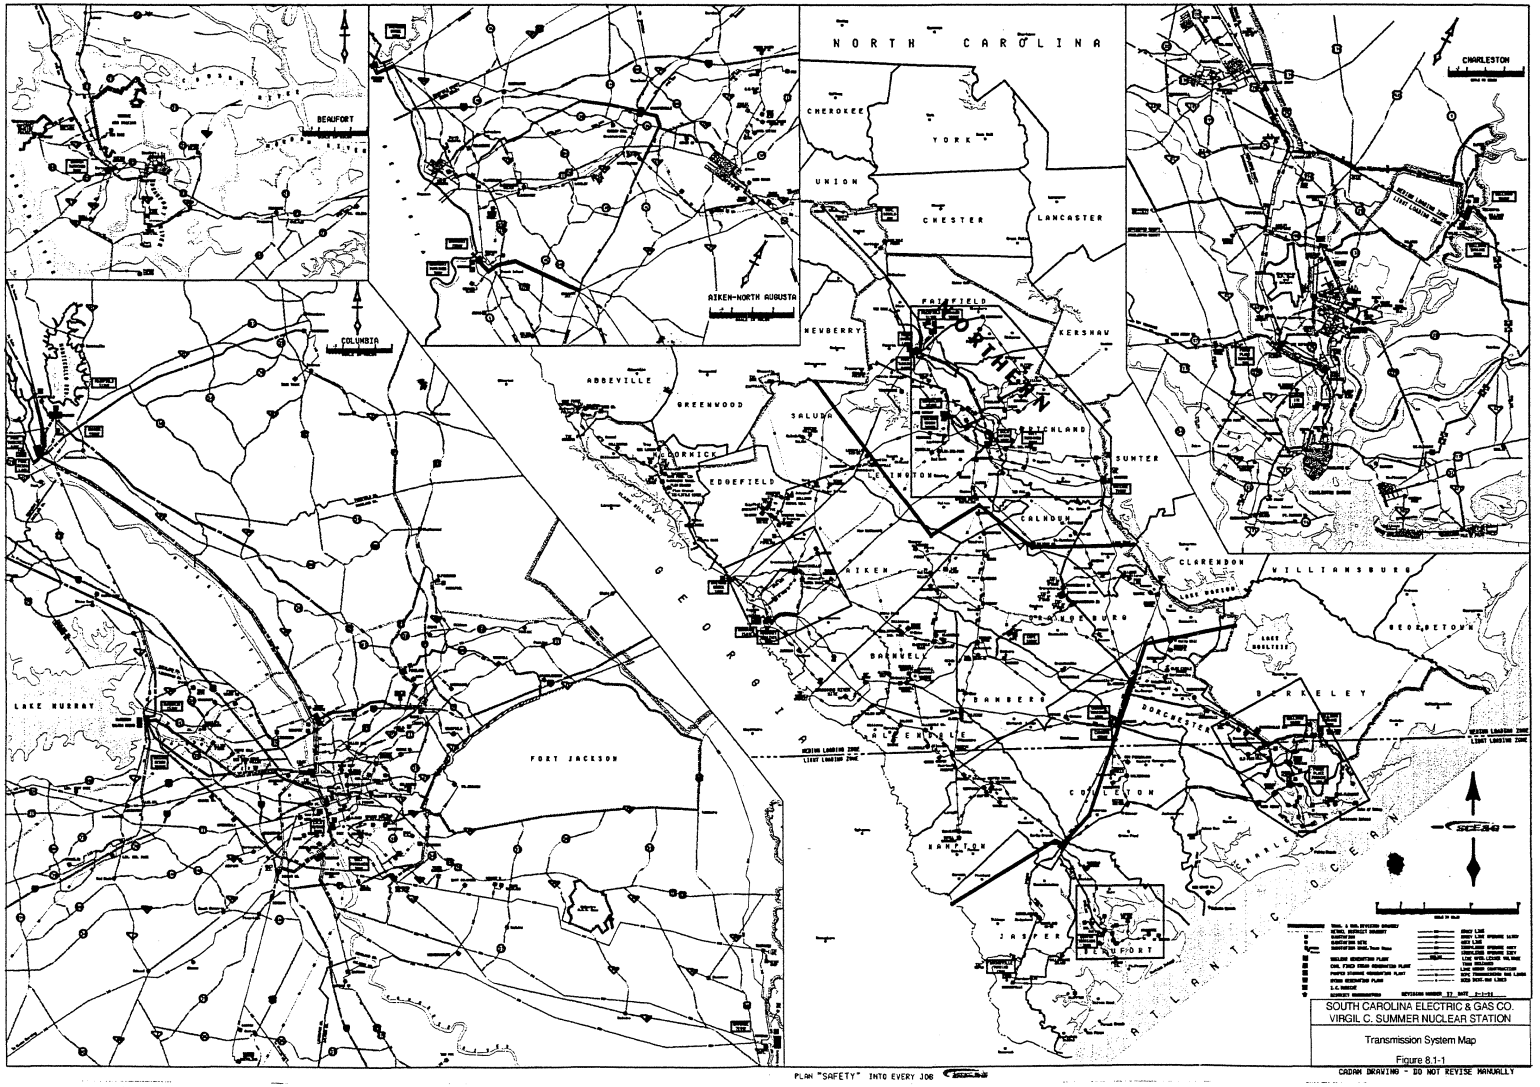
TRANSMISSION SYSTEM MAP



Amendment 98-01 April 1, 1998

8.2 OFFSITE POWER SYSTEM

8.2.1 Description

The SCE&G transmission system supplies offsite a-c power for operating the engineered safety features (ESF) buses as well as for startup and shutdown of the station. Two (2) separate sources of offsite power are provided for the Class 1E electric system, which is in compliance with General Design Criterion 17 and Regulatory Guide 1.32 (see Appendix 3A). One (1) source is the SCE&G transmission grid terminating at the Virgil C. Summer Nuclear Station 230 kV switchyard bus, which feeds the plant through a step down transformer. The second source is from the existing Parr Generating Complex over a 115 kV transmission line (see Figure 8.2-1). This source is connected to the plant through onsite step down transformers and a separate regulating transformer. These 2 sources have sufficient separation and isolation so that loss of the Virgil C. Summer Nuclear Station with the Fairfield Hydro Units offline will not degrade either of the sources below their acceptable voltage limit. Thus, loss of the station output, in conjunction with an accident, will not result in a degraded voltage condition on either source. Likewise, loss of a line or generation on the 115 kV network will not cause a degraded condition on the Emergency Auxiliary Transformer which is fed power from the 230 kV bus. Also, no single event such as an insulator or bushing failure, transformer failure, transmission line tower failure, line breakage, or similar event can cause simultaneous disruption of both sources. The offsite power system is not designed to withstand tornadoes, exceptionally severe hurricanes or ice storms. However, the circuit breakers for isolation of the 2 separate onsite power systems from the offsite power system are located within 2 separate, missile protected rooms. Therefore, any failure of the offsite power system, including the bus duct system between the offsite power system and the ESF buses, is isolated from the ESF buses before the emergency diesel generators are started (see Figure 8.2-2).

The allowable system voltage fluctuations for each of the 2 preferred offsite sources are defined in Table 8.2-2. As noted in the table, the allowable voltage range is dependent on generating unit availability, the number of buses connected to the source, and on the configuration of the transformers for the 115 kV line. The SCE&G dispatchers are provided with instructions to make every effort to maintain the system voltage fluctuations within these allowable ranges. The instructions require maintenance of the voltage limits during shutdown, as well as during operation, of Virgil C. Summer Nuclear Station. The transmission system voltage drop due to loss of the Virgil C. Summer Nuclear Station is included within the allowable voltage ranges during plant operation with the unit online. The transmission system voltage drop is not included within the allowable voltage ranges during plant operation with the unit offline because the unit is not generating. A direct communications link is provided between the SCE&G Dispatch Office in Columbia, SC, and all SCE&G generating plants. Through this communications link, the plant operators receive the instructions from the dispatch office for setting generator kilowatt, kilovar output, voltage level, and for controlling the VAR output on the Fairfield units when they are used for pumping.

The plant operators are provided with indicators for the engineered safety features (ESF) bus network as discussed in Section 8.3.1.2.1. Also, voltmeters, ammeters, kilowatt meters, kilovar meters, and frequency meters are provided for the main generator bus. If generator output differs

from that specified by the dispatch office, the operator notifies the dispatch office and receives a new set of operating levels for the generator.

Control and indication are provided locally at the substation relay house and/or the Unit 1 relay house and remotely in the system dispatcher's office for each of the incoming 230 kV transmission line circuit breakers and the 230 kV bus tie circuit breakers. Circuit breaker control consists of tripping and closing capability. Indication includes circuit breaker status (open or closed) and the amount and direction of the power being transmitted over each transmission line. Control power for the substation relay house is supplied from a 125 VDC battery, with a backup feed from the plant non-1E. Control power for the Unit 1 relay house is supplied from two (2) 125 volt d-c batteries, each sized to serve as back-up to the other.

The 230 kV buses are protected by bus differential relays. Each 230 kV line and the 115 kV line is protected by primary and backup relaying. Each 230 kV line terminal has relays that provide breaker failure protection that trips the appropriate bus lockout relay when the breaker fails to trip. Each line relays also provide a multi-shot, static reclosing function that is active in some breakers.

The 230 kV circuit breakers associated with the plant main transformer and emergency auxiliary transformers, as well as the circuit switches associated with the ESF transformers, are controlled from, and provide indication in, the control room. Also, the 230 kV circuit breakers can be tripped at the circuit breaker control panels mounted on the circuit breaker structures.

Manually operated disconnect switches are provided for the 230 kV circuit breakers to isolate each from the bus and associated lines. These manual disconnects permit testing and maintenance of each circuit breaker on an individual basis while allowing the 230 kV substation to remain energized, which satisfies General Design Criterion 18. Testing and maintenance are performed periodically in accordance with a SCE&G program.

As shown by Figure 8.2-2, the 115 kV line terminates in a rigid bus construction for the crossover of the 230 kV middle bus section. The 115 kV bus has no connection to the 230 kV bus. Therefore, any problems associated with the 230 kV bus do not affect the 115 kV bus. The rigid bus construction offers high reliability by eliminating the possibility of line dropping at this crossover point.

The preferred power source transformers, which are the emergency auxiliary transformers and the combination of the safeguard transformers and the voltage regulator are located out of doors and are physically separated from each other. Lightning arrestors are used where applicable for lightning protection. The transformers are protected by automatic water spray systems to extinguish oil fires quickly, thus preventing spreading. The transformer area is provided with a gravel filled sump pit to contain transformer oil should a rupture occur.

Power from both the emergency auxiliary transformer and from the combination of the 2 safeguard transformers and the voltage regulator is brought into the plant by independent 7200 volt buses. These buses are physically separated and independently supported throughout their length to the 2 separated, missile protected rooms which contain the separate Class 1E electric system 7200 volt buses, thus maintaining redundancy.

8.2.1.1 Unit Auxiliary, Emergency Auxiliary, and Safeguards Transformers

Normal station service power for non-Class 1E equipment, which includes that required during normal operation, startup, shutdown, and following shutdown, is provided from the unit auxiliary transformer. The primary side of the unit auxiliary transformer is connected to the generator isolated phase bus duct at a point between the generator circuit breaker and the low voltage connections to the main step up transformer as shown by Figure 8.2-3.

The unit auxiliary transformer is rated 22 kV - 7200 volts. The three 7200 volt secondaries are used to feed 3 independent 7200 volt non-Class 1E auxiliary buses. The 2 ESF system 7200 volt buses are fed independently from other sources.

Two (2) emergency auxiliary transformers are provided. The primary sides of these 2 transformers are connected in parallel to the 230 kV substation bus. The 2 secondary windings on each bank are rated 7200 volts. Three (3) of the 4 windings are used as an emergency power source for the three 7200 volt non-Class 1E auxiliary system buses. The fourth winding is a preferred offsite power source for either or both of the ESF system power trains (see Figures 8.2-3 and 8.2-4). Normally this winding is used to supply the 7200 volt ESF bus 1DB.

The primary windings of the 2 safeguard transformers, XTF-4 and 5, are connected in parallel to the 115 kV line. These 2 transformers, in combination with the regulating transformer, XTF-6, are the second preferred offsite power source for either or both of the ESF system power trains. Normally, safeguard transformer 4 is used in combination with the voltage regulator to supply 7200 volt ESF system bus 1DA. If the voltage regulator is out of service, the 2 safeguard transformers can be used in parallel to supply either or both of the 7200 volt ESF system buses; or 1 of the 2 transformers can be used to supply either or both of the buses (see Figure 8.2-4).

Connected to the same intermediate bus (1DX) as transformers XTF-4, 5 and 6 is the VC Summer Alternate AC Source (AAC). The AAC source is fed from an underground 13.8kV cable to the Parr Hydro Power Station main generator bus via Parr BKR 13123. This line feeds a 13.2/7.2 kV transformer located in the VCS Substation that feeds into the 1DX bus. All cabling and lightning protection equipment associated with this feed is weather protected. The installed cable is oversized for the potential load attached to it such that the 105º C normal rating of the cable cannot be reached with the maximum loading of a single ESF bus (750 mcm AL cable with most limiting rating of 490 amps will be loaded to a running maximum of 245 amps, 5.9MW load equivalent or 50% cable rating). Direct monitoring of underground cable temperature is not required as long as total ESF bus loading does not exceed 5.9MW (5MW calculated load with 15% conservatism). The loading of the AAC source onto either one of two ESF buses is to be done manually (sequencer Out-of-Service).

Each of the 2 principle 7200 volt ESF buses is provided with a manually initiated transfer scheme to shift the bus power supply between the 2 preferred offsite power sources.

8.2.1.2 Transmission System

The network interconnections between the Virgil C. Summer Nuclear Station and the SCE&G transmission system consist of eight 230 kV transmission lines which approach the site from 3 directions. The 230 kV transmission lines interconnect the Virgil C. Summer Nuclear Station with the major sources of generation on the SCE&G system through major transmission grid substations as shown by Figures 8.1-1 and 8.2-1. The lines are designed to meet or exceed NESC (ANSI-C2) 1973 edition, medium loading, grade B construction requirements.

Two of these eight transmission lines extend directly from the Virgil C. Summer Nuclear Station 230 kV bus section 2 to the SCE&G Fairfield Pumped Storage Facility.

In addition, two 230 kV transmission lines interconnect the Virgil C. Summer Nuclear Station with the South Carolina Public Service Authority (SCPSA) system.

One (1) 115 kV transmission line extends from the Virgil C. Summer Nuclear Station to the SCE&G Parr Generating Complex. The Parr 115kV substation and associated Transmission Grid connections serve as one of the preferred power sources for the ESF buses at the Virgil C. Summer Nuclear Station. Within the Parr 115kV substation are four gas-fired combustion turbines that with the substation form the Parr Generating Complex. The Parr Hydro station is connected to the Parr 115kV substation via a 115/13.2kV tap changing transformer, but is not considered part of the Parr Generating Complex even with its close proximity.

The 115 kV transmission line has no direct ties to the Parr Generating Complex 230 kV switchyard. This switchyard does have a tie from the Virgil C. Summer Nuclear Station 230 kV switchyard bus. The Parr Generating Complex 115 kV switchyard bus receives power from the Parr Generating Complex and from a 115 kV tie line to the Denny Terrace substation. With this arrangement, an outage at the Virgil C. Summer Nuclear Station 230 kV switchyard does not have a direct effect on the 115 kV ESF transmission line.

Figures 8.2-2 and 8.2-2a through 8.2-2d indicate the physical relationship between transmission lines entering the switchyard, between the switchyard and the plant and within the switchyard. All 230 kV transmission tie lines to other major interconnection points converge on the switchyard. All transmission line structures have a minimum of 60 feet center to center as they approach the switchyard.

Each transmission line has adequate capacity for the supply of the preferred power source emergency auxiliary transformer. The 230 kV transmission lines, 230 kV circuit breakers and 230 kV buses in the switchyard are designed to withstand and interrupt the maximum fault level at the bus.

Details of the construction of each transmission line are as follows:

1. Parr-Summer Safeguard 115 kV Line

   This line is about 2.6 miles long. Wood, H-frame construction and steel monopole structures are used. The line extends from the Parr 115 kV substation to the vicinity of the Parr 230 kV substation and then to Virgil C. Summer Nuclear Station. An approximately 600 foot segment of this line is routed from above ground to an underground duct bank and then returns to above ground routing. This underground segment eliminates the crossing of the 115 kV line over 230kV transmission lines near the Parr Substation.

   There is a switchable tie to the Parr-Winnsboro No. 1 line. It also crosses over the Norfolk-Southern Railroad at Parr and over a railroad spur at Virgil C. Summer Nuclear Station. The last 2 line structures at Virgil C. Summer Nuclear Station are steel monopole structures which raise this line above a VCS1-VCS2 tie. There are no structure or circuit conflicts since a failure of the towers would not result in loss of both sources of offsite power, as the VCS1-VCS2 tie breaker would trip leaving the other 230 kV lines intact.

2. Summer-Edenwood Line, 230 kV

   This line is about 33.02 miles long. At Virgil C. Summer Nuclear Station it is on 3 double circuit, 230 kV steel towers. The end of this line ties to the Edenwood 230 kV line about 1.2 miles from Parr. The line crosses over the Parr-Denny Terrace 230 kV line and the double circuit Parr-Denny Terrace 115 kV line. The line is of wood H-frame construction on a right-of-way with no other lines. The line continues past McMeekin Station on to Edenwood Substation.

3. Deleted

4. Summer-Pineland Line, 230 kV

   This line is on 3 double circuit, steel towers with the Summer-Denny Terrace line. These lines then are on wood H-frame structures designed for double circuits. The structures are in the center of a 240 foot wide right-of-way which extends for about 17.24 miles. In this area, the line parallels the SCPSA Summer-Blythewood 230 kV H-frame. There are structure conflicts in this area. For the next 1.62 miles, this line is on single circuit wood H-frame on a common right-of-way with the Summer-Denny Terrace line. There are no structural conflicts in this area. For the next 5.0 miles, this line is on single circuit, wood H-frame on its own right-of-way. For about the final 0.54 mile, this line is on double circuit, improved appearance, steel poles at Pineland substation. This line crosses over several transmission lines but none cross over it. Total length is about 24.4 miles.

5. Summer-Denny Terrace Line, 230 kV

   This line is attached to the same structures as the Summer-Pineland line at the Virgil C. Summer Nuclear Station and for the first 17.24 miles. From this point the Summer-Denny Terrace line is attached to single circuit H-frame structures and shares a common 240 foot right-of-way with the Summer-Pineland line for 1.62 miles. It is then on its own right-of-way for 5.91 miles. The Summer-Denny Terrace line then parallels the Denny Terrace-Rader double circuit 115 kV lines (crossing over them twice) to Denny Terrace, a distance of about 1.48 miles. Total length is 26.25 miles.

6. Deleted

7. South Carolina Public Service Authority, VCS1-Blythewood Line, 230 kV

   This line is installed on multi-pole single circuit (MPSC) structures with 1272 ACSR single conductor and is operated and owned by SCPSA. This line is located on variable width right-of-way (R/W) that extends for 20 miles from the VCS1 to SCPSA's Blythewood substation. This line is on common R/W with SCPSA's VCS1-Winnsboro 230 kV line and SCE&G's VCS1-Killian, Denny Terrace and Pineland 230 kV lines for 1.0 mile to a point referred to as Winnsboro Junction. From Winnsboro Junction, the line extends 2.8 miles to SCPSA Pomaria-Winnsboro 69 kV line. From the Pomaria-Winnsboro 69 kV line, the line extends 13.4 miles on common R/W with SCE&G's VCS1-Denny Terrace and Pineland 230 kV lines. From this point, the line veers off and extends 2.9 miles to SCPSA's Blythewood substation.

8. VCS2 Bus 2 Tie Line, 230 kV

   This line connects V. C. Summer Unit 1, Bus 2 to V. C. Summer Unit 2 switchyard. It parallels the Duke-Newport line for approximately 0.63 mile. Total length is 0.87 mile.

9. South Carolina Public Service Authority, Summer-Winnsboro Line, 230 kV

   This line is operated and owned by the SCPSA. It parallels the Summer-Blythewood line for a distance of 3.7 miles on the east side and abutting the existing right-of-way. From that point the line heads in a northeasterly direction and double circuits with the existing SCPSA Pomaria-Winnsboro 69 kV line. Total length is about 14 miles.

10. VCS1-Killian Line, 230 kV

    This line is installed on single pole single circuit (SPSC) and single pole double circuit (SPDC) steel monopole structures with bundled 1272 ACSR conductor. The line is located on variable width right-of-way (R/W) that extends for 35 miles from the VCS1 Switchyard to the Killian 230/115 kV Transmission substation. A SPSC section of this line is on common R/W with SCPSA's VCS1-Winnsboro and Blythewood 230 kV lines and SCE&G's VCS1-Denny Terrace and Pineland 230 kV lines for 1 mile to a point referred to as Winnsboro Junction. From Winnsboro Junction, the line extends 13 miles to Winnsboro and is constructed SPDC with the second circuit being the Parr-Winnsboro 115 kV Line #1. This line section is on common R/W with the Parr-Winnsboro 115 kV Line #2. From Winnsboro, the line extends 15 miles to a point referred to as Blythewood PMSS and is constructed SPDC with the second circuit being the Blythewood-Winnsboro 115 kV line. From Blythewood PMSS, the line extends 6 miles to the Killian 230/115 kV Transmission substation and is constructed SPDC with the second circuit being the Blythewood-Killian 115 kV line.

11. VCS1, Bus 1-VCS2 Tie, 230 kV

    This line is installed on single pole single circuit (SPSC) steel monopole structures with bundled 1272 ACSR conductor. This is one of three 230 kV bus ties each approximately 1 mile in length that runs between the VCS1 and VCS2 Switchyards.

Distances of all lines from the Virgil C. Summer Nuclear Station terminal to the first major substation are listed in Table 8.2-1.

8.2.2 Analysis

8.2.2.1 Introduction

The basis for design of DESC transmission facilities is such that a defined system will maintain stability with the loss of any system generator, including Virgil C. Summer Nuclear Station, or the most critical transmission line, or the loss of the largest system load. The system will also remain stable for the most severe fault condition on any transmission line or substation bus. As such, the loss of any single system generator, including Virgil C. Summer Nuclear Station, does not degrade the alternate system to where it cannot furnish shutdown power to Virgil C. Summer Nuclear Station on an uninterrupted basis. The Virgil C. Summer Nuclear Station buses and the location of the emergency auxiliary transformers and ESF transformers supplying shutdown power are such that no single permanent fault condition can prevent at least 1 of the auxiliary transformers from being available to furnish shutdown power. Table 8.2-1 lists the distances of lines from the Virgil C. Summer Nuclear Station switchyard to each first major substation.

8.2.2.2 Stability Study Results

The System Stability study was performed using power system simulator software. The dynamic simulation cases and dynamics data were updated versions of cases and data which were issued

by the NERC and which were modified to meet the specific requirements of this study. The dynamic simulation cases and data were validated using the simulator software case initialization and model testing features. This was followed by a 30 second steady state simulation in order to demonstrate that the cases and data represented non-disturbed conditions prior to simulating system contingencies. The results of the steady state simulations are not included in this report but are available for review.

Special attention was given to the analysis of disturbances in the vicinity of the V. C. Summer Nuclear Station during various system conditions. The simulations that were performed were selected as a result of discussions between V. C. Summer Design Engineering and DESC Transmission Planning.

The simulations which were performed for each contingency began with a 1 second steady state period which was followed by a sequence of contingency events and a subsequent new steady state period for a total of 30 seconds for each contingency simulation.

Both peak and light system load conditions were studied. System faults during peak load conditions are generally more challenging for offsite power voltage adequacy. System faults during light load conditions are generally more challenging for generator angular stability.

The base year chosen for summer peak and light load conditions is the year of the Study and is typically 3-4 years in the future. Since the previous study was completed, a number of changes have been made or have been planned for the DESC generating and transmission systems. All actual and planned system improvements are incorporated in the simulation models used for the current study. The base year chosen for summer peak and light load conditions is the year of the Study and is typically 3-4 years in the future. The study includes any actual system changes since the last study and any changes planned for 3-4 years beyond the base year.

The VCS FSAR required scenarios assume three MVAR levels (170, 330, and 484 MVAR). The peak load cases assume the VCS exciter provides 330 MVAR and 484 MVAR. The light load cases assume the VCS exciter provides 170 MVAR and 330 MVAR. 170 MVAR was modeled for a specific ESF bus alignment.

Use of the 484 MVAR and 330 MVAR levels for the VCS FSAR required scenarios is considered conservative for several reasons. The VCS generator exciter has a maximum momentary rating of 484 MVAR and a typical maximum continuous rating of 330 MVAR. Therefore, these values represent the maximum MVAR load the station can support for any loading scenario. These values can also represent a substantial portion of the total typical MVAR load seen on the DESC transmission system. Therefore, these values are consistent with the VCS generator exciter providing a significant portion of the voltage support for the entire DESC system. Therefore, these loadings conditions are considered extremely conservative and unlikely to occur.

V. C. Summer Balance of Plant (BOP) station loads were updated. In addition, because it is possible for Engineered Safeguard Features (ESF) bus loads to all be served from one bus, these loads were simulated as being located fully at each ESF bus (i.e., two ESF trains of equipment connected to each of the GDC 17 credited offsite sources).

For this study, the V. C. Summer generator governor model was disengaged from the simulation. A review of neighboring utilities' practices in modeling nuclear generators for transient stability simulations confirms that this is the accepted practice for representing block loaded nuclear generator governors.

The transfer of the Balance of Plant loads to the Emergency Auxiliary Transformers following a generator breaker operation has been incorporated into the study. The study models various contingencies and transmission operating scenarios. These scenarios resulted in a combined effect to lessen the available transmission voltage and angular stability support of V.C. Summer for the conditions studied. The practice of maintaining reactive power reserves in three separate areas of the Dominion Energy South Carolina system ensures that reactive power sources are available to provide voltage support to V.C. Summer.

The V. C. Summer 7.2 kV Engineered Safeguard Features (ESF) buses are supplied from the 230 kV and the 115 kV Offsite Power Supply buses. Protection from unacceptable voltage conditions is provided by Loss of Voltage and Degraded Voltage Relays that monitor the voltages of the 7.2 kV buses. The Loss of Voltage Relay scheme is modeled to operate after a 13.5 cycle (0.225 seconds) time delay at 82.00% of the nominal 7.2 kV bus voltage unless the voltage recovers to 82.75% during the time delay period of 0.225 seconds. The Degraded Voltage Relay scheme is set to operate after a 174.0 cycle (2.9 seconds) time delay at 91.75% of the nominal 7.2 kV bus voltage unless the voltage recovers to 92.328% during the 2.90 seconds time delay period. Because of the number of variables involving load tap changer settings and step change times, and ESF bus loads, no attempt has been made to report the voltages at the 7.2 kV ESF buses. Descriptions of loss of voltage and degraded voltage timer and relay operations assume that the per unit value of the 7.2 kV bus voltages are the same as those at the 230 kV and 115 kV Offsite Power Supply buses. The voltage results of the simulations are reported to V. C. Summer Design Engineering for use in calculations to determine acceptability of the voltage responses.

DESC load under frequency and generator over frequency/under frequency responses as a result of the studied conditions were also identified. The VCS generator frequency responses were monitored and evaluated in order to assess whether the VCS generator reactor coolant pump under frequency or over frequency relays would trip for frequency excursions.

CONCLUSIONS

Each of the contingencies which were simulated for this study were evaluated for generator rotor angle, generator frequency deviation, tie line flows, system under frequency load shedding, under/over frequency tripping operations, and system voltage responses. In addition, the effects of each contingency on the 230 kV and 115 kV V. C. Summer Offsite Power Supply buses were examined as well as the resulting steady state power flows on the transmission lines which are connected to the V. C. Summer transmission substation.

The generator rotor angle responses demonstrated that no conditions existed in which a generator would become unstable. None of the transmission lines connected to the V. C. Summer substation DESC system to neighboring systems remained in service throughout all conditions studied. No

conditions were found that would result in the islanding of the DESC system or neighboring systems.

Generator and system frequency responses were all within the normal operating ranges and there was no indication of system under frequency load shedding or generator under I over frequency tripping, Reactor Protection System under frequency operation, or Reactor Coolant Pump under frequency tripping.

The results of this study demonstrate that the DESC generating and transmission system is stable for the conditions that were studied. The contingencies were selected so as to test the capability and capacity of the 115 kV and 230 kV Offsite Power Supply buses at the V. C. Summer Station Unit 1 to supply the loads assigned in normal, abnormal, accident, or plant shutdown conditions. No contingency conditions were found to result in the simultaneous loss of both GDC 17 credited Offsite Power Supply buses.

Also, no conditions were found to result in under frequency load shedding operations or generator under/over frequency tripping. In addition, no System Operating Limits (SOLs) or Interconnection Reliability Operating Limits (IROLs) were identified. Finally, there were no indications of voltage instability or stability limits. None of the contingencies that were simulated in this study indicated generator rotor angle instability would develop for generators in neighboring systems.

8.3 ONSITE POWER SYSTEMS

8.3.1 A-C Power Systems

8.3.1.1 Description

The a-c power systems consist of the various auxiliary and engineered safety features electrical systems designed to provide reliable electrical power during all modes of station operation and under shutdown conditions. The a-c power systems are shown by Figures 8.2-3 and 8.2-4. The major electrical equipment is described in Table 8.3-1. Engineered safety features (ESF) auxiliaries are arranged so that loss of a single bus, for any reason, still leaves sufficient auxiliaries to safely perform required functions. In general, auxiliaries related to functions other than engineered safety features are connected to 3 auxiliary buses. A generator circuit breaker is provided to permit isolation of the generator from the system, which eliminates the necessity for a transfer from the emergency auxiliary transformer to the normal auxiliary transformer on plant startups. Engineered safety features loads are divided between 2 additional essential system buses in observance of the single failure criteria.

Controls are provided in the control room for selected 7200 volt and 480 volt switchgear units. These units are selected to provide the operator with control of the distribution network and remote control of selected loads.

8.3.1.1.1 Plant Distribution Network

1. 7200 Volt Network

   The 7200 volt network is arranged in 5 medium voltage primary bus sections. There are 2 additional medium voltage bus sections located in the Service Water Pumphouse. Each of these 2 buses is fed as a stub bus from the related ESF primary bus. Each bus consists of a separate, metal clad type, dead front construction, rated 7.2 kV nominal (8.25 kV max) volt, 500 MVA switchgear assembly. Each circuit breaker cubicle is isolated from the adjacent cubicle by metal barriers. Interrupting ratings for the switchgear breakers are 66 kA momentary, and 41 kA symmetrical at 6.6 kV, or 37.8 kA symmetrical at 7.2 kV (based on the symmetrical rating of 33 kA at 8.25 kV). These interrupting ratings are greater than any of the fault current levels on the various buses. Control power for tripping and closing the switchgear is obtained from the station batteries.

The 7200 volt buses 1A, 1B, and 1C supply power to non-safety-related auxiliaries. Each of these 3 buses supplies power to a reactor coolant pump. The normal power source for these buses is the main generator through the unit auxiliary transformer or back feed from the 230 kV bus through the main power transformer and unit auxiliary transformer. Upon tripping of the normal feeder breaker to these bus sections, the balance of plant (non-Class 1E) electrical system is automatically transferred to the emergency auxiliary transformers which are the emergency power sources. This automatic transfer is initiated when the normal feeder is tripped by main and unit transformer lockout relaying, generator differential protection relaying, generator and main transformer backup and field failure relaying, overall backup lockout relaying, and the condition of both the main transformer breaker and the generator breaker open. There is no automatic transfer when a bus over-current condition exists. Provisions are also available for manual transfer, as required.

In addition to the protective relays discussed above, there are 3 undervoltage sensing relays (1 for each phase) and 1 underfrequency sensing relay connected for each reactor coolant pump. These devices provide the reactor coolant pump undervoltage trip signal described in Section 7.2.1.1.2, Item 4.b, and the reactor coolant pump underfrequency trip signal described in Section 7.2.1.1.2, Item 4.c. These relays, together with the potential transformers from which they receive a voltage signal, are located in the reactor protection undervoltage and underfrequency relay panel. This panel is housed in the Seismic Category 1 Intermediate Building. Power feeds to the reactor coolant pumps are routed through this panel. Therefore, the voltage signal is sensed on the pump side of the supply circuit breaker.

To satisfy the single failure criteria, the panel is constructed in 3 sections, 1 section for each of the 3 reactor coolant pump power circuits. Each section is physically isolated from adjacent sections by a double, metal side sheet barrier. Any terminal blocks or fuse blocks mounted on a barrier side sheet are mounted on a polyester glass material. Polyester glass material is also placed under any wiring on a barrier side sheet. Thus, complete isolation of power cables, potential transformers and relays for each pump is maintained within the panel. The panel has been qualified to satisfy the requirements of IEEE-323 (Reference 11) and IEEE-344 (Reference 12). Electrical separation of circuits associated with the reactor protection inputs is in accordance with the criteria outlined in Section 8.3.1.4.

The 7200 volt buses 1DA and 1DB supply power to the ESF equipment. These ESF buses provide an adequate and reliable source of electrical power for safe reactor shutdown under conditions resulting from any design basis event and/or during loss of offsite power, as well as for all modes of normal station operation. The normal and preferred power source for bus 1DA is the emergency auxiliary transformer XTF-4 in conjunction with the voltage regulator XTF-6. In the event that the voltage regulator is out of service, either or both of the 2 emergency auxiliary transformers, XTF-4 and XTF-5, can be used to supply bus 1DA. When the voltage regulator is out of service, parallel operation of the 2 transformers is preferred since it provides more flexibility and a greater range of allowable offsite voltage for the 115 kV system. The normal and preferred power source for bus 1DB is also the backup power supply for 1DA. In addition to the normal power sources, each 7200 volt ESF bus has an onsite emergency power source. The AAC source ties into the same plant bus (1DX) as the ESF transformers.

The physical layout of the cable bus system for connecting the 2 power transformers (emergency auxiliary and safeguard transformers) and the voltage regulator or the AAC source to the 7.2 kV ESF buses is shown by Figures 8.3-0 through 8.3-0g. Figure 8.3-0b.1 shows the modifications to the bus shown in Figure 8.3-0b for the addition of the voltage regulator and its by-pass switches.

Each onsite power source is capable of carrying the total ESF load required for safe shutdown. The onsite standby power system consists of 2 fully equipped diesel generators which provide 7200 volt power to buses 1DA and 1DB, respectively, within 10.25 seconds after detection of a loss of the associated preferred power sources by loss of voltage relays and 13 seconds after detection of a degraded voltage condition. Buses 1DA and 1DB are provided with a manually initiated transfer to the alternate offsite power source.

Transfer switches are used to select power from 7.2 kV Channel A or Channel B sources for the C pump motors in the Service Water, Component Cooling and Safety Injection Systems. The switches are manually operated locally and are equipped with Kirk key interlock to prevent simultaneous closure of circuit breakers from both sources.

Speed switches are used to control the 2 speed, single winding motors used for the 3 component cooling water pumps.

2. 480 Volt Network

The 480 volt network distributes and controls power for all 480 volt and 120 volt a-c station demands. This network consists of 22 unit substations and 28 motor control centers. The unit substation switchgear is of metal clad, dead front construction, with 125 volt d-c operated air circuit breakers. Transformers for the 480 volt unit substations are air cooled and are directly connected to the switchgear. Except in special cases, motors rated above 50 hp to 350 hp are controlled directly by circuit breakers in the 480 volt switchgear. Motor control centers are used for control of motors 50 hp and smaller.

The maximum symmetrical interrupting capacity of the 480 volt motor control centers is 22,000 amperes. This interrupting capacity is greater than any of the fault levels on the motor control center buses. Current limiting reactors are provided in series with selected non-Class 1E motor control centers where the maximum symmetrical fault current that could otherwise occur at the motor control center would have exceeded 22,000 amperes.

The maximum symmetrical interrupting capacity of the 480 volt unit substations is dependent upon the frame size of individual unit substation cubicles. In each case the interrupting capacity of a cubicle exceeds the maximum symmetrical fault current. Frame size rating and capacity is listed in Table 8.3-2.

a. Balance of Plant 480 Volt Network

The balance of plant 480 volt network consists of 18 unit substations and 18 motor control centers. Fifteen (15) of the unit substations are 4 wire, consisting of transformers and metal clad switchgear; 3 are 3 wire, consisting of transformers and power distribution panels. The 3 wire 480 volt unit substations provide power to the pressurizer heaters. Two (2) of these unit substations are connected to redundant safety-related (Class 1E) buses. These are loaded manually from the 7.2 Kv diesel generator buses 1DA and 1DB and furnish power to the 2 groups of heaters designated as backup groups. The third unit substation is connected to a balance-of-plant bus (1C) which powers the control group of heaters which are the normally energized heaters. Main feeder breakers for the 2 backup groups have been qualified in accordance with safety-grade equipment. Safety class heater cables and trays are protected by jet spray shields in the event of a PRT diaphragm rupture. Procedures for energizing the pressurizer heaters are addressed in Emergency Operating Procedures and System Operating Procedures as appropriate. These procedures describe (1) precautions to be observed if pressurizer heaters are to be used to prevent overloading diesel generators, (2) suggested loads to trim, (3) the time required to accomplish the connection. This time shall be consistent with the timely initiation and maintenance of natural circulation conditions. This meets the requirements of NUREG-0578, Section 2.1.1, Position 3.1. All motor control centers are fed by 4 wire unit substations. The unit substations receive power from 7200 volt balance of plant buses 1A, 1B, and 1C through 7200 - 480/277 volt transformers. Each motor control center has a separate feed from the 480 volt unit substations. Selected motor control centers are provided with automatic transfer to an alternate power source.

b. Engineered Safety Features 480 Volt Network

The ESF 480 volt network consists of 6 unit substations and 9 motor control centers. The 480 volt ESF buses are fed through transformers with 7200 volt primaries and 480/277 volt secondaries which feed motor control centers, motors, and miscellaneous loads. These buses are independent from each other and there is neither automatic nor manual transfer capability. ESF 7200 - 480/277 volt transformers and switchgear are redundant and are located in separate areas of Seismic Category 1 structures to maintain isolation. ESF motor control centers are powered from the 480 volt ESF buses and have neither manual nor automatic transfer capability. The motor control centers are redundant and are located in separate areas of Seismic Category 1 structures or are separated by fire walls to maintain isolation. Under loss of offsite power conditions, power may be supplied to selected non-Class 1E 480 volt buses by the diesel generators. Equipment which is not safety-related but is considered essential for protection of the turbine or desired for convenience is manually activated by the operators.

The voltage fluctuates on the preferred sources within the limits defined in Table 8.2-2, as described in Section 8.2.1. Appendix 8D discusses the analytical method used for determining the optimum tap settings for the step down transformers in the plant distribution network. Also, included in the appendix is a tabulation of, or a referenced calculation for, the calculated voltages at the 7.2 kV and 480 volt distribution levels in the plant during light and accident load conditions with power being supplied from the offsite sources. The voltage fluctuation will be less than those given in Appendix 8E during diesel generator operation as the diesel's output is held to approximately + 0.5% of the voltage regulator's setting, and the regulator is set within the range of + 2%, - 5% of 7.2 kV. The light and accident condition loads were determined to be the worst case loads. The results indicate that with the design tap settings the motors terminal voltages will remain within the design limits of ± 10% of their rated voltages for the anticipated range of transmission system voltages.

If a degraded voltage occurs, with the established relay setting, the lowest voltage which could exist at a motor terminal is 90.0% of rated voltage (460 volts) and at a motor control center bus is 87.71% of rated voltage (480 Volts).

When the plant is at the startup stage and the design tap settings have been applied to the step down transformers, the voltages on the buses will be verified to ensure that they are not out of the range for proper equipment operation. Prior to fuel loading when the loads on the distribution system reflects the values to be expected during plant operation, the voltages and loads of the ESF system buses will be measured and the data used to verify the calculation of voltage levels. Appendix 8D discusses the calculation procedures and method of this verification of the calculation. Results were provided in a March 1, 1982 letter to the NRC. As part of the results, a tolerance study will be made and presented to show that the variations between the measured and calculated values are within the expected ranges.

The voltages on the buses are monitored during plant operation and recorded as part of operator logs to verify the proper range for equipment operation.

No load break, 480 volt a-c transfer switches are used to transfer power from 480 volt channel A or channel B sources for the motors for HVAC water chiller C and chilled water pump C. These switches are equipped with a walking beam interlock to prevent simultaneous closure of circuit breakers from both sources.

8.3.1.1.2 Onsite Standby Power Supplies

The onsite standby a-c power supplies for Virgil C. Summer Nuclear Station are 2, 12 cylinder, V configuration diesel engine driven generator sets. The generators operate at 514 rpm and provide 3 phase, 60 Hz, 7200 volt power. Each diesel generator has the following ratings:

1. Continuous, 4250 kW.
2. Short time, 4676 kW.
3. Overload (2000 hour), 4548 kW.

4. Seven (7) days, 4676 kW.
5. Thirty (30) minutes, 5100 kW.

The diesel generators are located in a building designed to satisfy Seismic Category 1 requirements and to protect the diesel generators against tornadoes, hurricanes and missiles. Within this building, the diesel generators, including associated starting equipment and other auxiliaries, are completely isolated from one another by a wall designed to withstand a safe shutdown earthquake (SSE).

Each diesel generator is provided with a separate, missile protected combustion air intake as shown by Figure 1.2-13 and a separate air discharge and engine exhaust. The diesel generators, together with associated fuel storage tanks, auxiliaries and related piping are designed to remain functional during an SSE and remain in a condition suitable for the performance of their function in shutting down and maintaining the plant in a safe condition.

Essential subsystems for each of the diesel generators and the physical arrangement of these subsystems are discussed in Sections 9.5.4 through 9.5.8.

8.3.1.1.2.1 Deleted by Amendment 98-01, April 1998

8.3.1.1.2.2 Deleted by Amendment 98-01, April 1998

8.3.1.1.2.3 Deleted by Amendment 98-01, April 1998

8.3.1.1.2.4 Diesel Generator Operation

Each 7200 volt ESF bus is continually energized from either the 230 kV or the 115 kV preferred power source transformer or from the onsite emergency diesel generators, as shown by Figures 8.2-2 and 8.2-3. The transfer from preferred power source to emergency diesel generator is accomplished automatically, when required, by the opening of the preferred power source air circuit breakers and closing of the emergency diesel generator air circuit breaker. The emergency buses and power supplies for all essential components are normally connected to the preferred offsite power sources.

The emergency diesel generators are automatically started upon receipt of an undervoltage signal from the associated bus from either the loss of voltage relays or degraded voltage relays, or upon receipt of a safety injection signal. They are also started upon receipt of a manually initiated signal from the control room. Loss of voltage on an ESF bus opens the normal or alternate supply circuit breaker (whichever is closed) and, when emergency diesel generator voltage and frequency are established, closes the emergency power source circuit breaker. In the case of a safety injection signal and/or ESF bus undervoltage, the ESF loading sequencer (see Section 7.3.1 for a detailed discussion) trips selected bus loads including all non-Class 1E loads. The bus is then reloaded in the sequence shown in Table 8.3-3, Parts A1 and B1. Items indicated by 0 second loading sequence in Table 8.3-3 are not tripped and, therefore, are immediately loaded when the emergency power source circuit breaker is closed. All other required loads are loaded in sequence by the ESF loading sequencer.

The 7.2 Kv ESF buses are each provided with 3 loss of voltage relays set at approximately 81% of the nominal bus voltage level and 3 degraded voltage relays set at approximately 91.34% of the nominal bus voltage level. Operation of a set of loss of voltage or degraded voltage relays will initiate a diesel generator start, a permissive for EFW turbine pump start, an ESF load sequence operation and a permissive for diesel generator circuit breaker close. These operations occur in a timed sequence as outlined in Table 8.3-5. The logic of the controls are illustrated in Figure 8.3-0o.

As illustrated in Table 8.3-5 the 7.2 Kv bus circuit breakers are tripped 4 seconds after the diesel generator is started on a degraded voltage condition as compared to 2 seconds for a loss of voltage condition. The delay in tripping for a degraded voltage condition allows the bus to be energized during the time the diesel generator is coming up to speed. Therefore, with the degraded voltage condition, the maximum dead bus time is 6 seconds as compared to a 10.25 seconds dead bus time allowed for a loss of voltage condition.

Appendix 8F provides a discussion of the time sequence of equipment operation with a degraded voltage condition coincident with an accident condition. When the diesel generators are started and loaded as a result of an undervoltage condition, the ESF loading sequencer logic prevents further undervoltage tripping of the safety related loads. When the buses are returned to the offsite power sources, the undervoltage tripping feature is automatically reinstated.

The emergency diesel generators and normal station service are synchronized only during periodic testing. Synchronizing capability is provided to reconnect the emergency diesel generators to the offsite power network when voltage is restored subsequent to the loss of offsite power. Synchronization is performed manually, when required. ESF equipment is duplicated on separate 7200 volt and 480 volt (as appropriate) buses as listed in Table 8.3-3, Parts A1 and B1. All equipment does not start simultaneously but is programmed to start automatically in sequenced steps. The first group, indicated by 0 load sequence seconds in Table 8.3-3, Parts A1 and B1, is connected to the ESF buses when the buses are energized. During recovery from step load increase, or from disconnection of the complete load, emergency diesel generator speed change will not exceed 75% of the difference between nominal speed and the overspeed trip setpoint or 115% of nominal speed, whichever is lower. Voltage is restored to within 10% and frequency to within 2% of the nominal values in less than 40% of each load sequence time interval. This complies with Regulatory Guide 1.9 (see Appendix 3A). Subsequent groups are each connected in sequence after short time delays.

The load profile after an accident, without offsite power, is generally outlined by Table 8.3-3, Parts A1 and B1. At no time following an accident will the load exceed the short time rating (110% of the continuous rating) of the diesel generators nor is it expected that the load will fall below 30% of the diesel generator rating.

In the event of an accident with offsite power available, the diesel generators will start and run at no load. Should a subsequent loss of offsite power occur, the diesel generators would be loaded automatically. If offsite power is not subsequently lost, the diesel generators would continue to run at no load until manually stopped by the operator.

The injection phase of a loss of coolant accident should not exceed 1 hour and the short term phase of a main steam line break accident is estimated to be 2 hours. Therefore, it is expected that both diesel generators can be stopped within 4 hours after an accident if offsite power is available. If the diesel generators are operated at no load or less than 20% load for a period of time longer than 4 hours, operating procedures will require paralleling of each machine with the bus and loading the generator to at least 50% of rated load. Only 1 diesel generator will be paralleled with a bus at a time.

Criteria discussed are conservative with respect to the manufacturer's recommendations (see Colt Industries, Fairbanks Morse Engine Division, "Operating and Maintenance Manual, South Carolina Electric and Gas Co., Virgil C. Summer Nuclear Station - Unit 1, Standby Diesel Generator Set," Colt-13-206152, Chapter 1, Tab 1, page 5-1) which, in part, are as follows:

> "In the event it is necessary to operate the engine for extended periods of time (over 24 hrs.) at from no load up to 20% of the engine rating, the engine should run at above 50% load for at least 1 hour in each 24 hour period in order to minimize the accumulation of products of combustion and lubricating products in the exhaust systems. Above 20% load rating, the engine may run continuously as required with the recommendation that the engine parameters be monitored closely and logged at least daily so as to be able to discover any problems early. (Changes in exhaust temperatures are of particular interest.)"

8.3.1.1.2.5 Diesel Generator Permissives

After the emergency diesel generator has received a starting signal, the following conditions must be satisfied before the generator is automatically connected to the ESF bus:

1. The diesel generator must be at approximately 90% of rated voltage and approximately 98% of rated frequency, based upon 2 out of 3 relaying schemes in each case.
2. The ESF bus normal and alternate power supply circuit breakers must be open.
3. There must be no electrical faults in the 7200 volt bus.

Figures 8.3-0h through 8.3-0j present diesel generator logic diagrams. Logic diagrams for the bus 1DA normal and alternate power supply circuit breakers are shown by Figures 8.3-0K and 8.3-0l. The bus 1DB normal and alternate supply circuit breakers use similar control schemes.

8.3.1.1.2.6 Diesel Generator Testing

The diesel generators are tested as follows at the manufacturer's plant prior to shipment to the plant site:

1. The diesel generators are initially started and run in accordance with the manufacturer's standard procedure which includes the following:
   a. Operation at reduced RPM for approximately 50 minutes.
   b. Operation at rated RPM and variable load for approximately 6-1/2 hours.

2. The engine overspeed setting is tested and operation at 115% overspeed is demonstrated.
3. Diesel generator starting system capacity is demonstrated.
4. Diesel generator speed governing system is tested for steady state and transient performance, including load rejection tests at 25, 50, 75, and 100% of rated load.
5. The diesel generators are started and automatically loaded with a combination of resistive and inductive loads to simulate design loading conditions for the Virgil C. Summer Nuclear Station. This test is performed 10 times on each diesel generator.
6. The ability of the diesel generators to start and accept load without service water flow and without 480 volt auxiliary power is demonstrated.
7. The starting margin of each diesel generator is demonstrated by simultaneously starting and accelerating a 1750 horsepower motor and a 500 horsepower motor with the generator carrying a resistive load of approximately 50% of rated capacity.
8. Operation of the diesel generator in parallel with a utility system is demonstrated.
9. The diesel generators are operated at variable load for a total of 11 hours, including 3 hours at 100% of rated load followed by 2 hours at 110% of rated load.

Certified evidence is supplied by the manufacturer of the diesel generators that a total of 300 start and load tests, with a maximum of 3 failures, have been performed on a diesel generator of the design supplied for Virgil C. Summer Nuclear Station.

Each start and load test consisted of starting the diesel generator and applying load within 10 seconds after the start signal, increasing load to at least 50% of the continuous rating within 30 seconds and operating under load for a minimum of 5 minutes.

Some of these tests are initiated from design cold ambient conditions (keep warm temperatures) and some from hot equilibrium temperature conditions.

Tests and inspections are performed to ensure that all components are properly mounted, connections are correct, circuits are continuous and components are operational. Tests are performed to ensure that emergency loads do not exceed diesel generator rating and that each diesel generator is suitable for starting and operating required loads.

Proper operation of the onsite standby power supply is tested periodically. An availability test is performed periodically when the plant is in operation. Only 1 diesel generator is tested at a given time. The test consists of a manually initiated start of the diesel generator, followed by manual synchronization with and connection to the station ESF buses and assumption of load by the diesel generators. Normal station operation is not affected by this test. The operational test, automatic starting, load shedding and loading of the diesel generators, initiated by a simulated loss of voltage on the ESF buses are performed normally during reactor shutdown for refueling. Preoperational testing according to Regulatory Guide 1.41 is discussed in Chapter 14 and Appendix 3A.

8.3.1.1.2.7 Deleted by Amendment 98-01, April 1998

8.3.1.1.2.8 Instrumentation and Control Systems

Control power required for operation of each diesel generator is supplied from the 125 volt d-c distribution system. Control power for the diesel generator breaker to the ESF bus is supplied from the 125 volt d-c distribution system associated with the corresponding ESF bus. Controls are provided locally and in the control room for manual start and stop of each diesel generator. An automatic control system is provided for automatic startup and adjustment of speed and voltage to a ready-to-load condition.

A start diesel signal overrides all other operating modes and immediately returns the controls for the diesel generator to the emergency mode except under the following conditions:

1. Engine tripped due to overspeed.
2. Engine tripped due to low lube oil pressure.
3. Generator tripped due to generator differential relay operation.
4. When maintenance is in progress.

A matrix arrangement is provided for tripping the diesel generator for low lube oil pressure. This matrix consists of 4 pressure relays set at 70, 65, 60, and 60 psi. To cause a diesel generator trip due to low lube oil pressure, 2 of the low pressure switches must be activated and at least 1 of the 2 activated switches must be 1 of the 2 with 60 psi setpoints.

The other protective functions for the diesel generator are able to cause a diesel generator trip only during testing. Under emergency conditions, these protective functions actuate alarms only and do not trip the diesel generator.

Table 8.3-3a is a list of the protective devices provided for the diesel generators. This list also includes the function of these devices under emergency start and test start conditions.

Also, the engine manual stop pushbutton cannot override an ESF signal.

Instrumentation is provided locally and in the control room to monitor diesel generator frequency, voltage, loading and circuit breaker position.

Alarms are provided locally for all critical variables and trip functions as shown in Figure 8.3-0n. The local annunciator provides “first out” indication to aid in determining the cause of any trips or malfunctions. Alarms and status indication are also provided in the control room as shown in Figure 8.3-0m to indicate diesel generator status and permit remote operation of the diesel generators.

Most of the instrumentation is designed and installed to permit inplace calibration.

Logic diagrams for the diesel generator starting and shutdown controls are presented by Figures 8.3-0h and 8.3-0i.

8.3.1.1.2.9 Diesel Generator Environment

Combustion air for the diesel generators is taken directly from the outside through an intake which is completely independent of the ventilation air intake. The bottom of the ventilation air intake is located 29 feet above grade, as shown in the Figures 1.2-13 and 1.2-14. This high elevation will minimize the amount of dust taken in by the ventilation system. In addition, all cabinets containing control relays and associated devices have gasketed doors and openings. Therefore, the ventilation system will introduce a minimum of dust into the building and the controls are protected from whatever dust does enter the building.

There are several elements which interact to assure the cleanliness of the Diesel Generator Room and the supportive electronic and electrical components contained therein. They are as follows:

1. All electrical and electric component cabinets are weather sealed with rubber gaskets and have filtering media provided where air is circulated through the cabinets.
2. The Diesel Generator Building is to be designated as a Cleanliness Zone IV, which requires periodic inspections, specifically for cleanliness.
3. The mandatory surveillances for assuring the diesel's ability to start are supported by a periodic preventive maintenance task which requires inspection of the electrical and electronic components to determine operability and condition. Cleanliness is one of the areas that is inspected during the performance of the preventive maintenance task.

8.3.1.1.3 120 Volt A-C Vital Bus System

Six (6) 120 volt a-c vital buses are provided. Each of 4 buses is supplied by 1 of 4 single phase static inverters. The normal feed to Panel APN5907 is from APN5901. The normal feed to Panel APN5908 is from APN 5903.

One (1) Channel A and 1 Channel D inverters are connected to ESF battery 1A, and 1 Channel B and 1 Channel E inverters are connected to ESF battery 1B.

The 120 volt a-c vital buses constitute a reliable electrical system which provides a stable power supply to vital equipment and guarantees proper action when power is required while eliminating spurious shutdowns. Controls for the backup groups of heaters, the pressurizer level transmitters and for the pressurizer relief block valve operators receive their power from this vital a-c bus source through the emergency power buses. The control power for the block valves is supplied from an emergency power bus different from that which supplies the associated PORV. Safety grade circuit breakers and fuses are used for circuit protection.

The normal source of power for the 120 volt a-c vital bus inverters is through the inverter static rectifier. These inverter rectifiers are fed from 480 volt buses 1DA2 and 1DB2. The station batteries and battery chargers constitute the standby power source. The battery chargers are fed from 480 volt buses 1DA2 and 1DB2. In the event of loss of 480 volt power, the power source for the vital bus inverters is the station batteries. These batteries are floating, on standby service. The change in power source, from normal to standby, occurs without exceeding the stated inverter

output voltage and frequency regulation. The station batteries are sized to carry this additional inverter load without being charged for no less than 4 hours. The battery chargers are sized to recharge from a design minimum charge to full charge in 12 hours while carrying the largest combined demand from the various steady-state loads.

An alternate power supply for the 120 volt a-c vital buses is provided through 480-120 volt transformers from 480 volt buses 1DA2 and 1DB2 for use when the inverters are out of service.

8.3.1.1.4 Equipment Criteria

1. Motor Size

   The criterion for motor size is that the motor develops sufficient horsepower to drive the mechanical load under maximum expected flow and pressure. Motors are sized to permit the driven equipment to develop its specified capacity without exceeding the temperature rise rating of the motor when operated at the duty cycle of the driven equipment. Motors are furnished with service factors ranging from 1.0 to 1.15. The service factor is a ratio of the safe load to the nameplate load and identifies the margin available for motor operation under overload conditions. When a motor is furnished with a service factor greater than 1.0, it is the design intent to size the motor to handle the normal operating requirements of the driven equipment without taking credit for the service factor. Motor size is determined based on the driven equipment load characteristics.

2. Engineered Safety Features Motor Starting Torque

   Motors are designed for across the line starting. ESF motors rated 6900 volts are capable of accelerating the driven equipment to rated speed at 70% of the motor nameplate voltage. ESF motors rated 460 volts are capable of accelerating the driven equipment to rated speed at 80% of rated voltage. The motors are designed to operate at ± 10% of rated voltage, ± 5% of rated frequency or a combined variation in voltage and frequency of ± 10% of absolute values, provided that frequency variation does not exceed ± 5% of rated frequency.

   Calculations based on the diesel generator factory test data indicate that the motor terminal voltage during starting will not go below 90% of the rated voltage for 6,900 volt motors or below 82% for 460 volt motors. The motor terminal voltage for the 6900 volt motors was calculated using the diesel generator voltage regulation for starting of a 1750 Hp motor. The motor terminal voltage for the 460 volt motors was calculated using the diesel generator voltage regulation for starting a 500 Hp motor and considering the voltage drop through the 7200/480 volt transformers. The actual largest system motors are 900 Hp and 350 Hp for the 7200 volt and 480 volt systems respectively (Refer to Appendix 8E). These voltage levels are well above those allowed by Regulatory Guide 1.9. The adequacy of bus voltage regulation during motor starting is confirmed during the preoperational testing program.

3. Motor Insulation

   Motor insulation is a minimum of Class B outside the Reactor Building and Class F inside the Reactor Building. The insulation temperature rating is greater than the sum of the motor temperature rise and the ambient temperature at the motor location.

   Service life is extended when necessary by 1, or a combination, of the following methods:

   a. Derating - use of a larger motor than required by the motor sizing criteria previously discussed.
   b. Insulation type - use of motor insulation with a higher temperature limit than specified for the operating conditions (e.g., specifying Class F insulation to Class B temperature limitations).
   c. Service factor - motors with 1.15 service factor are operated under normal conditions without encroaching upon the service factor.

4. Engineered Safety Features Motor Temperature Protection

   ESF motors rated 6900 volts and 600 Hp and larger are provided with 6 stator winding embedded, resistance type, 10 ohm, copper at 25°C, resistance temperature detectors (RTDs). Smaller horsepower motors are not equipped with stator RTDs due to the problems involved in embedding them in the stator. The exceptions are the 400 Hp reactor building spray pump motors which do have stator RTDs.

   Motors rated 6900 volts and selected 460 volt motors are provided with bearing thermocouples. Outputs from each of the 2 motor temperature measuring devices are routed to the plant computer which actuates an alarm and provides a printed output if the stator RTD or bearing thermocouple measured value exceeds a predetermined setpoint.

5. Interrupting Capacity

   Switchgear, unit substations, motor control centers and distribution panels are sized for interrupting capacity greater than the maximum short circuit availability at their location. The calculations to document this application take into account the fault contributions of all rotating machines and source transformers. Source impedances are selected to ensure adequate starting voltage for all motors and to limit short circuit currents at unit substation buses and motor control center buses.

6. Network Protection

   Each major motor or other major item of electrical equipment is protected by overcurrent relays that disconnect the equipment if the load current becomes excessive. Prior to plant operation protective relays are set and calibrated. Availability and proper operation of standby equipment are periodically tested during normal operation.

The protection philosophy for the 7200 volt and 480 volt systems is based upon the following considerations:

a. A faulted piece of equipment is cleared by isolating the smallest possible portion of the system.

b. A faulted piece of equipment is cleared in the minimum possible time to reduce damage to that equipment and limit the stress on the remainder of the system.

c. Protective devices are selected and set for fault sensing and overload sensing as required for applicable system/component protection.

d. Motor control centers that serve loads located inside the Reactor Building typically have starters, (with thermal overloads) magnetic molded case circuit breakers, and a current limiting circuit breaker in series. The current limiting circuit breakers have thermal and magnetic elements incorporated in their protection circuit. Loads that do not require a starter, that use a contactor without overload protection, or have overloads bypassed under accident conditions, or are mentioned in Section 8.3.1.4.1; have an additional thermal element provided in the molded case circuit breaker. This arrangement provides primary and backup protection in compliance with Regulatory Guide 1.63 (see Appendix 3A).

e. Overload elements provided for safety-related valve operators are bypassed under accident conditions by the safety injection signal contact that initiates the valve operation. This is in compliance with Regulatory Guide 1.106 (see Appendix 3A).

7. Grounding Requirements

Design criteria for grounding of safety-related systems are as follows:

a. All equipment hardware, exposed surfaces and potential induced voltage hazards are adequately grounded to assure that no danger to plant personnel exists.

b. A low impedance ground return path is provided to facilitate the operation of ground fault detection or protective devices in the event of ground fault or insulation failure on any electrical load or circuit.

The following are the methods for grounding electrical equipment:

a. A ground wire is connected to the equipment frame and the ground grid. The ground wire is run through the equipment conduit or lashed to the power cable for the equipment where no conduit is provided. The wire is either connected directly to the ground grid or to other equipment, such as a cable tray which is connected to the grounding grid.

b. Where conduit is used as the grounding path, the conduit is connected to the equipment and the grounding grid. The connection to the grounding grid is either a direct connection or is connected to other equipment such as a cable tray which is connected to the grounding grid.

The cable tray system is solidly grounded. Ground connections are made to the station grounding grid or building steel work, which is connected to the station grounding grid.

The station grounding grid is designed to maintain the station area at an effective ground potential during a worst case ground fault in any installed electrical equipment, including transmission facilities and unit main generators, as well as lightning effects. An effective ground is considered to be the maintenance of voltage potentials below a "safe touch" level for plant personnel.

8. Maintenance Program

   A maintenance program, in accordance with the recommendations of the manufacturers, is followed. This program includes periodic visual inspection and lubrication for each motor. A record is maintained for each motor indicating the date when each action is performed.

9. Starter Voltages

   Starter coils for motor control centers are designed to pull in at 85% of rated voltage and to hold in at 65% of rated voltage. The coils are energized through a 480/120 volt instrument transformer.

10. Heat tracing is provided for Nuclear Safety Related and Non-Nuclear Safety Related equipment, piping, and/or tubing for the purpose of process temperature maintenance and freeze protection of liquids and for prevention of condensation in instrument air lines.

    The heat tracing equipment protecting Safety Related systems (i.e., reactor makeup water storage tank and piping, refueling water storage tank and piping, and sodium hydroxide) includes redundant centralized control panels, temperature measuring equipment, wiring and conduit, and heat tracing cables, except for the refueling water storage tank and reactor makeup water storage tank. These tanks are monitored by redundant temperature instrumentation and are provided with 1 set of heat tracing each. Based upon the thermal capacity and insulated design of these tanks, the redundant instrumentation provides adequate operator control to prevent freezing. The centralized control panels provide power distribution, control and alarm functions from signals received from temperature measuring equipment attached to the piping systems. The primary and redundant heat trace circuits are each designed with the capability to provide the necessary freeze protection, or maintain the necessary process temperature. In the event of a failure to the primary heat trace circuit, the redundant heat trace circuit provides the necessary heat trace function. The heat tracing cables are of the parallel self-limiting type. The centralized control panels are powered from Class 1E Channel A and Channel B motor control centers. Alarms are transmitted to the control room from a local annunciator panel.

8.3.1.2 Analysis

8.3.1.2.1 Compliance Analysis

The basic design criteria are that the Class 1E electric power systems satisfy the single failure criterion and Regulatory Guide 1.32 (see Appendix 3A). The safety-related loads are assigned to 2 independent, separate 7200 volt ESF buses. Either of these buses is capable of supplying required ESF or shutdown loads. Each of these buses is continuously energized from the preferred source ESF transformer(s), 1 set of windings in emergency auxiliary transformer (XTF-31), or from 1 of the diesel generators. Each 7200 volt ESF bus serves as a power source for the safety-related loads on the 480 volt buses and for equipment which is not safety-related but is considered essential for protection of the turbine or desired for convenience. This design, including the ties to the non-ESF buses, satisfies the independence and redundancy requirements of Regulatory Guide 1.6 (see Appendix 3A) and General Design Criterion 17.

The main control board is provided with indicators to monitor the ESF bus operating levels. A voltmeter, ammeter, wattmeter, varmeter and kilowatt hour meter are provided on each of the incoming, preferred power sources. The onsite power source has a voltmeter, frequency meter, wattmeter and ammeter provided on the main control board to indicate the ESF bus operating levels. Figures 8.2-3 and 8.2-4 indicate the metering provided on the plant electrical system. Table 8.3-3b is a listing of the indicator types associated with the ESF electrical network.

The ESF buses have sufficient redundancy to allow testing of each safety-related item as a system, or in some cases as individual components to comply with General Design Criteria 17 and 18.

Two (2) diesel generators provide onsite power to the 7200 volt ESF buses. Each diesel generator is assigned exclusively to 1 bus and each is automatically started upon a loss of bus voltage, degradation of bus voltage or receipt of a safety injection actuation signal. Under conditions outlined in Section 7.3.1, normal loads, with the exception of the group indicated by 0 seconds in Table 8.3-3 Parts A1 and B1, are disconnected and the ESF loads are automatically loaded in sequence on each diesel generator in accordance with the sequence presented in Table 8.3-3.

If a loss of preferred power is not concurrent with a postulated accident, certain ESF equipment is not required. Under these conditions, other plant auxiliary equipment may be manually operated. Safety injection loads are sequenced on by the load sequencer in this case, but loads are not disconnected prior to the sequencing. Instrumentation is provided to indicate emergency diesel generator loading.

The onsite standby power supply complies with Regulatory Guide 1.9, including load limits, (see Appendix 3A). The diesel generators have a continuous rating of 4250 kw, a short time rating of 4676 kw for up to 7 days, and a 30 minute rating of 5100 kw. The limiting accident load is calculated to be 4390 kw and the maximum load under loss of offsite power conditions is calculated to be 4920 kw. These short time and continuous rating loads are verified by test during each periodically. (The largest bus connected load is calculated to be approximately 5450 kVA.)

8.3.1.2.2 Hostile Environments

8.3.1.2.2.1 Equipment Identification

The most severe environmental conditions expected to be imposed upon the equipment which would operate inside and outside the Reactor Building during normal operation and subsequent to a LOCA or main steam line break are presented in Section 3.11. Regulatory Guide 1.89 is discussed in Appendix 3A.

8.3.1.2.2.2 Loss of Ventilation

To ensure that loss of the air conditioning and/or ventilation systems does not adversely affect the operability of safety-related control and electrical equipment located throughout the plant, the environmental systems for these areas satisfy the single failure criterion. Section 9.4 presents a detailed discussion of ventilation systems. Section 3.11.4 discusses loss of ventilation.

8.3.1.2.2.3 Qualification Tests

See Section 3.11 for a discussion of the hostile environment for which electrical equipment is procured and the maximum DBA environmental conditions to which it may be subjected.

8.3.1.3 Conformance with Appropriate Quality Assurance Standards

The quality assurance procedures used during equipment design, fabrication, shipment, field storage, field installation and system and component checkout and the records pertaining to each of these during the construction and preoperational test phases are described in Chapter 17.

The Quality Assurance Program, as discussed in Chapter 17, is in conformance with IEEE-336 (Reference 1).

8.3.1.4 Independence of Redundant Systems

8.3.1.4.1 Criteria for Independence of Redundant Electric Systems

The electrical power supply, control and instrument cables for mutually redundant equipment are physically separated to preserve the redundancy and to ensure that no single, credible event will prevent operation of the associated function because of electrical conductor damage. Critical circuits and functions include power, control and instrumentation associated with reactor protection, ESF and reactor shutdown. Credible events include, but are not limited to, the effects of short circuits, pipe ruptures, fires, earthquakes, and missiles. The minimum electrical separation required for protection against design basis accidents is included in the basic plant design.

The separation of electrical circuits has been reviewed to the criteria of IEEE 384 (Reference 14) as modified by Regulatory Guide 1.75 (see Appendix 3A). The plant design complies with these criteria as described below:

1. Redundant Class 1E circuits are run in separate and independent raceways. In general plant areas, not subject to hazards, such as missiles, open ventilated cable trays for redundant circuits are separated by a minimum of 3 feet horizontally or 5 feet vertically. In cable spreading rooms open ventilated cable trays are separated by a minimum of 1 foot horizontally or 3 feet vertically. Totally enclosed raceways for redundant circuits are separated by a minimum of 1 inch. Where these separation criteria cannot be satisfied, suitable barriers are placed between the raceways. The design of these barriers is described in Appendix 8B.

2. In areas where redundant circuits are exposed to hazards, such as missiles, the minimum spacing between mutually redundant wireways is 20 feet. Where this spacing cannot be achieved, a suitable missile proof barrier is used to ensure that no common hazard could render more than 1 mutually redundant circuit inoperative. Barriers have been provided to protect trays for Class 1E circuits from the effects of jet impingement and piping is restrained to prevent pipe whip as described in Section 3.6.

3. Where non-Class 1E circuits are connected to Class 1E equipment or are routed in the same raceways with Class 1E circuits, they are designated as associated circuits. Circuits designated as associated are routed with the designated separation channel throughout their length. Where non-Class 1E circuits are connected to Class 1E equipment, an isolation device is provided to protect the Class 1E equipment. These isolation devices are further discussed in Appendix 3A under the discussion of Regulatory Guide 1.75.

4. Non-Class 1E circuits are routed in raceways independent from the raceways for Class 1E circuits. Where the separation between the raceways for non-Class 1E circuits and raceways for Class 1E circuits do not satisfy the criteria for raceways carrying redundant Class 1E circuits, as described in Item 1, above, a case by case analysis has been performed to ensure that adequate separation exists. This analysis reviewed 2 types of violations, single and multiple. Single violations are those in which a non-1E tray violates the minimum separation required at one point along its path. These cases are summarized in Appendix 8C. A multiple violation is defined as a non-Class 1E tray which violates the minimum separation required at 1 point, and then, within the same fire area, the same non-Class 1E tray violates another Class 1E tray which is of a redundant channel to the initial 1E tray. For identified multiple violations in control (4000 series) trays, tray covers have been provided between the non-Class 1E tray and one of the Class 1E trays. The remaining violation is then analyzed as a single violation (Appendix 8C). For power trays (1000, 2000 and 3000 series) which cannot be covered, periodic testing of certain cable protective devices is performed in accordance with a controlled breaker surveillance program. This testing ensures that adequate overcurrent protection exists for the cables in the non-Class 1E trays so that they cannot be a hazard to the Class 1E trays whose separation distance has been violated. The results of the analysis for identified multiple violations are summarized in the Fire Barriers Raceway Database.

   All 5000 series instrument trays are deemed as acceptable barriers for multiple violations without the use of top hats, Kaowool, or any other fire related enhancements. Because of this, multiple violations in which 1 or more of the trays involved were 5000 series were classified as single or no violations as appropriate.

5. The Class 1E circuits routed to the service water intake structure are installed in underground concrete duct banks. These duct banks are seismic Category 1 structures and, as such, are designed to protect the cables from postulated natural phenomena, including SSE. The layout of the duct banks and associated manholes is illustrated by Figures 8.3-2a through 8.3-2g.

6. Separation of safety-related circuits is maintained in the electrical penetrations of the Reactor Building. Circuits for nuclear and protection instrumentation are not mixed with other type circuits in the same penetration. The redundant circuits for the 4 nuclear and protection instrumentation channels enter containment through penetrations located around the periphery with a minimum horizontal separation of 20 feet, centerline to centerline, between any 2 channels (see Figure 8.3-3). Physical separation between penetrations containing redundant circuits, other than the 4 nuclear instrument channels, is maintained in accordance with Section 8.3.1.4.3, Item 2.

   The 4 penetrations containing the nuclear and protection instrumentation are provided with metal barriers. The metal barriers are used to separate the nuclear and protection instrumentation.

   These barriers are grounded and are arranged to provide an effective electromagnetic shield over the full length of the penetration assembly.

   Structural criteria require that penetrations be spaced on minimum horizontal and vertical centerlines as shown by Figure 8.3-3. This provides a 3 foot minimum separation between any electrical penetration and any other type of penetration. The design objective is to maintain maximum separation between safety related electrical penetrations and any large piping penetrations to minimize mechanical damage from the postulated rupture of steam or water lines. The design objective is also to maintain maximum separation between any safety-related penetrations and large power penetrations, such as those for reactor coolant pump or pressurizer heater power cables. Separation of safety-related electrical penetrations from main steam lines is maintained by a concrete floor or a minimum horizontal distance of 40 feet. One (1) exception is the penetrations for the power feeds to the Channel A Reactor Building cooling unit fans. The main steam lines and cooling unit fan power feeds both penetrate the Reactor Building above the operating floor. A 20 foot minimum separation is maintained between these penetrations. Separation from any other steam, high pressure water or large power electrical penetration is maintained by a concrete floor or by an 8 foot minimum horizontal centerline separation.

7. Cable trays, conduits and cables are marked for ready identification of the channel and to guard against violation of separation. Specific color coding is discussed in Section 8.3.1.5.

8. SP-834, “Electrical Construction Guideline for Electrical Circuit Physical Separation,” and Electrical Maintenance Procedure EMP-405.012, “Guide for Electrical Physical Separation,” identify the minimum separation guidelines for internal wiring and components within control boards, panels, relay racks, etc. A minimum separation distance of 6 inches between redundant components and/or wiring and between Class 1E and non-Class 1E components and/or wiring within the enclosures is required. Where 6 inches of air separation is not available, a suitable fire barrier is installed or an analysis is performed to demonstrate that

the separation distance is adequate. Design exceptions to the separation guidelines are addressed in Attachment 1 to SP-834.

8.3.1.4.2 Compliance with Criteria for Independence of Redundant Electric Systems

A discussion of the administrative responsibility and control provided to ensure compliance with the criteria, set forth in Section 8.3.1.4.1, during design and installation is presented in Chapter 17.

8.3.1.4.3 Criteria for Design and Installation of Electrical Cable

The recommendations of IEEE Proposed Guide P-422, (Reference 3) IEEE STD 384, (Reference 14) and Regulatory Guide 1.75 (see Appendix A) are used, except as modified by Items 1 through 6, below, as the general design criteria for the design of the power, control and instrument cable and cable tray systems related to all Class 1E electrical systems.

1. Power cable capacities are determined using derating factors listed in IPCEA P-46-426, (Reference 4) supplemented by IPCEA-NEMA P54-440. (Reference 5) Cable derating and cable tray fill are discussed in Section 8.3.3.1.
2. Cable routing in the Reactor Building, penetration areas, cable spreading room, control room, etc., is arranged following the recommendations in IEEE Proposed Guide P-422. (Reference 3) Channel separation and cable tray physical separation requirements are maintained in these areas in accordance with Section 8.3.1.4.1, item 6. Cables which must enter areas surrounded by shield walls are routed to minimize the cable length within the shields area.
3. Fire and/or smoke detection equipment is installed in areas of heavy cable concentration, as recommended by IEEE Proposed Guide P-422. (Reference 3) Fire stops are provided at cable tray penetrations through floors and fire barrier walls.
4. An exception is taken to IEEE Proposed Guide P-422 (Reference 3) recommendations for 30% cable tray fill. Experience has indicated that a design objective of 50% physical fill, including all anticipated future cables, is satisfactory. This fill calculation is based upon the summation of the cable diameter squared divided by the cross-sectional area in the tray. The tables referred to in Item 1, above, are used as the basis for ampacity rating. The allowable depth is determined from the physical fill calculations outlined above and in Section 8.3.3.1.
5. The design objective for the minimum physical vertical spacing between the power, control and instrument cable trays of the same redundant channel is 12 inches, measured from the top of the lower tray to the bottom of the upper tray and a 9 inch clearance between the top of a tray and beams, piping, etc., to facilitate installation of cables in the tray. However, in areas where physical limitations govern, the physical separation may be less than the 12 inches and 9 inches, respectively.
6. The same basic design considerations are incorporated for tray and conduit supports as for the structures to which they are attached. Therefore, the same supports can be used for redundant raceways or for a redundant and non-safety raceway.

8.3.1.5 Physical Identification of Safety-Related Equipment

Identification of cable and raceways is readily apparent in the design and installation stages and is such that any safety-related cable can be readily identified. Raceways and cables (particularly for redundant systems) are adequately identified to prevent violation of separation criteria. Channel identification for safety-related and associated circuits is based upon the 4 reactor protection process control channel colors: red, orange, blue, and yellow. In addition, green is used for C train and tan is used for non-safety-related circuits. Cable trays and cables for these circuits, as well as for power, control and instrumentation circuits for ESF Channels A and B are identified relative to the 6 colors as indicated in Table 8.3-4.

Cable identification is as follows:

1. Color coding

   Cables are marked at 5 foot intervals. The circumference of the cable is marked such that the marking is visible no matter how the cable is turned.

2. Tagging

   Tags are placed at each end of the cable. These tags are marked to indicate the circuit and channel. Any nonengineered safety feature cables in a safety-related tray are marked to distinguish them from the safety-related cables.

3. Conduits

   Conduits are marked with identification markers. Color coding is done with colored tape at 15 foot intervals. Tags for embedded conduit are attached to the concrete above the conduit.

4. Cable Trays

   Cable trays for safety-related cables are identified with tags. The color coded tags are located on the trays so they are visible from easily accessible vantage points, such as walkways, etc.

5. Equipment Identification

   Each piece of equipment has an identification (ID) tag attached which identifies the equipment. Channel designation for safety related and associated equipment is identified by a strip of color coded tape.

   Tags mounted on equipment inside the Reactor Building are of stainless steel and have the required information engraved. Where there is not room to mount the tag to the equipment, it will be attached by wire. In these cases, the color coded tape will be attached to the back of the tag. Stainless steel ID tags are also used outside the Reactor Building. Tags for associated equipment have 2 colors.

8.3.1.6 Electrical Penetration Areas

Electrical penetration areas are located as follows:

1. Fuel Handling Building penetration area (penetration access area - North). Number of penetrations is 7.
2. Intermediate Building penetration area (penetration access area - East). Number of penetrations is 5.
3. Intermediate and Auxiliary Building penetration area (penetration access area - West). Number of penetrations is 33.

No special designations have been assigned areas where penetrations enter the Reactor Building.

Redundant circuits are spatially separated by 40 feet or a concrete floor, except for nuclear instrumentation penetrations, which are spatially separated by 20 feet.

Provisions for fire detection and protection in the penetration access areas consist of the following:

1. An early warning fire detection system comprised of smoke detectors.
2. A fire hose/standpipe system.
3. Manual fire extinguishers.

Protection to ensure that missiles inside the Reactor Building will not jeopardize plant safety are discussed in Section 3.5.1.

All containment penetration seal assemblies are protected against major incidents, such as missiles and rupture of high energy piping. Additionally safety related penetrations are protected on both sides of the nozzle. Therefore, based upon good design practice, a separation of 3 feet from other penetrations, the failure of which could inflict only minor or insignificant damage to an electrical penetration, was provided.

8.3.2 D-C Power Systems

8.3.2.1 Description

Separate Class 1E and non-Class 1E d-c power systems are provided. Two (2) Class 1E 125 volt d-c systems provide sources of reliable, uninterruptible d-c power for control and instrumentation for normal operation and orderly shutdown of ESF equipment. A separate non-Class 1E 125 volt d-c system is provided to supply non-ESF d-c loads, including large power non-ESF loads. This system is also a manually switched backup d-c source for the Substation Relay House d-c system. The 125 volt d-c battery systems, located in the Substation Relay House and in the Unit 1 Relay House, are provided for 230 kV substation protection and control. These systems are shown in Figures 8.3-1, 8.3-2, 8.3-4, 8.3-5 and 8.3-5a.

The Class 1E d-c system for control and instrumentation consists of 2 full capacity, 125 volt d-c, lead calcium, 60 cell batteries, 2 125 volt d-c battery buses and 3 static battery chargers. Two (2) of the 3 battery chargers are supplied from separate, redundant motor control centers. One (1) of these 3 chargers serves as a standby charger and is provided for use during maintenance of, and to backup, either of the normal power supply chargers. The standby battery charger, 1A-1B, is provided with a set of 2 transfer switches which consist of mechanically interlocked circuit breakers on the a-c input and d-c output. These circuit breakers, as shown by Figures 8.3-6 and 8.3-7, are interlocked to allow only the 2 breakers associated with Channel A or the 2 breakers associated with Channel B to close at the same time. The battery chargers remain connected to the respective a-c source buses upon loss of offsite power. Each battery charger is protected by the molded case circuit breakers in the input and output circuits. The d-c circuit has a voltage adjustment of 100 to 145 volts d-c. During an equalizing charge, d-c voltage may be set at 140 volts. All Class 1E d-c loads can operate at 140 volts d-c without damage. An overvoltage alarm is provided to annunciate in the control room upon detection of voltages greater than 140 volts d-c.

The non-Class 1E 230 kV Substation d-c systems provided for the 230 kV substation control and relaying consists of the following:

1. For the Substation Relay House, the d-c system consists of a 125 volt battery with a main battery bus, two battery changers and two separate distribution panels for 230 kV circuit breaker tripping. Backup for non-1E loads is also provided by this system.
2. For the Unit 1 Relay House, the d-c system consists of two independent d-c systems. Each system is comprised of a 125 volt battery with two distribution panels, a battery charger and common bus-tie fuse-disconnect switch. One d-c system supplies the 230 kV substation system primary protection and control. The second d-c system supplies backup protection and control. Other 230 kV substation systems and relay house d-c loads and can be supplied from either d-c system.

The second non-Class 1E d-c system provided for the 230 kV substation control and relaying in the substation relay house consists of a 125 volt battery with a battery bus, 2 static battery chargers and 2 separate distribution panels for power circuit breaker tripping. Backup for large power non-ESF loads is also provided by the system.

The non-Class 1E d-c system in the Unit 1 relay house consists of two 125 volt d-c batteries, each with its battery charger, feeding 2 separate distribution panels for power circuit breaker tripping.

The non-Class 1E battery has adequate storage capacity to power the following loads for a period of 1 hour:

1. Main generator emergency seal oil pump.
2. Circuit breaker closing and tripping (non-ESF buses).
3. Miscellaneous non-ESF loads.
4. Non-ESF instrumentation inverter and computer inverter.

5. D-C turbine bearing oil pump.
6. Feedwater pump d-c oil pump (3 pumps).
7. Reactor and Diesel Generator Building emergency panels.

A 1 hour period is considered to be the minimum time for use in sizing the batteries. Complete loss of offsite and onsite a-c power for such a period of time is considered highly unlikely. Loss of both diesel generators during an assumed prolonged loss of offsite power is not postulated nor is complete loss of all battery chargers postulated. Battery chargers are considered to be available to sustain the bulk of the battery loads well within the 1 hour period of time.

The non-Class 1E battery supplying power to the d-c turbine bearing oil pumps is of sufficient capacity to power the pumps during turbine coastdown to avoid turbine bearing damage.

Battery capacity in addition to that which is absolutely essential is provided.

8.3.2.1.1 Uninterruptible Non-Class 1E System

The uninterruptible non-Class 1E 125 volt d-c system is an ungrounded system. The system is operated ungrounded with the battery floating on the system. Dual input inverter No. 5 (450 volt a-c normal input, 125 volt d-c backup input) provides uninterruptible 120 volt a-c power for the AMSAC system, secondary plant digital control systems, the station computer and other non-Class 1E loads. No Class 1E loads are supplied from this system. The secondary plant digital control system can also be powered by the ISFSI Electrical Building uninterruptible power supply.

The dual input inverter No. 5 provides continuous power to non-Class 1E 120 volt vital secondary digital control system and computer loads. Transfer from one input to the other is accomplished without interruption to the load. The inverter is protected by circuit breakers on the 480 volt a-c input side and the 125 volt d-c input side. Abnormal conditions in the dual input inverter cause alarms to occur in the control room.

The output of inverter No. 5 is connected to a distribution panel through an automatic static transfer switch. An alternate backup 480-120 volt transformer non-Class 1E power source is provided through the automatic static transfer switch. The feed to the transformer is from a 480 volt motor control center as indicated by Figures 8.3-4 and 8.3-4b.

All metering and monitoring is performed by a digital control system that includes a microprocessor. The operation of the microprocessor has no impact on the ability of inverter No. 5 to perform its function.

Inverter No. 6 is also powered from the non-Class 1E 125 volt d-c bus. A static switch is provided on the output of this inverter to switch the feed to the inverter distribution panel from the inverter output to a 120 volt ac supply upon detection of loss of inverter output.

8.3.2.1.2 Uninterruptible Class 1E Systems

Each uninterruptible Class 1E system contains a separate 125 volt d-c and 120 volt ac system.

The 125 volt d-c system is a 2 wire, ungrounded system centered around a full capacity 125 volt, lead calcium battery, 125 volt d-c main distribution panel and solid state battery chargers. Figures 8.3-2aa and 8.3-2ab show connection of the battery, battery charger and main distribution panel of each redundant Class 1E power system. No ties are provided between the redundant Class 1E 125 volt d-c systems. All non-Class 1E loads connected to the Class 1E d-c system are identified by Figure 8.3-1 (see Note 4, Figure 8.3-1). Connection of non-Class 1E loads to the Class 1E d-c system is discussed in the statement concerning Regulatory Guide 1.75 in Appendix 3A.

Eight (8) separate 125 volt d-c distribution panels including the 2 main distribution panels are provided. Each panel provides d-c instrumentation and control power as necessary for proper functioning of the plant.

The battery, battery charger and main distribution panel of each system are located in protected areas of the Intermediate Building, separate from the location of redundant channel equipment. The protected areas are separated by a fire resistant barrier. The inverters and other distribution panels are also located in protected areas.

Each ESF battery has a rated capacity of 2175 ampere hours (with an 8 hour discharge cycle to 1.75 volts per cell). This capacity is sufficient to power essential loads and normally connected non-essential loads for a 4 hour duty cycle following loss of all a-c power. The 4 hour duty cycle is based on coping requirements for Station Blackout (Reference 15) defined by NUMARC 87-00 (Reference 17) and endorsed by NRC Regulatory Guide 1.155 (Reference 16). The 4 hour duty cycle with loss of all a-c power envelopes the previous 2 hour duty cycle based on a LOCA in conjunction with the loss of all a-c. The 2 hour duty cycle represents standard industry practice for sizing batteries for generating stations and does not reflect V. C. Summer design basis requirements for demonstrating d-c system operability. Essential loads include the following:

1. Instrumentation inverters - with ESF and non-ESF loads.
2. Engineered safety features control.
3. Diesel generator control and field flashing.
4. Circuit breaker closing and tripping (ESF buses).
5. Controls and alarms, including Auxiliary Relay Racks, Isolator Cabinets, Main Control Boards, HVAC Boards and Control Room Annunciators.
6. Control Room emergency lighting.

During normal operation, the 125 volt d-c load is supplied from the battery chargers with the batteries floating on the system. Upon loss of station a-c power, the entire d-c load is supplied from the batteries until the a-c power to the chargers is restored by the emergency diesel generator or the preferred power source. The function of the battery is to provide sufficient stored energy to operate necessary d-c loads for as long as each load is required during the loss of a-c power. The

time duration for the loss of a-c power is the time required for the diesel generator to start and accept load. For the V. C. Summer Station, the diesel generator breaker will close and energize the battery charger within 10.25 seconds after a loss of a-c power. Failure of a battery charger or failure of a diesel generator to start would be a single failure for which there is a redundant train of electrical systems that will be used to achieve safe shutdown and mitigate design basis events. A failure of a battery charger would not prevent either start of the diesel generator or closure of the necessary breakers to re-establish a-c power to the auxiliary a-c system. In the event of a charger failure, a backup charger has been provided and can be connected well within the battery's 4 hour duty cycle. Thus, the minimum 4 hour battery capacity provides considerable margin for the battery to perform its intended function.

Separate evaluations were performed to demonstrate sufficient battery capacity and to demonstrate system operability based on sufficient voltage at d-c equipment/device terminals.

The evaluation to demonstrate sufficient Class 1E battery capacity was based on ampere loads associated with Class 1E and non-Class 1E equipment as shown on Figures 8.3-1, 8.3-2, 8.3-2aa, and 8.3-2ab.

The evaluation to demonstrate d-c equipment/device operability was based on ensuring that the available operating voltage (or current) for required equipment was equal to or greater than the minimum operating voltage recommended by the applicable vendor or by actual tests to demonstrate component operability with margin. Available operating voltages (or currents in the case of D.G. field flashing) were evaluated to ensure operability of Class 1E devices based on the required time of operation and the applicable system losses resulting from voltage drop. Operability of non-Class 1E loads which are supplied from the 1A and 1B batteries was not evaluated.

System operating voltages were determined based on the battery as the sole source during the first 10.25 seconds following LOOP with only 59 cells or 58 cells connected. System operating voltages after 10.25 seconds were determined based on the battery at float voltage following restoration of a-c power to the battery charger.

The evaluation conservatively determined voltage drop based on the d-c load currents established by the battery capacity evaluation, as modified to include design margins, and the equivalent circuit resistance, as modified to compensate for worst case conductor temperatures.

Although there is no accident analysis that requires d-c system operability with the battery as the sole source after 10.25 seconds, the design objective was to ensure the ESF 125 v d-c system is capable of supporting/operating normal and required emergency d-c loads in the event of a DBA, or required SBO loads in the event of a 4 hour station blackout. Required SBO loads are normal (non-accident) loads necessary to ensure the reactor core is cooled and containment integrity is maintained in the event all a-c power is lost for a 4 hour period.

8.3.2.1.3 Capacity

The ampere demand of each ESF battery was calculated for the loads listed in the preceding Items 1 through 6, as well as for other connected d-c loads, to establish the worst case 4 hour duty cycle. This calculation resulted in the following 4 hour load profile.

1. Battery 1A - 376.9 amperes for the first minute, 200.3 amperes for the next 238 minutes, and 246.3 amperes for the last minute.
2. Battery 1B - 392.4 amperes for the first minute, 215.8 amperes for the next 238 minutes, and 261.8 amperes for the last minute.

The capacity of each ESF battery was then checked to ensure that the batteries are capable of supplying required d-c loads for the duty cycle. In addition the battery capacity includes design margin, accounts for battery degradation with age, and considers the reduction of battery capacity due to temperature variations. The capacity evaluation was based on a final (end of discharge) battery terminal voltage of 108 V d-c (or greater), which provides sufficient margin to ensure device operability with a reduction of up to 2 cells (58 cells connected) on either battery.

The calculated ampere demand includes normally connected devices with no distinction as to whether devices are required to operate or are desirable loads. The inclusion of the latter precludes the need for any load shedding and no operator action is required to maintain power to essential safety related loads during the 4 hour duty cycle. However, any load shedding performed during the battery duty cycle adds to the existing capacity margin and results in a higher battery voltage at the end of the duty cycle.

The d-c system is designed so that the loads with common a-c and d-c power supplies, such as inverters, are powered by the batteries during blackout, but are automatically returned to the a-c system upon ac bus voltage restoration. As a result, the battery chargers are required to have a minimum capacity of 150 amperes to provide the necessary 12 hour recharge. This is well within the system’s 300 ampere battery charger rating.

8.3.2.1.4 Ventilation

The battery rooms and battery charger rooms are located in the Intermediate Building and are provided (as a group) with a once through ventilation system consisting of two (2) 100% capacity supply fans and two (2) 100% capacity exhaust fans as shown in Figure 9.4-16. The ventilation system is designed for continuous operation. Therefore, the chance of producing an explosive atmosphere due to evolution of hydrogen during the process of battery charging is minimized. The system is provided with high and low temperature alarm inputs to the HVAC control board annunciator system. The battery room ventilation system is discussed further in Section 9.4.6.

8.3.2.1.5 Equipment

8.3.2.1.5.1 Batteries and Battery Racks

All batteries are of the central station, lead calcium type and are designed for continuous float duty. Each cell is of the sealed type, assembled in a shock absorbing clear plastic container, with covers bonded in place to form a leakproof seal. The batteries are mounted on protected, corrosion resistant, steel racks for security and to facilitate maintenance. The Class 1E batteries and racks are designed to remain functional during a safe shutdown earthquake and remain in a satisfactory condition to perform their function in shutting down the reactor and maintaining the station in a safe condition.

8.3.2.1.5.2 Battery Chargers

Each solid state battery charger has an output for float and equalize modes with an input of 480 volt 3-phase, a-c power. Each charger is equipped with a d-c voltmeter, d-c ammeter, a-c failure relay, a ground detection annunciator alarm, low battery voltage alarm relay and fan failure alarm. A battery charger malfunction activates an alarm in the control room. Each battery charger is designed to prevent the 480 volt a-c system from becoming a load on the battery as a result of loss of 480 volt a-c input.

Tests have verified that battery charger stability is not load dependent.

There is no annunciator to alarm when the battery charger goes into a current limiting condition.

In addition to the charger output ammeter, a 0 center scale ammeter is connected to a shunt in the leads between the battery and the battery bus to indicate current flow to and from the battery. These 2 ammeters show the status of battery charging or discharging currents and d-c system loads at all times. Main breakers, as shown on Figures 8.3-1, 8.3-2, and 8.3-4 are equipped with auxiliary switches to operate indicator lights in the control room for an off normal position. Thus, the operator is provided with system status information. Following a loss of normal station power, the battery chargers are energized from the diesel generators.

Additional monitoring is provided by a special, narrow band, d-c voltage relay to monitor Class 1E battery voltage. The relay initiates an alarm in the control room if battery voltage falls slightly below normal float voltage.

Voltage monitoring in this manner provides a backup alarm if a charger fails since a fully charged battery suffers a rapid drop in voltage if its floating charge fails. Such a rapid voltage drop causes the voltage monitoring relay to initiate the associated alarm. Battery ground detection annunciation is provided on the main control board for both Class 1E and non-Class 1E Plant d-c systems.

The ratings for each battery charger continuous output are as follows:

1. Charger 1A - 300 amperes
2. Charger 1B - 300 amperes
3. Charger 1A-B - 300 amperes
4. Charger 1X - 400 amperes
5. Charger 1X-2X - 400 amperes

Each battery charger has capacity adequate to restore its associated battery to full charge while providing power to the largest combination of the various steady-state loads. The charging capacity is based upon restoring the battery to full charge from the design minimum charge within 12 hours after discharge regardless of the status of the station.

8.3.2.1.5.3 Main D-C Distribution Panels

Each battery distribution switchboard consists of a metal clad structure with 125 volt d-c, 2 wire, ungrounded main bus. Two (2) pole, manually operated, air circuit breakers protect each feed.

8.3.2.1.5.4 Class 1E Dual Input Inverters

The dual input inverter in each system provides continuous power to the 120 volt vital a-c buses. The output of the inverter is a regulated supply. Transfer from 1 input to the other is accomplished without interruption of the output. Each inverter is protected by circuit breakers on the 480 volt a-c input side, 120 volt vital a-c output side and 125 volt d-c input side. Each dual input inverter is provided with an a-c and a d-c ammeter. Abnormal conditions in the dual input inverter, including loss of a-c input, loss of d-c input, and loss of a-c output voltage cause alarms to occur in the control room.

The output of each inverter is connected to a distribution cabinet through an automatic static transfer switch and a normally closed circuit breaker. An alternate backup 480-120 volt transformer Class 1E power source is provided through the automatic static transfer switch. The feed to the transformers is from a 480 volt motor control center as indicated by Figures 8.3-1 and 8.3-2. The distribution cabinets have appropriately sized branch circuit breakers to feed reactor protection and other vital instrument channels. Most reactor protective schemes have 3 or 4 channels. Redundant instrument channels are fed from redundant vital buses.

Because of the preferred failure mode defined for the reactor protective instrumentation, failure of an instrument channel power source results in a reactor trip signal from the affected channel. Multiple power supplies are provided to prevent a single power supply failure from initiating a false reactor trip.

The vital bus rectifiers and inverters are assembled from high quality components, conservatively designed for long life and continuous operation.

By avoiding the use of electromechanical devices, routine maintenance downtime is greatly reduced. There are no vacuum tubes or moving parts in the completely static vital bus supply systems.

The ratings of each inverter are as follows:

1. Inverter No. 1 - 10 kVA.
2. Inverter No. 2 - 10 kVA.
3. Inverter No. 3 - 10 kVA.
4. Inverter No. 4 - 10 kVA.

8.3.2.1.5.5 Non-Class 1E Inverters

There are 2 non-Class 1E (balance of plant) inverters. Inverter No. 5 is a dual input inverter. The dual input inverter No. 5 provides continuous power to non-Class 1E 120 volt vital digital control systems and computer loads. Transfer from one input to the other is accomplished without interruption to the load. The output of inverter No. 5 is connected to a distribution panel through an automatic static transfer switch. An alternate backup 120 volt non-Class 1E power source is provided through the automatic static transfer switch. The AMSAC system, secondary plant digital control systems and the station computer constitutes the primary loads on this inverter. The secondary plant digital control system can also be powered by the ISFSI Electrical Building uninterruptible power supply.

Inverter No. 6 is a single input inverter supplied from the 125 volt d-c non-ESF system. Output from this inverter is paralleled with a supply from a 480-120 volt transformer which is connected, through a static transfer switch to the inverter main distribution panel. The transformer source serves as an alternate supply to the inverter main distribution panel. Upon loss of inverter output, automatic transfer of the inverter main distribution panel to the alternate supply is initiated. The primary load on inverter No. 6 is non-ESF instrumentation.

An alternate power source circuit breaker is provided in the distribution cabinet to permit manual transfer from the inverter or transformer power source to a backup power source as indicated by Figure 8.3-4.

Inverter ratings are as follows:

1. Inverter No. 5 - 10.0 kVA.
2. Inverter No. 6 - 10.0 kVA.

8.3.2.1.5.6 480-120 Transformer and Static Transfer Switch

An alternate source of power to each of the 120 volt vital a-c buses is provided by a 480-120 volt Class 1E, single phase transformer. The 480-120 volt transformer in each system is designed to supply the total 120 volt vital a-c bus load when the dual input inverter is out of service.

A static transfer switch is provided for inverter No. 6 to switch the 120 volt vital a-c bus loads from the single input inverter to the 480-120 volt transformer. The static transfer switch is a solid state device. Its operation is unaffected by load and power factor variations. Transfer of the 120 volt vital a-c bus loads from the single input inverter to the 480-120 volt transformer causes an alarm to occur in the control room. Transfer back to the inverter is performed manually at the discretion of the operator.

8.3.2.1.5.7 Nominal 120 Volt Vital A-C Bus System

The nominal 120 volt a-c vital bus system consists of 6 panels and 4 inverters which provide power to 4 independent channels of ESF instrumentations. Channels A and B consist of 2 panels and 1 inverter each while Channels D and E consist of 1 panel and 1 inverter each. Figures 8.3-1, 8.3-2, 8.3-2aa, and 8.3-2ab depict the system.

The vital bus system is a very reliable electrical system. It provides a stable supply to vital equipment and guarantees proper action when power is required, while eliminating spurious shutdowns.

The normal power source for each vital bus inverter is through the inverter static rectifier from a 480 volt ESF bus. Should the normal power source fail completely or be subject to transient voltage or frequency variations, the vital bus inverter power source becomes the battery charger or battery which is floating on standby service. This transition from static rectifier to battery power supply takes place without disturbing vital bus voltage or frequency. The station batteries are sized to carry this additional inverter load without chargers for no less than 4 hours. The chargers are sized to bring a fully discharged battery up to equalize charge voltage with the inverter load connected in 12 hours.

8.3.2.2 Analysis

8.3.2.2.1 Compliance

The Class 1E uninterruptible systems satisfy the criteria of Regulatory Guides 1.6 and 1.32 (see Appendix 3A), and General Design Criteria 17 and 18. The uninterruptible systems are designed so no action, automatic or manual, needs to be taken to make d-c or vital a-c power available to the equipment required immediately following LOCA or after a loss of a-c power. No operator action is required to maintain d-c or vital a-c power availability, based on single failure criteria, for safe shutdown or accident mitigation following a loss of a-c power.

Class 1E system components are identified and seismically qualified as described in Section 3.10. The battery was connected to a resistive load of approximately 20 amperes during seismic testing.

Class 1E equipment and the hostile environment to which it is subjected are discussed in Section 3.11.

Each uninterruptible system includes power sources and a distribution system arranged to provide power to associated system loads. No ties exist between Class 1E systems. Figures 8.3-1, 8.3-2,

8.3-2aa, and 8.3-2ab illustrate the independence of the Class 1E uninterruptible systems. Equipment, cables and other components are designed, identified and located in accordance with the criteria given herein. Sections 8.3.1.4 and 8.3.1.5 discuss general design criteria applicable to the uninterruptible systems as well as to the a-c systems.

8.3.2.2.2 Maintenance and Testing

The uninterruptible systems are subjected to periodic maintenance tests to determine the condition of each individual component. Batteries are checked for electrolyte level, specific gravity, cell voltage and visual signs of deterioration. A battery performance discharge test is performed according to IEEE-450 (Reference 7). Battery chargers, and inverters are checked by visual inspection weekly and performance tests are conducted periodically.

Maintenance and testing procedures for batteries are in accordance with IEEE-450 (Reference 7). Testing and inspection are performed according to the following:

1. General inspections and recording of data are performed in accordance with IEEE-450 (Reference 7).
2. Quarterly tests, inspections, and recording of data are performed in accordance with IEEE-450 (Reference 7).
3. Yearly inspections are performed in accordance with IEEE-450 (Reference 7).
4. Battery service tests are performed in accordance with IEEE-450 (Reference 7). The time interval between tests is based on a nominal 18 month refueling outage schedule. Service tests are not performed during outages that require performance of a capacity (performance discharge) test. (See Regulatory Guide 1.32 discussion in Appendix 3A.)
5. Battery capacity tests are performed in accordance with IEEE-450 (Reference 7) and IEEE-308 (Reference 8).

8.3.2.3 Physical Identification of Safety-Related Equipment

The physical identification of safety-related equipment is discussed in Section 8.3.1.5.

8.3.3 Fire Protection for Cable Systems

The 15,000 volt rated power cable, the 8,000 volt rated power cable, 600 volt rated power cable for 480 volt and 120 volt a-c systems and 125 volt d-c systems, 600 volt rated control cable for 120 volt a-c and 125 volt d-c controls and 300 volt instrument cable are constructed with an overall fire retardant outer jacket.

Cable for external circuits is type tested in accordance with Section 2.5 (Flame Tests) of IEEE-383 (Reference 9) and the cables are certified to be of fire retardant construction.

8.3.3.1 Cable Derating, Cable Tray Fill, and Cable Construction

Cables are derated to compensate for ambient temperatures and for the presence of adjacent power cables. Power cables are sized and derated on the basis of IPCEA P-46-426 (Reference 4), supplemented by IPCEA-NEMA P54-440 (Reference 5).

Motor feeders, power panel feeds and small lighting and receptacle panel transformer feeds are sized for 125% of full load current. Large power transformer feeders are sized for 140% of full load current at maximum rating. Motor control center feeders are sized for 140% of the calculated normal diversified load current. Feeders to resistive loads are sized on the basis of 110% of rated current at rated voltage.

In selecting IPCEA ampacity tables, a load factor of 100% is assumed.

Ampacities of 7200 volt power cables are in accordance with IPCEA P-46-426 (Reference 4) in air ratings, derated by factors of 0.70 in 40°C areas and 0.63 in 50°C areas.

Ampacities of 480 volt cables or large d-c cables in single layer power trays are in accordance with IPCEA P-46-426 (Reference 4) in air ratings and are derated by factors of 0.70 in 40°C areas and 0.63 in 50°C areas.

Ampacities of 480 volt cables or d-c cables in a random lay power tray are in accordance with IPCEA-NEMA P-54-440 (Reference 5). Derating factors for 3 inch depth are used.

Ampacities of small 480 volt cables or small 125 volt d-c cables (#10 AWG and smaller), when run in control trays, are in accordance with IPCEA P-46-426 (Reference 4) in air ratings derated by a factor of 0.50.

Ampacities for 7.2 kV and 480 V 3 conductor cables in conduit wrapped in Kaowool at 40°C ambient temperature are calculated to ensure a maximum copper surface temperature of 90°C. Basis for these calculations are data obtained from IPCEA P-46-426. The application ampacities of the cables are determined by applying a 1.25 derating factor to the design ampacities. The cable sizes are then selected so that the cable application ampacity is equal to or greater than the design current value determined from the cable sizing criteria.

No ampacity derating factors are applied to control and instrument cables.

Ampacities are determined on the basis of 90°C tables at 40°C ambient in all interior areas except containment. Containment or ESF motors in areas requiring forced ventilation of the motor are determined on the basis of 50°C ambient.

Pressurizer heater cables are sized by special ratings due to the operating environment.

The Reactor Building cooling unit fan motor power cables and the post accident hydrogen recombiner unit power cables (Reference 10) require special consideration since these motors must operate in the post accident containment environment. These cables are sized to carry the

required current during the post accident temperature and pressure transient without exceeding the recommended emergency operating temperature rating for the cable and to continue to operate for a minimum of 6 months after the accident.

A preventive maintenance program to test the insulation values of circuits and equipment is followed.

Ladder type tray systems are used for power and control trays. Instrument trays are solid bottom trays with top cover plates.

The 5 basic tray systems are as follows:

1. The 7200 volt power trays.
2. The 480 volt and below, single layer power trays.
3. The 480 volt and below, random lay power trays.
4. Control trays.
5. Instrument trays.

In vertical stacking the 7200 volt power trays are on top, 480 volt power trays next lower, control trays next lower, and instrument trays on the bottom.

8.3.3.1.1 7200 Volt Power Trays

No other type cable is mixed in the same tray with 7200 volt power cable. These trays are 4 inches deep (inside dimension). There is 1 layer of cable with no spacing between cables.

8.3.3.1.2 480 Volt and Below, Single Layer Power Trays

The 480 volt and below, single layer power tray system is exclusively for 480 volt, 3-conductor power cables or d-c power cables. This tray system is 4 inches deep (inside dimensions) and contains only large (MCM sizes) and 4/0 cables. There is 1 layer of cables with no spacing between cables.

8.3.3.1.3 480 Volt and Below, Random Lay Power Trays

The 480 volt and below, random lay power cable tray is for 480 volt power cables 4/0 and smaller. The tray is 6 inches deep (inside dimensions).

$$\text{Percent fill} = \frac{\left(d_1^2+d_2^2+\ldots.+d_n^2\right) x\, 100}{\text{Tray Depth x Tray Width}}$$

where: $d_1, d_2, \ldots . d_n$ = Diameters of all cables in the tray presently planned plus all known future cables.

Small 480 volt power cables (#10 AWG and smaller) may be run either in the random lay power cable tray or the control tray. Circumstances may dictate running an MCM size power cable in a random lay power tray. The cable is then derated with the derating factor appropriate to the random lay trays.

8.3.3.1.4 Control Trays

The control trays contain control cables, small 480 volt power cables (#10 AWG and smaller, except for selected motor operated valves which use larger sized cables) and small d-c power cables (#10 AWG and smaller). All of these cables carry either intermittent current or continuous current of 5 Amps or less. Single phase, 120 volt a-c circuits (#10 AWG and smaller) carrying 5 amps or less may also be run in the control trays. The amount of heat generated from cables which carry intermittent current is negligible based on the large majority of time the load is not operating.

The control trays are 6 inches deep (inside dimensions). The design limit for control tray fill is based on verifying that the weight of new and existing cable is within the tray and tray support weight capability.

8.3.3.1.5 Instrument Trays

Instrument trays contain low level analog signals cables. These trays are 6 inches deep (inside dimensions). The design limit for instrument tray fill is based on verifying that the weight of new and existing cable is within the tray and tray support weight capability. In addition to all low level analog signal cables, the instrument trays are used for digital contact (breaker contact) cables where the source of power is the reactor protection or computer packages, otherwise all digital circuits are in the control trays.

8.3.3.1.6 Cable Tray Fill Criteria

The 50% cable tray fill criteria is the design objective that applies only to random lay power trays. Random lay power trays contain 480 volt power cables smaller than MCM sizes. Power cables, No. 10 and smaller, may be run either in random lay power tray or in control tray.

The 30% fill criteria recommendation in IEEE Propose Guide P-422 (Reference 3) is based upon the summation of cross sectional areas of cables. The 50% fill noted in Section 8.3.1.4.3 is based upon the summation of the cable diameter squared areas. Fill of 50% on this basis is equivalent to 39% fill on the IEEE Propose Guide P-422 (Reference 3) basis (i.e., 3.1416/4.0 times 50%). Through experience, it has been found that approximately 40% fill on the basis of cross sectional area or 50% fill on the basis of diameter squared area is satisfactory with respect to physical tray loading and uses the tray more efficiently.

Power cables are rated on the basis of this 3 inch physical depth, using the derating factors of IPCEA-NEMA P-54-440 (Reference 5).

These derating factors are in agreement with the 50% or 3 inch depth physical loading. Control and instrument cables require no derating.

Where random lay power tray fill exceeds 50%, worst case conditions have been analyzed to assure the capability of the tray hangers to support the additional weight and, that sufficient margin exists in the cable sizing to account for the heating effects (Reference IEEE Transaction Paper 70TP557PWR “Ampacities for Cables in Randomly Filled Trays”, also, see FSAR Section 8A.1.2). For each random lay power tray, a calculation was performed to address the additional heat loading from the new power cable and its effect on the ampacity (heat loading) of other power cables in that tray. The existing and new power cables were derated if the total heat loading of the cables in the tray was not within the allowable heat loading based on the percent fill. In addition, this calculation determined the weight of the new and existing cables to ensure that their combined weight was less than the maximum weight that the tray support can carry. For trays filled to the maximum weight allowed by the tray supports, the maximum allowable cable sidewall pressures will not be exceeded (Reference FSAR Section 8A.1.3). In the event overfill occurs at tray intersections, protection will be provided to preclude cable damage.

The cable tray fill criteria for control and instrument trays is controlled by the cable management system computer program. This program contains an alarm limit for the maximum weight allowed for each tray size used. Therefore, manual calculations to monitor cable weight are not required since this calculation is done by the cable management system and an alarm is provided if the tray or tray support weight capability is exceeded. Heat loading is not a concern for control and instrumentation cables due to their small currents and/or intermittent operation.

For expanded cable and tray design considerations, see Appendix 8A.

8.3.3.1.7 Cable Construction

Feeder and motor cables in 7200 volt service are insulated cables rated at a minimum of 8000 volts. Single conductor cables or each conductor of multi-conductor cables in 7200 volt service are shielded.

Power cables for 480 volt service are insulated cable rated at a minimum of 600 volts. Single conductor cables and multi-conductor cables are provided with an overall flame retardant jacket.

Control cables are of single or multi-conductor construction with a 600 volt (minimum) insulation, total coverage electrostatic shield and overall flame retardant jacket.

Low voltage instrument cables are insulated cables rated at 300 volts, minimum. Where required, these cables are provided with a total coverage electrostatic shield and with an overall flame retardant jacket.

8.3.3.2 Fire Detection and Protection Devices

Fire detection and protection systems, either automatically or manually initiated, are provided in those areas required to preserve the integrity of circuits for redundant safety-related systems. A

fixed, low pressure carbon dioxide fire extinguishing system is installed in the relay room and computer room at elevation 436’ of the Control Building. A preaction sprinkler system is installed in the following areas of the Control Building:

1. Cable spreading room - elevation 425’.
2. Cable spreading room - elevation 448’.
3. Cable chase areas.

Smoke detection systems are installed in the switchgear rooms and penetration access areas. Section 9.5.1 provides greater detail concerning fire detection and protection.

The fire hazard to cables is reduced by cable construction as described in Section 8.3.3.1.7.

8.3.3.3 Fire Barriers and Separation Between Redundant Cable Trays

Criteria used for the separation between different Class 1E system trays and between Class 1E and non-Class 1E trays are given in Section 8.3.1.4. Where the required separation cannot be maintained, fire barriers are installed in accordance with IEEE P-422 (Reference 3), Section 8.3.2. The fire barriers are qualified in accordance with criteria given in Section 9.5.1.

In cases of multiple separation violations between non-safety related trays and redundant safety related trays in the same fire area, tray covers or circuit breaker surveillance has been provided as a resolution. Refer to FSAR Section 8.3.1.4.1, item 4 for details.

8.3.3.4 Fire Stops

Openings in walls, floors, and ceilings, which are provided for the routing of raceways, are protected by fire stops. Fire stops are designed with a fire rating equivalent to that required for the wall, floor or ceiling with which it is associated. The materials used in fabricating fire stops are rated in accordance with ASTM E 119. In addition to preventing the spread of fire, fire stops are designed to be reasonably leaktight, thereby limiting the propagation of smoke and gases from one area to another.

8.3.4 Safety Related Cable

No natural polyethylene materials are used in safety related inter-connecting circuits between equipment in the Virgil C. Summer Nuclear Station. Cables which have cross linked polyethylene are used for various plant applications.

8.4 STATION BLACKOUT

V. C. Summer Nuclear Station Unit No. 1 conforms to 10CFR50.63 entitled “Loss of All Alternating Current Power” (Station Blackout). V. C. Summer's program meets the guidance provided by Regulatory Guide (RG) 1.155, Station Blackout; Nuclear Management and Resources Council, Inc. (NUMARC) 87-00, Guidelines and Technical Bases for NUMARC Initiatives addressing Station Blackout at Light Water Reactors; and NUMARC 87-00 Supplemental Questions/Answers and Major Assumptions dated December 27, 1989. Virgil C. Summer Technical Report TR08200-003 entitled “Compliance to NRC Rule 10CFR50.63” (Station Blackout), documents VCSNS compliance. Additional details are provided in the NRC issued Safety Evaluations References 1 and 2.

8.4.1 Station Blackout Duration

NUMARC 87-00 was used to determine an SBO duration of four hours.

The following plant factors were identified in determining the proposed Station Blackout duration:

1. AC Power Design Characteristic Group is P1 based on:
   a. Independence of offsite power classification of Group “1 1/2”
   b. Severe weather (SW) classification of Group “1”
   c. An extreme severe weather (ESW) classification of Group “3”
2. The emergency AC power configuration group is C based on:
   a. There are two EDGs credited as AC power supplies
   b. One emergency AC power supply is necessary to operate safe shutdown equipment following a loss of offsite power.
3. The target EDG reliability is 0.95.
   a. A target EDG reliability of 0.95 was based on the Virgil C. Summer Station having an average EDG greater than 0.95 over the last 100 demands.
   b. EDG failure statistics for the last 20 and 50 demands, in accordance with the requirements of RG 1.155 was provided, which confirms that the target selection is appropriate.

8.4.2 Coping Method

The V. C. Summer Nuclear Station coping method is in accordance with the “AC-Independent Approach” delineated in NUMARC 87-00 for the required coping duration of four hours and recovery therefrom. In this approach for VCSNS, DC power is required to be available for the coping duration to operate equipment necessary to achieve safe shutdown conditions until offsite or emergency AC power is restored. The following plant systems and components are required to have the availability, adequacy, and capability to achieve and maintain a safe shutdown and to recover from an SBO for a four-hour coping duration.

8.4.2.1 Class 1E Battery Capacity

The V. C. Summer Nuclear Station has sufficient battery capacity and size to support decay heat removal during a Station Blackout for the required four-hour coping duration in accordance with NUMARC 87-00 without load stripping, as discussed in Section 8.3.2.1.2. The battery analysis is documented/maintained in SCE&G Calculation DC08320-005.

8.4.2.2 Condensate Inventory For Decay Heat Removal

The V. C. Summer plant has adequate condensate inventory for decay heat removal during a Station Blackout for a required duration of four hours. The necessary condensate inventory is assessed by a bounding analysis based on the NUMARC 87-00 Equation. The minimum permissible condensate storage tank level per technical specification requirements provides 172,700 gallons, which exceeds the required quantity for coping with a four-hour Station Blackout per SCE&G Technical Report TR08200-003.

8.4.2.3 Compressed Air

The V. C. Summer air operated valves required for decay heat removal have been evaluated and accepted for manual operation under Station Blackout conditions for the four-hour duration.

8.4.2.4 Effects of Loss of Ventilation

The effects of loss of ventilation within areas of the plant containing equipment necessary to achieve and maintain safe shutdown during a Station Blackout is evaluated per NUMARC 87-00. The dominant areas of concern (DACs) and analysis are documented in SCE&G Technical Report TR08200-003.

8.4.2.5 Containment Isolation

Containment isolation valves that must be operated under SBO conditions must have the ability to be positioned, with indication, independent of the preferred and Class 1E AC power supplies and that no modifications or procedure changes are necessary to ensure containment integrity can be obtained if it is needed under SBO conditions. Containment isolation valve design and operation at VCSNS meet the intent of the guidance described in RG 1.155.

8.4.2.6 Reactor Coolant Inventory

The ability to maintain adequate reactor coolant system (RCS) inventory to ensure that the core is cooled has been assessed for four hours. The generic analysis listed in NUMARC 87-00 was used in this assessment. The expected rates of RCS inventory loss under SBO conditions do not result in core uncovery.

Appendix 8A
Additional Cable and Tray Design Considerations

Intentionally Blank

APPENDIX 8A
ADDITIONAL CABLE AND TRAY DESIGN CONSIDERATIONS

8A.1 METHODS EMPLOYED

Sections 8A.1.1 through 8A.1.3 describe methods employed to show sufficient conservatism in the cable and tray design to assure that adequate cable tray hanger strength exists, that cables are sufficiently sized, and that the weight of upper cables in trays does not damage bottom layer cables.

8A.1.1 Weight on Hangar

Cables are routed in tray in two different configurations (e.g., single lay and random lay). The weight of the cables, tray, tray covers, fire barrier materials on the tray, and any conduits and pipes hung from the tray supports were used to establish the tray support capability. The allowable cable weight limit is based on the capability of the cable tray (e.g., 35 lbs/ft^2 of tray bottom area for single lay 4" deep trays and 45 lbs/ft^2 of tray bottom area for random lay 6" deep trays).

For single lay cable tray, percent fill and cable heating were not the deciding factors for limiting tray fill. Engineering determined that the maximum number of cables that a single lay tray can accommodate is based on the cable diameters versus the width of the tray.

The initial design criteria for random lay tray was based on a maximum of 50% fill. Engineering performed calculations to ensure that cable heating and cable weight were acceptable whenever the tray fill was less than 50%. Because the tray fill was conservatively calculated based on the square of the cable diameter in lieu of the cross sectional area of the cable, the actual tray fill is less than the calculated tray fill. The cable management system computer program was used to monitor tray fill. The 50% limit originally established was found to be inadequate as cables were added over the life of the plant. Therefore, calculations were performed whenever a random lay cable tray fill exceeded 50%. Subsequently the criteria for random lay power cable trays was changed to weight per tray support with an alarm point of either 50% fill for trays presently less than 50% filled or the last calculated allowable % fill for trays whose fill exceeded 50%. In addition, the criteria and alarm point for instrument and control tray were changed to weight only per tray support only, since heat loading was not a concern.

Whenever a power cable is added to a random lay power tray and the associated tray fill exceeds the previously accepted percent tray fill limit, a calculation is performed. The calculation addresses additional loading from the new power cables to ensure that the combined weight of the new and existing cables is less than the allowable design weight capability of the tray support. Heat loading is also evaluated to ensure that the existing ampacity derating factors are still applicable.

Engineering determined that cable heating was not a concern for the small currents and intermittent operating conditions associated with control and instrument cables and therefore only total cable weight needed to be considered. The design limit for control and instrumentation cable tray fill is based on verifying that the weight of the new and existing cable does not exceed the tray and tray support weight capability. The cable tray fill criteria for control and instrument trays is controlled by the cable management system computer program. This program contains an alarm limit for the maximum weight allowed for each tray size used. Therefore, manual calculations to monitor cable weight are not required because this calculation is performed by the cable management system and an alarm is provided if the tray or tray support weight capability is exceeded.

8A.1.2 Cable Heating

Single layer kV and 480 volt cable trays need not be considered with respect to possible cable overheating since, inherently, the fill is limited to the single layer of cable with appropriate derating factors applied. Rated ampacities are in accordance with ICEA P-46-426 (Reference 1); the free air ratings for the applicable ambient temperatures were derated for the presence of adjacent power cables. In addition, a load factor of 100 percent was assumed and feeders are sized for 110, 125, or 140 percent of rated current, depending upon type of service (resistive loads; motors, power panels and small transformers; and large power transformers, respectively).

No ampacity derating factors are applied to control and instrument cables due to the type of service and low current levels.

For random lay power trays (Reference 2, Table 12), a 3 inch depth was used to determine cable ampacity. Therefore, derating due to tray fill need only be considered for trays with fill greater than 50 percent design objective, since the 50 percent design fill is equivalent to a 3 inch depth. The 100 percent load factor feeder sizing considerations previously noted were also applied, along with appropriate derating where required for higher ambient temperatures.

In selected cases fill above 50% was authorized to larger values after specific evaluation of heat dissipation and weight loading. Heat dissipation was evaluated using the methods described in Reference 3.

From Figure 4 of Reference 3 the following linear approximation can be made for the allowable heat generation versus tray fill:

$$Q_d = \frac{6.5}{d^{1.47}} \quad (1)$$

Where:

Q_d = Allowable heat generation per unit area of cable cross-section to limit conductor temperature to 90°C

d = Depth of tray fill in inches

Since heat generation in a given cable at a fixed temperature is proportional to the square of the current, the following relationships can be established:

$$Q_d = KI_d^2 \quad (2)$$

Where:

I_d = Ampacity of cable for tray fill depth d

K = Constant

Combining into equation (1) and developing a ratio:

$$\frac{Q_{d'}}{Q_d} = \frac{KI_{d'}^2}{KI_d^2} = \frac{(d)^{1.47}}{(d')^{1.47}}$$

Using the relationship, the curve of Figure 4 in Reference 3 was extended to cover larger fills of six inch deep tray. Because Reference 3 was developed for three inch deep tray, the tray fill permitted is one-half the value shown in Figure 4. As long as the tray fill meets this criterion, the cable ampacities of Reference 2 are still permissible.

There is an additional margin of conservatism in the heat dissipation calculation. Tray fill is calculated using diameter squared to represent cable cross-sectional area instead of actual cable area. This represents a margin of 27.3 percent above actual tray fill. In addition, non-continuous current carrying cables are not included in heat density calculations but are included in tray fill and weight calculations, which ensures conservatism.

No ampacity derating of cables has been necessary because of heat dissipation.

8A.1.3 Cable Side Wall Pressure

In accordance with manufacture’s published information the maximum allowable side wall pressure of typical cables used is considerably higher than the pressure that cables on the bottom of a tray will experience from cables above, even for fills in excess of 50 percent. The minimum

allowable side wall pressure is 50 lb/ft, while the maximum loading per cable in a tray filled to the tray support limit, or 100% physical fill, will be less than 7 lb/ft [18] *.

8A.2 CONCLUSIONS

Tray fill is monitored by computer. Any tray that exceeds the design fill is reported on a separate printout. This printout is used in routing design, and cables are routed through other, less full trays. Late in construction other trays may exceed the maximum values justified in Sections 8A.1.1 through 8A.1.3. When this occurs, the situation will be evaluated and action will be taken to relieve such a condition. Alternatives are to calculate the actual tray load and verify that the load does not exceed the design capacity, enlarge the existing tray, strengthen the existing hangers, or in the case of random lay power trays where the concern is ampacity, each individual circuit application can be evaluated and the total ampacity calculated.

Appendix 8B
Cable Raceway Fire Barriers Design

Intentionally Blank

NOTE: Appendix 8B is being retained for historical purposes only.

APPENDIX 8B
CABLE RACEWAY FIRE BARRIERS DESIGN

8B.1 PURPOSE

This report describes the criteria, assumptions and design used by Gilbert Associates, Inc. (GAI) to locate and construct cable raceway fire barriers on the Virgil C. Summer Nuclear Station for the South Carolina Electric and Gas Company.

8B.2 CRITERIA

Fire barriers were designed to comply with IEEE Standard 384-1977 "Criteria for Independence of Class 1E Equipment and Circuits."

Fire barriers are required to prevent propagation of a fire between two, or more, raceways of redundant divisions or non-class 1E to Class 1E cable trays which do not maintain minimum physical separation. This minimum physical separation is specified in IEEE-384, and in SP-834 – "Electrical Construction Guideline for Electrical Circuit Physical Separation." In summary, the minimum separation distances are based on open ventilated cable trays and are as follows:

1. Cable spreading area - one foot horizontally and three feet vertically.
2. General plant area - three feet horizontally and five feet vertically.

Where the above separation is not provided the following specified criteria extracted from IEEE-384 are used:

1. The use of physical barriers or enclosed raceways, which qualify as barriers, shall be separated by a minimum distance of one inch.
2. Vertical barriers, separating redundant horizontal tray running parallel requiring horizontal separation will have a minimum of one foot (or to ceiling) extension above the top of the tray at the highest elevation in a stack.
3. Horizontal barriers, separating redundant horizontal trays crossing requiring vertical separation will have a minimum of three feet extension beyond each side of the widest tray (one foot in the cable spreading area).
4. Horizontal barriers, separating redundant horizontal trays running parallel requiring vertical separation will have a minimum of six inches extension beyond each side of the widest tray.

These barriers are intended to prevent redundant raceway-to raceway fires which are self-initiated only.

Based on the above, the following was extrapolated:

1. Solid tray covers and bottoms, referred to in this report as fire shields, may be added to open ladder tray to qualify it as an enclosed raceway. Trays containing power cables (480 volt and higher) may require barriers in lieu of fire shields since fire shields may inhibit ventilation.
2. Channel tray (4 inch open top, solid bottom) will be considered an enclosed, open top tray and may require covers only.
3. Instrument trays, in this plant are installed with solid covers and bottoms and constitute an enclosed raceway.
4. Conduit alone constitutes an enclosed raceway.
5. Conduit installed beneath or alongside of an open tray of a redundant division does not require a barrier.
6. Conduit installed less than five feet (three feet in a cable spreading area) above a tray of a redundant division requires a barrier.
7. Conduits may be wrapped with a flexible fireproof material which will suffice as a barrier. This may be used where space permits installation.

8B.3 MATERIALS AND INSTALLATION

8B.3.1 Fire Shields

Tray covers and bottoms will be made of 18 gauge steel. They will be attached to the tray by one of several methods described in detail by the tray vendor for other applications in the plant. Basically, the covers are strapped or clamped to the tray. Covers will be peaked to 1 inch, except for covers for fittings which will be flat; bottoms will be flat.

8B.3.2 Barriers

Board barriers will be made from Babcock and Wilcox M-Board in one inch thickness. Installation techniques are under development.

8B.3.3 Conduit Wrapping

Conduit wrapping will be done with Johns-Manville Cerablanket, or Babcock and Wilcox Kaowool blanket materials. These are high-temperature fiber blankets in a thickness of one inch and, typically, a width of 24 inches. The blanket will be wrapped around the conduit and fastened with fire resistant tape or by other similar method.

8B.4 ACTUAL CASES

Detailed in Figures 8.B-1 through 8.B-12 are representatives cases found in the Virgil C. Summer Nuclear Station where physical separation of redundant channels could not be maintained. The type of fire barrier designed for each case and the installation methods are described below. Options are provided for each case and an option may be selected, for individual cases, based on economics, available space and complexity (e.g., it may be more advantageous to use one board barrier rather than many covers and bottoms where several trays are involved).

1. Detail 1 - Redundant Horizontal Trays Crossing, Requiring Vertical separation.
   a. Option A - shows the use of fire shields on each tray.
   b. Option B - shows the use of a horizontal board barrier.
2. Detail 2 - Redundant Horizontal Trays Running Parallel Requiring Vertical Separation.
   a. Option A - shows the use of fire shields on each tray.
   b. Option B - shows the use of a horizontal board barrier.
3. Detail 3 - Redundant Horizontal Trays Running Parallel Requiring Horizontal Separation
   a. Option A - shows the use of fire shields on each tray.
   b. Option B - shows the use of a vertical board barrier.
4. Detail 4 - Horizontal Tray Crossing Redundant Vertical Tray Requiring Horizontal Separation.
   a. Option A - shows the use of a fire shield on each tray.
   b. Option B - shows the use of a vertical board barrier.
5. Detail 5 - Horizontal Conduit Crossing Over Redundant Horizontal Tray Requiring Vertical Separation.
   a. Option A - shows the use of a fire shield on each tray.
   b. Option B - shows the wrapping of conduit.
   c. Option C - shows the use of a horizontal board barrier.
6. Detail 6 - Horizontal Conduit Above Redundant Horizontal Tray Running Parallel Requiring Vertical Separation.

Appendix 8C
Summary of Analysis of Separation Between Tray for Non-Class 1E Circuits and Tray for Class 1E Circuits

Intentionally Blank

APPENDIX 8C
SUMMARY OF ANALYSIS OF SEPARATION BETWEEN TRAY FOR NON-CLASS 1E CIRCUITS AND TRAY FOR CLASS 1E CIRCUITS

8C.1 OBJECTIVE

Perform an analysis in accordance with IEEE 384-1974, Section 5.1.1.2, to ensure acceptable separation between trays for non-class 1E circuits and trays for Class 1E circuits.

8C.2 CRITERIA

Separation shall be sufficient that no single electrically initiated fire can result in the loss of a safety system function.

8C.3 BASIS

The Fire Protection Research Program tests performed at Sandia Laboratories for the U.S. Nuclear Regulatory Commission (NRC) were used as a source of data on the characteristics of cable fires. The following conclusions drawn from the reports were used in the analysis of individual situations:

1. It is difficult to initiate a fire from an electrical fault or overload in trays with cables which satisfy the flame retardant criteria of IEEE 384-1974.
2. If a fire can be started and propagated, it spreads through a stack of trays with an angle of spread of approximately 35 degrees from vertical.
3. In horizontal trays, the fire does not propagate horizontally within a given tray.
4. Fire does not propagate downward from one tray to the tray below.

The results of the IEEE 383 flammability tests for cable actually used at Virgil C. Summer Nuclear Station were also used to determine that the flammability of the cable used at Virgil C. Summer Nuclear Station is less than that used for the full scale tests at Sandia Laboratories.

8C.4 METHOD

The tray drawings for plant areas containing trays for Class 1E circuits are reviewed and each case where a tray for non-Class 1E circuits approaches a tray for Class 1E circuits is noted and given an identification number. Each case is then clarified with sections and details as necessary to determine separation distances and to categorize the situation. The cases are then individually reviewed using the basis given above to determine the adequacy of the separation. If

the criteria stated above are not satisfied by the existing design, suitable barriers are added to the raceway system design so that the final design satisfies the criteria.

1. Tray for non-Class 1E circuits parallel to tray for Class 1E circuits. Subcategories include: above, below, beside, and between.
2. Tray for non-Class 1E circuits crossing tray for Class 1E circuits. Subcategories include: above, below, and between.
3. Tray for non-Class 1E circuits bridging between routes of trays for redundant Class 1E circuits. Subcategories include: above, below, and between.
4. Trays for non-Class 1E circuits diagonally parallel trays for Class 1E circuits. Subcategories include: above and below.
5. Trays for non-Class 1E circuits vertical. Subcategories include: parallel to or crossing tray for class 1E circuits.

8C.5 ANALYSIS

A listing of cases analyzed is provided by Section 8C.6. In addition, detailed analyses for three typical cases are presented in Sections 8C.5.1 through 8C.5.3.

8C.5.1 CASE NO. 041-C

8C.5.1.1 Description

1. Location

   Control Building, Elevation 425’-0

2. Figure

   Figure 8C-1

3. Type of Area

   Cable spreading room

4. General Description

   A tray for non-Class 1E (channel X) control circuits passes over a vertical stack of trays for Class 1E, channel A circuits and further north passes over a vertical stack of trays for Class 1E, channel B circuits.

5. Category

   Bridging - above

6. Types of Trays

   All trays shown in Figure 8C-1 are open ventilated ladder type, except tray 5144 (A) which is the totally metal enclosed type.

7. Number of Circuits

   Tray 4290 (x) - 316 control circuits

   Tray 4351 (x) - 103 control circuits

   Tray 4650 (x) - 38 control circuits

   Tray 4314 (A) - 337 control circuits

   Tray 4284 (A) - 182 control circuits

   Tray 5144 (A) - 124 instrument circuits

   Tray 4326 (B) - 435 control circuits

   Tray 4325 (B) - 209 control circuits

8. Significant Circuits

   Both the channel A and B trays contain a number of circuits for the component cooling water, emergency feedwater, safety injection, and service water systems; as well as circuits for other safety systems.

8C.5.1.2 Analysis

All circuits are for control or instrumentation and have very low internal energy levels. Therefore, energy is not available to initiate a fire.

Any fire which might start in the trays for non-class 1E circuits will not propagate to either of the stacks of trays for the Class 1E circuits since tests have demonstrated that cable fires do not propagate downward. In addition, the tests have shown that a cable fire will not propagate horizontally over the 5 foot-8 inch distance between the stacks of trays for the Class 1E circuits.

A fire which might start in the trays for the Class 1E circuits could propagate to trays for the non-Class 1E circuits but, as stated above, tests have shown that the fire would not propagate

horizontally to the trays for the redundant Class 1E circuits nor would the fire propagate downward to the other stack.

Although the preceding analysis documents that a fire barrier is not required, a barrier was installed in the Channel B control trays in compliance with the licensing commitment to provide barriers for multiple separation violations as described in paragraph 8.3.1.4.1, Item 4.

8C.5.2 Case No. 102-A

8C.5.2.1 Description

1. Location

   Reactor Building Elevation, 436'-0"

2. Figure

   Figure 8C-2

3. Type of Area

   General plant area

4. General Description

   Trays for Class 1E circuits, channels A and D, run parallel to trays for non-Class 1E (channel X) circuits throughout this elevation of the Reactor Building. No trays of other channels are present.

5. Category

   Parallel – beside

6. Types of Trays

   The trays, as shown by Figure 8C-2, consist of both open ventilated ladder trays and totally metal enclosed trays.

7. Number of Circuits

   Tray 3098 (X) - 13 480 volt random layed power circuits

   Tray 4168 (X) - 33 control circuits

   Tray 5063 (X) - 22 instrument circuits

Tray 4174 (A) - 62 control circuits

Tray 5069 (A) - 3 instrument circuits

Tray 5077 (D) - 3 instrument circuits

8. Significant Circuits

Tray 4174 contains a number of circuits from the chemical and volume control system, reactor coolant system, and safety injection system; as well as from other systems.

8C.5.2.2 Analysis

The Class 1E, channel D circuits are in a totally metal enclosed raceway at the bottom of the stack. Therefore they are adequately separated from other trays.

The lower of the two trays for Class 1E channel A circuits is totally metal enclosed and therefore, is adequately separated. Any fires which might start in the upper of the two trays for Class 1E channel A circuits would not propagate to the tray for the channel D circuits nor to the trays for non-Class 1E circuits.

The bottom tray for non-Class 1E circuits is totally metal enclosed and therefore, is adequately separated from other trays.

The middle tray for non-Class 1E circuits contains control circuits which do not have adequate energy to initiate a fire. Should a fire occur, it could propagate to the top tray for the Class 1E, channel A circuits and to the top tray for non-Class 1E circuits. However, this is acceptable because only one channel of Class 1E circuits would be affected and, therefore, system safety functions would be maintained.

The top tray for non-Class 1E circuits contains power circuits which potentially could initiate a fire. However, the tests have shown that such a fire is very unlikely and should such a fire occur, it would not propagate to any other trays in this configuration.

Although the preceding analysis documents that a fire barrier is not required, a barrier was installed in the Channel D control trays in compliance with the licensing commitment to provide barriers for multiple separation violations as described in paragraph 8.3.1.4.1, Item 4.

8C.5.3 Case No. 073-A

8C.5.3.1 Description

1. Location

Auxiliary Building Elevation, 388'-0"

2. Figure

   Figure 8C-3

3. Type of Area

   General plant area

4. General Description

   Trays for Class 1E circuits, channels A and B, run parallel to trays for non-Class 1E circuits, channel X. This situation exists for a distance of 20 feet.

5. Category

   Parallel - above and beside

6. Types of Trays

   Both trays for Class 1E circuits contain control circuits. Trays for non-Class 1E circuits include instrument, control, and random layed power circuits.

7. Number of Circuits

   Tray 4062 (A) - 28 control circuits

   Tray 4064 (B) - 27 control circuits

   Tray 5022 (X) - 38 instrument circuits

   Tray 4059 (X) - 106 control circuits

   Tray 3033 (X) - 49 random layed power circuits

8. Significant Circuits

   Both trays 4062 and 4064 contain circuits for the chemical and volume control system and the leak detection system, as well other systems.

8C.5.3.2 Analysis

Tray 4064 for Class 1E, channel B circuits is separated by considerably more than 5 feet vertically and 3 feet horizontally from all other trays and, therefore, is adequately separated.

Tray 4062 for Class 1E, channel A circuits is 14 inches away from tray 5022 for non-Class 1E, channel X circuits. However, tray 5022 is totally metal enclosed and, therefore, is not a hazard to tray 4062. Tray 4062 is more than 5 feet horizontally and 3 feet vertically from all other trays and therefore, is adequately separated.

NOTES FOR SN-1

1 FIRE WILL NOT PROPAGATE DOWN OR HORIZONTAL

2 CONTROL OR INSTRUMENT TRAY HAVE VERY LOW INTERNAL ENERGY LEVELS THEREFORE, ENERGY IS NOT AVAILABLE TO INITIATE A FIRE

3 TRAYS ARE TOTALLY ENCLOSED

4 ADEQUATE SPACIAL SEPARATIONS MAINTAINED

5 ONLY ONE CHANNEL OF CLASS 1E CIRCUITS AFFECTED THEREFORE, SYSTEM SAFETY FUNCTIONS MAINTAINED

6. This analysis concluded a barrier was not required. However, a barrier was subsequently installed in compliance with the licensing commitment to provide barriers for multiple separation violations as described in paragraph 8.3.1.4.1, Item 4.

Appendix 8D
Analysis of the Acceptable Voltage Range to be Applied to the ESF System

Intentionally Blank

APPENDIX 8D
ANALYSIS OF THE ACCEPTABLE VOLTAGE RANGE TO BE APPLIED TO THE ESF SYSTEM

8D.1 CRITERIA

This calculation was based on two criteria:

- The voltage at each piece of safety related equipment must be within the safe operating range for that piece of equipment.
- The voltage of the offsite sources must be sufficient to operate the required loads in the event of an accident without actuating the degraded voltage relays.

NOTE: This section is being retained for historical purposes only.

8D.2 METHOD

In preparation for the development of the calculations, a “Feeder/Load Data Base” was developed and verified. This data base contains information on the characteristics of the safety related loads and their feeder circuits, including the demand load for various plant operating conditions. The characteristics for the system equipment and materials, such as transformers and cables, were taken from the “as-built” data for the specific equipment and materials.

The system calculations were performed using electrical analysis software. The first calculation established a base case model of the electrical power distribution system. This model includes the existing transformer tap settings which include a 2.5% boost for the 480 volt unit substation transformers 1DA1, 1DA2, 1DB1, and 1DB2. For unit substations, 1EA1 and 1EB1 and for the emergency auxiliary and safeguards transformers, the taps are set at the nominal position. Throughout the calculation process, the transformer tap settings were reviewed to determine if revised settings could improve the overall performance of the system. (Reference Calculation DC-820-001.)

The next calculation modified the base case system model to evaluate the system under the worst case loading conditions. This condition results from the large break LOCA accident during the injection phase. The source voltage in this model was manually reduced and the system was repeatedly analyzed in an iterative process until the worst case motor terminal voltage was reduced to 90% of its rated voltage. The motors in V. C. Summer Station were specified and designed for steady state operation with a terminal voltage in the range of ± 10% of their rated voltage. The voltage at the motor control center (MCC) buses was also checked and found to exceed 420 volts.

This ensures that there is sufficient voltage for the pick-up of the MCC contactors. The resulting system model established that a voltage equal to or greater than 90.2% on 7.2 kV buses 1DA and 1DB is sufficient to ensure adequate voltage at the terminals of the safety related motors. Since the purpose of this part of the evaluation is to determine the minimum 7.2 kV bus voltage to provide adequate terminal voltage for all Class 1E loads, the number of buses connected to the offsite source and the voltage of the offsite source are not significant. The results of this model are summarized in Table 7.3.3 of Calculation DC-820-001.

With the minimum 7.2 kV bus voltage established, the next effort determined the minimum setpoint for the degraded voltage relays. Since these relays have a tolerance on both their calibration and operation, a detailed evaluation of the total tolerance band was performed. This determined a total tolerance band of ± 0.328%. Since the relay must operate before the 7.2 kV buses reach the minimum acceptable voltage, the setpoint value must exceed the minimum value by an amount at least equal to the tolerance. To provide both a margin and consistency with the previous settings, the setpoint was established at 91.34% of rated voltage. (Reference Calculation DC-820-001.)

Based on the degraded voltage relay setting, the tolerance on the relay calibration and operation, and the response of the SCE&G transmission system to a trip of the V. C. Summer Nuclear Station, the next part of the effort determined the minimum acceptable offsite source voltages during normal plant operation.

Studies of the transmission system under extreme loading and system configuration conditions have determined that 230 kV system voltage will dip to 95.5% of the pre-trip voltage in the event of a unit trip. After less than 3 seconds, the system voltage will recover to 97.1% of the pre-trip voltage. Similarly, the 115kV system voltage will dip to 95.6% of the pre-trip voltage in the event of a unit trip and will recover in less than 3 seconds to 97.3% of the pre-trip voltage.

Electrical analysis software was used to model the effects of motor starting conditions due to an accident loading sequence on the 230 kV and 115 kV offsite sources. Based on the tolerance band of the relays and the motor inrush conditions, the 7.2 kV bus voltage must be at least 93.9% of rated voltage prior to motor starting to avoid relay actuation (including a 1% margin which was determined to be unnecessary subsequent to the completion of the calculation). The minimum pre-accident voltage is also dependent on the number of plant buses connected to each offsite source. In a further evaluation, the capabilities of the various combinations of safeguard transformers and the voltage regulating transformer were determined and combined with the worst case voltage dip resulting from a unit trip. The results of these evaluations are summarized in Table 8.2-2. (Reference Calculation DC-820-001.)

The final part of the analysis determined the maximum allowable offsite system voltages. Additional system models were developed with electrical analysis software for plant operation in modes 5 or 6, cold shutdown or refueling. One model evaluated the system using the emergency

auxiliary transformer, XTF-31, as the source and the second model used the safeguard transformers, XTF-4 and 5, as the source. The loading consisted of the minimum set of equipment that would be expected to be operational during plant shutdown and only one of the two trains of ESF equipment was supplied from each offsite source. The models were repeatedly analyzed with increased source voltages until the worst case motor terminal voltage reached 110% of motor rated voltage. The results of these models are summarized in Table 8.D-2, and the maximum voltage limits are included in Table 8.2-2.

8D.3 CONCLUSION

As described above, the 7.2 kV bus voltage must be at least 90.2% of rated voltage to ensure the voltage at motor terminals exceeds the rated minimum motor voltage for steady state operation. This voltage is also sufficient to ensure MCC contactor pick-up. (Reference Calculation DC-876-007.)

The setpoint for the degraded voltage relays must be at least 90.528% of rated voltage to ensure that the relays actuate when the 7.2 kV bus voltage reaches the minimum defined above. The actual relay setpoint is 91.34% of rated voltage.

The offsite system voltages must exceed the minimum values listed in Table 8.2-2 (Reference Calculation DC-820-001) in order to ensure that the degraded voltage relays will reset after the first loading step and will not (inadvertently) drop-out on subsequent steps in the event of an accident. These minimum voltages are dependent on the number of buses connected to each offsite source, the arrangement of transformers, and on whether the voltage regulator is in service.

The voltage of the offsite sources must not exceed 104.2% of rated in order to avoid excessive voltage on motor terminals. The 115 kV line voltage can be higher than this if the voltage regulator is in service.

No improvement in overall system performance can be obtained with alternative transformer tap settings.

Table 8.D-2
CALCULATED MOTOR VOLTAGES FOR MAXIMUM OFFSITE VOLTAGE

Two (2) cases, BLLXTF45 (115 kV source) and BLLXTF31 (230 kV source), were created to determine the maximum offsite system voltage allowable without producing excessive voltages at the motor terminals. Since "A" train was chosen as the worst case bus (heaviest load), "B" train was chosen as the bus to study under light load conditions (Mode 6). The criterion for evaluating worst case conditions was a running motor reaching 110% of rated terminal voltage (NEMA standard maximum).

The source used for the evaluation of the 230 kV system was an emergency auxiliary transformer, XTF-31. The source used for the evaluation of the 115 kV system was 2 ESF transformers, XTF-4 and 5, in parallel.

The offsite voltage was decreased by small increments of voltage from 1.0 per unit until the worst case motor was found.

			Maximum Offsite Voltage	
Dapper Bus #	Operating "B" Train Motors	Maximum Allowable Voltage	115kV Source Case BLLXTF45 120 kV (1.042 pu)	230kV Source Case BLLXTF31 240 kV (1.042 pu)

Appendix 8E
Analysis of the Voltage Drops on the ESF System When Starting a 6900 or 460 Volt Motor With the Diesel Generator as the Source

Intentionally Blank

APPENDIX 8E
ANALYSIS OF THE VOLTAGE DROPS ON THE ESF SYSTEM WHEN STARTING A 6900 OR 460 VOLT MOTOR WITH THE DIESEL GENERATOR AS THE SOURCE

8E.1 CRITERIA

The criteria was to determine (1) the voltage at the terminals of the largest safety related 6900 and 460 volt motors when they are started and (2) the voltage at the other Safety Related buses during the same period. The power source was considered to be the diesel generator with the safety injection signal loads operating on the buses.

8E.2 BACKGROUND

The 6900 volt charging/safety injection (CH/SI) pump motors and the 460 volt service water booster pump (SWBP) motors are the largest safety related motors for their respected voltages. Therefore, their characteristics were used in the calculations.

Electrical analysis software was used to simulate the restart of the largest motors and to determine the effect on system voltages. The diesel generator can be modeled as “an infinite source” with zero impedance when modeling the system under steady state conditions since the generator voltage regulator will hold the terminal voltage to within ± 1/2% of the setting. However, for transient conditions, the diesel generator model needs to include an internal impedance since the voltage regulator can not respond immediately to changes in loading. The source impedance for the transient model was based on the short circuit impedance of the generator as described below in section 8E.3. To obtain the internal source voltage, the source voltage of the model was manually adjusted to produce a machine terminal voltage of 0.945 per unit (under steady state conditions) with the generator load equal to the maximum system load, minus the load of the motor to be restarted. A terminal voltage of 0.945 per unit was used because the lower administrative limit for setting the voltage regulator is 95% and the regulator has a tolerance of ± 1/2%. To find the voltage levels during the initial inrush for motor starting, the source voltage was held constant and the starting load of the motor was added to the system. The system voltages were then calculated.

As described in Section 8D.2, the safety injection signal load is the largest load to be applied to the ESF system buses at any one time. Thus, this load was used as the running load on the buses.

8E.3 METHOD

An analytical software model (from calculation DC-836-008, case DSTEP8S) of the diesel generator steady state full load condition was used as a base case for developing the large motor restart model (Reference calculation DC-8360-012). This DSTEP8S case model determines the voltage at the "A" train buses when the Safety Injection loads are operating and when the Diesel Generator is supplying the load.

To evaluate the restart of large motors on the diesel generator, the steady state analytical software model was modified to incorporate a source impedance and to create two new cases. The first analytical software model, case DS825R, simulates the restart of the 6900 Volt Charging/SI pump (XPP43, 900 HP) and the second, case DS8101R, simulates the restart of the 480 volt service water booster pump (XPP45, 350 HP).

The source impedance was taken as equal to the short circuit impedance of the generator. This short circuit impedance was based on the generator test data which includes the following information:

Generator rating:	5845 KVA
Generator X/R ratio:	16
Short circuit reactance:	0.13 per unit

The steady state analytical software model was copied and modified by adding the source impedance and turning pumps XPP43A and XPP45A off-line in order to simulate the pumps tripping. The source voltage for the model was manually adjusted until the generator terminal voltage was equal to 0.945 per unit. This is the lowest value allowed by the combination of the regulator setting limit of 95% and the ± 1/2% tolerance of the regulator. The resulting source voltage was then held constant and the starting load for each of the two motors was added into each of the two respective models. The following are the load values used:

Model Bus	TAG	KW	KVAR
25	XPP43A	485	2992
101	XPP45A	231	1074

The resulting bus voltage from the two new model cases DS825R and DS8101R were then evaluated to determine the following:

a. Acceptance of the motor starting voltage by comparing the model case voltage with the motor's minimum required starting voltage.

b. Verification that the motor control center (MCC) contactors do not drop out during large motor restart.

The 6900 volt safety related motors were designed to start at 70% of rated voltage and, therefore, have a minimum starting voltage of 4830 volts. The 460 volt safety related motors were designed to start at 80% of rated voltage and, therefore, have a minimum starting voltage of 368 volts.

The contactors in the SQUARE D motor control centers have a dropout of 65% of nominal voltage. A value of 5% was added to account for voltage drop within the control circuit. Since the 480/120 Volt power transformers are wound to produce 120 volts on the secondary when fully loaded, a value of 70% of 480 volts (336V) on the MCC busses was used in the evaluation.

8E.4 CONCLUSION

Considering the diesel generator as the power source, the calculated voltage at the terminals of the 6900 volt CH/SI pump motor and 460 volt SWBP motor is above the minimum design starting voltage as mentioned in Section 8.3.1.1.4.2 and listed below:

		VOLTAGE		
Model Bus	TAG	MIN Start	Calculated	Margin
25	XPP43A	4830	6323	31%
101	XPP45A	368	415	13%

Since other safety related motors are smaller than the CH/SI pump motor and the SWBP motor for their respective voltage levels, the motor terminal voltage during the starting of all safety related motors will be above the design starting voltage for these motors.

The following table lists the voltages at each MCC bus for each of the two restart conditions. The table shows that all voltages are substantially above the 336 volt criteria and, therefore, verifies that the energized contactors will not drop out during large motor restart.

Model Bus	TAG	START XPP43A	START XPP45A
1000	XMC1DA1X-P	410	431
1500	XMC1DA2X-S	409	430
2000	XMC1DA2Y-P	408	429
2500	XMC1DA2Y-S	409	430
3000	XMC1DA2Z	407	428
4000	XMC1EA1X	418	438
8000	XMC1EC1X*	418	438

* Loads on this MCC are not energized. Therefore, the voltages are the same as for bus 4000.

Tables 8.E-1 and 8.E-2 list the calculated voltages of the ESF system buses and the motor terminals.

Appendix 8F
Starting Sequence of ESF Equipment Following an Accident Coincident With a Degraded Voltage Condition

Intentionally Blank

APPENDIX 8F
STARTING SEQUENCE OF ESF EQUIPMENT FOLLOWING AN ACCIDENT COINCIDENT WITH A DEGRADED VOLTAGE CONDITION

8F.1 INTRODUCTION

The following study identifies the timed sequence of starting the ESF system equipment for an accident coincident with degraded voltage on the offsite power system. The accidents considered are (1) Loss of Coolant Accident (LOCA) and (2) Main Steam Line Break (MSLB). The study compares the equipment starting times during accident conditions, with a degraded voltage to the starting times assumed in the accident analyses with total loss of voltage. See Tables 8.F-1 and 8.F-2.

8F.2 DISCUSSION

During these two accident scenarios, the diesel generator will start when safety injection is initiated at time zero. A maximum of 10 seconds is then required for the generator to reach the speed and voltage necessary to connect to the ESF buses.

The degraded voltage relays are set to actuate at 91.34% of nominal voltage. If the voltage drops below 80% of nominal, the undervoltage relays will actuate. A time delay of 3 seconds is provided before the degraded voltage relays signal a start to the diesel to allow for voltage dips caused by a large motor starting. However, it should be noted that for these accidents the diesel was started at time zero by safety injection; therefore the signal to start the diesel generated by the degraded voltage relay is duplicative. If the degraded voltage condition persists for 4 more seconds (now a total of 7 seconds), the 7.2 kV ESF buses are cleared. An additional time delay of 3 seconds is then provided to allow residual motor voltage to decay.

8F.3 CONCLUSION

Under the accidents discussed here, a maximum of 10 seconds is required before the diesel generator can be connected to the ESF buses. However, if there is no accident and a degraded voltage condition exists, a maximum of 13 seconds would be required before the diesel is connected.

Table 8.F-1
DEGRADED GRID VOLTAGE COINCIDENT WITH LOCA

CHAPTER 9 - AUXILIARY SYSTEMS

9.0 AUXILIARY SYSTEMS

9.1 FUEL STORAGE AND HANDLING

9.1.1 New Fuel Storage

9.1.1.1 Design Bases

New fuel is stored in racks (see Figure 9.1-1). Each rack is composed of individual vertical cells which are fastened together in any number to form a module that is firmly bolted to anchors in the floor of the new fuel storage area. The racks consist of two arrays of storage cells, each containing 30 cells in a 2 x 15 pattern. The new fuel storage racks are designed to include storage for 60 assemblies at a center to center spacing of 21 inches. The new fuel storage rack cells are 14 ft-4 in. high and 0.078 inches thick. This spacing provides a minimum separation between adjacent fuel assemblies of 12 inches which is sufficient to maintain a subcritical array even in the event the building is flooded with unborated water. Surfaces that come into contact with the fuel assemblies are made of annealed austenitic stainless steel, whereas the supporting structure may be painted carbon steel.

The racks are designed to withstand nominal operating loads as well as safe shutdown earthquake (SSE) and operating basis earthquake (OBE) seismic loads. The racks are Safety Class 2b and meet the allowable stresses in the ASME Code, Section III, Appendix 17. The new fuel racks are designed to withstand a maximum uplift force of 5000 pounds.

The new fuel storage racks are designed to accommodate Westinghouse 17x17 fuel assemblies (STANDARD, VANTAGE 5, and VANTAGE+) with a maximum nominal enrichment of 5.0 weight percent U-235.

9.1.1.2 Facilities Description

The new fuel storage facility is located in the eastern end of the fuel handling building (see Figure 1.2-6). The facility consists of a concrete pit 27 feet deep by 15 feet wide by 28 feet long, covered by a removable grating. The new fuel storage racks are anchored to the floor of the facility and are designed to store fuel assemblies for 1/3 of a core.

9.1.1.3 Safety Evaluation

The design of normally dry new fuel storage racks is such that the effective multiplication factor does not exceed 0.98 with fuel of the highest anticipated enrichment in place, assuming optimum moderation (under dry, fogged, or flooded conditions). Credit is taken for the inherent neutron-absorbing effect of the materials of construction.

The new fuel assemblies are stored dry and the 21 inch center to center spacing ensures an eversafe geometric array. Space between storage positions is blocked to prevent insertion of fuel. Under these conditions, a critically accident during refueling and storage is precluded.

An exemption from the requirements of 10CFR70.24, “Criticality Accident Requirements”, has been granted to VCSNS based on the design and administrative controls associated with new and spent fuel storage. In response to two VCSNS letters to the NRC requesting the 10 CFR 70.24 exemption (Reference 1 and Reference 2), the NRC granted an exemption listing seven criteria to maintain the exemption valid (Reference 3).

1. Plant procedures do not permit more than one PWR fuel assembly to be in storage or in transit between its associated shipping cask or storage rack at one time.
2. The k-effective of the fresh fuel storage racks filled with fuel of the maximum permissible U-235 enrichment and flooded with pure water does not exceed 0.95 at a 95% probability, 95% confidence level.
3. If optimum moderation of fuel in the fresh fuel storage racks occurs when the fresh fuel storage racks are not flooded, the k-effective corresponding to this optimum moderation does not exceed 0.98 at a 95% probability, 95% confidence level.
4. The k-effective of spent fuel storage racks filled with fuel of the maximum permissible U-235 enrichment and flooded with pure water does not exceed 0.95 at 95% probability, 95% confidence level.
5. The quantity of forms of special nuclear material, other than nuclear fuel, that are stored on site in any given area is less than the quantity necessary for critical mass.
6. Radiation monitors, as required by GDC 63, are provided in the fuel storage and handling areas to detect excessive radiation levels and to initiate appropriate safety actions.
7. The maximum nominal U-235 enrichment is 5 wt%.

9.1.2 Spent Fuel Pool Storage

9.1.2.1 Design Bases

Spent fuel is stored in racks (see Figure 9.1-2). The high density spent fuel racks consist of individual cells with 8.85" x 8.85" (nominal) square cross section, each of which accommodates a single fuel assembly. The cells are arranged in modules of varying size. A total of 1712 cells are arranged in 12 distinct modules in 2 regions. Figure 9.1-2a shows the arrangement of the rack modules in the spent fuel pool. Figure 9.1-2a and Figure 9.1-2b show the typical Region 1 rack structure and cell assemblage detail. Figure 9.1-2c and Figure 9.1-2d show the typical Region 2 rack structure and cell assemblage detail. Table 911-2 provides relevant design data on each region. The modules in the 2 regions are of 3 different types. Table 9.1-3 summarizes the physical data for each module type.

Region 1 is designated for storage of new or freshly discharged fuel assemblies with a maximum nominal enrichment of 4.95 weight percent U-235.

Region 2 is designed to accommodate the storage of fuel assemblies with a maximum nominal initial enrichment of 4.95 weight percent U-235 with a minimum burnup and up to 5.0 weight percent U 235 with a minimum burnup of 41,611 MWD/MTU or fuel of initial enrichment and burnup combinations within the acceptable domain depicted in Figure 4.3-44. The above limits are applicable to Westinghouse 17x17 fuel assemblies (STANDARD, VANTAGE 5, and VANTAGE+).

The modules are not anchored to the pool floor, to each other, or to the pool walls. A minimum gap of 1" is provided between the modules to ensure that kinematic movements of the modules during the plant design basis earthquake will not cause inter-module impact. Adequate clearance with other pool hardware, e.g., light fixtures, etc. is also provided.

The spent fuel storage rack design ensures the separation between spent fuel assemblies. Space between storage positions is sufficient to permit insertion of a fuel assembly. All rack surfaces that come into contact with fuel assemblies consist of austenitic stainless steel. These materials are resistant to corrosion during normal and emergency water quality conditions.

Spent fuel racks are designed to withstand shipping, handling, normal operating loads (impact and dead loads of fuel assemblies) as well as SSE loads. The racks are Safety Class 2b and meet the American Institute of Steel Construction (AISC) requirements. The spent fuel racks are also designed to meet the Seismic Category 1 requirements of Regulatory Guide 1.13 (see Appendix 3A).

The spent fuel storage racks are designed with adequate energy absorption capabilities to withstand the impact of a dropped spent fuel assembly from the maximum lift height of the fuel handing machine. Cranes capable of carrying loads heavier than that incurred in handling a failed fuel assembly are prevented by design from traveling over the spent fuel pool.

The spent fuel racks can withstand an uplift force greater than the uplift force of the fuel handling machine.

Shielding requirements are discussed in Section 9.1.4.3.4. Radiological considerations are discussed in Chapter 12.

9.1.2.2 Facilities Description

The spent fuel pool is located in the western end of the fuel handling building (see Figure 1.2-6). The pool is a stainless steel lined pit 39 feet long by 28 feet wide by 39 feet deep. The normal water level at elevation 461.5 feet provides approximately 24 feet of water shielding over the stored spent fuel assemblies.

During normal operation, the spent fuel pool is isolated from the fuel transfer canal by a removable stainless steel gate.

The stainless steel liner welds are equipped with a leak detection system to monitor and locate liner weld leaks.

9.1.2.3 Safety Evaluation

Design of this storage facility ensures a safe condition under normal and postulated accident conditions. Consideration of criticality safety analysis is discussed in Section 4.3.2.7. Compliance with Regulatory Guide 1.13 is discussed in Appendix 3A.

The spent fuel cooling system is discussed in Section 9.1.3.

9.1.3 Spent Fuel Cooling System

The spent fuel cooling system cools spent fuel pool water to remove decay heat from the spent fuel elements. It also provides for purification of the water in the spent fuel pool and refueling water storage tank (RWST), provides for transfer of water between the RWST and spent fuel pool, maintains boron concentrations, monitors radiation levels and monitors and maintains spent fuel pool water level to ensure adequate cooling and shielding.

9.1.3.1 Design Bases

The spent fuel cooling system is designed to perform the following functions:

1. While performing a core shuffle (72 assemblies off-loaded), maintain the Spent Fuel Pool Water temperature to less than 152.53°F using 1 Spent Fuel Cooling (SFC) heat exchange. This peak temperature is due to a heat load based on decay heat generation from 72 assemblies with an exposure of 55 GWD/MTU, cooled for 72 hours, and moved to the Spent Fuel Pool in exactly 20 hours; plus 1709 spent fuel assemblies with exposures up to 55 GWD/MTU and cooled for 18 months or more. All fuel assemblies discharged through 1996 are assumed to have been burnt at 2775 MWt. All Fuel assemblies discharged after 1996 are assumed to have been burnt at 2900 MWt. The maximum net heat load for this case is 20.71 MBTU/HR, considering passive heat losses (including evaporative cooling effects) of 1.01 MBTU/HR.
