> A system to transfer heat from structures, systems, and components important to safety to an UHS shall be provided. The system safety function shall be to transfer the combined heat load of these structures, systems, and components under normal operating and accident conditions. Suitable redundancy in components and features and suitable interconnections, leak detection, and isolation capabilities shall be provided to assure that for onsite electric power system operation (assuming offsite power is not available) and for offsite electric power system operation (assuming onsite power is not available) the system safety function can be accomplished, assuming a single failure.

Design Evaluation

The ESW system and the RHRSW system provide cooling water for the removal of excess heat from all structures, systems, and components that are necessary to maintain safety during all abnormal and accident conditions. These include the standby diesel generators, the RHR motor oil coolers and pump compartment unit coolers, the control room chillers, the CS pump compartment unit coolers, the RCIC pump compartment unit coolers, the HPCI pump compartment unit coolers, and the RHR heat exchangers.

The ESW system and the RHRSW system are designed to seismic Category I requirements. Redundant safety-related components served by the systems are supplied through redundant supply headers and returned through redundant discharge or return lines. Electric power for operation of redundant safety-related components of these systems is supplied from separate independent offsite and redundant onsite standby power sources. No single failure renders these systems incapable of performing their safety functions.

The ESW system and RHRSW system meet the requirements of GDC 44. Referenced sections are as follows:

a.	AC power systems	Section 8.3
b.	Service water system	Section 9.2.1
c.	ESW system	Section 9.2.2
d.	RHRSW system	Section 9.2.3
e.	UHS	Section 9.2.6

GDC 45 - Inspection of Cooling Water System

The cooling water system shall be designed to permit appropriate periodic inspection of important components, such as heat exchangers and piping, to assure the integrity and capability of the system.

Design Evaluation

The ESW system and RHRSW system are designed to permit appropriate periodic inspection to ensure the integrity of system components, thus meeting the requirements of GDC 45. Referenced sections are as follows:

a.	ESW system	Section 9.2.2
b.	RHRSW system	Section 9.2.3

GDC 46 - Testing of Cooling Water System

The cooling water system shall be designed to permit appropriate periodic pressure and functional testing to assure 1) the structural and leak-tight integrity of its components, 2) the operability and the performance of the active components of the system, and 3) the operability of the system as a whole and, under conditions as close to design as practical, the performance of the full operational sequence that brings the system into operation for reactor shutdown and for LOCAs, including operation of applicable portions of the protection system and the transfer between normal and emergency power sources.

Design Evaluation

The RHRSW system described in GDC 44 is in operation during all plant shutdowns. The ESW system is periodically tested when the diesel generators are tested. This testing includes transfer between the normal offsite power supply and the emergency onsite power system. These systems are designed to the extent practicable to permit demonstration of operability of the systems as required for operation during a LOCA or a LOOP. Thus, the ESW and RHRSW systems meet the requirements of GDC 46. Referenced sections are as follows:

a.	ESW system	Section 9.2.2
b.	RHRSW system	Section 9.2.3

GDC 50 - Containment Design Basis

The reactor containment structure, including access openings, penetrations, and the containment heat removal system, shall be designed so that the containment structure and its internal compartments can accommodate, without exceeding the design leakage rate and, with sufficient margin, the calculated pressure and temperature conditions resulting from any LOCA. This margin shall reflect consideration of 1) the effects of potential energy sources which have not been included in the determination of the peak conditions, such as energy in steam generators and energy from metal-water and other chemical reactions that may result from degraded emergency core cooling functioning, 2) the limited experience and experimental data available for defining accident phenomena and containment responses, and 3) the conservatism of the calculational model and input parameters.

Design Evaluation

The primary containment structure, access openings, penetrations, heat removal system, and internal compartments are designed with sufficient margin to meet the requirements of GDC 50. Containment design is described in Section 6.2.

GDC 51 - Fracture Prevention of Containment Pressure Boundary

> The reactor containment boundary shall be designed with sufficient margin to assure that under operating, maintenance, testing, and postulated accident conditions 1) its ferritic materials behave in a nonbrittle manner and 2) the probability of rapidly propagating fracture is minimized. The design shall reflect consideration of service temperatures and other conditions of the containment boundary material during operation, maintenance, testing, and postulated accident conditions, and the uncertainties in determining 1) material properties, 2) residual, steady-state, and transient stresses, and 3) size of flaws.

Design Evaluation

The primary containment boundary is designed to the load combination shown in Section 3.8, which covers the operational, testing, and postulated accident conditions. Each condition results in a stress level that is related to its corresponding temperature and is the basis for comparison with the allowable limits.

The ferritic steel used for the primary containment boundary is specified so that the toughness of the material meets the above established conditions.

The weld procedure qualification ensures that the toughness of the weld metal and heat-affected zones follow the same criteria as for the base metal.

Since the primary containment is located within the reactor enclosure, the possibility of brittle fracture of ferritic material under low temperature is considerably reduced.

The lowest design service temperature is conservatively taken as 30ºF. The actual service temperature is calculated to be approximately 135ºF. Thus sufficient margin is inherent in the design to account for the various uncertainties involved in design and fabrication. The design of the reactor containment boundary meets the requirements of GDC 51. Actual service conditions above 135°F do not adversely affect this conclusion.

Records for the materials of the flued head fittings, main steam piping, and MSIVs are available for inspection. Additional information is provided in Section 5.2.3.3.

GDC 52 - Capability for Containment Leakage Rate Testing

> The reactor containment and other equipment which may be subjected to containment test conditions shall be designed so that periodic integrated leakage rate testing can be conducted at containment design pressure.

Design Evaluation

The primary containment liner plate and all other equipment that may be subjected to containment test conditions are designed to permit Type A, integrated leak rate testing as described in 10CFR50,

Appendix J. The design of the primary containment thus meets the requirements of GDC 52. A more complete discussion is in Section 6.2.6 and Chapter 16.

GDC 53 - Provisions for Containment Testing and Inspection

> The reactor containment shall be designed to permit 1) appropriate periodic inspection of all important areas, such as penetrations, 2) an appropriate surveillance program, and 3) periodic testing at containment design pressure of the leak-tightness of penetrations which have resilient seals and expansion bellows.

Design Evaluation

The primary containment is designed to optimize the accessibility of important areas to permit required inspection and surveillance.

All penetrations with resilient seals are designed to permit local leak rate testing as described in 10CFR50, Appendix J. This is discussed further in Section 6.2.6.

Expansion bellows are not used on containment penetrations.

The reactor containment meets the requirements of GDC 53.

GDC 54 - Piping Systems Penetrating Containment

> Piping systems penetrating primary reactor containment shall be provided with leak detection, isolation, and containment capabilities having redundancy, reliability, and performance capabilities which reflect the importance to safety of isolating these piping systems. Such piping systems shall be designed with a capability to test periodically the operability of the isolation valves and associated apparatus and to determine if valve leakage is within acceptable limits.

Design Evaluation

Piping systems that penetrate the primary containment have been accorded special design considerations to reflect their importance in accomplishing safety-related functions and in achieving isolation, if required. The penetrations are discussed in Section 6.2.4. Both the isolation valves and the system that initiates isolation use components whose quality maximizes reliability. Sufficient independence and redundancy is provided to ensure effective isolation. Containment isolation is discussed in Section 6.2.4.

Piping systems penetrating the primary containment are designed to permit Type C local leak rate testing as described in Section 6.2.6. The operability of the isolation valves and associated equipment can be verified during the leak rate testing program. Containment leakage testing is further discussed in Section 6.2.6.

Piping systems penetrating primary reactor containment meet GDC 54.

GDC 55 - Reactor Coolant Pressure Boundary Penetrating Containment

> Each line that is part of the RCPB and that penetrates the primary reactor containment shall be provided with containment isolation valves as follows unless it can be demonstrated that

the containment isolation provisions for a specific class of lines, such as instrument lines, are acceptable on some other defined basis:

a. One locked closed isolation valve inside and one locked closed isolation valve outside containment, or

b. One automatic isolation valve inside and one locked closed isolation valve outside containment, or

c. One locked closed isolation valve inside and one automatic isolation valve outside containment. A simple check valve may not be used as the automatic isolation valve outside containment; or

d. One automatic isolation valve inside and one automatic isolation valve outside containment. A simple check valve may not be used as the automatic isolation valve outside containment.

Isolation valves outside containment shall be located as close to the containment as practical and upon loss of actuating power automatic isolation valves shall be designed to take the position that provides greater safety.

Other appropriate requirements to minimize the probability or consequences of an accidental rupture of these lines or of lines connected to them shall be provided as necessary to assure adequate safety. Determination of the appropriateness of these requirements (such as higher quality in design, fabrication, and testing, additional provisions for inservice inspection, protection against more severe natural phenomena, and additional isolation valves and containment) shall include consideration of the population density, use characteristics, and physical characteristics of the site environs.

Design Evaluation

The piping systems that are part of the RCPB and penetrate primary containment conform to the requirements of GDC 55 as described in Section 6.2.4. Similarly, for lines that do not penetrate the primary containment but form a portion of the RCPB, the design ensures that isolation from the RCPB can be achieved.

GDC 56 - Primary Containment Isolation

Each line that connects directly to the containment atmosphere and penetrates the primary reactor containment shall be provided with containment isolation valves, as follows, unless it can be demonstrated that the containment isolation provisions for a specific class of lines, such as instrument lines, are acceptable on some other defined basis:

a. One locked closed isolation valve inside and one locked closed isolation valve outside containment, or

b. One automatic isolation valve inside and one locked closed isolation valve outside containment, or

c. One locked closed isolation valve inside and one automatic isolation valve outside containment. A simple check valve may not be used as the automatic isolation valve outside containment; or

d. One automatic isolation valve inside and one automatic isolation valve outside containment. A simple check valve may not be used as the automatic isolation valve outside containment.

Isolation valves outside containment shall be located as close to the containment as practical and, upon loss of actuating power, automatic isolation valves shall be designed to take the position that provides greater safety.

Design Evaluation

The piping systems penetrating primary containment conform to the requirements of GDC 56 as described in Section 6.2.4.

GDC 57 - Closed System Isolation Valves

Each line that penetrates the primary reactor containment and is neither part of the RCPB nor connected directly to the containment atmosphere shall have at least one containment isolation valve which shall be either automatic, locked closed, or capable of remote manual operation. This valve shall be outside the containment and located as close to the containment as practical. A simple check valve may not be used as the automatic isolation valve.

Design Evaluation

The piping systems penetrating primary containment conform to the requirements of GDC 57 as described in Section 6.2.4.

GDC 60 - Control of Releases of Radioactive Materials to the Environment

The nuclear power unit design shall include means to control suitably the release of radioactive materials in gaseous and liquid effluents and to handle radioactive solid wastes produced during normal reactor operation, including anticipated operational occurrences. Sufficient holdup capacity shall be provided for retention of gaseous and liquid effluents containing radioactive materials, particularly where unfavorable site environmental conditions can be expected to impose unusual operational limitations upon the release of such effluents to the environment.

Design Evaluation

In all cases, the design for radioactivity control is on the basis of the requirements of 10CFR20, 10CFR50, and applicable regulations for normal operations and for any transient situation that might reasonably be anticipated to occur, and is on the basis of 10CFR50.67 dose limits for potential accidents of exceedingly low probability of occurrence. The activity level of waste gas effluents is substantially reduced by holdup of noble gases from the offgas system in charcoal decay beds and subsequent release at the plant exhaust duct.

Control of liquid waste effluents is maintained by batch processing of all liquids, sampling before discharge, and controlled rate of release. Radioactive liquid waste system tankage and external processing capacity is sufficient to handle any expected transient in the processing of liquid waste volume.

Solid wastes are shipped offsite for disposal in shielded and reinforced containers that meet applicable NRC and DOT requirements (Section 11.4).

The liquid, gaseous, and solid waste systems meet the requirements of GDC 60. Referenced sections are as follows:

a.	Liquid waste system	Section 11.2
b.	Gaseous waste system	Section 11.3
c.	Solid waste system	Section 11.4
d.	Process and effluent radiological monitoring system	Section 11.5
e.	Accident analyses	Chapter 15
f.	Technical Specifications	Chapter 16

GDC 61 - Fuel Storage and Handling and Radioactivity Control

The fuel storage and handling, radioactive waste, and other systems which may contain radioactivity shall be designed to assure adequate safety under normal and postulated accident conditions. These systems shall be designed 1) with a capability to permit appropriate periodic inspection and testing of components important to safety, 2) with suitable shielding for radiation protection, 3) with appropriate containment, confinement, and filtering systems, 4) with a residual heat removal capability having reliability and testability that reflects the importance to safety of decay heat and other residual heat removal, and 5) to prevent significant reduction in fuel storage coolant inventory under accident conditions.

Design Evaluation

a. New fuel storage

New fuel is stored in the spent fuel storage pool.

b. Spent fuel handling and storage

Irradiated fuel is stored submerged in the spent fuel storage pool located in the reactor enclosure. Fuel pool water is circulated through the FPCC system to maintain fuel pool water temperature, purity, water clarity, and water level. Storage racks preclude accidental criticality (GDC 62 design evaluation).

Reliable decay heat removal is provided by the FPCC system. The pool water is circulated through the system with suction taken from the pool and is discharged through diffusers at the bottom of the fuel pool. Pool water temperature will not

exceed 143°F during removal of the maximum normal heat load from the pool with the service water temperature at its maximum. The RHR system with its substantially larger heat removal capacity can be used as a backup for fuel pool cooling.

If there is a complete loss of capability to remove heat from the spent fuel pool using heat exchangers, heat can be removed by allowing the pool to boil and adding makeup water from the UHS (spray pond), by either of two seismic Category I flow paths, to maintain the pool water level.

High and low level switches indicate pool water level changes in the control room. Fission product concentration in the pool water is minimized by the fuel pool filter/demineralizer. This minimizes the radioactivity release from the pool to the reactor enclosure.

The reactor enclosure ventilation system and secondary containment are designed to limit the release of radioactive materials to the environment and ensure that offsite doses are lower than the limiting values specified in 10CFR50.67 during operation and all accident conditions.

No special tests are required, because at least one pump and one heat exchanger are continuously in operation while fuel is stored in the pool. Other cooling trains are operated periodically to handle high heat loads or to replace a unit for servicing. Routine visual inspection of the system components, instrumentation, and trouble alarms is adequate to verify system operability.

c. Radioactive waste systems

The radioactive waste systems provide all equipment necessary to collect, process, and prepare for disposal all radioactive liquids, gases, and solid waste produced as a result of reactor operation.

Liquid radwastes are classified, contained, and treated as high or low conductivity, chemical, detergent or sludge wastes. Processing includes filtration, ion exchange, analysis, and dilution. Wet solid wastes are dewatered and packaged in steel containers. Dry solid wastes are compressed and packaged in steel drums. Gaseous radwastes are monitored, processed, recorded, and released so that radiation doses to persons outside the controlled area are below those allowed by applicable regulations.

Accessible portions of the spent fuel pool area and radwaste enclosure have sufficient shielding to maintain dose rates within the limits set forth in 10CFR20 and 10CFR50. The radwaste enclosure is designed to preclude an accidental release of radioactive materials to the environment that exceeds the limits allowed by the applicable regulations.

The radwaste systems are used on a routine basis and do not require specific testing to ensure operability. Performance is monitored by radiation monitors during operation.

The fuel storage and handling and the radioactive waste systems are designed to ensure adequate safety under normal and postulated accident conditions. The design of these systems meets the requirements of GDC 61.

Referenced sections are as follows:

a.	RHR system	Section 5.4
b.	Containment systems	Section 6.2
c.	New fuel storage	Section 9.1
d.	Spent fuel storage	Section 9.1
e.	FPCC system	Section 9.1
f.	HVAC systems	Section 9.4
g.	Radioactive waste management	Chapter 11
h.	Radiation protection	Chapter 12

GDC 62 - Prevention of Criticality in Fuel Storage and Handling

Criticality in the fuel storage and handling system shall be prevented by physical systems or processes, preferably by use of geometrically safe configurations.

Design Evaluation

Appropriate plant fuel handling and storage facilities are provided to preclude accidental criticality for new and spent fuel. Criticality in new and spent fuel storage is prevented by the geometrically safe configuration of the storage rack. There is sufficient spacing between the assemblies to ensure that the array, when fully loaded, is substantially subcritical. Fuel elements are limited by rack design to only top loading and fuel assembly positions. The new and spent fuel storage racks are designed to seismic Category I requirements.

New fuel storage is discussed in Section 9.1.1. New fuel is stored in the spent fuel pool.

Spent fuel is stored underwater in the spent fuel pool. The racks in which spent fuel assemblies are placed are designed and arranged to ensure subcriticality in the storage pool. Spent fuel storage is discussed in Section 9.1.2.

Refueling interlocks include circuitry that senses conditions of the refueling equipment and control rods. These interlocks reinforce operational procedures that prohibit making the reactor critical. The fuel handling system is designed to provide a safe, effective means of transporting and handling fuel and is designed to minimize the possibility of mishandling or misoperation.

The use of geometrically safe configurations for new and spent fuel storage and the design of fuel handling systems precludes accidental criticality in accordance with GDC 62. Referenced section is as follows:

a.	Fuel storage and handling	Section 9.1

GDC 63 - Monitoring Fuel and Waste Storage

> Appropriate systems shall be provided in fuel storage and radioactive waste systems and associated handling areas 1) to detect conditions that may result in loss of residual heat removal capability and excessive radiation levels and 2) to initiate appropriate safety actions.

Design Evaluation

Appropriate systems are provided to meet the requirements of GDC 63. A malfunction of the FPCC system that could result in a loss of residual heat removal capability and excessive radiation levels is alarmed in the control room. Alarmed conditions include low fuel pool cooling water pump discharge pressure, high and low levels in the fuel storage pool and skimmer surge tanks, and flow in the drain lines between the fuel pool gates between fuel pool and reactor well. System temperature is also continuously monitored and alarmed in the control room. Spent fuel storage is discussed in Section 9.1.2, and fuel pool cooling and cleanup are discussed in Section 9.1.3.

The reactor enclosure and refueling floor ventilation radiation monitoring systems detect abnormal amounts of radioactivity and initiate appropriate action to control the release of radioactive material to the environment. These systems are discussed in Sections 9.4 and 11.5.

Area radiation and tank and sump levels are monitored and alarmed to indicate conditions that may result in excessive radiation levels in radioactive waste system areas. Area radiation monitoring is discussed in Section 12.3.

GDC 64 - Monitoring Radioactivity Releases

> Means shall be provided for monitoring the reactor containment atmosphere, spaces containing components for recirculation of LOCA fluids, effluent discharge paths, and the plant environs for radioactivity that may be released from normal operations, including anticipated operational occurrences, and from postulated accidents.

Design Evaluation

Appropriate means are provided for monitoring radioactivity releases to meet the requirements of GDC 64.

A fission products monitoring system is provided to sample the containment (both drywell and suppression pool) atmosphere for radioactive particulates, noble gases, and iodine during normal operation. A hydrogen-oxygen analyzer system is provided to monitor the hydrogen-oxygen concentration in the containment during normal operation and following an accident.

Means are provided to monitor radioactive effluent discharge paths and the site environment for radioactivity releases. Referenced sections are as follows:

a.	RCPB leakage detection system	Section 5.2
b.	ESF systems	Section 7.3
c.	All other systems required for safety	Section 7.6

d.	Control systems not required for safety	Section 7.7
e.	Radioactive waste management	Chapter 11
f.	Airborne radioactivity monitoring	Section 12.3

3.2 CLASSIFICATION OF STRUCTURES, COMPONENTS, AND SYSTEMS

Certain structures, components, and systems of the nuclear plant are considered important to safety because they perform safety actions required to avoid, or to mitigate the consequences of abnormal operational transients or accidents. The purpose of this section is to classify structures, components, and systems according to the importance of the safety functions they perform. In addition, design requirements are specified to ensure the proper performance of safety actions when required.

3.2.1 SEISMIC CLASSIFICATION

GDC 2 and 10CFR100, Appendix A require that nuclear power plant structures, systems, and components important to safety be designed to withstand the effect of earthquakes. Regulatory Guide 1.29 (Rev 3) provides additional guidance, and defines seismic Category I structures, components, and systems and those necessary to ensure:

a. The integrity of the RCPB,

b. The capability to shut down the reactor and maintain it in a safe shutdown condition,

c. The capability to prevent, or mitigate the consequences of accidents which could result in potential offsite exposures in excess of the dose limits of 10CFR50.67.

Plant structures, systems, and components, including their foundations and supports, that are designed to remain functional if there is a SSE are designated as seismic Category I, as indicated in Table 3.2-1. Class 1E electric equipment is seismic Category I equipment. Seismic classification of systems instrumentation is discussed in Chapter 7.

All seismic Category I structures, systems, and components are analyzed under the loading conditions of the SSE and OBE. Since the two earthquakes vary in intensity, the design of seismic Category I structures, components, equipment, and systems to resist each earthquake and other loads is based on levels of material stress, or load factors, whichever is applicable, and yields margins of safety appropriate for each earthquake. The margins of safety provided for safety-related structures, components, equipment, and systems for the SSE are sufficiently large to ensure that their design functions are not jeopardized.

Seismic Category I structures are sufficiently isolated, or protected, from other structures to ensure that their integrity is maintained at all times.

Components and their supporting structures that are not seismic Category I, but are located in the vicinity of seismic Category I items, are listed as seismic Category IIA in Table 3.2-1. Those components listed as seismic Category IIA are either designed to seismic Category I criteria or are reviewed to identify those whose failure could result in loss of required function of seismic Category I structures, equipment, or systems required after an SSE. Components identified by this review are considered safety-impact items and are either analytically checked to confirm their integrity against collapse when subjected to seismic loading from the SSE or are separated from seismic Category I equipment by a barrier.

Structures, systems, and components that are not required to maintain their structural integrity or function during or after, the SSE are classified nonseismic (seismic Category II). The boundaries of each seismic category portion of the systems are shown on the piping and instrument diagrams in appropriate sections of this document. A cross reference of system to former UFSAR figure number is provided in Section 1.7.

Clarifications and alternate approaches to the guidelines of Regulatory Guide 1.29, as applied to LGS, are the following:

a. Regarding the seismic design of the reactor core and internals of paragraph C.1.b, reactor internals that are not required for safe shutdown of the plant are designed to maintain their relative positions following an SSE, but may not remain functional.

These internals are listed below:

1. Feedwater spargers
2. Initial startup neutron sources
3. Surveillance sample holders
4. Incore instrument housings
5. Steam dryer
6. Shroud head and separator assembly
7. Guide rods

Generic evaluation has demonstrated that the failure of these structures will not jeopardize the safety function of other safety-related internals during a seismic event.

b. The spent fuel pool cooling system, and the associated service water supply, discussed in paragraph C.1.d and C.1.g of the guide, are seismic Category IIA rather than seismic Category I systems. However, two alternate seismic Category I cooling sources are provided via connections from the RHR system and the ESW system, as discussed in Section 9.1.3. The portions of the spent fuel pool cooling system necessary for use of these alternate cooling sources are seismic Category I. This arrangement meets the intent of the guide.

c. The seismic Category I boundary of the main steam system and connected piping outside primary containment may not always be at a valve that is normally closed, or capable of automatic isolation, as discussed in paragraph C.1.e of the guide. In these cases, the boundary is at a valve that is capable of remote manual closure to avoid unnecessary complication in lines that normally would not be provided with automatically closing valves. The remote manual valves are the following (shown in drawing M-01):

1. Main steam to air ejectors isolation valve, HV-150 and HV-250
2. Main steam to steam seal evaporator isolation valve, HV-111 and HV-211
3. Main steam to reactor feed pump-turbine high pressure steam supply valve, HV-108 and HV-208.

The use of remotely operated manual valves in lieu of normally closed or automatic valves is justifiable for the following reasons:

Those portions of the steam system extending from the outermost containment isolation valve up to but not including the turbine stop valves, and connected piping of 2½ inches nominal pipe size or larger up to and including the remotely operated manual valves are classified seismic Category I. In addition, these valves are Class 1E powered, and the controls are installed on seismic Category I panels located in the control room for ready operator access to remotely close the valves when required.

During normal plant operation, in case of a pipe break downstream of any one of the remotely operated manual valves, radiation monitors in the turbine enclosure exhaust will detect radiation and alert the operator in the control room. Temperature elements will also show an increase in temperature.

Each of the three remotely operated manual valves in question is downstream of the MSIVs which automatically close in the event of a large pipe break in the main steam line.

Following a Design Basis Large Break LOCA, the operator can manually align the MSIV Leakage Alternate Drain Pathway, as described in section 6.7. This alignment includes the shutting of each three remotely operated manual valves in question.

Even assuming the unlikely event of a pipe break downstream of any one of these remotely operated manual valves coincident with a LOCA, during the time period before the MSIV Leakage Alternate Drain Pathway is aligned, the radiation doses are well below the values of 10CFR50.67. The activity levels in the residual steam would be comparable to normal operation activity levels. Core activity would not be transported past the already closed MSIVs due to the transport delay time of the residual steam and water.

Consistent with Regulatory Guide 1.26, the turbine bypass valve chest is designed to Quality Group D. In accordance with the Regulatory Guide 1.29 for the turbine stop valve, the turbine bypass valve chest is not designed to seismic Category I requirements.

d. Paragraph C.3 of Regulatory Guide 1.29 recommends seismic Category I design requirements be extended "to the first seismic restraint beyond the defined boundaries." Since seismic analysis of a piping system required division of the system into discrete segments terminated by fixed points, this means that the seismic design cannot be terminated at a seismic restraint, but is extended to the first point in the system which can be treated as an anchor to the plant structure. In addition, paragraph C.4 of Regulatory Guide 1.29 states that the pertinent quality assurance requirement of 10CFR50, Appendix B, should be applied to the safety requirements of such items. Both these guidelines are considered to be met adequately by applying the following practices to such items:

1. Design and design control for such items are carried out in the same manner as that for items directly important to safety. This includes the performance of appropriate design reviews.

2. Field audits are performed by representatives of the originating design group to ensure that the final installation of such items is in accordance with documents that formed the basis for the seismic analysis of the items.

3. Such items are not included in the Q-List.

3.2.2 SYSTEM QUALITY GROUP CLASSIFICATIONS

GDC 1 of 10CFR50, Appendix A, requires that structures, systems and components important to safety be designed, fabricated, erected, and tested to quality standards commensurate with their importance to safety. Components of the RCPB meet the requirements of Class 1 components of the ASME B&PV Code, Section III, or equivalent quality standards, as required by 10CFR50.55a. Regulatory Guide 1.26 (Rev 3), describes a quality classification system that may be used to determine applicable standards for other components in nuclear power plants. Quality group classifications are assigned to systems and components in accordance with the reliance placed on these systems to:

a. Prevent, or mitigate the consequences of, accidents and malfunctions originating within the RCPB

b. Permit shutdown or the reactor, and maintain it in the safe shutdown condition

c. Contain radioactive material

A tabulation of quality group classification for each component so defined is shown in Table 3.2-1 under the heading "Quality Group Classification." The applicable codes and standards of each quality group, as described by Regulatory Guide 1.26, are given in Tables 3.2-2 and 3.2-3. The locations of these components, and the quality group classification of the piping, valves, and interfaces between components of different classifications, are indicated on the system piping and instrumentation diagrams in the pertinent section of the UFSAR. A cross reference of system to former UFSAR figure number is provided in Section 1.7.

System quality group classifications, and design and fabrication requirements as indicated in Table 3.2-1, meet the guidelines of Regulatory Guide 1.26, except as noted below.

The LGS design is based on quality group commitments made before Regulatory Guide 1.26 was issued, as shown in Table 3.2-3, and in some cases alternate approaches to the guide have been used, as follows:

a. Regarding systems important for reactor shutdown, as discussed in paragraph C.1.b (Quality Group B) of the guide, the CRD system HCUs are classified as "special equipment" by GE because the codes and standard of a quality group are not strictly applicable to the HCUs. A detailed discussion is given in the notes of Table 3.2-1.

b. The Quality Group B classification may terminate on some steam system connected piping at the first valve capable of remote manual closure, rather than at a normally, or automatically, closed valve. Additionally, Quality Group B is applied only to piping 2½ inches in diameter and larger, similar to the guidelines of Regulatory Guide 1.29 for application of seismic Category I classification.

c. Certain components in the normal spent fuel pool cooling system were designed , fabricated, procured, installed, and tested to the requirements of ASME Section III, Class 3, prior to May 1978. After May 1978, system design, fabrication, materials, procurement, installation, and testing are, at a minimum, in accordance with Quality Group D and the intent of Regulatory Guide 1.143 (Rev 1). However, as discussed in Section 3.2.1, backup cooling and makeup sources are provided. These sources are at least Quality Group C, as are the connecting portions of the normal cooling system.

d. The standby diesel generator piping is designed as shown in drawing M-20. Supplementary material certification, design, and examination requirements have been applied to the Seismic Category I off-skid portions of the emergency diesel auxiliary systems to ensure that their quality is essentially equivalent to ASME Section III, Class 3. The technical differences between ANSI B31.1 and ASME Section III, Class 3 are few. The major differences were addressed by supplemental requirements and are listed in Table 3.2-4.

The on-skid piping and components in the diesel generator auxiliary systems were provided in accordance with ASME Section III, Class 3 or manufacturer's standards, as shown in the vendor manual and also drawing M-20. Auxiliary system components were supplied to ASME Section III, Class 3 to the greatest extend practicable at the time of procurement. The referenced drawing indicate that this encompasses most of the equipment within the main process loop of each skid-mounted auxiliary system.

All skid-mounted components, regardless of design code, have been designed to withstand seismic accelerations (Seismic Category I) as well as normal diesel operating loads. Portions of the Air Start System, which do not have a safety related function, have been downgraded to Seismic Category IIA as shown on drawing M-20. Motors Associated with stand-by components such as the Oil Pre-Lube Pump, The Oil Circulating Pump and the Jacket Water Keep Warm Pump, have been reclassified as non-safety related. The associated pumps are considered safety related (passive) since they are required for pressure boundary integrity only. These non-safety related components will have mountings that are calssified as seismic Category IIA. Each assembled diesel generator skid was subjected to a series of operating tests including load acceptance and rejection, air start capacity, variable load, overspeed, 300 hr rating, normal operating, and contract acceptance tests. In addition, to the operating tests, the following specific component tests were conducted:

1. Fuel Oil Injectors - These were functionally tested and calibrated to deliver a metered amount of fuel to the combustion chamber. Each injector has a unique serial number which permits traceability to its shop test and calibration records.

2. Flexible Hose Assemblies and Pipe Coupling Connectors - These components (drawing M-20) are manufacturer unique designs used to ensure flexibility in the piping systems and are not supplied to ASME Section III, Class 3. However, these components were fabricated in

accordance with engineering specifications, and each component was hydrotested to in excess of 1.25 times design pressure.

3. ASME Section III, Class 3 and non-ASME Section III, Class 3 Piping - All piping systems were hydrostatically tested to 1.5 times the design pressure regardless of design code, except for the on-skid starting air system piping which was pneumatically tested to 1.25 times the design pressure. These tests are documented in the shop test records.

All diesel components were supplied or manufactured in accordance with the following vendor's quality control standards:

1. Subsupplied Components - Design and procurement controls were used in the procurement of all subsupplied components. These components were purchased to detailed engineering specifications and drawings. Upon receipt, all components (or a representative sample) were inspected against the specification, drawings, and purchase order requirements, and affixed with appropriate tags to be removed at the point of use in the manufacturing cycle. Periodic reviews of subsupplier performance and audits or vendor records were conducted to ensure that the quality of the items provided remained acceptable.

   Typical examples of subsupplied items procured under this program are as follows:

   - Air start solenoid valves, filters, strainers, and compressors
   - Inlet and exhaust expansion joints and the exhaust silencer
   - Motor-driven fuel oil, jacket water, and lube oil pumps
   - Combustion air coolers, lube oil and jacket water standby heaters
   - Fuel and lube oil strainers
   - Jacket water, air cooler coolant, and lube oil thermostatic bypass valves
   - Electrical and pneumatic instrumentation and controls.

2. Supplier Manufactured Components - Equipment and components designed and manufactured by the diesel generator vendor were designed in accordance with written procedures for design control which required appropriate reviews and approvals of all detail drawings, specifications, procedures, and instructions. During the manufacturing process, visual inspection, dimensional checks, final inspections, and customer hold and witness points were used. Also, procedures were developed and implemented for rejection of components, recall of materials, and internal audits. Typical examples of supplier manufactured components incorporating the above standards include the following:

- Air admission check valves, pilot valves, and air start distributors
- Engine-mounted intake and exhaust air piping, scavenger air receivers, evacuation system components
- Fuel injectors, dirty fuel drip tank, fuel and oil drip pan
- Governor control linkage.

The above standards are fully documented in the diesel generator suppliers' Quality Assurance Plan, which addresses the 18 criteria contained with 10CFR50, Appendix B. It is invoked upon all diesel generators supplied by this manufacturer for use in nuclear plants and has received the approval of the appropriate operating utilities and the NRC.

The above described controls were invoked on all piping and components supplied by the manufacturer. In addition to these requirements, the applicant invoked supplemental quality assurance requirements on the following selected diesel generator and auxiliary system components:

1. Subsupplier Items:
   - Generators, generator controls, and static exciters
   - Starting air receivers and inlet valves
   - Jacket water, lube oil, and air cooler coolant heat exchangers
   - Lube oil strainers and filters
   - Governors
   - Inlet air filters
   - Turbochargers
   - Fuel oil day tank
   - Lube oil storage tank
   - Jacket water expansion tank.
2. Diesel Generator Supplier Manufactured Items:
   - Engine blocks
   - Subbase oil pan
   - Cylinder liners
   - Exhaust belts

- Pistons and piston inserts
- Crankshafts and connecting rods
- Vertical drive assembly
- Scavenging air blower gears, housings, impellers
- Engine driven lube oil, jacket water, and air cooler coolant pumps
- Jacket liners
- Skid-mounted piping and valves provided to ASME Section III, Class 3.

The additional quality assurance requirements invoked by the applicant include: (1) periodic documented subsupplier audits (including plant visits), (2) review and approval of subsupplier QA programs and manuals, (3) test and inspection audits, (4) calibration of test gauges before and after use, and (5) control of calibration records and acceptance devices.
With the imposition of the above design, manufacturing, and testing controls, the on-skid and off-skid piping and components have been made to be equivalent to Quality Group C.

e. The chilled water piping system for the control structure chilled water system is designed to ANSI B31.1 with supplementary material certification and design requirements to ensure that the quality is essentially equivalent to ASME Section III, Class 3. The technical differences between ANSI B31.1 and ASME Section III, Class 3 are few. The major differences were addressed by supplemental requirements and are listed in Table 3.2-5.

f. Instrument tubing downstream of the containment isolation valve of instrument lines connected to the RCPB is Quality Group D for instruments that are "passive": (i.e., do not actuate safety systems), rather than Quality Group B or C as discussed in paragraphs 1.e and 2.c of the regulatory guide. This is based on considerations given in Regulatory Guide 1.11 for instrument lines penetrating containment and having two restriction devices.

g. The piping between the two containment isolation valves, and the outboard isolation valves, on the drywell chilled water system are the equivalent of Quality Group B although they were originally designed and constructed as ANSI B31.1. Equivalency has been assured through the imposition of supplemental design, fabrication, and testing requirements:

- Piping material properties are essentially equivalent to the requirements of ASME Section III, Class 2
- Seismic and hydrodynamic accelerations were considered in design and analysis

- Design temperatures and pressures are greater than design values for the primary containment
- Documented quality control inspections were performed (by trained and qualified inspectors) on piping installation, welds, valves, and hangers
- The installation is of fully welded construction except for the outboard isolation valves, which are flanged
- A hydrostatic test was performed at a pressure 3 times greater than containment design pressure

These provisions meet or exceed the commitments made in PSAR Appendix A and PSAR Figure A.2.1.

h. The water chillers in the control room HVAC system are designed and fabricated in accordance with ASME Section VIII, Division I requirements, with the exception of the ASME Section III, Class 3 condenser. The condenser is connected to the ESW system. Supplementary material certification and design requirements have been applied to the ASME Section VIII portions of the chillers to ensure that their quality is essentially equivalent to ASME Section III, Class 3 at the time of purchase. The chillers were designed to seismic Category I requirements and fabricated under an approved quality assurance program. The major similarities and differences are listed in Table 3.2-6 along with the supplementary requirements.

i. The control structure chilled water pumps are designed and fabricated in accordance with the manufacturer's standards with supplementary requirements applied. The pumps are designed to seismic Category I requirements and fabricated under an approved quality assurance program used for ASME Section III, Class 3 pumps. The pressure-retaining materials used are approved for use in ASME Section III, Class 3 pumps and were supplied with CMTRs. The pumps were hydrotested at a pressure greater than that required by the code. The electrical components were environmentally qualified. Therefore, the quality of the pumps is essentially equivalent to ASME Section III, Class 3.

j. The seismic Category I control structure chilled water cooling coils in safety-related air handling units are fabricated from ASME Section III, Class 3 approved materials, with CMTRs, for the pressure-retaining parts. The coils are fabricated in accordance with the same quality assurance program using equivalent processes, are tested to the same procedures, and are of the same design as the ASME Section III, Class 3 ECCS unit cooler cooling coils, but are not N-stamped.

k. The seismic Category I SLCS tank was designed to API-650 standards and supplementary ASME Section III, Class C testing and examination requirements. The tank meets key later requirements of NC-3800, ASME Section III, Class 2, and is judged to be of equivalent quality.

l. All three of the Unit 1 and one of the Unit 2 SLCS pump discharge accumulator vessels were designed to ASME Section VIII, Division 1 requirements. These

weldless vessels, except for stamping, meet the code requirements of ASME Section III, Class C cited in Table 3.2-3.

m. The HPCI turbine exhaust line globe stop-check valves meet the material, design, fabrication, inspection, and testing requirements of the 1968 Draft ASME Code for Pumps and Valves indicated in Table 3.2-3 and the nondestructive inspection requirements of ASME Section III. They are, therefore, equivalent to Quality Group B. These valves were manufactured, however, to ANSI B31.1 (1967), ANSI B16.5 and MSS-SP-66 requirements.

n. The CRD system piping between the HCUs and the containment isolation boundary valves was originally designed and constructed according to ANSI B31.1. This piping has been reanalyzed and reevaluated as part of the modification which provided new isolation valves. This piping is now considered to be equivalent to ASME Section III, Class 2. The Upgrade Program included the following:

- The design requirements of the piping and the applicable stress calculations have been reviewed and found adequate to meet the requirements of ASME III, Class 2 and Seismic Category I.
- The installation rules and processes have been reviewed and found adequate to meet the intent of ASME III, Class 2.
- The inspection and testing procedures and acceptance criteria have been reviewed and found adequate to meet the requirements of ASME III, Class 2.
- The documentation required by the specifications and programs satisfies the intent of ASME III, Class 2 to provide written evidence of an acceptable level of quality. Engineering review of the documents has been found to be satisfactory.

o. The Unit 1 Corrosion Monitoring Piping and Components for the RHR Heat Exchanger IBE205 (RHR HX "B") connected to the RHRSW system was installed using ANSI B31.1 materials. This piping and components are considered to be equivalent to ASME Section III, Class 3. This consideration is based on the following:

- The design requirements of the piping and the applicable stress calculations have been performed in accordance with the requirements of ASME III, Class 3 and Seismic Category I.
- This equipment and piping was installed in accordance with the requirements of ASME III, Class 3.
- The inspection and testing procedures and acceptance criteria have been done in accordance with the requirements of ASME III, Class 3.
- The documentation required by the specifications and programs satisfies the intent of ASME III, Class 3 to provide written evidence of an acceptable level of quality. Engineering review of the documents has been found to be satisfactory.

3.2.3 QUALITY ASSURANCE

Those structures, components, and systems necessary to ensure:

a. the integrity of the RCPB,

b. the capability to shut down the reactor and maintain it in a safe shutdown condition,

c. the capability to prevent, or mitigate the consequences of, accidents that could result in potential offsite exposures in excess of the values of 10CFR50.67.

are classified as Q-listed, require conformance to the applicable quality assurance requirements of 10CFR50, Appendix B and are summarized in Table 3.2-1 under the heading, "Q-List". Table 3.2-1 (LGS Design Criteria Summary) is intended, in part, to provide identification of safety-related structures, systems, and components. The LGS Q-List is not part of the UFSAR; it is a controlled QA program document that serves to identify structures, systems and components requiring compliance with 10CFR50, Appendix B.

Quality assurance during construction is discussed in the document "Limerick Generating Station Units 1 and 2; Summary Description of the Quality Assurance Program for Design and Construction," referenced in Section 17.1. The Quality Assurance Program during the Operational Phase is described in Section 17.2.

The Q-listed boundaries for piping systems terminate at the outermost containment or system isolation valve. The piping downstream of this boundary is not required to ensure items a, b, or c above and is therefore not required to be Q-listed. However, in order that failure of the non Q-listed piping not affect the Q-listed piping or the isolation valves, the non Q-listed piping is designed to seismic Category I requirements up to and including the first point in the system that can be treated as an anchor to the plant structure except as indicated in part c of the discussion on Regulatory Guide 1.29 in Section 3.2.1. Stress analysis, support design, and design control for this non Q-listed piping, classified as seismic Category IIA, is carried out in the same manner as it is for Q-listed, seismic Category I items.

The pertinent quality assurance requirements of 10CFR50, Appendix B, are considered to be adequately met for the seismic Category IIA piping as indicated in Section 3.2.1, part d.

The design control and construction control practices that were used during the design and construction phase are also applied during the operations phase to ensure that the same stringent requirements are maintained for any changes to seismic Category IIA piping. In addition, seismic Category IIA piping and supports which are included in seismic Category I stress calculations will be included as part of the ISI program, to the extent that repairs and replacements to the IIA supports are performed in accordance with the ASME Section XI Repair and Replacement Program. The ISI program is included in the operations phase of the Nuclear Quality Assurance Plan.

Table 3.2-1

LGS DESIGN CRITERIA SUMMARY

SYSTEM/COMPONENT[40]	UFSAR SECTION	SOURCE OF SUPPLY[1]	LOCATION[2]	QUALITY GROUP CLASSIFICATION[3]	PRINCIPAL CODES AND STANDARDS[4]	SEISMIC CATEGORY[5]	Q-LIST[6]	COMMENTS
I NSSS								
A. Reactor System	4,5							
1. Reactor vessel		GE	C	A	III-1	I	Y	(7)
2. Reactor vessel support skirt		GE	C	-	III-1	I	Y	(49)
3. Reactor vessel appurtenances, pressure-retaining portions		GE	C	A	III-1	I	Y	
4. CRD housing supports		GE	C	-	MF STD	I	Y	(50)
5. Reactor internals, ESFs		GE	C	-	MF STD	I	Y	
6. Reactor internals, other,		GE	C	-	MF STD	II	Y/N	(8)(62)
7. Control rods		GE	C	-	MF STD	I	Y	
8. Core support structure		GE	C	-	MF STD	I	Y	(72)
9. Power range detector hardware		GE	C	A	III-1	I	Y	
10. Fuel assembles		GE	C	-	MF STD	I	Y	
B. Nuclear Boiler System	4,5							(87)
1. Vessels, level instrumentation condensing chambers		GE	C	A	III-1	I	Y	(9)
2. Vessels, air accumulators (except in item 8 below)		P	C	C	III-3	I	Y	
3. Piping, relief valve discharge		P	C	C	III-3	I	Y	(48)
4. Piping and valves, RCPB		GE/P	C,R	A	III-1	I	Y	(7)(9)(48)
5. Mechanical components, instrumentation with safety function		GE	C	B	MF STD	I	Y	(11)
6. Electrical modules, with safety function		GE	C,R,CS	-	IEEE 323, 344	I	Y	(11),(12)

NOTES ON
LGS DESIGN CRITERIA SUMMARY

(1) GE - General Electric

W - Westinghouse Nuclear Automation

P - PECO Energy

PE - Preferred Engineering

(2) Location

R - Reactor Enclosure

C - Containment

T - Turbine Enclosure

CS - Control Structure

RW - Radwaste and Offgas Enclosure

G - Diesel Generator Enclosure

AB - Auxiliary Boiler Enclosure

F - Fuel Oil Pump Structure

W - Water Treatment Enclosure

ST - Sewage Treatment Enclosure

A - Administration Building

S - Spray Pond Pump Structure

SP - Schuylkill Pump Structure

PP - Perkiomen Pump Structure

CW - Circulating Water Pump Structure

O - Outdoors, Onsite

HS - Hot Maintenance Shop

CL - Chemistry Laboratory Expansion

(3) A,B,C,D - Quality group classification as defined in Regulatory Guide 1.26, see also Tables 3.2-2 and 3.2-3.
- = Not applicable to quality group classification

Table 3.2-1 (Cont'd)

(4) Notations for principal construction codes:

AA	-	Aluminum Association
ACI	-	American Concrete Institute
AFBMA	-	Anti Friction Bearing Manufacturers Association
AISC	-	American Institute of Steel Construction
AISI	-	American Iron and Steel Institute
AMCA	-	Air Moving and Conditioning Association
AMCA 210	-	"Test Codes for Air Moving Devices"
AMCA 211A	-	"AMCA Certified Ratings Program for Air Performance"
ANI	-	American Nuclear Institute
ANSI	-	American National Standards Institute
ANSI B9.1	-	"Safety Code for Mechanical Refrigeration"
ANSI B30.11	-	"Monorail Systems and Underhung Cranes"
ANSI B30.16	-	"Overhead Hoists"
ANSI B31.1	-	"Code for Pressure Piping"
ANSI B31.5	-	"Refrigeration Piping"
ANSI N509	-	"Nuclear Power Plant Air Cleaning Units and Components" (1976, 1980)
API	-	American Petroleum Institute
API 620	-	"Recommended Rules for Design and Construction of Large, Welded, Low Pressure Storage Tanks"
API 650	-	"Welded Steel Tanks for Oil Storage"
ARI	-	Air Conditioning and Refrigeration Institute
AWS	-	American Welding Society
BOCA	-	National Building Code

Table 3.2-1 (Cont'd)

CMAA 70	-	Crane Manufacturers Association of America, Specification Number 70, "Electric Overhead Traveling Cranes"
HEI	-	Heat Exchange Institute
HYD I	-	Hydraulic Institute
IEEE	-	Institute of Electrical and Electronics Engineers
IEEE 279	-	"Criteria for Protection Systems for Nuclear Power Generating Stations" (1971)
IEEE 308	-	"Standard Criteria for Class 1E Electric Systems for Nuclear Power Generating Stations" (1971)
IEEE 317	-	"Standard for Electrical Penetration Assemblies in Containment Structures for Nuclear Fueled Power Generating Stations" (April 1971)
IEEE 323	-	"General Guide for Qualifying Class 1E Electric Equipment for Nuclear Power Generating Stations" (1971, 1974)
IEEE 334	-	"Trial Use Guide for Type Test of Continuous-Duty Class 1 Motors Installed Inside the Containment of Nuclear Power Generating Stations (ANSI N41.9)" (1971)
IEEE 344	-	"Guide for Seismic Qualification of Class 1E Electric Equipment for Nuclear Power Generating Stations" (1971, 1975)
IEEE 383	-	"Type Test of Class 1E Electrical Cables, Field Splices, and Connections for Nuclear Power Generating Stations" (1974)
IEEE 387	-	"Criteria for Diesel Generator Units Applied as Standby Power Supplies for Nuclear Power Generating Stations" (1972)
MF STD	-	Manufacturer's Standard
NEC	-	National Electric Code
NEMA MG-1	-	National Electrical Manufacturers' Association, "Motors and Generators" (1971)
NFPA	-	National Fire Protection Association
RDT-M-16-1T-		Reactor Research and Development Gas Phase Adsorbents for Trapping Radioactive Iodine and Iodine Compounds
SMACNA	-	Sheet Metal and Air Conditioning Contractors National Association Inc.
TEMA C	-	Tubular Exchanger Manufacturers Association, Class C

Table 3.2-1 (Cont'd)

	UBC	-	Uniform Building Code
	UL	-	Underwriters Laboratories Standard
	III	-	"1, 2, 3, MC" - ASME B&PV Code, Section III, Class 1,2,3, MC (Certain NSSS mechanical components ordered prior to July 1, 1971, were built to the older code categories. Refer to Table 3.2-3 for the appropriate code)
	VIII-1	-	ASME B&PV Code, Section VIII, Division 1
(5)	I	-	The equipment is constructed in accordance with the seismic requirements for the SSE.
	IIA	-	The equipment of this category is designed so that it cannot adversely affect plant safety features during and after SSE.
	II	-	The equipment of this category is not designed for the SSE.
(6)	Y	-	Requires compliance with the requirements of 10CFR50, Appendix B
	N	-	Not within the scope of 10CFR50, Appendix B

(7) PECo's request to use alternative codes to those required in 10CFR50.55a for primary pressure boundary components was sent to the NRC on July 15, 1975. The applicable codes, code dates, and addenda are listed in the request letter for the following components which are still included in the LGS design:

A. RPV

B. Main steam SRVs

C. Main steam piping (26") from RPV to 2nd isolation valve

D. Main steam line suspension

E. Recirculation pump

F. Recirculation gate valves (motor-operated):
28" suction
28" discharge

G. Recirculation loop piping (28")

H. Recirculation loop suspension

Table 3.2-1 (Cont'd)

I. RHR valves
20" gate valve

J. Core spray valves
12" check valve (air-operated)

K. Nuclear Class I piping (all except main steam and recirculation)

NRC approval of the request was given on November 18, 1975 in a letter from R.C. De Young (NRC) to E.G. Bauer (PECo).

The applicable code for design, fabrication, and testing of the MSIVs is the ASME Standard Code for Pumps and Valves for Nuclear Power - 1968 Draft including March 1970 Addenda.

(8) See Section 3.2.1 for discussion of conformance to Regulatory Guide 1.29.

(9) Instrument and sampling lines Quality Group, seismic category, and quality assurance requirements are as follows:

A. Instrument Lines

1. From the process boundary through the process root valve (including restriction orifice adapter), or, for lines penetrating primary containment, through the containment isolation valve or excess flow check valve, whichever applies: same Quality Group, seismic category, and QA requirements as the process line

2. Downstream of the boundary defined in 1, above:

   a. Lines penetrating primary containment and whose associated instruments are required to function to perform a safety function (Q-active) are Quality Group B, seismic Category I, and are Q-listed.

   b. Lines penetrating primary containment and whose associated instruments are only required to maintain their pressure boundary integrity (Q-passive) are Quality Group D, seismic Category I, and are Q-listed.

   c. Lines not penetrating primary containment whose associated instruments are Q-active are Quality Group B, seismic Category I, and Q-listed.

   d. Lines not penetrating primary containment whose associated instruments are Q-passive are Quality Group D, seismic Category I, and Q-listed.

   e. Other lines are Quality Group D, nonseismic Category I, and not Q-listed.

   f. Certain adapters in nonsafety-related, non Q-listed instrument lines are not manufactured per ANSI B31.1.

Table 3.2-1 (Cont'd)

B. Sampling Lines

1. From process line to root valve: Same quality group, seismic category, and quality assurance as process line.

2. From root valve through sample rack isolation valve:

   a. Sampling lines from Q-listed Quality Group A, B, and C process lines are Quality Group B, seismic Category I, and Q-listed.

   b. Sampling lines from non Q-listed Quality Group C process lines are Quality Group B or D, nonseismic Category I, and not Q-listed

   c. Sampling lines from Quality Group D process lines are Quality Group D, nonseismic Category I, and non Q-listed.

3. Downstream of sample rack isolation valve: Quality Group D, nonseismic Category I, and non Q-listed

(10) Accident monitoring instrumentation was designed using the guidance provided in Regulatory Guide 1.97 Revision 2. Regulatory Guide 1.97 Category I and most of Category II instrumentation is Q-listed. For additional design criteria information, see Section 7.5.

(11) Components include any assembly of interconnected parts that constitutes an identifiable device or piece of equipment. For example, electrical components include sensors, power supplies, and signal processors; and mechanical components include turbines, strainers, and orifices.

(12) Refer to Section 7.1 for descriptions of conformance with IEEE 279, IEEE 308, IEEE 323, and IEEE 344.

(13) These bottles are not available as seismic Category I items. However, the piping from the bottles is seismic Category I and Q-listed. DOT specifications were used for the bottles.

(14) The HCU is a GE factory assembled, engineered module of valves, tubing, piping, and stored water that controls a single CRD by the application of precisely times sequences of pressures and flows to accomplish slow insertion, or withdrawal, of the control rods for power control, while providing rapid insertion for reactor scram.

Although the HCU is field installed and connected to process piping, many of its internal parts differ markedly from process piping components because of the more complex functions they must provide. Thus, although the codes and standards invoked by the Group A, B, C, and D pressure integrity quality levels clearly apply at all levels to the interfaces between the HCU and the connecting conventional piping components (e.g., pipe nipples, fittings, simple hand valves, etc), it is considered that they do not apply to the specialty parts (e.g., solenoid valves, pneumatic components, and instruments).

Table 3.2-1 (Cont'd)

The design and construction specifications for the HCU do invoke such codes and standards as can be reasonably applied to individual parts in developing required quality levels, but these codes and standards are supplemented by additional requirements for these parts, and for the remaining parts and details. For example, all welds are liquid penetrant inspected; all socket welds are inspected for gap between pipe and socket bottom; all welding is performed by qualified welders; and all work is done by written procedures.

The following examples are typical of the problems associated with codes designed to control field assembled components when applied to the design and production of factory fabricated specialty components:

A. The HCU nitrogen gas bottle is a punch forging that is mechanically joined to the accumulator. It stores the energy required to scram a drive at low vessel pressures. It has been code stamped since its introduction in 1966, although its size exempts it from mandatory stamping. It is constructed of a material listed by ASME B&PV Code Section VII that was selected for this strength and formability.

B. The scram accumulator is joined to the HCU by a split flange joint chosen for its compact design to facilitate both assembly and maintenance. Both the design and construction conform to ANSI B31.1, Power Piping Code, This joint, which requires a design pressure of 1750 psig, has been proof tested to 10,000 psi.

C. The accumulator nitrogen shutoff valve is a 6000 psi cartridge valve whose copper alloy material is listed by ASME Section VIII. The valve was chosen for this service partly because it is qualified by the U.S. Navy for submarine service.

D. The directional control valves are solenoid pilot-operated valves that are subplate mounted on the HCU. The valve has a body specially designed for the HCU, but the operating parts are identical to a commercial valve with a proven history of satisfactory service. The pressure-containing parts are stainless steel alloys chosen for service, fabrication and magnetic properties. The manufacturer cannot substitute a code material for that used for the solenoid core tube.

The foregoing examples are not meant to justify one pressure integrity quality level or another, but to demonstrate that the codes and standards invoked by those quality levels are not strictly applicable to special equipment and part designs. Group D Classification is generally applicable, supplemented by the QC techniques described above. Thus, the HCU is classified as "Special Equipment".

(15) Quality Group B on the CRD insert and withdraw lines and scram discharge lines extends from the drive flange up to, and including, the first valve on the HCU.

(16) The RWCU pump suction piping from its tap off the recirculation loop up to and including the first valve outside primary containment (HV-44-F004) is classified Group A. The piping between valve HV-44-F004 up to and including the second valve (HV-44-F040) is classified Group B. The remainder of the pump suction piping is classified Group C.

Table 3.2-1 (Cont'd)

The RWCU system discharges into the feedwater lines and the RCIC line. There are three RWCU discharge paths: a tap into the RCIC line outside containment, a tap to feedwater loop A outside containment, and a tap to feedwater loop A inside containment. The RWCU piping upstream of the feedwater outboard containment isolation valve (HV-44-F039) is classified Group C. Valve HV-44-F039 and piping up to the feedwater and RCIC line taps (outside primary containment) is classified Group B. The RWCU tap into the feedwater line inside primary containment is classified Group B up to the outboard containment isolation valve (41-1016). Valve 41-1016 and piping up to the tap into the feedwater line is classified Group A.

(17) The HPCI and RCIC turbine do not fall within the applicable design codes. To ensure that the turbine is fabricated to the standards commensurate with their safety and performance requirements, GE has established specific design requirements for this component in their specification.

(18) Certain major liquid, solid, and gaseous radwaste system components were designed, fabricated, procured, installed, and tested to the requirements of ASME Section III, Class 3, prior to May 1978. After May 1978, radwaste and deep bed spent resin system design, fabrication, materials, procurement, installation, and testing are at a minimum, in accordance with quality group D and the intent of Regulatory Guide 1.143 (Rev 1), subject to the following clarifications and exceptions:

A. Certain atmospheric tanks are welded to API/AWS standards in lieu of ASME Section IX.

B. Curbs or elevated thresholds are not provided for indoor tanks because of the watertight integrity of the surrounding structure.

C. Hydrotest pressure is held for 10 minutes, in accordance with ASME Section III, rather than 30 minutes. When in-place pressure testing is not practical, the tie-in welds will be examined via NDE per ANSI B31.1.

D. The radwaste enclosure is designed in accordance with seismic Category I criteria (Section 3.8.4). LGS does not use Regulatory Guide 1.60, as stated in Section 1.8. Alternate methods are discussed in Sections 3.7 and 3.8.

E. LGS's quality program during construction did not require audits of activities associated with radwaste systems, and items of nonconformance and their regulation are not always documented. Beginning February 14, 1983, auditing or monitoring is required for activities associated with radwaste systems, and items of nonconformance and their regulation shall be documented.

F. Cleaning and welding of piping is conducted in accordance with the specified piping quality group.

Table 3.2-1 (Cont'd)

G. Inspection of all Q-listed instrument installation is performed by Bechtel QC personnel. Inspection of BOP instrumentation installations is performed by Bechtel field engineering personnel. In addition, final inspection of instrumentation up to the first root valve is performed by PECo QC personnel. Calibration and functional testing of all instrumentation is performed by PECo personnel.

Decontamination equipment and facilities are associated with the liquid radwaste system and are not safety-related.

(19) See Section 3.2.2 for discussion of conformance to Regulatory Guide 1.26.

(20) These components and associated supporting structures must be designed to retain structural integrity during, and after, the SSE, but do not have to retain operability for protection of public safety. The basic requirement is prevention of structural collapse, and damage to equipment and structures required for protection of the public safety and health.

(21) The basis for classification of non-ASME Section III equipment as Quality Group B is given in Section 3.2.2.g.

(22) Diesel fuel oil storage tanks and transfer pumps were designed to ASME Section III, Class 3 but were not stamped.

(23) The structural design of seismic Category I and IIA HVAC ducts was verified by testing duct specimens as permitted by the AISI Code, to substantiate the duct width to duct sheet thickness ratio (w/t) and cut height to duct sheet thickness ratio (h/t) of up to 1500. Seismic Category II ducts were designed and constructed in accordance with SMACNA.

(24) Regulatory Guide 1.52 (July 1976) suggests various industry standards and codes for this equipment. These references were used for system design, with exceptions as noted in Section 6.5.

(25) Dampers with electro-hydraulic operators were designed to IEEE 323. Fire dampers are labeled by UL.

(26) Portions of ducts and dampers in the reactor enclosure and refueling floor HVAC system are seismic Category II non Q-listed, and the remainder are seismic Category I, Q-listed.

(27) For discussion of design criteria related to TMI Action Plan requirements, see Section 1.13.2.

(28) The main steam system from its outer isolation valve up to, but not including, the turbine stop valve and bypass valve chest, and all branch lines 2½ inches in diameter and larger up to, and including, the first valve (including their restraints), will be designed by the use of an appropriate dynamic seismic-system analysis to withstand the OBE and SSE design loads in combination with other appropriate loads, within the limits specified for Class 2 pipe in the ASME Section III Code. The mathematical model for the dynamic seismic analyses of the main steam system and branch line piping includes the turbine stop valves and the piping from the stop valves to the turbine casing. The dynamic input loads for design of the

Table 3.2-1 (Cont'd)

main steam system are derived from a history model analysis (or an equivalent method) of the reactor and applicable portions of the turbine building. An elastic multi-degree-of-freedom system analysis is used to determine the input to the main steam system. The allowable stress and associated deformation limits for piping are in accordance with the ASME Section III Class 2 requirements for the OBE loading combinations. The main steam system supporting structures (those portions of the turbine enclosure) are such that the main steam system and its supports can maintain their integrity.

(29) The following qualification has been met with respect to the certification requirements:

A. The manufacturer of the turbine stop valves, turbine control valves, turbine bypass valves, and main steam leads from turbine control valve to turbine casing has used quality control procedures equivalent to those defined in GE Publication GEZ-4982A, "General Electric Large Steam Turbine-Generator Quality Control Program".

B. The manufacturer of these valves and steam leads has certified that the quality control program so defined has been accomplished.

(30) This section of steam piping was seismically analyzed to ensure that it will not fail under loadings normally associated with an SSE.

(31) The main steam loads from the turbine control valve to the turbine casing meet all of the requirements of Group D, plus the addition of the following requirements:

A. All longitudinal and circumferential butt weld joints are radiographed (or ultrasonically tested to equivalent standards). Where size or configuration does not permit effective volumetric examination, magnetic particle or liquid penetrant examination may be substituted. Examination procedures and acceptance standards are at least equivalent to those specified in appropriate sections of ANSI B31.1.

B. All fillet and socket welds are examined by either magnetic particle or liquid penetrant methods. All structural attachment welds to pressure-retaining materials are examined by either magnetic particle or liquid penetrant methods. Examination procedures and acceptance standards are at least equivalent to those specified in appropriate sections of ANSI B31.1.

C. All inspection records are maintained for the life of the plant. These records include data pertaining to qualification of inspection personnel, examination procedures, and examination results.

(32) The classification of the feedwater line from the reactor vessel through the second isolation valve is Group A. The classification of the feedwater line from the second isolation valve through the third valve is Group B. Beyond the third valve the classification is Group D.

(33) The listed design criteria apply to the external and internal structure of each enclosure. Refer to Sections 3.7 and 3.8 for discussion of seismic design and Category I structure design, respectively.

Table 3.2-1 (Cont'd)

(34) The following construction activities are conducted under the quality assurance program to ensure that the pond will perform its safety function:

A. Inspection and treatment of the rock surface at the pond bottom and sides to ensure that permeability requirements are met.

B. Final survey and measurement of the as-built pond to ensure that the water volume and side slopes satisfy design requirements.

C. Performance of a seepage test to ensure that the design basis seepage rate assumptions are not exceeded.

In addition, material used for treatment of fracture zones and capping observation wells is Q-listed.

(35) The pond is built completely by excavation. Ability to meet seismic Category I criteria is verified by measurement of as-built side slope areas (see Note 34.b) to ensure that design requirements are met.

(36) Includes unreinforced concrete used for support column foundations.

(37) The final survey and measurement of the as-built emergency spillway are conducted under the applicable portions of the QA program to ensure that the geometry satisfies design requirements.

(38) A complete description of the codes and standards, seismic category, and Q-list status of piping and instrumentation within the spray pond is shown on drawing M-12.

(39) Containment isolation barriers listed in Table 6.2-17 are Q-listed. Containment isolation valves are also included in the entries for each applicable system in this table.

(40) Specific components that comprise parts of major components with the same design criteria are generally not listed. For example, transformers are a part of load centers or switchgear, and valves operators are a part of motor-operated valves. Class 1E valve operators are in compliance with IEEE 323 and IEEE 344.

(41) Raceway systems include conduit, cable trays, and their supports. Raceway fire stops and seals are not Q-listed. However, quality control provisions commensurate with BTP CMEB 9.5-1 are applied to the raceway fire stops and seals.

(42) Inverters do not supply power to safety-related loads. The Class 1E battery loads are discussed in Section 8.3.2.1.1.4.

(43) Primary, backup and fault current protection devices are subcomponents of switchgear, load centers, MCC and distribution panels, which are Q-listed as shown in items X.A, X.B and X.C.

(44) Exhaust piping beyond the roof penetration is not Q-listed.

Table 3.2-1 (Cont'd)

(45) Equipment is qualified in accordance with the conformance statements made in Section 7.2, 7.3, 7.4, 7.5, and 7.6 in reference to IEEE 279 paragraph 4.4 and IEEE 323.

(46) Primary containment gas sample lines from the sample taps to and including the outboard containment isolation valves are seismic Category I. Liquid sample lines from the RHR system are seismic Category I up to and including the second system isolation valves. The sample line from the jet pump instrument system is seismic Category I to the PASS isolation valves.

(47) Delineation of applicable codes or standards and seismic category is shown in applicable piping specification for line class as indicated in drawing M-20 and in vendor manual for on-skid piping. The basis for classification of non-ASME Section III equipment as Quality Group C is given in Section 3.2.2.d.

(48) Supports associated with this piping are constructed in accordance with quality assurance and seismic Category I requirements.

The parts of the ESW system that are seismic Category IIA are indicated on drawing M-11. Nonseismic Category I drain and vent lines and capped ends extending from seismic Category I piping are seismic Category IIA downstream of the last isolation valve.

The operator may also elect to provide ESW to the following nonseismic Category I equipment:

A. RECW heat exchanger

B. TECW heat exchanger

C. Reactor recirculation pump seal and motor oil coolers.

ESW flow to and from these components is controlled by redundant key-locked remote manual valves for RECW and TECW and locked closed manual valves for the recirculation pump.

(49) The reactor vessel support skirt is designed to ASME Section III, Class I, subsection NF criteria.

(50) CRD housing supports are designed in accordance with the AISC code.

(51) Equipment is qualified in accordance with the conformance statements made in Section 7.6.

(52) The original design was to ASME Section III. The actual requirements are that of ANSI B31.1. The cleaning and welding of piping is conducted in accordance with the specified piping quality group.

(53) The basis of classification of non-ASME Section III equipment as Quality Group C is given in Section 3.2.2.e.

Table 3.2-1 (Cont'd)

(54) The basis for classification of non-ASME Section III equipment as Quality Group C is given in Section 3.2.2.h.

(55) Short welded sections of ANSI B31.1 piping in the turbine stop valve seat drains, stop valve leak-offs, governing valve leak-offs, casing drains, ring drains, chest drains, and turbine shaft seal leak-offs that cannot be hydrotested will be inservice tested to ANSI B31.1 requirements and the welds will be surface examined.

(56) The basis for classification of non-ASME Section III equipment as Quality Group C is provided in Section 3.2.2.i.

(57) The basis for classification of non-ASME Section III equipment as Quality Group C is provided in Section 3.2.2.j.

(58) This piping was purchased and constructed to Quality Group C requirements and was subsequently upgraded to Quality Group B by volumetrically examining all circumferential welds over two inches using radiography. Visual examination will be performed inservice in accordance with the Inservice Inspection Program.

(59) The containment spray nozzles are fabricated to manufacturer's standards. Inservice inspection requirements will be consistent with Quality Group B requirements.

(60) Spray pond nozzles and junction boxes were designed and built to ASME III, Class 3 requirements, except that they were not N-stamped by the manufacturer. No manufacturer had an N-stamp at that time.

(61) ESF also include those systems in Chapter 6 and Table 6.1-1. Although RCIC is not an ESF, it is listed in this subsection because, although not required to mitigate the consequences of an accident, it may be used.

(62) The reactor internal structures, other, include the steam dryer, shroud head and steam separator assembly, incore guide tubes and incore guide tube stabilizers, differential pressure and liquid control lines inside the RPV, fuel orifices, and feedwater spargers. These structures are neither required for safe shutdown of the plant nor will their failure jeopardize the safety function of other safety-related reactor internals. Differential pressure and liquid control lines inside the RPV that form part of the RCPB are Q-listed. With the exception of these lines, the aforementioned components are not safety-related, are not Q-listed, and are not under 10CFR50, Appendix B. However, they are inspected as part of the inservice inspection program which is included in the operations phase of the QA Plan.

(63) Control room emergency lighting meets seismic Category I requirements as described in Section 9.5.3.2.2.

(64) The metal components for the primary containment (including hatches, liner plate, penetration sleeves, and downcomers) are designed and fabricated in accordance with the principal codes and standards noted in this table and Sections 3.8.1 and 3.8.2, but are not N-stamped except the personnel airlock.

Table 3.2-1 (Cont'd)

(65) Prefilters for the refueling area to SGTS alignment are installed in the refueling area duct-work. Prefiltering for the reactor enclosure to SGTS alignment is provided by the RERS.

(66) The tees supporting the vacuum relief valves are fabricated from ASTM material and welded into the downcomers. All welds have been radiographed.

(67) Exceptions: Valves HV-046-127, 128, 227, and 228 are seismic Class I and Q-listed. Isolation signals must close these block valves to prevent bypass leakage. Valves HV-046-125, 126, 225, and 226 are also seismic Class I and Q-listed. The piping and valves from the HCUs to and including the Containment Isolation Valves 46-1101, 46-1102, 46-1108, 46-1109, 46-1115, 46-1116, 46-1122, 46-1123, 46-2101, 46-2102, 46-2108, 46-2109, 46-2115, 46-2116, 46-2122, and 46-2123 are equivalent to ASME Section III, Class 2, seismic Class I and are Q-listed.

(68) The SLCS storage tanks were purchased before Article NC-3800 on atmospheric storage tanks was included in the ASME Section III, Class 2 code, and were hence designed and fabricated to API 650 and supplemental requirements at the time of purchase as discussed in Section 3.2.2(k).

(69) All three of the Unit 1 and one of the Unit 2 SLCS pump discharge accumulator vessels were purchased to ASME Section VIII, Division 1. These weldless vessels, except for the code stamping, also meet the ASME Section III, Class C requirements. Per Table 3.2-3, vessels purchased prior to July 1, 1971, are purchased to ASME Section III, Class C rather than Class 2.

(70) The HPCI turbine exhaust line globe stop-check valves were manufactured to ANSI B31.1 (1967), ANSI B16.5, and MSS-SP-66. They have been shown to meet the requirements of 1968 Draft ASME Code for Pumps and Valves and the nondestructive inspection requirements of ASME Section III.

(71) The shell side of the nonregenerative heat exchangers is constructed to ASME Section VIII, Division 1 and TEMA R.

(72) The core support structure was designed and procured prior to the issuance of subsection NG of ASME Section III. However, an earlier draft of the ASME Code was used as a guide in developing the design criteria in lieu of subsection NG.

Subsequent to the issuance of subsection NG, NG-3000 has been used, for evaluation purposes, in the core support structure evaluation. A detailed comparison between the original design basis and Appendix F (referenced by NG-3000) shows that the two sets of limits have no significant differences.

(73) The sample coolers were manufactured to the equivalent of ASME VIII, Division 1, but not code stamped. It was not customary at the time of manufacture to code stamp these coolers.

Table 3.2-1 (Cont'd)

(74) The safety-related portions of the HVAC systems are designed, fabricated, erected, and tested to quality standards commensurate with the safety function to be performed. Fans, filters, plenums, dampers, and duct-work in these systems are not classified as piping or pressure vessels and, as such, do not fall under the jurisdiction of ASME Section III. All of the equipment in these systems performing safety-related functions is Q-listed and seismic Category I, and all electrical components performing safety-related functions are environmentally qualified in accordance with Regulatory Guide 1.89. In addition, these systems provide substantial conformance with Regulatory Guide 1.52 as discussed in Sections 1.8 and 6.5.1 and Table 6.5-2.

(75) Includes shield walls identified by the plant shielding study (Section 1.13.2, Item II.B.2).

(76) Deleted

(77) Deleted

(78) Deleted

(79) The PASS does not function to mitigate the consequences of an accident. Therefore, with the exception of its interfaces with Q-listed systems, the PASS is not Q-listed. The PASS design is consistent with the guidance of Regulatory Guide 1.97 for the monitoring of Type E variables. While not a mitigating system, PASS is an integral part of the plant's capability to obtain and analyze samples and is therefore administratively controlled based on the guidance in Generic Letter 83-36, enclosure I.

(80) Select valves per QAD-M-15, to Unit 1 & 2 inflatable seals 1, 2, 3, 4, 7 and 10 are leak tested under the ASME section XI IST program but are not required to be installed to meet ASME class codes, but rather to ANSI B31.1 codes. These valves have been upgraded to meet seismic category I requirements and are Q-listed.

(81) Portions of the Air Start System have been downgraded to Seismic Category IIA as shown on drawing M-20. These portions were designed and installed to Seismic Category I standards, however, they do not perform a safety related function.

(82) Portion of external pneumatic connection beyond 59-*137 is seismic category IIA. The remainder of Item F.6 is seismic category II.

(83) The Emergency Diesel Generator Air Cooler Coolant, Jacket Water, and Lube Oil Cooler Heat Exchangers, sub-assembly parts purchased after 11/2000 have been procured in accordance with US NRC Generic Letter 89-09 and ASME Section III, Class 3 equivalent requirements.

(84) A portion of the piping connecting the Unit 2 RCIC Pump suction to the RHR heat exchangers has been downgraded to ANSI/ASME B31.1 Power Piping and Seismic Category IIA because it no longer serves a safety-related function.

(85) The original RPV strongback was replaced in 1994 with a RPV strongback carousel by GE that was designed and fabricated to ANSI N14.6-1978. GE later identified that the hook

Table 3.2-1 (Cont'd)

pins, clevis pins, and clevis rods did not meet the material testing as required by paragraph 3.2.6 of ANSI N14.6-1978. Because the new RPV strongback carousel was proof tested and is periodically inspected and load tested, its design function to provide a single-failure proof device to lift the RPV head during refueling is not impacted although it is not completely compliant to ANSI N14.6-1978.

(86) This system has been categorized under 10 CFR 50.69. See Section 13.5.5 for further information.

(87) Components within this system have been categorized under the 10 CFR 50.69 process. This is based on the 10 CFR 50.69 system boundaries as defined in the associated System Categorization Document. See Section 13.5.5 for further information.

Table 3.2-2

CLASSIFICATION AND CODE COMPLIANCE REQUIREMENTS FOR NON-NSSS MECHANICAL COMPONENTS

	CODE CLASSIFICATIONS			
COMPONENT	GROUP A	GROUP B	GROUP C	GROUP D[1]
Pressure Vessels	ASME B&PV Code, Section III, Nuclear Power Plant Components-CLASS 1	ASME B&PV Code, Section III, Nuclear Power Plant Components-CLASS 2	ASME B&PV Code, Section III, Nuclear Power Plant Components-CLASS 3[5]	ASME B&PV Code, Section VIII, Division 1
Piping Systems [4] (including pipe supports)	As above [3]	As above [3]	As above [3]	ANSI B 31.1 Power Piping
Pumps	As above	As above	As above	Manufacturer's Standards
Valves	As above	As above	As above	ANSI B 31.1
0-15 psig Storage Tanks	-	As above	As above	API 620, or ASME B&PV Code Section VIII, Division 1
Atmospheric Storage Tanks	-	As above	As above [2]	API 650, AWWA D 100, ANSI B 96.1, or ASME B&PV Code Section VIII, Div. 1

[1] Certain portions of the radwaste systems meet the additional requirements of Quality Group D (Augmented), as defined in BTP ETSB 11-1, Parts B.4 and B.5.

[2] Atmospheric storage tanks fabricated to Group C requirements may be used in a Group D or Group D (Augmented) system.

[3] ASME Section III piping systems (including pipe supports) are constructed in accordance with ASME Section III, 1971 Edition with Addenda through Winter 1971, except:

a. Piping material conforms to ASME Section III, 1971 Edition with Addenda through Winter 1971, ASME Section II, Part D 1999 Addenda of the 1998 Edition, or to later editions or addenda approved by the AE.

b. Field fabrication, installation, examination, and testing are in accordance with ASME Section III, 1974 Edition with Addenda through Winter 1974.

c. Paragraphs NC-4436 and ND-4436 of ASME Section III, 1980 Edition with Addenda through Winter 1981, is used for installation of attachments to Class 2 and 3 piping systems after testing.

Table 3.2-2 (Cont'd)

d. Pipe supports are constructed and installed in accordance with the 1969 Edition of ANSI B31.7 with Addenda approved March 10, 1971. Snubbers supplied through the architect-engineer are manufactured in accordance with ASME Section III, 1977 Edition with Addenda through Winter 1977, and installed in accordance with the 1969 Edition of ANSI B31.7 with Addenda approved March 10, 1971.

e. Stress analysis is in accordance with ASME Section III, 1971 Edition with Addenda through Winter 1972, except:

1. Class 1 piping systems stress analysis is in accordance with the 1977 Edition with Addenda through Summer 1979.

2. Class 2 and 3 flange stress analysis is in accordance with the 1977 Edition with Addenda through Summer 1979.

3. Unit 2 only. The SIF values for nuclear class 2 and 3 weldolets, sockolets and half coupling branch connections are in accordance with the 1974 Edition of the code.

f. Containment penetration flued heads are manufactured in accordance with ASME Section III with Addenda through Summer 1974, and installed in accordance with item b above. Diaphragm penetration flued heads are manufactured in accordance with ASME Section III, 1980 Edition with Addenda through Winter 1981, and installed in accordance with item b above.

g. Group B and C instrument sensing lines that are attached to Group A instrument sensing lines are hydrotested in accordance with ASME Section III, 1974 Edition with Addenda through Winter 1975.

h. Orifice plates (which are clamped between flanges and used in flow measuring service) that do not exceed ½ inch nominal thickness are not considered to be an ASME piping subassembly, part, appurtenance, component, or material in accordance with Paragraph NCA-1273 of ASME Section III, 1980 Edition with Addenda through Summer 1980.

i. For installation of instrument lines supplied through the architect-engineer, the minimum fillet weld size is in accordance with figure NB/NC/ND-4427-1 of ASME Section III 1980 Edition with Addenda through Summer 1980.

j. The NSSS piping systems supplied by GE and installed by the architect-engineer are installed in accordance with ASME Section III, 1974 Edition with Addenda through Winter 1974. Supports are manufactured and installed and snubbers are installed for the GE-supplied systems in accordance with ANSI B31.7, 1969 Edition with Addenda approved March 10, 1971. Snubbers are manufactured in accordance with ASME Section III, 1977 Edition with Addenda through Winter 1977.

k. Paragraph NB-4436 of ASME Section III, 1977 Edition, is used for installation of attachments to Class 1 piping systems after testing.

l. Subparagraph N(X)-4453.1 of ASME Section III, 1983 Edition with Addenda through Summer 1983, is used for making repairs to welds in Class 1, 2, and 3 piping systems.

m. Unit 2 only. Nameplate removal/replacement of N-stamped items shall be in accordance with the 1983 Edition through the Winter of 1984 Addenda, Paragraph NCA-8240.

n. Unit 2 only. Venting prior to hydrostatic test shall be in accordance with the 1980 Edition through the Summer 1981 Addenda, Paragraph NB/NC/ND-6211.

(4) CRD and TIP piping systems are constructed in accordance with ASME Section III, 1974 Edition with Addenda through Summer 1976. For evaluation of CRD insert/withdrawal piping interference with the CRD housing, Paragraph NC-3600 of the 1974 Edition with Addenda through Winter 1976 is used.

(5) The Emergency Diesel Generator Air Cooler Coolant, Jacket Water, and Lube Oil Cooler Heat Exchangers, sub-assembly parts purchased after 11/2000 have been procured in accordance with US NRC Generic Letter 89-09 and ASME Section III, Class 3 equivalent requirements.

Table 3.2-3

CLASSIFICATION AND CODE COMPLIANCE REQUIREMENTS FORNSSS MECHANICAL COMPONENTS

Group Classification	ASME III Code Classes 1968 Ed.	1971 Ed.	Components Ordered on or after January 1, 1970 to July 1, 1971	Components Ordered on or after July 1, 1971

Table 3.2-3 (Cont'd)

(1) Metal containment vessel (as applicable) and extensions of containment only.

(2) PECo's request to use alternative codes to those required in 10CFR50.55a for primary pressure boundary components was sent to the NRC on July 15, 1975. The applicable codes, code dates, and addenda are listed in the request letter for the following components that are still included in the LGS design:

a. PRV
b. Main steam SRVs
c. Main steam piping (26 inches) from RPV to second isolation valve
d. Main steam line suspension
e. Recirculation pump
f. Recirculation gate valves (motor-operated):
   28 inch suction
   28 inch discharge
g. Recirculation loop piping (28 inches)
h. Recirculation loop suspension
i. RHR valves
   20 inch gate valve
j. Core spray valves
   12 inch check valve (air operated)
k. Nuclear Class 1 piping (all except main steam and recirculation)

NRC approval of the request was given on November 18, 1975 in a letter from R.C. De Young (NRC) to E.G. Bauer (PECo).

The applicable code for design, fabrication, and testing of the MSIVs is the ASME Standard Code for Pumps and Valves for Nuclear Power - 1968 Draft including March 1970 Addenda.

Paragraphs NB-4433 and NB-3123.2 of the 1980 Edition of the ASME Section III are applicable for the design of hanger lugs welded to the main steam piping pressure boundary.

(3) Class D tanks shall be designed, constructed, and tested to meet the intent of API 620/650, AWWA D100, or ANSI B96.1

(4) For pumps classified Group D and operating above 150 psi or 212°F, ASME Section VIII, Division 1 shall be used as a guide in calculating the wall thickness for pressure- retaining parts and in sizing the cover bolting. For pumps operating below 150 psi and 212°F, manufacturer's standard pump for service intended may be used.

Table 3.2-3 (Cont'd)

(5) For pumps classified A, B, or C, applicable Subsections NB, NC, or ND respectively in ASME Section III shall be used as a guide in calculating the thickness of pressure-retaining portions of the pump and in sizing cover bolting.

(6) The SLCS storage tanks were designed and constructed to API 650; ASME Section III, Class 2 did not contain Article NC-3800 on atmospheric storage tanks at the time these tanks were purchased.

(7) All three of the Unit 1 and one of the Unit 2 SLCS accumulator vessels are ASME Section VIII, Division 1. The ASME Section III, Class C code requires only that these weldless vessels meet the ASME Section VIII, Division 1 standards, and hence, except for the code stamping, they meet all ASME Section III, Class C requirements.

(8) The HPCI turbine exhaust line globe stop-check valves meet the requirements of the cited code but were manufactured to ANSI B31.1 (1967), ANSI B16.5, and MSS-SP-66 requirements.

3.3 WIND AND TORNADO LOADINGS

3.3.1 WIND LOADINGS

Design wind loads for all exposed structures are based on Reference 3.3-1 and Reference 3.3-2.

3.3.1.1 Design Wind Velocity

Exposed structures are designed to withstand a basic wind velocity of 90 mph at 30 feet above ground. The recurrence interval of this wind velocity is estimated to be at least 100 years (Reference 3.3-1). A gust factor of 1.1 is used in conjunction with this basic wind velocity. The variation of wind velocity with height is given in Table 3.3-1.

3.3.1.2 Determination of Applied Forces

The dynamic pressures on the exposed structural surfaces due to the design wind are computed in accordance with the requirements of Reference 3.3-1, which are summarized as follows:

$$q = 0.002558V^2$$

where:

q = dynamic pressure (psf)

V = design wind velocity, mph

$$V = G\,(v)$$

where:

G = gust factor

v = basic wind velocity

The total design pressure for a structure is the product of dynamic pressure and shape coefficient. A shape coefficient of 1.3 is applied with all wind loads. This total design pressure is distributed among different exposed surfaces of the structure, on the basis of location with respect to the wind direction. Pressures and suction developed by using the above procedure and used in the design of plant structures are given in Table 3.3-1.

Table 3.3-4 provides a comparison between the maximum expected external pressure and the external design pressures. This table shows that an adequate margin of safety for wind loadings exists for the secondary containment structure.

3.3.2 TORNADO LOADINGS

Structures that directly affect the ultimate safe shutdown of the plant are designed to resist applicable design basis tornado forces. Table 3.3-2 lists the systems and components that are protected against tornados and the enclosures that provide this protection. The radwaste enclosure is tornado-resistant only to the extent of protecting the gaseous radwaste treatment system and retaining approximately 500,000 gallons of solid and liquid radwaste within the confines of the enclosure.

3.3.2.1 Applicable Design Parameters

Structures required to be tornado-resistant are designed for the following effects of a design basis tornado:

a. Dynamic wind loadings - These are the external pressure or suction forces on a structure due to the passage of a tornado funnel. The design basis tornado has a rotational speed of 300 mph and a translational speed of 60 mph. Conservatively, this is taken as a 300 mph wind applied uniformly over an entire structure.

b. Differential pressures - When the low pressure within a tornado funnel engulfs a structure, a rapid depressurization occurs and produces differential pressures between the inside and outside of the structure and between the compartments inside the structure depending on the available vent paths. The pressure transient caused by the design basis tornado is a 3 psi pressure drop at the rate of 1 psi/sec, followed by a 2 second calm and then a repressurization to the original pressure at a rate of 1 psi/sec.

c. Tornado missiles - The types of missiles postulated to be generated by a tornado are discussed in Section 3.5.1.4.

Regulatory Guide 1.76, "Design Basis Tornado for Nuclear Power Plants", calls for a pressure drop of 3 psi at the rate of 2 psi/sec, however, the increased depressurization rate of 2 psi/sec in Regulatory Guide 1.76 would have no significant effect on the external structural elements of tornado-resistant structures. These structures are designed for the maximum pressure differential due to a tornado of 3 psi regardless of the rate of depressurization.

The increased depressurization rate would increase the maximum differential pressure for internal structural elements. These elements were checked for the maximum differential pressure caused by the following design basis tornado pressurization profile: a 1 psi/sec pressure decrease for 3 seconds; a 2 second calm; a 1 psi/sec pressure increase for 3 seconds. An analysis to determine the effects of the increased maximum differential pressures on the internal structural elements has not been performed because the 1 psi/sec depressurization rate is considered to be conservative. The design basis tornado pressurization profile used was committed to in the LGS PSAR, Appendix C, Section C.2.4, prior to the issuance of Regulatory Guide 1.76. This pressurization profile was based on Reference 3.3-4. Previous documents used as the design basis for tornado effects were References 3.3-5 and 3.3-6. Actual tornado parameters were developed by studies of the tornado damage, eyewitness accounts of the maximum tornado depressurization on barometric instruments, and analysis of films of actual tornadoes. The depressurization effects defined in References 3.3-4, 3.3-5, and 3.3-6 substantiate the conservatism of the 1 psi/sec depressurization rate because they exceed the observed effects of actual tornadoes.

To further demonstrate the conservatism of the 1 psi/sec depressurization rate, site specific tornado parameters have been determined for LGS using the methodology of Reference 3.3-7. This reference is the basis document for Regulatory Guide 1.76.

In accordance with Regulatory Guide 1.76, LGS is in zone I, a region which encompasses a wide variation of tornado risks, from high tornado risk areas such as the Midwest to low risk areas such as New England. For the following analysis, a site specific tornado risk data base is used to determine the design basis tornado parameters.

Tornado data was obtained from the National Severe Storms Forecast Center for the years 1950 through 1981 for an area 125 nautical miles in radius centered on Pottstown, Pennsylvania. During this period, these were 322 tornadoes, or 10.1 tornadoes per year.

The probability that a tornado will strike a particular area is given by Reference 3.3-7 as:

$$P_s = \bar{n}\ (a/A)$$

where:

P_s = tornado strike probability

$\bar{n}$ = average number of tornadoes per year

a = average individual tornado area

A = land area within 125 nm of Pottstown (1 square nautical mile = 1.32 square miles)

From the tornado data, tornado areas were calculated for 307 tornadoes (data was not available for 15 tornadoes). The average area was 0.24 square miles. The land area within 125 nm of Pottstown is approximately 53,500 square miles (the total area is 64,900 square miles), of which 82% is land area. Therefore, the average probability of a tornado strike is:

$$P_s = \frac{10.1(0.24)}{53{,}500} = 4.6\times10^{-5} \text{ per year}$$

In accordance with Reference 3.3-7, the probability of occurrence of a tornado that exceeds the design basis tornado should be on the order of 10^{-7} per year to adequately protect public health and safety. Therefore:

$$P_s \cdot P_i \leq 10^{-7}$$

where:

P_i = acceptable intensity probability

Thus,

$$P_i = 10^{-7}/4.6\times10^{-5} = 2.2\times10^{-3} \text{ per year} = 0.22\%$$

Each tornado in the tornado data base has been classified according to a wind speed scale (the Fujita parameters). The distribution of tornadoes with respect to wind speed is given in Table 3.3-3. The cumulative distribution from Table 3.3-3 is plotted in Figure 3.3-1. Using Figure 3.3-1, the maximum wind speed corresponding to a probability P_i of 0.22% is 280 mph.

To determine the rotational and translational components of the maximum wind speed, the values obtained from table 4 of Reference 3.3-7 are used for interpolation. The values thus obtained are translational wind speed of 56.5 mph and rotational wind speed of 223.5 mph.

The depressurization rate is calculated by Reference 3.3-7 as follows:

$$\frac{dp}{dt} = \frac{T}{r_m} \rho V_m^2$$

where:

p = pressure

t = time

T = translational wind speed

V_m = rotational wind speed

ρ = density of air

r_m = radius of maximum rotational wind speed

From table 4 and table 5 of Reference 3.3-7, the parameters for a Region I design basis tornado are:

T = 70 mph

V_m = 290 mph

$\frac{dp}{dt}$ = 2 psi/sec

Therefore, by ratio

$$\frac{dp_2}{dt} = \frac{dp_1}{dt} \frac{T_2 V_{m2}^2}{T_1 V_{m1}^2} = \frac{2.0 \cdot 56.5 \cdot (223.5)^2}{70 \cdot (290)^2}$$

= 0.96 psi/sec

These site specific tornado parameters are less limiting than the values used for the design basis tornado in Section 2.3.1.

3.3.2.2 Determination of Forces on Structures

The procedures used to transform the tornado loadings into effective loads on structures are described below under separate headings for each parameter described in Section 3.3.2.1.

a. Dynamic wind loadings - The procedure used to transform the tornado wind velocity into an effective pressure is the same as described in Section 3.3.1.2, with the following exceptions: velocity and velocity pressure are not assumed to vary with height, and a gust factor of 1.0 is used. The resulting pressure loadings are as follows:

1. Pressure on windward side (0.8q) 185 psf

2. Suction on leeward side (0.5q) 115 psf

3. Total pressure on structure (1.3q) 300 psf

4. Uplift on roof (0.6q) 140 psf

b. Differential pressures - The maximum differential pressure between the inside and outside of fully enclosed areas is taken as 3.0 psi. Blowout panels are provided where necessary to lower the design differential pressures. For vented compartments, a flow analysis of all interconnecting air volumes is performed and the maximum transient pressure differentials across walls, floors, and roofs are calculated. All structural components in the vented and nonvented compartments are then checked to confirm that they can withstand the maximum calculated transient differential pressure.

c. Tornado missiles - The procedures and methods outlined in Reference 3.3-3 are used to transform the dynamic loads into effective loads and to determine the structural response of the elements subjected to missile impingement.

All of the above design basis tornado loadings are considered as loadings that act simultaneously.

Analytical techniques were used for estimating the values of tornado parameters for purposes of design with an adequate level of conservatism. Although the tornado parameters used in the LGS external design pressure analyses differ slightly from those defined in Regulatory Guide 1.76, the LGS analyses are either equivalent or conservative compared to analyses using the Regulatory Guide 1.76 parameters (Section 2.3.1.2.4). The use of these parameters for calculating the external design pressure ensures an adequate margin above the maximum expected external pressure.

3.3.2.3 Effect Of Failure Of Structures Or Components Not Designed For Tornado Loadings

Structures such as the turbine enclosure and outdoor storage tanks, which are not designed for tornado loads, are investigated and checked to ensure that they cannot produce missiles that have more severe effects than those listed in Section 3.5.1.4. The modes of failure of these structures are analyzed to verify that their failure due to tornado loading cannot prevent structures or components needed for safe shutdown from performing their intended functions.

NOTE * The SGTS and the RERS are provided to reduce airborne radiation concentrations in the secondary containment prior to release to the environment for low probability events such as a LOCA. They are not required to achieve safe shutdown. In accordance with Regulatory Guide 1.117, such systems are not required to be protected against tornadoes. However, they are totally enclosed in the reactor enclosure and control structure, which are tornado-resistant enclosures.

Table 3.3-3

WIND SPEED AND CUMULATIVE WIND SPEED DISTRIBUTION FOR TORNADOES WITHIN 125 nm OF POTTSTOWN, PA

Wind Speed Classification	No. of Tornadoes	Percent of Total	Cumulative Percentage
F5 (261 - 308 mph)	0	0.0	0.0
F4 (207 - 260 mph)	0	0.0	0.0
F3 (158 - 206 mph)	15	4.9	4.9
F2 (113 - 157 mph)	93	30.2	35.2
F1 (73 - 112 mph)	154	50.2	85.3
F0 (40 - 72 mph)	43	14.0	99.3
F-1 (<40 mph)	2	0.7	100.0

Table 3.3-4

CALCULATION OF MARGIN BETWEEN DESIGN
AND MAXIMUM EXPECTED WIND LOADINGS

Height Above Ground (Feet)	Fastest Mile[1] (mph)	Max. Expected Wind Pressure on Wall[2] (psf)	Basic Wind Velocity[3] (mph)	Total Design Pressure on Wall[3] (psf)	Margin[4]
30	82	27	90	33	1.22
100	97	38	105	44	1.16
200 (Reactor Enclosure Roof)	108	47	125	63	1.34
300	114	52	125	63	1.21

(1) The fastest mile values of wind are taken from Table 2.3.1-8.

(2) The maximum expected wind pressure on the wall included a gust factor of 1.1 and a shape factor of 1.3 corresponding to its respective fastest mile velocity. The approach described in Section 3.3.1.2 can be used to calculate the maximum expected wind pressure, i.e., $0.002558 (\text{fastest mile } V \cdot 1.1)^2 \cdot 1.3$ or $0.004024V^2$.

(3) Data are taken from Table 3.3-1.

(4) The horizontal and vertical components of the wind pressure are based on the height above ground. Therefore, the margin associated with roof pressure (suction) will be the same as that due to the horizontal pressure on the walls (i.e. 34%).

3.4 WATER LEVEL (FLOOD) DESIGN

3.4.1 FLOOD PROTECTION

3.4.1.1 Flood Protection Measures for Seismic Category I Structures

Seismic Category I structures and the safety-related systems and components housed within them are listed in Table 3.4-1. As discussed in Section 2.4.2.2, the design basis flood level of the Schuylkill River at the site is 207 feet, including wave activity. The shortest horizontal distance from the contour at el 207' to the nearest safety-related structure is approximately 200 feet. Grade level is no lower than el 215' at any of the safety-related structures, and none of the safety-related structures has exterior openings below el 217'. Therefore, the safety-related structures are secure from Schuylkill River flooding and no special provisions for flood protection are necessary. Flooding from internal events is discussed in Section 3.6.1. The impact of local intense precipitation is discussed in Section 2.4.2.3.

Table 2.4-1 lists the access openings in safety-related structures. Two of these doors are below the design basis flood (el 207' MSL) but do not represent a flooding concern. The doors between the reactor enclosure and water pipe tunnel room 202 at el 201' are watertight. The doors between the control structure and the turbine enclosure at el 200' are watertight because the turbine enclosure is not watertight against the PMP as discussed in Section 2.4.2.3.

The failure of nonseismic Category I and nontornado protected tanks, vessels, and major pipes located outside buildings (Table 3.4-2) has also been evaluated and determined to not adversely affect safety-related structures, systems, and components as discussed below.

Tank Failure

The location of tanks in the yard area is shown in Figure 3.8-58. Failure of the tanks on the west and south sides of the power plant complex (Table 3.4-2, items 1 through 5) will not cause potential flooding of safety-related structures, systems, and components. Any flooding due to a failure of these tanks will be contained within seismic Category IIA earth dikes, which will remain stable under both static and dynamic conditions. The design of the earth dikes is discussed in Sections 2.4.12 and 2.5.5.5.

The tanks on the north side of the power plant complex (Table 3.4-2, items 6 through 9) do not have seismically designed containments around them. Failure of these tanks could cause local flooding. This flooding would not adversely affect safety-related facilities for the following reasons:

a. Surface drainage in this area will drain water towards the Schuylkill River and Possum Hollow Run before it can reach the power plant complex.

b. Seismic Category I electrical cable and duct banks located in the vicinity of these tanks are adequate, as discussed below.

Even if the above dikes were to fail, there would be no impact on other safety-related structures, systems, or components due to site drainage.

Failure of Cooling Tower Basin Wall

The failure of the cooling tower basin wall (Table 3.4-2, items 10 & 11) would not adversely affect safety-related structures, systems, and components as discussed below.

The runoff pattern of water from the cooling tower basin wall failure would be similar to that caused by intense storm precipitation as discussed in Section 2.4.2.3 and shown in Figures 2.4-4, 2.4-5 and 2.4-6. Most of the flood water from the cooling tower basin would run away from the power plant complex. The worst case flood conditions for the power plant complex would be created by a failure of the south side of the Unit 1 cooling tower basin wall. For this case, a portion of the cooling tower basin water would flow towards the turbine enclosure. Although some limited turbine enclosure flooding may occur, there would be no impact on safety-related components.

The seismic Category I electrical cable and duct banks and valve pits located in the flow path of the water from the failed cooling tower basin are adequately protected as discussed below.

Failure of Circulating Water Conduit

Failure of the conduit within the yard area between the cooling tower basin and the turbine enclosure (Table 3.4-2, item 12) will cause flooding of this area. Water from the damaged conduit will erode the soil cover and flood the yard.

The runoff pattern will be similar to that shown in Figure 2.4-4. The seismic Category I electrical cable and duct banks and valve pits, located in this area are adequate, as discussed below.

In the most severe case, all the water from the cooling tower basin could drain through the damaged conduit into the yard area between the cooling water pumphouse and turbine enclosure and cause flooding of the condenser pit. However, safety-related systems and components would not be damaged, as discussed in Section 10.4.1.3.3.

Failure of Major Yard Piping

Failure of any of the pipes identified in Table 3.4-2, items 13 through 17, may cause local flooding. However, the intensity and volume of water discharge from any of the pipes is less than that of the cooling water conduit failure discussed above and would not cause damage to any safety-related facilities. Soil erosion caused by failure of these pipes is discussed in Section 3.8.4.1.6.

Safety-related structures, systems, and components, including underground cables, will not be adversely affected by flooding or wetting caused by (1) design basis flood, (2) design basis precipitation or (3) failure of an outdoor tank or tank truck.

The safety-related structures, systems, and components located within the yard area are shown in Figure 3.8-58. Excavation for seismic Category I structures, pipelines, electrical duct banks, manholes, and underground diesel oil storage tanks are shown in Figure 2.5-37.

The design basis flood is not applicable to structures and yard facilities. The design basis flood level with respect to the Schuylkill River is 207 ft (Section 2.4.2.2), which is 10 feet lower than the lowest grade level entrance to any of the safety-related facilities.

The protection of safety-related structures, systems, and components with respect to flooding caused by the design basis precipitation is discussed in Section 2.4.2.3. The runoff patterns for flood water caused by precipitation are shown in Figures 2.4-4 and 2.4-5. Below-grade parts of structures are protected from water intrusion as stated in Table 3.4-1.

The following seismic Category I yard facilities may be susceptible to flooding:

a. 5 Valve pits for RHRSW and ESW piping

b. 8 Valve pits for diesel generator fuel oil storage tanks

The valve pits may be temporarily covered with water during an intense storm or major failure of an outdoor tank. However, the following protective features have been provided to resist resultant flooding of these facilities:

a. They are built as reinforced concrete boxes and are equipped with solid steel manhole covers with gaskets.

b. The tops of slabs of these facilities are elevated 3 to 12 inches above grade.

c. The RHRSW/ESW valve pits are equipped with drain pipes leading seepage water into normal waste drainage system.

d. The diesel generator fuel oil storage tank valve pits' drain lines have been sealed off from the normal waste drainage system to minimize the potential for back flow from the downstream drainage pipe. Administrative controls shall assure that:

- These pits are periodically inspected (at least quarterly) at a frequency sufficient to assure that seepage water does not accumulate to a level at which it would enter the fuel oil tank or jeopardize safety related components in the pits.

- Accumulated seepage water is pumped out of the pits and out of the collection sumps of the concrete base surrounding the fuel oil storage tanks, as necessary.

- The pits are periodically inspected for material conditions adverse to pit flood resistance.

All electrical cables are designed to operate under water. Water absorption characteristics for all cables have been reviewed to confirm that even under flooded conditions, electrical cabling in manholes and duct banks will continue to operate properly. In addition, all electrical conduits that travel to electrical manholes outside the structures are sealed to prevent water from entering the structures through the electrical duct banks (Table 3.4-1).

The design features described above will also protect seismic Category I structures and yard facilities against internal flooding in case of failure of an outdoor tank or tank truck.

3.4.1.2 Permanent Dewatering System

All safety-related structures founded below the design basis groundwater levels can withstand the resulting hydrostatic loading. Safety-related systems and components not located within structures are founded above the maximum groundwater levels. Furthermore, the groundwater levels by safety-related structures, systems, and components are located below the top of rock. Therefore, a permanent dewatering system to protect safety-related structures, systems, and components is not required.

Groundwater does not affect the yard facilities because the design groundwater elevation (Section 2.4.13.5) is generally below yard facilities.

Rubberized flat dumbbell-type water stops have been provided at construction joints below the maximum expected groundwater level listed in Section 2.4.13.5 for all safety-related enclosures.

3.4.2 ANALYTICAL AND TEST PROCEDURES

The safety-related structures listed in Table 3.4-1 are built of reinforced concrete with below-grade exterior walls that are a minimum of 1 foot thick for yard structures and 2 feet thick for the remaining listed structures. The roofs and parapets of all safety-related structures have been analyzed to verify their ability to withstand the static loading resulting from any water confined on the top of the structures due to local intense precipitation (discussed in Section 2.4.2.3).

The safety-related structures founded below the design basis groundwater levels (see Section 2.4.13.5) have been analyzed to verify their ability to withstand the resulting hydrostatic loading.

The spray pond pump structure and other safety-related structures at the spray pond have been designed to withstand the maximum water level in the spray pond.

Table 3.4-1

FLOOD LEVELS AT SAFETY-RELATED STRUCTURES

	STRUCTURE	SAFETY-RELATED SYSTEM OR COMPONENTS HOUSED IN STRUCTURE	ELEVATION OF LOWEST EXTERIOR ACCESS OPENING[1]	DESIGN FLOOD ELEVATION
1.	Reactor Enclosure	Primary containment, ECCS, miscellaneous safety-related systems and components	217'-0"	207.0'
2.	Diesel Generator Enclosure	Diesel generator	217'-0"	207.0'
3.	Spray Pond and Spray Pond Pump Structure	ESW system and RHRSW system	268'-0"	254.9'[2]
4.	Miscellaneous Yard Structures	See Figure 3.8-58	See Figure 3.8-58	207.0'

(1) Penetrations below the lowest exterior access openings typically include underground electrical and piping penetrations. These penetrations are sealed water-tight.

(2) The design basis flood level for the spray pond pumphouse in based on the design basis flood level of the spray pond (Section 2.4.8.2.1).

Table 3.4-2

YARD TANKS AND MAJOR PIPING (NONSEISMIC)

ITEM NO.	TANK OR PIPE DESCRIPTION	CAPACITY OR FLOWS	LOCATION	TYPE OF CONTAINMENT	TORNADO PROTECTION
1	Unit 1 CST tank	200,000 gal.	West of power plant complex	Earth dikes	None
2	Refueling Water	550,000 gal.	West of power plant complex	Earth dikes	None
3	Unit 2 CST tank	200,000 gal.	South of power plant complex	Earth dikes	None
4	Fuel oil storage tank	200,000 gal.	South of power plant complex	Earth dikes	None
5	Deleted				
6	Deleted				
7	Deleted				
8	Clarified water tank	200,000 gal.	Water treatment plant north of power plant complex	None	None
9	Demineralized water tank	50,000 gal.	Water treatment plant north of power plant complex	None	None
10	Cooling tower Basin 1	$7x10^6$ gal.	North of power plant complex	Reinforced concrete walls	None
11	Cooling tower Basin 2	$7x10^6$ gal.	North of power plant complex	Reinforced concrete walls	None
12	Cooling water pipes 8.0 ft diam. 4 pressure pipe each unit	450,000 gpm per unit	Between cooling tower and turbine enclosure	Underground	Soil cover
13	36" ϕ makeup water pressure pipe	30,000 gpm	From Schuylkill River to cooling tower	Underground	Soil cover
14	36" ϕ blowdown gravity pipe	18,000 gpm	From cooling tower to Schuylkill River	Underground	Soil cover

Table 3.4-2 (Cont'd)

15	36" ϕ makeup water pressure pipe	30,000 gpm	From Perkiomen Creek to cooling tower	Underground	Soil cover
16	36" ϕ service water pressure pipe	35,000 gpm	From cooling tower to turbine enclosure	Underground	Soil cover
17	12" ϕ fire loop pressure pipe	2,500 gpm	Around plant complex	Underground	Soil cover

3.5 MISSILE PROTECTION

Where possible, the seismic Category I and safety-related structures, equipment, and systems are protected from missiles through basic station component arrangement so that the missile does not cause the failure of these structures, equipment, or systems. Where it is impossible to provide protection through plant layout, suitable physical barriers are provided to isolate the missile or to shield the critical system or component. Also, redundant seismic Category I components are suitably protected so that a single missile cannot simultaneously damage a critical system component and its backup system. Missile protection provides for either safe operation or shutdown during all operating conditions, operational transients, and postulated accident conditions. Table 3.2-1 provides a tabulation of safety-related structures, systems, and components, along with their applicable seismic category and quality group classification.

3.5.1 MISSILE SELECTION AND DESCRIPTION

3.5.1.1 Internally Generated Missiles (Outside Primary Containment)

There are three general sources of postulated missiles outside the primary containment:

a. Rotating component failure missiles

b. Pressurized component failure missiles

c. Gravitationally generated missiles

3.5.1.1.1 Rotating Component Failure Missiles

The systems located outside the primary containment have been examined to identify and classify potential missiles. Redundant equipment is normally located in different areas of the plant or separated by walls so that a single missile from a rotating mass does not damage both redundant systems.

Catastrophic failure of rotating equipment such as pumps, fans, and compressors leading to the generation of missiles is not considered credible. Massive and rapid failure of these components is unlikely because of the conservative design, material characteristics, inspections, quality control during fabrication and erection, and prudent operation as applied to the particular component.

Additionally, the bases for considering it unlikely for rotating components, other than those identified in this section, to break through their casings and adversely impact safety-related equipment are the following:

A review of event reports on file at the Nuclear Safety Information Center, Oak Ridge National Laboratory, concerning failures of fans and missile generation indicated that a few fan failures have resulted in generation of missiles in safety-related areas of a nuclear facility. Small pump failures resulting in generation of missiles are considered more improbable than fan failures resulting in generation of missiles because pump casings are generally thicker than fan casings and pump speeds are generally lower than fan speeds. Even in the unlikely event that a rotating component does break through its casing, much of the component's kinetic energy would be dissipated in moving through the casing, thereby decreasing the probability of the component adversely

damaging a safety-related component. Therefore, generation of secondary missiles from the internally generated missiles described above is not considered credible. It is an even lower probability that a rotating component would adversely affect redundant safety-related systems because redundant equipment is generally located in different areas or separated by barriers.

Large pumps, such as the RHR and CS pumps, are installed so that the impeller section is surrounded by concrete; additionally, these pumps are located in separate compartments. Therefore, they are not considered a missile hazard to other systems.

Missiles from HPCI or RCIC turbines would be contained by the walls of their compartments that form suitable barriers so that no other systems can be affected by a HPCI or RCIC turbine failure.

Other rotating equipment is not considered to constitute missile hazards because of its small size and/or the unlikelihood that it could move its rotating components through its housing. A review of the analyses of internally generated missiles performed for Palo Verde and San Onofre verified that postulated missiles from pumps and fans (e.g., a pump impeller or fan blade) typically do not have sufficient energy to penetrate the component casings. Because LGS uses pumps and fans that are generally designed and constructed in accordance with the same recognized industry codes and standards as those installed at Palo Verde and San Onofre, the results of the rigorous structural analyses conducted for those plants are indicative of the integrity of LGS equipment.

It was further verified that no internally generated missiles will cause loss of function of any system required for safe shutdown. The plant arrangement was reviewed to ensure that all essential systems or components are either remote from or separated by adequate barriers from potential missile sources.

In any case where a direct path exists between a potential missile source and equipment required for safe shutdown, potential missiles cannot impact more than a single component; therefore redundant equipment will be available to effect safe shutdown.

All HVAC fans located in safety-related enclosures are listed in Table 3.5-6, along with the reason why they are not credible missiles that could adversely affect redundant equipment needed for safe shutdown. For many fans, there are barriers that separate the potential fan blade missiles from essential systems. These barriers consist of walls, floors, and ceilings that totally enclose the potential missile and are sufficiently thick to prevent spalling. All redundant fans needed for safe shutdown are separated by adequate barriers. Class I seismic duct-work of a thickness substantially greater than normal duct-work is utilized in safety-related areas that have duct-work, which should preclude escape of a potential missile from connecting duct-work.

A review was also made of the fan installation drawings to ensure no inlet conditions to fans existed that could result in operating conditions that would impose cyclical fatigue on fan blades resulting in blade cracks. No such conditions exist.

The only fan blades that have the potential for damaging redundant components needed for safe shutdown, if they escape through their casing, are the drywell area unit cooler fans. A study was performed for these fans which demonstrated that the fan blades do not have sufficient kinetic energy to penetrate their casings. In addition, a complete physical inspection of all drywell unit cooler fan blades for blade angle, verification of proper torque on blade retaining bolts, and lock

wiring of the bolts by the manufacturer's representative was conducted to ensure that no blades would loosen during operation. This inspection is documented in the quality records.

3.5.1.1.2 Pressurized Component Failure Missiles

The following are potential internal missiles from pressurized equipment:

a. Valve bonnets

b. Valve stems

c. Temperature detectors

d. Nuts and bolts

Pressurized components in systems where service pressure exceeds 275 psig are evaluated as to their potential for becoming missiles.

Most valves of ANSI 900 psig rating and above and most valves of 600 psig rating, constructed in accordance with ASME Section III, are pressure seal bonnet type valves. For pressure seal bonnet valves, valve bonnets are prevented from becoming missiles by the retaining ring, which would have to fail in shear, and by the yoke, which would capture the bonnet or reduce bonnet energy. Because of the highly conservative design of the retaining ring of these valves, bonnet ejection is highly improbable and hence the bonnets are not considered credible missiles.

The remaining valves of ANSI rating 900 psig and below are valves with bolted bonnets. Valve bonnets are prevented from becoming missiles by limiting stresses in the bonnet-to-body bolting material by requirements set forth in the ASME Section III and by designing flanges in accordance with applicable code requirements. Even if bolt failure were to occur, the likelihood of all bolts experiencing simultaneous complete severance failure is remote. The widespread use of valves with bolted bonnets and the low historical incidence of complete severance failure of bonnets confirm that bolted valve bonnets need not be considered as credible missiles.

Valve stems are not considered potential missiles if at least one feature in addition to the stem threads is included in their design to prevent ejection. Valves with back-seats are prevented from becoming missiles by this feature. In addition, air or motor-operated valve stems are effectively restrained by the valve operators.

Temperature or other detectors installed on piping or in wells are considered highly improbable missiles, since a complete and sudden failure of a circumferential weld is needed for a detector to become a missile.

Nuts, bolts, nut and bolt combinations, and nut and stud combinations have little stored energy and thus are of no concern as potential missiles.

In addition, high pressure gas cylinders and accumulators are not considered credible internally generated missiles impacting on redundant safety-related equipment for the following reasons:

a. All accumulators located in areas that contain safety-related equipment are listed in Table 3.5-3, along with the maximum pressure and temperature at which they operate. These accumulators have low stresses and operate in the "moderate energy" range. Therefore, any failures would not be of concern for missile generation.

b. Safety-related gas cylinders and accumulators are seismically supported, which ensures that they will not become gravity-generated missiles during design basis conditions. Nonsafety-related cylinders and accumulators are seismically restrained if they are located in the vicinity of safety-related components.

c. High pressure gas (H_2, O_2, N_2, Kr) cylinders meet the manufacturing and test requirements of the DOT standards, 49CFR178.37, Specification 3AA and ICC standards. Vessel wall thickness requirements of both standards are comparable to ASME Section III, Class 3 requirements. Because of this highly conservative design, any failure of these cylinders that would cause them to become missiles is highly improbable.

d. Halon gas cylinders used in the fire protection system are located in the turbine enclosure and are isolated from safety-related equipment.

3.5.1.1.3 Gravitationally Generated Missiles

Installed equipment and components in safety-related plant areas outside containment are designed and installed so that they would not present gravitational missile hazards to safety-related structures, systems, or components during or after an SSE. This is achieved for safety-related equipment by seismic Category I design and installation (in accordance with Regulatory Guide 1.29 criteria) and for nonsafety-related equipment by seismic Category IIA design and installation (Section 3.2). Nonpermanently installed equipment is either removed from the safety-related areas, adequately separated from safety-related components, or secured in place before reactor operation to ensure that it would not present a missile hazard.

The information requested in the generic letter dated December 22, 1980 regarding conformance to the criteria contained in NUREG-0612, "Control of Heavy Loads at Nuclear Power Plants" is provided in Reference 9.1-1.

3.5.1.2 Internally Generated Missiles (Inside Containment)

There are three general sources of postulated missiles inside the primary containment:

a. Rotating component failure missiles

b. Pressurized component failure missiles

c. Gravitationally generated missiles

3.5.1.2.1 Rotating Component Failure Missiles

The most substantial piece of NSSS rotating equipment is the recirculation pump and motor. This potential missile source is covered in detail in Reference 3.5-1.

It is concluded in Reference 3.5-1 that destructive pump overspeed can result in certain types of missiles. A careful examination of shaft and coupling failures shows that the fragments do not result in damage to the containment or to vital equipment.

a. Low energy missiles (kinetic energy less than 1,000 ft-lbs):

   Low energy level missiles may be created at motor speeds of 300% of rated through failure of the end structure of the rotor. The structure consists of the retaining ring, the end ring, and the fans. Missiles potentially generated in this manner would strike the overhanging ends of the stator coils, the stator coil bracing, support structures, and two walls of ½ inch thick steel plate. Due to the ability of these structures to absorb energy, it is concluded that missiles would not escape this structure. It is at this point that frictional forces would tend to bring the overspeed sequence to a stop.

b. Medium energy missiles (kinetic energy less than 20,000 ft-lbs):

   In the postulated event that the body of the rotor bursts, medium energy missiles could be created. The likelihood that these missiles would escape the motor is considered less than the likelihood of escape for the low energy missiles described above, due to the additional amount of material constraining missile escape, such as the stator coils and stator frame directly adjacent to the rotor.

c. The motor as a potential missile:

   Since bolting is capable of carrying greater torque loads than the pump shaft, pump bolt failure is precluded. Since pump shaft failure decouples the rotor for the overspeed driving blowdown force, only those cases with peak torques less than that required to fail the pump shaft (five times rated) have the capability to drive the motor to overspeed. When missile generation probabilities are considered along with a discussion of the actual load-bearing capabilities of the system, it is evident that these considerations support the conclusion that it is unrealistic that the motor would become a missile.

It is concluded that the other rotating components inside the containment, such as fans, do not have sufficient energy to move the masses of their rotating parts through the housings in which they are contained and therefore are not considered missile hazards. Additional evaluation and discussion of the potential for rotating equipment generated missiles to impact safety-related equipment is provided in Section 3.5.1.1.1 above.

3.5.1.2.2 Pressurized Component Failure Missiles

It is concluded that potential internal missiles inside the containment from pressurized components are not considered credible for the same reasons listed in Section 3.5.1.1.2.

3.5.1.2.3 Gravitationally Generated Missiles

Installed equipment and components in the containment are designed so that they would not present gravitational missile hazards to safety-related structures, systems, or components during or

after an SSE. This is achieved for safety-related equipment by seismic Category I design and for nonsafety-related equipment by seismic Category IIA design, as discussed in Section 3.2. Nonpermanently installed equipment is either removed from the containment or secured in place before reactor operation to ensure that it does not become dislodged and present a missile hazard.

3.5.1.3 Turbine Missiles

The turbine inspection program which is being implemented in Section 10.2.3.6 uses a probabilistic approach for scheduling the inspection and replacement of the low pressure turbine rotors with shrunk-on discs. This turbine inspection program is based upon the missile probability analysis methodology in Reference 3.5-15 and the probabilistic approach established in NUREG 1048 (Reference 3.5-14). The approach in Reference 3.5-14 was found acceptable by the NRC for use in establishing maintenance and inspection schedules for specific turbine systems including the original Main Turbines installed at Limerick Generating Station. As a result of the replacement of the original Main Turbines, the missile probability analysis methodology in Reference 3.5-15 has been adopted to maintain the probabilistic approach to determine the inspection program for the installed turbine system. The overspeed protection system and turbine valve test interval was determined by References 3.5-16 and 3.5-17 in accordance with the missile probability analysis methodology in Reference 3.5-15.

The intent of the program is to ensure that the probability of a turbine generating a missile is maintained less than $1x10^{-5}$ per year. The program takes into account specific turbine wheel operating conditions, material properties, results of periodic in service inspections, and other factors. The program's determination of missile probability is based on the probabilities of individual parameters which may lead to the generation of the turbine missile. As a result, the program can facilitate evaluations of the effects of changes in any parameter. Table 3.5-9, Turbine System Reliability Criteria, has been extracted from table U.1 of Reference 3.5-14, for use with an unfavorably oriented turbine. The probability of unacceptable damage from turbine missile will be maintained at less than or equal to $1x10^{-7}$ per year.

Schedules for future inspection and replacement of low pressure turbine rotors with shrunk-on discs will be based on the probabilistic approach.

3.5.1.4 Missiles Generated by Natural Phenomena

Only tornado-generated missiles have been considered. Missiles used in the design and assessment of structures and openings are listed in Table 3.5-4. All safety-related structures, systems, and components listed in Table 3.2-1 were reviewed for adequacy against tornado-generated missiles listed in Table 3.5-4. These safety-related structures, systems, and components are designed either to resist tornado missiles in accordance with Reference 3.5-6 or are protected by these tornado-resistant enclosures. The structures designed for these tornado missiles and the systems protected are listed in Table 3.3-2. Table 3.5-8 provides information on the characteristics of these barriers. Additionally, ESW and RHRSW systems yard piping is protected by burial and separation of redundant loops.

The exterior walls and roof thicknesses have been evaluated for the tornado-resistant enclosures listed in Table 3.3-2 and are capable of withstanding all of the missiles listed in Table 3.5-4. The 4000 psi strength concrete walls and roofs have minimum thicknesses of 24 inches and 18 inches, respectively (Table 3.5-8). This exceeds the minimum acceptable missile barrier thickness requirements specified in table 1 of SRP (NUREG-0800, July 1981) section 3.5.3.

Where necessary to protect safety-related components, the doors in these enclosures have been designed to withstand the 1 inch steel rod, the utility pole, the 6 inch steel pipe, and the 12 inch pipe in addition to the original three design basis missiles. This design is in accordance with the SRP (NUREG-0800, July 1981).

The probability of any of the above tornado missiles penetrating any of the openings and structures (not specifically designed to be resistant to the above missiles) and adversely impacting safety-related components, such that safe shutdown is prevented, is considered low for the following reasons:

a. The total area of the nontornado-resistant features that have safety-related components located behind them is extremely small compared to the total area of the tornado-resistant portions of the enclosures.

b. To penetrate a nontornado-resistant feature and travel a sufficient distance to impact a safety-related component, a missile would need to strike the feature at a perpendicular angle.

c. Much of the missile's kinetic energy would be dissipated in breaking through the nontornado-resistant feature, which reduces the possibility of the missile adversely damaging a safety-related component even if it strikes one.

d. Redundant safety-related components are normally located in different areas of the plant or yard or are separated by walls so that a single tornado missile would not damage both redundant systems.

Evaluations have been carried out considering all seven tornado missiles listed in Table 3.5-4 and their penetration/impact on the openings and nontornado designed structures of the plant including manhole covers and valve pit roofs. Even though some singular safety-related components may be affected, damage would not occur to all redundant systems, and safe shutdown could be achieved even when assuming an additional single active failure.

LGS is in conformance with Regulatory Guide 1.117 regarding systems to be protected from tornado missiles except as discussed below where unacceptable damage to unprotected spray networks is not considered credible.

As described in Section 9.2.6, the ultimate heat sink at LGS is an excavated spray pond with a surface area of 9.9 acres. Four spray networks, each having 50% capacity for shutdown of two units, are provided.

Details of the spray pond excavation and finished grading are shown in Figures 3.8-55, 3.8-56, and 3.8-57. The general arrangement of the spray pond, spray networks, and spray pond pump structure is shown in Figure 9.2-6. The layout of the spray networks is shown in M-384.

As discussed in Section 3.5.1.4, all essential structures, systems, and components related to the ESW system, RHRSW system, and the UHS are protected from the effects of tornadoes and tornado missiles. Protection of the spray networks from tornado missiles is provided by location of

the network piping and sprays below the surrounding grade and by physical separation of the networks:

a. In all but the spillway area, the surrounding grade is in excess of el 260' while the top of the sprays are at el 258' and the spray network piping is between el 253'-5" and el 256'-8".

b. The closest branches of adjacent spray networks are separated by 65 ft.

c. The supply piping to adjacent networks is separated by 215 ft.

d. The networks are located at a minimum distance of 72 ft from the edge of the pond.

The use of elevational differences and physical separation to provide protection of the spray pond networks from tornado missiles is justified by the following considerations:

a. Only two spray networks are required for the safe shutdown of both units.

b. The only active failure that can compromise the operability of a spray network is failure of its supply valve (HV-012-032A, B, C or D). These valves may be manually operated to isolate damaged networks or to initiate the use of undamaged networks if their controls or motors are inoperable.

c. The physical arrangement of the spray networks precludes the possibility that large missiles can damage more than one spray network due to trajectory considerations. Multiple missiles of sufficient energy and distribution to substantially damage multiple networks are unlikely. Network piping varies in size from the 30 inch diameter supply headers to the 2 inch diameter piping at the extreme ends of the distribution branches. Network piping wall thickness varies from 0.337-0.500 inch.

d. The loss of some sprays in a network does not result in substantial loss of heat removal capability for the entire network (each network contains 240 spray nozzles).

e. The design thermal performance of the spray pond is based on conservative design values of initial pond temperature and meteorology as described in Section 9.2.6.4. For all expected conditions, the margin in thermal performance would be considerably greater than the 10% margin demonstrated under design conditions. In fact, for average meteorological conditions, a single spray network is sufficient for the removal of the heat rejected from both units for at least a 24 hour period.

f. Interconnections are provided that allow the use of the cooling towers as a heat sink for ESW and RHRSW systems. Such operation may be initiated from the control room or locally by manual operation.

It is unlikely that tornado winds would compromise the heat removal capability of the spray pond networks, or the cooling towers, to the extent that safe shutdown of the units would be affected. The spray networks have been designed to withstand design basis tornado winds. While not specifically designed to withstand design

basis tornado winds, the cooling tower shell and supporting structure have been designed to withstand the following wind loading when either operating or dry:

Elevation Above Grade (ft)	Wind Velocity (mph)
30	90
150	113
200	118
300	125
400	130
500	135

The cooling towers are expected to provide sufficient heat removal capability for the safe shutdown of the units even in the event that the tower fill is extensively damaged.

g. The loss of more than two spray networks and the coincident loss of the cooling towers due to tornado missiles is unlikely due to physical separation of the cooling towers and the spray pond. The cooling towers are located approximately 600 feet from the nearest portion of a spray network.

The likelihood of tornado winds and/or missiles affecting the safe shutdown capability of the cooling towers and spray networks at the same time is quite remote when the above described design factors are considered together with the variation in tornado intensity along its path length and width (Reference 3.5-2).

h. Tornado missiles are an insignificant contributor to plant risk because of the low frequency of occurrence of tornadoes in this region (EROL section 2.3.1.2.2) and the low likelihood of damaging missiles if one were to occur.

Even if the safe shutdown capability of the cooling towers and spray networks were compromised by tornado effects, use of the cooling tower basins and/or UHS in a "cooling pond type" mode would allow substantial time for spray network repair. A plant procedure governs such repair activities. This procedure will contain, at a minimum, the following elements:

1. Repair work on damaged spray networks will begin immediately, using materials, equipment, and personnel that have been verified to be available. Procedure verification will be made each year.

2. On current loss of all UHS spray headers and all cooling tower cooling capacity, the spray pond will be operated as a closed cycle cooling pond until the temperature of the water reaches the design limit of 95°F. In this mode, water will be returned to the pond via the winter bypass line to promote thermal mixing and minimize the likelihood or recirculation.

   Under design basis conditions of initial pond temperature and meteorology, it would take approximately 6 hours for the pond to reach the 95°F limit.

Under average conditions, it would take approximately 10 hours to reach this limit. Both numbers are for two-unit, full power operation. For single-unit operation, these times would be approximately 12 hours and 20 hours, respectively. The heat rejection rate can be further reduced by depressurizing the reactor at a slower rate than 100°F/hr assumed in the design basis analysis.

3. When the pond reaches the design temperature limit, the sluice gates between the spray pond pumphouse wet wells and the spray pond will be closed. Water will be released from the cooling tower basins into the wet wells and pumped through the plant to service the required heat loads. The water will be returned to the spray pond and allowed to discharge over the blowdown weir and storm spillway.

   The two cooling tower basins contain a total of 14 million gallons. If it is conservatively assumed that only one-half of this volume of water is available, there is sufficient water to provide makeup for the ESW and RHRSW pumps, operating in a once-through mode, for an additional 4 hours. In the unlikely event that the cooling tower basin walls have failed due to tornado missiles, the additional time of 4 hours would not be available. However, the spray pond PRA demonstrates that it is extremely improbable that the four spray pond networks would not be available.

4. Sufficient makeup water can be supplied to the cooling tower basins to sustain continuous operation in this mode for a number of sources as described in Item i.

i. The Schuylkill River makeup pumphouse is located approximately 1500 ft from the nearest cooling tower, making it unlikely that the pumphouse would be damaged by a tornado that would also compromise the spray pond networks and the cooling towers. The pumphouse is powered from the 2300 V plant services switchgear. The switchgear can be fed using offsite power from either of the two plant substation via underground lines. The two substations are approximately 2000 ft apart, making it highly unlikely that both substation would be disabled by a tornado that would also compromise the spray pond networks and the cooling towers.

   While an additional source of water is available from the pump station to provide the Perkiomen makeup supply located approximately 8 miles from the plant site, no reliance is being placed on this intake for the purpose of safety analysis nor the safety licensing basis for the facility.

   If existing sources of makeup cannot be made available in a timely manner, makeup will be provided using available portable pumps of required size and capacity to pump water from the Schuylkill River to the spray pond pumphouse wet wells. The water would be pumped via a tie-in to the existing underground water pipeline from the Schuylkill River intake pumphouse to the cooling tower basins. It would flow via gravity to the pump pits. If a tie-in to the existing pipeline is not possible, the water would be pumped directly to the wetwell through temporary

lines. The portable pumps that would be used are either licensee owned or rental pumps. The required pumps will be verified to be available on an annual basis.

j. Plant EOPs address the various contingency actions available to the operators to deal with degraded UHS conditions. As indicated in the above discussions, substantial time is available for corrective operator actions. If UHS capability should be lost for such a period of time that conditions degraded considerably, the EOPs would direct the use of equipment that would achieve a safe stable state regardless of UHS capability.

3.5.1.5 Missiles Generated by Events Near the Site

The safety-related structures, systems, and components were reviewed for adequacy against missiles externally generated by railroad explosions. The safety-related facilities are either designed to resist the externally generated missiles in accordance with Reference 3.5-6 or are protected by these missile-resistant barriers. The barriers designed to resist externally generated missiles and the corresponding systems and components protected by these missile barriers are listed in Table 3.5-7.

The nearest possible train explosion accident and its consequent missiles are considered to be the most severe missile-generating event that could occur near the site. The postulated missiles resulting from such an accident considered in the design of structures protecting safety-related systems are listed in Table 3.5-5. Missiles resulting from truck, industrial, and pipeline explosions would be less severe and therefore are not considered. As demonstrated in Section 2.2, there is no potential for missiles from ship or barge explosions or military installations. Descriptions of the railroad, its location relative to the plant, the railroad explosion, and explosions from other sources are given in Section 2.2.

3.5.1.6 Aircraft Hazards

The safety-related structures, systems, and components were reviewed for adequacy against missiles externally generated by aircraft accidents. The safety-related facilities are either designed to resist the externally generated missiles in accordance with Reference 3.5-6 or are protected by these missile-resistant barriers. The barriers designed to resist externally generated missiles and the corresponding systems and components protected by these missile barriers are listed in Table 3.5-7.

Airports and aircraft activity in the vicinity of the site are discussed in Section 2.2.2. Based on the airport and aircraft information provided in Section 2.2.2, an analysis has been performed using the methodology of SRP section 3.5.1.6 to demonstrate that the probability of an aircraft accident causing damage to safety-related equipment or structures sufficient to result in radiological consequences that are a significant fraction of 10CFR50.67 exposure guidelines is lower than the acceptance criteria of SRP section 3.5.1.6.

3.5.1.6.1 Design of Safety-Related Structures

Aircraft operating or capable of operating out of nearby airports are listed in Table 3.5-1. Based on the estimated maximum kinetic energy at impact and corresponding local damage to concrete elements, the Learjet is determined as the design aircraft for the design of safety-related structures.

The characteristics of the Learjet are presented in Table 3.5-2, and the associated load curve acting on structures due to the impact is shown in Figure 3.5-1. The design aircraft is assumed to impact perpendicularly to the vertical surface of the buildings or to impact at a glide angle of 15° from horizontal on the roof of buildings. The reactor enclosure, control structure, and spray pond pump structure are designed to withstand the impact of the design aircraft without loss of structural integrity. Safety-related equipment and systems located therein are designed to remain functional. The diesel generator enclosures are not designed to withstand aircraft impact.

3.5.1.6.2 Analysis Method

The probability of damage to structures containing safety-related equipment (P) is calculated from the formula:

$$P = \sum_{i=1}^{L} \sum_{j=1}^{M} N_{ij} C_{ij} A_{ij} \qquad \text{(EQ. 3.5-1)}$$

where:

L	=	number of different flight paths that affect the site
M	=	number of different types of aircraft that may constitute a hazard
N_{ij}	=	number of movements per year by aircraft j operating in flight path i
C_{ij}	=	probability of a crash per square mile per aircraft movement for aircraft j operating in flight path i
A_{ij}	=	effective plant area (square miles) for aircraft j operating in flight path i

Values for the above parameters and related assumptions are discussed in the following sections.

3.5.1.6.2.1 Aircraft Movements (N_{ij})

In addition to the movements, type of aircraft, and other particulars of aircraft operation described in Section 2.2.2, the following considerations for each of the sources of aircraft movement apply.

Pottstown-Limerick Airport - The analysis assumes that 90% of the takeoffs (45% of the movements) are towards the west, in the direction of the site, and that 10% of the landings (5% of the movements) are from the west, in the direction of the site. This is based on the VFR and IFR information provided in Section 2.2.2. The flight restrictions discussed in Section 2.2.2 are accounted for in the analysis.

Based on the approach pattern for Pottstown-Limerick Airport, the holding area is at least 3.8 miles northeast of the runway, which would locate the holding area more than 5 miles northeast from the site. Due to the distance and direction, no additional movements involved with the holding pattern were considered in calculating the aircraft crash probability.

Pottstown Municipal Airport - The proportions of single-engine and twin-engine aircraft using the airport are assumed to be 70% and 30%, respectively. Based on the information provided in Section 2.2.2, it is assumed that 50% of the takeoffs involve eastbound passes over the site, with the remainder to be north and west away from the site. Similarly, it is assumed that 50% of the landings involve northbound flight patterns over the site.
New Hanover Airport, Sunset Landing Strip and Perkiomen Valley Airport - The projected annual number of operations for these facilities located between 5 and 10 miles from the site is less than 500 D^2. In accordance with SRP section 3.5.1.6, their contributions to the total probability are extremely small and are not considered in the analysis.

Federal Airways - The traffic data presented in Section 2.2.2 are employed in the analysis. It is conservatively assumed that the Boeing 727 is representative of traffic in these airways.

LGS Plant Site Heliport - The analysis is based on 156 landings and 156 takeoffs per year. The helicopter parameters used are given in Table 3.5-1. These parameters are bounded by those of the Learjet, which was the design basis aircraft for impact.

3.5.1.6.2.2 Aircraft Crash Probability (C_{ij})

Pottstown-Limerick and Pottstown Municipal Airports

Aircraft crash probabilities from the SRP section 3.5.1.6, are used in this analysis. The SRP specifies the crash probability per square mile in an annular sector 60° on each side of the extended runway centerline as a function of the distance from the end of the runway.

Accordingly, the crash probability for U.S. general aviation at a distance of 1-2 miles of 1.5×10^{-7} per square mile per aircraft movement is used for Pottstown-Limerick Airport. This probability is also applied to the rotary-wing operations at that airport. For Pottstown Municipal Airport, the U.S. general aviation probability for 4-5 miles, 1.2×10^{-8} per square mile per aircraft movement, is used. The use of this value for Pottstown Municipal Airport is conservative because LGS lies outside the 60° sector of the extended runway centerline.

LGS Plant Site Heliport

The crash probability for the helicopter traffic using the plant site heliport is based on NTSB and FAA nationwide statistics on the estimated number of helicopter flight hours for 1979 and the number of fatal helicopter crashes during takeoff and landing during that same year, and is equal to 4.88×10^{-7} per takeoff or landing.

Federal Airways

For commercial aircraft in the Federal airways, a model for the probability that an aircraft crash will result at a distance (x) normal to its flight path is employed, which was developed by Solomon (References 3.5-7 and 3.5-8) using a negative exponential distribution. Solomon's model requires estimation of the deviation, which was determined by a 20° angle from the flight path. A deviation is estimated here by referencing Solomon's angle at 14,000 feet, and adding one mile for deviation in the airway. This gives the probability:

$$f(x) = \frac{1}{3.94} e^{-x/1.97} \qquad \text{(EQ. 3.5-2)}$$

Where:

x = distance in miles

The probability that an enroute crash will occur is about 0.45×10^{-9} per flight path mile, based upon U.S. commercial aviation performance in the period 1970-75 (Reference 3.5-9). Thus, the crash probability at the site per passage in each of the Federal airways can be estimated by the product of these two probabilities.

The resulting probabilities are as follows:

Airway	x (miles)	Probability (per square mile)
V29/147	1.3	5.9×10^{-11}
Pottstown VOR 320° radial	1.3	5.9×10^{-11}
V210	8.0	2.2×10^{-12}
V276	10.0	7.1×10^{-13}

3.5.1.6.2.3 Critical Target Areas (A_{ij})

The aircraft crash probability estimates the chance that a given aircraft maneuver (passage, takeoff, or landing) would result in striking the ground within a specific unit area, without regard to the obstruction of surrounding objects. If the assumed flight ray of the aircraft in crashing should pass through an obstructing object, then the probability of crash into that obstructing object is the same as for the associated unit ground area.

The determination of target areas are based on the following considerations:

a. The skid area, associated with a ground strike ahead of a wall, followed by sliding into the wall. The controlling parameters for the target area of this mode are the width of the wall normal to the skid path (augmented by the wingspan of the striking aircraft), and the distance the aircraft will slide.

b. The roof or plan area (augmented by the wingspan of the striking aircraft), which may be projected to an equal ground area regardless of the angle of flight path slope.

c. The wall shadow area, (Bh) cot (A), which is the ground area projected by a wall of vertical dimension (h), width (B) normal to the flight path (and augmented by the

wingspan of the striking aircraft), with aircraft glide path making an angle (A) with the ground.

d. Shadowing of target structures by other structures.

Skid lengths are calculated from the equation provided in Reference 3.5-5:

$$L_s = \frac{6.3 \times 10^{-6}}{k} V^2 \qquad \text{(EQ. 3.5-3)}$$

where:

L_s = skid length (miles)

k = roughness factor (set equal to 2.5)

V = velocity (mph)

The glide angle is assumed to be 15° for fixed-wing aircraft. For rotary-wing aircraft, it is assumed to be 0° because of the poor aerodynamic characteristics of such aircraft. The skid length for rotary-wing aircraft is therefore considered to be zero feet.

The impact velocity for single-engine and twin-engine general aviation aircraft is estimated to be 110 mph. Therefore, from Equation 3.5-3, the skid length is 0.0305 miles or 161 feet. The impact velocity of a Boeing 727, assumed to be the average aircraft in the Federal airways, as discussed in Section 3.5.1.6.2.1, is taken as 290 mph, yielding a skid length of 0.212 miles or 1120 feet.

The analysis assumes that single-engine aircraft have a wingspan of 32 feet, twin-engine aircraft have a wingspan of 50 feet, and the wingspan of a Boeing 727 is 110 feet.

Pottstown-Limerick and Pottstown Municipal Airports

As discussed in Section 3.5.1.6.1, the reactor enclosure, control structure, and spray pond pump structure are designed to withstand the impact of the largest aircraft capable of operating out of the nearby airports, the design basis Learjet, and are therefore not considered in the calculation of critical target areas.

The spray pond itself is not susceptible to aircraft damage because it is constructed completely in excavation, as discussed in Section 2.5. Aircraft damage to the spray pond spray network is not considered because the design provides for separation and redundancy so that the loss of a network would not affect the systems safety function.

The diesel generator enclosures for Units 1 and 2 each have an east-west dimension of 108 feet, a north-south dimension of 84.5 feet, and a height of 29 feet. The two structures are separated by 54 feet in the east-west direction.

Flight paths of concern for the diesel generator enclosures are those in the east, west, and northbound directions. There are no intervening structures for northbound aircraft. The critical

target area for single-engine aircraft is 3.51×10^{-3} square miles and 4.01×10^{-3} square miles for twin-engine aircraft.

For westbound traffic, the reactor enclosures and the administration building provide shadowing to the diesel generator enclosures. The reactor enclosures, located north of the diesel generator enclosures, reduce the effective target area for westbound aircraft to 84.5 feet plus one-half the aircraft's wingspan. The warehouse and shop area, located to the east of the diesel generator enclosures, effectively eliminates the skid area. The resultant critical target areas for single-engine aircraft is 1.36×10^{-3} square miles, and 1.49×10^{-3} square miles for twin-engine aircraft.

For eastbound traffic, shadowing to the diesel generator enclosures is provided by the reactor enclosures and the radwaste enclosures. The resultant critical target areas are 1.68×10^{-3} square miles for single-engine aircraft and 1.86×10^{-3} square miles for twin-engine aircraft.

For southbound traffic, the critical target area for diesel generators is zero due to the shadowing afforded by the reactor enclosure.

For rotary-wing aircraft, the critical target area of the diesel generator enclosure is 6.55×10^{-4} square miles.

LGS Plant Site Heliport

The probability of a crashing helicopter impacting the diesel generator building is determined based on the known flight path of the helicopter traffic using the heliport, the closest distance this flight path comes to the diesel generator building, and the deviation from the flight path.

The possible deviation from the bounding traffic pattern for landing or takeoff path is represented by an exponential density function of the form:

$$f(x;\lambda) = \lambda e^{-\lambda x} \qquad \text{(EQ. 3.5-4)}$$

where:

$f(x;\lambda)dx=$ the probability that the deviation is in the range (x, x+dx);

x = the perpendicular distance (deviation) from the flight path;

λ = the exponential distribution parameter.

The exponential distribution parameter, λ, is the inverse of the expected value of x. The expected value of x, *x* has been chosen as the mean distance which the helicopter can travel from an altitude (h). Therefore, *x* is given by:

$$x = h \tan(\phi)$$

The angle ϕ is conservatively assumed to be the helicopter glide angle due to loss of a rotor. The expected altitude (h) of the helicopter on an approach or departure from the helipad is given by:

$$h = a \tan(\theta)$$

The angle θ, the approach angle, is conservatively assumed to be 15°, and (a) is the distance from the helipad.

Using the above information, λ is given by:

$$\lambda = \frac{1}{a \tan(\phi) \tan(\theta)}$$

The probability of impacting at a distance greater than (d) perpendicular to the flight path on one side of the flight path, is then given by the cumulative distribution function:

$$P(>d) = 0.5\, e^{-\lambda|d|}$$

The probability of impact on the diesel generator enclosure is greatest when the helicopter is on the approach path 675 feet from the helipad and 1,100 feet laterally from the diesel generator enclosure. The average conditional probability of impacting the diesel generator enclosure from a crash for all three types of helicopters given in Table 3.5-1 is 7.66×10^{-4}.

Federal Airways

The reactor enclosure, control structure, and diesel generator enclosures are considered in the calculation of critical target areas. The spray pond pump structure represents only about 5% of the total target areas of safety-related structures, and its contribution to the overall probability is considered negligible.

The spray pond is not susceptible to aircraft damage because it is constructed completely in excavation, as discussed in Section 2.5. Aircraft damage to the spray pond spray network is not considered because the design provides for separation and redundancy so that the loss of a network would not affect the systems safety function.

Because the majority of airway traffic is northbound, the analysis considers the south faces of the diesel generator enclosures and the reactor enclosures as the target area. The calculated critical target area is 3.33×10^{-2} square miles.

3.5.1.6.3 Crash Probabilities

Based on the given data and assumptions regarding the number of aircraft movements (N_{ij}), aircraft crash probability (C_{ij}), and critical target areas for the plant (A_{ij}), the probability of an aircraft striking to safety-related structures has been calculated.

For operations out of the Pottstown Municipal Airport, the probability of an aircraft striking the diesel generator enclosures is given by:

$$P = 1.2 \times 10^{-8} \bullet [1.73N_e + 1.40N_w + 3.66N_n] \times 10^{-3}\ yr^{-1} \quad \text{(EQ. 3.5-5)}$$

where:

N_e = number of eastbound movements over the site

N_w = number of westbound movements over the site

N_n = number of northbound movements over the site

and the target areas have been weighted to reflect the proportion of single and twin-engine traffic.

For

$N_e = N_n = 4000; N_w = 0,$

this yields a crash probability of 2.59×10^{-7} per year.

Similarly, for operations out of the Pottstown-Limerick Airport, the probability is given by:

$$P = 1.5 \times 10^{-7} \cdot [1.73N_e + 1.40N_w + 3.66N_n + 0.655N_r] \times 10^{-3} \text{ yr}^{-1}$$

(EQ. 3.5-6)

where:

N_r = number of rotary-wing operations over the site from the Pottstown-Limerick Airport.

For

$N_e = 1500, N_w = 13500, N_n = 0; N_r = 0,$

this yields a crash probability of 3.2×10^{-6} per year.

For operations out of the LGS plant site heliport, the probability of a helicopter striking the diesel generator enclosure is the product of the number of takeoffs and landings per year, the probability of the helicopter crashing during takeoff or landing, and the probability that the crashing helicopter will impact the diesel generator building:

$$P = 312 \cdot 4.88 \times 10^{-7} \cdot 7.66 \times 10^{-4}$$

$$= 1.17 \times 10^{-7} \text{ per year}$$

The probability of an aircraft in one of the airways near the site striking the diesel generator enclosures, or the reactor enclosures is given by:

$$P = [(8395 + 20240)(590) + (46355)(22) + (4745)(7.1)] \times 10^{-13} \cdot 0.0333$$

$$= 5.98 \times 10^{-8} \text{ yr}^{-1} \quad \text{(EQ. 3.5-7)}$$

3.5.1.6.4 Probability of Aircraft Strike Resulting in Unacceptable Consequences

Given the aircraft impact resistant design of all safety-related structures except the diesel generator enclosures, an aircraft strike could jeopardize safe shutdown capability or have potential offsite dose consequences only under the following scenarios:

(1) The impacting aircraft is larger in size than the design basis aircraft described in Section 3.5.1.6.1, and the impact causes structural failure and/or damage to systems required to achieve or maintain safe shutdown, resulting in the possibility of offsite consequences in excess of 10CFR50.67 guidelines.

(2) The impacting aircraft strikes a diesel generator enclosure, damaging more than 2 diesel generators, thereby leaving that unit dependent on offsite power for achieving and maintaining shutdown. During the period required to return at least 2 diesel generators to service, a complete loss of offsite power occurs, which leaves the affected unit dependent on its Class 1E battery system to achieve and/or maintain safe shutdown. If offsite power is not restored before the batteries are exhausted, inadequate core cooling and offsite radiological consequences in excess of 10CFR50.67 guidelines could result.

The probabilities of scenarios (1) and (2) occurring are calculated as follows:

Scenario 1: Impact By Aircraft Larger Than Design Basis Aircraft

This scenario is credible only for aircraft in Federal airways. It is conservatively assumed for this analysis that the impact of any aircraft using the Federal airways causes damage such that offsite radiological consequences in excess of 10CFR50.67 occur. The probability of such an impact causing unacceptable radiological consequences is therefore equal to the crash probability of an aircraft in one of the airways near the site, shown in Section 3.5.1.6.3 to be 5.98×10^{-8} per year.

Scenario 2: Diesel Generator Damage Caused By Impact Of Design Basis or Smaller Aircraft

The probability that aircraft operating out of the Pottstown- Limerick Airport, the Pottstown Municipal Airport, and the LGS plant site heliport will impact the diesel generator enclosures is shown in Section 3.5.1.6.3 to be 3.2×10^{-6} per year, 2.59×10^{-7} per year, and 1.17×10^{-7} per year respectively, or a total probability,

$P_{ac} = 3.58 \times 10^{-6}$ per year.

Given that each unit's diesel generator enclosure is 108 ft wide, and that each of the 4 diesels per unit is located in a separate compartment inside that unit's diesel generator enclosure, it is highly unlikely that the impact of a typical twin-engine plane with a wingspan of 50 ft could disable more than 2 diesel generators.

In addition, only 2 of a unit's 4 diesel generators are required to achieve and maintain safe shutdown, assuming no additional failures. Despite the above, it is conservatively assumed for this analysis that any aircraft impacting a diesel generator enclosure disables all 4 diesel generators therein, leaving that unit dependent on offsite power for achieving and maintaining safe shutdown. It is further conservatively assumed that immediate action would be taken to repair the diesel generators, and that at least 2 of the 4 would be restored to service 1 year following the aircraft impact.

Using the methodology of appendix III of Reference 3.5-10, the probability, P_{LOOP}, that a LOOP occurs (during the 1 year in which the affected unit would have no onsite ac backup power) is conservatively determined to be 0.2 per year, thus leaving that unit dependent on its Class 1E dc battery system to achieve or maintain shutdown.

It has been shown (Reference 3.5-11) that under loss of all ac power (station blackout) conditions, in a BWR with electrical and mechanical system designs similar to LGS, the batteries could power all systems required to achieve or maintain safe shutdown for as long as 7 hours before exhaustion. For this analysis, it is conservatively assumed that battery exhaustion occurs 4 hours after the LOOP occurs, after which inadequate core cooling and offsite radiological consequences in excess of 10CFR50.67 could occur.

Again using the methodology of appendix III of Reference 3.5-10, the probability, P_4, that at least one offsite source of power is not returned to service within 4 hours following the LOOP is conservatively estimated to be 0.05 per LOOP event.

Based on the preceding information, the probability per year of an aircraft crash that disables one unit's diesel generators, leading to offsite radiological consequences in excess of 10CFR50.67 dose limits, can be calculated as follows:

$$P = P_{AC} \cdot P_{LOOP} \cdot P_4$$

$$= (3.58 \times 10^{-6}\ yr^{-1})(0.2\ yr^{-1})(0.05) \qquad \text{(EQ. 3.5-8)}$$

$$= 3.58 \times 10^{-8} \text{ per year.}$$

Conclusion

The total probability per year of an aircraft impact resulting in offsite radiological consequences in excess of 10CFR50.67 dose limits is the sum of the probabilities associated with Scenarios 1 and 2, or 9.56×10^{-8} per year. Realistically, this probability would be lower.

It is concluded that the acceptance criteria of SRP section 3.5.1.6 are met.

3.5.2 SYSTEMS TO BE PROTECTED

Safety-related systems and structures are reviewed for missile protection and are listed in Table 3.2-1. Structures and barriers designed to provide for protection from external missiles are discussed in Section 3.5.1 and listed in Table 3.5-7, and their characteristics are listed in Table 3.5-8.

As discussed in Section 3.5.1, the only postulated internally generated missiles are those arising from failure of the HPCI and RCIC pump turbines. In this case, the pump-room walls are designed as barriers to isolate such missiles from other safety-related components.

The locations of safety-related equipment and the arrangement of the various compartments are shown in drawings M-110, M-111, M-112, M-113, M-114, M-115, M-116, M-117, M-118, M-119, M-120, M-121,M-122, M-123, M-124, M-125, M-126, M-127, M-128, M-129, M-130, M-131, M-132,

M-133, M-134, M-135, M-136, M-137, M-138, M-140, M-141, M-142, M-143, M-144, M-145, M-146, M-388, M-389, and M-390.

3.5.3 BARRIER DESIGN PROCEDURES

Safety-related components necessary for safe shutdown and housed in the Category I structures are adequately protected against tornado missiles. The characteristics of structural wall barriers for Category I structures are shown in Table 3.5-8. Figure 3.5-2 shows typical reinforcement provided in the southernmost reactor enclosure concrete wall barrier.

The structures and barriers are designed to resist missile hazards in accordance with the procedures detailed in Reference 3.5-6.

The procedures include:

a. Prediction of local damage (penetration, perforation, and spalling) in the impact area, including estimation of the depth of penetration

b. Estimation of the barrier thickness required to prevent perforation

c. Prediction of the overall structural response of the barrier, and portions thereof, to missile impact

Tornado missiles, as described in Table 3.5-4, were considered as deformable upon impact, and the structures were considered as rigid targets. Eighteen inch thick concrete, with a compressive strength of 4000 psi, was used in concrete walls and roofs subject to tornado missile impact. This satisfies the penetration formulae for elements subject to missiles as specified in Reference 3.5-6.

The ESW and RHRSW piping located within the yard area are installed underground with adequate cover for missile protection. A detailed assessment of soil cover for Category I yard piping shows a minimum depth of 4 feet, with most soil coverings exceeding 6 feet. The 4 foot depth was found to be adequate for tornado missiles (Table 3.5-4) in accordance with the criteria set forth in Reference 3.5-3.

The physical routing of the piping and typical profiles showing soil cover and installation details are shown in Figure 2.5-37. The cementitious backfill for pipe bedding is shown in detail 3 of Figure 2.5-37. This backfill was used predominantly for Category I piping to provide additional missile protection. The properties of cementitious backfill are defined in Section 2.5.4.5.4. Figure 2.5-37 shows the 4 foot minimum depth dimension of soil cover for Category I yard piping.

Doors are designed for tornado missiles unless internal secondary barriers are provided to protect safety-related components. Louvers are not designed for tornado missiles; however, internal secondary barriers are provided to protect safety-related components which are located behind the louvers. Figure 3.5-3 shows a typical secondary barrier for the south wall of the diesel generator enclosure (concrete labyrinth behind the door) used for tornado missile protection.

AIRCRAFT IMPACT DESIGN PARAMETERS

AIRCRAFT DESCRIPTION	GROSS WEIGHT (lb)	APPROACH VELOCITY (knots)	(ft/sec.)	KINETIC ENERGY (K-ft)
Single reciprocating engine	<5,000	110	186	2,686
Cessna (twin recip engine)	7,250	111	188	3,979
Cessna jet (twin gas turbine)	10,500	115	194	6,136
Learjet(1) (twin gas turbine)	13,500	139	235	11,577
Navajo Chieftrain	7,000	100	169	3,104
Beech King Air-200	12,500	103	174	5,877
Cheyenne Turbo-Prop	11,200	115	194	6,545
Bell Long Ranger (helicopter)	4,150	50	85	466
Aerospatiale Twin Star (helicopter)	5,291	50	85	594
Bell 222 Model A (helicopter)	7,850	70 (takeoff)	118	1,697

(1) Largest aircraft capable of operating out of nearby airports; none are presently known to exist.

Table 3.5-2

CHARACTERISTICS OF LEARJET

Aircraft Components[1]	Weight (lbs)	Mass (Kip-sec^2/ft)	K.E. (Kip-ft)	Resultant Load on Walls[2]		
				Momentum (Kip-sec)	Assumed Impact Duration (sec)	Peak Force (Kips)
Fuselage	7,178	0.2229	6,155	52.3	0.10	846
Tip Tanks	1,358	0.0422	1,165	9.9	0.05	396
Wing	3,503	0.1088	3,005	25.6	0.10	512
Engines	1,158	0.0360	995	8.5	0.05	340
Empennage	305	0.0095	260	2.2	0.05	88
Total	13,500	0.4194	11,580	98.5	-	(2)

(1) All components are assumed traveling at 235 fps (139 knots) at impact.
(2) Resultant load curves on structure due to the different components and total are shown in Figure 3.5-1.

Table 3.5-3

ACCUMULATORS LOCATED IN SAFETY-RELATED AREAS

Description	Maximum Pressure (psig)	Maximum Temperature (°F)
MSRV Accumulators	125	150
MSIV Accumulators	125	150
Diesel Air Start Reservoirs	250	120
Instrument Gas Receivers	125	135

Table 3.5-4

TORNADO-GENERATED MISSILE PARAMETERS

MISSILE	WEIGHT (lb)	IMPACT AREA (ft^2)	HORIZONTAL[4] VELOCITY (mph)/(ft/sec)	KINETIC ENERGY (ft-lb)
1. Wood plank (4"x12"x12')	200	0.333	300/440	6.01×10^5
2. Steel pipe (3" dia x 10', schedule 40)[3]	78	0.067	144/211	5.39×10^4
3. Automobile[2][3]	4000	20	72/106	6.98×10^5
4. Steel rod (1" dia x 3')	8	0.007	216/317	1.25×10^4
5. Utility pole (13½" dia x 35', not more than 30' above all grade elevations within ½ mile of the plant)	1490	1.266	144/211	1.03×10^6
6. Steel pipe (6" dia x 15', schedule 40)[1]	285	0.239	144/211	1.97×10^5
7. Steel pipe (12" dia x 15', schedule 40)[1]	743	0.886	144/211	5.14×10^5

(1) The design basis for LGS included only missiles 1, 2, 3, 4 and 5. All safety-related structures and openings in structures have been assessed for the effects of missiles 6 and 7.

(2) LGS was originally designed for a postulated automobile missile not more than 25 ft above grade for all safety-related structures. All safety-related structures have been reassessed for the effect of the automobile at elevations up to 30 ft above all grade levels within ½ mile of the plant.

(3) LGS was originally designed for postulated missile velocities equal to 100 mph for the 3 in diameter steel pipe and 50 mph for the automobile. All safety-related structures have been reassessed for the revised velocities shown on the table.

(4) These missiles are considered to be capable of striking in all directions with vertical velocities equal to 80% of the horizontal velocities.

Table 3.5-5

RAILROAD ACCIDENT GENERATED MISSILE PARAMETERS

MISSILE	WEIGHT (lb)	INITIAL VELOCITY (mph)
Part of tank car tank (112" dia x 50')[1]	62,000	200 (during ignition, traveling end on)
Steel pipe (3" dia x 10' schedule 40)	78	200 (tumbling)
Rail (3' long, 130 lb/yd)	130	200 (tumbling)
Type E coupler (7 in^2 shank)	200	200 (tumbling)
Unfused bomb	750	100

(1) These have been observed being propelled by burning gases at a very low trajectory not exceeding 30-35 feet above the ground. The elevation difference (77 feet) between the railroad and safety-related structures prevents impingement of this missile, and therefore it was not considered in the design.

Table 3.5-6 (Cont'd)

(1) These potential missiles are installed in equipment that is only used during accident situations. They are not considered credible potential missiles because internal missile generation is not postulated to occur concurrently with other accidents.

(2) These potential missiles are either remote from or separated by adequate barriers from all essential systems. Therefore, essential systems are protected from these potential missiles.

(3) The potential missiles cannot impact on more than a single component. Therefore, redundant equipment will be available to effect safe shutdown.

(4) The casing thickness is sufficient to prevent penetration by a loose blade. (During the September 24, 1982 Palo Verde event where the description indicated that a portion of a fan blade cut the liner plate, investigation revealed that the portion of blade escaped through a neoprene-coated fiberglass flexible connection between the fan discharge connection and the downstream duct. Pieces of blade struck the fan casing and the downstream duct. The duct was dented but no penetration of the fan casing or duct by the blade occurred. In the case of the LGS drywell unit coolers, the fan discharge connections are connected to a Class I Seismic Y duct fitting directly. Downstream of the fitting, stainless steel bellows with sliding metal flow liners are utilized rather than flexible fabric connections, thus precluding blade penetration.)

Table 3.5-7

MISSILE BARRIERS AND PROTECTED COMPONENTS FOR EXTERNALLY GENERATED MISSILES

PROTECTED COMPONENTS	MISSILE BARRIER
Reactor coolant and other safety-related equipment inside the containment	Primary containment structure, reactor enclosure walls, refueling cavity walls, internal structures and beams
Control room, cable spreading room, switchgear, batteries, SGTS	Control structure
ECCS and other safety-related equipment outside the primary containment	Reactor enclosure and internal walls
Standby diesel generators	Diesel generator enclosure(1)
Diesel fuel oil tank	Earth; the tank is buried underground
Spent fuel pool	Reactor enclosure and fuel pool walls
ESW pumps and RHRSW pumps	Spray pond pump structure
ESW and RHRSW yard piping	Earth; piping is buried

(1) The diesel generator enclosure is not designed for design aircraft accident.

Table 3.5-9

TURBINE SYSTEM RELIABILITY CRITERIA

CRITERION	PROBABILITY, YR^{-1} UNFAVORABLY ORIENTED TURBINE	REQUIRED ACTION
(A)	$P_1 < 10^{-5}$	This is the general, minimum reliability requirement for loading the turbine and bringing the system on-line.
(B)	$10^{-5} < P_1 < 10^{-4}$	If this condition is reached during operation, the turbine may be kept in service until the next scheduled outage, at which time the licensee is to take action to reduce P_1 to meet the appropriate A criterion (above) before returning the turbine to service.
(C)	$10^{-4} < P_1 < 10^{-3}$	If this condition is reached during operation, the turbine is to be isolated from the steam supply within 60 days, at which time the licensee is to take action to reduce P_1 to meet the appropriate (A) criterion (above) before returning the turbine to service.
(D)	$10^{-3} < P_1$	If this condition is reached at any time during operation, the turbine is to be isolated from the steam supply within 6 days, at which time the licensee is to take action to reduce P_1 to meet the appropriate (A) criterion (above) before returning the turbine to service.

3.6 PROTECTION AGAINST DYNAMIC EFFECTS ASSOCIATED WITH THE POSTULATED RUPTURE OF PIPING

This section describes the treatment of postulated ruptures in high energy and moderate energy piping located both inside and outside of the primary containment. The methods used to determine pipe rupture locations and to analyze the results of the ruptures, including jet thrust forces, jet impingement forces, piping dynamic responses, and compartment pressure-temperature transients, are described. Description is also provided for the design measures that have been implemented to ensure that the effects of any postulated rupture do not result in the loss of a required function that is necessary to mitigate the consequences of that pipe rupture.

The definitions of certain terms used within this section are provided in Section 3.6.3. The use of the term "low reactor level" in this section is generic rather than referring to a specific isolation signal set point.

NOTE: The computer program "COPDA", as described in Bechtel Topical Report BN-TOP-4 (Reference 3.6-1), was originally used to determine compartment pressure and temperature resulting from line breaks in Unit 1. The computer program "FLUD" (Reference 3.6.3), which replaced COPDA, was typically used for the same analysis in Unit 2. The mainframe program "FLUD" was later replaced in 1985 with a personal computer version "PCFLUD" (Reference 3.6-12). The "PCFLUD" program had additional features added in 1993 (hot pipes, multiple HVAC fans, and "CONCOIL" room air cooler routine) and was renamed "CONCOIL-FLUD" or "CFLUD" (Reference 3.6-13). The supporting calculations for UFSAR Table 3.6-7 must be consulted for information regarding which specific program was used.

3.6.1 POSTULATED PIPING FAILURES IN FLUID SYSTEMS

The failure of piping containing high energy or moderate energy has the potential of causing damage to surrounding structures, systems, and components. Depending on the fluid system involved and the rupture location, postulated piping failures can result in one or more of the effects described below. Essential systems and components are protected from these effects unless it can be demonstrated that their function is not impaired.

Pipe Whip

Pipe whip is the unrestrained movement of a pipe due to the reaction force imposed on the pipe by fluid discharging from a rupture. Protection against pipe whip can be provided by intervening structural members between high energy piping and the essential systems and components, by providing pipe whip restraints on the high energy piping, or by locating essential systems and components sufficiently distant from high energy piping. Examples of typical pipe whip restraints and bumpers are shown in Figure 3.6-1.

Jet Impingement

The blowdown of fluid from a rupture of a high energy pipe can exert forces on nearby equipment that could be high enough to cause damage to the equipment. Protection against jet impingement can be provided by installing jet impingement barriers to deflect the blowdown jet, or by locating essential systems and components a sufficient distance from high energy piping.

Environmental Effects

Pipe ruptures in high energy and moderate energy lines release fluid that can increase temperature, pressure, and humidity in the vicinity of the pipe rupture and also in remote areas that communicate with the local atmosphere. Essential systems and components may be exposed to abnormal conditions that have the potential of degrading the capability of the equipment to perform its function.

Piping systems whose rupture might generate hazardous environmental conditions are generally located in compartments that are capable of being isolated from other compartments containing essential systems and components. Isolation of compartments that enclose high energy lines is provided by maintaining normally closed access ways, automatically isolating ventilation duct-work, and sealing penetrations through walls and slabs. Compartments are designed to withstand the maximum internal pressurization developed as a result of a pipe rupture. Essential systems and components are either located in areas not affected by pipe ruptures or are qualified for operation under the maximum environmental conditions that they may be subjected to as a result of pipe ruptures.

Figures 3.6-43 through 3.6-45 are provided to show additional details of a typical pipe break analysis performed in accordance with SRP 3.6.1 and BTP ASB 3-1. The pipe break chosen is a break of the HPCI steam supply line in the HPCI compartment.

Water Spray

Water released from pipe ruptures is a hazard to certain equipment, particularly electrical components. In most cases, spatial separation is adequate to prevent water spray from reaching essential systems and components. Essential systems and components that can potentially be subjected to water spray are either designed to operate when wetted or will be provided with barriers to deflect the spray.

Flooding

Significant ruptures of fluid system piping may result in flooding in the vicinity of the rupture and in compartments through which the released fluid drains. The flooding rate and the total fluid volume released are computed based on the rupture configuration, the service of the fluid system, and the time required to isolate the rupture. The plant's drainage system handles minor releases of fluid with no adverse effects on essential systems and components.

Compartments that contain fluid systems with the potential for major releases of fluid are designed to contain the flooding and prevent significant leakage to adjoining compartments containing essential systems and components. Essential systems and components are either located in areas not subject to significant flooding or are designed to operate in a flooded environment.

3.6.1.1 Design Bases

Pipe breaks are postulated to occur in high energy fluid system piping in accordance with the criteria stated in Section 3.6.2.1.1. Pipe cracks are postulated to occur in moderate energy fluid system piping in accordance with the criteria stated in Section 3.6.2.1.2. The effects of these piping ruptures require special consideration to ensure the following:

a. The ability to shut the reactor down safely is maintained.

b. Primary containment integrity is maintained.

c. Resultant offsite doses are below the values of 10CFR50.67.

In analyzing the effects of postulated piping ruptures, the following assumptions are made:

a Each break in high energy fluid system piping or crack in moderate energy fluid system piping is considered separately as a single postulated initial event occurring during normal plant conditions.

b. Offsite power is assumed to be unavailable if a trip of the turbine-generator or the RPS is a direct consequence of the postulated piping rupture.

c. A single active component failure is assumed to occur in systems used to mitigate the consequences of the postulated piping rupture and to shut the reactor down, except as noted in item d. below.

d. Where the postulated piping rupture is assumed to occur in one of the two redundant loops of either the RHR system or the RHRSW system, single active failures of components in the other loop of that system need not be assumed. These two systems are dual-purpose moderate energy systems powered from both onsite and offsite sources and are designed, constructed, and inspected to standards appropriate for nuclear safety systems.

e. All available systems, including those actuated by operator actions, may be employed to mitigate the consequences of the postulated piping rupture. In judging the availability of systems, the postulated piping rupture and its direct consequences, and the assumed single active component failure and its direct consequences are considered. The feasibility of carrying out operator actions is judged on the availability of ample time and adequate access to equipment for the required actions.

f. An unrestrained whipping pipe is considered capable of causing breaks in impacted piping of smaller nominal pipe size and developing through-wall leakage cracks in impacted piping of equal or larger nominal pipe size with thinner wall thickness, except where experimental or analytical data demonstrates the capability to withstand the impact without failure. If such experimental or analytical data are used, additional documentation will be submitted to the NRC for review.

g. The effect of the jets resulting from each postulated pipe break in high energy fluid systems is reviewed and is evaluated only when such jets may have an effect on specific safety-related components that are required to effect a safe shutdown, maintain containment integrity, provide post-LOCA monitoring, or limit radioactive releases to site-allowable limits, as a result of a specific postulated pipe break event.

The effects of jet impingement on the piping required to effect a safe shutdown, maintain containment integrity, provide post-LOCA monitoring, or limit radioactive releases to site-allowable limits, regardless of size or wall thickness, are also reviewed. Bounding cases are evaluated to ensure that acceptable stress levels in such piping are not exceeded.

3.6.1.2 Description

A listing of high energy fluid system piping is provided in Table 3.6-1. All other piping in the plant that is pressurized above atmospheric pressure is considered to be moderate energy piping. The routing of piping within the reactor enclosure and the primary containment is shown in Figures 1.2-40 through 1.2-72.

For each pipe rupture location determined in accordance with the criteria of Section 3.6.2.1, an analysis is performed using the assumptions of Section 3.6.1.1 to verify that the consequences of the pipe rupture are acceptable. These analyses are summarized below for high energy and moderate energy fluid systems.

3.6.1.2.1 High Energy Fluid Systems

3.6.1.2.1.1 Reactor Recirculation System

The two reactor recirculation loops are located entirely within the primary containment and are arranged on opposite sides of the reactor pedestal and reactor shield wall. Pipe whip restraints anchored in the reactor pedestal and reactor shield wall are provided for the recirculation loops and are arranged as shown in Figure 3.6-2. This system of restraints prevents unrestrained pipe whip resulting from a postulated rupture at any of the identified break locations. The restraints consist of two basic components: the frame attached to a support member and straps attached to the frame (two straps per frame). Either carbon steel cables or stainless steel bars are used as straps. The restraints on the 28-inch recirculation loop piping utilize stainless steel bars. The restraints on the 22-inch discharge header and the 12-inch risers utilize carbon steel cables. A schematic detail of a restraint is shown in Figure 3.6-3.

A review of the potential consequences of jet impingement resulting from recirculation loop ruptures has shown that breaks at the lower end of two of the 12-inch risers in each recirculation loop could result in impingement on the CRD withdraw piping. An evaluation of the consequences of damage to CRD withdraw piping resulting from jet impingement has shown that such damage would not prevent the associated control rods from being inserted into the reactor as necessary to affect a reactor shutdown. Electrical cabling associated with essential systems and components is routed to avoid jet impingement from postulated ruptures of recirculation loop piping.

Pipe Break Locations

The postulated pipe break locations for the recirculation loop piping are shown in Figure 3.6-4. The calculated stress levels and usage factors, and the postulated break types, are listed in Table 3.6-2. Blowdown thrust time histories for each break location are provided in Table 3.6-3. The recirculation piping design basis has been evaluated for the effects of power rerate and demonstrated to be adequate for the increases in pressure, temperature and flow due to power rerate. Details of the evaluation performed are documented in Reference 3.6-11.

Compartment Pressure-Temperature Transient

The pressure-temperature transient in the primary containment resulting from a complete circumferential rupture of one recirculation loop is discussed in Section 6.2.1.

Verification of Reactor Shutdown Capability

The sequence of events that would occur automatically to shut the reactor down and cool the core in the event of a recirculation loop rupture is discussed in Section 6.3.3. A combination of pipe whip restraints, jet impingement barriers, and separation by distance is used to ensure the availability of sufficient equipment to accomplish these functions.

3.6.1.2.1.2 Main Steam System

The four 26-inch main steam lines are routed as shown in Figure 5.1-7 for the portion inside the primary containment, and in Figure 3.6-5 for the portion outside the primary containment. The A and B steam lines are connected to the east side of the reactor vessel and the C and D steam lines are connected to the west side of the vessel. All four steam lines penetrate the north side of the primary containment. The portion of the reactor enclosure through which the main steam lines are routed (between the primary containment and the turbine enclosure) is referred to as the main steam tunnel and is separated from other areas of the reactor enclosure by concrete walls and slabs. Only piping, valves, and associated instrumentation are located in the main steam tunnel. Figure 3.6-6 shows an elevation view of the main steam tunnel.

The following features are incorporated into the design of the main steam line and nearby structures to mitigate the consequences of a main steam line break or to minimize the probability of its occurrence:

a. A venturi-type flow restrictor is located in each main steam line inside the primary containment. The flow restrictor reduces the rate of loss of reactor coolant from a main steam line break for break locations downstream of the restrictor. (The flow restrictors are described in Section 5.4.)

b. Each main steam line is provided with either three or four MSRVs that reduce the probability of breaks by protecting the steam line against overpressurization. (The MSRVs are described in Section 5.2.)

c. Each main steam line is provided with two fast-acting fail-safe MSIVs, one upstream and one downstream of the primary containment penetration. These valves close automatically upon receipt of signals indicating high steam flow or high temperature in the vicinity of the piping outside the primary containment (as well as upon receipt of other initiating signals), in order to terminate blowdown through breaks outside the primary containment. (The MSIVs are described in Section 5.4.)

d. Moment-limiting pipe whip restraints are located upstream of the inboard MSIVs and downstream of the outboard MSIVs in order to ensure the operability of these valves in the event of a main steam line break in the general vicinity of the valves.

The main steam lines are provided with pipe whip restraints inside the primary containment and in the main steam tunnel. Typical restraints inside the primary containment are shown in Figure

3.6-1. Figure 3.6-6 shows the locations of the restraints in the main steam tunnel. As shown in Figure 3.6-7, the first two restraints downstream of the outboard MSIVs span between the east and west walls of the tunnel and restrain all four steam lines. Corbels extending out from the north wall of the main steam tunnel limit the possible upward movement of the upper elbow of each steam line in the tunnel. Additionally, the vertical portion of the steam line run in the tunnel is restrained against the north wall of the tunnel at two separate locations.

After entering the Unit 1 turbine enclosure from the main steam tunnel, the main steam lines are routed along the west side of the control structure before turning westward to run the length of the turbine enclosure. This arrangement is shown in Figure 3.6-5. In order to prevent a main steam line break in this portion of piping from causing pipe whip impact on the control structure wall, bumpers are provided between the control structure and the elbows of the two steam lines closest to the control structure (26" EBB-103 and 26" EBB-104). The Unit 2 arrangement is similar, but opposite hand.

In reviewing the potential consequences of jet impingement resulting from main steam line breaks, it was determined that breaks at the elbow at the lower end of the near-vertical piping run inside the primary containment could result in impingement on the CRD withdraw piping. An evaluation of the consequences of damage to CRD withdraw piping resulting from jet impingement has shown that such damage would not prevent the associated control rods from being inserted into the reactor core as necessary to affect a reactor shutdown. Electrical cabling associated with essential systems and components is routed to avoid jet impingement from postulated breaks of main steam piping.

Pipe Break Locations

The postulated pipe break locations for the main steam piping, and also the pipe whip restraint locations, are shown in Figures 3.6-8 and 3.6-9. The calculated stress levels and usage factors, and the postulated break types, for the main steam piping inside the primary containment are listed in Table 3.6-4. Breaks for the main steam piping outside containment are postulated to occur at each location of potential high stress, such as pipe fittings, valves, and welded attachments. The main steam piping basis has been evaluated for the effects of power rerate and demonstrated to be adequate for the increases in pressure, temperature and flow due to power rerate. Details of the evaluation performed are documented in Reference 3.6-11.

Compartment Pressure-Temperature Transients

The pressure-temperature transient in the primary containment resulting from a complete circumferential break of one main steam line is discussed in Section 6.2.1.

Protection against overpressurization of the main steam tunnel in the event of a main steam line break in the tunnel is provided by two sets of blowout panels. One set of blowout panels is located in the north wall of the tunnel and vents to the turbine enclosure. The second set of blowout panels is located in the vent stack that leads upward from the tunnel and discharges to the atmosphere above the top of the reactor enclosure. This vent stack can be seen in drawings M-123 and M-138.

A pressure-temperature transient analysis for the case of a main steam line break in the tunnel was performed using the analytical technique described in BN-TOP-4 (Reference 3.6-1) and the blowdown data provided in Table 3.6-6 and Figure 3.6-10. The flow model is shown in Figure 3.6-11 and the results of the analysis are listed in Table 3.6-7. The main steam tunnel is designed

to withstand the maximum pressure developed, and the MSIVs are qualified to operate under environmental conditions more severe than those calculated to occur.

Protection against overpressurization of the Unit 1 turbine enclosure as a result of a main steam line break within its boundaries is provided by blowout panels along the north exterior wall of the turbine enclosure. As shown in drawings M-111 and 112, these blowout panels are located between column lines 12 and 18 and vent the main condenser area of the turbine enclosure directly to the atmosphere. The main steam lines are routed in areas that communicate directly with the main condenser area for the entire length of their run within the turbine enclosure. The Unit 2 arrangement is similar.

A pressure-temperature transient analysis for the case of a main steam line break in the turbine enclosure was performed using the analytical technique described in Reference 3.6-1 and with the blowdown data provided in Table 3.6-6. The flow model is shown in Figure 3.6-12 and the results of the analysis are listed in Table 3.6-7. The turbine enclosure is designed to withstand the maximum pressure developed.

The secondary containment structure is capable of withstanding the effects of a high energy pipe rupture occurring inside the secondary containment without loss of integrity. For all pipe breaks except those in the RWCU system, the time-dependent mass and energy release rates are calculated using the Moody model including friction effects. Blowdown for the main steam line breaks is determined in accordance with the assumptions in Reference 3.6-14. A double-ended guillotine break is assumed, and both forward and reverse flows are included for all cases except for HPCI and RCIC line breaks in the HPCI and RCIC compartments, respectively. The postulated pipe breaks in the HPCI and RCIC compartments are at the upstream side of a normally closed isolation valve, therefore only forward flow is considered.

Mass and energy release rates for pipe breaks in the RWCU system are calculated with RELAP4/MOD5 using the Henry-Fauske model option for subcooled conditions and the Moody critical flow model option for saturated conditions.

Verification of Reactor Shutdown Capability

Breakage of a main steam line inside the primary containment would result in an unisolable blowdown of the reactor vessel. The sequence of events that would occur automatically to shut the reactor down and cool the core is discussed in Section 6.3.3.

For a main steam line break outside the primary containment, the MSIVs will be closed automatically because of high steam flow, low reactor water level, or high temperature in the vicinity of the main steam lines. Closure of the MSIVs will cut off steam flow to the feedwater pump turbines, causing the pumps to coast down and stop. The reactor will be scrammed by low reactor water level or closure of the MSIVs. After isolation of the reactor vessel, the RCS pressure will increase until the setpoint of the MSRVs is reached. Steam will then be automatically discharged to the suppression pool to limit the pressure rise.

Low reactor water level will initiate operation of the HPCI and RCIC systems to maintain reactor water level. If both the HPCI and RCIC systems are unavailable, the ADS will be automatically initiated to depressurize the reactor vessel so that the LPCI and core spray systems can inject

water into the vessel. These latter two systems are initiated automatically by low reactor water level, and will provide sufficient flow to restore reactor water level and cool the core.

After reactor water level has been restored, and the RCS pressure and temperature have decreased sufficiently, the shutdown cooling mode of the RHR system can be initiated to bring the reactor to cold shutdown.

A combination of pipe whip restraints, jet impingement barriers, and separation by distance or intervening structure is used to ensure the availability of essential systems and components in the event of a main steam line break in either the primary containment or the main steam tunnel. Essential systems and components located in these areas are qualified to operate under the environmental conditions resulting from a break. Since no essential systems and components are located in the turbine enclosure, no special provisions are necessary to provide protection for equipment in this area from the effects of pipe breaks. Blowout panels are provided to prevent overpressurization of the turbine enclosure, and bumpers are provided to prevent a whipping main steam line from impacting the control structure.

3.6.1.2.1.3 Feedwater System

The discharge lines from the three feedwater pumps are routed into a common mixing header in the turbine enclosure. From this header, two parallel 24-inch feedwater lines enter the main steam tunnel and then penetrate the primary containment. Inside the primary containment, the two lines diverge to form symmetrical headers on opposite sides of the reactor vessel. Each header splits into three 12-inch risers that attach to the reactor vessel nozzles. The routing of the feedwater lines in the main steam tunnel and primary containment is shown in drawings M-234, M-305 and Figure 3.6-6.

Each feedwater containment penetration is provided with three check valves as containment isolation valves, one inside the drywell and two in the main steam tunnel. In the event of a feedwater line break outside the primary containment, these check valves will, as described below, close to prevent backflow from the reactor vessel. Thus, flow from the break would be from the feedwater pump side only.

The operability of the first outboard containment isolation valve (i.e. closest to the drywell penetration) is ensured in the event of a feedwater line break by providing moment-limiting whip restraints designed for this purpose. The operability of the check valve inside containment and the second outboard check valve need not be protected from overstress due to pipe whip, since only two isolation valves are necessary to provide adequate redundancy to ensure the containment isolation function, and it is not possible for one pipe break to affect both the inboard and second outboard check valves. More detailed discussion of feedwater check valve operability is provided in Section 3.9.3.2b.2.

The feedwater lines are provided with pipe whip restraints inside the primary containment, in the main steam tunnel, and in the turbine enclosure immediately outside the main steam tunnel. Typical restraints inside the primary containment are shown in Figure 3.6-1. As shown in Figure 3.6-13, the restraint in the tunnel spans between the east and west walls of the tunnel and restrains both feedwater lines. Corbels extending out from the north wall of the main steam tunnel limit the possible upward movement of the upper elbows of the feedwater startup recirculation lines that connect to the feedwater lines in the main steam tunnel. Feedwater line restraints located in the turbine enclosure and which are attached to the control structure and reactor enclosure walls are

shown in Figure 3.6-14. Bumpers on the control structure walls protect the control structure from a whipping feedwater line.

Electrical cabling associated with other essential systems and components is routed to avoid jet impingement from postulated breaks of feedwater piping.

Pipe Break Locations

The postulated pipe break locations for the feedwater piping, and also the pipe whip restraint locations, are shown in Figures 3.6-15 and 3.6-16. The calculated stress levels and usage factors, and the postulated break types, for the feedwater piping inside the primary containment are listed in Table 3.6-8. Breaks for the feedwater piping outside containment are postulated to occur at each location of potential high stress, such as pipe fittings, valves, and welded attachments.

Compartment Pressure-Temperature Transients

The pressure-temperature transient in the primary containment resulting from a break of any of the sizes of feedwater lines in the drywell is exceeded in severity by the transients resulting from recirculation loop and main steam line breaks, which are discussed in Section 6.2.1. The pressure-temperature transient resulting from a feedwater line break in the main steam tunnel or turbine enclosure is exceeded in severity by the transient resulting from a main steam line break, which is discussed in Section 3.6.1.2.1.2.

Verification of Reactor Shutdown Capability

Breakage of a feedwater line inside the primary containment would result in an unisolable blowdown of the reactor vessel. The sequence of events that would occur automatically to shut the reactor down and cool the core is discussed in Section 6.3.3.

For a feedwater line break outside the primary containment, differential pressure across the containment isolation check valves in the reverse direction will cause these valves to close rapidly, isolating the reactor vessel from the break. The loss of feedwater flow will cause the reactor water level to drop, initiating a reactor scram. Water level will continue to drop because of steam generation from decay heat, causing closure of the MSIVs as well as initiation of the RCIC and HPCI systems. Once the reactor has been scrammed and the RCS isolated, the sequence of events is similar to that for a main steam line break outside the primary containment.

A combination of pipe whip restraints, jet impingement barriers, and separation by distance or intervening structure is used to ensure the availability of essential systems and components in the event of a feedwater line break in either the drywell or the main steam tunnel. Since no essential systems and components are located in the turbine enclosure, no special provisions are necessary to provide protection for equipment in this area from the effects of pipe breaks. Bumpers are provided in the turbine enclosure to protect the control structure from the impact of a whipping feedwater line.

3.6.1.2.1.4 Condensate System

The condensate system is located entirely within the turbine enclosure. No pipe whip restraints are provided for the condensate piping.

Pipe Break Locations

Since the condensate system consists of non-nuclear class piping, breaks are postulated to occur at each location of potential high stress, such as pipe fittings, valves, and welded attachments.

Compartment Pressure-Temperature Transients

Since the normal fluid temperature in the condensate system is less than 135°F, no significant pressure-temperature transient would result from condensate line breaks.

Verification of Reactor Shutdown Capability

In the event of a condensate line break, the feedwater pumps would trip because of low suction pressure. The resulting loss of feedwater flow would result in closure of the containment isolation check valves, preventing reactor blowdown through the break. The sequence of events that would occur from this point on is the same as for breakage of a feedwater line outside the primary containment.

Since no essential systems and components are located in the turbine enclosure, no special provisions are necessary to provide protection for equipment in this area from the effects of pipe breaks. The flooding effects of a condensate line break are exceeded by the effects of a circulating water line expansion joint rupture in the turbine enclosure, a discussion of which is contained in Sections 10.4.1 and 10.4.5.

3.6.1.2.1.5 Reactor Water Cleanup System

The RWCU system takes suction from reactor recirculation loop B via the RHR shutdown cooling suction line inside primary containment. The 6-inch RWCU suction line is routed up to el 297'-3", at which point it penetrates the primary containment. The RWCU piping is then routed through the various RWCU equipment compartments at el 283' and el 313' in the reactor enclosure, including the containment penetration compartment, three RWCU pump compartments, the regenerative heat exchanger compartment, two nonregenerative heat exchanger compartments, two RWCU holding pump compartments, and two RWCU filter/demineralizer compartments. The RWCU return piping is routed from the containment penetration compartment directly into the main steam tunnel, where the piping splits into two 4-inch lines. One line connects to the A feedwater line (DBB-103) and the other line connects to the RCIC injection line immediately upstream of its connection to the B feedwater line (DBB-104). Both of these connections to the feedwater lines are located between the two outboard containment isolation valves in the feedwater lines. Another RWCU line, the 4-inch RWCU alternate return line, has a branch connection to the RWCU return line at a point just upstream of the location where the return line splits into the two lines leading to the feedwater lines. From this branch connection, the RWCU alternate return line is routed downward to a containment penetration at elevation 261 feet, which is also in the main steam tunnel. The routing of this RWCU piping is shown in drawings M-210, M-211, M-225, M-231, M-232, M-235, M-296, M-302, M-303, M-306, M-322, and M-323.

The RWCU suction line is provided with two fast-acting isolation valves, one upstream and one downstream of the primary containment penetration. These valves close automatically upon receipt of signals indicating high differential flow (RWCU suction vs. return) or high temperature in

the vicinity of the piping outside the drywell (as well as upon receipt of other initiating signals), in order to terminate blowdown through breaks outside the drywell. In order to ensure the operability of these valves in the event of an RWCU suction line break, moment-limiting pipe whip restraints are located upstream of the inboard containment isolation valve and downstream of the outboard containment isolation valve. Whip restraints are also located on the portion of the RWCU suction line within the drywell and on the portion of the return line within the main steam tunnel.

In reviewing the potential consequences of jet impingement resulting from RWCU line breaks, it was determined that breaks near the connection of the RWCU return lines to the RCIC injection and feedwater line in the main steam tunnel could result in impingement

on the outboard MSIV operators. A steel plate barrier is provided to protect the MSIV operators from this potential source of jet impingement. It was also determined that RWCU line breaks in the RWCU containment penetration compartment could result in impingement on the RWCU outboard containment isolation valve. A steel plate barrier is provided to protect the isolation valve from this potential source of jet impingement.

Pipe Break Locations

The postulated pipe break locations for the RWCU pump suction piping inside the primary containment, and also the pipe whip restraint locations, are shown in Figure 3.6-17. The calculated stress levels and usage factors, and the postulated break types, for this portion of the RWCU piping are listed in Table 3.6-10. Piping isometrics for the RWCU pump suction piping in the RWCU isolation valve compartment and for the RWCU return piping in the main steam tunnel are shown in Figures 3.6-39 and 3.6-18, respectively. Breaks in the latter portions of the RWCU piping are postulated to occur at each location of potential high stress, such as pipe fittings, valves, and welded attachments.

Compartment Pressure-Temperature Transients

The pressure-temperature transient in the primary containment resulting from a break in the portion of the RWCU suction line in the drywell is exceeded in severity by the transients resulting from recirculation loop breaks, main steam line breaks, and small steam leaks, which are discussed in Section 6.2.1.

Protection against overpressurization of the RWCU equipment compartments in the reactor enclosure as a result of RWCU line breaks in these areas is provided by interconnecting steam venting paths between the various compartments and by blowout panels leading to the outside atmosphere. The two nonregenerative heat exchanger compartments are vented into the regenerative heat exchanger compartment via a short steam venting plenum. The regenerative heat exchanger compartment is vented in turn to the adjacent containment penetration compartment. Each of the three pump rooms is vented individually to the containment penetration compartment. The containment penetration compartment is vented, via a blowout panel, to an exhaust stack located on the west side of the reactor enclosure for Unit 1 and on the east side of the reactor enclosure for Unit 2. The stack is open to the atmosphere at its upper and lower ends. The venting pathway from the containment penetration compartment to the exhaust stack is shown in drawings M-215 and M-316.

Pressure-temperature transient analyses for the cases involving RWCU line breaks in the RWCU equipment compartments were performed using the analytical technique described in Reference 3.6-1 and with the blowdown data provided in Table 3.6-6. These blowdown data were developed using Reference 3.6-2. The flow model for breaks in the RWCU equipment compartments is shown in Figure 3.6-19, and the results of the analyses are listed in Table 3.6-7. No analyses are performed for the RWCU holding pump compartments and filter/demineralizer compartments since the piping in these areas contains fluid at a temperature of 150°F or less, so that no significant pressure-temperature transient results from a pipe break.

The RWCU equipment compartments are designed to withstand the maximum pressure developed due to a pipe break. The outboard containment isolation valves for the RWCU system and other systems located in the containment penetration compartment are qualified to operate under environmental conditions more severe than those calculated to occur due to pipe break.

Verification of Reactor Shutdown Capability

Breakage of the RWCU suction line inside the drywell would result in an unisolable blowdown of the reactor vessel. The sequence of events that would occur automatically to shut the reactor down and cool the core is discussed in Section 6.3.3.

For an RWCU line break outside the drywell, the RWCU containment isolation valves will be closed automatically due to high flow in the RWCU suction line or high temperature in the RWCU equipment compartments. Backflow from the feedwater lines into the RWCU return line will be prevented by closure of the check valve in the return line. If the break occurs in the RWCU piping within the main steam tunnel, the MSIVs will close automatically due to high temperature in the tunnel. Once MSIV isolation has occurred, the sequence of events is similar to that for a main steam line break outside the primary containment. If the break occurs in the RWCU equipment compartments, no reactor scram or MSIV closure will occur, due to the isolation of the RWCU system and rapid termination of the blowdown. After an RWCU isolation, there is sufficient capability to shutdown the reactor. The operator will investigate the cause of the RWCU isolation and take appropriate actions, in accordance with the plant Technical Specifications and approved operating procedures. The Technical Specifications and/or the operating procedures, which include off normal and EOPs, may, based on plant conditions, require the operator to initiate a normal shutdown of the reactor.

A combination of pipe whip restraints, jet impingement barriers, and separation by distance or intervening structure is used to ensure the availability of essential systems and components in the event of an RWCU line break occurring in the drywell, main steam tunnel, or RWCU equipment compartments. Essential systems and components located in these areas are qualified to operate under the environmental conditions resulting from the break. Among the RWCU equipment compartments, only the containment penetration compartment contains safety-related equipment: the primary containment purge line, two of the four LPCI injection lines, and the RWCU outboard containment isolation valve. The containment isolation valves in the purge line and the LPCI injection lines are normally closed during reactor operation and are not required to operate after a RWCU line break outside primary containment; therefore they require no protection. The RWCU outboard containment isolation valve is protected from jet impingement by a steel plate barrier, and the cabling to the valve is routed so as to avoid jet impingement.

3.6.1.2.1.6 Reactor Vessel Drain

The reactor vessel drain consists of 2-inch piping originating at a nozzle on the reactor vessel bottom head. From this location inside the reactor vessel pedestal, the piping increases to 2½ inches in diameter, penetrates the pedestal into the general drywell area, increases to 4 inches in diameter, and is routed upward to its point of connection to the 6-inch RWCU suction line inside the drywell.

Pipe Break Locations

The postulated pipe break locations for the reactor vessel drain line, and also the pipe whip restraint locations, are shown in Figure 3.6-20. The calculated stress levels and usage factors, and the postulated break types, are listed in Table 3.6-12.

Compartment Pressure-Temperature Transients

Since the reactor vessel drain line is located entirely within the drywell, breakage of this line would have no effect on plant areas outside the primary containment. The pressure-temperature transient in the primary containment resulting from a reactor vessel drain line break is exceeded in severity by the transients resulting from recirculation loop breaks and main steam line breaks, which are discussed in Section 6.2.1.

Verification of Reactor Shutdown Capability

Breakage of the reactor vessel drain line would result in an unisolable blowdown of the reactor vessel. The sequence of events that would occur automatically to shut the reactor down and cool the core is discussed in Section 6.3.3. A combination of pipe whip restraints and separation by distance or intervening structure is used to ensure the availability of essential systems and components in the event of a reactor vessel drain line break.

3.6.1.2.1.7 HPCI Steam Supply Line

The HPCI steam supply piping has a nominal diameter of 10 inches for the portion inside the drywell and 12 inches for the portion outside the drywell. The supply line connects to main steam line C inside the drywell. From its connection to the main steam line, the HPCI steam supply line is routed downward and then horizontally along the drywell wall. The line then penetrates the drywell at el 244'-8", entering the isolation valve compartment located at floor el 217' in the reactor enclosure. The steam supply line penetrates the floor of the isolation valve compartment and enters the HPCI pump compartment located at el 177'. The routing of this line is shown in drawings M-213, M-225, M-226, M-227, M-228, M-295, M-297, M-296, M-318, M-319, M-229, and M-320. During normal reactor operation, the line is pressurized from main steam line C up to the HPCI turbine steam supply valve (HV-55-F001).

The HPCI steam supply line is provided with two fast-acting isolation valves, one upstream and one downstream of the primary containment penetration. These valves close automatically upon receipt of signals indicating high steam flow or high temperature in the vicinity of the piping outside the drywell (as well as upon receipt of other initiating signals), in order to terminate blowdown through breaks outside the drywell.

Moment-limiting pipe whip restraints are located upstream of the inboard containment isolation valve and downstream of the outboard containment isolation valve in order to ensure the operability of these valves in the event of a break in the HPCI steam supply line near the valves.

Whip restraints are also located on the HPCI steam supply line and in the isolation valve compartment at el 217' in the reactor enclosure. A typical restraint inside the drywell is shown in Figure 3.6-1.

Pipe Break Locations

The postulated pipe break locations for the HPCI steam supply line, and also the pipe whip restraint locations, are shown in Figure 3.6-21 for the portion of the line inside the drywell and in Figure 3.6-22 for the portion of the line outside the drywell. The calculated stress levels and usage factors, and the postulated break types, are listed in Tables 3.6-13 and 3.6-14.

Compartment Pressure-Temperature Transients

The pressure-temperature transient in the primary containment resulting from a break in the portion of the HPCI steam supply line in the drywell is exceeded in severity by the transients resulting from recirculation loop breaks and main steam line breaks, which are discussed in Section 6.2.1.

Protection against overpressurization of the HPCI pump compartment and the isolation valve compartment at el 217' in the reactor enclosure as a result of HPCI steam supply line breaks in these areas is provided by steam venting paths and blowout panels leading to the outside atmosphere. The isolation valve compartment is vented to the atmosphere via blowout panels located on the south side of the reactor enclosure, as shown in drawings M-118, M-123 and M-138. The HPCI pump compartment is vented to the isolation valve compartment via hinged, metal plate blowout panels located in the floor at el 217'. These latter panels lift to relieve pressurization in the HPCI pump compartment but do not allow pressurization in the isolation valve compartment to result in steam flow in the reverse direction, i.e., down into the HPCI pump compartment.

Pressure-temperature transient analyses for the cases involving HPCI steam supply line breaks in the HPCI pump compartment and the HPCI piping area were performed using the analytical technique described in Reference 3.6-1 and the blowdown data provided in Table 3.6-6. The flow model for breaks in these two compartments is shown in Figure 3.6-23, and the results of the analyses are listed in Table 3.6-7. Figures 3.6-43 through 3.6-45 provide additional details of a typical pipe break analysis. The case of an HPCI steam supply line break in the isolation valve compartment was analyzed using the CFLUD computer program (Reference 3.6-13) and the blowdown data provided in Table 3.6-6. The flow model for this case is shown in Figure 3.6-24, and the results of the analysis are listed in Table 3.6-7.

The HPCI pump compartment and the isolation valve compartment are designed to withstand the maximum pressures developed due to pipe break. All equipment located in the isolation valve compartment that is required to operate following breakage of the HPCI steam supply line is qualified to operate under environmental conditions more severe than those calculated to occur due to pipe break. No equipment located in the HPCI pump compartment is required to operate following breakage of the HPCI steam supply line.

Verification of Reactor Shutdown Capability

Breakage of the HPCI steam supply line inside the drywell would result in an unisolable blowdown of the reactor vessel. The sequence of events that would occur automatically to shut the reactor down and cool the core is discussed in Section 6.3.3.

For an HPCI steam supply line break outside the drywell, the steam supply line containment isolation valves will be closed automatically, terminating reactor vessel blowdown. No reactor scram will occur, due to the isolation of the HPCI steam line and rapid termination of the blowdown. After a HPCI isolation, there is sufficient capability to shutdown the reactor. The operator will investigate the cause of the HPCI isolation and take the appropriate actions, in accordance with the plant Technical Specifications and approved operating procedures, to assure that the plant is in safe condition. The Technical Specifications and/or the operating procedures, which include off normal and EOPs, may, based on plant conditions, require the operator to initiate a normal shutdown of the reactor.

A combination of pipe whip restraints and separation by distance or intervening structure is used to ensure the availability of essential systems and components in the event of an HPCI steam supply line break occurring in the drywell, the isolation valve compartment, or the HPCI pump compartment. Essential systems and components located in these areas are qualified to operate under the environmental conditions resulting from the break. Electrical cabling associated with essential systems and components is routed so as to avoid jet impingement from the postulated break.

No pipe whip restraints are provided for the portion of the HPCI steam supply line located within the HPCI pump compartment. Since no essential systems and components (other than the HPCI system itself) are located in the HPCI pump compartment, such protection is not necessary.

3.6.1.2.1.8 RCIC Steam Supply Line

The RCIC steam supply line has a nominal diameter of 4 inches for the portion inside the drywell and 6 inches for the portion outside the drywell. The supply line connects to main steam line B inside the drywell. From its connection to the main steam line, the RCIC steam supply line is routed generally downward and then horizontally along the drywell wall. The line then penetrates the drywell at el 243'-6", entering the isolation valve compartment located at floor el 217' in the reactor enclosure. The steam supply line penetrates the floor of the isolation valve compartment and enters the RCIC pump compartment located at el 177'. The routing of this line is shown in drawings M-213, M-215, M-225, M-226, M-227, M-229, M-239, M-295, M-296, M-297, M-310, M-316, M-318, and M-320. During normal reactor operation, the line is pressurized from main steam line B up to the RCIC turbine steam supply valve (HV-50-F045).

The RCIC steam supply line is provided with two fast-acting isolation valves, one upstream and one downstream of the primary containment penetration. These valves close automatically upon receipt of signals indicating high steam flow or high temperature in the vicinity of the piping outside the drywell (as well as upon receipt of other initiating signals), in order to terminate blowdown through breaks outside the drywell.

Moment-limiting pipe whip restraints are located upstream of the inboard containment isolation valve and downstream of the outboard containment isolation valve in order to ensure the

operability of these valves in the event of a break in the RCIC steam supply line near the valves. Whip restraints are also located on the RCIC steam supply line inside the drywell and in the isolation valve compartment at el 217' in the reactor enclosure. A typical restraint inside the drywell is shown in Figure 3.6-1.

Pipe Break Locations

The postulated pipe break locations for the RCIC steam supply line, and also the pipe whip restraint locations, are shown in Figure 3.6-25 for the portion of the line inside the drywell and in Figure 3.6-26 for the portion of the line outside the drywell. The calculated stress levels and usage factors, and the postulated break types, are listed in Tables 3.6-15 and 3.6-16.

Compartment Pressure-Temperature Transients

The pressure-temperature transient in the primary containment resulting from a break in the portion of the RCIC steam supply line in the drywell is exceeded in severity by the transients resulting from recirculation loop breaks and main steam line breaks, which are discussed in Section 6.2.1.

Protection against overpressurization of the RCIC pump compartment and the isolation valve compartment at el 217' in the reactor enclosure as a result of RCIC steam supply line breaks in these areas is provided by steam venting paths and blowout panels leading to the outside atmosphere. The isolation valve compartment is vented to the atmosphere via blowout panels located on the south side of the reactor enclosure, as shown in drawings M-118, M-123 and M-138. The RCIC pump compartment is vented to the isolation valve compartment via hinged, metal plate blowout panels located in the floor at el 217'. These latter panels lift to relieve pressurization in the RCIC pump compartment but do not allow pressurization in the isolation valve compartment to result in steam flow in the reverse direction, i.e., down into the RCIC pump compartment.

Pressure-temperature transient analyses for the cases involving RCIC steam supply line breaks in the RCIC pump compartment and the RCIC upper pipe tunnel were performed using the analytical technique described in Reference 3.6-1 and the blowdown data provided in Table 3.6-6. The flow model for breaks in these two compartments is shown in Figure 3.6-27, and the results of the analyses are listed in Table 3.6-7.

The RCIC pump compartment is designed to withstand the maximum pressure developed due to pipe break. No equipment located in the RCIC pump compartment is required to operate following breakage of the RCIC steam supply line. The pressure-temperature transient in the isolation valve compartment at el 217' resulting from a break in the portion of the RCIC steam supply line within that compartment is exceeded in severity by the transient resulting from HPCI steam supply line breakage in the same compartment. All equipment located in the isolation valve compartment that is required to operate following breakage of the RCIC steam supply line is qualified to operate under environmental conditions more severe than those calculated to occur due to breakage of the HPCI steam supply line.

Verification of Reactor Shutdown Capability

Breakage of the RCIC steam supply line inside the drywell would result in an unisolable blowdown of the reactor vessel. The sequence of events that would occur automatically to shut the reactor down and cool the core is discussed in Section 6.3.3.

For an RCIC steam supply line break outside the drywell, the steam supply line containment isolation valves will be closed automatically, terminating reactor vessel blowdown. No reactor scram will occur, due to the isolation of the RCIC steam line and rapid termination of the blowdown. After a RCIC isolation, there is sufficient capability to shutdown the reactor. The operator will investigate the cause of the RCIC isolation and take appropriate actions, in accordance with the plant Technical Specifications and approved operating procedures, to assure that the plant is in a safe condition. The Technical Specifications and/or the operating procedures, which include off normal and EOPs, may, based on plant conditions, require the operator to initiate a normal shutdown of the reactor.

A combination of pipe whip restraints and separation by distance or intervening structure is used to ensure the availability of essential systems and components in the event of an RCIC steam supply line break occurring in the drywell, the isolation valve compartment, or the RCIC pump compartment. Essential systems and components located in these areas are qualified to operate under the environmental conditions resulting from the break. Electrical cabling associated with essential systems and components is routed so as to avoid jet impingement from the postulated break.

No pipe whip restraints are provided for the portion of the RCIC steam supply line located within the RCIC pump compartment. Since no essential systems and components are located within the RCIC pump compartment, such protection is not necessary.

3.6.1.2.1.9 Main Steam Drain Lines

The main steam drainage piping connects to the four main steam lines both inside and outside the drywell. Inside the drywell, 2-inch drain lines that connect to each of the main steam lines are headered together into a single 3-inch line, which then penetrates the drywell wall. This 3-inch drain header is provided with two containment isolation valves, one upstream and one downstream of the containment penetration, both of which are normally closed. Outside the drywell (in the main steam tunnel), 2-inch drain lines that connect to each of the main steam lines are headered together into a single 3-inch line, which then connects to the drain header from the drain lines inside the drywell. Downstream of the connection of the two drain headers, the common line splits into two 3-inch lines again, one routed to the main condenser and one routed to the liquid waste management system. These latter two lines are both provided with normally closed valves located within the main steam tunnel. The routing of the main steam drain lines is shown in drawings M-217, M-226, M-297, and M-326.

Pipe Break Locations

The postulated pipe break locations for the main steam drain lines inside the drywell are shown in Figure 3.6-28. The calculated stress levels and usage factors, and the postulated break types, are listed in Table 3.6-17. Breaks in the main steam drain lines within the main steam tunnel are postulated to occur at each location of potential high stress, such as pipe fittings, valves, and welded attachments.

Compartment Pressure-Temperature Transients

The pressure transient in the primary containment resulting from a break in a main steam drain line within the drywell is exceeded in severity by transients resulting from recirculation loop breaks and main steam line breaks. The temperature transient in the primary containment resulting from a

main steam drain line break is exceeded in severity by the transient resulting from a small steam leak. These design basis transients are discussed in Section 6.2.1.

The pressure-temperature transient in the main steam tunnel resulting from a main steam drain line break within the tunnel is exceeded in severity by the transient resulting from a main steam line break.

Verification of Reactor Shutdown Capability

Breakage of a main steam drain line inside the drywell would result in an unisolable blowdown of steam from the reactor vessel through the broken line. The sequence of events that would occur automatically to shut the reactor down and cool the core is discussed in Section 6.3.3.

For the case of a main steam drain line break inside the main steam tunnel, the resultant temperature rise in the tunnel would cause the MSIVs and the MSL drain isolation valves, if open to close automatically, thereby terminating steam blowdown through the break. Once the MSIVs and MSL drain isolation valves have been closed, the sequence of events is similar to that for a main steam line break outside the drywell.

Separation by distance and intervening structure is used to ensure the availability of essential systems and components in the event of a main steam drain line break in either the drywell or the main steam tunnel.

3.6.1.2.1.10 RPV Head Vent Line

The RPV head vent line is located entirely within the drywell. From its connection point to a 4-inch flanged nozzle on the RPV head, the line reduces to 2 inches in diameter and then is routed generally downward to a penetration through the containment seal plate. From this point, the line continues on downward to its connection with 26-inch main steam line C.

Pipe Break Locations

The postulated pipe break locations for the RPV head vent line, and also the pipe whip restraint locations, are shown in Figure 3.6-30. The calculated stress levels and usage factors, and the postulated break types, are listed in Table 3.6-19.

Compartment Pressure-Temperature Transients

Since the RPV head vent line is located entirely within the drywell, breakage of this line has no effect on plant areas outside the primary containment. The pressure transient in the primary containment resulting from a break in the RPV head vent line is exceeded in severity by transients resulting from recirculation loop breaks and main steam line breaks. The temperature transient in the primary containment resulting from a break in the RPV head vent line is exceeded in severity by the transient resulting from a small steam leak. These design basis transients are discussed in Section 6.2.1.

Verification of Reactor Shutdown Capability

Breakage of the RPV head vent line would result in an unisolable blowdown of steam into the drywell. The sequence of events that would occur automatically to shut the reactor down and cool the core is discussed in Section 6.3.3.

Separation by distance and intervening structure is used to ensure the availability of essential systems and components in the event of an RPV head vent line break.

3.6.1.2.1.11 Standby Liquid Control System Injection Line

The discharge lines from the SLCS injection pumps penetrate the drywell through two separate penetrations and are headered together inside the drywell to form a single 2-inch line. From the vicinity of the drywell penetrations (between el 265' and el 271'), this line is routed horizontally and upward to its connection to core spray injection line B (12" DCA-319). In addition to the containment isolation valves, the SLCS injection line is provided with a check valve near the connection to the core spray line. Only that portion of the SLCS injection line between the core spray line and the inboard check valve is considered high energy during periods when the reactor is pressurized.

Pipe Break Locations

The postulated pipe break locations for the SLCS injection line are shown in Figure 3.6-31. The calculated stress levels and usage factors, and the postulated break types, are listed in Table 3.6-20.

Compartment Pressure-Temperature Transients

Since the high energy portion of the SLCS injection line is located entirely within the drywell, breakage of this line would have no effect on plant areas outside the primary containment. The pressure-temperature transient in the primary containment resulting from a break in the SLCS injection line is exceeded in severity by the transients resulting from recirculation loop breaks and main steam line breaks, which are discussed in Section 6.2.1.

Verification of Reactor Shutdown Capability

Breakage of the SLCS injection line between the RPV and the first check valve in that line would result in an unisolable blowdown from the reactor vessel into the drywell. The sequence of events that would occur automatically to shut the reactor down and cool the core is discussed in Section 6.3.3.

Separation by distance and intervening structure is used to ensure the availability of essential systems and components in the event of an SLCS injection line break.

3.6.1.2.1.12 RHR Shutdown Cooling Suction Line

The RHR shutdown cooling suction line is a 20-inch line connected to recirculation loop B in the drywell. The line is routed downward and then horizontally to its containment penetration at el 244'-8". The line is provided with two containment isolation valves (one inboard and one outboard

of the penetration), both of which are normally closed. Thus, only that portion of the line between the recirculation loop and the inboard containment isolation valve is considered high energy. The routing of the line is shown in drawings M-213, M-217, M-225, M-295, M-296, and M-326.

The RHR shutdown cooling suction line is provided with pipe whip restraints on the portion of the line inside the drywell. Examples of these restraints are shown in Figure 3.6-1.

Pipe Break Locations

The postulated pipe break locations for the RHR shutdown cooling suction line, and also the pipe whip restraint locations, are shown in Figure 3.6-32. The calculated stress levels and usage factors, and the postulated break types, are listed in Table 3.6-21.

Compartment Pressure-Temperature Transients

Since the high energy portion of the RHR shutdown cooling suction line is located entirely within the drywell, breakage of the line would have no effect on plant areas outside the primary containment. The pressure-temperature transient in the primary containment resulting from a break in the RHR shutdown cooling suction line is exceeded in severity by the transients resulting from recirculation loop breaks and main steam line breaks, which are discussed in Section 6.2.1.

Verification of Reactor Shutdown Capability

Breakage of the RHR shutdown cooling suction line would result in an unisolable blowdown of the reactor vessel. The sequence of events that would occur automatically to shut the reactor down and cool the core is discussed in Section 6.3.3.

A combination of pipe whip restraints and separation by distance and intervening structure is used to ensure the availability of essential systems and components in the event of a break in the RHR shutdown cooling suction line.

3.6.1.2.1.13 RHR Shutdown Cooling Return Line

One 12-inch RHR shutdown cooling return line is associated with RHR loop A and a second return line is associated with RHR loop B. Since the two return lines are routed symmetrically on opposite sides of the drywell, the following discussion applies to both lines. The RHR shutdown cooling return line, from the discharge of the associated RHR pump and heat exchanger, penetrates the south side of the drywell at el 244'-8". The line is then routed horizontally following the curvature of the drywell wall until a point due west (for loop A; due east for loop B) of the reactor vessel centerline is reached. From this point, the line is routed upward to el 265'-4" and then horizontally to its connection with the discharge riser of the reactor recirculation loop. The routing of this piping is shown in drawings M-213, M-217, M-225, M-295, M-296, and M-326.

The RHR shutdown cooling return line is provided with two containment isolation valves: a normally closed globe valve outside the drywell and a check valve inside the drywell. Only that portion of the line between the reactor recirculation line and the inboard check valve is considered high energy during periods when the reactor is pressurized.

The RHR shutdown cooling return line is provided with one pipe whip restraint, located at the upper elbow of the vertical portion of the line. A detail of this restraint is shown in Figure 3.6-1.

Pipe Break Locations

The postulated pipe break locations for the RHR shutdown cooling return line, and also the pipe whip restraint locations, are shown in Figure 3.6-32. The calculated stress levels and usage factors, and the postulated break types, are listed in Table 3.6-21.

Compartment Pressure-Temperature Transients

Since the high energy portion of the RHR shutdown cooling return line is located entirely within the drywell, breakage of the line would have no effect on plant areas outside the primary containment. The pressure-temperature transient in the primary containment resulting from a break in the RHR shutdown cooling return line is exceeded in severity by the transients resulting from recirculation loop breaks and main steam line breaks, which are discussed in Section 6.2.1.

Verification of Reactor Shutdown Capability

Breakage of the RHR shutdown cooling return line would result in an unisolable blowdown of the reactor vessel. The sequence of events that would occur automatically to shut the reactor down and cool the core is discussed in Section 6.3.3.

A combination of pipe whip restraints and separation by distance and intervening structure is used to ensure the availability of essential systems and components in the event of a break in the RHR shutdown cooling return line.

3.6.1.2.1.14 LPCI Injection Line

There are four 12-inch LPCI injection lines, one associated with each of the four RHR pumps. The four lines are routed symmetrically inside the drywell, with the A and C injection lines entering the west side of the drywell and the B and D lines entering the east side of the drywell. The following discussion applies to all four lines. The LPCI injection line penetrates the drywell at el 285'-2" and is routed up to el 297'-3" inches where it connects to the reactor vessel nozzle. The routing of this piping is shown in drawings M-215, M-217, M-234, M-235, M-305, M-306, M-316, and M-326.

The LPCI injection line is provided with two containment isolation valves: a normally closed gate valve outside the drywell and a check valve inside the drywell. Only that portion of the line between the reactor vessel nozzle and the inboard check valve is considered high energy during periods when the reactor is pressurized.

The LPCI injection line is restrained to prevent pipe whip inside the drywell. A typical restraint is shown in Figure 3.6-1.

Pipe Break Locations

The postulated pipe break locations for the LPCI injection line, and also the pipe whip restraint locations, are shown in Figure 3.6-33. The calculated stress levels and usage factors, and the postulated break types, are listed in Table 3.6-22

Compartment Pressure-Temperature Transients

Since the high energy portion of the LPCI injection line is located entirely within the drywell, breakage of the line would have no effect on plant areas outside the primary containment. The pressure-temperature transient in the primary containment resulting from a break in the LPCI injection line is exceeded in severity by the transients resulting from recirculation loop breaks and main steam line breaks, which are discussed in Section 6.2.1.

Verification of Reactor Shutdown Capability

Breakage of the LPCI injection line would result in an unisolable blowdown of the reactor vessel. The sequence of events that would occur automatically to shut the reactor down and cool the core is discussed in Section 6.3.3.

A combination of pipe whip restraints and separation by distance and intervening structure is used to ensure the availability of essential systems and components in the event of a break in the LPCI injection line.

3.6.1.2.1.15 Core Spray Injection Line

There are two core spray injection lines, one associated with core spray pumps A and C and one associated with core spray pumps B and D. Since the two lines are routed symmetrically within the drywell, the following discussion applies to both lines. The core spray injection line penetrates the north side of the drywell at el 297'-3" and is routed up to el 306'-7" before connecting to the RPV nozzle. The routing of the piping is shown in drawings M-217, M-235, M-306, and M-326.

The core spray injection line is provided with containment isolation valves both inside and outside the drywell, the inboard valve being a check valve. Only that portion of the line between the reactor vessel nozzle and the inboard check valve is considered high energy during periods when the reactor is pressurized.

The core spray injection line is restrained to prevent pipe whip inside the drywell. Typical restraints are shown in Figure 3.6-1.

Pipe Break Locations

The postulated pipe break locations for the core spray injection line, and also the pipe whip restraint locations, are shown in Figure 3.6-34. The calculated stress levels and usage factors, and the postulated break types, are listed in Table 3.6-23.

Compartment Pressure-Temperature Transients

Since the high energy portion of the core spray injection line is located entirely within the drywell, breakage of the line would have no effect on plant areas outside the primary containment. The pressure-temperature transient in the primary containment resulting from a break in the core spray injection line is exceeded in severity by the transients resulting from recirculation loop breaks and main steam line breaks, which are discussed in Section 6.2.1.

Verification of Reactor Shutdown Capability

Breakage of the core spray injection line would result in an unisolable blowdown of the reactor vessel. The sequence of events that would occur automatically to shut the reactor down and cool the core is discussed in Section 6.3.3.

A combination of pipe whip restraints and separation by distance and intervening structure is used to ensure the availability of essential systems and components in the event of a break in the core spray injection line.

3.6.1.2.1.16 Control Rod Drive Hydraulic

The 2 CRD water pumps are located in the turbine enclosure. The high energy discharge pipes from the 2 pumps are headered together, and a single 2-inch pipe is routed from the turbine enclosure into the reactor enclosure at el 201'. This 2-inch line is then routed upward to the CRD hydraulic system master control station located at el 253' of the reactor enclosure. From the master control station, a 2-inch cooling water header and a 2-inch charging water header are routed to the groups of HCUs on the west side and east side of the drywell. Containment isolation valves are provided in each header between the master control station and the HCUs. The piping between the isolation valves has been upgraded to be equivalent to ASME III, Class 2.

Pipe Break Locations

Since the CRD pump discharge line, the cooling water header, and the charging water header originally consisted entirely of non-nuclear class piping, breaks are postulated to occur at each location of potential high stress, such as pipe fittings, valves, and welded attachments. The original analysis bounds the effects of the addition of containment isolation valves in the headers.

Compartment Pressure-Temperature Transients

Since the normal fluid temperature in the CRD hydraulic system is less than 120°F, no significant pressure-temperature transient would result from postulated breaks.

Verification of Reactor Shutdown Capability

Loss of water pressure due to a break in the CRD pump discharge line, cooling water header, or charging water header will not prevent the control rods from being inserted into the reactor core. At reactor pressures of 450 psig or higher, reactor pressure alone is sufficient to fully insert the control rods. At lower reactor pressures, the scram accumulators assist in supplying the energy necessary to insert the control rods.

3.6.1.2.1.17 Auxiliary Steam Line

From the auxiliary boiler, auxiliary steam is distributed via an 8-inch header to the various steam-consuming components in the turbine enclosure and the radwaste enclosure. This auxiliary steam header passes through the offgas pipe tunnel north of the control structure at el 187'. The auxiliary steam system also provides steam to the RCIC and HPCI systems for testing purposes.

Pipe Break Locations

Since the auxiliary steam line consists of non-nuclear class piping, breaks are postulated to occur at each location of potential high stress, such as pipe fittings, valves, and welded attachments.

Compartment Pressure-Temperature Transients

A pressure-temperature transient analysis for the case of an auxiliary steam line break in a safety-related area was not performed because the piping does not pass through any safety related areas with the exception of the test lines to HPCI and RCIC. However, a pressure-temperature transient analysis was performed for the auxiliary steam line break in the offgas pipe tunnel to ensure control structure integrity. The HPCI and RCIC test lines are normally isolated from the reactor enclosure by closed valves. The lines are only energized in the reactor enclosure for short periods (i.e., less than 1% of the time) and are therefore considered as moderate energy lines.

Verification of Reactor Shutdown Capability

Breakage of the auxiliary steam line would have no effect on operation of the reactor. Except for the test lines for HPCI and RCIC, auxiliary steam lines are not located in areas containing safety related equipment. In the case of the HPCI and RCIC test lines, they are considered to be moderate energy lines based on the short periods in which they are energized. As moderate energy lines, they are acceptable since all rooms containing safety related equipment are qualified for a moderate energy line break.

3.6.1.2.1.18 Plant Heating Steam Piping

From the auxiliary boiler, plant heating steam is distributed to various steam-consuming components in the turbine enclosure and the diesel generator compartments. Additionally, heating steam is provided to the refueling floor and the railroad air-lock in the reactor enclosure and in the diesel corridor outside of the reactor enclosure, however, none of these areas contain safety related equipment necessary to shut down the reactor or maintain primary containment integrity.

Pipe Break Locations

Because the plant heating steam piping consists of non-nuclear class piping, breaks are postulated to occur at each location of potential high stress, such as pipe fittings, valves, and welded attachments.

Verification of Reactor Shutdown Capability

Breakage of the plant heating steam piping would have no effect on operation of the reactor because reactor systems are not located in areas through which the heating steam piping is routed. The only areas of the plant through which heating steam piping is routed that contain safety-related systems are the diesel generator compartments, the refuel floor, the diesel corridor, and the railroad air lock. In addition to the diesel generators, the safeguard MCCs for the following valves are located within diesel generator enclosures:

a. ESW to RHRSW valves (HV-11-11A, 11B, 15A, 15B; drawing M-11).

b. ESW to TECW heat exchanger valves (HV-11-105, 107, 205, 207; Figure 9.2-2).

c. TECW heat exchanger to RHRSW valves (HV-12-110, 210; drawing M-12).

d. CST to ECCS (HV-55-124, 224; drawing M-55).

The MCCs for these valves are distributed throughout the diesel generator cells such that the loss of the MCCs in any one cell would not compromise the safety function of the systems. Thus, an HELB in one cell would not affect the safe shutdown capability of the plant.

A rupture of the plant steam heating piping in one cell would not affect the diesel generators located in other cells. Thus, a failure of this system would result in loss of only the one diesel. The safe shutdown capability of the plant would therefore not be compromised because only three of the four diesels are required in the event of a LOOP.

Because the loss of components in any diesel generator compartment from a high or moderate energy line break would not precipitate a trip of the turbine-generator or a trip of the RPS, offsite power is assumed to remain available in the analysis of the effects of postulated piping failures in these systems (BTP ASB 3.1, paragraph 3.b.1).

There are no essential systems or components as defined in Branch Technical Position SPLB 3-1 (Protection against postulated piping failures in fluid systems outside containment) on the refueling floor, the diesel corridor or the railroad airlock.

3.6.1.2.2 Moderate Energy Fluid Systems

Each room, compartment, or area containing components essential for safe shutdown has been evaluated for the effects of postulated ruptures in moderate energy piping.

Safe shutdown components were evaluated for operability in the postulated water spray and/or flooding environment. Safe shutdown components in the reactor enclosure, the control structure, the diesel generator enclosure, the spray pond pumphouse, the main steam tunnel, and the RHRSW pipe tunnel were considered.

Those components not designed for operability in a water spray and/or a flooding environment were assumed to fail. Electrical components that are needed for safe shutdown, but that would fail under the water spray/flooding conditions, were protected from water spray and flooding conditions.

The synergistic effects of an independent single active failure, in addition to the effects of the pipe break, were evaluated and were found acceptable subject to any limitations discussed below. For some systems (such as RHR), a single active failure in the redundant loop of the same system has been excluded in accordance with Section 3.6.1.1.

The crack sizes postulated, and the nominal pipe sizes in which moderate energy pipe cracks are postulated to occur, are discussed in Section 3.6.2.1.3. Additional criteria used in the moderate energy fluid systems analysis are discussed in Section 3.6.1.1.

3.6.1.2.2.1 Primary Containment

All equipment within the primary containment that must operate during or after a LOCA is qualified for the appropriate environmental conditions, as described in Section 3.11. Wetting associated

with the postulated failure of any moderate energy pipe is within the bounds of that qualification. Consequently, no item-by-item discussion of this less severe event is required to verify that capability of safely shutting down the plant.

3.6.1.2.2.2 Reactor Enclosure

Compartments or areas on each elevation that contain safe shutdown electrical equipment were evaluated. Piping and mechanical drawings for each elevation of the reactor enclosure are provided in Section 1.2. All safety-related equipment whose operability in a water spray or flooding environment must be ensured were either protected from the consequences of the pipe break or are designed to remain operable in that environment.

3.6.1.2.2.3 Control Structure

Compartments or areas that contain safety-related equipment on each elevation were evaluated beginning with el 200', the lowest elevation of the control structure. All safety-related equipment whose operability in a water spray or flooding environment must be ensured were either protected from the consequences of the pipe break or were designed to operate in that environment. Piping and mechanical drawings for each elevation of the control structure are provided in Section 1.2.

3.6.1.2.2.4 Diesel Generator Compartments

Moderate energy piping systems that are routed through the diesel generator compartments include:

a. ESW to the diesel generator heat exchangers

b. diesel fuel oil supply lines

c. diesel generator starting air

d. demineralized water from the jacket water expansion tank to the diesel generator

e. lube oil from the storage tank to the diesel generator

f. fire protection system (normally dry)

Each of the moderate energy piping systems is integral to the operation or protection of the diesel generator located in the same compartment as the piping. Thus, a failure of one or more of these systems would result in loss of only the one diesel. The safe shutdown capability of the plant would therefore not be compromised because only three of the four diesels are required in the event of a LOOP.

In addition to the diesel generators, a safeguard MCC is located within each diesel generator enclosure. The impact of a pipe break in the diesel generator enclosure on these MCCs is discussed in Section 3.6.1.2.1.18.

3.6.1.2.2.5 Spray Pond Pumphouse

The spray pond pumphouse contains two separate ESW and RHRSW pump areas, two RHRSW and ESW pipe-ways, two RHRSW valve compartments, and several other compartments.

Each pump-room contains two RHRSW pump motors and two ESW pump motors. The pumps are common to both Unit 1 and Unit 2.

During normal plant operation, the ESW and RHRSW piping is depressurized except during surveillance testing of ESW, RHRSW, and the diesel generators; and during operation for reactor shutdown cooling, suppression pool cooling, and spray pond cooling/chemistry control. The frequency of the surveillance tests is in accordance with the Technical Specifications, and the frequency of operation for other purposes varies with plant conditions.

A moderate energy line break in these lines during normal plant operation is unlikely. However, if a line break should occur, water spray could impinge on the pump motors in the room. In this event, up to two ESW and two RHRSW pumps could be disabled. The loss of the two ESW pumps is of no concern because shutdown cooling loads would be provided by the service water system. Because nonsafeguard heat removal systems are available, the RHRSW system is not critical for safe shutdown of the reactors.

The RHRSW valve compartments contain valves that are essential for the safe operation of the ESW system. However, as discussed above, shutdown cooling loads would be provided by the service water system because offsite power would be assumed to be available.

A pipe break in the wet pit, the ESW and RHRSW pipe-way, or the access hatch area would not impact safe shutdown capability because these compartments do not contain components that are essential for safe shutdown.

Spray pond pumphouse flooding is limited to the compartments adjoining the pump area. The pump area itself cannot flood because water would flow through open grating into the spray pond.

Flooding in the adjacent compartments could damage at most a single mechanical division. Because it is not necessary to postulate a single active failure in the redundant RHRSW system, and because flooding can damage only one mechanical division of RHRSW, safe shutdown capability will not be impaired.

3.6.1.2.2.6 Main Steam Tunnel

Safe shutdown components in the main steam tunnel include the outboard MSIVs.

The MSIVs are qualified to operate in environments more severe than that caused by moderate energy water spray. The valves are located well above the maximum water flood level. Therefore, the occurrence of a moderate energy pipe crack in this compartment would have no effect on safe shutdown capability.

3.6.1.2.2.7 RHRSW Pipe Tunnel

A moderate energy pipe break in the RHRSW pipe tunnel would not impact safe shutdown capability.

The only safe shutdown components on this elevation are two RHRSW valves. Each of these valves are qualified to be submersible and would withstand postulated water spray and flooding conditions.

3.6.1.3 Safety Evaluation

The analyses of postulated pipe ruptures summarized in Section 3.6.1.2 verify that the consequences of any single rupture of fluid system piping in the plant will not prevent safe shutdown of the reactor from being achieved.

The offsite radiological consequences of piping ruptures are enveloped by a reactor recirculation system break for all breaks inside primary containment, and by main steam system and feedwater system breaks for all breaks outside primary containment. The radiological consequences of these breaks are presented in Sections 15.6.5, 15.6.4, and 15.6.6, respectively.

Special consideration has been given to protecting the control room and other areas of the control structure containing essential systems and components from the effects of postulated pipe ruptures. Exterior walls of the control structure above the slab at el 217' are designed as steam-tight in those areas where the walls could be subject to steam pressurization resulting from rupture of high energy fluid system piping outside the control structure. HVAC ducts penetrating these portions of the control structure walls are equipped with back pressure dampers, and other types of penetrations through the walls are designed as steam-tight.

As described in Sections 3.6.1.2.1.2 and 3.6.1.2.1.3, those portions of the main steam and feedwater lines routed near the control structure are provided with pipe whip restraints and bumpers to prevent a postulated rupture of these lines from causing unacceptable damage to the control structure walls.

3.6.2 DETERMINATION OF PIPE FAILURE LOCATIONS AND DYNAMIC EFFECTS ASSOCIATED WITH POSTULATED PIPING FAILURES

Information concerning break and crack location criteria and methods of analysis is presented in this section. The location criteria and methods of analysis are needed to evaluate the dynamic effects associated with postulated ruptures of high energy and moderate energy piping inside and outside the primary containment.

3.6.2.1 Criteria Used to Determine Pipe Break and Crack Locations and Their Configurations

3.6.2.1.1 Break Locations in High Energy Fluid System Piping

3.6.2.1.1.1 Piping in Containment Penetration Areas

High energy pipes penetrating the primary containment are provided with moment-limiting restraints that are located reasonably close to the containment isolation valves and are designed to

withstand the loadings resulting from a pipe break either inboard of the inboard isolation valve or outboard of the outboard isolation valve so that neither isolation valve operability nor leak-tight integrity of the containment penetration would be impaired as a result of such pipe breaks. Terminal ends of high energy piping that penetrate the containment are considered to originate beyond the containment isolation valve and its moment-limiting restraint, both inboard and outboard.

Breaks are not postulated in these portions of high energy piping in containment penetration areas provided that the following design stress and fatigue limits are satisfied:

For ASME Section III, Class 1 Piping

a. The stress intensity range S_n, calculated for normal and upset conditions by equation (10) of paragraph NB-3653, does not exceed 2.4 S_m, and the cumulative usage factor associated with normal, upset, and testing conditions is less than 0.1, or

b. The stress intensity range S_n, calculated for normal and upset conditions by equation (10) of paragraph NB-3653 exceeds 2.4 S_m but does not exceed 3.0 S_m and the cumulative usage factor associated with normal, upset, and testing conditions is less than 0.1, or

c. The stress intensity range S_n, calculated for normal and upset conditions by equation (10), exceeds 3.0 S_m, but the stress intensity ranges computed by equations (12) and (13) of paragraph NB-3653 are less than 2.4 S_m and the cumulative usage factor associated with normal, upset, and testing conditions is less than 0.1

d. Breaks are always postulated whenever the usage factor exceeds 0.1 regardless of stress.

e. The loading resulting from a postulated pipe break beyond these portions of the piping does not cause the stress as calculated by equation (9) in paragraph NB-3652 to exceed 2.25 S_m, except for the portion of piping between the isolation valve and the adjacent restraints protecting the operability of the valve. For this latter portion of piping, higher stresses are permitted provided that a plastic-hinge is not formed and the operability of the isolation valve is ensured.

After the as-built analysis is completed, the licensee will conduct a comparison against the SRP criteria (NUREG-0800) (BTP MEB 3-1) and demonstrate no additional breaks for the following situations:

a. The stress calculated by equation (10) is between 2.4 S_m and 3.0 S_m and

b. The ASME Code version of 1979 Summer Addenda or later is used for analysis.

For ASME Section III, Class 2 and 3 Piping

a. The maximum stress ranges as calculated by the sum of equations (9) and (10) in paragraph NC-3652, considering normal and upset plant conditions, does not exceed $0.8(1.2\ S_h + S_A)$.

b. The maximum stress, as calculated by equation (9) in paragraph NC-3652, under the loadings resulting from a postulated rupture of fluid system piping beyond these portions of piping does not exceed $1.8\ S_h$, except for the portion of the piping between the isolation valve and the adjacent restraints protecting the operability of the valve. For this latter portion of the piping, higher stress is permitted, provided that a plastic-hinge is not formed and the operability of the isolation valve is assured.

In addition to these stress and fatigue criteria, high energy piping in containment penetration areas must meet the following requirements:

a. Welded pipe support attachments are avoided to eliminate stress concentrations.

b. The number of circumferential and longitudinal pipe welds and branch connections is minimized.

c. The length of the piping run is minimized, consistent with requirements to keep stress levels low and provide access for inservice inspection.

d. The design at points of pipe fixity (such as pipe anchors or welded connections at containment penetrations) does not require welding directly to the outer surface of the piping (flued, integrally forged pipe fittings are acceptable), except where such welds are 100% volumetrically examinable in service and a detailed stress analysis is performed to demonstrate compliance with the limits of the stress and fatigue criteria stated above.

e. In accordance with the inservice inspection plan, the inservice examination completed during each inspection interval will provide either a 100% volumetric examination of circumferential pipe welds within these portions of piping or those examinations required by the Risk Informed Inservice Inspection (RISI) Program as applied to these portions of piping also known as the Break Exclusion Region (BER). Inservice inspection of the RCPB is discussed in Section 5.2.4.

f. For piping constructed in accordance with ANSI B31.1, all welds will be fully radiographed.

After the as-built analysis is completed, the licensee will conduct a comparison against the SRP criteria (NUREG-0800) (BTP MEB 3-1) and demonstrate no additional breaks for the following situations:

a. The stress calculated by equation (10) is between $2.4\ S_m$ and $3.0\ S_m$ and

b. The ASME Code version of 1979 Summer Addenda or later is used for analysis.

3.6.2.1.1.2 Recirculation System Piping

Pipe breaks in the Unit 1 recirculation system are postulated to occur at the following locations:

a. Terminal ends of a piping run or branch run.

b. At intermediate locations between terminal ends where the maximum stress range between any two load sets (including the zero load set), as calculated according to ASME Section III, subarticle NB-3600, for upset plant conditions and an independent OBE event, meets the following requirements:

1. The stress range, as calculated using equation (12) or (13), exceeds 2.4 S_m and the cumulative usage factor associated with normal, upset, and testing conditions is less than 0.1.

2. The stress range calculated using equation (10) exceeds 2.4 S_m but is less than 3.0 S_m, and the cumulative usage factor exceeds 0.1.

3. The stress range calculated using equation (10) exceeds 3.0 S_m, and the cumulative usage factor exceeds 0.1.

4. Breaks are always postulated whenever the usage factor exceeds 0.1 regardless of stress.

5. If two or more intermediate break locations cannot be determined by stress or usage factor limits, two arbitrary intermediate break locations are selected on a reasonable basis. This basis includes consideration of fitting locations and/or highest stress or usage factor locations. Where more than two such intermediate locations are possible using the application of the above reasonable basis, those two locations possessing the greatest damage potential are used. A break at each end of a fitting can be classified as two discrete break locations when the stress analysis is sufficiently detailed to differentiate stresses at each postulated break.

After the as-built analysis is completed, the licensee will conduct a comparison against the SRP criteria (NUREG-0800) (BTP MEB 3-1) and demonstrate no additional breaks for the following situations:

a. The stress calculated by equation (10) is between 2.4 S_m and 3.0 S_m, and

b. The ASME Code version of 1979 Summer Addenda or later is used for analysis.

For Unit 2, break locations are similarly postulated except that the two arbitrary intermediate break locations of b.4 above need not be postulated provided the following criteria are met:

a. The piping system is adequately resistant to IGSCC and is not susceptible to unanticipated water hammer thermal transient events.

b. The piping system is included in the startup testing program for piping steady-state vibrations.

c. The elimination of the break location does not change equipment environmental qualification or structural design criteria.

3.6.2.1.1.3 Class 1 Piping (Other Than Recirculation System Piping and Piping in Containment Penetration Areas)

Breaks in Class 1 piping (ASME Section III) for Unit 1 are postulated to occur at the following locations:

a. At terminal ends of piping runs or branch runs.

b. At intermediate locations between terminal ends, as determined by one of the two following criteria:

1. At each location of potential high stress such as pipe fittings (elbows, tees, reducers, etc) valves, and welded attachments.

2. At each location where, for normal and upset load conditions, none of the following stress and fatigue limits are met:

(a) The stress intensity range S_n, calculated by equation (10) of paragraph NB-3653, does not exceed 2.4 S_m and the cumulative usage factor associated with normal, upset, and testing conditions is less than 0.1.

(b) The stress intensity range S_n, as calculated by equation (10) of paragraph NB-3653, exceeds 2.4 S_m but is less than 3.0 S_m, and the cumulative usage factor is less than 0.1.

(c) The stress intensity range S_n exceeds 3.0 S_m, but the stresses computed by equations (12) and (13) of paragraph NB-3653 are less than 2.4 S_m, and the cumulative usage factor is less than 0.1.

(d) Breaks are always postulated whenever the usage factor exceeds 0.1 regardless of stress.

3. When the above stress and fatigue criteria result in less than two intermediate break locations, a minimum of two locations are chosen based on highest stress, as calculated by equation (10) of paragraph NB-3653. The two locations are separated by a change of direction of the force resulting from pipe break. If the piping run has no more than one change of direction, a minimum of one intermediate break location is chosen. Any given fitting is considered as a single break location regardless of the number of breaks postulated at different locations on that fitting.

Intermediate pipe break locations are initially based on committed design piping stress calculations in accordance with the above criteria. As a result of piping reanalysis, the highest stress locations may be shifted. An initially determined pipe break location will not be changed as a consequence, however, unless one of the following conditions exists:

(a) Reanalysis shows that maximum stress range or cumulative usage factor at another location not only exceeds that for the initial pipe break location but also exceeds the above pipe break criteria. In addition, the break at the new location results in more serious consequences to safety-related systems than the initial break location.

(b) Significant changes are made in the routing, size, or wall thickness of the pipe after the initial pipe break determination.

4. After the as-built analysis is completed, the licensee will conduct a comparison against the SRP criteria (NUREG-0800) (BTP MEB 3-1) and demonstrate no additional breaks for the following situations:

(a) The stress calculated by equation (10) is between 2.4 S_m and 3.0 S_m and

(b) The ASME Code version of 1979 Summer Addenda or later is used for analysis.

For Unit 2, break locations are similarly postulated except that arbitrary intermediate breaks from b.3 above need not be postulated provided the following criteria are met:

a. The piping system is adequately resistant to IGSCC and is not susceptible to unanticipated water hammer thermal transient events.

b. The piping system is included in the startup testing program for piping steady-state vibrations.

c. The elimination of the break location does not change equipment environmental qualification or structural design criteria.

The following Unit 2 class 1 piping systems meet all of the above criteria:

- Main Steam Inside Containment
- Feedwater Inside Containment
- RWCU Inside Containment
- Reactor Vessel Drain
- HPCI Steam Supply Inside Containment

- RCIC Steam Supply Inside Containment
- SLCS
- RHR Shutdown Cooling Suction
- RHR Shutdown Cooling Return
- LPCI Injection
- Core Spray Injection

3.6.2.1.1.4 Class 2 and 3 Piping (Other Than Recirculation System Piping and Piping in Containment Penetration Areas)

Breaks in Class 2 and 3 piping (ASME Section III) for Unit 1 are postulated to occur at the following locations:

a. At terminal ends of piping runs or branch runs.

b. At intermediate locations between terminal ends, as determined by one of the three following criteria:

1. At each location of potential high stress, such as pipe fittings (elbows, tees, reducers, etc), valves, and welded attachments.

2. At each location where the maximum stress range, as calculated by the sum of equations (9) and (10) of paragraph NC-3652, considering normal and upset plant conditions, exceeds $0.8(1.2\ S_h + S_A)$.

3. When the above stress and fatigue criteria result in less than two intermediate break locations, a minimum of two locations are chosen based on highest stress, as calculated by the sum of equations (9) and (10) of paragraph NC-3652. The two locations are separated by a change of direction of the force resulting from pipe break. If the piping run has no more than one change of direction, a minimum of one intermediate break location is chosen. Any given fitting is considered as a single break location regardless of the number of breaks postulated at different locations on that fitting.

Intermediate pipe break locations are initially based on committed design piping stress calculations in accordance with the above criteria. As a result of piping reanalysis, the highest stress locations may be shifted. An initially determined pipe break location will not be changed as a consequence, however, unless one of the following conditions exists:

(a) Reanalysis shows that maximum stress range or cumulative usage factor at another location not only exceeds that for the initial pipe

break location but also exceeds the above pipe break criteria. In addition, the break at the new location results in more serious consequences to safety-related systems than the initial break location.

(b) Significant changes are made in the routing, size, or wall thickness of the pipe after the initial pipe break determination.

4. At each extreme of the piping run adjacent to basic protective structures, when the piping system contains no fitting, valve, or welded attachment.

For Unit 2, break locations are similarly postulated except that the arbitrary intermediate breaks from b.3 above need not be postulated provided the following criteria are met:

a. The piping system is adequately resistant to IGSCC and is not susceptible to unanticipated water hammer thermal transient events.

b. The piping system is included in the startup testing program for piping steady-state vibrations.

c. The elimination of the break location does not change equipment environmental qualification or structural design criteria.

The following Unit 2 Class 2, 3 piping systems meet all of the above criteria:

- RWCU Outside Containment
- HPCI Steam Supply Outside Containment
- RCIC Steam Supply Outside Containment
- Main Steam Outside Containment

3.6.2.1.1.5 Non-Nuclear Class Piping

Breaks in non-nuclear class piping are postulated to occur at the following locations:

a. At terminal ends of piping runs or branch runs.

b. At each intermediate location of potential high stress, such as pipe fittings (elbows, tees, reducers, etc), valves, and welded attachments.

Alternatively, the break locations for non-nuclear class piping can be selected according to the same criteria used for Class 2 and 3 piping, provided that all necessary analyses are made.

These breaks in nonseismic Category I piping have been postulated at those locations that would result in the maximum amount of damage and the safety-related systems and components have adequate protection from these piping breaks as discussed below.

The only high energy seismic Category II piping in the control structure is the portion of the steam supply line to the offgas recombiner preheater that is located within the recombiner compartments. The only high energy seismic Category II piping in the reactor enclosure is the RWCU piping inside the RWCU filter/demineralizer compartments and the RWCU holding pump compartments. In both cases, the walls of the compartments are capable of withstanding the pipe whip and jet impingement forces and the compartment pressurization that could result from breaks at the most adverse locations. Because there are no safety-related components located in these compartments, safety-related components will not be affected by high energy pipe breaks within these compartments.

The diesel generator enclosures have high energy seismic Category IIA piping in the form of heating steam supply lines (1½" JBD-330/430). A rupture of such a line could create maximum temperatures of less than 340°F and pressures less than 15 psia (0.3 psig) due to the large "bird grill" vent openings. As only one diesel generator enclosure is affected at any one time, the assumed loss of one diesel generator is acceptable.

Other safety-related structures, such as the spray pond pumphouse, do not contain high energy seismic Category II piping.

Safety-related components are protected from the effects of high energy pipe breaks in nonsafety-related structures by the walls that separate the safety-related structures from the nonsafety-related structures. To the extent necessary to prevent unacceptable damage to safety-related components, these walls are designed to withstand the pipe whip and jet impingement forces and compartment pressurization that could result from breaks at the most adverse locations in high energy seismic Category II piping within the nonsafety-related structures.

3.6.2.1.2 Crack Locations in Moderate Energy Fluid System Piping

Through-wall leakage cracks are postulated to occur in moderate energy piping located in areas containing essential systems and components. Cracks are postulated to occur at terminal ends of piping runs or branch runs, and at intermediate locations selected in accordance with either of the two following criteria:

a. At each location of potential high stress, such as pipe fittings (elbows, tees, reducers, etc), valves, and welded attachments

b. For Class 1 piping (ASME Section III), at locations where the maximum range of stress intensity as calculated by equation (10) of paragraph NB-3653 exceeds 1.2 S_m, and for Class 2 or 3 piping (ASME Section III) or non-nuclear piping, at locations where the maximum stress range as calculated by the sum of equations (9) and (10) of paragraph NC-3652 exceeds $0.4(1.2\ S_h + S_A)$.

The above criteria notwithstanding, cracks are not postulated in those portions of moderate energy piping located in the following areas:

a. Areas in which high energy pipe breaks are postulated, provided that moderate energy piping cracks would not result in more severe environmental conditions than the high energy pipe breaks.

b. Between containment isolation valves, provided that:

1. The piping meets the requirements of subarticle NE- 1120 of the ASME B&PV Code

2. The maximum range of stress intensity for Class 1 piping (ASME Section III) as calculated by equation (10) of paragraph NB-3653 does not exceed 1.2 S_m, and the maximum stress range for Class 2 and 3 (ASME Section III) or non-nuclear piping as calculated by the sum of equations (9) and (10) of paragraph NC-3652 does not exceed $0.4(1.2\ S_h + S_A)$.

3.6.2.1.3 Types of Breaks and Cracks in Fluid System Piping

Circumferential Breaks

A circumferential break is assumed to result in (a) severance of a high energy pipe on a plane perpendicular to the pipe axis, and (b) separation amounting to at least a one diameter lateral displacement of the ruptured piping ends unless physically limited by piping restraints, structural members, or piping stiffness. Pipe whipping is assumed to occur in the plane defined by the piping geometry and configuration, and to cause pipe movement in the direction of the jet reaction.

All analyses to determine the blowdown (reaction) force on the segment of piping that contains a circumferential break are based on unobstructed discharge from 100% of the cross-sectional area of the pipe. This is consistent with the assumption of a one diameter lateral displacement of the ruptured piping ends. The only pipe break analyses that have involved lateral displacements of less than one pipe diameter are analyses concerning jet impingement forces. In certain cases where pipe whip restraints are located on both sides of a postulated circumferential break, and the design of the restraints prevents the two ends of the break from achieving a one diameter displacement, credit is taken for one end of the broken pipe causing partial blockage of the fluid being discharged from the opposite side of the break. Similarly, in certain cases where one side of the break is an RPV nozzle safe-end and the other side of the break is restrained from achieving a one diameter displacement relative to the nozzle, credit is taken for partial blockage of the fluid discharging from the restraint pipe end. This methodology can result in a reduction of the jet impingement force on potential impingement targets.

Circumferential breaks are postulated in high energy fluid system piping of nominal pipe size greater than 1-inch, at the locations determined by the criteria listed in Section 3.6.2.1.1, except where it can be shown that the maximum stress is in the circumferential direction and is at least 1.5 times the longitudinal stress, in which case only a longitudinal break is postulated.

Longitudinal Breaks

A longitudinal break is assumed to result in an axial split parallel to the pipe axis, without causing pipe severance. The break opening area is assumed to be equal to the effective cross- sectional flow area of the pipe at the break location. The split is assumed to be oriented (but not concurrently) at two diametrically opposed points on the piping circumference so that the jet reaction force causes out-of-plane bending of the piping configuration. Piping movement is assumed to occur in the direction of the jet reaction unless limited by piping restraints, structural members, or piping stiffness.

Longitudinal breaks are postulated in high energy fluid system piping of nominal pipe sizes of 4 inches and larger, at the locations determined by the criteria listed in Section 3.6.2.1.1, with the following exceptions. Longitudinal breaks are not postulated:

a. At terminal ends

b. At intermediate break locations chosen to satisfy the criterion for a minimum number of break locations

c. At locations where it can be shown that the maximum stress is in the longitudinal direction and is at least 1.5 times the circumferential stress, in which case only circumferential breaks need to be postulated.

Through-Wall Leakage Cracks

Through-wall leakage cracks are postulated to occur in moderate energy fluid system piping exceeding a nominal pipe size of 1 inch, at the locations determined by the criteria listed in Section 3.6.2.1.2. A crack is assumed to occur at any orientation about the circumference of a pipe. Fluid flow from a crack is based on a circular opening with an area equal to that of a rectangle one-half pipe diameter in length and one-half pipe wall thickness in width.

3.6.2.2 Analytical Models to Define Forcing Functions and Response Models (Recirculation System Only)

3.6.2.2.1 Analytical Methods to Define Blowdown Forcing Functions

The rupture of a pressurized pipe causes the flow characteristics of the system to change, creating reaction forces that can dynamically excite the piping system. The reaction forces are a function of time and space and depend upon the fluid state within the pipe prior to rupture, break flow area, frictional losses, plant system characteristics, piping system, and other factors. The methods used to calculate the reaction forces for recirculation system piping are presented below.

The criteria that are used for calculation of fluid blowdown forcing functions include:

a. The dynamic force of the jet discharge at the break location is based on the effective cross-sectional flow area of the pipe and on a calculated fluid pressure as modified by an analytically or experimentally determined thrust coefficient. Limited pipe displacement at the break location, line restrictions, flow limiters, positive pump-controlled flow, and the absence of energy reservoirs may be taken into account, as applicable, in the reduction of jet discharge.

b. All breaks are assumed to attain full pipe break area instantaneously, i.e., a rise time not exceeding one millisecond is used for the initial pulse.

Blowdown forcing functions are determined by either of two methods as described below.

Moody Model

The predicated blowdown forces on pipes fed by a pressure vessel can be described by transient and steady-state forcing functions. The forcing functions used are based on methods described in Reference 3.6-4. These are simply described as follows:

a. The transient forcing functions at points along the pipe result from the propagation of waves (wave thrust) along the pipe, and from the reaction force due to the momentum of the fluid leaving the end of the pipe (blowdown thrust).

b. The waves cause various sections of the pipe to be loaded with time-dependent forces. It is assumed that the pipe is one-dimensional, in that there is no attenuation or reflection of the pressure waves at bends, elbows, and the like. Following the rupture, a decompression wave is assumed to travel from the break at a speed equal to the local speed of sound within the fluid. Wave reflections occur at the break end, changes in direction of piping, and the pressure vessel until a steady flow condition is established. Vessel and free space conditions are used as boundary conditions. The blowdown thrust causes a reaction force perpendicular to the pipe break.

c. The initial blowdown force on the pipe is taken as the sum of the wave and blowdown thrusts and is equal to the vessel pressure (P_o) times the break area (A). After the initial decompression period (i.e., the time it takes for a wave to reach the first change in direction), the force is assumed to drop off to the value of the blowdown thrust (i.e., 0.7 P_oA).

d. Time histories of transient pressure, flow rate, and other thermodynamic properties of the fluid can be used to calculate the blowdown force on the pipe using the following equation:

$$F = \left[(P-P_a) + \frac{\rho u^2}{g_c}\right] A \qquad \text{(EQ. 3.6-1)}$$

where:

F = blowdown force

P_a = pressure at exit plane

P = ambient pressure

u = velocity at exit plant

ρ = density at exit plane

A = area of break

g_c = Newton's constant

e. Following the transient period, a steady-state period is assumed to exist. Steady-state blowdown forces are calculated including frictional effects. For saturated steam, these effects reduce the blowdown forces from the theoretical maximum of 1.26 P_oA. The method accounting for these effects is presented in Reference 3.6-4. For subcooled water, a reduction from the theoretical maximum of 2.0 P_oA is found through the use of Bernoulli's equation and standard equations such as Darcy's equation, which account for friction.

RELAP3

The computer code RELAP3 (Reference 3.6-5) is used to obtain exit plane thermodynamic states for postulated ruptures. Specifically, RELAP3 supplies exit pressure, specific volume, and mass rate. From these data the blowdown reaction load is calculated using the following relation:

$$\frac{T}{A_E} = P_E - P_{oo} + \frac{G_E^2 \overline{V}_E}{G_c} \qquad \text{(EQ. 3.6-2)}$$

$$R = -\frac{T}{A_E} \cdot A_E \qquad \text{(EQ. 3.6-3)}$$

where:

$\frac{T}{A_E}$ = thrust per unit break area (lb_f/ft^2)

P_E = exit pressure (lb_f/ft^2)

P_{oo} = receiver pressure (lb_f/ft^2)

G_E = exit mass flux ($lb_m/sec\text{-}ft^2$)

$\overline{V}_E$ = exit specific volume (ft^3/lb_m)

g_c = Newton's constant (32.174 $ft\text{-}lb_m/lb_f\text{-}sec^2$)

R = reaction force on the pipe (lb_f)

3.6.2.2.2 Pipe Whip Dynamic Response Analyses

The prediction of time-dependent and steady-thrust reaction loads caused by blowdown of subcooled, saturated, and two-phase fluid from a ruptured pipe is used in design and evaluation of dynamic effects of pipe breaks. A detailed discussion of the analytical methods employed to compute these blowdown loads for recirculation system piping is given in Section 3.6.2.2.1. Analytical methods used to account for this loading are discussed below.

The criteria used for performing the pipe whip dynamic response analyses for recirculation system piping include:

a. A pipe whip analysis is performed for each postulated pipe break. However, a given analysis can be used for more than one postulated break location if the

blowdown forcing function, piping and restraint system geometry, and piping and restraint system properties are conservative for other break locations.

b. The analysis includes the dynamic response of the pipe in question and the pipe whip restraints that transmit loading to the structures.

c. The analytical model adequately represents the mass/inertia and stiffness properties of the system.

d. Pipe whipping is assumed to occur in the plane defined by the piping geometry and configuration, and is assumed to cause pipe movement in the direction of the jet reaction.

e. Piping within the broken loop is no longer considered part of the RCPB. Plastic deformation in the pipe is considered as a potential energy absorber. Limits of strain are imposed that are similar to strain levels allowed in restraint plastic members. Piping systems are designed so that plastic instability does not occur in the pipe at the design dynamic and static loads, unless damage studies are performed to show that the consequences do not result in direct damage to any essential system or component.

f. Components such as vessel safe ends and valves that are attached to the broken piping system and do not serve a safety function, or whose failure would not further escalate the consequences of the accident, are not designed to meet limits imposed by the ASME B&PV Code for essential components under faulted loading.

The pipe whip analysis was performed using the PDA computer program (Reference 3.6-6). PDA is a computer program used to determine the response of a pipe subjected to the thrust-force occurring after a pipe break. The program treats the situation in terms of generic pipe break configuration, which involves a straight, uniform pipe fixed at one end and subjected to a time-dependent thrust-force at the other end. A typical restraint used to reduce the resulting deformation is also included at a location between the two ends. Nonlinear and time-independent stress-strain relations are used for the pipe and the restraint. A static nonlinear cantilever beam analysis is used for these locations to obtain the relationship between the pipe bending moment and the deflection (or rotation). Similar to the plastic-hinge concept, bending of the pipe is assumed to occur only at the fixed end and at the location supported by the restraint.

Shear deformation is also neglected. The pipe bending moment- deflection (or rotation) relation used for these locations is obtained from a static nonlinear cantilever beam analysis. Using the moment-rotation relation, nonlinear equations of pipe motion are formulated using an energy consideration, and the equations are numerically integrated in small time steps to yield time history information of the deformed pipe.

Considerable testing and analyses have demonstrated that potential rebound does not cause unacceptable increases in restraint deformation following the first quarter cycle loading for the GE restraint design and piping system experiencing blowdown thrust forces. Generic tests were performed on a 12-inch pipe size restraint with two primary loading configurations that represent the typical conditions during the postulated pipe rupture. Any other loading condition results in a combination of these two extremes. These loading configurations are:

a. Load applied perpendicular to the restraint frame base against the cable

b. Load applied parallel to the base against one side of the frame.

The mass/inertia and stiffness properties of the recirculation system in the pipe dynamic analysis (PDA model) are represented as described below. A generic representation of the pipe in any given analysis is shown in Figure 3.6-41. If the stiffness of the piping segment located between A and B is such that:

a. The slope of BD at B = 0, then in the analysis, the pipe is treated as built-in at B.

b. The slope of BD at B ≠ 0 (considerably different), then in the analysis, the pipe is considered to have a fixed, simple support (pinned end) at B.

To analyze the pipe with both ends supported (Figure 3.6-42) with the above computer model, two simplifications were made in the PDA program. First, an equivalent point mass is assumed at D instead of pipe length DE. The inertia characteristics of this mass rotating around point B are calculated to be identical to those of pipe length DE rotating around point E. Secondly, an equivalent resisting force is calculated for any deflection for the case of a built-in end from the bending moment-angular deflection relationship for pipe length DE. This equivalent force is subtracted from the applied thrust-force when calculating the net energy. The new model resulting from these simplifications is shown in Figure 3.6-42. The PDA computer program is further described in Section 3.9.1.2.2.6.

A comprehensive verification has been performed to demonstrate the conservatisms inherent in the PDA pipe whip computer program and the analytical methods utilized. This is described in Reference 3.6-7. Part of this verification program included an independent analysis of the recirculation system piping for the 1969 Standard Plant Design by Nuclear Services Corporation, under contract to GE. The recirculation system piping was chosen for study due to its complex piping arrangement and assorted pipe sizes. The analysis included elastic-plastic pipe properties, elastic-plastic restraint properties, and gaps between the restraint and pipe as documented in Reference 3.6-7. The piping/restraint system geometry and properties and fluid blowdown forces were the same in both analyses. However, a linear approximation was made by Nuclear Services Corporation for the restraint load-deflection curve supplied by GE. This approximation is demonstrated in Figure 3.6-36. The effect of this approximation is to give lower energy absorption of a given restraint deflection. Typically, this yields higher restraint deflections and lower restraint-to-structure loads than the GE analysis. The deflection limit used by Nuclear Services Corporation is the design deflection at one-half of the ultimate uniform strain for the GE restraint design. The restraint properties used for both analyses are provided in Table 3.6-24.

A comparison of the Nuclear Services Corporation analysis with the PDA analysis, as presented in Table 3.6-25 and Figure 3.6-37, shows that PDA predicts higher loads in 15 of the 18 restraints analyzed. This is due to the Nuclear Services Corporation model including energy-absorbing effects in secondary pipe elements and structural members. However, PDA predicts higher restraint deflections in 50% of the restraints. The higher deflections predicted by Nuclear Services Corporation for the lower loads are caused by the linear approximation used for the force-deflection curve rather than by differences in computer techniques. This comparison demonstrates that the simplified modeling system used in PDA is adequate for pipe rupture loading, restraint

performance, and pipe movement predictions within the meaningful design requirements for these low probability postulated accidents.

3.6.2.3 Analytical Models to Define Forcing Functions and Response Models (Systems Other Than Recirculation System)

Analyses to determine the jet impingement effects and the piping and restraint displacements resulting from a pipe break are performed in accordance with BN-TOP-2 (Reference 3.6-8). Analysis of jet thrust forces are described in section 2.2 of BN-TOP-2. Fluid jet impingement forces are discussed in section 2.3 of BN-TOP-2. Impulsive loading and impact combined with impulsive loading are described in sections 3.2 and 3.3, respectively, of BN-TOP-2.

Alternatively, nonlinear time history dynamic analyses are performed. The forcing function used in piping dynamic analysis is obtained using either Reference 3.6-2 or 3.6-9. A typical forcing function and the piping system model used for the dynamic response analysis is provided in Figure 3.6-38. Pipe restraint rebound effects are also considered in this analysis.

A specific case for which time history dynamic analyses are used is the analysis of pipe breaks near containment isolation valves whose operability following the break must be ensured. For each break postulated to occur near a containment isolation valve in a high energy line, a dynamic analysis is performed using the appropriate pipe break forcing function in order to determine the stresses in the pipe and the loads on the moment-limiting restraints near the valve. The dynamic analysis verifies that the stress in the pipe at the isolation valve is maintained below the yield strength of material, in order to ensure valve operability. Since the section modulus of the valve is much greater than that of the pipe, the stress in the valve body is kept below the yield strength of the valve. Therefore, deformation in the valve body as a result of nearby pipe breaks is severely limited and remains in the elastic range so that binding of the valve internals cannot occur.

The criteria for dynamic analyses when used in verifying valve operability are as follows:

a. An analysis of the piping system is performed for the most severe of the postulated longitudinal and circumferential breaks at the break locations determined in accordance with the criteria of Section 3.6.2.1.

b. The loading condition of a piping system prior to a postulated rupture in terms of internal pressure, temperature, and stress state is that condition associated with reactor operation at 100% power.

   The basis of selecting 100% power as the loading condition of a piping system prior to rupture is as follows:

   1. Pipe rupture analysis state-of-the-art involves several conservative steps and assumptions in all phases of break design (e.g., probability of break, the postulated speed of break propagation, the structural material properties, and the structural stability characteristics of pipe break restraint structures).

   2. For those portions of piping systems that are normally pressurized during normal plant operation at power mode, the thermodynamic states in the piping systems are those of full (100%) thermal power.

3. There is a much higher probability for scheduled plant operation at 100% power (or less) than at higher ratings.

The combined effects of these considerations result in designs sufficiently capable of sustaining breaks at higher power levels.

c. For a circumferential break, pipe break dynamic transient force analyses are performed only for that end (or ends) of the pipe or branch that is connected to a contained fluid energy reservoir having sufficient capacity to develop a jet stream.

d. Dynamic analytic methods used for calculating the piping and piping/restraint system response to the pipe break forces adequately account for the effects of the following:

1. Translational masses (and rotational masses for major components) and stiffness properties of the piping system, restraint system, major components, and support walls

2. Transient forcing function(s) acting on the piping system

3. Elastic and inelastic deformation of piping and/or restraint

4. The design clearance between the pipe and the restraint

e. A 10% increase in minimum specified design yield strength (S_y) is used to account for strain rate effects in dynamic analyses.

The criteria for dynamic analyses when used in verifying the design of pipe whip restraints other than valve operability restraints are as follows:

a. A design analysis of the pipe whip restraint system is performed for each postulated longitudinal and circumferential break at the break locations determined in accordance with Section 3.6.2.1.

b. The loading condition of a piping system prior to a postulated break in terms of internal pressure, temperature, and stress state is that condition associated with reactor operation at 100% power.

c. For a circumferential break, pipe break dynamic transient forcing function calculations are performed only for that end (or ends) of the pipe or branch that is connected to a contained fluid energy reservoir having sufficient capacity to develop a jet stream.

d. An energy balance is established between the work done by the pipe break force on the pipe during the first quarter cycle of movement and the sum of the strain energy temporarily stored as elastic strain energy and that energy dissipated as plastic strain energy in members of the whip restraint.

e. In the event that the energy balance design analysis criteria are not satisfied, a dynamic analysis of the piping and piping restraint system is performed. This analysis is described by the same criteria described for valve operability dynamic analysis.

f. Dynamic analytical methods used for designing the pipe whip restraints adequately account for the effects of the following:

1. Transient forcing functions acting on the piping system.

2. Design clearance between the pipe and the restraint in the direction of pipe whip motion 3. Elastic stiffness and yield load capacity of the restraint under load applied in the direction of the pipe motion

4. Impact energy-absorbing capacity of crushable material used in the restraint is equivalent to 100% of the available capacity

5. Ductility capacity of the restraint loaded under impact beyond its yield load corresponds to not more than 50% of the ultimate uniform strain of the material.

3.6.2.4 Dynamic Analysis Methods to Verify Integrity and Operability (Recirculation System Only)

Pipe whip restraints, as differentiated from piping supports, are designed to function and carry load for an extremely low probability gross failure in a piping system carrying high energy fluid. The piping integrity does not usually depend on the piping whip restraints for any loading combination. When the piping integrity is lost because of a postulated break, the pipe whip restraint acts to limit the movement of the broken pipe to an acceptable distance. The pipe whip restraints (i.e., those devices that serve only to control the movement of a ruptured pipe following gross failure) will be subjected to once in a lifetime loading. For the purpose of design, the pipe break event is considered to be a faulted plant condition and the pipe, its restraints, and the structure to which the restraint is attached, are analyzed and designed accordingly.

As described in Section 3.6.1.2.1.1, the pipe whip restraints used for the recirculation system consist of straps (either carbon steel wire ropes or stainless steel bars) attached to a steel frame. The analytical methods used in the design of these restraints are similar to those used for the Fermi Unit 2 and Duane Arnold plants. They have, however, been improved by incorporation of the latest force-deflection data available for wire rope and by using the GE PDA code for the dynamic analysis. Load capacities for the restraint frames were developed by using the SAP code (a finite-element structural analysis program), and were confirmed by a test series using slowly applied loading methods to determine restraint load-deflection data in the tangential direction (parallel to the restraint base). The results of this test program are presented in Reference 3.6-10. The specific design objectives for the restraints are:

a. The restraints shall in no way increase the RCPB stresses by their presence during any normal mode of reactor operation or condition

b. The restraint system shall function to stop the movement of pipe failure (gross loss of piping integrity) without allowing damage to critical components or missile development

c. The restraints shall provide minimum hinderance to inservice inspection of the process piping.

For the purposes of design, the pipe whip restraints are designed for the following dynamic loads:

a. Blowdown thrust of the pipe section that impacts the restraint

b. Dynamic inertia loads of the moving pipe section that is accelerated by the blowdown thrust and subsequent impact on the restraint

c. Design characteristics of the pipe whip restraints are included and verified by the pipe whip dynamic analysis described in Section 3.6.2.2.2

d. Since the pipe whip restraints are not contacted during normal plant operation, the postulated pipe rupture event is the only design loading condition.

As previously described, the recirculation loop pipe whip restraints are composed of two parts, the straps and the restraint frame. Both parts of the restraining device function as load-carrying members, and will deflect under load. The load configurations for a restraint are shown in Figure 3.6-3. The components of the restraints are categorized as Type I and II, as described below:

a. Type I - radial load-carrying members: These members, consisting of cables or bars, will absorb energy when loaded in the direction perpendicular to the restraint base by elastic and plastic deformations (Figure 3.6-3).

b. Type II - tangential load-carry members: These members, consisting of restraint frames, will absorb energy when loaded in the direction parallel to the base by plastic deformation (Figure 3.6-3).

Each of these components is constructed of a different material in order to fulfill different design objectives. The design requirements and design limits for each component are therefore different. They are specified as below:

a. Type I - Straps

1. For carbon steel wire ropes, the maximum acceptable load is 90% of the load-carrying capacity of the cable in the restraint configuration. This limit takes into consideration the efficiency reduction experienced when a cable is wrapped around a pipe. This means that the design load is limited to about 75% of the minimum certified load-carrying capacity of the cable in tension.

2. For stainless steel bars, the design limit base was 50% of the minimum uniform ultimate tensile elongation.

b. Type 2 - Restraint Frames

Design limits for the ASTM A36 restraint frames are as follows:

1. Design Load

The load-bearing member is primarily a cantilever beam with an extra support (the diagonal plate) at approximately mid-span. At loads approaching the plastic moment capability of the beam, the plastic-hinge forms at the section determined by an elastic structural analysis. The maximum design load and the ultimate load are calculated based on plastic moment capability of this section, with the diagonal plate stressed uniformly at the minimum ultimate stress of 58,000 psi as specified for ASTM A36 material.

2. Design Deflection

The design and ultimate deflection are calculated assuming the beam remains straight and rotates about a point on the upper surface of the beam. The maximum design deflection at the load point is calculated assuming the diagonal plate undergoes 10% elongation. This corresponds to 50% of the minimum ultimate elongation of 20%, as specified for ASTM A36 material. The ultimate deflection of the beam is based on 20% ultimate elongation of the diagonal plate.

3.6.2.5 Dynamic Analysis Methods to Verify Integrity and Operability (Systems Other Than Recirculation System

The pipe whip restraints provided for protection from high energy pipe breaks are of two basic types: independent restraints and operability restraints. Independent restraints are provided solely to protect nearby structures and equipment from damage due to whipping pipes, and are designed so that a gap is maintained between the pipe and the restraint during normal plant conditions. Operability restraints are provided near primary containment isolation valves whose operability is required following a break of the pipe in which they are installed. These operability restraints are designed to limit the stress in the piping near the valve to below the yield strength of the material in order to ensure operability of the valve. To accomplish this function, it is necessary to minimize the gap between the pipe and the restraint so that contact will occur during normal plant conditions.

The following high energy piping systems in the drywell are not provided with pipe whip restraints:

a. Reactor vessel drain line (4" DCA-101)

b. Main steam drain lines (2" and 3" DBA-105)

c. RPV head vent line (2" DBA-108)

d. SLCS injection line (2" DCA-112)

Each of these lines has been evaluated, using the guidance of Regulatory Guide 1.46, to verify that in the event of a pipe break, damage to structures, systems, or components needed for safe shutdown would not occur. Therefore, the ability to shut the reactor down safely is maintained if a break should occur in any of these lines.

3.6.2.5.1 Design Loading Combinations

The design loading combinations applied in the design of pipe whip restraints are categorized with respect to the plant operating conditions which are identified as normal, upset, emergency, and faulted as described in Section 3.9.3.1.1. Pipe break is considered as a faulted plant condition.

3.6.2.5.2 Design Stress Limits

Operability Restraints

When restraints for piping are designed so that contact between pipe and restraint will occur during normal plant conditions, the design loading combinations for normal, upset, emergency, and faulted conditions are applicable. In evaluating the supports and restraints for ASME Section III Class 1, 2, and 3, the design stress limits applied in evaluating loading combinations for normal, upset, emergency, and faulted (except for pipe rupture) conditions are those given in Tables 3.9-12 and 3.9-16. After rupture of the supported pipe occurs, the piping system is no longer within the jurisdiction of ASME Section III because the pressure boundary has been breached. The restraints are evaluated for pipe rupture loads as described in Section 3.6.2.3.

Pipe restraints are included on main steam, feedwater, RWCU, HPCI, and RCIC system to ensure the operability of the containment isolation valves during a postulated break event that touch the pipe during normal operation. The restraints are modeled in the thermal and dynamic analysis as active (1/16 inch or less gaps) during all loading conditions.

The operability of the isolation valves protected by operability restraints is assured by limiting the pipe break dynamic stress in the adjacent pipe. Stresses at the junction of this component with the pipe are limited to the dynamic yield strength of the pipe material (1.1 S_y). Between the containment penetration inboard/outboard isolation valves, pipe dynamic stress is limited to be less than 2.25 S_m.

Independent Restraints

When restraints are designed solely to control movement following a postulated pipe rupture and to function independently of the normal support system, only the design pipe rupture loads are applicable.

To ensure that restraints function independently of the normal support system, the motions of the intact pipe due to all normal and upset plant conditions and the vibratory motion of the SSE are calculated and used to specify a minimum clearance between the pipe and the restraint. Wherever possible, gaps between pipes and restraints are maximized to avoid possible contact during plant operation. Where a particular location requires minimizing a gap, special features are provided to permit adjustment of the gap size during hot functional testing.

Independent restraints are evaluated for the pipe rupture loads as described in Section 3.6.2.3.

3.6.2.6 Guard Pipe Assembly Design Criteria

Guard pipe assemblies are not used in this plant.

3.6.3 DEFINITIONS

Certain terms used in Sections 3.6.1 and 3.6.2 have specified meanings as described below:

Essential Systems and Components - Systems and components required to shut down the reactor and mitigate the consequences of a postulated piping failure, without offsite power.

High Energy Fluid Systems - Fluid systems that, during normal plant conditions, are either in operation or maintained pressurized under conditions where either or both of the following are met:

a. Maximum operating temperature exceeds 200°F

b. Maximum operating pressure exceeds 275 psig

Moderate Energy Fluid Systems - Fluid systems that, during normal plant conditions, are either in operation or maintained pressurized (above atmospheric pressure) under conditions where both of the following are met:

a. Maximum operating temperature is 200°F or less

b. Maximum operating pressure is 275 psig or less

A system that qualifies as a high energy fluid system for only short periods and qualifies as moderate energy fluid system for the majority of the time is classified as a moderate energy fluid system provided that the total time the system operates within high energy pressure/temperature conditions is less than either of the following:

a. 2% of the time that the system operates as a moderate energy fluid system

b. 1% of the normal operating life span of the plant

Normal Plant Conditions - Plant operating conditions during reactor startup, operation at power, hot standby, or reactor cooldown to cold shutdown condition.

Upset Plant Conditions - Plant operating conditions during system transients that may occur with moderate frequency during plant service life and are anticipated operational occurrences, but not during system testing.

S_h and S_A - Allowable stresses at maximum (hot) temperature and allowable stress range for thermal expansion, respectively, as defined in ASME Section III, Article NC-3600.

S_m - Design stress intensity as defined in ASME Section III, Article NB-3600.

S_n - Primary plus secondary stress intensity range for normal and upset conditions as defined in ASME Section III, paragraph NB-3653.

Single Active Component Failure - Malfunction or loss of function of a component of electrical or fluid systems. The failure of an active component of a fluid system is considered to be a loss of component function as a result of mechanical, hydraulic, pneumatic, or electrical malfunction, but not the loss of component structural integrity. The direct consequences of a single active component failure are considered to be part of the single failure.

Terminal Ends - Extremities of piping runs that connect to structures, components (e.g., vessels, pumps, valves), or pipe anchors that act as rigid constraints to piping thermal expansion. A branch connection to a main piping run is a terminal end of the branch run, except when all three of the following conditions are in effect:

a. The nominal size of the branch run is at least half that of the main run

b. The intersection is not rigidly constrained to the building structure

c. The branch run and main run are included together in the same piping stress analysis model

For piping in containment penetration areas, terminal ends are selected at points located immediately beyond the required moment-limiting restraints inside and outside containment. In piping runs which are maintained pressurized during normal plant conditions for only a portion of the run (i.e., up to the first normally closed valve), a terminal end of such runs is the piping connection to this closed valve.

Table 3.6-4 (Cont'd)

(1) Locations of nodes are shown in Figure 3.6-8.

(2) Node types are designated as follows:

BW - Butt-welding tee
CUR - Elbow
CURB - Elbow beginning
CURE - Elbow ending
SWE - Sweepolet
FLA - Flange

(3) Break types are indicated as follows:

C - Circumferential
L - Longitudinal

(4) Symbols used to denote the basis for break selection are as follows:

TE - Terminal end
SFL - The stress and fatigue limits established in Section 3.6.2.1.1.3 are not met.
MBL - Intermediate break location selected to satisfy the criteria for a minimum number of break locations.

(5) Stress values not calculated; terminal end break assumed.

(6) Refer to Section 3.6.2.1.1.3.

(7) The main steam piping design basis has been evaluated for the effects of power rerate and demonstrated to be adequate for the increase in pressure, temperature and flow due to power rerate. Details of the evaluation performed are documented in Reference 3.6-11.

(8) The information posted in this table was used for original System piping analysis. Refer to System ASME III piping analysis for current information.

(1) Valve closure time is not applicable for HV44-F039 since it is a check valve. This valve prevents backflow of water from the feedwater lines into the RWCU equipment compartments in the event of a break.

(2) The blowdown table is based on original power level. Environmental effects from blowdown are addressed based 3527 MWt conditions in Table 3.6-7 and 3.6-9, which bounds the operation at MUR power level of 3515 MWt.

(3) Enthalpy of system is conservatively assumed for saturated steam at 1000 psig (0% moisture carryover) based on original design conditions.

(1) Compartment numbers used in this table correspond to the compartment numbers used in the flow models (Figures 3.6-11, 3.6-12, 3.6-19, 3.6-23, 3.6-24, and 3.6-27).
(2) The compartment design pressures and the pressure-temperature transient analysis results are in Table 3.6-9.
(3) For Unit 2, design bulk temperatures may be less. Note also that temperatures in this area due to breaks elsewhere may be bounding.
(4) The value shown is based on original power level. It is bounded by another break in this compartment where the value shown is for the 3527 MWt power level.
(5) Time shown is based on original power level and was not recalculated for rerate since it is not used for any design basis evaluations.
(6) Values shown unless noted are based on power level of 3527 MWt. The values (except the main steam line valves) were established based on the original values and a multiplier. The multiplier was calculated based on a maximum pressure increase associated with a power level of 3527 MWt and its impact on the blowdown and subsequent impact to subcompartment pressures and temperatures.

(1) Locations of the nodes listed in this table are shown in Figure 3.6-15.

(2) Node types are designated as follows:
- TEE - butt-welding tee
- TTJ - tapered transition joint
- EL - elbow
- SWP - sweepolet

(3) Break types are indicated as follows:
- C - circumferential
- L - longitudinal

(4) Symbols used to denote basis for break selection are as follows:
- TE - terminal end
- SFL - the stress and fatigue limits established in Section 3.6.2.1.1.3 are not met
- MBL - intermediate break location selected in order to satisfy the requirement for a minimum number of break locations

(5) The values provided above are based upon original licensed power conditions. These CUF values are conservatively based derived by using Sm for design temperatures instead of the load pair operating temperatures. For rerate power conditions, using the more realistic approach, the CUF values are found to be equal to or less than those in the table. No new pipe break is required for rerate power conditions. The maximum equation 10 stresses may be increased by up to 2% for the rerate condition.

(6) The information posted in this table was used for original System piping analysis. Refer to System ASME III piping analysis for current information.

RWCU Penetration	2.8	2.92	2.8	2.92

(1) In each compartment, the maximum pre-rerate peak transient pressure was used as a basis to establish the compartment design pressure. This is considered to be appropriate because of the conservatism in the analytical models used to calculate the mass and energy release rates.

(2) Maximum transient peak pressures are for power rerate conditions (3527 mwt). Although some peak pressures exceed listed design pressures, there are sufficient margin and conservatism in the existing design to accommodate the rerate condition. These pressures have been evaluated to be acceptable for each compartment.

240	SW	38.93	0.0320	42.2	C	TE
295	SW	57.16	0.0582	42.2	C	TE

(1) Locations of the nodes listed in this table are shown in Figure 3.6-28.

(2) Node types are designated as follows:
- TEE - butt-welding tee
- TTJ - tapered transition joint
- SW - socket weld

(3) Break types are indicated as follows:
- C - circumferential
- L - longitudinal

(4) Symbols used to denote the basis for break selection are as follows:
- TE - terminal end
- SFL - the stress and fatigue limits established in Section 3.6.2.1.1.3 are not met
- MBL - intermediate break location selected in order to satisfy the requirement for a minimum number of break locations

(5) The values provided above are based upon original licensed power conditions. These Cumulative Usage Factor (CUF) values are conservatively based derived by using Stress maximum (Sm) for design temperatures instead of the load pair operating temperatures. For rerate power conditions, using the more realistic approach, the CUF values are found to be equal to or less than those in the table. No new pipe break is required for rerate power conditions. The maximum equation 10 stresses may be increased by up to 2% for the rerate condition.

(6) The information posted in this table was used for the original System piping analysis. Refer to System ASME III piping analysis for current information.

[1] Break designations and restraint designations are shown on Figure 3.6-37.

3.7 SEISMIC DESIGN

All systems and equipment of the NSSS are defined as either seismic Category I or nonseismic Category I. The requirements for seismic Category I qualification are given in Section 3.2, along with a list of systems, components, and equipment which are so categorized. Seismic design requirements for nonseismic Category I items are also defined in Section 3.2. These items are classified as either Category II or Category IIA.

All systems, components, and equipment related to plant safety are designed to withstand SSE and OBE.

The SSE is that earthquake which is based upon an evaluation of the maximum earthquake potential considering the regional and local geology, and seismology and specific characteristics of local subsurface material. It is that earthquake which produces the maximum vibratory ground motion for which seismic Category I systems and components are designed to remain functional. These systems and components are those necessary to ensure:

a. The integrity of the RCPB.

b. The capability to shut down the reactor and maintain it in a safe shutdown condition.

c. The capability to prevent or mitigate the radiological consequences of accidents which could result in potential offsite exposures, comparable to the dose limits of 10 CFR 50.67.

The OBE is that earthquake which, considering the regional and local geology, and seismology and specific characteristics of local subsurface material, could reasonably be expected to affect the plant site during the operating life of the plant. It is that earthquake which produces the vibratory ground motion for which those features of the nuclear power plant necessary for continued operation, without undue risk to the health and safety of the public, are designed to remain functional.

In addition to seismic loads, Category I structures, systems and components are also reviewed for hydrodynamic loads as described in Appendix 3A.

3.7.1 SEISMIC INPUT

3.7.1.1 Design Response Spectra

The site design response spectra used are shown in Figures 3.7-1 and 3.7-2. These spectra are for the horizontal components of the OBE and the SSE respectively. The response spectra for the OBE are scaled or normalized to a maximum horizontal ground acceleration of 7½% of gravity. The response spectra for the SSE are normalized to a maximum horizontal ground acceleration of 15% of gravity. The values for the vertical component of the design response spectra are 2/3 of the horizontal design response spectra described above. The response spectra are based on data developed from records of previous earthquake activity and represent an envelope of motion expected at a sound rock site from a nearby earthquake (Section 2.5.2).

Regulatory Guide 1.60 (December, 1973) "Design Response Spectra for Seismic Design of Nuclear Power Plants" was not used for the development of the spectra, because LGS Units 1 and 2 were docketed for construction permit review in March 1970, and the spectra were finalized in

1973. Further, a letter dated December 21, 1973 from J.M. Hendrie (NRC) to R.M. Collins (Bechtel) states that Regulatory Guide 1.60 is applicable only to the plants docketed for construction permit review after April 1, 1973.

3.7.1.2 Design Time History

A synthetic time history of motion was generated by modifying the actual records of the 1952 Taft earthquake according to the techniques proposed in Reference 3.7-1. This synthetic time history was then further modified to develop the time history shown in Figure 3.7-3, which corresponds to the design response spectra. The duration of the time history is 15 seconds. Figures 3.7-4 through 3.7-9 show a comparison of the time history response spectra and the design response spectra for 0.5%, 1%, 2%, 3%, 5%, and 7% damping values.

The spectra are computed at the frequency values as given in table 5-1 of Reference 3.7-2.

3.7.1.3 Critical Damping Values

3.7.1.3.1 Critical Damping Values (NSSS)

The damping values indicated in Table 3.7-1 are used in the response analysis of various structures and systems, and in preparation of floor response spectra used as forcing inputs for piping and equipment analysis or testing. It can be seen that the values given in Table 3.7-1 are somewhat less than those given in Regulatory Guide 1.61 (October 1973), "Damping Values for Seismic Design of Nuclear Power Plants". The calculated responses are, therefore, conservative. Alternative critical damping values for piping may be used as described in Section 3.7.1.3.3.

3.7.1.3.2 Critical Damping Values (Non-NSSS)

Critical damping values expressed as a percentage of critical damping and used for seismic Category I structures, equipment, and piping for both the OBE and SSE are given in Table 3.7-2. Alternative critical damping values for piping may be used as described in Section 3.7.1.3.3.

Regulatory Guide 1.61 is not used as a design basis as discussed in Section 1.8, except as discussed in Section 3.7.1.3.3. However, all the values shown in Table 3.7-2 are equivalent to or more conservative than those in Regulatory Guide 1.61 with the exception of the SSE value for welded steel structures. The damping value of 5% (PSAR table C.2.1) is based on information given in Reference 3.7-6. The 5% value has been used, with appropriate design margins, because the stress levels for SSE conditions are allowed to approach the yield point.

3.7.1.3.3 Alternative Critical Damping Values and Spectral Peak Broadening for Piping (NSSS and Non-NSSS)

Alternative critical damping values, as provided in ASME B&PV Code, Section III, Division 1 Code Case N-411 may be used. When used, the provisions listed below are applied unless otherwise approved by References 3.7-12 and 3.7-13. References 3.7-12 and 3.7-13 approved the use of Independent Support Motion (ISM) response spectra methodology in conjunction with the damping values specified in ASME Code Case N-411, as the basis for eliminating snubbers from 31 piping systems on Unit 1 and Unit 2.

- The code case damping is applied only to uniform (or envelope) response spectra loading analysis for seismic and seismiclike building filtered hydrodynamic loads and the annulus pressurization loading.

- The code case damping is applied to a spectral analysis load case in its entirety and is not mixed with other damping values within that one load case.

- Modal and direction combination of the three earthquake directions are combined in accordance with Regulatory Guide 1.92.

- Consideration of a sufficient number of modes such that the inclusion of additional modes would not result in more than a 10% increase in response.

- Assurance that the predicted piping displacements are such that adequate clearance exists with respect to adjacent components and equipment.

- Line mounted equipment is designed to withstand the increased pipe motion.

- The code case damping is not used for analyzing the dynamic response of piping systems incorporating supports designed to dissipate energy by yielding.

- The code case damping is not applied to piping analytical models that incorporate equipment with natural frequencies below 20 hertz.

- The code case damping is not applied to piping in which stress-corrosion cracking has occurred unless a case specific evaluation is reviewed by the NRC.

When time history or independent support motion response spectrum analysis is utilized, the following critical damping values are applied:

a. Time history analysis with 0.5% damping for OBE, 1% damping for SSE, or Regulatory Guide 1.61 damping for hydrodynamic loads.

b. Independent support motion response spectra analysis with Regulatory Guide 1.61 damping.

ASME Section III, Division I Code Case N-397, "Alternative Rules to the Spectral Broadening Procedures of N-1226.3 for Classes 1, 2 and 3 Piping, Section III, Division 1" may be selectively used on a load case basis. This code case is applicable to all spectral analysis load cases and all methodologies except it was not applied to a spectral analysis load case that utilized the independent support motion analysis methodology.

3.7.1.4 Supporting Media for Seismic Category I Structures

All seismic Category I structures are supported on sound rock or concrete backfill bearing on sound rock, except for some yard facilities such as valve pits and portions of electrical duct banks and underground piping which are supported on natural soil or fill (Section 2.5.4.10).

For the dynamic analysis of the rock-founded structures, soil-structure interaction is considered to be negligible due to the high stiffness of the rock. However, the floor response spectra developed

for the reactor enclosure and the containment for equipment analysis are based on a model that considered the flexibility of the supporting medium. The modulus of elasticity, the shear-wave velocity, and the density of the supporting medium used in the analysis are 3.0×10^6 psi, 6000 fps, and 150 lbs/ft^3, respectively. Additional soil-structure interaction studies were performed for the containment structure and reactor and control enclosures to assess the sensitivity of the structural response to variations in the design basis rock modulus. Modal analyses have demonstrated that for a ±50% of the design elastic modulus range, variations in structural frequency do not exceed 10% for predominant modes. These results indicate that a reduction in rock modulus to 1.5×10^6 psi would not produce significant effects on the structural response. It is therefore concluded that the average dynamic elastic modulus value of 3.0×10^6 psi is adequate for design.

3.7.2 SEISMIC SYSTEM ANALYSIS

Seismic Category I structures and systems, and components of the NSSS that fall under the category of a seismic system, are discussed here. Seismic systems are analyzed for both OBE and SSE.

3.7.2.1 Seismic Analysis Method

3.7.2.1.1 Seismic Analysis Methods (NSSS)

Analysis of seismic Category I NSSS systems and components was accomplished, where applicable, using the response spectrum or time history approach. Either approach utilizes the natural period, mode shapes, and appropriate damping factors of the particular system. Certain pieces of equipment having very high natural frequencies may be analyzed statically. In some cases, dynamic testing of equipment may be used for seismic qualification.

A time history analysis involves the solution of the equations of the dynamic equilibrium (Section 3.7.2.1.1.1) by means of the methods discussed in Section 3.7.2.1.1.2. In this case, the duration of motion is of sufficient length to ensure that the maximum values of response are obtained.

A response spectrum analysis involves the solution of the equations of motion (Section 3.7.2.1.1.1) by the method discussed in Section 3.7.2.1.1.3.

3.7.2.1.1.1 The Equations of Dynamic Equilibrium

Assuming that the force due to damping is proportional to velocity, the dynamic equilibrium equations for a lumped-mass, distributed stiffness system are expressed in matrix form as:

$$[M]\{\ddot{u}(t)\} + [C]\{\dot{u}(t)\} + [K]\{u(t)\} = \{P(t)\} \qquad \text{(EQ. 3.7-1)}$$

where:

$u(t)$ = time-dependent displacement of nonsupport points relative to the supports

$\dot{u}(t)$ = time-dependent velocity of nonsupport points relative to the supports

$\ddot{u}(t)$ = time-dependent acceleration of nonsupport points relative to the supports

[M] = diagonal matrix of lumped masses

[C] = damping matrix

[K] = stiffness matrix

P(t) = time-dependent inertial forces acting at nonsupport points

3.7.2.1.1.2 Solution of the Equations of Motion by Mode - Superposition

The first technique used for the solution of the equations of motion is the method of mode-superposition.

The set of homogeneous equations represented by the undamped free vibration of the system is:

$$[M]\{\ddot{u}(t)\} + [K]\{u(t)\} = \{0\} \qquad \text{(EQ. 3.7-2)}$$

Since the free oscillations are assumed to be harmonic the displacements can be written as

$$\{u(t)\} = \{\phi\}\, e \qquad \text{(EQ. 3.7-3)}$$

where:

$\{\phi\}$ = column matrix of the amplitude of displacement {u}

ω = circular frequency of oscillation

t = time

Substituting Equation 3.7-3 and its derivatives into Equation 3.7-2 and noting that (e) is not necessarily zero for all values of (ωt) yields

$$[-\omega^2[M] + [K]]\{\phi\} = \{0\} \qquad \text{(EQ. 3.7-4)}$$

Equation 3.7-4 is the classical algebraic eigenvalue problem, wherein the eigenvalues are the frequencies of vibrations, w_i, and the eigenvectors are the mode shapes, $\{\phi\}_i$.

For each frequency here is a corresponding solution vector $\{\phi\}_i$. It can be shown that the mode shape vectors are orthogonal with respect to the weighting matrix [K] in the n-dimensional vector space.

The mode shape vectors are also orthogonal with respect to the mass matrix [M].

The orthogonality of the mode shapes is used to effect a coordinate transformation of the displacements, velocities, and accelerations, so that the response in each mode is independent of the response of the system in any other mode. Thus, the problem becomes one of solving (n) independent differential equations rather than (n) simultaneous differential equations; and, since the system is linear, the principle of superposition holds, and the total response of the system oscillating simultaneously in (n) modes is determined by direct addition of the responses in the individual modes.

3.7.2.1.1.3 Analysis by Response Spectrum

As an alternative to the step-by-step mode-superposition method described in Section 3.7.2.1.1.2, the response spectrum method may be used. The response spectrum method is based on the fact that the modal responses can be expressed as a set of integral equations, rather than a set of differential equations. The advantage of this form of solution is that for a given ground motion, the only variables under the integral are the damping factor and the frequency. Thus, for a specified damping factor, it is possible to construct a curve which gives a maximum value of the integral as a function of frequency. This curve is called a response spectrum for the particular input motion and the specified damping factor. The integral has units of velocity, consequently the maximum of the integral is called the spectral velocity.

Using the calculated natural frequencies of vibration of the system, the maximum values of the modal responses are determined directly from the appropriate response spectrum. The modal maxima are then combined as discussed in Section 3.7.3.7.1.

The total seismic structural response is predicted by combining the response calculated from the two horizontal and the vertical analyses. When the response spectrum method is used, the methods for combining the loads from the three analyses is based on the method described in Section 3.7.2.6.

3.7.2.1.1.4 Support Displacements in Multisupported Structure

The methods described in Section 3.7.2.1.1.5 are used, where applicable, to account for the effects of relative anchor motion in the case of a multisupported structure.

3.7.2.1.1.5 Dynamic Analysis of Seismic Category I Systems and Components

The time history technique and the response spectrum technique were used as applicable for the dynamic analysis of seismic Category I NSSS systems and components which are sensitive to dynamic seismic events.

a. Dynamic Analysis of Piping Systems

Each pipeline is idealized as a mathematical model consisting of lumped masses connected by elastic members. The stiffness matrix for the piping system is determined using the elastic properties of the pipe. This includes the effects of torsional, bending, shear, and axial deformations, as well as change in stiffness due to curved members. Next the mode shapes and the undamped natural frequencies are obtained. The dynamic response of the system is calculated by using the response spectrum method of analysis. When the piping system is being anchored and supported at points with different excitations, the response spectrum analysis is performed using a response spectrum which envelopes all the response spectra of anchors and supports. Alternatively, except as restricted by Section 3.7.1.3.3, the multiple response spectra/independent support motion method of analysis may be used where distinct time histories or response spectra are applied to all piping system attachment points.

The relative modal displacement between anchors is determined from the dynamic analysis of the primary structures. The results of the relative anchor point

displacement per mode are used for a static analysis to determine the secondary stresses due to relative anchor point displacements. The modal stresses are combined by the SRSS method to obtain the resultant secondary stresses.

b. Dynamic Analysis of Equipment

Equipment is idealized as a mathematical model consisting of lumped masses connected by elastic members or springs. The Table 3.9-6 series documents calculated and allowable loads for various loading combinations, including seismic loads, applied to major NSSS systems and components.

The response spectrum analysis is performed using the enveloped response spectrum of all attachment points. Alternatively, for equipment supported at two or more points located at different elevations in the same primary structure, the response spectrum for the most severe single support can be applied uniformly to all support points. As a second alternative, if appropriate, the response spectra at the elevation near the center of gravity of the equipment may be taken as the design spectra.

The relative modal displacement between supports is determined from the dynamic analysis of the structure. The relative support point displacements per mode are used for a static analysis to determine the secondary stresses due to support displacements. The modal stresses are combined by the SRSS method to obtain the resultant secondary stresses. Further details are given below.

c. Differential Seismic Movement of Interconnected Components

The procedure for considering differential displacements for equipment anchored and supported at points with different displacement excitations is as follows:

The relative displacements between the supporting points induces additional stresses in the equipment supported at these points. These stresses can be evaluated by performing a static analysis where each of the supporting points is displaced a prescribed amount. From the dynamic analysis of the complete structure, the time history of displacement at each supporting point is available. These displacements are used to calculate stresses by determining the peak modal responses. The stresses thus obtained for each natural mode are then superimposed for all modal displacements of the structure by the SRSS method.

In the static calculation of the stresses due to relative displacements in the response spectrum method, the maximum value of the modal displacement is used. Therefore, the mathematical model of the equipment is subjected to the maximum displacement at its supporting points obtained from the modal displacements. This procedure is repeated for the significant modes (modes contributing most to the total displacement response at the supporting point) of the structure. The total stresses due to relative displacement are obtained by combining the modal results using the SRSS method. Since the maximum displacements for different modes do not occur at the same time, the SRSS method is a realistic and practical method.

When a component is covered by the ASME B&PV Code, then the stresses due to relative displacement as obtained above are treated as secondary stresses.

3.7.2.1.1.6 Seismic Qualification by Testing

For certain seismic Category I equipment and components where dynamic testing is necessary to ensure functional integrity, test performance data and results reflect the following:

a. Performance data of equipment which, under the specified conditions, has been subjected to dynamic loads equal to or greater than those to be experienced under the specified seismic conditions

b. Test data from previously tested comparable equipment which, under similar conditions, has been subjected to dynamic loads equal to or greater than those specified

c. Actual testing of equipment in accordance with one of the methods described in Sections 3.9 and 3.10

Alternate test procedures that satisfy the requirements of these criteria are allowed, subject to review by the responsible engineer.

3.7.2.1.2 Seismic Analysis Methods (Non-NSSS)

In the analysis of seismic Category I structures, two distinct objectives must be satisfied:

a. Development of in-structure seismic response characteristics, where necessary, for use in the analysis and design of seismic Category I systems, equipment, and components

b. Determination of seismic force distribution within the various structures resulting from the design criteria free-field seismic input, for use in the design of seismic Category I structures

Two analytical procedures were employed to determine the seismic responses to the Category I structures. In general, a modal response spectrum analysis was used to compute the in-structure seismic responses, including nodal accelerations, nodal displacements, and member forces. Alternatively, a time history analysis procedure was used to generate the in-structure seismic responses discussed above. In addition, time history analysis was used to generate all floor response spectra. The mathematical idealization of the structural characteristics of the various seismic Category I structures was accomplished by a lumped-parameter beam-stick model. The general analytical methods and modeling techniques used in these analyses are in accordance with Reference 3.7-2. The seismic design criteria input is defined in terms of the OBE and SSE design response spectra (Section 3.7.1.1), the synthetic time history (Section 3.7.1.2), and the soil-structure interaction parameters (Section 3.7.2.4) used for development of floor response spectra for equipment assessment. Refer to Figures 3.7-10 through 3.7-19 for either a pictorial representation or an actual sketch of the mathematical models used. A complete description of the formulation of the mathematical models and their use is provided in Section 3.7.2.3.2.

3.7.2.2 Natural Frequencies and Response Loads

The natural frequencies of the primary containment, the reactor enclosure, and the control structure below 33 cps are shown in Tables 3.7-5 and 3.7-6 respectively. The significant mode

shapes of the containment and the reactor enclosure and control structure are shown on Figures 3.7-20 through 3.7-30. The mode shapes for the primary containment are for the horizontal and vertical directions. The reactor enclosure and control structure mode shapes are for each of the three principal directions: east-west, north-south, and vertical.

Tables 3.7-7 through 3.7-16 show the response (i.e., displacements, accelerations, shear forces, bending moments, and axial forces) of the primary containment and the reactor enclosure and control structure for both OBE and SSE.

Response spectra at critical locations are shown on Figures 3.7-31 through 3.7-40. The curves are shown for each of the principal directions at the damping values shown (Section 3.7.2.15 for further discussion of damping values). Figures 3.7-41 and 3.7-42 represent the response spectra of the refueling area using soil-structure interaction.

3.7.2.3 Procedures Used for Modeling

3.7.2.3.1 Procedures Used for Modeling (NSSS)

3.7.2.3.1.1 Modeling Techniques for Seismic Category I Systems and Components

An important step in the seismic analysis of seismic Category I NSSS systems and components is the procedure used for modeling. The techniques currently being used are represented by lumped masses and a set of spring-dashpots idealizing both the inertial and stiffness properties of the system. The details of the mathematical models are determined by the complexity of the actual structures and the information required for the analysis.

3.7.2.3.1.2 Modeling of Reactor Pressure Vessel and Internals

The seismic loads on the RPV and internals are based on a dynamic analysis of an entire RPV enclosure complex, with the appropriate forcing function applied at ground level. For this analysis, the models shown in Figure 3.7-19 and the mathematical model of the enclosure are coupled together.

This mathematical model consists of lumped masses connected by elastic (linear) members. The stiffness properties of the model are determined using the elastic properties of the structural components. This includes the effects of both bending and shear. In order to facilitate hydrodynamic mass calculations, several mass points (fuel, shroud, vessel) are selected at the same elevation. The various lengths of CRD housings are grouped into the two representative lengths as shown in Figure 3.7-19. These lengths represent the longest and shortest housings in order to adequately represent the full range of frequency response of the housings. The high fundamental natural frequencies of the CRD housings result in very small seismic loads. Furthermore, the small frequency differences between the various housings, due to the length differences, result in negligible differences in dynamic response. Hence, the modeling of intermediate length members becomes unnecessary. Not included in the mathematical model are the stiffnesses of light components such as jet pumps, incore guide tubes and housings, spargers, and their supply headers. This is done to reduce the complexity of the dynamic model. To find seismic responses of these components, the floor response spectra generated from the system analysis are used.

The presence of fluid and other structural components (e.g., fuel within the RPV) introduces a dynamic coupling effect. Dynamic effects of water enclosed by the RPV are accounted for by

introduction of a hydrodynamic mass matrix, which serves to link the acceleration terms of the equations of motion of points at the same elevation in concentric cylinders with a fluid entrapped in the annulus. The details of the hydrodynamic mass derivation are given in Reference 3.7-5. The seismic model of the RPV and internals has two generalized coordinates in the horizontal directions for each mass point considered in the analysis. The remaining generalized vertical coordinate is excluded because the vertical mode frequencies of RPV and internals are well above the significant horizontal mode frequencies. A separate vertical analysis is performed. The two rotational coordinates about each node point are excluded because the moment contribution from rotary inertia is negligible. Since all deflections are assumed to be within the elastic range, the rigidity of some components may be accounted for by equivalent linear springs.

The shroud support plate is loaded in its own plane during a seismic event and hence is extremely stiff, and, therefore, may be modeled as a rigid link in the translational direction. The shroud support legs and the local flexibilities of the vessel and shroud contribute to the rotational flexibilities and are modeled as an equivalent torsional spring.

3.7.2.3.2 Procedures Used for Modeling (Non-NSSS)

The mathematical models used for the analysis of all major Category I structures are fixed base, lumped-mass, elastic spring models, except for the primary containment, the reactor enclosure and control structure, where the lumped-mass seismic model considers a rigid mass resting on soil springs. The soil spring constants are determined from formulae given in table 3-2 of Reference 3.7-2. Two separate and independent analyses are done for the containment structure. The section properties for these two analyses are based on uncracked and cracked concrete sections, respectively. The same models are used both for the response spectrum and time history analyses. The mathematical models of the primary containment are shown in Figures 3.7-10 and 3.7-11, and those of the reactor enclosure and control structure are shown in Figures 3.7-14 and 3.7-15. The additional mathematical models used for development of floor response spectra, using soil-structure interaction for these structures, are shown in Figures 3.7-12, 3.7-13, 3.7-16, and 3.7-17.

For all models, the masses are located at elevations of mass concentrations, such as floors and roofs. However, in the case of the containment, a structure of continuous mass distribution, masses are lumped at approximate maximum intervals of 15 feet along the containment shell and reactor pedestal. These methods of mass distribution are in accordance with the procedures of section 3.2 of Reference 3.7-2. All equipment, components, and piping systems are lumped into the supporting structure except for the reactor vessel, which is incorporated into the lumped-parameter analysis of the containment structure to account for potential coupling. The detailed analysis of the NSSS is performed using a decoupled model as discussed in Section 3.7.2.3.1.

A more refined RPV model is being used in the DAR (Appendix 3A) to evaluate the anticipated effects of hydrodynamic loads in combination with seismic loads.

3.7.2.4 Soil-Structure Interaction

Since the seismic Category I structures are founded on competent bedrock, a soil spring approach to characterize soil-structure interaction is not used in the dynamic analysis. A simplified lumped-mass method using a fixed base model is used. However, for a more refined analysis of containment and reactor enclosure, the underlying foundation medium is considered to interact with the structure. The equivalent soil spring constant and damping coefficient are computed in accordance with the formulae of table 3-2 of Reference 3.7-2, and the analysis carried out by the

methods discussed in appendix D of Reference 3.7-2. The resulting structure-foundation interaction coefficients are listed in Table 3.7-17.

3.7.2.5 Development of Floor Response Spectra

3.7.2.5.1 Floor Response Spectra (NSSS)

See Section 3.7.3.6.1.

3.7.2.5.2 Floor Response Spectra (Non-NSSS)

The time history method of analysis was used to develop the floor response spectra. A discussion of the technique of finding the nodal time history and then producing the spectrum may be found in Sections 4.2 and 5.2 of Ref 3.7-2.

3.7.2.6 Three Components of Earthquake Motion

3.7.2.6.1 NSSS

See Section 3.7.3.6.1.

3.7.2.6.2 Non-NSSS

The response spectrum method was used in seismic analysis of structures. Independent analyses are performed for the vertical and two horizontal (east-west and north-south) directions. Regulatory Guide 1.92, "Combining Responses and Spatial Components in Seismic Response Analysis" states that the design response value is obtained by taking the SRSS of the maximum co-directional responses caused by each of the three components of earthquake motion at a particular point of the structure. However, for design purposes, the response value used is the maximum value obtained by adding the response due to the vertical earthquake with the larger value of the response due to one of the horizontal earthquakes by the absolute sum method. A discussion of the adequacy of the conservatism provided by this two-component absolute summation technique as compared to the Regulatory Guide 1.92 requirement of a three-component SRSS procedure is provided below.

The general conditions for which the absolute summation of two resultants method is conservative may be demonstrated by considering the following:

$$R_H^{min} = fR_H^{max} \quad \text{where } 0 \leq f \leq 1 \text{ where } f = R_H^{min}/R_H^{max}$$

and

$$R_V = CR_H^{max} \quad 0 \leq C < \infty \text{ where } C = R_V/R_H^{max}$$

where:

R_H^{max} = Larger of the two seismic co-directional responses due to either of the horizontal earthquake components

R_H^{min} = Smaller seismic co-directional responses due to the other orthogonal horizontal earthquake component

R_V = Seismic co-directional response due to vertical earthquake

f = ratio of R_H^{min} to R_H^{max}

C = ratio of R_V to R_H^{max}.

Therefore SRSS of three components can be expressed as follows:

$$\sqrt{(R_H^{max})^2 + (R_H^{min})^2 = (R_V)^2}$$

$$\sqrt{(R_H^{max})^2 + f^2 \ (R_H^{max})^2 + C^2 \ (R_H^{max})^2}$$

$$\left(\sqrt{1 + f^2 + C^2} \ R_H^{max} \right) \qquad \text{(EQ. 3.7-5)}$$

The absolute sum of two components can be expressed as follows:

$$R_H^{max} + R_V$$

$$R_H^{max} + CR_H^{max}$$

$$(\sqrt{(1 + C)^2}) R_H^{max}$$

$$(\sqrt{1 + 2C + C^2}) R_H^{max} \qquad \text{(EQ. 3.7-6)}$$

Equation 3.7-6 (absolute sum of two components) will be greater than or equal to Equation 3.7-5 (three-component SRSS) when:

$$\sqrt{1 + 2C + C^2} \geq \sqrt{1 + f^2 + C^2}$$

or

$$1 + 2C + C^2 \geq 1 + f^2 + C^2$$

or

$$2C \geq f^2$$

or $C \geq \frac{1}{2} f^2$ where $0 \leq f = \frac{R_H^{min}}{R_H^{max}} \leq 1$ (EQ. 3.7-7)

This relationship is shown in Figure 3.7-46.

The relative conservatism of the two-component absolute and the three-component SRSS summation techniques may be illustrated by considering the ratio of Equations 3.7-6 and 3.7-5. This ratio will be defined as y. Then:

$$y = \frac{\text{ABS of EQ. 3.7-6}}{\text{SRSS of EQ. 3.7-5}} = \frac{\left(\sqrt{1 + 2C + C^2}\right) R_H^{max}}{\left(\sqrt{1 + f^2 + C^2}\right) R_H^{max}}$$

$$y = \left(\frac{1 + 2C + C^2}{1 + f^2 + C^2}\right)^{1/2} \quad \text{(EQ. 3.7-8)}$$

where:

$$0 \leq f = \frac{R_H^{min}}{R_H^{max}} \leq 1, \text{ as before}$$

This relationship is shown in Figure 3.7-47.

As shown above, the LGS two-component absolute summation method is conservative when the co-directional response due to the vertical excitation is equal to or greater than one-half the higher of the two horizontal responses ($C \geq ½$), regardless of the relationship between the two horizontal responses.

The minimum possible ratio between the two-component absolute summation method and the three-component SRSS procedure is equal to 0.707. This would occur only when the response due to the vertical excitation is zero (C = 0) and the two horizontal responses resulting from the two horizontal excitations are equal (f = 1). However, this case is unlikely to occur, and any other relationship of the various response components would produce a ratio larger than 0.707. The ratio between the two procedures, as shown in Figure 3.7-47 would be greater than one in most cases.

To further demonstrate the relationship of the seismic response components on the LGS structures, an evaluation has been performed for selected critical structural elements within the structures. Details of the evaluation are provided in the following paragraphs.

a. Containment Exterior Shell

   For the structural design of the containment shell, consideration of two horizontal components is not necessary due to the axisymmetric nature of the shell. The maximum resulting loads from two horizontal earthquake components would not be coincident and would occur 90° apart on the circumference of the shell. Furthermore, when the resultant force from one horizontal component is maximum at a given location, the resultant force from the orthogonal horizontal component would be zero. This relationship corresponds to f = 0 in Figures 3.7-46 and 3.7-47. Therefore, the two-component absolute summation technique would produce a more conservative design.

b. Reactor Enclosure and Control Structure

Stress evaluations were performed for critical locations in the reactor enclosure and control structure. The northeast control structure and southwest reactor enclosure corner model locations are selected because of their sensitivity to large orthogonal responses due to out-of-plane seismic motion. The results obtained from the SSE seismic analysis are combined by the two-component ABS and three-component SRSS methods and are compared in Table 3.7-20. For 14 out of 20 wall locations evaluated, the seismic stress response comparison shows that the two-component ABS method is more conservative than the three-component SRSS method. In general, the two-component ABS method and the three-component SRSS method produce comparable results. Although the differences between the combined stress from the two methods are small, the values for some locations suggest that the two-component ABS method may be conservative when the seismic load is considered to act alone.

There are 6 wall locations where the two-component ABS method is less conservative. The critical wall location is the southwest corner of the reactor enclosure, at el 177', where the differential between ABS stresses and SRSS stresses equals 14% (Table 3.7-20). (This location is considered critical not only because of the difference between the ABS and SRSS stresses but also because of the level of the stresses.) However, when the seismic stresses are combined with the stresses due to other design loads, the effect of the differential between ABS stresses and SRSS stresses is reduced in proportion with the ratio of seismic wall load to total wall load. In addition, the critical wall (wall line "D" at el 177') is loaded to only 52% of its capacity (based on combined axial and bending stresses due to all design loads as shown in Figure 3A-432).

Therefore, when considering the reduced effect of ABS vs. SRSS in conjunction with the ample excess capacity of the wall, the use of the ABS method for calculating seismic stresses provides adequate conservatism when considered in combination with other loads in the design of the reactor enclosure and control structure.

3.7.2.7 Combination of Modal Responses

3.7.2.7.1 Combination of Modal Responses (NSSS)

See Section 3.7.3.7.1.

3.7.2.7.2 Combination of Modal Responses (Non-NSSS)

The modal responses (i.e., shears, moments, deflections, accelerations, and inertia forces) are combined by either the sum of the ABS method, or by the SRSS method with consideration of closely spaced modes. Two consecutive modes are defined as closely spaced when their frequencies differ from each other by 10% or less of the lower frequency. When the SRSS method is used, Regulatory Guide 1.92 shall be adopted for the combination of modal responses.

3.7.2.8 Interaction of Non-Category I Structures with Seismic Category I Structures

The turbine enclosure, auxiliary boiler enclosure, and the administration building are the only major non-Category I structures adjacent to seismic Category I structures. These non-Category I

structures are designed for seismic loading in accordance with the UBC (Reference 3.7-3). In addition, the turbine enclosure was dynamically analyzed to ensure the capacity to withstand a SSE without collapsing on or impairing the integrity of the adjacent reactor and control structures. Similarly, the other non-Category I structures were analytically evaluated to ensure that they will not collapse on or otherwise impair the integrity of adjacent seismic Category I structures when subjected to the design seismic loads.

Structural separations have been provided to ensure that interaction between Category I and non-Category I structures does not occur. The minimum separation gap between the buildings is twice the relative displacement for the design seismic loads.

3.7.2.9 Effects of Parameter Variations on Floor Response Spectra

3.7.2.9.1 Effects of Parameter Variations on Floor Response Spectra (NSSS)

To account for potential variations in the primary structure frequencies due to uncertainties in material properties of the soil and structure, soil-structure interaction techniques, approximation in damping, and approximation in dynamic modeling, the computed floor response spectra are peak-broadened by ±15%. This is consistent with the requirements of Regulatory Guide 1.122, although this regulatory guide is not the design basis requirement for the LGS construction permit.

3.7.2.9.2 Effects of Parameter Variations on Floor Response Spectra (Non-NSSS)

To account for variations in the structural frequencies owing to uncertainties in the material properties of the structure and to approximations in the modeling techniques used in the seismic analysis, the computed floor response spectra are smoothed, and peaks associated with each of the structural frequencies are broadened. In lieu of making a parametric study considering changes in the material properties and other variables, the spectrum is broadened on either side of the peak value by 15% of the frequency at which the peaks occur.

3.7.2.10 Use of Constant Vertical Static Factors

Vertical seismic system multimass dynamic models are used to obtain vertical response loads for the seismic design of seismic Category I structures. Therefore, constant vertical static factors are not used to account for vertical response to earthquakes for the seismic design of Category I structures.

3.7.2.11 Methods Used to Account for Torsional Effects

Torsional effects for the reactor enclosure, diesel generator enclosure, spray pond pumphouse, and radwaste enclosure are accounted for as follows:

A static analysis is performed to account for torsion on these structures. The eccentricity is determined using the distance between the center of mass and the center of rigidity of the individual structure. The inertial force from the response spectrum analysis is applied at the center of mass. The resulting torsional moment is equal to the inertial force times the eccentricity. The shear forces due to the torsional moment are then distributed to the walls. The total seismic shear in a given structural element is equal to the sum of the absolute values of the shear due to translation and torsion. Torsional effects are negligible for the containment because of the symmetry of the structure about the vertical center line.

Dynamic analyses have been performed to verify the adequacy of the static-equivalent method described above. These dynamic analyses were performed for the reactor enclosure, diesel generator enclosure and spray pond pumphouse where structural eccentricities are larger than 5% of the larger building plan dimension.

Inertia forces, obtained from dynamic analysis, are multiplied by the mass eccentricity (distance between center of mass and center of rigidity) to obtain a torsional moment, which is distributed to structural walls for design assessment. This equivalent static method was found to produce conservative design torsional moments; more so than results obtained from a 3-D dynamic analysis which included structural eccentricities. The dynamic analysis was performed as follows:

a. 3-D horizontal stick models were constructed for the reactor enclosure, diesel generator enclosure, and spray pond pumphouse with structural masses at calculated eccentricities (Figures 3.7-48, 3.7-49, and 3.7-50). The direction that has the larger mass eccentricity was selected for dynamic response analysis.

b. Modal analysis was performed to determine the vibration frequencies of the structures with eccentricity accounted for. The vibration frequencies with eccentricity were compared to the vibration frequencies with zero eccentricity (Tables 3.7-21 through 3.7-23).

c. Time history analyses were performed for the east-west models of the spray pond pumphouse, diesel generator enclosure, and reactor enclosure.

Torsional moments and shear forces at the base slab were compared with the moments and shear forces of the original design obtained using the equivalent static approach (Tables 3.7-24 through 3.7-27) .

Torsional moment and shear data comparisons show that the original design values using the static approach are conservative.

3.7.2.12 Comparison of Responses

A comparison of the results of modal design response spectrum analysis and modal time history analysis for the containment is shown in Figures 3.7-4 through 3.7-9. The responses are calculated for both OBE and SSE. The uncracked containment model as described in Section 3.7.2.3.2 is used for the analyses. The responses due to synthetic time history input are lower than those due to response spectrum, because the sum of the absolute modal responses are used in the latter analysis, whereas the phase differences of the modal responses are considered in the time history analysis.

3.7.2.13 Methods for Seismic Analysis of Dams

Dams are not provided on LGS.

3.7.2.14 Determination of Seismic Category I Structure Overturning Moments

The overturning moment for seismic Category I structures is the absolute sum of the moments at the base of each stick of the mathematical model. For each stick, the moment at the base is

determined by combining the modal overturning moments. The modal moments are combined by the methods described in Section 3.7.2.7.

The components of the earthquake motion used are the same as those discussed in Section 3.7.2.6. Section 3.8.5 discusses the factor of safety against overturning for several loadings, including seismic loads.

3.7.2.15 Analysis Procedure for Damping

3.7.2.15.1 Analysis Procedure for Damping (NSSS)

In a linear dynamic analysis, the procedure to be utilized to properly account for damping in different elements of a coupled system model is as follows:

a. The values for structural damping of the various structural elements of the model are first specified. Each value is referred to as the damping ratio (B_j) of a particular component which contributes to the complete stiffness of the system.

b. Perform a modal analysis of the linear system model. This will result in a modal matrix (ϕ) normalized so that:

$$\phi_i^T K \phi_i = W_i^2$$

where:

K = the stiffness matrix

W_i = circular natural frequency of mode i

ϕ_i^T = the transpose (ϕ) which is a column vector of (ϕ) corresponding to the mode shape of mode i

Matrix (ϕ) contains all translational and rotational coordinates.

c. Using the strain energy of the individual components as a weighting function, the following equation can be derived to obtain a suitable damping ratio (B_i) for the ith mode.

$$B_i \quad \frac{\sum_{j=1}^{N} [\phi_i^T \beta_j K_j \phi_i]}{W_i^2} \qquad \text{(EQ. 3.7-9)}$$

where:

N = Total number of structural elements

ϕ_i = Mode shape for mode i (ϕ_i^T as transpose)

β_i = Percent damping associated with element j

K_j = Stiffness matrix of element j

W_i = Circular natural frequency of mode i

3.7.2.15.2 Analysis Procedure for Damping (Non-NSSS)

The structures consist of reinforced concrete and welded/bolted structural steel. Damping values for these materials are shown in Table 3.7-2. However, in the seismic analysis of structures supported on rock, damping values of 2% and 5% are used for OBE and SSE respectively for welded/bolted structural steel, as well as for reinforced concrete. Therefore, the analysis by composite modal damping is not necessary.

For the time history analysis of containment and reactor enclosure where the soil-structure interaction is taken into account, the composite modal damping technique was used as described in appendix D of Reference 3.7-2.

3.7.3 SEISMIC SUBSYSTEM ANALYSIS

This section discusses the seismic analysis of subsystems, i.e., equipment, piping, Class 1E cable trays, and supports for seismic Category I HVAC ducts and cable trays.

3.7.3.1 Seismic Analysis Methods

3.7.3.1.1 Equipment

Seismic qualification of equipment was performed by using one of the following methods:

a. Analysis

b. Dynamic testing

c. Combination of analysis and dynamic testing

3.7.3.1.1.1 Analysis

For the purpose of analysis, equipment is idealized as a system of lumped masses and springs, for which frequencies and mode shapes are determined for vibration in the vertical direction and two orthogonal horizontal directions. For each direction of vibration, the spectral acceleration per mode is obtained from the appropriate response spectrum curve (i.e., corresponding to the location of the equipment) at the natural frequency of the equipment. Seismic loading, in terms of inertia forces, moments and shears, is determined for each direction using the response spectrum technique, summing the absolute values per mode. If the orientation of the equipment is not designated on the equipment location drawing, the horizontal seismic loading is taken as the maximum loading (worst case) obtained, using each horizontal direction of vibration and the appropriate horizontal response spectrum curve(s). If the frequencies of all equipment modes (determined by either analysis or testing) are above the frequency of the appropriate response spectrum curve at which the acceleration is constant in the rigid (high frequency) range, the seismic loading consists of static loading corresponding to that acceleration level. If the equipment damping is unknown, the response spectrum curve for 0.5% damping is used to arrive at a conservative seismic loading.

The damping value used for the OBE is increased for the SSE, where sufficient justification is established.

3.7.3.1.1.2 Dynamic Testing

In lieu of performing dynamic analysis, seismic adequacy may be established by providing dynamic test or previous dynamic environmental (performance) data which demonstrate that the equipment meets the seismic design criteria. The data include at least one of the following:

a. Recent test data acquired from dynamic tests of equipment

b. Dynamic test data from previously tested comparable equipment

c. Performance data from equipment which, during normal operating conditions, have been subjected to dynamic loads equal to or greater than those defined in Section 3.7.3.1.1.1

Typical test methods used are as follows:

a. Single-frequency sine beat test

b. Single-frequency dwell test

c. Multifrequency test

3.7.3.1.1.3 Combination of Analysis and Dynamic Testing

Certain equipment was qualified by a combination of analysis and dynamic testing. Experimental methods are used to aid in the formulation of the mathematical model for the equipment. Mode shapes and frequencies are determined experimentally and incorporated in the mathematical model of the equipment. The model is then subsequently analyzed by the procedure described in Section 3.7.3.1.1.1.

3.7.3.1.2 Piping Systems

Reference 3.7-4 describes the methods used for seismic analysis of piping systems. Reference 3.7-4 is followed on LGS with the following exceptions:

In seismic analysis the modal responses are combined by SRSS, and lower damping values than specified in Reference 3.7-4 are used. Alternative analytical methods and damping values may be utilized as described in Section 3.7.1.3.3.

See Section 3.7.3.7.2.

3.7.3.1.3 Class 1E Cable Trays

The cable trays are seismically qualified by the capacity evaluation method which consists of the following:

a. Calculation of the fundamental frequency of the cable tray based on the tray properties obtained from static tests

b. Seismic load computation based upon the tray frequency and the design spectra

c. Calculation of the tray allowable capacity

d. Evaluation of the tray capacity by interaction formula

3.7.3.1.4 Supports for Seismic Category I HVAC Ducts

The supports for HVAC ducts are analyzed by the response spectrum method (Reference 3.7-2).

3.7.3.1.5 Supports for Seismic Category I Electrical Raceway Systems

This section defines the procedures used for the design of the supports of electrical raceway systems, i.e., cable tray, conduit, and wireway gutter systems, subject to the seismic and other applicable loads. The raceway support system usually consists of raceways, horizontal and vertical support members, and lateral and longitudinal bracing members.

3.7.3.1.5.1 Loading Combinations

The adequacy of raceway systems to withstand seismic and other applicable static loads is determined according to the loading combinations and allowable responses given in Table 3.7-3. Load combinations and allowable stresses including the effects of hydrodynamic loads due to LOCA and SRV discharge are given in Table 3A-21.

3.7.3.1.5.2 Analytical Techniques

Either of two methods of analysis is used. Method 1 is a simplified method of analysis which determine the fundamental frequency of braced supports using two-dimensional analysis. Frequencies are determined in each of three principal directions. Then loads are determined by taking the spectral accelerations times the weight; and stresses are determined from static analysis. All members and connections are checked using stress criteria.

Method 2 uses a three-dimensional computer analysis and includes springs to represent joint stiffnesses. Response spectrum analyses are done to determine stresses and deformations. The number of stress cycles is determined by multiplying the time of maximum earthquake motion by the natural frequency of the system.

The allowable number of cycles is taken from Reference 3.7-8 for the joint rotations calculated. Only overhead connections are checked for fatigue because the test results (Reference 3.7-8, p. 7-19) demonstrate that failures occur only in overhead connections.

The basis for the design criteria and analysis Method 2 is the "Cable Tray and Conduit Raceway Test Program" (References 3.7-7 through 3.7-10).

3.7.3.1.5.3 Damping

Damping of 10% of the critical is used for the design of cable tray support systems; 7% damping for conduit and wireway gutter trapeze-type support systems; 5% damping for conduit and wireway gutter nontrapeze-type support systems. The recommended damping values for cable tray and conduit systems, developed from the test program, are shown in Figure 3.7-45. Wireway gutters were not tested: however, the manner in which they are constructed (with more bolted connections and more cables than conduit) provides more damping mechanisms than are present in conduit systems so that using the same damping value as in conduit systems is conservative.

3.7.3.1.5.4 Operating Basis Earthquake

The OBE is considered in the load combinations only for the overhead connections which are checked for fatigue. The OBE stresses are not checked during design for two reasons: first, raceway systems do not fail in a brittle or catastrophic mode as demonstrated by the test program in which such failures did not occur and the electrical systems were able to continue to function in all cases. Thus, there is no need to limit the OBE stresses to the low levels usually used to preclude such failures. Second, the OBE stresses will always be less than the SSE stresses as demonstrated below.

Based on Figure 3.7-45, a comparison of response spectra for corresponding damping values specified in Section 3.7.3.1.5.3 demonstrates that for all response spectra the OBE acceleration values are less than the corresponding SSE acceleration values (References 3.7-8 and 3.7-10). Thus, the OBE acceleration response and stresses are below the SSE acceleration response and stresses.

3.7.3.2 Determination of Number of Earthquake Cycles

3.7.3.2.1 Determination of Number of Earthquake Cycles (NSSS)

3.7.3.2.1.1 NSSS Piping

Fifty peak OBE cycles are postulated for fatigue evaluation.

3.7.3.2.1.2 Other NSSS Equipment and Components

To evaluate the number of cycles which exist within a given earthquake, a typical BWR enclosure/reactor dynamic model was excited by three different recorded time histories: May 18, 1940, El Centro NS component 29.4 sec; 1952, Taft N 69° W component, 30 sec; and March 1957, Golden Gate S 80° E component, 13.2 seconds. The modal response is truncated so that the response of three different frequency bandwidths could be studied: 0-10 Hz; 10-20 Hz; and 20-50 Hz. This is done to give a good approximation to the cyclic behavior expected from structures with different frequency content.

Enveloping the results from the three earthquakes and averaging the results from several different points of the dynamic model, the cyclic behavior as given in Table 3.7-18 was formed. A comparison has shown that the LGS design basis response spectrum is bounded by the spectra of the three earthquakes (Golden Gate, Taft, and El Centro) in the GE base study (Figure 3.7-43).

Independent of earthquake or component frequency, 99.5% of the stress reversals occur below 75% of the maximum stress level, and 95% of the reversals lie below 50% of the maximum stress level.

In summary, the cyclic behavior number of fatigue cycles of a component during an earthquake was found in the following manner:

a. The fundamental frequency and peak seismic loads are found by a standard seismic analysis.

b. The number of cycles which the component experiences are found from Table 3.7-18 according to the frequency range within which the fundamental frequency lies.

c. For fatigue evaluation, 0.5% (0.005) of these cycles are conservatively assumed to be at the peak load and 4.5% (0.045) at or above three quarter peak. The remainder of the cycles have negligible contribution to fatigue usage.

The SSE has the highest level of response. However, the encounter probability of the SSE is so small that it is not necessary to postulate the possibility of more than one SSE during the 40 year life of a plant. Fatigue evaluation due to the SSE is not necessary, since it is a faulted condition, and thus the evaluation is not required by ASME Section III.

The OBE is an upset condition, and therefore, must be included in fatigue evaluations according to ASME Section III. Investigation of seismic histories for many plants show that during a 40 year life, it is probable that five earthquakes with intensities of one-tenth of the SSE intensity, and one earthquake of approximately 20% of the proposed SSE intensity, will occur. To cover the combined effects of these earthquakes and the cumulative effects of even lesser earthquakes, ten peak OBE cycles are postulated for fatigue evaluation.

Table 3.7-19 shows the calculated number of fatigue cycles and the number of fatigue cycles used in design.

3.7.3.2.2 Determination of Number of Earthquake Cycles (Non-NSSS)

In general, the design of the equipment is not fatigue controlled. For equipment qualified by analysis, fatigue is not a controlling factor because the equipment is designed to remain below 90% of the yield strength of the material for the extreme loading condition. The number of stress cycles considered is 60 (5 OBE and 1 SSE events at 10 cycles each). Based on ASME Section III, appendix I criteria (figure I-9-1), this number of cycles will not result in a reduction of allowable stresses.

Any fatigue effects in tested equipment are accounted for by the duration of the test. Consequently, the number of cycles of the earthquake is considered.

In order to conduct a fatigue evaluation for nuclear Class I piping, the number of cycles for a given load set is obtained. This is done by considering ten maximum stress cycles per earthquake and 5 OBEs and 1 SSE to occur within the life of the plant. The results of the fatigue calculations for the most limiting BWR/4 component are shown in Table 3.7-4.

3.7.3.3 Procedures Used for Modeling

3.7.3.3.1 Procedures Used for Modeling (NSSS)

3.7.3.3.1.1 Modeling of Piping Systems

The continuous piping system is modeled as an assemblage of beams. The mass of each beam is lumped at the nodes connected by weightless elastic members representing the physical properties of each segment. The pipe lengths between mass points are no greater than the length which would have a natural frequency of 33 Hz, when calculated as a simply supported beam. All concentrated weights on the piping system such as main valves, relief valves, pumps, and motors are modeled as lumped masses. The torsional effects of the valve operators and other equipment with offset centers of gravity, with respect to the center line of the pipe, is included in the analytical model. Where the torsional effect is found to cause pipe stresses less than 500 psi, this effect is neglected.

3.7.3.3.1.2 Modeling of Equipment

For dynamic analysis, seismic Category I equipment is represented by lumped-mass systems which consist of discrete masses connected by weightless springs. The criteria used to lump masses are:

a. The number of modes of a dynamic system is controlled by the number of masses used. Therefore, the number of masses is chosen so that all significant modes are included. A mode is considered significant if the corresponding natural frequency is less than 33 Hz, and the stresses calculated from this mode are greater than 10% of the total stresses obtained from lower modes.

b. Mass is lumped at any point where a significant concentrated weight is located. Examples are: the motor in the analysis of pump motor stand; the impeller in the analysis of pump shaft; etc.

c. If the equipment has a free-end overhang span whose flexibility is significant compared to the center span, a mass is lumped at the overhang span.

d. When a mass is lumped between two supports, it is located at a point where the maximum displacement is expected to occur. This tends to conservatively lower the natural frequencies of the equipment, because the natural frequencies of the equipment are generally in the higher frequency range of the floor spectra. Similarly, in the case of live loads (mobile) and a variable support stiffness, the location of the load and the magnitude of support stiffness are chosen so as to yield the lowest frequency content for the system. This is to ensure conservative dynamic loads, since equipment frequencies are higher than the frequency at which the floor spectra peak occurs. If such is not the case, the model is adjusted to give more conservative results.

3.7.3.3.1.3 Field Location of Supports and Restraints

The field location of seismic supports and restraints for seismic Category I piping and piping systems components was selected to satisfy the following two conditions:

a. The location selected must furnish the required response to control strain within allowable limits.

b. Adequate structure strength for attachment of the components must be available.

The final location of seismic supports and restraints for seismic Category I piping, piping system components, and equipment (including the placement of snubbers), was checked against the

drawings and instructions issued by the engineer. An additional examination of these supports and restraining devices was made to ensure that the location and characteristics of these supports and restraining devices are consistent with the dynamic and static analyses of the systems.

3.7.3.3.2 Procedures Used for Modeling (Non-NSSS)

Mathematical models which describe the mass and the stiffness properties of the equipment are used. The models define the dynamic behavior of the equipment within the frequency range of interest. The boundary conditions are modeled to reflect the actual mounting conditions. The equipment is represented by lumped-mass models. Massless elastic members are used to connect the masses.

Supports for HVAC ducts are modeled as two-dimensional, lumped- mass, plane frame models. The masses are lumped at the center of the ducts. The electrical raceway support system analytical techniques are discussed in Section 3.7.3.1.5.2. Equivalent structural properties for cable tray analysis were determined from the load-deflection tests (Reference 3.7-11).

Sections 2 and 3 of Reference 3.7-4 discuss the techniques and procedures used to model piping other than the buried type.

3.7.3.4 Basis of Selection of Frequencies

3.7.3.4.1 Basis of Selection of Frequencies (NSSS)

All frequencies in the range of 0.25-33 Hz are considered in the analysis and testing of structures, systems, and components. These frequencies cover the natural frequencies of most of the components and structures under consideration. If the fundamental frequency of a component is $\geq$33 Hz, it is treated as rigid and analyzed accordingly. Frequencies less than 0.25 Hz are not considered, as they represent very flexible structures and are not encountered in this plant.

The frequency range of between 0.25 Hz and 33 Hz covers the range of the broad-band response spectrum used in the design.

3.7.3.4.2 Basis of Selection of Frequencies (Non-NSSS)

The natural frequencies of components are calculated. Only those modes which have natural frequencies <33 Hz are considered in the dynamic analysis. If a component has a frequency $\geq$33 Hz, it is considered as rigid. If the natural frequency of the component falls within the broadened peak of the response spectrum curve, then it is designed to take the applied load.

3.7.3.5 Use of Equivalent Static Load Method of Analysis (Non-NSSS)

The equivalent static load method is used when the natural frequency of the equipment is not determined. If the equipment can be adequately represented by a single-degree-of-freedom system, then the applied inertia load is equal to the weight of the equipment times the peak value of the response spectrum curve. Seismic acceleration coefficients for multidegree of freedom systems, which may be in the resonance region of the amplified response spectra curves, are increased by 50% to account conservatively for the increased modal participation.

Appendix D of Reference 3.7-4 discusses the use of equivalent static load method of analysis as applicable to piping.

3.7.3.6 Three Components of Earthquake Motion

3.7.3.6.1 Three Components of Earthquake Motion (NSSS)

The simultaneous use of three components of earthquake motion was not a design basis requirement of the construction permit for the LGS plant. However, the NSSS systems and components are evaluated to the requirement of Regulatory Guide 1.92.

a. Response Spectrum Method

Response spectra generated by GE are developed considering three components of earthquake motion. The individual responses in each orthogonal direction are combined by SRSS of the colinear contribution due to the three directions of earthquake motion. These are used to predict the total response at each frequency.

b. Time history Method

When the time history method of analysis is used, one of the following options is used to obtain the peak value of any particular response of interest:

1. When maximum colinear contributions due to the three directions of earthquake motion are calculated separately, the total response is obtained as the SRSS combination of the colinear values.

2. When colinear time history responses from each of the three components of the earthquake motion are calculated individually by the step-by-step method and then combined algebraically at each time step, the maximum response is obtained as the peak value from the combined time solution.

3. When a response at each time step is calculated directly based on the simultaneous application of the three earthquake components, the maximum response is determined by scanning the combined time history solution.

The components of earthquake motion must be statistically independent for Options 2 and 3. Also, the time history method precludes the need to consider closely spaced modes.

3.7.3.6.2 Three Components of Earthquake Motion (Non-NSSS)

For equipment, cable trays, and supports for cable trays and HVAC ducts, the three spatial components of the earthquake are considered in the same manner as for structures (Section 3.7.2.6).

The criteria used for combining the results of horizontal and vertical seismic responses for piping systems are described in section 5.1 of Reference 3.7-4.

3.7.3.7 Combination of Modal Responses

3.7.3.7.1 Combination of Modal Responses (NSSS)

All piping and equipment analyzed or supplied by GE are evaluated to the requirements of Regulatory Guide 1.92.

When the response spectra method of modal analysis is used, all modes except the closely spaced modes (i.e., the difference between any two natural frequencies is equal to or less than 10%) are combined by the SRSS as described in Section 3.7.3.7.1.a. Closely spaced modes are combined by the double sum method with absolute sign as described in Section 3.7.3.7.1.b.

In the time history method of dynamic analysis, the vector sum at every time step is used to calculate the combined response. The use of the time history method precludes the need to consider modal spacing.

a. SRSS

The SRSS method is defined mathematically as:

$$R = \left[\sum_{i=1}^{n} (R_i)^2 \right]^{1/2} \qquad \text{(EQ. 3.7-10)}$$

where:

R = Combined response

R_i = Response in the (i) mode

n = Number of modes considered in the analysis

b. Procedure of Combining Closely Spaced Modal Response

This method is defined mathematically as:

$$R = \left[\sum_{k=1}^{N} \sum_{s=1}^{N} |R_k R_s| E_{ks} \right]^{1/2} \qquad \text{(EQ. 3.7-11)}$$

where:

R = representative maximum values of a particular response of a given element to a given component of excitation

R_k = peak value of the response of the element due to the kth mode

N = number of significant modes considered in the modal response combination

R_s = peak value of the response of the element attributed to the sth mode

also:

$$E_{ks} = 1 + \left[\frac{\bar{w}_k^1 - \bar{w}_s^1}{\beta_k^1 w_k + \beta_s^1 w_s} \right]^2 \qquad \text{(EQ. 3.7-12)}$$

in which:

$$\bar{w}_k^1 = w_k (1 - \beta_k^2)^{1/2} \quad \text{and}$$

$$\beta_k^1 = \beta_k + \frac{2}{t_d w_k}$$

where:

w_k = modal frequency

β_k = damping ratio in the kth mode

t_d = duration of the earthquake.

3.7.3.7.2 Combination of Modal Responses (Non-NSSS)

The modal responses of equipment are combined by the SRSS method. The absolute values of two closely spaced modes are added first before combining with the other modes by the SRSS method. Two consecutive modes are defined as closely spaced when their frequencies differ from each other by 10% or less.

Procedures given in Regulatory Guide 1.92 for combining modal responses, when closely spaced modes are present, are not complied with in the seismic response spectra analysis for piping. All modal responses are combined by SRSS in the response spectra method of modal analysis for seismic loading (OBE and SSE). Seismic response spectra used in the piping analysis corresponds to conservative damping values of ½% for OBE and 1% for SSE. Alternative analytical methods and damping values may be utilized as described in Section 3.7.1.3.3.

3.7.3.8 Analytical Procedure for Piping

3.7.3.8.1 Analytical Procedure for Piping (NSSS)

The analytical procedures for piping analysis have been described in Section 3.7.2.1.1.5.a. Methods to include differential piping support movements at different support points are also described there.

3.7.3.8.2 Analytical Procedure for Piping (Non-NSSS)

The design criteria and the analytical procedures applicable to piping systems are as described in section 2 of Reference 3.7-4. Alternatively, except as restricted by Section 3.7.1.3.3, the multiple response spectra/independent support motion method of analysis may be used where distinct response spectra are applied to the piping system attachment points. The methods used to consider differential piping support movements at different support points are described in section 4 of Reference 3.7-4.

3.7.3.9 Multiple Supported Equipment Components with Distinct Inputs

3.7.3.9.1 Multiple Supported Equipment Components with Distinct Inputs (NSSS)

The procedure and criteria for analysis has been described in Section 3.7.2.1.1.5.b.

3.7.3.9.2 Multiple Supported Equipment Components with Distinct Inputs (Non-NSSS)

For cable trays and HVAC ducts whose supports have two or more distinct inputs, a response spectrum curve envelopes the curves at all support locations. When a piping system whose supports have two or more distinct inputs, a response spectrum curve may be used for analysis that envelopes the curves at all locations. Alternatively, except as restricted by Section 3.7.1.3.3, the multiple response spectra/independent support motion method of analysis may be used where distinct response spectra are applied to the piping system attachment points. Section 4 of Reference 3.7-4 discusses the methods used for the analysis of multiple supported piping due to differential seismic anchor movement.

3.7.3.10 Use of Constant Vertical Static Factors

3.7.3.10.1 Use of Constant Vertical Static Factors (NSSS)

Constant vertical static factors are not used for NSSS components.

3.7.3.10.2 Use of Constant Vertical Static Factors (Non-NSSS)

Constant vertical static factors are not used in the seismic design of subsystems.

3.7.3.11 Torsional Effects of Eccentric Masses

3.7.3.11.1 Torsional Effects of Eccentric Masses (NSSS)

Torsional effects of eccentric masses is discussed in Section 3.7.3.3.1.1.

3.7.3.11.2 Torsional Effects of Eccentric Masses (Non-NSSS)

The torsional effects of valves and other eccentric masses are considered in the seismic analysis of piping by the techniques discussed in section 3.2 of Reference 3.7-4.

3.7.3.12 Buried Seismic Category I Piping Systems and Tunnels (Non-NSSS)

Buried seismic Category I piping is analyzed and designed for seismic effects in accordance with section 6.0 of Reference 3.7-2. For portions of buried piping in soil, the soil response along the pipeline is determined in accordance with the procedure in Section 2.5.4.7.1.

The diesel oil storage tank structures and the ESW/RHRSW pipe tunnel (located beneath the diesel generator enclosure) are seismic Category I and are analyzed using an equivalent static load method.

Other tunnels at LGS are nonseismic Category I.

3.7.3.13 Interaction of other Piping with Seismic category I Piping

3.7.3.13.1 Interaction of other Piping with seismic Category I Piping (NSSS)

When other piping is attached to seismic Category I piping, the other piping is analytically simulated in a manner that does not significantly degrade the accuracy of the seismic Category I piping analysis. Furthermore, the other piping is designed to withstand the SSE without failing in a manner that would cause the seismic Category I piping to fail.

3.7.3.13.2 Interaction of Other Piping with seismic Category I Piping (Non-NSSS)

The techniques used to consider the interaction of seismic Category I piping with non-Category I piping are as follows:

Seismic boundary anchors are designed for the combined loads generated from both sides of a boundary anchor. The loads from the seismic Category I side are actual calculated loads, and the loads from the nonseismic Category I side are determined by one of the following:

a. The actual calculated seismic loads if the nonseismic side piping is dynamically analyzed for seismic events

b. The actual calculated loads if the nonseismic side piping is designed to a conservative simplified seismic design criteria (e.g., by simplified span methods such as those used for designed of small piping)

c. The loads determined by the plastic capability of the piping.

3.7.3.14 Seismic Analysis for Reactor Internals (NSSS)

The modeling of RPV internals is discussed in section 3.7.2.3.1.2. The damping values are given in Table 3.7-1.

3.7.3.15 Analysis Procedures for Damping

3.7.3.15.1 Analysis Procedures for Damping (NSSS)

Analysis procedures for damping are discussed in section 3.7.2.15.1.

3.7.3.15.2 Analysis Procedure for Damping (Non-NSSS)

If the equipment damping is unknown, the response spectrum curve for 0.5% damping is used to arrive at a conservative seismic loading. The damping values used for the OBE are increased for the SSE, where sufficient justification is established.

3.7.4 SEISMIC INSTRUMENTATION

3.7.4.1 Comparison with Seismic Monitoring System Regulatory Guides

The seismic monitoring system instrumentation was designed to comply with the intent of Regulatory Guide 1.12 (Rev. 2), Regulatory Guide 1.166 and Regulatory Guide 1.167.

3.7.4.1.1 Comparison to Regulatory Guide 1.12, Rev. 2

Regulatory Guide 1.12 describes the seismic instrumentation that is acceptable to the NRC for satisfying the requirements of Part 20 and Appendix S to Part 50. Limerick is in compliance with the guidance with this Reg Guide and takes no exceptions.

3.7.4.1.2 Comparison to Regulatory Guide 1.166

Regulatory Guide 1.166 describes the pre-earthquake planning and post earthquake responses to a seismic event. The Reg Guide states that the response spectrum and Cumulative Absolute Velocity (CA V) be calculated to determine OBE exceedance. Limerick is in compliance with the guidance with this Reg Guide and takes no exceptions.

3.7.4.1.3 Comparison to Regulatory Guide 1.167

Regulatory Guide 1.167 describes the guidance on the restart of a nuclear reactor after a seismic event. Limerick is in compliance with the guidance with this Reg Guide and takes no exceptions.

3.7.4.2 Location and Description of Instrumentation

The following instrumentation is provided for Unit 1 only, as essentially the same response is expected at Unit 2.

a. Six triaxial time history Strong Motion Recorders with built in sensors.

b. One response spectrum analyzer (software run on local laptop computer).

c. A system control panel which provides seismic event visual and audible annunciators.

d. Analysis software for monitoring of equipment and determination of exceedance of QBE based on CAV and response spectra.

All instrument characteristics meet the requirements of Regulatory Guide 1.12, Rev. 2, Section 4.0.

The operability of the seismic monitoring instrumentation ensures that sufficient capability is available to promptly determine the magnitude of a seismic event and evaluate the response of those features important to safety. This capability is required to permit comparison of the measured response to that used in the design basis for the unit.

3.7.4.2.1 Triaxial Time History Strong Motion Recorders

Triaxial time history Strong Motion Recorders (SMR) contain solid state seismic sensors and they measure and record the time varying acceleration at the sensor location. This data is stored locally and then sent to the main control panel when requested by the system for conversion and comparison with reference information. Each SMR contains a three axis solid state accelerometer mounted inside the SMR. All SMR's have their principal axes oriented identically, with one horizontal axis parallel to the major horizontal axis assumed in the seismic analysis. The SMR's are located as shown in table 3. 7-28.

3.7.4.2.2 Remote Triaxial Time History Strong Motion Recorders

There are two self contained Strong Motion Recorders (SMR) located in the Spary Pond Pump House. The Spray Pond Pump House is the Alternate Category 1 building being monitored per Reg Guide 1.12. The first SMR is located at the building foundation at elevation 237' and the second SMR is located at elevation 268'. These two SMR's are not connected to the seismic control panel in the Main Control Room (MCR). These SMR are accessible by a dedicated laptop for download of the time history seismic response.

3.7.4.2.3 Triaxial Seismic Switch (DELETED)

3.7.4.2.4 Response Spectrum and CAV Analyzer

The response spectrum and CAV analyzer is software that resides in the Network Control Center (NCC) and Earthquake Analysis PC which is located in the seismic control panel in the MCR. This software is used for calculation of CAV based on the recorded seismic response to an earthquake, and to compare the recorded data with the site design spectra for each of the connected SMRs location. It determines if the response spectra or CAV has exceeded the OBE criteria for signaling the local annunciator to alarm.

3.7.4.2.5 System Control Panel

A panel located in the control room (OO-C693) houses the monitoring, and spectrum analysis units which are used in conjunction with the SMR sensors to produce a time history and frequency-amplitude record of the seismic event. The panel also contains display and alarm equipment associated with the NCC, Earthquake Analysis PC, and the system power supply units.

3.7.4.3 Control Room Operator Notification

Activation of the seismic monitoring system causes an audible and visual annunciation in the control room alerting plant operators in the MGR to the seismic monitoring system panel.

Should the system or seismic SMRs develop errors or equipment failures, the system will activate an audible and visual Trouble alarm at the Seismic Control panel.

Should the system sense a seismic event from the Free Field or the reactor building foundation sensor, of a large enough magnitude, the system will activate an audible and visual System Triggered alarm at the Seismic Control panel.

Should the system sense and analyze a seismic event that exceeds the OBE limits, the system will activate an audible and visual OBE Exceeded alarm at the Seismic Control panel.

The spray pond pump house SMRs are not interconnected, and have only local indication of error, data, run, and power. The locally recorded data from these two SMRs can be downloaded and analyzed.

3.7.4.4 Comparison of Measured and Predicted Responses

Initial determination of the seismic event level is performed immediately after the event by comparing the measured response spectra from the Free Field with the calculated OBE and SSE response spectra for the corresponding location. An outline of the order of actions to be taken after a seismic event is provided in Figure 3.7-44.

3.7.4.5 Controls

Applicability: The seismic monitoring instrumentation shall be operable at all times. This instrumentation is considered operable when it is capable of performing its specified functions and when all necessary attendant instrumentation, controls, electrical power, cooling or seal water, lubrication or other auxiliary equipment that are required for the system, subsystem, train, component, or device to perform its functions are also capable of performing their related support functions.

Actions: For requirements when one or more seismic monitoring instruments are inoperable, reference the TRM actions.

3.7.4.6 Surveillance Requirements

Each of the seismic monitoring instruments shall be demonstrated operable by the performance of the channel check, channel functional test and channel calibration at the frequencies shown and defined in Table 3.7-29.

Each of the seismic monitoring instruments which is accessible during power operation and which is actuated during a seismic event greater than or equal to 0.01g, and which does not self-reset, shall be restored to operable status within 24 hours and a channel calibration performed within 5 days following the seismic event. Data shall be retrieved from the actuated instruments and analyzed to determine the magnitude of the vibratory ground motion. A Special Report shall be prepared and submitted to the Nuclear Regulatory Commission pursuant to Specification 6.9.2 of the Technical Specifications within ten days describing the magnitude, frequency spectrum and resultant effect upon unit features important to safety.

Table 3.7-1

CRITICAL DAMPING VALUES FOR NSSS MATERIALS[1,2]

ITEM	CRITICAL DAMPING (%) OBE CONDITION	SSE CONDITION
Reinforced concrete structures	2.0	5.0
Welded structural assemblies (equipment and supports)	1.0	2.0
Bolted or riveted structural assemblies	2.0	3.0
Vital piping systems	0.5	1.0
Drywell (coupled)	2.0	5.0
RPV support skirt, shroud head, separator, and guide tubes	2.0	2.0
CRD housings	3.5	3.5
Fuel	7.0	7.0
Steel frame structures	2.0	3.0

(1) Other values may be used if they are indicated to be reliable by experiment or study.

(2) Alternative critical damping values for piping systems may be used as described in Section 3.7.1.3.3.

Table 3.7-2

CRITICAL DAMPING VALUES FOR NON-NSSS MATERIALS[1]

ITEM	CRITICAL DAMPING (%) OBE CONDITION	SSE CONDITION
Equipment	0.5	1
Piping systems	0.5	1
Welded steel structures	2	5
Bolted steel structures	3	7
Reinforced concrete structures (except as noted below for specific loading conditions in primary containment)	2	5
Primary containment (for those loading conditions in which DBA and seismic loadings are combined)	3	7

(1) Alternative critical damping values for piping systems may be used as described in Section 3.7.1.3.3

Table 3.7-3

LOAD COMBINATIONS AND ALLOWABLE RESPONSES FOR ELECTRICAL RACEWAY SYSTEM

Equation	Condition	Load Combination[1]	Allowable Response[1]
1	Normal	D+L	F_s[4]
2[5]	Normal/ Severe	D+E	[2,4]
3	Abnormal/ Extreme	D+E'	[2,3,4]

(1) For notations, see Tables 3.8-2 and 3.8-9.

(2) The following equation is applicable for bending in overhead connections:

$$\frac{5n_{EQ}}{N_{OBE}} + \frac{n_{EQ}}{N_{SSE}} \leq 1.0$$

where:

n_{EQ} = Total number of load/stress cycles per earthquake.

N_{OBE} = Allowable number of load/stress cycles per OBE event.

N_{SSE} = Allowable number of load/stress cycles per SSE event.

(3) The following criteria are used for checking the members. In no case shall the allowable stress exceed 0.90 F_y in bending, 0.85 F_y in axial tension or compression, and 0.50 F_y in shear. Where the design is governed by requirements of stability (local or lateral buckling), the actual stress shall not exceed 1.5 F_s.

(4) Allowable shear and normal loads in connections are determined from the manufacturers' data or from code allowable stresses, whichever is applicable. The allowable values are increased 50% for load combination equation 3.

(5) Equation 2 applies only to connections for fatigue considerations.

Table 3.7-4

RESULTS OF FATIGUE CALCULATIONS FOR THE MOST LIMITING BWR/4 COMPONENT

BWR/4 RPV FEEDWATER NOZZLE[1]	
Loading	Fatigue Usage
10 OBE Cycles	0.006
All Others[2]	0.967
Total	0.973

(1) The most limiting calculation for the BWR/4 product line.

(2) All other fatigue contributions due to SRV, thermal operating transients, etc.

3.8 DESIGN OF CATEGORY I STRUCTURES

3.8.1 CONCRETE CONTAINMENT

3.8.1.1 Description of the Containment

The primary containment is divided by a horizontal diaphragm slab into two major volumes: the drywell and the suppression chamber. The drywell encloses the reactor vessel, reactor recirculation system, and associated piping and valves. The suppression chamber stores a large volume of water.

The primary containment, shown on Figures 3.8-1 through 3.8-8, is in the form of a truncated cone over a cylindrical section, with the drywell being the upper conical section and the suppression chamber being the lower cylindrical section. These two sections comprise a structurally integrated, reinforced concrete pressure vessel, lined with welded steel plate and provided with a steel domed head for closure at the top of the drywell. Connection of the drywell head to the top of the drywell wall is shown on Figure 3.8-9. The diaphragm slab is a reinforced concrete slab structurally connected to the containment wall, as shown on Figure 3.8-10.

The primary containment is structurally separated from the surrounding reactor enclosure.

The concrete dimensions of the primary containment are as follows:

a. Inside diameter

   1. Suppression chamber - 88'-0"

   2. Base of drywell - 86'-4"

   3. Top of drywell - 36'-4½"

b. Height

   1. Suppression chamber - 52'-6"

   2. Drywell - 87'-9"

c. Thickness

   1. Base foundation slab - 8'-0"

   2. Containment wall - 6'-2"

3.8.1.1.1 Base Foundation Slab

The containment base foundation slab is a reinforced concrete mat, the top of which is lined with carbon steel plate.

3.8.1.1.1.1 Reinforcement

The base foundation slab is reinforced with #18, Grade 60 rebar at the top and bottom faces. The maximum rebar spacing is 18 inches. Shear reinforcement consists of #8 and #9 vertical and inclined ties. Cadweld splices are used for splicing all main reinforcing bars. Figure 3.8-11 shows the plan and section views of reinforcement.

3.8.1.1.1.2 Liner Plate and Anchorages

The steel liner plate is ¼ inch thick, and is anchored to the concrete slab by structural steel beams embedded in the concrete and welded to the plate. Figure 3.8-12 shows details of the liner plate and anchorages.

3.8.1.1.1.3 Reactor Pedestal and Suppression Chamber Column, Base Liner Anchorages

Figures 3.8-13 and 3.8-14 show the base foundation slab liner anchorages for the reactor pedestal and the suppression chamber columns, respectively. For the pedestal anchorage, Cadweld sleeves are welded to the top and bottom surfaces of the thickened base liner to permit anchoring of the pedestal vertical rebar into the base foundation slab. Metal studs are welded to the top and bottom surfaces of the thickened base liner in order to transfer radial and tangential shear forces from the pedestal to the base foundation slab. For the suppression chamber column anchorage, pipe caps are welded to the thickened base liner at the locations where the column anchor bolts penetrate the base liner, in order to ensure the leak-tight integrity of the base liner.

3.8.1.1.2 Containment Wall

The containment wall is constructed of reinforced concrete 6'-2" thick, and is lined with carbon steel plate on the inside surface.

3.8.1.1.2.1 Reinforcement

The containment wall is reinforced with #18, Grade 60 rebar at the inner and outer faces. The inner rebar curtain consists of two meridional layers and one hoop layer. The outer rebar curtain consists of one meridional layer, two hoop layers, and two helical layers. Radial shear reinforcement consists of #6 horizontal and inclined ties. Cadweld splices are used for splicing all main reinforcing bars. Figures 3.8-15 and 3.8-16 show sections and developed elevation views of the suppression chamber wall reinforcement and drywell wall reinforcement, respectively.

3.8.1.1.2.2 Liner Plate and Anchorages

The steel liner plate is ¼ inch thick, and is anchored to the concrete wall by vertical stiffeners, using structural tees spaced horizontally every 2 feet, or less. Horizontal plate stiffeners provide additional stiffening. Figures 3.8-17 and 3.8-18 show details of the liner plate and anchorages.

Loads from internal containment attachments, such as beam seats and pipe restraints, are transferred directly into the containment concrete wall. This is accomplished by thickening the liner plate, and attaching structural weldments that transfer any type of load to the concrete, without relying on the liner plate or its anchorages. Where internal containment attachment loads are large, the structural weldments penetrate the liner plate, rather than being welded to opposite sides of the liner plate. This eliminates the possibility of lamellar tearing. Section 3.8.1.1.2.5 contains a further description of internal containment attachments.

3.8.1.1.2.3 Penetrations

Services and communications between the inside and the outside of the containment are performed through penetrations. Basic penetration types include pipe penetrations, electrical penetrations, and access hatches (equipment hatches, personnel lock, suppression chamber access hatches, and CRD removal hatch). Each penetration consists of a pipe sleeve with an annular ring welded to it. The ring is embedded in the concrete wall, and provides an anchorage for the penetration to resist normal operating and accident loads. The pipe sleeve is also welded to the containment liner plate to provide a leak-tight penetration.

Meridional and hoop reinforcement is bent around typical penetrations. Additional local reinforcement in the hoop and diagonal directions is added at all large penetrations, as shown on Figures 3.8-19 and 3.8-20. Local thickening of the containment wall at penetrations is generally not required. Section 3.8.2.1 contains further discussion of penetrations.

a. Pipe Penetrations

Details of typical pipe penetrations are shown on Figure 3.8-21. There are two basic types of pipe penetrations. For piping systems containing high temperature fluids, a sleeved penetration is furnished, providing an air gap between the containment concrete wall and the hot pipe. This air gap is large enough to maintain the concrete temperature below 200°F in the penetration area. A flued head outside the containment connects the process pipe to the pipe sleeve. For piping systems containing low temperature fluid, a separate sleeve for the penetration is not furnished. For this type of penetration, the process pipe is welded directly to the two ends of the embedded pipe penetration.

b. Electrical Penetrations

Figure 3.8-22 shows a typical electrical penetration assembly used to extend electrical conductors through the containment. The penetrations are hermetically sealed, and provide for leak testing at design pressure.

c. Equipment Hatches and Personnel Lock

Two equipment hatches, with inside diameters of 12 feet, are furnished in the drywell wall. One of these equipment hatches includes a personnel lock. Figure 3.8-21 shows a detail of an equipment hatch. Figures 3.8-16 and 3.8-23 show details of reinforcement around the equipment hatches. Additional meridional, hoop, helical, and shear reinforcement is used to accommodate local stress concentrations at the opening. The containment wall is thickened at the equipment hatches to accommodate the additional rebars.

d. Suppression Chamber Access Hatches

Two access hatches, with internal diameters of 4'-4", are furnished in the suppression chamber wall, as shown on Figure 3.8-21. Figure 3.8-15 shows a detail of reinforcement around the suppression chamber access hatches. Additional local reinforcement in the meridional and diagonal directions is added as shown on this figure.

3.8.1.1.2.4 Drywell Head Assembly

The drywell head lower flange is anchored to the top of the drywell wall by rigid attachment to 108 meridional reinforcing bars in the inner curtain of the containment wall, as shown on Figure 3.8-9. The remainder of the drywell head assembly is discussed in Section 3.8.2.1.1.

3.8.1.1.2.5 Internal Containment Attachments

The principal items attached to the containment wall from the interior are the diaphragm slab, beam seats, pipe restraints, and the seismic truss.

a. Diaphragm Slab Embedments

The diaphragm slab is attached to the containment wall by a structural weldment at the junction of the two components, as shown on Figure 3.8-10. Radial force and bending moment, carried by the diaphragm slab main reinforcement, are transferred to the containment wall by Cadwelding the diaphragm slab rebar to the top and bottom flanges of the structural weldment. The top and bottom flanges of the structural weldment are embedded in the containment concrete wall, and are anchored using structural steel anchors. Flexural shear in the diaphragm slab is transferred to the containment wall through the web of the structural weldment, which is welded to opposite sides of the thickened containment liner plate.

b. Beam Seat Embedments

Beam seats are provided to support the drywell platforms. A typical beam seat embedment is shown on Figure 3.8-24.

c. Pipe Restraint Embedments

Pipe restraints are provided to prevent pipe whip caused by rupture of high energy piping. Typical pipe restraint embedments are shown on Figure 3.8-25.

d. Seismic Truss Support Embedments

The seismic truss provides lateral support for the reactor vessel and reactor shield. A typical seismic truss support embedment in the drywell wall is shown on Figure 3.8-26.

3.8.1.1.2.6 External Containment Attachments

There are no major external structural attachments to the primary containment wall, except brackets providing vertical support for some of the reactor enclosure floor beams. These floor beams support checkered plate blowout panels, and are small enough to not cause any vertical interaction between the containment structure and the reactor enclosure. In addition, the beam-to-bracket connections are sliding connections, preventing horizontal interaction between the containment structure and the reactor enclosure.

3.8.1.1.2.7 Steel Components Not Backed by Structural Concrete

Descriptions of steel portions of the primary containment that are not backed by concrete, such as the drywell head, equipment hatches, personnel lock, suppression chamber access hatches, CRD removal hatch, and piping and electrical penetrations, are given in Section 3.8.2.

3.8.1.2 Applicable Codes, Standards, and Specifications

The codes, standards, and specifications used in the design and construction of the primary containment are listed in Table 3.8-1.

Specifications were prepared to cover the areas related to the design and construction of the containment. These specifications were prepared by Bechtel specifically for this containment. These specifications emphasize important points of the industry standards for this containment, and reduce options such as would otherwise be permitted by the industry standards. Unless specifically noted otherwise, these specifications do not deviate from the applicable industry standards, and, as such, are not included in the UFSAR. These specifications cover the following areas:

a. Furnishing and delivering concrete

b. Forming, placing, finishing, and curing concrete

c. Furnishing, detailing, fabricating, delivering, and placing reinforcing steel

d. Splicing reinforcing bars

e. Furnishing, delivering, and erecting liner plate

Section 1.8 provides references to regulatory guides discussed in the UFSAR. Regulatory guides specific to this section are discussed in this section.

3.8.1.3 Loads and Loading Combinations

Table 3.8-2 lists the loading combinations used for the design and analysis of the containment. Loading combinations listed in ASME Section III, Division 2 were considered for the containment design. Table 3.8-21 identifies and explains differences between the loads listed in Table 3.8-2 and the ASME Code.

The containment is also analyzed and designed for hydrodynamic loads resulting from MSRV discharge and LOCA phenomena. For a definition of these loads and loading combinations, including hydrodynamic loads, refer to Reference 3.8-1 and Appendix 3A.

3.8.1.3.1 Dead Load

The dead load includes the weight of the structure and major equipment, plus any other permanent loads, such as soil or hydrostatic loads, or operating pressure.

3.8.1.3.2 Live Load

The live load includes those loads expected to be present when the plant is operating, such as movable equipment, piping, and cables.

3.8.1.3.3 Design Basis Accident Pressure Load

Transients resulting from the DBA LOCA are presented in Section 6.2.1, and serve as the basis for the containment internal design maximum pressure of 55 psig.

3.8.1.3.4 Thermal Loads

The thermal loads used in the design of the primary containment are shown in Table 3.8-3 for the operating and the postulated accident conditions.

Thermal effects anticipated at the time of the structural integrity test are not considered. The ambient air temperature during testing is close to that of construction; therefore, the effects of thermal gradient are negligible.

3.8.1.3.5 Wind and Tornado Loads

Wind and tornado loads are not considered because the containment is enclosed by the reactor enclosure.

3.8.1.3.6 Seismic Loads

Loads from the OBE result from a horizontal ground acceleration of 0.075 g and a vertical ground acceleration of 0.05 g, acting simultaneously.

Loads from the SSE result from a horizontal ground acceleration of 0.15 g and a vertical ground acceleration of 0.10 g, acting simultaneously.

3.8.1.3.7 External Pressure Load

The containment shell is designed to withstand an external pressure of 5 psi above the internal pressure.

3.8.1.3.8 Pipe Rupture Loads

The containment wall is designed to withstand the loads due to a postulated rupture of a 26 inch diameter main steam pipe, which produces the largest loads on the containment wall. These loads include the effects of jet impingement, pipe whip, and pipe reaction. An equivalent static load of 1000 kips is considered. This load includes an appropriate dynamic load factor to account for the dynamic nature of the load. Section 3.6 contains a detailed discussion of postulated pipe ruptures and their effects. For pipe whip and impact on restraints, the steel stress may exceed yield stress. For jet impingement, these stresses should not exceed yield stress. See Section 3.8.1.4 for further explanation.

3.8.1.3.9 Prestress Loads

The primary containment uses reinforced concrete; therefore, prestress loads have not been considered.

3.8.1.4 Design and Analysis Procedures

This section describes the procedures used for the design and analysis of the containment. For a description of the design and analysis procedures that consider the effects of hydrodynamic loads resulting from MSRV discharge and LOCA phenomena, refer to Reference 3.8-1 and Appendix 3A.

The analysis procedure consists of two parts. First, the uncracked forces, moments, and shears for both axisymmetric and nonaxisymmetric loads are determined. Axisymmetric loads are dead

load, live load, design accident pressure load, vertical seismic load, and operating and design accident thermal loads. Nonaxisymmetric loads are horizontal seismic load and localized pipe rupture load. The second part of the procedure consists of taking into account the expected cracking of the concrete, and determining the concrete and reinforcing steel stresses and strains. The liner plate is not assumed to resist any load.

The 3D/SAP computer program, described in Section 3.8.7.1, is used to determine the uncracked forces, moments, and shears due to axisymmetric loads. The operating and design accident temperature gradients are computed using the ME 620 computer program, which is described in Section 3.8.7.9. For transient loads such as design accident pressure and thermal loads, the most critical combination of these loads is considered.

The seismic loads on the structure are determined by seismic analysis using the methods described in Section 3.7. The 3D/SAP program is used to analyze the containment for nonaxisymmetric loads due to missile and postulated pipe rupture, and for local construction loads.

The Concrete Element Cracking Analysis Program (CECAP), described in Section 3.8.7.3, is used to determine the extent of concrete cracking, and the concrete and rebar stresses and strains. The input data for the CECAP program consist of the uncracked forces, moments, and shears calculated by the 3D/SAP and seismic analysis programs. The CECAP program models a single element of unit height, unit width, and depth equal to the thickness of the wall or slab. The program assumes isotropic, linear-elastic material properties, and uses an iterative technique to obtain stresses, considering their redistribution due to cracking. The program determines the redistribution of thermal-stresses due to the relieving effect of concrete cracking.

3.8.1.4.1 Containment Wall

Figure 3.8-27 shows the 3D/SAP finite-element model used to analyze the containment wall for axisymmetric loads. A 10° wedge of the containment is modeled using solid finite-elements having isotropic, linear-elastic material properties. The model includes the containment wall, base foundation slab, diaphragm slab, reactor pedestal, and the foundation material. Boundary conditions are imposed on the analytical model by specifying nodal point forces or displacements. With reference to Figure 3.8-27, the nodal points lying along boundary A are allowed to move within the X-Z plane, and those along boundary B within the X-Y plane. Points along boundary C are prevented from moving in the radial direction, and points along boundary D are prevented from moving in the hoop direction. Nodal forces, moments, and shears are applied to boundaries E and F to account for reaction loads from the drywell head, and from the reactor vessel and reactor shield wall, respectively.

Figure 3.8-28 shows the 3D/SAP finite-element model used to analyze the drywell wall for nonaxisymmetric pipe rupture loads. A 180° half-model of the drywell wall, consisting of isotropic, linear-elastic, solid finite-elements, is used. With reference to Figure 3.8-28, the nodal points lying along boundary A are allowed to move within the X-Z plane. Points along boundary B are prevented from moving in the vertical and radial directions. Nodal forces, moments, and shears are applied to boundary C to account for reaction loads from the drywell head.

Tangential shears caused by seismic loads are totally resisted by helical reinforcing bars and concrete in compression. In calculating the reinforcing steel requirement, the helical reinforcement is designed to resist stresses due to design accident pressure and thermal loads, as well as tangential shears caused by seismic loads.

3.8.1.4.2 Base Foundation Slab

Figure 3.8-29 shows the 3D/SAP finite-element model used to analyze the base foundation slab. A 180° half-model of the base foundation slab, consisting of isotropic, linear-elastic solid finite-elements is used. The model includes the base foundation slab, a portion of the containment wall, and the foundation material. By virtue of continuous modeling of base slab and wall elements as finite elements in the 3D/SAP analysis, strain compatibility and stress equilibrium at the wall and slab boundary are satisfied. With reference to Figure 3.8-29, the nodal points lying along boundary A are allowed to move within the X-Z plane, and those along boundary B within the X-Y plane. Points along boundary C are prevented from moving in the radial direction. Axisymmetric forces, moments, and shears calculated using the 3D/SAP containment model, and seismically induced, tangential shears are applied to boundary D. The height of the model is chosen so that the overturning moment caused by the tangential shear is the same as the overturning moment determined by the seismic analysis. In order to be able to consider uplifting of the base foundation slab from its foundation, a thin layer of foundation material immediately beneath the foundation slab is considered separately from the remainder of the foundation material. If the computer output indicates tension in any of the elements in this thin layer of foundation material, the elements' modulus of elasticity is reduced to almost zero. Then a second computer run is made, and any additional uplift is identified. Further iterations and modifications of foundation material properties are made until the complete extent of uplift is determined.

3.8.1.4.3 Analysis of Areas Around Equipment Hatches

Figure 3.8-30 shows the 3D/SAP finite-element model used to analyze the areas of the containment wall around the equipment hatches. A 60° wedge of the containment wall is modeled using solid finite-elements having isotropic, linear-elastic material properties. To reduce the size of the analytical model, boundary A follows the equipment hatch's vertical plane of symmetry. The points delineating the outermost boundaries of the model are located at a sufficient distance from the opening so that the behavior of the model along the boundaries is compatible with that of the undisturbed shell. With reference to Figure 3.8-30, the nodal points lying along boundary A are allowed to move within the X-Z plane, and those lying along boundary B within the X-Y plane. Points along boundary C are prevented from moving in the hoop direction. Axisymmetric forces, moments, and shears calculated using the 3D/SAP containment model are applied to boundary D. Seismic loads calculated by the seismic analysis are applied locally to the elements. Seismically induced tangential shears around the equipment hatches are resisted by helical reinforcing bars and concrete in compression.

3.8.1.4.4 Liner Plate and Anchorages

The design and analysis of the liner plate and anchorages are performed in accordance with Reference 3.8-3.

3.8.1.5 Structural Acceptance Criteria

3.8.1.5.1 Reinforced Concrete

The containment wall, the diaphragm slab, and the reactor pedestal are designed for the factored load combinations listed in Table 3.8-2, in accordance with the strength method of ACI 318. The following allowable stresses are used:

a. Concrete

1. Compression - 0.85 $f_c^{'}$

2. Tension - not permitted

3. Radial shear - as specified in Chapter 11 of ACI 318 (1971)

4. Tangential shear - not permitted

b. Reinforcing Steel

1. Tension - 0.90 F

2. Compression - 0.90 F

The notations are defined as:

f_c' = specified compressive strength of concrete

F = specified yield strength of reinforcing steel

The calculated stresses are within the allowable limits.

3.8.1.5.2 Liner Plate and Anchorages

The structural acceptance criteria for the liner plate and anchorages are in accordance with Reference 3.8-3.

3.8.1.6 Materials, Quality Control, and Special Construction Techniques

3.8.1.6.1 Concrete Containment

The concrete and reinforcing steel materials for the containment are discussed in Section 3.8.6.

3.8.1.6.2 Liner Plate, Anchorages, and Attachments

a. Materials

Liner plate materials conform to the requirements of the standard specifications listed below:

Item	Specification
Liner plate (¼ inch thick)	ASTM A285, Grade A, Firebox Quality
Liner plate (>¼ inch thick)	ASME SA516, Grade 60 conforming to the requirements of ASME Section III, Subsection B, Article 12
Structural steel shapes, plates, and bars used for anchorages and attachments to the liner plate	ASTM A36

Pipe restraint attachments	ASTM A36 or ASTM A441

b. Welding

Liner plate and structural steel welding conforms to the applicable portions of Part UW, "Requirements for Unfired Pressure Vessels Fabricated by Welding" of ASME Section VIII. Welders and weld procedures are qualified in accordance with ASME Section IX. For seam welds of liner plate and attachments that penetrate the liner plate (penetrations), Paragraphs UW-26 through UW-38, except UW-35, apply in their entirety. In lieu of Paragraph UW-35, undercuts that do not exceed 1/32 inch and do not encroach on the required section thickness are in accordance with ASME Section III, Subsection NB(4424). The welding of liner plate butt welds and penetration attachment welds are performed by either the shielded metal arc, or the automatic, submerged arc process. The minimum number of individual weld layers for welds that must maintain leak-tightness is two. In addition, liner plate seam and penetration attachment welds are inspected in accordance with paragraph (d) below. Welding of liner anchorages and internal containment attachments to the liner plates are also performed in accordance with ASME Section VIII Paragraphs UW-26 through UW-38, and the visual inspection/acceptance of the nonpressure-retaining attachment weldments are in accordance with NCIG-01 (Reference 3.8-22).

c. Materials Testing

Liner plate material greater than ¼ inch thick, used with Cadweld connectors and other anchorages, is vacuum- degassed and ultrasonically tested, in accordance with the ASME Section III, Section A-N321-1, and conforms to the requirements of Article 12, Materials, of ASME Section III, Subsection B.

d. Nondestructive Examination of Liner Plate Seam Welds

Nondestructive examination of welds complies with Regulatory Guide 1.19, with the following alternate approaches:

Spot radiographic examination is performed for all radiographable liner plate seam welds. Radiography is performed in accordance with ASME Section V, Article 2. Personnel performing radiographic examinations are qualified in accordance with the Society for Nondestructive Testing's Recommended Practice No. SNT-TC-1A, Supplement A, Radiographic Testing Method, plus any additional requirements of the ASME Section V. Acceptance standards are in accordance with Paragraph UW-51 of ASME Section VIII, Division 1. Twelve inches of the first 10 feet of weld for each welder, and welding position are radiographed. Thereafter, one 12 inch long radiograph is taken for each welder and weld position, for each additional 50 foot increment of weld. A minimum of 2% of all liner seam welds are examined by radiography.

Where nonradiographable weld joints are used, the entire length of weld is magnetic particle examined. All magnetic particle examinations conform to the ASME Section V. Personnel performing magnetic particle examinations are qualified in accordance with SNT-TC-1A, plus any additional requirements of the ASME Section V. Acceptance standards are in accordance with the ASME Section VIII, Division 1, Appendix VI.

The vacuum box soap bubble test is performed on all accessible liner plate seam welds, except welds connecting thickened reinforcing liner plate to penetration nozzles with nominal diameter of 6 inches or less. A 5 psi minimum pressure differential is maintained for a minimum of 20 seconds. The leak detecting solution is continuously observed for bubbles that indicate leaks. If a leak is detected, the defective weld is repaired, and reinspected by vacuum box testing.

Welds that are inaccessible for vacuum box testing are 100% liquid penetrant tested. Liquid penetrant examinations conform to the ASME Section V. Personnel performing liquid penetrant examinations are qualified in accordance with SNT-TC-1A, plus any additional requirements of the ASME Section V. Acceptance standards conform to the ASME Section VIII, Division 1, Appendix VIII.

A leak chase channel system is provided only on liner plate seam welds which are inaccessible after the completion of construction, and those under water in the suppression chamber. Following installation, the leak chase system is pressurized with air to 72 psig. The pressure is monitored by valving off the air supply, and measuring any pressure decay with a pressure gauge. Any pressure decay in excess of the pressure gauge rated accuracy, observed within 15 minutes, is cause to reject that portion of the liner plate seam welds and the leak chase system. All leaks are repaired, and following repair, the affected portion of the leak chase system is retested.

e. Quality Control

Quality control requirements during construction are discussed in the document "Limerick Generating Station Units 1 and 2; Summary Description of the Quality Assurance Program for Design and Construction," referenced in FSAR Section 17.1.

f. Erection Tolerances

The erection tolerances for the liner plate are summarized as follows:

1. The slope of any 10 foot section of cylindrical liner plate, referred to as true vertical, does not exceed 1:180. The deviation from the theoretical slope of any 10 foot section of conical liner plate, measured within a vertical plane, does not exceed 1:120.

2. The cylindrical shell is plumb within 1/400 of the height, plus a 2 inch allowance for local "out-of- roundness." The vertical axis of the conical shell, as established at the top and bottom of the conical section, is plumb within 1/200 of the height.

3. The radial dimension to any point on the liner plate does not vary from the design radius by more than ±1 inch in the suppression chamber, or ±1½ inches in the drywell, except that the radial tolerance is ±2 inches for local "out-of-roundness." Local "out-of-roundness" tolerance is used where the maximum diameter minus the minimum diameter at the elevation does not exceed 4 inches. Radial measurements are taken at 24 locations, spaced equally around the containment at any elevation.

4. Plates joined by butt-welding are matched accurately, and retained in position during the welding operation. Misalignment in completed joints does not exceed the limitations of Paragraph UW-33 of ASME Section VIII, Division 1.

3.8.1.7 Testing and Inservice Surveillance Requirements

3.8.1.7.1 Preoperational Testing

3.8.1.7.1.1 Structural Acceptance Test

Structural and Pressure Integrity Tests were performed according to Article CC-6000 of the ASME Section III, Division 2, as applicable, after complete installation of all penetrations in the drywell and suppression chamber, and prior to initial fuel loading. The Structural and Pressure Integrity Tests complies with Regulatory Guide 1.18, with the following alternate approaches:

Paragraph C.1

A continuous increase in containment pressure, rather than incremental pressure increases, was used. This was considered justifiable because data observations at each pressure level were made rapidly by the computerized data acquisition system. "Rapidly" is defined as requiring a time interval for the data point sample sufficiently short so that the change in pressure during the observation would cause a change in structural response of less than 5% of the total anticipated change. Also, the rate of pressurization was limited to 3 psig/hr average to ensure that the structure responds to the pressure loading without any time lag. However, retesting for Unit 2 is performed at a rate of pressurization limited to 8 psig/hr average with adequate hold time at peak pressure to assure there is no time lag for the structural response. For a description of the structural integrity test for each unit, see the alternate approach to Paragraph C.12 in this section (3.8.1.7.1.1).

Measurements were recorded at atmospheric pressure, and at 5 psi increments of the pressurization and depressurization cycles. The data acquisition system allowed the measurements at all locations to be made and recorded simultaneously.

The pressure was held constant for at least 1 hour at the maximum test pressure, or for such time as was necessary for recording crack patterns.

Paragraph C.2

The number and distribution of measuring points for monitoring radial deflections were selected so that the as-built condition could be considered in the assessment of general shell response. In general, the locations of the measuring points for radial deflections were in agreement with figure B of the Regulatory Guide, with the exception of Point 1. Point 1 was provided at a distance of two times the wall thickness (12 feet) from the basemat. This variation was made to properly predict the containment behavior near the basemat to wall connection. If Point 1 was located at a height of three times the wall thickness (18 feet), it would be very close to Point 2 (suppression chamber wall midheight is 26 feet) and would not yield any additional behavior pattern of the containment.

Paragraph C.3

Radial deflections, but not tangential deflections, were recorded. The magnitude of the expected local tangential deformation under the test pressure conditions is negligibly small. The diametrical displacement of the hatch parallel to the tangential direction was measured and compared to the predicted displacement. This was in the location of largest predicted displacements for the hatch discontinuity and provided the most comprehensive check on structural integrity. The measurement of absolute tangential deflections at locations away from the immediate edge of the discontinuity was difficult because fixed reference points are difficult to define, making it impractical to attempt measurement of these small local deflections.

Paragraph C.9

The LGS containment is located inside and isolated from the reactor enclosure. The environmental conditions under which the test was conducted were controlled by the reactor enclosure internal environment. Therefore, limitations on testing during periods of extreme weather conditions, such as snow, heavy rain, and strong wind, had negligible effect on structural response and were not applicable.

Paragraph C.10

Rather than as suggested in the guide, if the test pressure dropped to, or below, the next lower pressure level due to an unexpected condition, the test would have continued without a restart at atmospheric pressure, unless the structural response deviated significantly from that expected. The LGS containment pressurization was not conducted using pressure increments. Therefore, the provisions of ASME Section III, Division 2, subsection CC-6252(b) were met, using a 3 psi pressure drop as a criterion for investigating deviation in structural response.

Paragraph C.12

LGS has provided a detailed description of the structural integrity test in the report prepared after the test.

The Structural and Pressure Integrity Test was conducted at 115% of the following design conditions:

a. A design pressure condition of 55 psig in both the drywell and suppression chamber

b. A design pressure condition of 55 psig in the drywell, and 25 psig in the suppression chamber

Additional pressure integrity tests may be made subsequently, during periods of plant shutdown.

The differential pressure test of the diaphragm slab described in item (b) above was accomplished by capping the downcomers above the diaphragm slab's upper surface.

The LGS Unit 1 test was performed in one test sequence which demonstrated the structural adequacy of the containment structure for both of the design conditions described above. However, for LGS Unit 2, the structural integrity test was conducted in two stages because the maximum differential pressure on the diaphragm slab could not be maintained during the initial

pressurization of the containment structure. During the initial test, the structural adequacy of the containment structure for the design condition of 55 psig in both the drywell and the suppression chamber was satisfactorily demonstrated. Subsequent to the re-isolation of the drywell and the suppression chamber, the containment structure was retested at a rate of pressurization limited to 8 psig/hr average to 115% of the design condition "b" described above (drywell pressure equal to 63.25 psig and suppression chamber pressure equal to 28.75 psig).

Provisions are made to test the integrity of the primary containment system during the life of the plant.

The seals on the personnel airlock doors, hatches, and drywell head are capable of being tested for leakage at design pressure without pressurizing the drywell. In addition, provisions are made so that the space between the airlock doors can be pressurized to full drywell design pressure.

Electrical penetrations are testable at 115% of design pressure. Locations of test taps and seals allow electrical penetrations to be tested without entering or pressurizing the drywell or suppression chamber.

A more detailed description of the structural integrity test was provided in the report prepared after the initial test.

3.8.1.7.1.2 Leak Rate Testing

Preoperational leak rate testing is discussed in Section 6.2.6.

3.8.1.7.2 Inservice Leak Rate Testing

Inservice leak rate testing is discussed in Section 6.2.6.

3.8.2 ASME CLASS MC STEEL COMPONENTS OF THE CONTAINMENT

This section pertains to the ASME Class MC steel components of the concrete containment that form a portion of the containment pressure boundary, and are not backed by structural concrete. These components include the drywell head assembly, the equipment hatches, the personnel lock, the suppression chamber access hatches, the CRD removal hatch, and piping and electrical penetrations.

3.8.2.1 Description of the ASME Class MC Components

3.8.2.1.1 Drywell Head Assembly

The drywell head provides a removable closure at the top of the containment for reactor access during refueling operations. The drywell head assembly consists of a 2:1 hemi-ellipsoidal head and a cylindrical lower flange. The lower flange is supported on the top of the drywell wall as shown on Figure 3.8-9. The head is made of 1½ inch thick plate and is secured with eighty 2¾ inch diameter bolts at the 4 inch thick mating flange. The head-to-lower flange connection is made leak-tight by two replaceable gaskets. The space between the gaskets is provided with test connections to allow pneumatic testing from a remote location, outside the primary containment. The inside diameter of the drywell head at the mating flange is 37 feet 7½ inches. A double-gasketed manhole is provided in the drywell head. Figure 3.8-31 shows details of the drywell head assembly.

3.8.2.1.2 Equipment Hatches and Personnel Lock

Two 12 foot diameter equipment hatches are furnished in the drywell wall to permit the transfer of equipment and components into and out of the drywell. One hatch consists of a double-gasketed flange and a bolted dished door. The other hatch is furnished with a personnel lock welded to the removable door. The personnel lock is an 8'-7" diameter cylindrical pressure vessel, with inner and outer flat bulkheads. Interlocked doors, 2'-6" wide by 6' high, with double tongue-and-groove single element compression seals, are furnished in each bulkhead. A quick-acting, equalizing valve vents the personnel lock to the drywell to equalize the pressure in the two systems when the doors are opened and then closed. The two doors in the personnel lock are mechanically interlocked to prevent them from being opened simultaneously, and to ensure that one door is closed before the opposite door can be opened. The personnel lock has an ASME Code N-stamp. Figures 3.8-32 and 3.8-33 show details of the equipment hatch, and the equipment hatch with personnel lock, respectively.

3.8.2.1.3 Suppression Chamber Access Hatches

Two 4'-4" diameter access hatches are furnished in the suppression chamber wall to permit personnel access, and the transfer of equipment and components into and out of the suppression chamber. Each hatch consists of a double-gasketed flange and a bolted flat cover. Details of a suppression chamber access hatch are shown in Figure 3.8-21.

3.8.2.1.4 Control Rod Drive Removal Hatch

One 3 foot diameter CRD removal hatch is furnished in the drywell wall to permit transfer of the CRD assemblies into and out of the drywell. The hatch is furnished with a double-gasketed flange and a bolted flat cover. Figure 3.8-34 shows details of the CRD removal hatch.

3.8.2.1.5 Piping and Electrical Penetrations

A portion of each of the penetration sleeves extends beyond the containment wall, and is not backed by concrete. The entire length of any penetration sleeve, therefore, is considered an MC component, and, as such, is designed in accordance with ASME Section III, subsection B. Figures 3.8-21 and 3.8-22 show details of typical pipe and electrical penetrations, respectively.

3.8.2.2 Applicable Codes, Standards, and Specifications

The codes, standards, and specifications used in the design and construction of the containment are listed in Table 3.8-1.

Specifications are prepared to cover the areas related to the design and construction of the containment. These specifications are prepared by Bechtel specifically for this containment. These specifications emphasize important points of the industry standards for this containment, and reduce options that would otherwise be permitted by the industry standards. Unless specifically noted otherwise, these specifications do not deviate from the applicable industry standards, and as such are not included in the UFSAR. These specifications cover the following areas:

a. Furnishing and delivering concrete

b. Forming, placing, finishing, and curing concrete

c. Furnishing, detailing, fabricating, delivering, and placing reinforcing steel

d. Splicing reinforcing bars

e. Furnishing, delivering, and erecting liner plate

Section 1.8 provides references to regulatory guides discussed in the UFSAR. Regulatory guides specific to this section are discussed in this section.

3.8.2.3 Loads and Loading Combinations

Table 3.8-4 lists the loading combinations used for the design and analysis of the ASME Class MC components.

The ASME Class MC components are also assessed for Mark II hydrodynamic loads resulting from MSRV discharge and LOCA phenomena. For a definition of loads and loading combinations including hydrodynamic loads, refer to Reference 3.8-1 and Appendix 3A.

3.8.2.3.1 Dead and Live Load

For descriptions of dead and live load, see Sections 3.8.1.3.1 and 3.8.1.3.2, respectively.

3.8.2.3.2 Design Basis Accident Pressure Load

The drywell head is designed for a DBA internal pressure of 56 psi. The other MC components are designed for a DBA internal pressure of 62 psi.

3.8.2.3.3 External Pressure Load

The MC components are designed to withstand an external pressure of 5 psi above the containment internal pressure.

3.8.2.3.4 Thermal Loads

The operating and postulated design accident temperatures for the MC components are as follows:

	Temperature (°F)	
Condition	Drywell	Suppression Chamber
Operating	135 ①	95 (maximum)
Design Accident	340	220

Thermal cycles used in design are as follows:

a. Startup and shutdown - 500 cycles, 105°F range

b. Design Basis Accident - 1 cycle, 220°F range

3.8.2.3.5 Seismic Loads

The MC components are designed for acceleration values which were calculated using the methods described in Section 3.7.

The following seismic acceleration values are used for the design of the drywell head assembly:

a. OBE - 0.60 g horizontal, ±0.30 g vertical

b. SSE - 0.80 g horizontal, ±0.40 g vertical

The following seismic acceleration values are used for the design of the equipment hatch, personnel lock, and CRD hatch:

a. OBE - 0.40 g horizontal, ±0.20 g vertical

b. SSE - 0.45 g horizontal, ±0.25 g vertical

The following seismic acceleration values are used in the design of the suppression chamber hatches:

a. OBE - 0.20 g horizontal, ±0.15 g vertical

b. SSE - 0.30 g horizontal, ±0.20 g vertical

① This information is based on original design basis conditions. Further evaluation has validated the MC components for a drywell operating temperature of 150°F. The Stresses indicated in UFSAR Figures 3A-362 to 3A-380, Design Assessment Report for Containment Structures reflect current plant conditions.

3.8.2.3.6 Pipe Rupture Loads

The drywell head assembly is designed for a local pipe rupture load of 48,000 pounds, uniformly distributed over a circular area of 0.56 square foot, at any location on the drywell head. This load is due to the postulated rupture of the 6 inch diameter reactor head spray pipe, which produces the largest load on the drywell head. The head spray line does not exist for Unit 2 and has been removed from Unit 1. However, the analysis is still applicable because it envelopes loads from rupture of any other pipe in this region.

The equipment hatches are designed for a postulated pipe rupture load of 130,000 pounds, uniformly distributed over a circular area 12 feet in diameter.

The CRD removal hatch is designed for a postulated pipe rupture load of 160,000 pounds, uniformly distributed over a circular area 3 feet in diameter.

The loads on the equipment hatches and the CRD removal hatch are based on the rupture of a 28 inch diameter recirculation loop outlet pipe, which produces the largest load on the components.

The above values of static load include an appropriate dynamic load factor to account for the dynamic nature of the load. Section 3.6 contains a detailed discussion of postulated pipe ruptures and their effects, including pipe whip, jet impingement, environmental effects, flooding, and water spray.

3.8.2.3.7 Missile Impact Loads

As discussed in Section 3.5.1 and summarized in Table 3.5-7, missile impact is not considered credible for safety-related components inside the containment or the reactor enclosure.

3.8.2.4 Design and Analysis Procedures

This section describes the procedures used for the design and analysis of ASME Class MC steel components.

ASME Class MC components are also assessed for Mark II hydrodynamic loads resulting from MSRV discharge and LOCA phenomena. Assessment procedures that consider the effect of hydrodynamic loads are described in Appendix 3A.

3.8.2.4.1 Drywell Head Assembly

The analysis of the drywell head assembly uses the thin-shell computer program E0781, described in Section 3.8.7.7. This program calculates the stresses and displacements in thin-walled, elastic shells of revolution, when subjected to static edge, surface, and/or temperature loads with an arbitrary distribution over the surface of the shell.

The drywell head assembly is divided into two analytical models. Figure 3.8-35 shows the drywell head model and the lower flange model. Displacement compatibility of the two models at the mating flange surface is maintained in the analysis. Boundary conditions are imposed on the analytical models by specifying boundary forces or displacements. With reference to Figure 3.8-35, the translation and rotation of the top of the drywell wall are imposed as boundary conditions to boundary A. Boundary forces applied to boundary B are calculated in accordance with thin-shell theory.

See Section 3A.7.2.1.9.1 for discussion of analysis to reduce the drywell head bolt preload.

3.8.2.4.2 Access Hatches

Access hatches, including the equipment hatches, personnel lock, suppression chamber access hatches, and the CRD removal hatch, are designed as pressure-retaining components. The portions of the sleeves not backed by concrete are designed and analyzed according to the provisions of ASME Section III, Subsection B.

At the junction of the hatch cover to the flange on the sleeve, where local bending and secondary stresses occur, the computer program E0119, described in Section 3.8.7.7, is used for analysis. This program is also used for the analysis of the flat head covers.

3.8.2.4.3 Piping and Electrical Penetrations

For nuclear Class I flued head penetrations, the procedures used in design and analysis comply with ASME Section III, Subsection B.

For Class 1E electrical cable penetrations, the procedures used in design and analysis comply with ASME Section III, Subsection B.

3.8.2.5 Structural Acceptance Criteria

The structural acceptance criteria comply with Regulatory Guide 1.57, with the clarification that the Code Addenda in effect at the time of design rather than that cited in the guide were used. Table 3.8-4 lists the allowable stress criteria for the design and analysis of the ASME Class MC components.

3.8.2.6 Materials, Quality Control, and Special Construction Techniques

3.8.2.6.1 Materials

All carbon steel materials and stainless steel materials for the CRD hydraulic line penetrations conform to the requirements of ASME Section III, Subsection B. The drywell head assembly and other steel components are painted to protect against corrosion.

3.8.2.6.1.1 Drywell Head Assembly

Materials used in construction of the drywell head assembly conform to the following ASME specifications:

Item	Specification
Drywell head and lower flange	SA516, Grade 70, normalized
Bolts	SA320, Grade L43
Nuts	SA194, Grade 7

3.8.2.6.1.2 Access Hatches

Materials used in construction of the access hatches conform to the following ASME specifications:

Item	Specification
Sleeve and cover	SA516, Grade 60 or 70, normalized
Bolts	SA193, Grade B7
Nuts	SA194, Grade 7

3.8.2.6.1.3 Penetrations

Materials used in construction of piping and electrical penetrations conform to the following ASME specifications:

Item	Specification
Carbon steel sleeves	SA333, Grade 1 or SA516, Grade 60 or 70, normalized
Carbon steel caps for spare penetrations	SA234, Grade WPB
Stainless steel sleeves for CRD hydraulic line penetrations	SA312, Type 304L

Stainless steel fittings for CRD hydraulic line penetrations	SA182, Type 304

3.8.2.6.2 Welding

Welding conforms to the requirements of ASME Section III, Subsection NE-4000 except that all welding of the CRD hydraulic line penetrations conforms to the requirements of ASME Section III, Subsection NC. All pressure boundary welds are full penetration welds of double-welded, bevel-type. Welders and weld procedures are qualified in accordance with ASME Section IX.

Penetrations, access hatches, and the drywell head flange are postweld heat treated in accordance with ASME Section III, Article NE-4000. Penetrations are preassembled into the liner plate sections, and postweld heat treated as complete subassemblies.

3.8.2.6.3 Nondestructive Examination of Welds

All welds between penetrations and liner plate, access hatches and liner plate, and pressure-retaining welds not backed by concrete are examined in accordance with ASME Section III, Article NE-5000. Nondestructive examination of welds complies with Regulatory Guide 1.19, with the following alternate approaches:

Paragraph C.1.a

LGS uses an alternate approach with respect to radiographic examination of the first 10 feet of weld. For each welder and welding position, only 12 inches of the first 10 feet of weld is examined radiographically, instead of the entire 10 foot length. LGS conforms with all other guidelines for nondestructive examination of liner seam welds.

Paragraph C.4

LGS conforms with the intent, subject to the following interpretation: Nondestructive examinations are performed by employees of the liner plate Subcontractor. Bechtel, as licensee's agent, verifies that all personnel performing nondestructive testing are qualified in accordance with ASME Section V.

Paragraph C.7.a

LGS radiography acceptance standards are in accordance with UW-51 of the ASME Section VIII, Division I.

Paragraph C.7.b

Magnetic particle acceptance standards are in accordance with the ASME Section VIII, Division I, Appendix VI.

3.8.2.6.4 Quality Control

Quality control requirements during construction are discussed in the document "Limerick Generating Station Units 1 and 2; Summary Description of the Quality Assurance Program for Design and Construction," referenced in FSAR Section 17.1.

3.8.2.6.5 Erection Tolerances

The specified erection tolerances for ASME Class MC steel components of the containment are summarized as follows:

a. Suppression chamber penetrations are within 1 inch of their design elevations and circumferential locations.

b. Drywell penetrations are within 1 inch of their design circumferential locations. Critical penetrations, such as main steam, feedwater, core spray, etc, are within 1 inch of their design elevations. All other drywell penetrations vary from within 1 inch of design elevations for penetrations near the base of the drywell wall, to within 2 inches of design elevations for penetrations near the top of the drywell wall.

c. Alignments of penetrations are within 1° of the design alignments.

d. The average elevation of the drywell head lower flange is within 3 inches of the design elevation. The lower flange is within ½ inch of level.

3.8.2.7 Testing and Inservice Inspection Requirements

3.8.2.7.1 Preoperational Testing

3.8.2.7.1.1 Structural Acceptance Test

The drywell head assembly, equipment hatches, suppression chamber access hatches, CRD removal hatch, and piping and electrical penetrations are pneumatically tested to 1.15 times the design accident pressure during the containment structural acceptance test.

The personnel lock is pneumatically tested to 1.25 times the design pressure of 62 psig, following shop fabrication, or following field erection if final assembly of lock is performed in the field, to verify its structural integrity.

The CRD hydraulic line penetrations are hydrotested to 1.5 times the design pressure of 1250 psig following shop fabrication, in accordance with the ASME Section III, Subsection NC.

3.8.2.7.1.2 Leak Rate Testing

Leak-tightness of the containment pressure-retaining Class MC components is verified during the integrated leak rate test. Section 6.2.6 contains a description of the containment integrated leak rate test.

The personnel air lock is leak rate tested to 100% of the design accident pressure following shop fabrication, and following field erection. The maximum allowable leak rate for the personnel air lock shall be 5% of the allowable leak rate for the containment, L_a. L_a is 0.5% by weight of the air in the containment per 24 hours at test pressure, P_a (44.0 psig).

3.8.2.7.2 Inservice Leak Rate Testing

Inservice leak rate testing is discussed in Section 6.2.6.

3.8.3 CONTAINMENT INTERNAL STRUCTURES

3.8.3.1 Description of the Internal Structures

The functions of the containment internal structures include: support and shielding of the reactor vessel, support of piping and equipment, and formation of the pressure-suppression boundary. The containment internal structures are constructed of reinforced concrete and structural steel. The containment internal structures include the following:

a. Diaphragm slab

b. Reactor pedestal

c. Reactor shield wall

d. Suppression chamber columns

e. Drywell platforms

f. Seismic truss

Figures 3.8-1 through 3.8-8 show an overview of the containment including the internal structures.

3.8.3.1.1 Diaphragm Slab

The diaphragm slab serves as a barrier between the drywell and the suppression chamber. It is a reinforced concrete circular slab, with an outside diameter of 88 feet, and a thickness of 3'-6". Figure 3.8-36 shows details of the diaphragm slab reinforcement.

The diaphragm slab is supported by the reactor pedestal, the containment wall, and 12 steel columns. The connection of the diaphragm slab to the containment wall is shown on Figure 3.8-10. The diaphragm slab is penetrated by 87, 24 inch diameter downcomers. Additional reinforcement is furnished at downcomer penetrations. Section 6.2.1 contains a description of the downcomers.

A ¼ inch thick, carbon steel liner plate is provided on top of the diaphragm slab, and is anchored to it. The liner plate prevents bypass flow around the downcomers during a LOCA. Refer to Section 6.2.1, for a description of the bypass leakage requirements. Figure 3.8-37 shows the diaphragm slab liner plate and anchorage system.

3.8.3.1.2 Reactor Pedestal

The reactor pedestal is an 82 foot high, upright cylindrical reinforced concrete shell that rests on the containment base foundation slab, and supports the diaphragm slab, reactor vessel, and reactor shield wall, as well as drywell platforms, pipe restraints, and recirculation pumps. The connection of the reactor pedestal to the base foundation slab is shown on Figure 3.8-13. The reactor pedestal below the diaphragm slab has an inside diameter of 20'-1", and a wall thickness of 4'-9". The reactor pedestal above the diaphragm slab has an inside diameter of 20'-3", and a wall thickness of 4'-5". The thickness at the top of the pedestal increases to 5'-4" where it supports the reactor vessel and the reactor shield wall. Attachment of the reactor shield wall to the pedestal is described in Section 3.8.3.1.3. Attachment of the reactor vessel to the pedestal is accomplished

through a ring girder, as described in Section 5.3.3.1.4.1. The ring girder is attached to the pedestal by 120, 3¼ inch diameter high strength anchor bolts, as shown on Figure 3.8-38.

Figures 3.8-39 and 3.8-40 show reinforcement details. Openings are provided in the reactor pedestal, to permit the flow of air and suppression pool water into and out of the pedestal cavity. Additional reinforcement is furnished at the openings. A ¼ inch thick carbon steel form plate is provided on the inside and outside surfaces of the reactor pedestal below the diaphragm slab. This plate acts as a concrete form during construction, and preserves the water quality of the suppression pool by preventing the leaching of chemicals from the reactor pedestal concrete into the suppression pool.

3.8.3.1.3 Reactor Shield Wall

The reactor shield wall is a 49 foot high upright cylindrical shell which rests on the top of the reactor pedestal, and provides primary radiation shielding, as well as support for pipe restraints and drywell platforms. The reactor shield wall is constructed of inner and outer carbon steel plates, with unreinforced concrete between the two plates. Figure 3.8-41 shows details of the reactor shield wall. The reactor shield wall has an inside diameter of 25'-7", and a wall thickness of 1'-9". The outer steel plate is 1½ inches thick, and is designed to withstand local loads transferred through pipe restraints and drywell platform attachments. The inner steel plate is ½ inch thick, and is designed to act with the outer plate to withstand local and nonlocal loads. The inner and outer plates are connected with shear ties spaced on approximately 5° centers in the hoop direction. The annular space between the inner and outer plates is filled with unreinforced high density concrete for radiation shielding. The reactor shield wall is connected to the top of the reactor pedestal by 48, 2 inch diameter high strength anchor bolts, as shown on Figure 3.8-38.

The seismic truss and reactor vessel stabilizer, which provide lateral support to the reactor vessel and reactor shield, are attached to the top of the reactor shield wall. Penetrations with hinged doors or removable plugs are provided in the reactor shield wall to accommodate piping connections to the reactor vessel, and to provide access for inservice inspection. The wall thicknesses of penetration sleeves are large enough to prevent local stress concentrations in the inner and outer plates.

3.8.3.1.4 Suppression Chamber Columns

Twelve hollow steel pipe columns are furnished to support the diaphragm slab. Each column is 52'-3" long, with an outside diameter of 42 inches, and a wall thickness of 1¼ inches. The columns are connected to the base foundation slab at the bottom, and to the diaphragm slab at the top with embedded anchor bolts. Figure 3.8-14 shows the connection to the base foundation slab; and Figure 3.8-42 shows the connection to the diaphragm slab.

3.8.3.1.5 Drywell Platforms

Platforms are furnished at six elevations in the drywell to provide access and support to electrical and mechanical components. The platforms consist of structural steel framing, with steel grating. Built-up box shapes are used for beams that must resist biaxial bending. Beams that span between the pedestal or reactor shield wall, and the containment wall are provided with sliding connections at one end. Figures 3.8-3 through 3.8-8 show details of the drywell platforms.

3.8.3.1.6 Seismic Truss and Reactor Vessel Stabilizer

The seismic truss and the reactor vessel stabilizer provide lateral support for the reactor vessel during earthquake and pipe rupture loading. The seismic truss horizontally spans the gap between the containment wall and the reactor shield wall; the reactor vessel stabilizer spans the gap between the reactor shield wall and the reactor vessel. The seismic truss is shaped like an eight-pointed star, and is fabricated of steel plates. Figure 3.8-43 shows details of the seismic truss. Figure 3.8-26 shows the connection of the seismic truss to the containment wall. This connection is designed to allow vertical and radial movement of the seismic truss relative to the containment wall, but to prevent tangential movement.

3.8.3.2 Applicable Codes, Standards, and Specifications

The codes, standards, and specifications used in the design and construction of the containment internal structures are listed in Table 3.8-1.

Specifications were prepared to cover the areas related to design and construction of the containment. These specifications were prepared by Bechtel specifically for this containment. These specifications emphasize important points of the industry standards for this containment, and reduce options that would otherwise be permitted by the industry standards. Unless specifically noted otherwise, these specifications do not deviate from the applicable industry standards, and as such are not included in the UFSAR. These specifications cover the following areas:

a. Furnishing and delivering concrete

b. Forming, placing, finishing, and curing concrete

c. Furnishing, detailing, fabricating, delivering, and placing reinforcing steel

d. Splicing reinforcing bars

e. Furnishing, detailing, fabrication, and delivering the suppression chamber columns, pedestal liner, structural steel for the diaphragm slab, and miscellaneous structural steel

f. Furnishing, delivering, and erecting liner plate

Section 1.8 provides references to regulatory guides discussed in the UFSAR. Regulatory guides specific to this section are discussed in this section.

3.8.3.3 Loads and Loading Combinations

Tables 3.8-2 and 3.8-5 through 3.8-8 lists the loading combinations used for the design and analysis of the containment internal structures. Tables 3.8-5 through 3.8-8 list only the most severe factored loading combinations used for miscellaneous internal steel components of the containment. These structures have been designed according to the working stress methods, except for the pipe restraints supported on the drywell platforms. Design of the pipe restraints and their box beam supports allows inelastic deformations due to postulated pipe rupture loads. However, there is no loss of restraint function due to pipe break load.

Apparent differences between the loads listed in Tables 3.8-5 through 3.8-8 and SRP 3.8.3, for the governing loading conditions, are identified and explained in Table 3.8-20.

The internal structures are also analyzed for hydrodynamic loads resulting from MSRV discharge and LOCA phenomena. For a definition of loads and loading combinations (including hydrodynamic loads), see Reference 3.8-1 and Appendix 3A.

3.8.3.3.1 Diaphragm Slab and Reactor Pedestal

Table 3.8-2 lists the loading combinations used for the design of the diaphragm slab and reactor pedestal. Descriptions of the loads are as follows:

a. Dead Load, Live Load, and Seismic Loads

For a description of dead load, live load, and seismic loads, see Section 3.8.1.3.

b. DBA Pressure Load

The diaphragm slab and the reactor pedestal are designed for the following pressures:

1. Maximum pressure: 55 psig in the drywell and the suppression chamber

2. Maximum differential pressure: 30 psig downward (55 psig in the drywell and 25 psig in the suppression chamber); 20 psig upward (55 psig in the suppression chamber and 35 psig in the drywell).

c. Thermal Loads

The temperatures above and below the diaphragm slab for the operating and the postulated design accident conditions are shown in Table 3.8-3. The portions of the reactor pedestal above and below the diaphragm slab are designed for the drywell and suppression chamber maximum temperatures listed in Table 3.8-3.

Thermal effects anticipated at the time of the structural acceptance test are insignificant, since the difference in temperatures inside and outside the containment during the test is small.

d. Pipe Rupture Loads

The diaphragm slab and the reactor pedestal are designed to withstand the pipe rupture loads due to a postulated rupture of a 28 inch diameter recirculation loop pipe, which produces the largest loads on the structures. These loads include the effects of jet impingement, pipe whip, and pipe reaction. An equivalent static load of 1000 kips is considered. This load includes an appropriate dynamic load factor to account for the dynamic nature of the load. Section 3.6 contains a detailed discussion of postulated pipe ruptures and their effects.

3.8.3.3.2 Reactor Shield Wall

The reactor shield wall was designed as a steel member using AISC working stress methods. This wall is filled with a high density grout that has a main function of shielding. No composite action is

assumed between the steel and the concrete. Table 3.8-5 lists the load combination used for the design of the reactor shield wall. The governing loading combination is the abnormal/extreme loading condition that combines the design basis accident loads with the maximum seismic loads. Descriptions of the loads are as follows:

a. Dead Load, Live Load, and Seismic Loads

For a description of dead load, live load, and seismic loads, see Section 3.8.1.3.

b. DBA Pressure Load

The reactor shield wall is designed for internal pressurization due to a postulated pipe rupture at the connection of the pipe to the reactor vessel nozzle safe end. The two following pressure conditions are considered:

1. Maximum unbalanced pressure: a pressure condition shortly after pipe break, which produces the largest lateral load on the reactor shield wall, resulting in a jet force of 1330 kips.

2. Maximum uniform pressure: a 94 psig internal pressure

c. Thermal Loads

The reactor shield wall is designed for the maximum drywell temperature listed in Table 3.8-3.

d. Pipe Rupture Loads

The reactor shield wall is designed to withstand the pipe rupture loads due to a postulated rupture of any high energy pipe penetrating the reactor shield wall, and connecting to the reactor vessel, such as the recirculation and feedwater pipes. These loads include the effects of jet impingement, pipe whip, and pipe reaction. Equivalent static loads are considered, which include an appropriate dynamic load factor to account for the dynamic nature of the load. Section 3.6 contains a detailed discussion of postulated pipe ruptures and their effects.

3.8.3.3.3 Suppression Chamber Columns

Table 3.8-6 lists the load combinations used for the design of the suppression chamber columns. The columns are designed to resist the reaction loads from the diaphragm slab, for the LOCA conditions. Section 3.8.3.3.1 includes a description of the diaphragm slab loads. Normal loading conditions are not listed because the abnormal loading conditions govern the design. Allowable stresses for the suppression chamber columns are in accordance with AISC (1970), 7th edition, for steel.

3.8.3.3.4 Pipe Whip Restraints/Drywell Platforms

The drywell platforms are designed using the AISC working stress design methods, except for the pipe whip restraints supported on the platforms. Design of the pipe whip restraints and their support structure allows inelastic deformations due to postulated pipe rupture loads. When considering elastic behavior, the design of pipe whip restraints is based on AISC working stress method with allowables up to 0.9 times the yield strength. For elasto-plastic behavior, the design is

in accordance with the procedure outlined in Reference 3.8-6. However, there is no loss of restraint function due to pipe break loads. All safety-related items which the inelastic deformations may affect are evaluated to verify that no required safety function would be compromised.

Table 3.8-7 lists the load combinations used to design the pipe whip restraints and the drywell platforms. Design accident pressure loads are small in comparison with pipe restraint and jet force loads and therefore do not affect the designs of the drywell platforms. The thermal load has been included in the loading combination as given in Table 3.8-7. Seismic loads due to the dead weight of the platform members are insignificant when compared with pipe rupture loads and are ignored. The uniform design live load for the grating and framing beams is 200 lb/ft^2. The live load for the framing beams also includes the gravity load, thermal reaction load, and seismic SSE reaction load of all piping and equipment supported on the beams. This design procedure is also applicable to pipe whip restraints and their support structures outside of the containment structure.

3.8.3.3.5 Seismic Truss

The seismic truss is designed using the AISC working stress design methods. It is designed primarily for lateral seismic loads. However, it is also designed for jet impingement loads due to the postulated rupture of a 26 inch diameter main steam pipe. Design accident pressure and design live loads are negligible in comparison with the main steam pipe jet forces and therefore do not affect the design of the seismic truss. The expansion of structural members under thermal loadings is permitted. Therefore, thermal loads are negligible. Table 3.8-8 lists the governing load combination used to design the seismic truss.

3.8.3.4 Design and Analysis Procedures

This section describes the procedures used for design and analysis of the containment internal structures. All computer programs referenced are described in Section 3.8.7.

For a description of the design and analysis procedures that consider the effects of hydrodynamic loads resulting from MSRV discharge and LOCA phenomena, refer to Reference 3.8-1 and Appendix 3A.

3.8.3.4.1 Diaphragm Slab

The design and analysis procedures used for the diaphragm slab are similar to those used for the containment wall. Computer programs used in the analysis include 3D/SAP, CECAP, ME620, and seismic programs. See Section 3.8.1.4 for a detailed description of the analysis procedures.

Figure 3.8-44 shows the 3D/SAP finite-element model used to analyze the diaphragm slab for all loads, other than the seismic loads. A 15° wedge of the diaphragm slab is modeled using solid finite-elements having isotropic, linear-elastic material properties. The model includes the diaphragm slab, suppression chamber wall, reactor pedestal below the diaphragm slab, and a suppression chamber column. One vertical boundary plane goes through a suppression chamber column, and the other is halfway between two columns. Boundary conditions are imposed on the analytical model by specifying nodal point forces, or displacements. With reference to Figure 3.8-44, the nodal points lying along boundary A are allowed to move within the X-Z plane, and those along boundary B within the X-Y plane. Points along boundary C are prevented from moving in the hoop direction. Points along boundary D are prevented from moving in the radial direction, to account for the restraining effect of the inner portion of the diaphragm slab. Nodal forces, moments,

and shears are applied to boundaries E and F, to account for reaction loads from the drywell wall and the reactor pedestal above the diaphragm slab, respectively.

Analytical techniques as described in Section 3.7 are used to analyze the diaphragm slab for seismic loads.

3.8.3.4.2 Diaphragm Slab Liner Plate and Anchorages

The design and analysis of the diaphragm slab liner plate and anchorages is in accordance with Reference 3.8-3.

3.8.3.4.3 Reactor Pedestal

The reactor pedestal is designed for axisymmetric loads using the FINEL computer program. Both concrete and reinforcing steel materials are included in the model. The operating and design accident temperature gradients are computed using the ME620 computer program. For transient loads such as design accident pressure and thermal loads, the most critical combination of these loads is considered. Figure 3.8-45 shows a vertical section through the FINEL model of the containment, used to analyze the reactor pedestal below the diaphragm slab. Points along boundary A are prevented from moving in the vertical direction, and points along boundary B are prevented from moving in the radial direction.

Figure 3.8-46 shows the FINEL model used to analyze the reactor pedestal above the diaphragm slab. The model includes the reactor pedestal above the diaphragm slab, and portions of the reactor vessel and the reactor shield wall. Local thermal effects at the top of the reactor pedestal due to heat input from the reactor vessel are determined by using the ME620 computer program. With reference to Figure 3.8-46, nodal points along boundary A are prevented from moving vertically and radially. Nodal forces, moments, and shears are applied to boundaries B and C to account for reaction loads from the reactor vessel and the reactor shield wall, respectively.

Nonaxisymmetric loads on the reactor pedestal include seismic loads, and reactor vessel and reactor shield reaction loads. Seismic forces, moments, and shears are calculated by the methods described in Section 3.7. Vertical forces, horizontal shears, and overturning moments at the base of the reactor shield wall are determined as described in Section 3.8.3.4.4. These loads are applied to the top of the reactor pedestal. Concrete and reinforcing steel stresses in the reactor pedestal due to the above loads are calculated using the design methods of ACI 307. ACI 307 includes equations for determining the neutral axis of reinforced concrete cylindrical shells subjected to axial force and overturning moment. The position of the neutral axis satisfies the equilibrium of internal stresses and external forces and moments.

Concrete and reinforcing steel stresses due to axisymmetric and nonaxisymmetric loads are combined to determine the total stress. Additional meridional, hoop, and shear reinforcement is provided at the top of the pedestal, as shown in Figure 3.8-38, to resist local loads on the pedestal from the reactor vessel and the reactor shield wall. Helical reinforcement is not needed in the reactor pedestal to resist seismically induced tangential shears. Meridional and hoop reinforcement is designed to carry the entire tangential shear by shear friction, using the design methods of ACI 318.

3.8.3.4.4 Reactor Shield Wall

The reactor shield wall is analyzed as an axisymmetric structure. The FINEL computer program is used for the axisymmetric loads, which include dead load and design accident thermal load. The temperature gradient across the thickness of the wall is determinedby using the ME620 computer program. For nonaxisymmetic loads, which include design accident pressure load, seismic load, and pipe rupture load, the ASHSD computer program is used. Figure 3.8-47 shows a vertical section through the model used for FINEL and ASHSD programs. Points along boundary A are prevented from moving vertically and radially. For nonaxisymmetric loads, boundary B, at the connection of the seismic truss to the containment wall, is prevented from moving radially. Total stresses in the reactor shield wall are determined by summing the axisymmetric and nonaxisymmetric stresses.

A second set of analyses of the reactor shield wall, as shown in Figure 3.8-48, was done by modeling a full 360° section of the wall, and by using the EASE finite-element computer program. This analysis ensures the integrity of the shield for loads equivalent to the DBA. The model includes one 64 inch diameter recirculation outlet penetration, and two adjacent 48 inch diameter recirculation inlet penetrations. Finer mesh sizes are used in the areas of the openings to obtain a good representation of the stress gradient. With reference to Figure 3.8-48, points along boundary A are prevented from moving vertically and radially. Boundary B is a free edge. No significant local stress concentrations are noted around the openings. The stiffening of the shell is provided by the thick walled penetration sleeves.

3.8.3.4.5 Suppression Chamber Columns

Axial force, shear, and moment in the columns due to axisymmetric loads, such as dead load, and design accident pressure and thermal loads, were determined using the FINEL computer program. Figure 3.8-45 shows the FINEL model of the containment used to analyze the suppression chamber columns. Boundary conditions are described in Section 3.8.3.4.3. Since the FINEL program can consider only axisymmetric structures, the 12 columns are modeled as an equivalent cylinder having the same axial stiffness as the total of the individual column stiffnesses. The axial force in the columns is calculated from the axial stress determined by the FINEL program. Shear and moment in the columns are calculated from relative displacements of the diaphragm slab and the base foundation slab determined by the FINEL program.

Axial force, shear, and moment in the columns due to seismic loads are determined using several methods. Axial force in the columns due to horizontal seismic load is determined using the ASHSD program. Figure 3.8-49 shows the model. Axisymmetric shell and solid finite-elements having isotropic, linear-elastic material properties are used. Nodal points lying along boundary A are prevented from moving vertically, and points along boundary B are prevented from moving radially. The load applied to the ASHSD model is the seismic horizontal shear and overturning moment for the containment calculated by the methods described in Section 3.7.

Shear and moment in the columns due to horizontal seismic load are determined using the analytical procedures described in Section 3.7. The lumped-mass model of the containment, including columns and downcomers, is shown in Figure 3.8-50.

Axial force in the columns due to vertical seismic load is determined by applying the vertical forces calculated from the containment seismic analysis, to the diaphragm slab at its connections to the containment wall and the reactor pedestal. The vertical force transmitted to the columns through the diaphragm slab is calculated considering the relative vertical stiffnesses of the containment wall, reactor pedestal, and columns.

The postulated rupture of a 28 inch diameter recirculation loop pipe produces a vertical jet impingement load on the top of the diaphragm slab, and, therefore, produces loads in the columns. Axial force, shear, and moment in the columns due to jet force are calculated by the CE 668 computer program. Figure 3.8-51 shows the 180° model of the diaphragm slab. A vertical jet force is applied along the axis of symmetry, and the reaction is calculated in the column adjacent to the applied load. Edges of the diaphragm slab along boundaries A and B are considered to have fixed supports.

The total axial force, shear, and moment in the columns for all load combinations are determined by summing the results of the separate analyses. Stability of the columns for the most critical load combinations is checked using the plastic design methods of Part 2 of the AISC "Specification for the Design, Fabrication, and Erection of Structural Steel for Buildings."

3.8.3.4.6 Drywell Platforms

The drywell platforms are designed using conventional elastic design methods, in accordance with the AISC Specification, Part 1.

3.8.3.4.7 Seismic Truss

Seismic forces in the seismic truss are calculated using the methods described in Section 3.7. Axial force, shear force, and moment in the seismic truss due to postulated pipe rupture loads are calculated using moment distribution. Figure 3.8-52 shows the rigid frame model including boundary conditions.

3.8.3.5 Structural Acceptance Criteria

3.8.3.5.1 Reinforced Concrete

The allowable stresses for the reinforced concrete portions of the containment internal structures are the same as the allowable stresses for the reinforced concrete portions of the containment, as discussed in Section 3.8.1.5.1. The calculated stresses are within the allowable limits.

3.8.3.5.2 Diaphragm Slab Liner Plate and Anchorages

The structural acceptance criteria for the diaphragm slab liner plate and anchorages are in accordance with Reference 3.8-3.

3.8.3.5.3 Structural Steel

Structural steel portions of the containment internal structures include the reactor shield wall, suppression chamber columns, drywell platforms, and seismic truss. For normal loading conditions, the allowable stresses are in accordance with the AISC Specification. For extreme environmental and abnormal loading conditions, the allowable stresses are as follows:

a. Bending - 0.90 F_y

b. Axial tension or compression - 0.85 F_y, except that where allowable stress is governed by requirements of stability (local or lateral buckling), allowable stress does not exceed 1.5 F_s

c. Shear - 0.50 F_y

where:

F_s = allowable stress according to the AISC Specification, Part 1

F_y = specified yield strength of structural steel

The calculated stresses in all the structural steel elements are within the above allowable limits.

3.8.3.6 Materials, Quality Control, and Special Construction Techniques

The criteria of ACI 349, "Proposed ACI Standard: Code Requirements for Nuclear Safety-Related Concrete Structures," applicable to this section of the UFSAR are not used by LGS. This section discusses the alternate criteria used.

3.8.3.6.1 Concrete Containment Internal Structures

The concrete and reinforcing steel materials for the containment internal structures are discussed in Section 3.8.6.

3.8.3.6.2 Diaphragm Slab Liner Plate, Anchorages, and Attachments

a. Materials

Liner plate materials conform to the requirements of the following standard specifications:

Item	Specification
Liner plate (¼ inch thick)	ASTM A285, Grade A, Firebox Quality
Liner plate (>¼ inch thick)	ASME SA516, Grade 60 conforming to the requirements of the ASME Section III, Article NE-2000
Anchorages and attachments	ASTM A36 or ASTM A441

b. Welding

Welding requirements for the diaphragm slab liner plate and anchorages are the same as the welding requirements for the containment liner plate and anchorages. See Section 3.8.1.6.2 for a description of the welding requirements.

c. Nondestructive Examination of Liner Plate Seam Welds

Spot radiographic examination is performed for all radiographable liner plate seam welds. All nonradiographable liner plate seam welds are 100% magnetic particle examined, and 100% vacuum box soap bubble tested. Welds that are inaccessible

for vacuum box testing are 100% liquid penetrant tested. Examination procedures, personnel qualification, and acceptance standards are as described in Section 3.8.1.6.2.

3.8.3.6.3 Reactor Shield Wall and Seismic Truss

a. Materials

Materials used in construction of the reactor shield wall and the seismic truss conform to the following standard specifications:

Item	Specification
Inner reactor shield plate, seismic truss, and pipe restraint	ASTM A36 or ASTM A516, Grade 70
Outer reactor shield plate	ASTM A516, Grade 70

b. Welding and Nondestructive Examination of Welds

All welding and welder qualification procedures are in accordance with the requirements of ASME Section IX.

c. Materials Testing

The 1½ inch thick outer plate of the reactor shield wall is vacuum-degassed in accordance with supplementary requirements S-1 of ASTM A20, and is ultrasonically tested in accordance with ASME Section III, Subsection NB-2532-1.

d. Erection Tolerances

1. Each of the two concentric cylinders of the reactor shield wall is plumb within 1:500 of the height, plus a 1 inch allowance for local "out-of-roundness."

2. The radial dimension to any point on the reactor shield plates does not vary by more than ±1 inch from the center line as established by the design.

3. The clear distance between the two steel plates does not vary more than ±½ inch from the theoretical distance at any point.

4. The penetration sleeve center line is within ±1 inch of the projected center line of the theoretical location of RPV nozzles.

5. The elevation of the top of the shield is within ±¼ inch of that shown on the design drawings.

6. Seismic truss members do not deviate from axial straightness by more than 1/1000 of axial length.

3.8.3.6.4 Suppression Chamber Columns

a. Materials

The column shafts, base plates, and top plates are fabricated of ASME SA516, Grade 70 material.

b. Welding

Weld procedures and qualifications conform to the provisions of ASME Section III, Subsection NE, Class MC. All welders are qualified in accordance with ASME Section IX.

c. Nondestructive Examination of Welds

Complete magnetic particle examinations are performed on the welds of the suppression chamber columns, and on the top plate welds (anchor bolts to top plate and column to top plate) in accordance with the requirements of the ASME Section III, Subsection NE-5000.

d. Fabrication Tolerances

The specified fabrication tolerances for the suppression chamber columns are as follows:

1. The outside diameter, based on circumferential measurements, does not deviate from the theoretical outside diameter by more than 0.5%.

2. Out-of-roundness, defined by the difference between the maximum and minimum diameters related to the theoretical diameter, is in accordance with the ASME Section VIII, Division 1, Paragraph UG-80.

3. The finished length does not differ from the theoretical length by more than ¼ inch.

4. The finished column shaft does not deviate from straightness by more than 1/8 inch in 1 foot, with a maximum for the full length of 1/1000 of the total length.

3.8.3.6.5 Drywell Platforms

a. Materials

Materials used in construction of the drywell platforms conform to the following standard specifications.

Item	Specification
Box beams and built-up wide flange beams	ASTM A441 and ASTM A588, Grade A
Structural shapes, plate,	ASTM A36

and bar

Connection bolts ASTM A325

b. Welding

Welding is performed in accordance with the Structural Welding Code, AWS D1.1. Visual inspection and acceptance of structural welds is performed in accordance with NCIG-01 (Reference 3.8-22).

c. Nondestructive Examination of Welds

Welds in box beams and fabricated wide flange beams are subjected to magnetic particle examination in accordance with ASTM E109 (Reapproved 1971); the standards of acceptance are in accordance with paragraph 8.15 of AWS D1.1.

d. Erection Tolerances

Erection tolerances for the drywell platforms are in accordance with the AISC Specification.

3.8.3.6.6 Quality Control

Quality control requirements during construction are discussed in the document "Limerick Generating Station Units 1 and 2; Summary Description of the Quality Assurance Program for Design and Construction," referenced in FSAR Section 17.1.

3.8.3.7 Testing and Inservice Inspection Requirements

3.8.3.7.1 Preoperational Testing

3.8.3.7.1.1 Structural Acceptance Test

The diaphragm slab is tested to 1.15 times the design downward differential pressure. Section 3.8.1.7 contains a description of the structural acceptance test. Structural acceptance test results are available after testing is complete.

3.8.3.7.1.2 Leak Rate Testing

Preoperational leak rate testing is discussed in Section 6.2.6.

3.8.3.7.2 Inservice Leak Rate Testing

Inservice leak rate testing is discussed in Section 6.2.6.

3.8.4 OTHER SEISMIC CATEGORY I STRUCTURES

This section gives information on all seismic Category I structures, other than the primary containment and its internal structures. It also describes the turbine enclosure, which is a nonseismic Category I structure. The following structures are included in this section:

Seismic Category I, Safety-Related Structures

Secondary containment (Reactor enclosures and refueling area)
Control structure
Diesel generator enclosure
Spray pond pump structure
Spray pond
Miscellaneous structures

Seismic Category I, Nonsafety-Related Structure

Radwaste enclosure (including offgas portion)

Nonseismic Category I, Nonsafety-Related Structure

Turbine enclosure

The general arrangement of these structures is shown on drawing C-2.

3.8.4.1 Description of Structures

3.8.4.1.1 Secondary Containment

The reactor enclosures enclose the primary containments and, with the refueling area, provide secondary containment (Figures 1.2-2 through 1.2-16). The secondary containment houses the auxiliary systems of the NSSS, the spent fuel pool, the refueling facility, and equipment essential to the safe shutdown of the reactor. The secondary containment is structurally integral with the control structure described in Section 3.8.4.1.2.

The secondary containment, up to and including the roof slab, is of reinforced concrete construction. Exterior bearing walls are reinforced concrete, and are additionally designed as shear walls to resist lateral loads. The floors and roof are constructed of reinforced concrete, supported by steel beam and column framing systems. The concrete slabs are designed as diaphragms to transmit lateral loads to the shear walls. The structural steel beams and girders are supported by either structural steel columns, or reinforced concrete bearing walls. The steel columns are supported by base plates attached to the foundation. The reinforced concrete walls and floors meet structural, as well as radiation shielding, requirements. At certain locations, concrete block masonry walls are used to provide better access for erecting and installing equipment. The block walls also meet the structural and the radiation shielding requirements.

The refueling facility is located above the reactor enclosures. It consists of the spent fuel pool, the steam dryer and separator storage pool, the reactor well, the cask loading pit, the skimmer surge tank vaults, a 48 foot long refueling platform crane, and a 129 foot long reactor enclosure crane. The facility is supported by end bearing walls, and by two post-tensioned concrete girders with grouted tendons. The girders run east-west, and span over the primary containments without intermediate supports. Each girder spans approximately 162 feet, and is 6 feet wide. The depth is 46 feet at the supports, and is reduced to 26 feet at midspan, where the girders straddle the containments. The ends of the girders are supported by concrete pilasters. A gap between the bottom of the girders and the top of the containments ensures that loads from the refueling facility

are not transferred to the containment. The details of the post-tensioned girders, including the tendon layout, are shown in Figure 3.8-53. The walls and slabs of the spent fuel pool, the cask loading pit, the reactor cavity, and the steam dryer and separator storage pool are lined on the inside with a stainless steel liner plate. The refueling facility meets the radiation shielding requirements.

The reactor enclosure crane consists of a main and an auxiliary hoist, with capacities of 125 tons and 15 tons, respectively. The crane is used during maintenance and refueling operations. It spans approximately 129 feet, and is 28 feet above the refueling floor. The crane is mounted on two 175 pound rails, supported by a pair of runway girders. The runway girders are supported by a series of built-up columns spaced at 27 foot centers, which in turn are supported by bearing walls. Figure 3.8-54 shows the details of the runway girders and the supporting columns. The reactor enclosure crane is discussed in Section 9.1.5.

The reactor enclosure is separated from the primary containment by a gap filled with compressible material. A gap is also provided at the interface of the secondary containment with the diesel generator, radwaste, and turbine enclosures.

3.8.4.1.2 Control Structure

The control structure, shown in drawings M-110, M-111, M-112, M-113, M-114, M-115, M-124, M-125, M-126, M-127, M-128, M-129, and M-130, is a reinforced concrete enclosure, structurally integrated with the secondary containment. The bearing walls are of reinforced concrete, and are additionally designed as shear walls to resist lateral loads. The floors and roof are constructed of reinforced concrete supported by steel beams. They are designed as diaphragms to transmit lateral loads to the shear walls. The beams span in the north-south direction and are supported at the ends by the bearing walls. The reinforced concrete walls and floors meet structural, as well as radiation shielding requirements. At certain locations, concrete block masonry walls are used to provide better access for erection and installation of equipment. The block walls also meet the structural and radiation shielding requirements.

The control structure is separated from the turbine enclosure by a seismic gap.

3.8.4.1.3 Diesel Generator Enclosure

The diesel generator enclosures, shown in drawings M-145 and M-146, house the standby diesel generators, which are essential for safe shutdown of the plant.

Concrete walls separate each diesel generator enclosure into four cells, one for each of the four diesel generators provided per unit. Each diesel generator unit is enclosed in its own concrete missile-protected cell. The walls between each generator unit are 2 feet thick and are 3 hour fire rated. All penetrations are small (2-3 inches), cast in concrete conduits for electrical cables. A concrete overhang on the south side of the enclosure serves as an air intake plenum. A concrete exhaust plenum is located on the north side of the enclosure roof.

The diesel generator enclosure is a reinforced concrete structure on wall foundations. The bearing walls are of reinforced concrete, and are additionally designed as shear walls to resist lateral loads. The floors and roof are constructed of reinforced concrete supported by steel beams. They are designed as diaphragms to transmit lateral loads to the shear walls. The north side of the enclosure bears on the pipe tunnel beneath. At certain locations, concrete block masonry walls are used to provide better access for erection and installation of equipment. The diesel generators are supported by the floors.

The diesel generator structures provide protection from missiles generated by internal rotating or pressurized mechanisms to prevent any credible missiles from damaging more than one engine. Any postulated missiles from a crankcase explosion are expected to be of low energy and incapable of penetrating the concrete barrier into any other cell. Failure of one or all of the starting air receivers by explosion is not expected to produce any credible missiles capable of penetrating the 2 foot thick cell walls. The diesel generator piping is designed to withstand pipe breaks and cracks.

3.8.4.1.4 Spray Pond Pump Structure

The spray pond pump structure, shown in drawings M-388, M-389 and M-390, contains the ESW and RHRSW pumps, auxiliary equipment, and related piping and valves.

The spray pond pump structure is a two-story reinforced concrete structure. The bearing walls are of reinforced concrete, and are additionally designed as shear walls to resist lateral loads. The operating floor and roof are constructed of reinforced concrete supported by steel beams. They are designed as diaphragms to transmit lateral loads to the shear walls. A mezzanine floor composed of grating over steel beams is provided to support the heating and ventilating equipment. An intermediate floor in the wing areas is provided to support valves and piping.

3.8.4.1.5 Spray Pond

The spray pond serves as the UHS for the plant. It is shown in Figures 3.8-55 through 3.8-57. The operation of the spray pond system is discussed in Section 9.2.6.

Spray pond dimensions are given in Table 9.2-18. The spray pond is designed so that normal operating water is retained in excavation only, i.e., not by constructed embankments.

An emergency spillway is provided at the north side of the pond. The only anticipated use of this spillway is either during a malfunction of the blowdown line, or during certain postulated conditions of heavy rainfall. The emergency spillway is designed to ensure that the maximum water level does not adversely affect the spray pond system, and to direct run-off water away from safety-related facilities in a controlled manner. The roadway surrounding the remainder of the spray pond provides a minimum freeboard of 4 feet.

The bottom and soil cut slopes of the spray pond are lined with a 12 inch thick layer of soil-bentonite lining. The soil-bentonite lining is covered with a 12 inch thick layer of soil. The rock-cut slopes are lined with shotcrete.

The stability of the subsurface materials, slopes, and lining at the spray pond site are discussed in Sections 2.5.4 and 2.5.5. Protection of slopes against waves is discussed in Section 2.5.5.

The spray network piping, which is located above the water, is supported by reinforced concrete columns. The columns are founded on bedrock or on concrete fill on top of bedrock.

3.8.4.1.6 Miscellaneous Structures

Subgrade pits, manholes, and tunnels which contain safety-related components are constructed of reinforced concrete. The locations of these miscellaneous structures are shown on Figure 3.8-58.

Safety-related piping, tanks, and electrical ducts, which are not located inside structures, are buried underground with adequate cover for missile protection. Additionally, soil erosion due to failure of

nonseismic piping has also been considered. The integrity of safety-related seismic Category I buried pipe will not be impaired through soil erosion by a failure of one buried nonseismic Category I pipe. This conclusion was based on the following conditions.

a. All but approximately 170 feet of common trench has been constructed in rock, where erosion of the supporting medium would be insignificant.

b. The 170 feet of trench not constructed in rock is in Type 1 fill.

   The nonpressure pipes (gravity lines) in this section, such as the blowdown line and waste and storm lines, do not pose a significant erosion problem. The nonseismic Category I pressure lines in this section consist of a 36 inch Schuylkill River makeup water line and a 12 inch fire line (Figure 3.8-58).

   Failure of the nonseismic Category I pressure pipe may create progressive erosion in the Type 1 fill. It is anticipated that water under pressure would penetrate to the surface, creating a progressively enlarging crater. However, because the water will flow in the direction of least resistance, once the water penetrates to the surface, the crater will be enlarged at a relatively slow pace. The span capacity needed to support the weight of the safety-related pipes in the trench is conservatively estimated to be in excess of 30 feet, based on the maximum allowable spans given in the ASME code. A considerably long time would be required to erode a crater large enough to exceed this span capacity.

c. Instrumentation would give indication in the control room if a break occurred in the nonseismic Category I pressure pipe. Loss of flow from the makeup water line to the cooling tower would result in an alarm in the control room when low level is reached in the cooling tower basin. It is conservatively estimated that low level would be reached within 30 minutes.

   Low pressure in the 12 inch fire line, following a break, starts a fire pump that gives an alarm in the control room without a fire signal.

   Following an SSE, if either alarm described above is activated, personnel will investigate for evidence of a faulty condition in the pipelines described in (b) above and will initiate any necessary corrective action.

d. The procedures for operator response to a seismic event will include the requirement that, within two hours after an SSE, personnel will investigate for evidence of a faulty condition in the pipelines described in (b) above and will initiate any necessary corrective action.

3.8.4.1.7 Radwaste Enclosure

The radwaste enclosure is designed in accordance with seismic Category I criteria, even though: its integrity is not required to protect the RCBP, or to ensure the capability to safely shut down the reactor; and its failure would not result in potential offsite exposures comparable to the guideline exposures of 10CFR50.67. The radwaste enclosure, shown in drawings M-140 through M-144, houses systems for receiving, processing, and temporarily storing the radioactive waste products generated during the operation of the plant.

The radwaste enclosure, which includes the offgas enclosure, is a reinforced concrete structure. The bearing walls are of reinforced concrete, and are additionally designed as shear walls to resist

lateral loads. The exterior walls are waterproofed, and are designed for hydrostatic effects as necessary. The floors and roof in the main portion of the radwaste enclosure are constructed of reinforced concrete supported by beam and column framing systems. They are designed as diaphragms to resist lateral loads. The columns are supported by base plates on the foundation. The floors and roof of the offgas portion of the radwaste enclosure are of reinforced concrete supported by steel beams and bearing walls. The reinforced concrete walls and floors meet structural, as well as radiation shielding requirements. At certain locations, concrete block masonry walls are used to provide better access for erection and installation of equipment. The block walls also meet the structural and radiation shielding requirements.

The radwaste enclosure is separated from the turbine enclosure and reactor enclosure by seismic gaps.

3.8.4.1.8 Turbine Enclosure

The turbine enclosure, which is shown in drawings M-110, M-111, M-112, M-113, M-114, M-115, M-124, M-125, M-126, M-127, M-128, M-129, and M-130, is divided into two units, separated by an expansion joint. It houses two inline turbine-generator units, and auxiliary equipment including condensers, condensate pumps, moisture separators, air ejectors, feedwater heaters, reactor feed pumps, ASDs for reactor recirculation pumps, interconnecting piping and valves, switchgear, and heating and ventilating equipment.

Three 110 ton overhead cranes are provided above the operating floor for servicing both turbine-generator units. Two reinforced concrete tunnels, one for each unit, are provided for the offgas pipelines at the foundation level, running from the area around the control structure to the radwaste enclosure.

The turbine enclosure rests on a reinforced concrete mat foundation. The superstructure is framed with structural steel and reinforced concrete. Rigid steel frames support the two turbine enclosure cranes. They also resist all transverse (north-south) lateral loads. Steel bracings resist longitudinal (east-west) lateral loads above the operating floor. Below this level, reinforced concrete shear walls transfer all lateral loads to the foundations.

Seismic separation gaps are provided at the interface of the turbine enclosure with the reactor, control, and radwaste enclosures.

The floors of the turbine enclosure are of reinforced concrete supported by structural steel beams. They are designed as diaphragms for lateral load transfer to the shear walls. The roof is built-up roofing on metal decking.

Exterior walls are covered by nonstructural precast reinforced concrete panels.

Interior walls required for radiation shielding or fire protection are constructed of reinforced concrete block. These walls are not used as elements of the load resistant system.

The seismic Category II turbine enclosure may undergo some plastic deformation under seismic loading resulting from the SSE, but the plastic deformation is limited to a ductility factor of 2. Those portions of the turbine enclosure which support the main steam lines are designed so that the main steam lines and their supports maintain their integrity under the seismic loading resulting from the SSE. Furthermore, the Turbine Enclosure will maintain its integrity to ensure that the MSIV Leakage Alternate Drain Pathway will be capable of performing its function as described in Section 6.7 during and following an SSE.

The turbine-generator units are supported on freestanding reinforced concrete pedestals. The mat foundations for the pedestals are founded on rock at the same levels as the basemat for the turbine enclosure. Separation joints are provided between the pedestals, and the turbine enclosure floors and walls, to prevent transfer of vibration to the enclosure. The operating floor of the turbine enclosure is supported on vibration damping pads at the top edge of the pedestal.

3.8.4.2 Applicable Codes, Standards, and Specifications

The codes, standards, and specifications used in the design, fabrication, and construction of seismic Category I structures are listed in Table 3.8-1.

3.8.4.3 Loads and Load Combinations

Tables 3.8-9, 3.8-10, and 3.8-11 list the loading combinations considered in the design seismic Category I structures (other than the primary containment).

The reactor enclosure and control structure are also assessed for Mark II hydrodynamic loads resulting from MSRV discharge and LOCA phenomena. For a definition of loads and loading combinations including hydrodynamic loads, refer to Reference 3.8-1 and Appendix 3A. Hydrodynamic loads have no significant effect on other seismic Category I structures described in Section 3.8.4.

3.8.4.3.1 Description of Loads

3.8.4.3.1.1 Normal Loads

Normal loads are loads which are encountered during normal plant operation and shutdown. They include dead loads, live loads, thermal loads due to operating temperature, and other permanent loads contributing stress, such as hydrostatic loads. Dead and live loads are described in Sections 3.8.1.3.1 and 3.8.1.3.2, respectively.

3.8.4.3.1.2 Severe Environmental Loads

Severe environmental loads are loads that could infrequently be encountered during the plant life. They include those loads induced by the OBE and the design wind. Loads due to OBE are discussed in Sections 3.7 and 3.8.1.3.6. Wind loads are discussed in Section 3.3.

3.8.4.3.1.3 Extreme Environmental Loads

Extreme environmental loads are loads which are credible, but which are highly improbable. They include those loads induced by the SSE and the design tornado. Loads due to the SSE are discussed in Sections 3.7 and 3.8.1.3.6. Tornado loads are discussed in Section 3.3.

3.8.4.3.1.4 Abnormal Loads

Abnormal loads are loads generated by a DBA. Abnormal plant conditions generated by a DBA include the postulated rupture of high energy piping. Loads induced by such an accident include elevated temperatures and pressures within or across compartments, and jet impingement and impact forces associated with such ruptures. Loads due to postulated rupture of piping are discussed in Section 3.6. Other loads that may be generated by a DBA include railroad accident

blast loads and tornado loading (including missiles generated from both), and loading from aircraft impact, as described in Sections 2.2.3 and 3.5.1.6.

3.8.4.3.2 Load Combinations

Table 3.8-9 describes the load combinations applicable to the reactor enclosure and control structure. Table 3.8-10 contains the load combinations applicable to seismic Category I structures, other than the primary containment, reactor enclosure, and control structure. Load combinations considered in the design of miscellaneous structural components of seismic Category I structures are listed in Table 3.8-11. Applicable load combinations from Table 3.8-10 are used in the design of the turbine enclosure.

3.8.4.4 Design and Analysis Procedures

The structures are designed to maintain elastic behavior for the load combinations defined in Section 3.8.4.3. All reinforced concrete components of the structure are designed by the ultimate strength method, in accordance with ACI 318. Design of major reinforced and prestressed concrete structural components was completed prior to the formal adoption of ACI 349, and this standard was therefore not used for LGS. All structural steel components are designed by the working stress method, in accordance with the AISC Specification.

Roof and floor diaphragms transfer the horizontal loads to the shear walls, which then transfer the loads to the foundation. Standard analytical procedure is used to analyze the distribution of lateral loads from the diaphragms to the shear walls. Vertical loads are transferred to the foundation by bearing walls and steel columns.

Seismic analysis of the structures uses the techniques described in Section 3.7. The enclosures are analyzed dynamically.

Design of structures for missile and aircraft protection is covered in Section 3.5.3.

The design and analysis of the fuel pool girders of the reactor enclosures are in accordance with ACI 318.

Design and analysis of concrete block walls are by the working stress method, in accordance with the UBC.

The stainless steel liner plates, used on the inside of the spent fuel pool, the cask loading pit, the reactor well, and the steam dryer and separator storage pool, are designed to function as a leak-tight membrane and to facilitate decontamination. The liner plate is designed to accommodate stresses due to the combined effect of long-term shrinkage of the underlying structural concrete and temperature effects inside the pools.

The spray pond is basically a soil-structure. Its design is discussed in Sections 2.5.4 and 2.5.5.

The reactor enclosure and control structure are also assessed for Mark II hydrodynamic loads resulting from MSRV discharge and LOCA phenomena. Assessment procedures that consider the effect of hydrodynamic loads are described in Appendix 3A.

3.8.4.5 Structural Acceptance Criteria

3.8.4.5.1 Reinforced and Prestressed Concrete

The reinforced and prestressed concrete structural components are designed by the strength method, in accordance with ACI 318, for the loads and load combinations described in Section 3.8.4.3. The stresses resulting from the load combinations are within allowable limits.

3.8.4.5.2 Structural Steel

The structural steel components are designed by the working stress method in accordance with the AISC Specification for the loads and load combinations described in Section 3.8.4.3. The allowable stresses for different load combinations are indicated therein. The stresses developed in the structural components are within the allowable limits.

3.8.4.5.3 Concrete Masonry Block Walls

The design of masonry walls was performed in accordance with the criteria in the UBC. The masonry wall design was re-evaluated for conformance with the criteria in NRC IE Bulletin 80-11. A comparison of the LGS design criteria for masonry walls with the SEB criteria shows that the two are in good agreement except in the following two areas:

a. Under extreme environmental loading conditions, the LGS criteria (appendix I, part 1, Reference 3.8-21) lists the following combinations:

   1. $D + L + T_a + H_a + R + P + E'$

   2. $D + L + W' + T_o + H_o$

   where:

D	=	Dead load of structure and equipment plus any other permanent loads
L	=	Live loads expected to be present when the plant is operating
E'	=	Design basis earthquake loads
W'	=	Tornado loads
T_o	=	Operating temperature loads
T_a	=	Accident temperature loads
H_o	=	Thermal operating condition pipe load
H_a	=	Thermal accident condition pipe load
R	=	Jet impingement load and/or pipe whip
P	=	Pressurization load due to HELB

The SEB criteria, under similar conditions, lists the following load combinations:

1. $D + L + T_o + R_o + E'$

2. $D + L + T_o + R_o + W_t$

3. $D + L + T_a + R_a + 1.5P_a$

4. $D + L + T_a + R_a + 1.25P_a + 1.0 (Y_r + Y_j + Y_m) + 1.25E$

5. $D + L + T_a + R_a + 1.0P_a + 1.0 (Y_r + Y_j + Y_m) + 1.0E'$

where:

R_o = H_o of the LGS criteria

E = OBE loads

W_t = W' of the LGS criteria

R_a = H_a of the LGS criteria

P_a = P of the LGS criteria

Y_r = Equivalent static load on the structure generated by the reaction on the broken high energy pipe during the postulated break, and including an appropriate dynamic load factor to account for the dynamic nature of the load.

Y_j = Jet impingement equivalent static load on a structure generated by the postulated break, and including an appropriate dynamic load factor to account for the dynamic nature of the load, = R of the LGS criteria.

Y_m = Missile impact equivalent static load on a structure generated by or during the postulated break, as from pipe whipping, and including an appropriate dynamic load factor to account for the dynamic nature of the load, = R of the LGS criteria.

Comparing the load combination under the two criteria, it is seen that combinations (1) and (2) of the LGS criteria are the same as combinations (v) and (ii) of the SEB criteria. Further, combination (v) of SEB is clearly more severe than combination (k) of SEB which is, therefore, not used in the LGS criteria. A study made on the masonry walls and their applicable load combinations indicated that load combination (v) of SEB will, in most cases, be more severe than combinations (iii) and (iv). For the cases where this was not true, the difference in loadings was not significant and additional calculations were made to ensure that the walls would be structurally adequate under SEB load combinations (iii) and (iv).

The results of the re-evaluation contained in Reference 3.8-21 are unaffected if the SEB load combinations (iii) and (iv) are considered in addition to the LGS load combinations in the re-evaluation of the masonry walls.

b. The LGS criteria permits the use of an increase factor for shear and bond of 1.67 which, when multiplied with the allowable stresses for normal operating conditions, gives that allowables for extreme environmental conditions. The increase factors under the SEB criteria are 1.5 for tension parallel to bed joint and shear in the reinforcement and 1.3 for tension normal to the bed joint and masonry shear.

   All block walls at LGS contain steel tension reinforcement which takes all tension normal or parallel to the bed joint. Therefore the LGS allowable masonry tension stress normal or parallel to the bed joint was not used, i.e., zero psi was assumed for the reanalysis of block walls. Because the masonry tension strength at the bed joint was assumed to be zero, the increase factor stated in the question was also not used in the reanalysis of the block walls. Further, the factor 1.67 has also not been used for shear or bond calculations for the masonry wall re-evaluation; instead a factor of 1.0 has been used.

Because the code allowable stresses (Reference 3.8-23, chapter 10.1 of the commentary) are generally associated with a safety factor of 3, the 1.67 increase factor for stresses for masonry load combinations involving abnormal and/or extreme environmental conditions, provides a factor of safety against failure of 1.8 (3 divided by 1.67). The factor of safety of 1.8 is conservative and allows sufficient margin for abnormal and/or extreme conditions.

Reference 3.8-21 provides additional details and results of this evaluation.

3.8.4.6 Materials, Quality Control, and Special Construction Techniques

3.8.4.6.1 Reinforced Concrete, Masonry, and Prestressed Concrete

The reinforced concrete, masonry, and prestressed concrete materials are discussed in Section 3.8.6.

3.8.4.6.2 Structural Steel

3.8.4.6.2.1 Materials

The various structural steel components conform to the following ASTM Specifications:

Item	ASTM Specification
Beams, girders, and plates	A36 or A441
High strength bolts	A325 or A490
Anchor bolts	A36 or A307

3.8.4.6.2.2 Welding and Nondestructive Testing

All welding and nondestructive testing is performed in accordance with the AWS Structural Welding Code.

3.8.4.6.2.3 Fabrication

The fabrication of structural steel conforms to the AISC Specification.

3.8.4.6.3 Quality Control

Quality control requirements during construction are discussed in the document "Limerick Generating Station Units 1 and 2; Summary Description of the Quality Assurance Program for Design and Construction," referenced in FSAR Section 17.1.

3.8.4.6.4 Special Construction Techniques

No special construction techniques are involved in the construction of seismic Category I structures.

3.8.4.7 Testing and Inservice Inspection Requirements

Testing and inservice inspections are not required for seismic Category I structures (other than the primary and secondary containment). The operational test, to verify the inleakage requirements of SGTS in the reactor enclosure, is covered in Sections 6.5.3 and 9.4.2.

3.8.5 FOUNDATIONS

This section describes foundations for all seismic Category I structures, other than the primary containment and the spray pond. The primary containment foundation is described in Section 3.8.1. The spray pond is basically a soil-structure; its design is discussed in Sections 2.5.4 and 2.5.5. A description of the foundation for the turbine enclosure, which is a nonseismic Category I structure, is also included in this section.

3.8.5.1 Description of the Foundations

Reinforced concrete foundations resting on sound rock, or lean concrete on sound rock, are provided for the structures.

Bearing walls of the structures are rigidly connected to the foundation. Steel columns are attached to the foundation by base plates and anchor bolts. The bearing walls and the steel columns carry all the vertical loads; they also carry the vertical axial loads due to the overturning effect of lateral forces, from the structure to the foundation. Horizontal shears due to wind, tornado, and seismic loads are transferred to the shear walls by the roof and floor diaphragms. The shear walls transfer the horizontal shears to the foundation, and from there, to the foundation medium through friction and/or direct bearing. The sides of all structure foundations are keyed to the foundation rock by poured concrete. This helps transfer the horizontal shears to the foundation rock.

The foundation for each structure is separated from each adjacent foundation by a 1 inch minimum seismic gap, except along the east side of the radwaste enclosure foundation, which is supported by the reactor enclosure foundation (Figure 3.8-59).

Peripheral subterranean walls are designed to resist lateral pressures due to backfill and surcharge loads, in addition to dead loads, live loads, and seismic loads.

3.8.5.1.1 Reactor Enclosure and Control Structure

The foundation for the reactor enclosure and control structure is a single integral unit. The foundation plan and representative sections are shown in Figure 3.8-60. The reactor enclosure and control structure walls are supported on continuous wall footings. Columns are supported on spread footings. The wall footings and spread footings vary in dimension and reinforcing.

All of these elements of the foundation for the reactor enclosure and control structure are joined together by a continuous 3'-0" thick mat in the reactor structure area, and by a continuous 2'-0" thick mat in the control structure. The 3'-0" thick mat surrounds the primary containment basement, with a 1 inch seismic gap separating the two.

3.8.5.1.2 Diesel Generator Enclosure

Figure 3.8-61 shows the foundation plan and typical sections of the diesel generator enclosure. The wall foundations extend well below the diesel generator base slab to competent bedrock. The base slab is supported on fill, which for design purposes is considered to be both yielding and nonyielding. In addition, the base slab is designed to span between the wall foundations, without support from the fill.

3.8.5.1.3 Spray Pond Pump Structure

Figure 3.8-62 shows the foundation plan and typical sections of the spray pond pump structure. The walls are founded on competent bedrock. The walls do not have independent footings, but are connected monolithically by a 2'-0" thick slab at the foundation level.

3.8.5.1.4 Radwaste Enclosure

Figure 3.8-59 shows the foundation plan and typical sections of the radwaste enclosure. The walls of the radwaste enclosure are founded on competent bedrock and are supported on continuous wall footings. Columns are supported on spread footings. The wall footings and spread footings of the main portion of the radwaste enclosure are joined together by a 1'-10" thick slab at the foundation level.

The walls of the offgas portion of the radwaste enclosure are supported on continuous wall footings, connected by a 1'-6", or 2'-2" thick slab at the foundation level.

3.8.5.1.5 Turbine Enclosure

Figure 3.8-63 shows the foundation plan and typical sections of the turbine enclosure. The walls are supported on continuous wall footings. Columns are supported on spread footings. The wall footings and spread footings vary in dimension and reinforcing. All of these elements of the foundation are joined together by a continuous 1'-3" to 1'-6" thick mat.

3.8.5.1.6 Miscellaneous Structures

Figure 3.8-64 shows typical foundation details of some safety-related miscellaneous structures. These structures are founded on competent bedrock, compacted fill, or lean concrete which can safely withstand the superimposed loads. The walls of the subgrade pits, manholes, and trenches are connected monolithically with the floor slabs at the foundation level. The minimum thicknesses of the walls and the floor slabs are 1'-6" and 1'-0", respectively.

3.8.5.2 Applicable Codes, Standards, and Specifications

The codes, standards, and specifications used in the design, fabrication, and construction of structure foundations are listed in Table 3.8-1.

3.8.5.3 Loads and Load Combinations

The loads and load combinations used in the design of the primary containment foundation are described in Section 3.8.1.3. The loads and load combinations used in the design of other seismic Category I structure foundations are discussed in Section 3.8.4.3.

3.8.5.4 Design and Analysis Procedures

The foundations of all seismic Category I structures are designed in accordance with the same codes and standards as used in the design of the superstructure. The design and analysis procedures are discussed in Section 3.8.1.4 and Section 3.8.4.4 for the primary containment and other seismic Category I structures, respectively. The design loads and load combinations are discussed in Section 3.8.5.3.

The bearing walls and steel columns carry all the vertical loads from the structure to the foundation. The lateral loads are transferred to the shear walls by the roof and floor diaphragms, which then transmit them to the foundation. Determination of overturning moment due to seismic loads is discussed in Section 3.7.

Settlement of all seismic Category I structure foundations is considered negligible, as the foundations are supported by sound rock, or lean concrete on top of sound rock, except those of some yard facilities, such as valve pits, manholes, pipe trenches, electrical ducts, etc, which are supported on select fill and yard fill on dense residual fill, or on sound rock.

The sliding of seismic Category I structure foundations cannot occur because, as explained in Section 3.8.5.1, the sides of the foundations are keyed to the foundation rock by poured concrete.

Detailed description of the foundation rock and soil is contained in Section 2.5.4.

3.8.5.5 Structural Acceptance Criteria

The seismic Category I structure foundations are designed to meet the same structural acceptance criteria as the structures themselves. These criteria are discussed in Sections 3.8.1.5 and 3.8.4.5. In addition, for the load combinations described in Section 3.8.5.3, the minimum factor of safety against overturning is 1.5.

3.8.5.6 Materials, Quality Control, and Special Construction Techniques

The seismic Category I structure foundations are constructed of reinforced concrete. The reinforced concrete materials are discussed in Section 3.8.6. Cement for the ESW/RHRSW cross tie valve pits in the spray pond pump house yard is Type II. Concrete for these pits is commercial grade material dedicated for nuclear safety related use. The material characteristics identified in Section 3.8.6 were used as a basis for the dedication plan.

No special construction techniques are involved in the construction of these foundations.

3.8.5.7 Testing and Inservice Inspection Requirements

Foundation testing and inservice inspection are not considered necessary, since all seismic Category I structure foundations are supported on sound rock, or lean concrete on sound rock. The only testing carried out is as described in Section 3.8.1.7.

3.8.6 CONCRETE, REINFORCING, PRESTRESSED CONCRETE, AND MASONRY MATERIALS

Materials, workmanship, and quality control associated with the construction of reinforced concrete, prestressed concrete, and masonry features of seismic Category I structures are based on the codes, standards, recommendations, and specifications listed in Table 3.8-1. These documents are modified as required to suit the particular conditions associated with nuclear power plant design and construction while maintaining structural adequacy. The extent of application and principal exceptions are indicated herein, and as follows:

a. ACI 301-66

The provisions of ACI 301-66, "Specification for Structural Concrete for Buildings", are modified as follows:

1. The requirements of section 7.3.2 of ACI 318-71 apply in lieu of section 504(b).

2. The following requirements apply in lieu of section 804(b)2:

(b)2 Hot weather - Concrete deposited in hot weather shall have a placing temperature which shall not cause difficulty from loss of slump, flash set, or cold joints and not greater than 90°F.

3. Vertical construction joints are cleaned and roughened by waterblasting, sandblasting, or bush hammering after the concrete has reached its final set. Prior to receiving additional concrete, vertical construction joints are wetted in lieu of the use of neat cement grout as specified in section 805(c).

4. The following requirements apply in lieu of section 901(a) and the fifth sentence of section 902(d):

(a) Surface defects, such as form blowholes, honeycomb, etc., are repaired as soon as practicable, but no later than 28 days after form removal.

(b) Form tie holes on the structures below grade level and in concrete which is coated with a special protective coating are patched as soon as practicable, but no later than 28 days after form removal. Form tie holes in areas other than the above need not be patched. Form tie holes which are patched need not be cured or kept moist.

5. The following requirements apply in lieu of the requirements specified in section 1202(a) and (c) and 1405(d):

The requirements of ACI 306-66 apply during cold weather. In addition, when heated enclosures are used for curing and freezing protection for all thicknesses of concrete, the temperature at the surface of the concrete is maintained between 50°F and 70°F. Any housing, covering, or other protection remains in place and intact for at least 24 hours after the artificial heating is discontinued. The maximum allowable gradual drop in temperature throughout the first 24 hours after the end of the 7 day curing period is 30°F for concrete thicknesses greater than 36 inches.

6. The following requirements apply in lieu of the requirements of sections 1401(a), 1404(a), 1404(c), 1405(a), and 1405(c), respectively:

   (a) Concrete sections more than 3 feet in the least dimension are termed mass concrete.

   (b) The maximum working limit slump of the concrete is 3 inches, with an inadvertency margin of +2 inches, except for starter mixes, which have a maximum slump of 5 inches.

   (c) Concrete is placed in layers not more than 24 inches, with vibrator heads extending into the previously placed layer.

   (d) The minimum curing period is 7 days.

   (e) The concrete is either moist cured or liquid membrane cured for 7 days. Liquid membrane compounds are applied at the time that the free water on the surface has disappeared, and no water sheen is seen, but not so late that the liquid curing compound is absorbed into the surface pores of the concrete.

   (f) The following requirements apply in lieu of section 601(c):

   The surface of the concrete at all joints is thoroughly cleaned, and all laitance removed, except where a mechanical joint is used, in which case all laitance need not be removed. The use of a mechanical joint without the removal of laitance is permitted in areas not exposed to excessive moisture.

b. ACI 318-71

The provisions of ACI 318-71, "Building Code Requirements for Reinforced Concrete", are modified as follows:

1. Section 3.5.1(a) of the 1974 Supplement to ACI 318-71 applies in lieu of section 3.5.1(a) of ACI 318-71.

2. Starter mixes, defined as concrete with a 1 inch maximum size aggregate 3 inches and 5 inches, are used as an alternate to mortar in section 5.4.4 and grout in section 6.4.1.

3. The following requirements apply in place of the requirements specified in section 5.5.1:

   The concrete is moist cured or liquid membrane cured for 7 days. Liquid membrane compounds are applied at the time that the free water on the surface has disappeared and no water sheen is seen, but not so late that the liquid curing compound is absorbed into the surface pores of the concrete.

4. The following requirements apply in place of the requirements specified in section 6.3.2.2:

   The temperature of the liquid, gas or vapor shall not exceed 150°F except in local areas such as penetrations through walls and slabs where the temperature shall not exceed 200°F.

5. The following requirements apply in place of the requirements specified in section 6.3.2.4:

   Piping and fittings are tested in accordance with the requirements of the code governing that piping system (e.g., ASME B&PV Code, ANSI B31.1, state or local plumbing codes, etc.), as specified in other sections of the UFSAR.

   Whenever the piping system is not governed by such applicable codes or code cases, such systems are tested for leaks prior to concreting. The testing pressure above atmospheric pressure is 50% above the pressure to which the piping and fittings may be subjected in service; but the minimum testing pressure is not less than 150 psig. The pressure test is held for 4 hours, with no drop in pressure, except that which may be attributable to changes in ambient air temperatures; or the system is maintained at the hydrostatic test pressure for a minimum of 10 minutes, while all joints are visually examined for leakage.

6. The following requirements apply in place of the requirements specified in section 6.3.2.6:

   Piping systems not governed by applicable codes or code cases, carrying liquid, gas, or vapor, which is potentially explosive or injurious to health, are retested in accordance with item b.4 above, subsequent to the hardening of the concrete.

7. The following requirements apply in place of the requirements specified in section 6.3.2.7:

   Piping systems may be energized with water exceeding neither 50 psig, nor 90°F at any time, if approved by the responsible field engineer.

   Piping systems, including systems governed by piping system codes, may be energized above either 50 psig or 90°F, or energized with fluids other

than water during the period beyond 7 days after the concrete placement, provided that the temperature of the fluid does not exceed 150°F, and the pressure does not exceed 200 psig. Piping systems may be energized prior to, and remain energized during, placement of concrete, provided that: the above temperature and pressure restrictions are applied, and if the pressure in the energized system drops during concrete placement, the lowest pressure reached becomes the limiting pressure until the 7 day postplacement time limit has elapsed. However, if the pressure drops further within 24 hours after completion of the concrete placement, the system can be re-energized only up to the limiting pressure at any time after the 24 hour period has elapsed.

8. Vertical construction joints are cleaned and roughened by waterblasting, sandblasting, or bush hammering after the concrete reaches its final set. Prior to receiving additional concrete, vertical construction joints are wetted, in lieu of the use of neat cement grout specified in section 6.4.1.

9. The following requirements apply in lieu of the second sentence of section 6.4.1:

   Where a joint is to be made, the surface of the concrete is thoroughly cleaned. All standing water and laitance are removed, except where a mechanical joint is used, in which case all laitance need not be removed. The use of a mechanical joint without removing the laitance is permitted only in areas not exposed to excessive moisture.

10. The following requirements apply in lieu of the first sentence of section 4.14:

    f'_c for 5000 psi design strength concrete shall be based on tests of 90 days. f'_c for all other concrete design strengths shall be based on 28 day tests.

11. The following requirements apply in lieu of the last sentence of section 4.3.1:

    Each strength test result shall be the average of two cylinders from the same sample tested at 28 days for concrete with a design strength of 4000 psi or less and at 90 days for concrete with a design strength of 5000 psi.

c. ACI 613-54

The provisions of ACI 613-54, "Recommended Practice for Selecting Proportions for Concrete", are adhered to, except that the following recommended laboratory tests, mentioned on pages 211-14 through 211-16, are not used:

1. Fineness of Portland-Cement by Air Permeability Apparatus - ASTM Designation C204

2. Specific Gravity of Hydraulic Cement - ASTM Designation C188

3. Percentage of Shale in Aggregate - AASHTO Designation T10.

4. Alkali Reactivity, Potential, of Cement-aggregate Combinations - ASTM Designation C227

5. Air Content (volumetric) of Freshly Mixed Concrete - ASTM Designation C173

6. Air Content of Fresh Concrete by Pressure Methods (Washington-type meter) - Bureau of Reclamation Concrete Manual, Designation 24

7. Air Content of Freshly Mixed Concrete - U.S. Army Corps of Engineers Handbook for Concrete and Cement, Designation CRD-C 41

8. Laboratory Concrete Mixing - Bureau of Reclamation Concrete Manual, Designation 28

9. Flow of Portland-cement Concrete by Use of the Flow Table - ASTM Designation C124

10. Compressive Strength of Concrete Using Portions of Beams Broken in Flexure (modified cube method) - ASTM Designation C116

11. Flexural Strength of Concrete (using beam with third-point loading) - ASTM Designation C78

12. Fundamental Transverse and Torsional Frequencies of Concrete Specimens - ASTM Designation C215

13. Hardened Concrete, Securing, Preparing, and Testing Specimens from, for Compressive and Flexural Strengths - ASTM Designation C42

14. Cement Content of Hardened Portland-cement Concrete - ASTM Designation C85

15. Volume Change of Cement, Mortar and Concrete - ASTM Designation C157

16. Absorption of Concrete - AASHTO Designation T25

d. ACI 614-59

The provisions of ACI 614-59, "Recommended Practice for Measuring, Mixing, Transporting, and Placing Concrete", are modified as follows:

1. In addition to the requirements of ACI 614-59, storage of concrete materials shall be in accordance with ACI 304-73.

2. The following requirement applies in lieu of the second sentence of part II, item 6:

   The fineness modulus does not vary more than 0.20 from the value assumed in selecting proportions for the concrete.

3. The following requirements apply in lieu of the fourth sentence of part V, item 2:

   Concrete is not allowed or caused to flow to a distance, within the mass, more than the amount required for proper consolidation, and in no case more than 5 feet from the point of deposition.

4. The following requirements apply in lieu of the requirements of part VI, item 6:

   Immediately before the concrete is placed, all horizontal surfaces are covered with a nominal ½ inch of flowable grout mix thoroughly broomed into horizontal surfaces. For congested areas where brooming is impossible, the grout mix is forced ahead of the concrete. If the congestion may cause segregation, the grout thickness is increased to a nominal 1 inch thickness. Starter mixes, as defined above in item b.2, may be used as an alternate to the ½ inch or 1 inch grout. Starter mixes may be used to cover the bottom mat of reinforcing steel to a nominal depth of 2 inches above the reinforcing steel, or 6 inches above existing concrete on construction joints where no reinforcing mat exists.

5. The following requirement applies in lieu of the requirement of the fourth sentence of part VI, item 7:

   The maximum working limit slump of the concrete is 3 inches, with an inadvertency margin of +2 inches, except for starter mixes, which have a maximum slump of 5 inches.

e. ACI SP-2, Fifth Edition

The provisions of ACI SP-2, "Manual of Concrete Inspection", are modified as follows:

1. All samples are taken in accordance with ASTM C172.

2. Samples for cylinder strength tests of central mixed concrete are taken at the point of discharge from the central mixer plant. Samples for cylinder strength tests of truck mixed concrete, and slump, air content, and concrete temperature tests for all concrete are taken at the point of discharge from the delivery truck or at the end of the pump line for pumped concrete.

3. In order to establish a correlation between concrete properties at the central mixer plant and at the end of the pump line, pumped concrete is sampled at both of these locations to determine slump, air content, and concrete temperature. These correlation samples are taken from the same batch of concrete that is sampled for concrete cylinder strength tests at the central mixer plant, and again from this same batch of concrete as it reaches the end of the pump line. The correlation samples are taken at the following frequencies:

(a) Samples for slump and concrete temperature are taken from the first batch of each class of concrete produced per day, and for every 200 cubic yards of each class of concrete produced thereafter.

(b) Samples for air content are taken from every 400 cubic yards of each class of concrete produced, with a minimum of once per day for each class of concrete produced.

4. Vertical construction joints are cleaned and roughened by waterblasting, sandblasting, or bush hammering after the concrete has reached its final set. Prior to receiving additional concrete, vertical construction joints are wetted in lieu of using neat cement grout.

3.8.6.1 Concrete and Concrete Materials

3.8.6.1.1 Concrete Material Qualifications

3.8.6.1.1.1 Cement

Cement is Type II, Type I after June 1983, Portland-cement conforming to ASTM C150 except for RPV pedestal repair where the cement used is an expansive cement Type E-1(K) complying with ASTM C845. The following initial user tests are performed to ascertain conformance with ASTM Specification C-150:

Test	Designation
Chemical Analysis of Hydraulic Cement	ASTM C114
Fineness of Portland-Cement by the Turbidimeter	ASTM C115
Autoclave Expansion of Portland-Cement	ASTM C151
Time of Setting of Hydraulic Cement by Gillmore Needles	ASTM C266
Compressive Strength of Hydraulic Cement Mortars	ASTM C109
Air Content of Hydraulic Cement Mortar	ASTM C185

In addition, these tests are repeated during construction to check storage environmental effects on cement characteristics. The tests supplement visual inspection of material storage procedures.

Certified copies of material test reports showing chemical composition of the cement and verification that the cement being furnished complies with requirements are furnished by the manufacturer for each batch or lot.

3.8.6.1.1.2 Normal Weight Aggregate

Fine and coarse aggregates conform to ASTM C33. The following initial user tests are performed to ascertain conformance with ASTM C33:

Test	Designation
Organic Impurities in Sand for Concrete	ASTM C40
Effect of Organic Impurities in Fine Aggregate on Strength of Mortar	ASTM C87
Soundness of Aggregates by Use of Sodium Sulfate or Magnesium Sulfate	ASTM C88
Materials Finer Than No. 200 Sieve in Mineral Aggregates by Washing	ASTM C117
Lightweight Pieces in Aggregate	ASTM C123
Specific Gravity and Absorption of Coarse Aggregate	ASTM C127
Specific Gravity and Absorption of Fine Aggregate	ASTM C128
Resistance to Abrasion of Small Size Coarse Aggregate by Use of the Los Angeles Machine	ASTM C131
Sieve or Screen Analysis of Fine and Coarse Aggregates	ASTM C136
Clay Lumps and Friable Particles in Aggregates	ASTM C142
Scratch Hardness of Coarse Aggregate Particles	ASTM C235
Potential Reactivity of Aggregates	ASTM C289
Petrographic Examination of Aggregates for Concrete	ASTM C295
Test for Flat and Elongated Particles in Coarse Aggregate (except that the acceptance criteria for the ratio of flatness and elongation shall be 4 in lieu of 3)	CRD C119

Coarse aggregate grading is in accordance with size Nos. 4, 57, and 67, as defined in ASTM C33. The quantity of flat and elongated particles in the coarse aggregate is limited to 15% by weight.

3.8.6.1.1.3 High Density Aggregates

The requirements specified for normal density aggregates apply for high density aggregates, except as noted below.

Fine and coarse aggregates have a minimum bulk specific gravity of 4.4, as determined by ASTM C127 and ASTM C128. The high density aggregates are combined to produce a workable mix which meets all shielding requirements.

Certified test reports are prepared by the supplier for each material shipment, attesting to aggregate conformance to cleanliness requirements when tested per ASTM C117, and specific gravity requirements when tested per ASTM C127 and ASTM C128.

Metal aggregate consists of commercial S-930 and S-780 chilled iron or steel shot. This shot conforms to the appropriate SAE gradation presented in table 1 of the SAE Handbook.

3.8.6.1.1.4 Mixing Water and Ice

Water and ice used in mixing concrete is free of injurious amounts of oil, acid, alkali, organic matter, or other deleterious substances, as determined by AASHTO T26. Such water and ice contains no injurious impurities that would cause either a change in the setting time of portland-cement of more than 25%, as determined in accordance with ASTM C266, or a reduction in compressive strength of mortar of more than 5%, compared with results obtained with distilled water, as determined in accordance with ASTM C109 (using 2 inch cube specimens).

3.8.6.1.1.5 Admixtures

Air entraining admixtures conform to ASTM C260. Water reducing and retarding admixtures conform to ASTM C494, Type A and/or D. Types A and D are used in accordance with the manufacturer's recommendations. Certificates stating conformance to the applicable ASTM specification are furnished with each shipment. The use of any other admixture is not permitted.

3.8.6.1.2 Concrete Mix Design

3.8.6.1.2.1 Concrete Properties

Concrete properties required for each type of mix design are verified by testing for the applicable properties indicated below:

Property	Test Designation
Compressive strength	ASTM C39
Unit weight	ASTM C138
Slump	ASTM C143
Air content	ASTM C231

Samples for property testing are taken in accordance with ASTM C172.

The following additional properties of selected mix designs have been determined to ascertain material compatibility with design assumptions:

Property	Test Designation
Modulus of elasticity	ASTM C469
Poisson's ratio	ASTM C469
Thermal diffusivity	CRD C36
Thermal coefficient of expansion	CRD C39

3.8.6.1.2.2 Concrete Mix Proportions

Concrete mix designs are prepared in accordance with paragraphs 4.2.2.2 and 4.2.3 of ACI 318-71. Trial batches are prepared in accordance with ACI 613-54.

Four compressive strength cylinders are cast at each time of sampling for all normal density concrete. Two of these cylinders are tested at 7 days. The two remaining cylinders are tested at 28 days for concrete with a design strength of 4000 psi or less and at 90 days for concrete with a design strength of 5000 psi. For high density concrete, three compressive strength cylinders are cast at each time of sampling; one is tested at 7 days, and the other two are tested at 28 days.

Concrete design strengths for the various structures are in accordance with the following table:

Item	Strength (psi)
Fuel pool girders, critically stressed walls in the reactor enclosure	5000
Reactor enclosure, primary containment, control structure, spray pond pump structures, diesel generator enclosure, radwaste enclosure, cooling towers, turbine enclosure foundation and walls below el 217'	4000
All other structural concrete	3000
Mass concrete fill	2000

The total air content of the concrete, except for grout, varies with the concrete mix and aggregate size as follows:

Concrete mixes with a 1 inch maximum aggregate size (except for D-1 (5000 psi) concrete mix) have a total air content of not less than 4%, nor more than 7% of the concrete volume.

D-1 (5000 psi) concrete mix with a 1 inch maximum aggregate size has a total air content of not less than 4%, nor more than 6% of the concrete volume for onsite concrete, 7% for offsite concrete.

Concrete mixes with a maximum aggregate size of 1½ inches have a total air content of not less than 3%, nor more than 6% of the concrete volume.

Testing for air content is in accordance with ASTM C231.

In lieu of establishing limits on the water-cement ratio, the concrete is proportioned, mixed, and placed at specified slumps. The average slump at the point of placement is less than the "working limit", which is the maximum slump for estimating the quantity of mixing water used in the concrete. An "inadvertency margin" is the allowable deviation from the "working limit" for those occasional batches which may inadvertently exceed the "working limit." Job-site tests indicate that concrete with slumps at the "inadvertency margin" produce acceptable quality concrete.

3.8.6.1.3 Grout

3.8.6.1.3.1 Construction Grout

Construction grout for use at horizontal construction joints and similar applications is proportioned from the same materials as for concrete. Such grouts have a sand/cement ratio comparable to the concrete with which it is to be used. Grout strength is determined in accordance with ASTM C109.

3.8.6.1.3.2 Starter Mix

Starter mixes are used in applications, such as at the bottom of foundation slabs, and in lieu of construction grout. They are defined as concrete with a 1 inch maximum size aggregate, with a slump between 3 inches and 5 inches.

3.8.6.1.3.3 Nonshrink Grout

Nonshrink grout is prepared from proprietary materials such as Embeco 636 by Master Builders Company, or Five Star Grout by US Grout Corporation. Such grouts are proportioned in accordance with the manufacturer's recommendations, and are tested prior to use for expansion, compressive strength, and flow characteristics, with maximum water content recommended by the manufacturer.

3.8.6.1.4 Batching, Placing, Curing, and Protection

3.8.6.1.4.1 Storage

Storage of aggregates, cement, and admixtures is in accordance with the recommendations of ACI 614-59.

3.8.6.1.4.2 Batching, Mixing, and Delivering

Concrete for principal structures is provided as central mixed concrete from an onsite batch plant, or as truck mixed concrete from an offsite plant after June 1983. Concrete blockout grout, however, may be batched by volume and provided from a mortar mixer. Batch plant facilities are certified by the National Ready Mix Concrete Association. Measuring devices are calibrated at required intervals, and more frequently where deemed appropriate.

The measuring of materials, batching, mixing, and delivery of all concrete conforms to ASTM C94, except as otherwise noted.

3.8.6.1.4.3 Placing

Placing of concrete is in accordance with the recommendations of ACI 301-66, ACI 306-66, ACI 318-71, ACI 605-59, and ACI 614-59.

3.8.6.1.4.4 Consolidation

Consolidation of concrete is in accordance with the recommendations of ACI 614-59, and as specified below.

Concrete is placed with the aid of mechanical vibrating equipment, and supplemental hand spading and tamping. The vibrating equipment is of the internal type, with a minimum frequency of 7000 revolutions per minute.

Surface vibrators, or manual jitterbugs are permitted to consolidate concrete in slabs 8 inches thick or less.

3.8.6.1.4.5 Curing

Curing of concrete is in accordance with the recommendations of ACI 301-66, ACI 306-66, ACI 318-71, and ACI 605-59.

3.8.6.1.4.6 Hot and Cold Weather Concreting

Methods and means of placing and curing concrete in cold and hot weather comply with the recommended practices of ACI 306-66 and ACI 605-59, respectively.

3.8.6.1.5 Construction Testing of Concrete and Concrete Materials

A concrete and concrete materials testing laboratory operated by Bechtel QC personnel is established at the project site to monitor the quality of such work and materials, and to promptly report any deviations from specified conditions. Such testing personnel are qualified to meet the guidelines of Regulatory Guide 1.58. Qualifications and procedures in use by Bechtel QC personnel conform with Regulatory Guide 1.94. During operation, if repairs to concrete or concrete materials are required, the Company and contractor personnel performing NDE are trained, tested, qualified, or certified in accordance with a company procedure that meets applicable requirements of 10 CFR 50.55a and ASME Section XI with specific exceptions and clarifications as discussed in the QATR.

Production testing for concrete and concrete materials is as shown in Table 3.8-12. Production testing for concrete conforms with Regulatory Guide 1.94, with the following clarification.

For central mixed concrete, samples for concrete cylinder strength and unit weight tests are taken at the point of discharge from the central mixing plant. The concrete temperature is taken at the point of discharge from the central mixer when obtaining compressive strength samples. In addition, for each load of concrete represented by compressive strength samples, the concrete temperature is taken at the point of discharge from the delivery trucks, or at the end of the pump line for pumped concrete. For truck mixed concrete furnished from an offsite source, samples for concrete cylinder strength and unit weight tests, together with temperature readings, are taken at the point of discharge from the delivery truck or at the end of the pump line for pumped concrete. Materials that do not meet test requirements are not used in the construction.

Concrete cylinder test results are reviewed for compliance with section 4.3.3 of ACI 318-71, and are evaluated in accordance with ACI 214-65. Materials or portions thereof that do not meet the above criteria, but may inadvertently be used are handled as described in the document "Limerick Generating Station Units 1 and 2; Summary Description of the Quality Assurance Program for Design and Construction," referenced in FSAR Section 17.1.

3.8.6.2 Concrete Reinforcement Materials

3.8.6.2.1 Qualification

Reinforcing steel for concrete structures conforms to ASTM A615, Grade 60, including section S1 for bar sizes 14 and 18. Certified copies of material test reports indicating chemical composition, physical properties, and dimensional compliance are furnished by the manufacturer for each heat. Spiral reinforcing steel is plain wire conforming to ASTM A82.

Prior to installation at the job-site, all reinforcing steel is subjected to a testing program meeting the guidelines of Regulatory Guide 1.15. Any reinforcing steel which does not meet these requirements is not used in the construction.

Sleeves for reinforcing steel mechanical splices conform to ASTM A519 for Grades 1018 and 1026. Certified copies of material test reports indicating chemical composition and physical properties are furnished by the manufacturer for each sleeve lot.

3.8.6.2.2 Fabrication

3.8.6.2.2.1 Bending of Reinforcement

Hooks and bends are fabricated in accordance with ACI 318-71, section 7.1. Bars partially embedded in concrete are bent subject to the following conditions:

a. Bending Partially Embedded Reinforcement

Bending of reinforcement partially embedded in concrete is performed in accordance with the following description. The diameter of the bend measured on the inside of the bar, and the distance between the beginning of the bend and the existing concrete surface is not less than "D", shown below:

Bar Size	"D"
Nos. 3 through 8	6 bar diameters
Nos. 9, 10, and 11	8 bar diameters
Nos. 14S and 18S	10 bar diameters

Bar Nos. 3 to 5 inclusive may be bent once, and straightened once, cold.

Bar Nos. 6 to 9 inclusive may be bent once, and subsequently straightened. Heating is required for both bending and straightening, as described below.

However, when the bending does not exceed 30°, bar Nos. 6 to 9 *inclusive may be bent once, and straightened once, cold.

When only cold bending is applied, the distance between the beginning of the bend and the existing concrete may be decreased to a minimum of 0.5 "D" as shown above.

When heat is used, it is applied as uniformly as possible over a length of bar equal to 10 bar diameters, and is centered at the middle of the arc of the completed bend. The maximum bar temperature is between 1100°F and 1200°F, and is maintained at that level until bending (or straightening) is complete.

Temperature-measuring crayons, or a contact pyrometer is used to determine the temperature. Heat is applied with care so as to avoid damage to the concrete. Care is taken to prevent rapid quenching of heated bars.

The bars, which are heated for straightening and bending, are visually inspected to determine whether they are cracked, reduced in cross-section, or otherwise damaged. Any damaged portions are removed and replaced.

3.8.6.2.2.2 Splicing of Reinforcement

Lap Splices

In general, lapped splices are used for No. 11 and smaller bars. Such lap splices are in accordance with sections 7.5, 7.6, and 7.7 of ACI 318-71.

Mechanical Splices

Cadweld splices conform with Regulatory Guide 1.10, except for the alternate approaches to tensile testing frequency, and the procedure for substandard tensile test results, discussed below.

Cadweld splices are used most frequently for Nos. 14 and 18 main bars in the category I concrete structures. Cadweld splices are used most frequently for Nos. 14 and 18 main bars in other Category I concrete structures. Most completed splices are visually inspected for the presence of slag, excessive porosity, or voids in the filler metal, and for proper alignment and centering of the reinforcing bar. However, there are some instances where longitudinal centering of the splice sleeve on the splice ends is off center, and probing for voids in the filler metal cannot be performed due to interferences. In these instances, a test program simulating these conditions is performed. The test results conform with the tensile strength guidelines of Regulatory Guide 1.10.

For purposes of quality control, splices representing the work of each splicing crew are tensile tested for each position, bar size, and series (T or B). Bar-to-bar splices are designated as T-series splices. Bar-to-embedment splices are designated as B-series splices.

A crew is defined as the unique combination of persons preparing, assembling, and igniting the splice. Each unique combination of persons on a crew is considered as a separate crew. In the event that one or more members of the crew is unavailable for completing a production splice lot, or performing a sister splice, the remaining member or members of the crew complete the production splice lot, or perform the sister splice. For purposes of the tensile testing program, the remaining member or members are considered as comprising the crew.

A T-series "sister splice" consists of two 14 inch (+1 inch) bars spliced in sequence with, at the same location, under the same condition, and in an otherwise identical manner as the corresponding production splice. Straight sister splice samples are taken in lieu of production splice test samples for curved reinforcing bars, and for the splices in locations outside the primary containment where space limitations prohibit taking production splice test samples.

A B-series "sister splice" is made in the configuration shown on the design drawings, and is spliced in sequence with, at the same location, under the same condition, and in an otherwise identical manner as the corresponding production splice.

The number and frequency of Cadweld splice tensile tests performed by each crew for each position, bar size, and series are as follows:

a. One sister splice is tested, prior to the start of any production splicing. Qualification splices meet this requirement if performed by each member of the crew within the previous three calendar days, and the crew has made no production splices with visual defects or which fail tensile testing since making the qualification splices.

   Deviation from this criteria was allowed in some cases for the Cadweld splice installation. This deviating condition was documented in nonconformance report NCR#14244. The Cadweld splices installed without prior sister splice testing are acceptable per engineering review documented in the nonconformance report. The omission of sister splice testing prior to production splicing does not affect the performance safety-related structures because LGS meets the intent of Regulatory Guide 1.10. For the Cadweld installation without prior sister splice testing, the test frequency as stated in paragraph (b) below was implemented and completed satisfactorily. Therefore, the satisfactory completion of the testing frequency of paragraph (b) in conjunction with the crew qualification requirements, and the visual inspection requirement for production splices, combined to assure that the level of safety required for mechanical splices discussed in Regulatory Guide 1.10 is provided.

b. One test sample out of each lot of 25 consecutive production splices is tested, including the first group of 25.

   For T-series splices, each consecutive group of three such samples consists of one production splice and two sister splices. All test samples are sister splices for the B-series splices, and for splices of No. 18 bars to square Cadweld bars of the flange skirt assembly.

   Production splice test samples are selected at random by the inspector from any within the lot of 25 splices represented. Sister splice samples are made upon completion of the lot of 25 production splices. Horizontal sister splices are side or top filled to conform to the fill location of the majority of the splices.

   If fewer than a complete lot of 25 splices are made prior to the date of a concrete placement containing any of the splices in the incomplete lot, the test splices for that lot are made prior to the placement to determine the acceptability of the splices in that lot, and the lot is then treated as a complete lot.

Welded Splices

Whenever both lap and mechanical splices have been determined to be impractical, welded splices are used on a case-by-case approval basis. Such welding is performed by qualified welders using a procedure conforming to the basic recommendations of AWS D12.1.

3.8.6.2.2.3 Placing of Reinforcement

Reinforcement is securely tied with wire, and held in position by spacers, chairs, and other supports to maintain placement accuracy within the tolerances established for reinforcement protection, and the design requirements.

3.8.6.2.2.4 Spacing of Reinforcement

Spacing of reinforcement is in accordance with ACI 318-71.

3.8.6.2.2.5 Surface Condition of Reinforcement

Reinforcement surface conditions at the time of concrete placement are in compliance with section 7.2 of ACI 318-71.

3.8.6.2.3 Construction Testing of Concrete Reinforcement Materials

Inspection of reinforcement materials to ensure that bending, placing, splicing, spacing, and surface condition requirements are met is in accordance with Regulatory Guide 1.94, except as described in Section 3.8.6.2.2.2.

3.8.6.2.4 Formwork and Construction Joints

Formwork is constructed in accordance with the applicable provisions of ACI 347-68, so that the finished concrete surfaces do not exceed the tolerances of ACI 347-68.

Construction joints are made in accordance with ACI 301-66, ACI 318-71, and ACI 614-59. In addition, all horizontal construction joints are covered, immediately before the concrete is placed, with a nominal ½ inch of flowable grout mix, or a nominal ¾ inch of starter mix.

Concrete is placed in accordance with Regulatory Guide 1.55, except as discussed below.

Regulatory positions 2 and 3 of the Regulatory Guide state the presumed functional responsibilities of the "designer" and the "constructor." Under the designer's role, are listed the responsibilities for checking shop drawings and locations of construction joints. On this project, the former responsibility is fully delegated to the Bechtel field, although the design engineering office may check significant portions, and may advise the field accordingly. The responsibility for construction joint location is partly delegated to the field, in the sense that the field has to follow the guidelines set out in the design drawings and specifications prepared by the design engineering office.
Also, Regulatory Guide 1.55 references ACI 301-72 and ACI 305-72. However, concrete at LGS is placed in accordance with ACI 301-66 and ACI 605-59 respectively.

3.8.6.3 Prestressed Concrete

3.8.6.3.1 Post-Tensioning System for Prestressed Concrete

The post-tensioning system used for prestressed concrete is the VSL E5-55 post-tensioning system, described in the 1976 Edition of the Post-Tensioning Manual, published by the Post-Tensioning Institute.

3.8.6.3.2 Concrete for Prestressed Members

The concrete used for prestressed members is a 5000 psi concrete, designed and tested in accordance with Section 3.8.6.1.

3.8.6.3.3 Prestressing Steel

Prestressing steel consists of 7 wire, stress-relieved prestressing strands meeting the requirements of ASTM A416, and having a guaranteed minimum ultimate tensile strength of 270 ksi. Stress relaxation tests in accordance with ASTM E328 are also performed. The tests are performed for each 50 tons of a heat or fraction thereof. Any prestressing steel which does not meet the test requirements is not used in the construction.

3.8.6.3.4 Sheathing

Sheathing is spiral-wrapped, semirigid corrugated tubing, fabricated from a galvanized sheet, 24 gauge minimum split strip of lock-forming quality. The sheathing meets the requirements of ASTM A527, Coating Designation G90. It is not chemically treated, or oiled.

3.8.6.3.5 Anchorage Assembly

The anchorage assembly is the system of components consisting of the anchor head, wedge, bearing plate, and trumpet. The anchor head, wedge, and bearing plate materials meet the requirements of AISI 1026, AISI 86L20, and ASTM A537, respectively. After fabrication, bearing plates are galvanized in accordance with ASTM A123. Trumpets are fabricated from galvanized sheet meeting the requirements of ASTM A569.

3.8.6.3.6 Grout

The prestressing steel is bonded to the concrete by completely filling the entire void space between the sheathing and the tendon with grout. The grout consists of a mixture of Portland-cement, water, and admixture. The cement and water used to make the grout meet the testing requirements stipulated in Section 3.8.6.1. The grout is designed to have a minimum 7 day compressive strength of 2500 psi, in accordance with ASTM C109, and a minimum 28 day compressive strength of 3500 psi, in accordance with U.S. Army Corps of Engineers CRD-C589. Three samples for each test are taken each day grouting is performed for every 5 cubic yards, or fraction thereof produced.

3.8.6.3.7 Post-Tensioning System Performance Tests

Prior to actual post-tensioning operations, the post-tensioning system is subjected to static and dynamic tests in accordance with the recommendations of section 3.1.8 of the 1976 Edition of the Post-Tensioning Manual, published by the Post-Tensioning Institute.

3.8.6.4 Concrete Unit Masonry and Masonry Material

3.8.6.4.1 Material Qualification

3.8.6.4.1.1 Concrete Unit Masonry and Building Brick

Concrete unit masonry conforms to either ASTM C90, Type I, Grade N for hollow masonry units, or ASTM C145, Type I, Grade N for solid masonry units. Concrete building brick conforms to ASTM C55, Type I, Grade N. Certified test reports are prepared for each material.

3.8.6.4.1.2 Masonry Mortar

Masonry mortar conforms to ASTM C476, Type PL.

3.8.6.4.1.3 Masonry Grout

The three types of masonry grout described below have been used for filling cavities in masonry.

a. Chemtree Grout

Chemtree grout is a premixed grout manufactured by Chemtree Corporation. It has a minimum plastic unit weight of 206 lb/ft^3, and a minimum compressive strength of 1500 psi. Tests for unit weight and compressive strength are in accordance with Section 3.8.6.1.2.1.

Chemtree grout is used to fill the cavity and cells of a small number of multiple wythe walls in the radwaste enclosure and in the auxiliary bay portion of the turbine enclosure.

b. 2000 psi Masonry Grout

The second masonry grout used for filling cavities in masonry is a 2000 psi grout designed and tested in accordance with Section 3.8.6.1, as modified below:

1. Aggregate

Coarse and fine aggregate are combined as a single aggregate, graded to produce a workable mix that meets all shielding requirements.

2. User Tests

The following user tests are performed every 6 months during production:

Test	Designation
Potential Reactivity of Aggregates	ASTM C289
Specific Gravity and Absorption of Fine Aggregate	ASTM C128

Soundness of Aggregates by Use of Sodium Sulfate or Magnesium Sulfate	ASTM C88
Materials Finer than No. 200 Sieve in Mineral Aggregates by Washing	ASTM C117
Organic Impurities in Sand for Concrete	ASTM C40

3. Compressive Strength, Unit Weight, and Slump

   Three compressive strength cylinders are cast. One cylinder is tested at 7 days, and two are tested at 28 days. The minimum compressive strength, determined at 28 days, is 2000 psi.

   The minimum plastic unit weight for the masonry grout is 152 lb/ft^3.

   The masonry grout is allowed a slump of 9 inches ±1 inch.

c. 2000 psi Masonry Grout Using High Density Aggregates

   The third masonry grout used for filling cavities is a 2000 psi grout using high density and normal weight aggregates, designed and tested in accordance with Section 3.8.6.1, as modified below:

   1. Aggregate

      Normal weight and high density fine aggregate are used to produce a workable mix that meets all shielding requirements.

   2. User tests

      The user tests for normal weight fine aggregate are defined in Section 3.8.6.1.1.2. The user tests for high density fine aggregate are defined in Section 3.8.6.1.1.3

   3. Compressive Strength, Unit Weight, and Slump

      These requirements are the same as those discussed in Section 3.8.6.4.1.3.b.3

3.8.6.4.1.4 Concrete Infill

Concrete infill is used as an alternative to masonry grout for filling cavities in masonry. Concrete infill conforms to the requirements described in Section 3.8.6.1.

3.8.6.4.1.5 Steel Reinforcement

Steel reinforcement conforms to the requirements described in Section 3.8.6.2.

3.8.6.4.2 Construction Testing

Testing to monitor the quality of masonry work and masonry materials is in accordance with the program described in the document "Limerick Generating Station Units 1 and 2; Summary Description of the Quality Assurance Program for Design and Construction," referenced in FSAR Section 17.1.

Test frequency during the construction of concrete unit masonry is as shown in Table 3.8-12.

Materials that are inadvertently used in the construction, but do not meet test requirements, are handled as described in the document "Limerick Generating Station Units 1 and 2; Summary Description of the Quality Assurance Program for Design and Construction," referenced in FSAR Section 17.1.

3.8.7 COMPUTER PROGRAMS FOR STRUCTURAL ANALYSIS

This section describes the computer programs used for the structural analysis of all seismic Category I structures. Each program description includes a statement of the program's area of application, and a discussion of the modifications and assumptions made. In addition, the descriptions of the computer programs not in the public domain include a selection of the sample problems used to verify their solution accuracy.

3.8.7.1 3D/SAP (Finite-Element Analysis of Three-Dimensional Elastic Solids)

3.8.7.1.1 Application

Finite-element structural analysis program 3D/SAP is capable of performing static analyses of three-dimensional solid structures subjected to concentrated or distributed loadings, thermal expansion, and/or arbitrarily directed static body forces. It is a modern version of SAP (Reference 3.8-4) written as a general purpose structural analysis computer program.

3.8.7.1.2 Program Background

Program 3D/SAP was developed by the Control Data Corporation, and is in the public domain.

3.8.7.2 ASHSD (Axisymmetric Shell and Solid)

3.8.7.2.1 Application

ASHSD is a special purpose program which can be used in the elastic, static, or dynamic analysis of structural systems capable of being represented as axisymmetric shells and/or solids.

This program allows a useful study of the interaction between a typical nuclear containment structure, modeled as an axisymmetric shell, and the subsoil, modeled as an axisymmetric solid.

3.8.7.2.2 Program Background

This program is a refinement of the original ASHSD code developed at the University of California at Berkeley. The present program is highly modified for the special purpose of static and dynamic analysis of nuclear containment structures. The modified program has the following features:

a. The code has a shell finite-element which uses an interaction stiffness, allowing analysis of layered shells.

b. Since shell layers may be bonded or unbonded from each other, it is possible to describe concrete shells in their actual geometric form. For example, it is possible to describe liner plate, concrete, reinforcing steel, and post-tensioning steel in their real spatial locations.

c. Post-tension forces may be applied to the shell by subjecting only the unbonded post-tensioning elements to a pseudothermal loading.

d. Isotropic or orthotropic elastic constants are possible for both shell and solid elements. The orthotropic material properties may be used to describe the different stiffness of reinforcing steel in the hoop and meridional directions, for example.

e. Nonuniform thermal gradients through the wall thickness may be imposed.

f. Eigenvalues and eigenvectors may be computed by the program.

g. Three dynamic response routines are available in the program. They are:

    1. Arbitrary dynamic loading, or earthquake-based excitation using an uncoupled (modal) technique.

    2. Arbitrary dynamic loading, or earthquake-based excitation using a coupled (direct integration) technique.

    3. Response spectrum modal analysis for ABS and SRSS displacements and element stresses.

h. The coupled time history solution has the capability to allow an arbitrary damping matrix.

i. The stiffness and mass matrices may be obtained as punched output for input into other programs.

The version of this program currently used by Bechtel is maintained by the Control Data Corporation.

3.8.7.2.3 Sample Problems

This program is verified by comparing the computer results with hand-calculated solutions and published references. Three sample problems are presented as examples of verification.

a. Sample Problem A: Closed Cylinder Under Internal Pressure

This problem demonstrates the membrane state of stress in a closed cylinder subjected to a uniformly distributed internal pressure. Hand calculations are used to verify this aspect of the program.

The selected problem is a cylinder with closed ends subjected to internal pressure. Only one-half of the cylinder is required in the model because of symmetry. Furthermore, it is assumed that the closed ends are distant from the section being analyzed, and they are therefore excluded.

Two models of the cylinder are actually analyzed. One model uses the thin-shell elements, and the other uses the axisymmetric solid elements. These models are shown in Figures 3.8-65 and 3.8-66 with their key dimensions.

The problem parameters for both test cases are as follows:

Boundary Conditions

Node 1: Z displacement = 0
θ displacement = 0
Rotation in R-Z plane = 0
(free to move radially)

Node 16: θ displacement = 0
(free to move axially, radially, and to rotate about the θ axis)

Numerical Data

Material: concrete

Modulus of elasticity (E) = 4.031×10^6 psi

Thickness (t) = 36 inches

Radius (R) = 900 inches

Poisson's ratio (ν) = 0.17

Pressure (p) = 60 psi

Length (L) = 1800 inches

N = 27,000 lb/in (an equivalent node load applied at Node 16)

The theoretical values for the membrane force resultants are calculated to be pR/2 (= 27,000 lb/in) axial force, and pR (= 54,000 lb/in) for the circumferential force (hoop stress).

The results obtained from the ASHSD program are presented in Table 3.8-13, both for the thin-shell and the layered shell models. Analytical computations indicate

maximum errors at Node 16 of 0.4% for the longitudinal force and 3.2% for the circumferential force.

b. Sample Problem B: Cylindrical Shell Subjected to Internal Pressure and Uniform Temperature Rise

This test example demonstrates the use of a combined static load and thermal load condition. A short circular cylindrical shell clamped at both ends is subjected to an internal pressure and a uniform temperature rise.

The theoretical solutions given in Reference 3.8-4 are used to verify this analysis.

The general arrangement of the cylinder is shown in Figure 3.8-67. Only one-half of the cylinder is used for the finite-element model because of symmetry. This is shown in Figure 3.8-68, with Node 1 located at the middle of the cylinder.

The problem parameters are as follows:

Boundary Conditions

At center of cylinder,
Node 1:
Z displacement = 0
θ displacement = 0
Rotation in the R-Z plane = 0

At end of cylinder,
Node 26:
R displacement = 0
Z displacement = 0
θ displacement = 0 (tangential)
Rotation in the R-Z plane = 0

Numerical Data

Material: concrete

Modulus of elasticity (E) = 4.031×10^6 psi

Poisson's ratio (υ) = 0.17

Thermal coefficient of expansion (α) = 55×10^{-7} in/in/°F

Thickness (t) = 30 inches

Radius (R) = 600 inches

Length (L) = 1200 inches

Height (Z) = 600 inches

Pressure (p) = 60 psi

Temperature (T) = 150°F

R/t = 20

L/R = 2

The theoretical results are shown in Figure 3.8-69. These values are obtained by using the following equations from Reference 3.8-4:

Axial Moment: $M_x = 2\mu^2 D_x \left(\frac{PR^2}{Et} + R\alpha T\right)$ (EQ. 3.8-1)

where:

$$\mu^2 = \left[\frac{3(1-\upsilon^2)}{R^2t^2}\right]$$

$$D_x = \frac{Et^3}{12(1-\upsilon^2)}$$

Normalized length: Ln = (Z/R)(L/2R)

Figure 3.8-69 compares the results obtained from the ASHSD program and the theoretical solution. The results of ASHSD agree well with those of the reference.

c. Sample Problem C: Asymmetric Bending of a Cylindrical Shell

This sample problem illustrates the use of higher harmonics for asymmetric loading cases. As a comparison to the computer output, results for this problem are taken from Reference 3.8-5.

The cylindrical shell analyzed is a short, wide cylinder as shown in Figure 3.8-70. The finite-element idealization of the cylinder and the pertinent data are illustrated in Figure 3.8-71. At each end of the cylinder, moments of the form $M = M_o \cos\eta\theta$ were input for harmonics η = 0, 2, 5, 20.

The problem parameters are:

Material: steel

Modulus of elasticity (E) = 29×10^6 psi

Thickness (t) = 1.25 inches

Radius (R) = 60.0 inches

Poisson's ratio (υ) = 0.3

Length (L) = 60.0 inches

L/R = 1

R/t = 48

$$M_o = \frac{Et^2}{100(1-\upsilon^2)} = 497939.56 \text{ in-lb/in} \quad \text{(EQ. 3.8-2)}$$

The comparison results are taken directly from Reference 3.8-5. Those results are plotted in Figure 3.8-72.

The comparison of the computer results to the reference results are shown in Figure 3.8-72. (Note that the longitudinal moments and radial displacements are expressed as nondimensional ratios).

The reference and computer program results show good agreement. This verifies the accuracy of the program for this type of analysis.

3.8.7.3 CECAP (Concrete Element Cracking Analysis Program)

3.8.7.3.1 Application

CECAP computes stresses in a concrete element under thermal and/or nonthermal (real) loads, considering effects of concrete cracking. The element represents a section of a concrete shell or slab, and may include two layers of reinforcing, transverse reinforcing, prestressing tendons, and a liner plate.

The program outputs stresses and strains at selected locations in the concrete, reinforcement, tendons, and liner plate, and resultant forces and moments for the composite concrete element.

3.8.7.3.2 Program Background

CECAP assumes linear stress-strain relationships for steel and for concrete in compression. Concrete is assumed to have no tensile strength. The solution is an iterative process, whereby tensile stresses found initially in concrete are relieved (by cracking) and redistributed in the element. The equilibrium of nonthermal loads is preserved. For thermal effects, the element is assumed free to expand inplane, but is fixed against rotation. The capability for expansion and cracking generally results in a reduction in thermal-stresses from the initial condition.

The version of this program currently used by Bechtel is maintained by the Control Data Corporation.

3.8.7.3.3 Sample Problems

Sample problems are analyzed by CECAP and compared with hand-calculated solutions. These sample problems consider a reinforced concrete beam as shown in Figure 3.8-73. The parameters for all sample problems are as follows:

Modulus of elasticity of concrete (E_c) = 3×10^6 psi

Modulus of elasticity of reinforcing steel (E_s) = 30×10^6 psi

Poisson's ratio for concrete (υ_c) = 0.22

Coefficient of thermal expansion of concrete
(α_c) = 6×10^{-6} in/in/°F

Temperature difference (ΔT) = 100°F

Coefficient of thermal expansion of reinforcing steel
(α_r) = α_c

Three sample problems are presented as examples of verification.

a. Sample Problem A: Beam with a Thermal Moment

The analysis of a reinforced concrete beam subjected to a linear thermal gradient is performed to test the redistribution of thermal-stresses due to the relieving effect of concrete cracking.

Figure 3.8-74 shows the reinforced concrete beam, and the corresponding CECAP concrete element used in the analysis. Boundary conditions, geometry, and applied loads are illustrated.

The following illustrates how thermal loads are treated in a cracked section analysis of a reinforced concrete beam. The main assumptions pertaining to thermal boundary conditions are:

1. The beam is allowed to freely expand axially.

2. There is no rotation of the initial thermal-stress slope.

The beam cross-section and initial thermal-stress distribution are shown in Figure 3.8-75. For ΔT = 100°F, the equivalent thermal moment and thermal-stresses in concrete and steel are:

Thermal moment (M) = $\Delta T \alpha_c E_c b t^2/12$ (EQ. 3.8-3)
= 3,175,000 in-lbs

Concrete stress (σ_c) = $\Delta T \alpha_c E_c/2$ (EQ. 3.8-4)
= 900 psi (compression)

Rebar stress (σ'_c) = $\frac{(t/2-2)}{t/2}\sigma_c$ (EQ. 3.8-5)
= 814 psi (tension)

where:

b = width of beam = 12 inches

t = depth of beam = 42 inches

E_c = modulus of elasticity = 3×10^6 psi

α_c = coefficient of linear expansion for concrete
= 6×10^{-6} in/in/°F

The stress diagram used for the cracked section analysis with thermal loading is shown in Figure 3.8-76. The assumptions of free movement axially and constant thermal-stress slope are maintained by a lateral translation of the initial reference axis to a final cracked position.

From force equilibrium:

$$F_{rebar} + F_{concrete} = 0 \qquad \text{(EQ. 3.8-6)}$$

where:

$F_{rebar} = f_s$ = total stress in steel

$= 1.0\ (814 + \Delta\sigma_c)\ 10$ psi

$F_{concrete} = f_c$ = total stress in concrete

$$= -900\left(\frac{42}{2}\right)\left(\frac{12}{2}\right) + \frac{\Delta\sigma_c\,(12)}{2}\left[21 + \left(\frac{900-\Delta\sigma_c}{900}\right)2\right]$$

Solving for $\Delta\sigma_c$:

$\Delta\sigma_c = 582$ psi

From above, the rebar and concrete stresses are:

$f_s = (814+582)10 = 13{,}970$ psi (tension)

$f_c = 900-582 = 318$ psi (compression)

The location of the cracked neutral axis is:

$$kd = x = \frac{900-582}{900}\ (21) = 7.42 \text{ in} \qquad \text{(EQ. 3.8-7)}$$

The self-relieved thermal moment is:

$$M_T = \frac{f_s A_s (d - x/3)}{12} = 43{,}690 \text{ in-lb} \qquad \text{(EQ. 3.8-8)}$$

The rebar and concrete stresses, self-relieved thermal moment, and neutral axis location obtained from the CECAP program are compared with the hand calculations in Table 3.8-14. It can be seen that the CECAP results compare favorably with the hand calculation.

b. Sample Problem B: Beam with a Real Moment

The analysis of a reinforced concrete beam subjected to a real moment tests the CECAP program for nonthermal moments.

Figure 3.8-77 shows the loading and geometry for the reinforced concrete beam, and the corresponding CECAP concrete element model.

The following illustrates the working stress analysis of reinforced concrete beams. The beam cross-section, stress block, and transformed sections are shown in Figure 3.8-78. The resultant forces and moment are:

$$C = f_c\,(kd)(b)/2 \qquad \text{(EQ. 3.8-9)}$$

$$T = A_s(f_s) \qquad \text{(EQ. 3.8-10)}$$

$$M = Cjd = Tjd \qquad \text{(EQ. 3.8-11)}$$

Equating the first moments of the compression and tension areas about the neutral axis of the transformed section,

$$kd(b)\left(\frac{kd}{2}\right) = nA_s\,(d - kd) \qquad \text{(EQ. 3.8-12)}$$

where:

$$n = E_s/E_c = 10.0$$

which yields:

$$(kd)^2 + 1.67kd - 66.67 = 0$$

Solving for kd:

$$kd = 7.37 \text{ in}$$

For an applied moment (m) of 3,175,000 in-lbs, the resultant forces are:

$$C = T = \frac{M}{jd} = \frac{3{,}175{,}000}{(40 - \frac{7.37}{3})} = 84{,}570 \text{ lb} \qquad \text{(EQ. 3.8-13)}$$

Rebar and concrete stresses, respectively, are:

$$f_s = \frac{T}{A_s} = 84{,}570 \text{ psi (tension)} \qquad \text{(EQ. 3.8-14)}$$

$$f_c = \frac{2C}{kd(b)} = \frac{2(84{,}570)}{(7.37)(12)} \qquad \text{(EQ. 3.8-15)}$$

$$= 1193 \text{ psi (compression)}$$

Table 3.8-14 shows a comparison of rebar and concrete stresses, and neutral axis locations obtained from the CECAP program and hand calculations. The CECAP results are shown to compare to hand calculations within the force accuracy limits in the program.

c. Sample Problem C: Beam with a Real Moment and a Real Axial Load

This sample problem involves the analysis of a reinforced concrete beam subjected to both a real moment, and a real axial compressive load.

The loading and geometry for the reinforced concrete beam and corresponding CECAP model are illustrated in Figure 3.8-79.

The following illustrates the working stress analysis of reinforced concrete beams subjected to both moments and axial compressive loads. The beam cross-section and stress block are shown in Figure 3.8-80. The analysis uses the equations presented in Reference 3.8-7, simplified as follows:

$$(kd)^3 + 3\left[\frac{M}{N} - \frac{t}{2}\right](kd)^2 + \frac{6nA_s}{b}\left[d - \frac{t}{2} + \frac{M}{N}\right](kd) - \frac{6nA_s d}{b}\left[d - \frac{t}{2} + \frac{M}{N}\right] = 0 \qquad \text{(EQ. 3.8-16)}$$

$$f = \frac{N}{A_s}\left[\frac{M}{N} + \frac{kd}{3} - \frac{t}{2}\right] \Big/ \left[d - \frac{kd}{3}\right] \qquad \text{(EQ. 3.8-17)}$$

$$f = \frac{f_s kd}{n(d - kd)} \quad \text{for } \frac{M}{N} \geq t/6 \qquad \text{(EQ. 3.8-18)}$$

where:

M = moment = 375,000 in-lbs

N = axial load = 101,000 lbs

t = depth of beam = 42 inches

b = width of beam = 12 inches

Equation 3.8-16 becomes:

$kd^3 + 55.8kd^2 + 293kd - 11720 = 0$

$M/N = \frac{3{,}175{,}000}{101{,}000} = 31.4 \geq t/6 = \frac{42}{6} = 7$

Solving the above by iteration for (kd) yields:

kd = 12.7 in

The resulting rebar and steel stresses are:

f_s = 41,320 psi (tension)

f_c = 1922 psi (compression)

The rebar and concrete stresses, and neutral axis location obtained from the CECAP program are compared with the hand calculations in Table 3.8-14. The results for the two solution methods agree very closely.

3.8.7.4 CE668 (Plate Bending Analysis)

3.8.7.4.1 Application

This program performs the linear-elastic analysis of a plate with arbitrary shape and support, stiffener beams, and elastic subgrade, under loads normal to the middle plane of the plate.

3.8.7.4.2 Sample Problems

Sample problems were analyzed by CE668, and compared with hand-calculated solutions.

a. Sample Problem A: Rectangular Plate with a Concentrated Load at the Center

The simply supported rectangular plate, shown in Figure 3.8-81, is subjected to a concentrated load of 300 pounds at its center. Only one-half of the plate is modeled by finite-elements, because of symmetry. The boundary conditions are zero-displacement with free normal rotation at the simply supported edges, and free displacement with zero normal rotation at the symmetry axis. The plate has isotropic structural properties.

The problem parameters are:

Poisson's ratio (υ) = 0.3

Modulus of elasticity (E) = 29×10^6 psi

Plate thickness (h) = 0.5 in

Concentrated load (P) = 300 lb

Width of plate (a) = 10 inches

Length of plate (b) = 40 inches

The formulas for the deflections and moments are taken from Reference 3.8-8.

Deflection (at Center)

$$\omega = 0.01695 \frac{Pa^2}{D} \qquad \text{(EQ. 3.8-19)}$$

where:

$$D = \frac{Eh^3}{12(1-\upsilon^2)}$$

ω = 0.00153 in at Node 116

Moments

M_x: (for b >> a) (at x = 2, y = 0)

$$M_x = \frac{-P(1+\upsilon)}{8\pi} \ln \left[\frac{1 - \sin \frac{\pi x}{a}}{1 + \sin \frac{\pi x}{a}} \right] \quad \text{(EQ. 3.8-20)}$$

M_x = 20.92 in-lb at Node 113

M_y: (for b >> a) (at x = 6, y = 0)

$$M_y = -P \frac{(1+\upsilon)}{8\pi} \ln \left[\frac{1 - \sin \frac{\pi x}{a}}{1 + \sin \frac{\pi x}{a}} \right] \quad \text{(EQ. 3.8-21)}$$

M_y = 57.198 in-lb at Node 117

The hand-calculated values for deflections and moments are compared with the CE668 values in Table 3.8-15. The results for the two solution methods are in very close agreement, the largest difference being 1.55%.

b. Sample Problem B: Uniform Load on a Rectangular Plate with Various Edge Conditions

For this problem, the rectangular plate has one edge fixed, one edge free, and two edges simply supported, as shown in Figure 3.8-82. The plate is subjected to a uniformly distributed load (q) equal to 2.0 psi. Only one-half of the plate is modeled by finite-elements, because of symmetry. Boundary conditions are specified in accordance with the edge support conditions.

The problem parameters are as follows:

Poisson's ratio (υ) = 0.3

Modulus of elasticity (E) = 29×10^6 psi

Plate thickness (h) = 0.2 in

Uniformly distributed load (q) = 2.0 psi

Plate width (b) = 15 inches

Plate length (a) = 30 inches

The formulas for the deflections and moments were taken from Reference 3.8-8.

Deflection (at x = 15, y = 15)

$$\omega = 0.0582 \frac{qb^4}{D} \qquad \text{(EQ. 3.8-22)}$$

where:

$$D = \frac{Eh^3}{12(1-\upsilon^2)}$$

ω = 0.277 in at Node 11

Moments

M_x: (at x = 15, y = 15)

$$M_x = 0.0293\ qa^2$$

$$= 52.74 \text{ in-lb at Node 11} \qquad \text{(EQ. 3.8-23)}$$

M_y: (at x = 15, y = 0)

$$M_y = 0.319\ qb^2$$

$$= 143.55 \text{ in-lb at Node 121} \qquad \text{(EQ. 3.8-24)}$$

The hand-calculated values for deflections and moments are compared with the CE668 values in Table 3.8-15. The results for the two solution methods are in close agreement, the largest difference being 3.4%.

3.8.7.5 EASE (Elastic Analysis for Structural Engineering)

3.8.7.5.1 Application

EASE is a finite-element program which performs static analyses of two-dimensional and three-dimensional trusses and frames, plane elastic bodies, and plate and shell structures. The program library contains various types of elements, including truss, beam, plane stress and strain, plate bending, and shell elements. The EASE program accepts thermal loads, as well as pressure, gravity, and concentrated loads.

The program output includes joint displacements, beam forces and element stresses, and forces and moments.

3.8.7.5.2 Program Background

EASE was developed by the Engineering/Analysis Corporation, Redondo Beach, California, in 1969, and is in the public domain. The version currently used by Bechtel is maintained by the Control Data Corporation, Cybernet Service.

3.8.7.6 E0119

3.8.7.6.1 Application

This program analyzes a bolted flange. The program calculates allowable and actual bolt stresses, and longitudinal, radial, and tangential flange stresses.

3.8.7.6.2 Program Background

The symbols, terms, and analysis procedures used in this program are in accordance with ASME Section III, Appendix XI.

The version of this program currently used by Bechtel is maintained by the Control Data Corporation.

3.8.7.6.3 Sample Problems

Sample problems were analyzed by E0119 and compared with the solutions published in Reference 3.8-9.

The problem parameters for the two sample problems are as follows:

Design pressure = 400 psi

Design temperature = 500°F

Atmospheric temperature = 75°F

Poisson's ratio = 0.30

Corrosion allowance = 0

Gasket width = 0.75 inches

Effective gasket width = 0.306 inches

Gasket factor = 2.75

Gasket seating strength = 3700 psi

a. Sample Problem A: Welding Neck Flange

   Figure 3.8-83 details the dimensions of the welding neck flange. Table 3.8-16 compares the results obtained using E0119 with the results published in Reference 3.8-9.

b. Sample Problem B: Slip-on Flange

Figure 3.8-84 details the dimensions of the slip-on flange. Table 3.8-16 compares the results obtained using E0119 with the results published in Reference 3.8-9.

In both problems, the results obtained using E0119 compare favorably with the published results.

3.8.7.7 E0781 (Shells of Revolution Program)

3.8.7.7.1 Application

This program calculates the stresses and displacements in thin-walled elastic shells of revolution when subjected to static edge, surface, and/or temperature loads with arbitrary distribution over the surface of the shell. The geometry of the shell must be symmetric, but the shape of the median is arbitrary. It is possible to include up to three branch shells with the main shell in a single model. In addition, the shell wall may consist of different orthotropic materials, and the thickness of each layer and the elastic properties of each layer may vary along with the median.

3.8.7.7.2 Program Background

The Shells of Revolution Program is based on the analysis described in Reference 3.8-10.

The program numerically integrates the eight ordinary first-order differential equations of thin-shell theory. The equations are derived so that the eight variables chosen are those appearing on the boundaries of the axially symmetric shell; thus the entire problem is expressed in these fundamental variables.

The program has been altered so that a 4x4 force-displacement relation is used as a boundary condition, as an alternative to the usual procedure of specifying forces or displacements. This force-displacement relation describes the forces at the boundary in terms of displacements at the boundary, or the displacements at the boundary in terms of forces, or some compatible combination of the two. In this manner, it is possible to study the behavior of a large complex structure. It is also possible to introduce a "Spring Matrix" at the end of any part of the stress model. This matrix must be expressed in the form, Force = Spring Matrix · Displacement. In addition to the above changes, the program has been modified to increase the size of the problem that can be considered and to improve the accuracy of the solution.

3.8.7.7.3 Sample Problems

This program is verified by comparing the computer results with experimental measurements and published references. Two sample problems are presented as examples of verification.

a. Sample Problem A: Comparison of 2:1 Ellipsoidal and Torispherical Heads Subjected to an Internal Pressure Load

   This problem illustrates the program's ability to generate cylindrical, torispherical, and ellipsoidal shapes. The E0781 program's "solution" is compared to the experimental investigation of 2:1 ellipsoidal heads subjected to internal pressure discussed in Reference 3.8-11.

   The problem compares a 2:1 ellipsoidal head, to an equivalent torispherical head subjected to the same uniformly distributed internal pressure. An equivalent torisphere is defined as one having the same height above the tangent line as the

ellipsoid, and a minimal L/b ratio (thus having the least possible discontinuity between the torus and the sphere). For the geometry shown in Figure 3.8-85:

$$(L-b) \sin \phi_o = A-r \qquad \text{(EQ. 3.8-25)}$$

$$(L-b) \cos \phi_o = L-B \qquad \text{(EQ. 3.8-26)}$$

Minimizing L/b using equations 3.8-25 and 3.8-26:

$$\tan \phi_o = B/A = 0.5019 \qquad \text{(EQ. 3.8-27)}$$

$$\phi_o = 26.653^\circ$$

$$L/A = \frac{c \pm (c^2 - 2c)^{1/2}}{2} \qquad \text{(EQ. 3.8-28)}$$

where:

$c = B/A + A/B = 2.494$

$L = \frac{18.19}{2} [2.5 + (6.22 - 4.99)^{1/2} = 32.778$ in

$b = B [B/A - L/A] + A = 6.32$ in

and:

A = radius of cylinder = 18.19 inches

B = height of torisphere or ellipsoid above the base (tangent line) = 9.31 inches

L = major radius of torisphere

b = minor radius of torisphere

t = thickness of the shell

Segment lengths used are:

<u>cylinder</u>

$$(rt)^{1/2} = 2.37 \text{ inches} \qquad \text{(EQ. 3.8-29)}$$

where:

r = distance to pole = 18.16 inches

t = thickness of shell = 0.31 inches

<u>torisphere</u>

5° to 10° - 4 angular segments @ 1.25°

10° to 26.567° - 4 angular segments @ 4.13°

26.567° to 90° - 6 angular segments @ 10.57°

ellipsoid

5° to 10° - 2 4 angular segments @ 1.25°

10° to 30° - 4 angular segments @ 5°

30° to 90° - 6 angular segments @ 10°

Boundary Conditions:

It is assumed that at 5° from the pole, a membrane stress exists in both the ellipsoid and the torisphere:

$$Q = M\phi = 0 \qquad \text{(EQ. 3.8-30)}$$

$$N\phi = \frac{pr}{2 \sin \phi} \qquad \text{(EQ. 3.8-31)}$$

where:

r = distance to pole = 32.778 in

Q = transverse shear in ϕ direction, lb/in

$M\phi$ = moment resultant in ϕ direction, in-lb/in

$N\phi$ = membrane force in ϕ direction, lbs/in

Letting (p) = pressure = 680 psi, then for the torisphere:

$N\phi = (680/2)(32.778) = 11,144.5$ lb/in

If $N\phi = 11,144.5$ lb/in, a preliminary run yields:

Q = 95.202 lb/in, so a new value for $N\phi$ for the torisphere is calculated:

$$\Delta N = \frac{\Delta Q}{\tan \phi} \qquad \text{(EQ. 3.8-32)}$$

$N\phi = 11,144.5 + \Delta N = 10056.3$ lb/in and an appropriate membrane state was generated.

For the ellipsoid:

$$r = \frac{A \sin \phi}{R} \qquad \text{(EQ. 3.8-33)}$$

where:

$R = [C_1 + (1 - C_1)\sin^2\phi]^{1/2}$

$C_1 = (B/A)^2 = 0.2519$

$R = 0.5075$

$N\phi = \frac{A \sin\phi}{R} \frac{P}{2\sin\phi} = 12{,}185.78$ lb/in

To better compare the heads, it seems desirable to have the longitudinal displacement at the center of the cylinder equal to zero ($\mu\phi = \phi$). Thus the problem is run twice; the first run yielding the radial displacement, W, required for zero-displacement at the center (W = 0.0966 in).

Start	W = 0.0966 in
	$N\phi$ = 10,056 lb/in
	$M\phi = N = 0$
End	$Q = N = M0 = 0$
	$N\phi$ = 12,186 lb/in

Figure 3.8-86 shows the analytical model, with boundary conditions.

In order to check the results, the answers at the boundaries are examined first. It is assumed that there is a membrane state of stress at the boundaries. Therefore, at the edges Q and $M\phi$ must be approximately zero.

	Q (lb/in)	$M\phi$ (lb-in/in)
Start	-0.08636	0.0
End	-0.0009252	0.0001487

To satisfy equilibrium in the cylinder:

$N\phi \approx 0.5pr = 6169$ lb/in

Plots of the hoop force and longitudinal bending from E0781 results compare the ellipsoidal and torispherical heads. Even though the change in radii is minimized, the disturbance at the junction of the sphere and torus is considerable (Figure 3.8-87).

A comparison with the experimental ellipsoidal head shows a good correlation of stress values. Plots of $\nabla\phi$ and $\nabla\theta$ on the inside, outside, and meridian of the head

are shown in Figures 3.8-88 through 3.8-92. Any deviations are caused by the changes in thickness, and by the experimental head's variation from a true 2:1 ellipsoidal head. These variations are shown in Figures 3.8-93 and 3.8-94.

b. Sample Problem B: Cylindrical Water Tank with Tapered Walls

This problem illustrates the program's capability to analyze a pressure load with one fixed boundary and one free boundary.

The problem used for this verification is "Shell of Variable Thickness," taken from Reference 3.8-12 (pp. 289-295).

The problem consists of a tapered shell filled with water. The shell has a radius of 9 feet, and is 12 feet high. The shell thickness varies from 11 inches at the bottom, to 3 inches at the top. These dimensions, and the location of the Z axis, are shown in Figure 3.8-95. The length of a segment is 18 inches $[(rt)^{1/2}]$, where r and t are the same as defined in Sample Problem A.

Since the pressure varies linearly, only two points are needed in the function generator in order to fully describe the function.

It is known that the pressure at the top of the tank, exposed to the atmosphere, is zero. Assuming that the density of the water is 62.5 lb/ft^3, the pressure at the bottom of the tank is:

$$p = \frac{(12\ ft)(62.5\ lb/ft^3)}{(144\ in^2/ft^2)} = 5.21\ psi$$

The boundary conditions for this problem are as follows:

W = displacement normal to surface

$U\phi$ = displacement component in ϕ direction

$\beta\phi$ = rotation of reference surface in ϕ direction

Q = transverse shear in ϕ direction

$N\phi$ = membrane force in ϕ direction

$M\phi$ = moment resultant in ϕ direction

Fixed at start $W = U\phi = \beta\phi = 0$

Free at end $Q = N\phi = M\phi = 0$

Table 3.8-17 lists the Program E0781 results, and compares them with the theoretical solutions from Reference 3.8-12 at two locations.

Program E0781 yields a maximum hoop force, $N\phi$, equal to 346.8 lb/in (4160 lb/ft), 54 inches from the base. This value differs from the theoretical solution of 4180 lb/ft by 0.48%.

Program E0781 yields a maximum moment at the base, M□, equal to -1539 in-lb/in (-1539 ft-lb/ft). This value differs from the theoretical solution of -1470 ft-lb/ft by 4.69%.

3.8.7.8 FINEL (Finite-Element Program for Cracking Analysis)

3.8.7.8.1 Application

This program performs a static analysis of stresses and strains in plane and axisymmetric structures by the finite-element method. The program computes the displacements of the corners of each element, and the stresses and strains within each element.

3.8.7.8.2 Program Background

In this program, the structure is idealized as an assemblage of two-dimensional finite-elements of triangular or quadrilateral shapes, having arbitrary material properties. Reinforcement of concrete materials is included by adjusting the element material properties. Bilinearity in compression, and bilinearity or cracking in tension are specially emphasized.

The version of this program currently used by Bechtel is maintained by Control Data Corporation.

3.8.7.8.3 Sample Problems

To verify this program, sample problems were analyzed by FINEL, and compared to experimental and/or hand-calculated solutions. Three sample problems are presented as examples of verification.

a. Sample Problem A: Simply Supported Beam with a Concentrated Load at the Center

The beam shown in Figure 3.8-96 is investigated experimentally and analytically. This investigation compares results obtained from the FINEL program with those obtained from References 3.8-13 and 3.8-14.

The finite-element mesh used in Reference 3.8-14, and in the FINEL analysis are shown in Figures 3.8-97 and 3.8-98, respectively. The FINEL analysis requires a finer mesh because it uses linear displacement elements. Reference 3.8-14 uses quadratic displacement elements.

The material properties of the concrete and reinforcing steel, and the loading history used in the FINEL analysis are given in Table 3.8-18.

The cracking patterns obtained from Reference 3.8-14 and FINEL are shown in Figure 3.8-99. The load-deflection curves from References 3.8-13 and 3.8-14 and the FINEL analysis are shown in Figure 3.8-100. The load-deflection curve obtained from the FINEL analysis shows very good agreement with the experimental results. The cracked region grows faster in the FINEL analysis, and more slowly in Reference 3.8-14, since the FINEL and Reference 3.8-14 load-deflection curves show different gradients (stiffnesses).

The results of analytical, experimental, and FINEL solutions are shown in Figure 3.8-100. The FINEL analysis agrees well with the experimental results, up to the point where the reinforcing steel in the beam yields. After the yield point, the FINEL analysis incorrectly calculated the effective stiffness of elements which have yielded. Therefore, the solution is not valid for further loadings. However, since all reinforcing steel remains elastic for the containment analysis, the FINEL program is verified for that application.

b. Sample Problem B: Axially Constrained Hollow Cylinder with a Distributed Pressure Loading

This problem investigates the response of an axially constrained hollow cylinder to internal pressure. A hand-calculated solution yields values of tangential, axial, and radial stresses at various radii from the center of the cylinder, which are then compared to the FINEL values.

The finite-element model is illustrated in Figure 3.8-101. Nodal points are free to move only in the radial direction, representing the conditions of axisymmetry and plane strain.

The problem parameters are as follows:

Poisson's ratio (υ) = 0.25

Modulus of elasticity (E) = 4.32×10^5 ksf

Number of nodal points = 22

Number of elements = 10

Internal pressure (p) = 1.0 ksf

From References 3.8-15 and 3.8-16, the following equations were used:

Hoop or tangential stress, T :

$$T = p \frac{a^2 (b^2 + r^2)}{r^2 (b^2 - a^2)} \qquad \text{(EQ. 3.8-34)}$$

Axial stress, T_2:

$$T_2 = \frac{2\upsilon P a^2}{b^2 - a^2} = \frac{P}{2} \frac{a^2}{b^2 - a^2} \qquad \text{(EQ. 3.8-35)}$$

Radial stress, T_R:

$$T_R = - p \frac{a^2 (b^2 - r^2)}{r^2 (b^2 - a^2)} \qquad \text{(EQ. 3.8-36)}$$

where:

a = 65.0 feet

b = 68.75 feet

p = 1.0 ksf

$a \leq r \leq b$

The results from FINEL for the hollow cylinder tangential, axial, and radial stresses are compared with the hand-calculated values in Table 3.8-19. The results are exactly the same, except for one value, where there is a 4.17% difference.

c. Sample Problem C: Axially Constrained Hollow Cylinder with a Linear Temperature Gradient

This problem evaluates the response of an axially constrained hollow cylinder, to a radially varying linear temperature gradient. The tangential, axial, and radial stresses are determined by hand calculations, and compared to the FINEL results.

Figure 3.8-102 illustrates the finite-element mesh. The conditions of axisymmetry and plane strain are imposed by using the axisymmetric quadrilateral element, and restraining all nodes against axial displacement.

The temperature profile is shown in Figure 3.8-103.

The problem parameters are as follows:

Poisson's ratio (υ) = 0.25

Modulus of elasticity (E) = 4.32×10^5 ksf

Coefficient of thermal expansion (α) = 6×10^{-6} ft/ft/°F

Number of nodal points = 22

Number of elements = 10

From References 3.8-16 and 3.8-17, the following equations are used:

Hoop or tangential stress, ∂_θ :

$$\partial_\theta = \frac{\alpha E}{1-\upsilon}\frac{1}{r^2}\left[\frac{(r^2+a^2)}{b^2-a^2}\int_a^b Trdr + \int_a^r Tr'dr' - Tr^2\right] \qquad \text{(EQ. 3.8-37)}$$

Axial stress, ∂_z :

$$\partial_z = \frac{\alpha E}{1-\upsilon} \left[\frac{2\upsilon}{b^2 - a^2} \int_a^b Trdr - T \right] \quad \text{(EQ. 3.8-38)}$$

Radial stress, ∂_R :

$$\partial_R = \frac{\alpha E}{1-\upsilon} \frac{1}{r^2} \left[\frac{(r^2 - a^2)}{b^2 - a^2} \int_a^b Trdr - \int_a^r Tr'dr' \right] \quad \text{(EQ. 3.8-39)}$$

where:

a = 65.0 feet

b = 68.75 feet

T = T(r) = temperature above reference, °F (reference temperature = 100°F)

Expressions for the temperature field are:

$T(r) = C_2 r + C_1$ (EQ. 3.8-40)

$T(a) = 25 = C_1 + 65.0C_2$ (EQ. 3.8-41)

$T(b) = -25 = C_1 + 68.75C_2$ (EQ. 3.8-42)

Solving:

$$C_2 = \frac{-50}{68.75 - 65} = -13.33$$

$C_1 = -25 - 68.75(-13.33) = 891.67$

Then:

$T(r) = -13.33r + 891.67$

Evaluating the integral:

$$\int Trdr = \int (-13.33r + 891.67)rdr$$

$$= -\frac{13.33r^3}{3} + \frac{891.67r^2}{2} + C$$

$$= -4.44r^3 + 445.83r^2 + C$$

$$\int_a^b Trdr = -4.44(b^3 - a^3) + 445.83(b^2 - a^2)$$

$$\int_s^b Tr'dr' = -4.44(r^3 - a^3) + 445.83(r^2 - a^2)$$

The results from FINEL for the tangential, axial, and radial stresses are compared with the values obtained by hand calculations in Table 3.8-19. The results between the two methods of solution agree very closely.

3.8.7.9 ME620 (Transient Temperature Analysis of Plane and Axisymmetric Solids)

3.8.7.9.1 Application

The heat conduction program, ME620, is used to determine the temperature distribution as a function of time, within a plane or axisymmetric solid body subjected to step-function temperature or heat flux inputs. The program is also used for steady-state temperature analysis.

3.8.7.9.2 Program Background

The program utilizes a finite-element technique coupled with a step-by-step time integration procedure, as described in Reference 3.8-18.

The program was developed at the University of California, Berkeley, by Professor E. L. Wilson, and has been modified by Bechtel to incorporate the save and restart capabilities. The version of this program currently used by Bechtel is maintained by the Control Data Corporation.

3.8.7.9.3 Sample Problems

To verify this program, sample problems were analyzed by ME620 and compared with published data. Two sample problems are presented as examples of verification.

a. Sample Problem A: Heat Conduction in a Square Plate with One Edge Quenched

This problem tests the ability of the program to solve the temperature changes in a plane region subjected to conduction boundary conditions. The plate is brought to an equilibrium temperature, and one edge quenched while the other three edges are kept insulated.

A square plate is brought to equilibrium at a given initial temperature, T_o. Three edges are perfectly insulated, while a third edge is suddenly brought to a lower temperature, T_1. This quench is kept constant for the entire analysis. A temperature-time history is then obtained for the corner farthest from the quenched edge.

Figure 3.8-104 shows the actual plate arrangement, while Figure 3.8-105 shows a diagram of the finite-elements.

The problem parameters are as follows:

Nomenclature

L = length of longest heat flow path, inches

T_o = initial temperature of plate, °F

T_1 = quenching temperature of edge, °F

Data

The plate is 10 inches square

T_o = 100°F

T_1 = 0°F

Diffusivity α = 1.0 in^2/sec (chosen for convenience)

Time increment (ΔT) = 1 second for numerical solution

At any time, t, during the transient state, the time factor T (or characteristic time) is given by:

$$T = \alpha t/L^2$$

The time to reach steady-state is given when T = 1.0; hence the transient time is $t = L^2/\alpha$ = 100 seconds. The results derived from Reference 3.8-19 are plotted in Figure 3.8-106.

The temperature variation at point A is plotted in Figure 3.8-106 according to the results of ME620, and is compared with the theoretical transient change. The curves are seen to agree quite well. Deviations are due to the selected finite-element mesh size, and to the selected time step for the analysis.

b. Sample Problem B: Heat Conduction in a Surface Quenched Sphere

This problem tests the ability of ME620 to analyze the temperature distribution in an axisymmetric solid, with given temperature boundary conditions. The results of the program analysis are compared to a closed-form solution derived from Reference 3.8-20.

This problem considers a solid steel sphere (shown in Figure 3.8-107) which is brought to an equilibrium temperature, and suddenly quenched to a lower uniform temperature on its surface. The quenching environment is held at a constant temperature. A temperature-time history for three seconds is obtained from the program for all node points. The points used for the comparison are at a radius of 0.2 inches; only one time period is checked. The finite-element model is shown in Figure 3.8-108.

The problem parameters are as follows:

Nomenclature

L = length of the longest heat flow path (radius of sphere), inches

T_o = initial temperature of sphere, °F

T_1 = quenching temperature of outer surface, °F

Data

Radius of sphere (R) = 0.59 inches

T_o = 1472°F

T_1 = 68°F

Conductivity = 6.02×10^{-4} Btu/(in-sec-°F)

Diffusivity (α) = 0.0193 in^2/sec

Specific heat = 0.11 Btu/(lb-°F)

Density (p) = 0.284 lb/in^3

Time increment = 0.2 sec

At any time, t, during the transient state, the time factor T (or characteristic time) is given by:

$$T = \alpha t/L^2$$

The time to reach steady-state is given when T = 1.0; hence the transient time is $t = L^2/\alpha$ = 3.0 seconds.

The result from Reference 3.8-20 for the temperature at a radius of 0.2 inches and at time t = 1.8 seconds, is 933.8°F. The result obtained from ME620 is 923.4°F. The difference between these two values is 1.1%.

3.8.7.10 ANSYS

3.8.7.10.1 Application

The ANSYS engineering analysis system computer program is a large-scale general purpose computer program employing finite-element technology for the solution of several classes of engineering analysis problems. Analysis capabilities include static and dynamic; plastic, creep, and swelling; small and large deflections; steady-state and transient heat transfer; and steady-state fluid flow. A variety of finite-elements are available for use in the program. Structural loadings may be forces, displacements, pressures, temperatures, or response spectra. The program output includes joint displacements, element stresses, forces, and moments.

3.8.7.10.2 Program Background

ANSYS was developed by Swanson Analysis Systems, Inc, and is in the public domain. The version of the program currently used by Bechtel is maintained by the Control Data Corporation, Cybernet Service. Version 5.0 was used to evaluate the Spent Fuel Pool for increase storage capacity. This evaluation was performed by Gilbert/Commonwealth and Version 5.0 is maintained by Gilbert/Commonwealth.

3.8.7.11 IMAGES 3D

3.8.7.11.1 Application

The IMAGES 3D computer program is a three-dimensional general purpose finite element program for use on an IBM-compatible personal computer. Analysis capabilities include static, modal, and dynamic analysis of structures composed of frame, plates, shell and solid elements. Structural loadings may be forces, displacements, pressures, temperatures, response spectra, or time history. The program output includes joint displacements, element stresses, forces and moments. It also calculates natural frequencies and mode shapes.

3.8.7.11.2 Program Background

IMAGES 3D was developed by Celestial Software, which is a division of Robert L. Cloud & Associates. The program is in the public domain. Version 3.0 of the program is currently used by the licensee. The documentation package for IMAGES 3D includes a verification manual which documents a series of test problems that demonstrates that the results from IMAGES 3D are similar to those results of other public domain programs or classical solutions.

(1) For exceptions to the above codes, standards, recommendations and specifications, see Section 3.8.6.
(2) The contractor or fabricator may also qualify its welding procedures and welders in accordance with the latest edition of AWS D1.1 code at the time of qualification.
(3) Principal editions used for design are listed; later editions may be used for specific plant modifications.

Table 3.8-2

LOAD COMBINATIONS FOR PRIMARY CONTAINMENT WALL, DIAPHRAGM SLAB, AND REACTOR PEDESTAL

The primary containment, diaphragm slab, and reactor pedestal are designed for the following load combinations:

1. Normal Operating Conditions

   a. $U=1.5D+1.8L+1.0T_o+1.25H_o$

   b. $U=1.25(D+L+E+H_o)+1.0T_o$

   c. $U=0.9D+1.25(E+H_o)+1.0T_o$

   d. $U=1.0D+1.0L+1.8E+1.0T_o+1.25H_o$

2. Design Accident and Extreme Environmental Conditions

   a. $U=1.05D+1.05L+1.0T_A+1.0H_A+1.0R+1.5P$

   b. $U=1.05D+1.05L+1.0T_A+1.0H_A+1.0R+1.25P+1.25E$

   c. $U=1.0D+1.0L+1.0T_A+1.0H_A1.0R+1.0P+1.0E'$

   d. $U=0.95D+1.25E+1.0T_A+1.0H_A+1.0R$[1]

   e. $U=1.05D+1.0B+1.25P'+1.25E$

The pressure-retaining steel elements are designed for the following load combinations[2]:

		Stress Limits
a.	$D+L+1.15P$	1.15 times ASME Section III, Class B for "Normal Operating Conditions"
b.	$D+L+T_A+P$	ASME Section III, Class B for "Normal Operating Conditions"
c.	$D+L+T_A+P+H_A+R+E$	ASME Section III, Summer 1970 Addenda, Figure N-414, "For Emergency Conditions"
d.	$D+L+T_A+P+H_A+R+E'$	ASME Section III, Summer 1970 Addenda, Figure N-414, "For Faulted Conditions"

Table 3.8-2 (Cont'd)

Definitions:

U = Required ultimate load capacity, as defined in ACI 318-71

D = Dead load of structure and major equipment, plus any other major permanent loads contributing stress, such as soil or hydrostatic loads or operating pressures

L = Live loads expected to be present when the plant is operating. For loading conditions that include vertical seismic, replace L by $L_p + L_o$, where:

- L_p = permanent live load to include minor piping, minor equipment and the weight of equipment in lay-down areas: to be accelerated vertically
- L_o = 100 psf (except 50 psf for grating and platforms): not to be accelerated vertically

T_o = Thermal effects due to temperature gradient through the wall, under operating conditions

T_A = Thermal effects due to temperature gradient through the wall, under accident conditions

P = Design basis accident pressure load

R = Steam/water jet forces or reactions resulting from the rupture of process piping

E = Load due to the OBE resulting from a horizontal ground acceleration of 0.075 g, and a vertical ground acceleration of 0.05 g

E' = Load due to the design basis earthquake resulting from a horizontal ground acceleration of 0.15 g, and a vertical ground acceleration of 0.10 g

B = Hydrostatic loading due to postaccident flooding of the primary containment to the level of the reactor core

P' = Pressure of the atmosphere in the primary containment, with the containment flooded to the level of the reactor core

Table 3.8-2 (Cont'd)

H_o = Force on the structure due to thermal expansion or contraction of hanger critical pipes

H_A = Force on the structure due to thermal expansion of pipes, under accident conditions

T = Thermal loads resulting from temperature increases under accident conditions.

(1) Where overturning forces cause net tension in the absence of live load

(2) Bending from jet forces are considered as primary stresses.

Table 3.8-3

PRIMARY CONTAINMENT DESIGN PRESSURE AND TEMPERATURE CRITERIA

PORTION OF CONTAINMENT	TIME AFTER START OF ACCIDENT	CONTAINMENT ATMOSPHERE PRESSURE (psig)	CONTAINMENT ATMOSPHERE TEMPERATURE (°F)
Drywell	0 sec[2]	0.75	135[3]
Suppression Chamber	0 sec[2]	0.75	95
Drywell	0-45 sec	55	340
Suppression Chamber	0-45 sec	55	175
Suppression Chamber[1]	0-45 sec	25	175
Drywell	45 sec-60 min	35	340
Suppression Chamber	45 sec-60 min	35	175
Drywell	1-3 hrs	35	340
Suppression Chamber	1-3 hrs	35	220
Drywell	3-6 hrs	35	320
Suppression Chamber	3-6 hrs	35	220
Drywell	6-24 hrs	20	220
Suppression Chamber	6-24 hrs	20	220
Drywell	1-4 days	20	200
Suppression Chamber	1-4 days	20	200
Drywell	4-30 days	10	175
Suppression Chamber	4-30 days	10	175

(1) Drywell/suppression chamber maximum differential pressure condition

(2) Just before start of accident (i.e., at operating condition)

(3) This information is based on original design basis conditions. Further evaluation has validated the primary containment design for an initial drywell containment atmosphere temperature of 150°F. The stress indicated in UFSAR Figures 3A-362 to 3A-380, Design Assessment Report for Containment Structures reflects current plant conditions.

Table 3.8-4

LOAD COMBINATIONS AND ALLOWABLE STRESSES FOR ASME CLASS MC COMPONENTS[1]

The drywell head assembly, equipment hatches, personnel lock, suppression chamber access hatches, and CRD removal hatch are designed for the following loading combinations and allowable stresses:

	Stress Limits
D+L+1.15P	1.15 times ASME Section III, Class B for "Normal Operating Conditions"
$D+L+T_A+P$	ASME Section III, Class B for "Normal Operating Conditions"
$D+L+T_A+P+H_A+R+E$	ASME Section III, Summer 1970 Addenda, Figure N-414, "For Emergency Conditions"
$D+L+T_A+P+H_A+R+E'$	ASME Section III, Summer 1970 Addenda, Figure N-414, "For Faulted Conditions"

Piping and electrical penetrations are designed for the following load combinations and allowable stresses:

a. The loads used in the design are as follows:

   1. Moments and forces transmitted by the piping to the penetration due to thermal expansion, weight, earthquake (including inertial effects and anchor movements), and other dynamic loads
   2. Pressures
   3. Thermal transients
   4. Number of operating cycles
   5. Pipe failure loads for faulted condition

b. The loading combinations are specified in Section 3.9.

c. Stress limits specified in ASME Section III, Article NB-3220 are used as the design criteria for Class I flued heads for design, normal and upset, and emergency condition. The rules contained in ASME Section III, Appendix F are used in evaluating the faulted condition for Class I and II flued heads.

---

[1] Definitions of symbols are given in Table 3.8-2.

Table 3.8-5

LOAD COMBINATION FOR THE REACTOR SHIELD WALL[1]

The reactor shield wall is designed for the following loading combination:

Condition	
Abnormal/Extreme	$D+L+T_A+R+P+E'$

[1] Symbols are defined in Table 3.8-2.

Table 3.8-6

LOAD COMBINATIONS FOR THE SUPPRESSION CHAMBER COLUMNS[1]

The suppression chamber columns are designed for the following loading combinations:

Condition	
Abnormal	$1.05D+1.05L+1.0T_A+1.0R+1.5P$
Abnormal/Severe	$1.05D+1.05L+1.0T_A+1.0R+1.25P+1.25E$
Abnormal/Extreme	$1.0D+1.0L+1.0T_A+1.0R+1.0P+1.0E'$

(1) Symbols are defined in Table 3.8-2.

Table 3.8-7

LOAD COMBINATIONS FOR THE PIPE WHIP RESTRAINTS AND DRYWELL PLATFORMS(1)

The pipe whip restraints and drywell platforms are designed for the following loading combinations:

Condition	
Normal	D+L
Abnormal(2,3)	D+L+R+T

(1) Symbols are defined in Table 3.8-2, except as noted below.

(2) For the design of pipe whip restraints which also support other pipe support(s), either pipe support SSE reaction load or the pipe rupture load (R) is considered.

(3) Thermal loads can be neglected when it can be shown that they are secondary and self-limiting in nature and where the material is ductile.

Table 3.8-8

LOAD COMBINATION FOR THE SEISMIC TRUSS[1]

The seismic truss is designed for the following loading combination:

Condition	
Abnormal/Extreme	D+R+E'

(1) Symbols are defined in Table 3.8-2.

Table 3.8-9

LOAD COMBINATIONS FOR THE REACTOR ENCLOSURE[6]

A. Reinforced Concrete

1. Normal Operating and Severe Environmental Conditions

a. $U=1.5D+1.8L+1.0T_o+1.25H_o$

b. $U=1.25(D+L+H_o+E)+1.0T_o$

c. $U=1.25(D+L+H_o+W)+1.0T_o$

d. $U=0.9D+1.25(H_o+E)+1.0T_o$[1]

e. $U=0.9D+1.25(H_o+W)+1.0T_o$[1]

f. $U=1.0D+1.0L+1.8E+1.0T_o+1.25H_o$[2]

2. Design Accident and Extreme Environmental Conditions

a. $U=1.05D+1.05L+1.0T_A+1.0H_A+1.0R+1.5P$

b. $U=1.05D+1.05L+1.0T_A+1.0H_A+1.0R+1.25P+1.25E$

c. $U=1.0D+1.0L+1.0T_A+1.0H_A+1.0R+1.0P+1.0E'$

2.	Design Accident and Extreme Environmental Conditions		Stress Limits
	a.	$D+L+R+T_o+H_o+P+E'$	See note (3)
	b.	$D+L+R+T_A+H_A+P+E'$	See note (3)
	c.	$D+L+A+T_o+H_o$	See note (3)
	d.	$D+L+T_o+H_o+W'$(4)	See note (3)
	e.	$D+L+R_o$	

C. Post-tensioned Concrete Fuel Pool Girders

1.	Normal Operating Conditions (Including Refueling)		Stress Limits
	For elastic analysis by straight line theory:		
	a.	$D+L+T_o+F$	F_c
	b.	$D+L+E+T_o+F$	$1.25F_c$
	c.	$D+E+T_o+F$(5)	$1.25F_c$
	d.	$D+E'+T_o+F$(5)	$1.50F_c$
	For ultimate strength method:		
	e.	$U=1.5D+1.8L+1.0T_o$	
	f.	$U=1.25(D+L+E)+1.0T_o$	
2.	Design Accident and Extreme Environmental Conditions		
	a.	$U=1.05D+1.05L+1.0T_A$	
	b.	$U=1.05D+1.05L+1.25E+1.0T_A$	
	c.	$U=1.0D+1.0L+1.0E'+1.0T_o$	

Definitions:

W = Wind load

W' = Tornado wind load

Table 3.8-9 (Cont'd)

B_o = Hydrostatic loading due to flooding of the ECCS and RCIC compartments in the reactor enclosure, to suppression pool equilibrium water level

A = Hydrostatic load due to probable maximum flood

f_s = Calculated stress in structural steel

F_s = Allowable stress for structural steel

F_y = Yield strength of structural steel

F = Prestressing force

F_c = Allowable flexural concrete stress, by straight-line theory

R_o = Blast pressure due to railroad accident or pipeline explosion as discussed in Section 2.2.3.1.1 and defined in Reference 2.2-1. (The effect of ground shock due to blast load is a subject of separate investigation.)

For all other definitions, see Table 3.8-2

---

(1) Where overturning forces cause net tension in the absence of live load

(2) For structural elements carrying mainly earthquake forces

(3) The allowable stress in structural steel does not exceed 0.9 F_y in bending, 0.85 F_y in axial tension or compression, and 0.5 F_y in shear. Where F_s is governed by requirements of stability (local or lateral buckling), f_s does not exceed 1.5 F_s. Thermal loads can be neglected when it can be shown that they are secondary and self-limiting in nature and where the material is ductile.

(4) Where protection against tornado forces is required

(5) When effects of upward vertical acceleration under earthquake conditions are considered

(6) Unless they are shown, stress limits comply with the ACI codes and AISC specifications. Deviations shown are consistent with typical nuclear power plant design practices.

Table 3.8-10

LOAD COMBINATIONS APPLICABLE TO SEISMIC CATEGORY I STRUCTURES OTHER THAN PRIMARY CONTAINMENT AND REACTOR ENCLOSURE[5]

A. Reinforced Concrete

1. Normal Operating and Severe Environmental Conditions

a. $U=1.5D+1.8L+1.0T_o+1.25H_o$

b. $U=1.25(D+L+H_o+E)+1.0T_o$

c. $U=1.25(D+L+H_o+W)+1.0T_o$

d. $U=0.9D+1.25(H_o+E)+1.0T_o$[2]

e. $U=0.9D+1.25(H_o+W)+1.0T_o$[2]

For structural elements carrying mainly earthquake forces:

f. $U=1.0D+1.0L+1.8E+1.0T_o+1.25H_o$

2. Design Accident and Extreme Environmental Conditions

a. $U=1.05D+1.05L+1.25E+1.0T_A+1.0H_A+1.0R$

b. $U=0.95D+1.25E+1.0T_A+1.0H_A+1.0R$[2]

c. $U=1.0D+1.0L+1.0E'+1.0T_o+1.25H_o+1.0R$

d. $U=1.0D+1.0L+1.0E'+1.0T_A+1.0H_A+1.0R$

e. $U=1.0D+1.0L+1.0A+1.0T_o+1.25H_o$

f. $U=1.0D+1.0L+1.0W'+1.0T_o+1.0H_o$

g. $U=1.0D+1.0L+1.0R_o$

B. Steel Structures

		Stress Limits
1.	Normal Operating and Severe Environmental Conditions	
a.	$D+L+T_o+H_o$	F_s
b.	$D+L+T_o+H_o+E$	$1.25F_s$
c.	$D+L+T_o+H_o+W$	$1.33F_s$
d.	$D+L+T_o+H_o+E$ (3)	F_s
2.	Design Accident and Extreme Environmental Conditions	Stress Limits
a.	$D+L+R+T_o+H_o+E'+P$	See note (4)
b.	$D+L+R+T_A+H_A+E'+P$	See note (4)
c.	$D+L+A+T_o+H_o$	See note (4)
d.	$D+L+T_o+H_o+W'$	See note (4)
e.	D+L+Ro	

(1) Symbols are defined in Table 3.8-9.

(2) Where overturning forces cause net tension in the absence of live load

(3) For structural elements carrying mainly earthquake forces

(4) The allowable stress in structural steel does not exceed 0.9 F_y in bending, 0.85 F_y in axial tension, and 0.5 F_y in shear. Where F_s is governed by requirements of stability (local or lateral buckling), f_s does not exceed 1.5 F_s. Thermal loads can be neglected when it can be shown that they are secondary and self-limiting in nature and where the material is ductile.

(5) Unless they are shown stress limits comply with the ACI codes and AISC specifications. Deviations shown are consistent with typical nuclear power plant design practices.

Table 3.8-11

LOAD COMBINATIONS APPLICABLE TO MISCELLANEOUS STRUCTURAL COMPONENTS OF SEISMIC CATEGORY I STRUCTURES[3]

A.	Anchor Bolts		
	1.	Normal Operating and Severe Environmental Conditions	Stress Limits
		a. $D+L+H_o$	F_s
		b. $D+L+H_o+(E \text{ or } W)$	$1.25F_s$
	2.	Design Accident and Extreme Environmental Conditions	
		a. $D+L+R+H_o+P+E'$	[4]
		b. $D+L+R+H_A+P+E'$	[4]
B.	Masonry		
	1.	Normal Operating and Severe Environmental Conditions	Stress Limits
		a. D+L	1.0xUBC[2]
		b. D+L+E	1.25xUBC[2]
	2.	Design Accident and Extreme Environmental Conditions	
		a. D+L+P	1.0xUBC[2]
		b. D+L+P+E'	1.33xUBC[2]

(1) Symbols are defined in Table 3.8-9.

(2) As specified in UBC, but without the customary increase in normal allowable working stress due to earthquake

(3) Stress limits shown are deviations from the ACI codes and AISC specifications; these values are consistent with typical nuclear power plant design practices.

(4) Strength method is used. Stress limit in steel shall not exceed 0.85 F_y for tension and 0.50 F_y for shear. The allowable stress in concrete shall be in accordance with ACI 318-71.

Table 3.8-12

MINIMUM TESTING FREQUENCY FOR CONCRETE, CONCRETE MATERIALS, CONCRETE MASONRY, AND MASONRY MATERIALS

MATERIAL	REQUIREMENT	TEST	FREQUENCY
Cement properties	Standard physical and chemical	ASTM C150	Once for each 5000 cubic yards of concrete production
Aggregate	Organic impurities	ASTM C40	Once per 8 hour shift during concrete production
	Soundness of aggregate	ASTM C88	Once for each 5000 cubic yards of concrete production
	Material finer than No. 200 sieve	ASTM C117	Once for each 5000 cubic yards of concrete production
	Lightweight pieces in aggregates	ASTM C123	Once for mix qualification
	Specific gravity and absorption	ASTM C127/C128[(1)]	Once for mix qualification
	Abrasion of coarse aggregate	ASTM C131	Once for each 5000 cubic yards of concrete production
	Gradation of coarse aggregate	ASTM C136	Once for each size of coarse aggregate during each 8 hour shift of production
	Gradation of fine aggregate	ASTM C136	Twice during each 8 hour shift of production
	Potential reactivity	ASTM C289	Once for each 5000 cubic yards of concrete production
	Petrographic examination	ASTM C295	Once for mix qualification
	Flat and elongated particles	CRD C119	Once per week on each size of coarse aggregate
Water and ice	Quality of water to be used in concrete (to meet the requirements herein)	AASHTO T26	Once every 3 months
Admixtures	Air entraining agent	ASTM C260	Upon delivery at job-site, prior to approval for use
	Water reducing and retarding agent(s)	ASTM C494	Upon delivery at job-site, prior to approval for use

Table 3.8-12 (Cont'd)

MATERIAL	REQUIREMENT	TEST	FREQUENCY
Concrete	Mixer uniformity	National Ready Mix Concrete Association (NRMCA)	Initially, and then once every 2 years
	Slump	ASTM C143	Once for every 35 cubic yards of each class of concrete produced for concrete used in seismic Category I structures. For all other structures, once for every 50 cubic yards of each class of concrete.
	Air content, temperature, unit weight	ASTM C231/C138	Once for each 100 cubic yards of each class of concrete produced
	Compressive strength	ASTM C31/C39	The specified number of cylinders to be tested for design strength at the date specified are cast for each 100 cubic yards of each class of concrete, or at least once per day for each class of concrete
Masonry units	Compressive strength, absorption, weight, and moisture content	ASTM C140	Test frequency is in accordance with ASTM C140
Mortar aggregate	Physical properties	ASTM C144	The first load and each tenth successive load of masonry aggregate is tested
Cement for mortar	Standard physical and chemical properties	ASTM C150	Initially, and thereafter for every 10,000 pounds of cement delivered
Hydrated lime	Physical and chemical properties	ASTM C207, Type S or SA	Initially, and thereafter for every 5000 pounds of lime delivered
Chemtree grout	Compressive strength	ASTM C39	Two cylinders cast each day that grout is placed
	Unit weight	ASTM C138	Three times, at approximately equal time intervals, each day that grout is placed
Mortar	Compressive strength	UBC 24.23	Once per shift per mixer

(1) ASTM C128 is performed more frequently for medium and high density grout/concrete and masonry grout

Table 3.8-20

COMPARISON OF CONTAINMENT LOAD COMBINATIONS WITH SRP 3.8.3

LGS UFSAR TABLE	TYPE OF STRUCTURE	CONDITION	OMISSION	JUSTIFICATION
3.8-5 thru 3.8-8	Concrete and Steel internal structures of containment	All accident conditions	Thermal pipe (R_a)[1] were not included	Thermal pipe reactions are checked locally for structural adequacy. These loads are generally small compared to pipe loads and negligible in combination with other loads.
3.8-7	Drywell Platforms	1) Abnormal	1) Seismic not included	1) Seismic is small in comparison with pipe restraints and jet force loads which have been considered.
		2) Normal	2) Seismic not included	2) Combining seismic with dead and live loads gives higher allowable stresses and thus does not control the design.
3.8-7	Drywell Platforms	Normal Abnormal	1) T_a Neglected	1) Expansion of structural members under thermal loadings are permitted; therefore, thermal-stresses are negligible.
	Seismic Truss	Abnormal/ Extreme	2) P_a Neglected	2) The pressure differential along the supporting beams is negligible.
3.8-8	Seismic Truss	Abnormal/ Extreme	Live load (L) not included	Live loads are negligible in comparison with main steam pipe jet forces (R)[1]

[1] "R" as defined in the UFSAR is equivalent to the expression ($Y_r + Y_j + Y_m$) as defined in the SRP

Table 3.8-21

COMPARISON OF CONTAINMENT LOAD COMBINATIONS WITH ASME CODE, ARTICLE CC-3000

ASME LOAD	DIFFERENCES	ASME CATEGORY	JUSTIFICATION
F	Prestress not applicable	All	LGS has a reinforced concrete containment and no prestress loads exist.
W & W_t	Wind and tornado loads not considered	Construction Severe environmental Abnormal/Severe Environmental Extreme Environmental	Tornado or wind loadings do not apply. The primary containment is protected by the reactor enclosure.
T_t	Thermal not considered for structural integrity test.	Test	LGS design criteria addresses the structural integrity test. Pressure has been increased 15% over ASME. The ambient air temperature during testing is close to that of construction; therefore, the effects of thermal gradient are negligible.
E_o, P_a	Load Factors for E_o and P_a have been slightly reduced.	Abnormal Abnormal/Severe Environmental	Load factors for loading combination are based on probable occurrence. By introducing the hydrodynamic event, a slight load factor reduction for these loads (E_o, P_a) is justifiable.

3.9 MECHANICAL SYSTEMS AND COMPONENTS

The system and component design criteria and analyses in Section 3.9 are referenced to LGS operation at the originally licensed rated reactor power of 3293 MWt. The effects of increased power, pressure, and flow rates for power rerate conditions on the reactor vessel and internals, and main steam and recirculation piping were evaluated. The results demonstrate LGS compliance with appropriate design and licensing criteria at rerate conditions. These are documented in Ref. 3.9-23 and 3.9-24. Additional analyses were also performed which considered the use of GE13 and GE14 fuel; these analyses are documented in Reference 3.9-28 and Reference 3.9-34, respectively. The GE14 fuel is demonstrated to be bounded by the GE13 results. The reactor vessel components were evaluated for the effects of MUR power uprate in Reference 3.9-31. The results show that the reactor vessel components continue to comply with the structural requirements. The RPV internals were evaluated for loads associated with the MUR power uprate in Reference 3.9-32. The RPV internal components are demonstrated to be structurally qualified for operation in the MUR conditions. Reference 3.9-33 identifies new design basis values for Fuel Lift Margin and Control Rod Guide Tube Lift Forces under MUR conditions. Subsequently, analyses were performed which considered the use of GNF2 fuel; these analyses aere documented in Reference 3.9-35. The GNF2 fuel is demonstrated to be bounded by the analyses in Reference 3.9-33.

Analyses were performed which considered the use of GNF3 fuel. Reference 3.9-39 identified new design basis values for the reactor internal pressure differences for unbounded reactor internals during normal, upset, and faulted conditions. The GNF3 analyses also identified a new design basis value for maximum Control Rod Guide Tube Lift force at faulted conditions. Structural evaluations for the reactor internals were conducted based on these GNF3 results which demonstrated that all vessel internal components continue to meet structural requirements.

3.9.1 SPECIAL TOPICS FOR MECHANICAL COMPONENTS

3.9.1.1 Design Transients

This section discusses the transients used in the design and fatigue analysis of the ASME Code Class 1 components, component supports, and reactor internals. The number of cycles or events for each transient based on available and projected plant operating data at the time of design is included. The design transients shown in this section are included in the design specifications for the components. Transients or combinations of transients are classified with respect to the component operating condition categories, identified as "normal," "upset," "emergency," "faulted," or "testing" in the ASME B&PV Code, if applicable. The first four operating conditions correspond to service levels A, B, C and D, respectively.

3.9.1.1.1 Control Rod Drive Transients

The normal and test service load cycles used for design purposes in the 40 year life of the CRD are as follows:

	Transient	Category	Cycles
a.	Reactor startup and shutdown	Normal/Upset(1)	120
b.	Vessel pressure tests	Normal/Upset	130
c.	Vessel overpressure	Normal/Upset	10

d.	Scram test plus startup scrams	Normal/Upset	300
e.	Operational scrams	Normal/Upset	300[2]
f.	Jog cycles	Normal/Upset	30,000[3]
g.	Shim/drive cycles	Normal/Upset	1,000[3]

(1) In Section 3.9.1.1, whenever a transient is categorized with two classifications, i.e., normal/upset, the most limiting of the two is considered in the design.

(2) 180 scram cycles constitute the design basis; however, 300 cycles are applied to the CRD for conservatism.

(3) 30,000 jog cycles and 1000 shim/drive cycles are applied because they impose mechanical loads on the CRD while contributing negligible thermal loads.

In addition to the above cycles, the following have been considered in the design of the CRD:

	Transient	Category	Cycles
h.	Scram with inoperative buffer	Normal/Upset	10
i.	Scram with stuck control blade	Normal/Upset	1
j.	OBE[3]	Upset	10
k.	SSE	Faulted	1

All ASME Class 1 components of the CRD have been analyzed according to ASME Section III. The capability of the CRD to withstand other emergency and faulted conditions is verified by test rather than analysis.

3.9.1.1.2 CRD Housing and Incore Housing Transients

Transients, classifications, and number of cycles considered in the design and fatigue analysis of the CRD housing and incore housing are as follows:

	Transient	Category	Cycles
a.	Normal startup and shutdown	Normal/Upset	120
b.	Vessel pressure tests	Normal/Upset	130
c.	Vessel overpressure tests	Normal/Upset	10
d.	Interruption of feedwater flow	Normal/Upset	80[1]
e.	Scram	Normal/Upset	200[2]
f.	OBE	Upset	10
g.	SSE	Faulted	1

(1) The interruption of feedwater flow imposes thermal loads on the CRD housing while contributing negligible mechanical loads.

(2) 180 scram cycles constitute the design basis; however, 200 cycles are applied to the CRD housing for conservatism.

(3) The frequency of occurrence of this transient indicates the emergency category. However, for conservatism, the OBE was analyzed as an upset condition. Ten peak stress cycles are postulated.

CRD HOUSING ONLY

h.	Stuck rod scram	Normal/Upset	1
i.	Scram with no buffer	Normal/Upset	1

3.9.1.1.3 Hydraulic Control Unit Transients

	Transient	Category	Cycles
a.	Reactor startup and shutdown	Normal/Upset	120
b.	Scram tests	Normal/Upset	300
c.	Operational scrams	Normal/Upset	300
d.	Jog cycles	Normal/Upset	30,000
e.	Scram with stuck scram discharge valve	Emergency	1
f.	OBE	Upset	10
g.	SSE	Faulted	1

3.9.1.1.4 Core Support and Reactor Internals Transients

Cycles considered in the reactor internals design and fatigue analysis are listed in Table 3.9-2.

3.9.1.1.5 Main Steam System Transients

Transients considered in the main steam piping stress analysis are as follows:

	Transient	Category	Cycles
a.	Startup	Normal	120(1)
b.	Loss of feedwater pumps, isolation valves closed	Upset	10
c.	Scram	Upset	180
d.	Shutdown	Normal	111(1)
e.	Hydrostatic test	Test	3

(1) In the design of NSSS piping systems, there are 9 transients not counted for the shutdown; 8 are due to SRV blowdown and 1 is due to automatic depressurization.

f.	Design hydrotest	Test	130
g.	OBE	Upset	50
h.	Turbine stop valve closure	Upset	120
i.	Relief valve lift (at 3 cycles per actuation)	Upset	34,200

3.9.1.1.6 Recirculation System Transients

Transients considered in the recirculation piping stress analysis are as follows:

	Transient	Category	Cycles
a.	Startup	Normal	120(1)
b.	Turbine roll and increase to power	Normal	120
c.	Loss of feedwater heater	Upset	10
d.	Partial feedwater heater bypass	Upset	70
e.	Scrams	Upset	180
f.	Shutdown	Normal	111(1)
g.	Loss of feedwater pumps, isolation valves closed	Upset	10
h.	Single SRV blowdown	Upset	8
i.	Design hydrotest	Test	130
j.	OBE	Upset	50

3.9.1.1.7 Reactor Assembly Transients

The reactor assembly includes the RPV, support skirt, shroud support, and shroud plate. The cycles listed in Table 3.9-2 are as specified in the reactor assembly design and fatigue analysis.

---

(1) In the design of NSSS piping systems, there are 9 transients not counted for the shutdown; 8 are due to SRV blowdown and 1 is due to automatic depressurization.

3.9.1.1.8 Main Steam Isolation Valve Transients

The MSIVs are designed for the following service conditions and thermal cycles:

	Transient	Category	Cycles
a.	Preop @100°F/hr	Normal/Upset	150
b.	Startup (heating @100°F/hr)	Normal/Upset	120
c.	Shutdown		
	1. Cooling cycles @100°F/hr, 540°F to 375°F	Normal/Upset	120
	2. Cooling cycles @270°F/hr, 375°F to 330°F	Normal/Upset	120
	3. Cooling cycles @100°F/hr, 330°F to 100°F	Normal/Upset	120
d.	Scram cooling cycles @100°F/hr	Normal/Upset	180
e.	Emergency and faulted transients		
	1. 546°F to 281°F in 15 seconds	Emergency/Faulted	1
	2. 546°F to 375°F in 3.3 minutes	Emergency/Faulted	1
	375°F to 281°F @300°F/hr	Emergency/Faulted	1
	3. 546°F to 375°F in 10 minutes	Emergency/Faulted	8
	375°F to 281°F @100°F/hr	Emergency/Faulted	8
	4. 546°F to 583°F in 2 seconds	Emergency/Faulted	1
	583°F to 538°F in 30 seconds	Emergency/Faulted	1
	538°F to 400°F @100°F/hr	Emergency/Faulted	1
	400°F to 546°F @100°F/hr	Emergency/Faulted	1
	5. 561°F to 500°F in 7 minutes	Emergency/Faulted	10
	500°F to 400°F @100°F/hr	Emergency/Faulted	10
	400°F to 546°F @100°F/hr	Emergency/Faulted	10

3.9.1.1.9 Main Steam Relief Valves Transients

The transients used in the analysis of the MSRVs are as follows:

	Transient	Category	Cycles
a.	Preop and inservice testing (100°F/hr)	Normal/Upset	150
b.	Startup (100°F/hr) and pressure increase (0 psig to 1000 psig)	Normal/Upset	120
c.	Shutdown (100°F/hr, pressure decrease to 0 psig, 270°F/hr between 375°F and 330°F)	Normal/Upset	120
d.	Scram	Normal/Upset	180
e.	System pressure and temperature decay is from 1000 psig and 546°F, to 35 psig and 281°F within 15 seconds.	Emergency/Faulted	1
f.	System temperature change is from 546°F to 375°F within 3.3 minutes, and from 375°F to 281°F at a rate of 300°F/hr. Pressure change is from 1000 psig to 35 psig.	Emergency/Faulted	1
g.	System temperature change is from 546°F to 375°F within 10 minutes, and from 375°F to 281°F, at a rate of 100°F/hr. Pressure change is from 1000 psig to 35 psig.	Emergency/Faulted	8
h.	System temperature change is from 546°F to 583°F within 2 seconds, from 583°F to 538°F within 30 seconds, and from 538°F to 400°F with return to 546°F at a rate of 100°F/hr. Pressure change is from 1000 psig to 1350 psig, thence to 240 psig, with return to 1000 psig.	Emergency/Faulted	1

i.	System temperature changes greater than 30°F, are from 561°F to 500°F within 7 minutes, and from 500°F to 400°F, with return-to-normal operating temperature of 546°F, at a rate of 100°F/hr. Pressure change is from 1000 psig to 1180 psig, to 240 psig, with return-to-normal operating pressure of 1000 psig.	Emergency/Faulted	10

In addition, for RPV, RPV internals and piping New Loads Adequacy Evaluation, at least 7700 SRV cycles are considered to account for the pool dynamic loads. These 7700 cycles are based on 1100 actuations (total for 40 years) of all SRVs times seven stress cycles per actuation. Further, 4700 actuations (total for 40 years) for the most frequently actuated SRV times three stress cycles per actuation (14,100 total cycles) are used in the analysis of the SRV downcomers and SRV discharge lines in the wetwell and in the main steam piping analysis. The 4700 actuations over the 40 year plant design life for the most frequently actuated SRV is based on the original two-stage Target Rock SRV design used for LGS. This SRV has a longer blowdown time, similar to the Crosby SRV design.

ASME Section III, Paragraph NB3552 excludes various transients, and provides means for combining those which are not excluded. Review and approval of the equipment supplier's certified calculation provides assurance of proper accounting for the specified transients.

3.9.1.1.10 Recirculation Flow Control Valve Transients

Not applicable; LGS has no flow control valve.

3.9.1.1.11 Recirculation Pump Transients

The following transients are listed in the design specification as a requirement for design considerations. The vendor was required to submit a certification of compliance with certified design calculations which considered only a pressure transient (no thermal-stresses were required to be considered). Nozzle piping loads were considered in accordance with the following paragraph from the design specification:

> "The pump case shall be designed to withstand secondary stresses due to piping reactions in accordance with Paragraph 452.4b of the ASME Standard Code for Pumps and Valves for Nuclear Power (1968 Draft)."

	Transient	Category	Cycles
a.	Heatup and cooldown at 100°F/hr	Normal/Upset	30
b.	±29°F temperature changes	Normal/Upset	600
c.	±50°F temperature changes	Normal/Upset	200
d.	RPV pressure transients to 110% design pressure	Normal/Upset	30
e.	SRV blowdowns	Emergency	1
f.	Improper pump startup, 100°F to 546°F in 15 seconds	Emergency	1
g.	Cooling transient, 552°F to 281°F in 15 seconds	Faulted	2
h.	Hydrotest to 1300 psig	Test	130
i.	Hydrotest to 1670 psig	Test	3

3.9.1.1.12 Recirculation Gate Valve Transients

The following transients are considered in the design of the recirculation gate valves.

	Transient	Cycles
a.	50°F-575°F-50°F at 100°F/hr	300
b.	±29°F between limits of 50°F and 575°F, instantaneous	600
c.	±50°F between limits of 50°F and 546°F, instantaneous	200
d.	546°F to 375°F, over a 10 minute period	30
e.	546°F to 281°F, over a 15 second period	2
f.	130°F to 546°F, over a 15 second period	1
g.	110% design pressure at 575°F	1
h.	1300 psi at 100°F installed hydrostatic test	130
i.	1670 psi at 100°F installed hydrostatic test	3

3.9.1.2 Computer Programs Used in Analysis

Sections 3.9.1.2.1 through 3.9.1.2.5 discuss computer programs used in the analysis of specific NSSS components (computer programs were not used in the analysis of all components, thus not all components are listed). Non-NSSS programs are discussed in Section 3.9.1.2.6.

GE Programs

The verification of the following GE programs has been performed in accordance with the requirements of 10CFR50, Appendix B. Evidence of the verification of input, output, and methodology is documented.

a. PIPST01
b. MASS
c. SNAP (MULTISHELL)
d. GASP
e. NOHEAT
f. FINITE
g. DYSEA
h. SHELL 5
i. HEATER
j. FAP 71
k. CREEP PLAST
l. ANSYS
m. SAP4
n. ANSI-7
o. NOZAR
p. TSFOR
q. PISYS
r. PDA
s. EZPYP
t. LION4
u. SIMOK
v. DISPL
w. WTNOZ
x. SPECA04
y. GEAPL01
z. POSUM
aa. FTFLG

Vendor Programs

The verification of the following two groups of vendor programs is assured by contractual requirements between GE and the vendors. In accordance with the requirements, the quality assurance procedure of these proprietary programs used in the design of N-stamped equipment and non-ASME code items is in full compliance with 10CFR50, Appendix B.

Pump Motor Vendor Programs

a. RTRMEC

Chicago Bridge and Iron Programs

p. 1634N

3.9.1.2.1 Reactor Vessel and Internals

3.9.1.2.1.1 Reactor Vessel

The computer programs used in the preparation of the reactor vessel stress report are identified, and their use summarized in the following paragraphs.

3.9.1.2.1.1.1 Chicago Bridge and Iron Program 7-11 - GENOZZ

The GENOZZ computer program is used to proportion barrel and double taper-type nozzles to comply with the specifications of ASME Section III, and contract documents. The program either designs such a configuration or analyzes the configuration input to comply to code. If the input configuration does not comply with the specifications, the program modifies the design and redesigns it to yield an acceptable result.

3.9.1.2.1.1.2 Chicago Bridge and Iron Program 9-48 - NAPALM

The basis for the Nozzle Analysis Program - All Loads Mechanical (NAPALM) is to analyze nozzles for mechanical loads and find the maximum stress intensity and location. The program provides analyses at each mechanical load point of application. The maximum stress intensity is calculated for both the inside and outside surfaces at each reference location. The program measures the maximum stress intensity for both the inside and outside surfaces of the nozzle, as well as their angular locations as measured from the 0° reference location. The principle stresses are also listed.

Stresses resulting from each component of loading (bending, axial, shear, and torsion) are listed, as well as the loadings which cause these stresses.

3.9.1.2.1.1.3 Chicago Bridge and Iron Program 1027

This program is a computerized version of the analysis method contained in Reference 3.9-1.

Part of this program provides for the determination of the shell stress intensities (S) around the perimeter of a loaded attachment on a cylindrical or spherical vessel. Eight (S) values are calculated, one at each of four cardinal points, for both the upper and lower shell plate surfaces (ordinarily considered outside and inside surfaces). With the determination of each (S), the components of that (S) (two normal stresses, δ_x and δ_y, and shear stress τ) are also determined. This program provides the same information as the manual calculation, and the input data is essentially the geometry of the vessel and attachment.

3.9.1.2.1.1.4 Chicago Bridge and Iron Program 846

This program computes the required thickness of a hemispherical head with a large number of circular parallel penetrations, by means of the area replacement method, in accordance with ASME Code, Section III.

In cases where the penetration has a counterbore, the thickness is determined so that the counterbore does not penetrate the outside surface of the head.

3.9.1.2.1.1.5 Chicago Bridge and Iron Program 781 - KALNINS

The KALNINS thin-shell program is used to establish the shell influence coefficient, and to perform the detailed stress analysis of the vessel. The stresses and the deformations of the vessel can be computed for any combination of the following axisymmetric loading:

a. Preload condition

b. Internal pressure

c. Thermal load

This program is a thin elastic shell program for shells of revolution developed by Dr. A. Kalnins of Lehigh University. Extensive revisions and improvements have been made by Dr. J. Endicott, to yield the Chicago Bridge and Iron version of this program.

The basic method of analysis was published by Professor Kalnins (Reference 3.9-2).

3.9.1.2.1.1.6 Chicago Bridge and Iron Program 979 - ASFAST

The ASFAST program performs the stress analysis of axisymmetric, bolted closure flanges between the head and cylindrical shell.

3.9.1.2.1.1.6.1 ANSYS Engineering Analysis System, Revision 5.6, ANSYS, Inc.

ANSYS Program performed the stress analysis of the reactor vessel head, flange & upper shell for reduced pass tensioning/detensioning of RPV studs connecting RPV head to RPV shell.

3.9.1.2.1.1.7 Chicago Bridge and Iron Program 766 - TEMAPR

This program reduces any arbitrary temperature gradient through the wall thickness to an equivalent linear gradient. The resulting equivalent gradient has the same average temperature, and the same temperature-moment as the given temperature gradient. The input consists of the wall thickness and actual temperature distribution. The output contains the average temperature and total gradient through the wall thickness. The program is written in FORTRAN IV.

3.9.1.2.1.1.8 Chicago Bridge and Iron Program 767 - PRINCESS

The PRINCESS program calculates the maximum alternating stress amplitudes from a series of stress values, by the method in ASME Section III.

3.9.1.2.1.1.9 Chicago Bridge and Iron Program 928 - TGRV

The TGRV program is used to calculate temperature distributions in structures or vessels. Although it is primarily a program for solving the heat conduction equations, some provisions have been made for including radiation and convection effects at the surfaces of the vessel.

The TGRV program is a highly modified version of the TIGER heat transfer program, written about 1958 at Knolls Atomic Power Laboratory, by A.P. Bray.

The program utilizes an electrical network analogy to obtain the temperature distribution of any given system as a function of time. The finite-difference representation of the three-dimensional equations of heat transfer are repeatedly solved for small time increments, and continually

summed. Linear mathematics is used to solve the mesh network for every time interval. Three basic forms of heat transfer (conduction, radiation, and convection), as well as internal heat generation, are included in the analysis.

TGRV calculates and outputs the steady-state or transient temperature distributions in a given structure, as a function of time. The program inputs are any odd-shaped structure which can be represented by a three-dimensional field, its geometry and physical properties, boundary conditions, and internal heat generation rates.

3.9.1.2.1.1.10 Chicago Bridge and Iron Program 962 - E0962A

Program E0962A is one of a group of programs (E0953A, E1606A, E0962A, E0992N, E1037N, and E0984N) which are used together to determine the temperature distribution and stresses in pressure vessel components, using the finite-element method.

Program E0962A is primarily a plotting program. Using the nodal temperatures calculated by program E1606A or Program E0928A, and the node and element cards for the finite-element model, it calculates and plots lines of constant temperature (isotherms). These isotherm plots are used as part of the stress report to present the results of the thermal analysis. They are also useful in determining at which points in time the thermal-stresses should be determined.

In addition to its plotting capability, the program can also determine the temperatures of some of the nodal points by interpolation. This feature of the program is intended primarily for use with the compatible TGRV and finite-element models that are generated by program E0953A.

3.9.1.2.1.1.11 Chicago Bridge and Iron Program 984

Program 984 is used to calculate the stress intensity of stress differences, on a component level, between two different stress conditions. The calculation of the stress intensity of stress component differences (the range of stress intensity) is required by ASME Section III.

3.9.1.2.1.1.12 Chicago Bridge and Iron Program 992 GASP

The GASP program, originated by Professor E.L. Wilson of the University of California at Berkeley, uses the finite-element method to determine the stresses and displacements of plane or axisymmetric structures of arbitrary geometry, and is written in FORTRAN IV. See Reference 3.9-3, for a detailed account. GASP structures may have arbitrary geometry, and have linear or nonlinear material properties. The loadings may be thermal, mechanical, accelerational, or a combination of these.

A structure to be analyzed is broken up into a finite number of discrete elements or "finite-elements", which are interconnected at a finite number of "nodal points" or "nodes." The actual loads on the structure are simulated by statically equivalent loads acting at the appropriate nodes. The basic input to the program consists of the geometry of the stress model and the boundary conditions. The program then gives the stress components at the center of each element and the displacements at the nodes, consistent with the prescribed boundary conditions.

3.9.1.2.1.1.13 Chicago Bridge and Iron Program 1037 - DUNHAM'S

DUNHAM'S program is a finite ring element stress analysis program. It determines the stresses and displacements of axisymmetric structures of arbitrary geometry subjected to either axisymmetric loads, or nonaxisymmetric loads represented by a Fourier series.

This program is similar to the GASP program (Chicago Bridge and Iron Program 992). The major differences are that DUNHAM'S can handle nonaxisymmetric loads (which requires that each node have three degrees of freedom), while the material properties for DUNHAM'S must be constant. As in GASP, the loadings may be thermal, mechanical, and accelerational.

3.9.1.2.1.1.14 Chicago Bridge and Iron Program 1335

To obtain stresses in the shroud support, the baffle plate must be made a continuous circular plate. The program makes this modification and allows the baffle plate to be included in Chicago Bridge and Iron program 781 (KALNINS) as two isotropic parts, with an orthotropic portion at the middle (where the diffuser holes are located).

3.9.1.2.1.1.15 Chicago Bridge and Iron Programs 1606 and 1657 - HAP

The HAP program is an axisymmetric nonlinear heat analysis program. It is a finite-element program, used to determine nodal temperatures in a two-dimensional or axisymmetric body subject to transient disturbances. Programs 1606 and 1657 are identical, except that 1606 has a larger storage area allocated, and can thus be used to solve larger problems. The model for program 1606 is compatible with Chicago Bridge and Iron stress programs 992 (GASP) and 1037 (DUNHAM'S).

3.9.1.2.1.1.16 Chicago Bridge and Iron Program 1634N

This program is used to analyze thin cylindrical shells subjected to local loading beyond the range where Bijlaard's curves are directly applicable, i.e., R/t >300.

This program computes stress and displacements in thin-walled elastic cylindrical shells subjected to mechanical loading such as radial loads, longitudinal and circumferential moments.

3.9.1.2.1.2 Reactor Internals

3.9.1.2.1.2.1 Core Plate Beam Buckling - PIPST01

PIPST01 is a computer program that calculates approximate core plate beam buckling capability. It uses the Rayleigh-Ritz energy method to determine the applied moment needed to begin yielding and then to buckle a given tee beam. The tee beam models a segment of a BWR/2-5 core plate with a stiffener beam. The pressure differential across the plate that would have created this moment is calculated for a given length of beam or size of core plate.

Generic dimension and material properties are all input by the user.

3.9.1.2.1.2.2 Other Programs

Other computer codes used for the analysis of the internal components are:

a. MASS
b. SNAP (MULTISHELL)
c. GASP
d. NOHEAT
e. FINITE
f. DYSEA
g. SHELL 5
h. HEATER
i. FAP 71
j. CREEP PLAST
k. ANSYS

Descriptions of these programs are given in Section 4.1.4.1.

3.9.1.2.2 Piping

3.9.1.2.2.1 Structural Analysis Program - SAP4

SAP4 is a general Structural Analysis Program for static and dynamic analysis of linear elastic complex structures. The finite-element displacement method is used to solve the displacements, and to compute the stresses of each element of the structure. The structure can be composed of unlimited numbers of three-dimensional truss, beam, plate, shell, solid, plate strain-plane stress, brick, thick shell, spring, or axisymmetric elements. The program can treat thermal and various forms of mechanical loading, as well as internal element loading. The dynamic analysis includes mode- superposition, time history, and response spectrum analyses. Earthquake loading, as well as time-varying pressure, can be treated. The program is very versatile and efficient in solving large and complex structural systems. The output contains displacements of each nodal point, as well as stresses at the surface of each element.

3.9.1.2.2.2 Component Analysis - ANSI-7

The ANSI-7 Computer Program determines stress and accumulative usage factors in accordance with NB-3600 of ASME Section III. The program performs stress analyses in accordance with the ASME sample problem, and has been verified by reproducing the results of the sample problem analysis.

3.9.1.2.2.3 Area Reinforcement - NOZAR

The computer program Nozzle Area Reinforcement Program (NOZAR) performs an analysis of the required reinforcement area for openings. The calculations performed by NOZAR are in accordance with the rules of the 1974 edition of ASME Section III.

3.9.1.2.2.4 Turbine Stop Valve Closure - TSFOR

The TSFOR program computes the time history forcing function in the main steam piping due to turbine stop valve closure. The program utilizes the method of characteristics to compute fluid momentum and pressure loads at each change in pipe section or direction.

3.9.1.2.2.5 Piping Analysis Program/PISYS

PISYS is a computer code for analyzing piping systems subjected to both static and dynamic piping loads. Stiffness matrices representing standard piping components are assembled by the program to form a finite-element model of a piping system. The piping elements are connected to each other via nodes called pipe joints. It is through these joints that the model interacts with the environment, and loading of the piping system becomes possible. PISYS is based on the linear-elastic analysis in which the resultant deformations, forces, moments, and accelerations at each joint are proportional to the loading and the superposition of loading is valid.

PISYS has a full range of static and dynamic load analysis options. Static analysis includes dead weight, uniformly distributed weight, thermal expansion, externally applied forces, moments, imposed displacements, and differential support movement (pseudostatic load case). Dynamic analysis includes mode shape extraction, response spectrum analysis, and time history analysis by modal combination or direct integration. In the response spectrum analysis, i.e., Uniform Support Motion Response Spectrum Analysis (USMA) or Independent Support Motion Response Spectrum Analysis (ISMA), the user may request modal response combination in accordance with Regulatory Guide 1.92. In the ground motion (uniform motion) or independent support time history analysis, the normal mode solution procedure is selected. In analysis involving time-varying nodal loads, the step-by-step direct integration method is used.

The PISYS program has been benchmarked against NRC piping models. The results are documented in a report to the Commission, "PISYS Analysis of NRC Benchmark Problems," NEDO-24210, August 1979, for mode shapes and USMA options. The ISMA option has been validated against NUREG/CR-1677, "Piping Benchmark Problems Dynamic Analysis Independent Support Motion Response Spectrum Method," published in August 1985.

3.9.1.2.2.6 Piping Dynamic Analysis Program - PDA

The pipe whip analysis was performed using the PDA computer program. PDA is used to determine the response of a pipe subjected to the thrust-force occurring after a pipe break. The program treats the situation in terms of generic pipe break configuration, which involves a straight, uniform pipe fixed at one end, subjected to a time-dependent thrust-force at the other end. A typical restraint used to reduce the resulting deformation is also included at a location between the two ends. Nonlinear and time-independent stress-strain relations are used to model the pipe and the restraint. Similar to the popular elastic-hinge concept, bending of the pipe is assumed to occur at the fixed end, and at the location supported by the restraint, only.

Shear deformation is also neglected. The pipe bending moment-deflection (or rotation) relation used for these locations is obtained from a static nonlinear cantilever beam analysis. Using moment-rotation relations, nonlinear equations of motion are formulated using energy considerations, and the equations are numerically integrated in small time steps to yield the time history of the pipe motion. Additional discussion of PDA is provided in Section 3.6.2.2.2.

3.9.1.2.2.7 Piping Analysis Program - EZPYP

EZPYP links the ANSI-7 and SAP programs together. The EZPYP program can be used to run several SAP cases by making user- specified changes to a basic SAP pipe model. By controlling

files and SAP runs, the EZPYP program makes it possible to perform a complete piping analysis in one computer run.

3.9.1.2.2.8 Thermal Transient Program - LION4

The LION4 program is used to compute radial axialthermal gradients in piping. The program calculates a time history of ΔT_1, ΔT_2, T_a, and T_b (defined in ASME Section III, Class 1 piping analysis) for uniform and tapered pipe wall thickness.

3.9.1.2.2.9 Synthetic Time History Program - SIMOK

The SIMOK program provides a time history that is equivalent to an input response spectrum. The synthetic time history is used to generate a new spectrum that is plotted with the input spectrum, to verify that the time history and spectrum are equivalent. Synthetic time histories are used in a multiple input analysis of the piping.

3.9.1.2.2.10 Differential Displacement Program - DISPL

The DISPL program provides differential movements at each piping attachment point, based on building modal displacements.

3.9.1.2.2.11 WTNOZ Computer Program

WTNOZ is a time-share program for piping weight calculations.

3.9.1.2.3 Pumps and Motors

3.9.1.2.3.1 Recirculation Pumps

No computer programs were used in the design of the recirculation pumps.

3.9.1.2.3.2 Core Spray Pumps and Motors

The RTRMEC computer program is used in the analysis of a motor design representative of (or very similar in mechanical construction to) the core spray pump motor.

RTRMEC calculates and displays the results of a mechanical analysis of a motor rotor assembly acted upon by external forces at any point along the shaft (rotating parts only). The shaft deflection analysis, including magnetic and centrifugal forces, was conducted. The calculation for the seismic condition assumes that the motor is operating, and that the seismic, magnetic, and centrifugal forces all act simultaneously and in phase on the rotor-shaft assembly. Note that the distributed motor assembly weight is lumped at the various stations. The shaft weight at a station is the sum of one-half the weight of the incremental shaft length just before the station, plus one-half the weight of the adjacent incremental shaft length just after the station. Bending and shear effects are accounted for in the calculations.

The FTFLG computer program was used to analyze the flange joints connecting the pump bowl castings. The description of this program is provided in Section 3.9.1.2.5.3.

3.9.1.2.4 Dynamic Loads Analysis

3.9.1.2.4.1 Acceleration Response Spectrum Program/SPECA04

The SPECA04 computer program generates acceleration response spectrum, consistent with Regulatory Guide 1.122 for an arbitrary input of time history of piecewise-linear accelerations, i.e., to compute maximum acceleration responses for a series of single-degree-of-freedom systems subjected to the same input. It can accept acceleration time histories from a random file.
It also has the capability of generating the broadened/enveloping spectra in conformance with Regulatory Guide 1.122 when the spectral points are generated equally spaced in a logarithmic scale axis of period/frequency. This program is also used in seismic and SRV transient analysis.

3.9.1.2.4.2 Forces and Moment Time Histories Program/GEAPL01

The GEAPL01 computer program converts distributed asymmetric pressure time histories over a given area into equivalent time-varying nodal forces and moments for use as input to perform dynamic analysis of a system. The overall resultant forces and moment time histories at specified points of resolution can also be obtained from GEAPL01.

3.9.1.2.5 Residual Heat Removal Heat Exchangers

3.9.1.2.5.1 Structural Analysis Program - SAP4

SAP4 is used to analyze the structural and functional integrity of the RHR heat exchangers. The description of this program is provided in Section 3.9.1.2.2.1.

3.9.1.2.5.2 Beam Element Data Processing Program/POSUM

POSUM is used to process SAP4 generated data. POSUM is a computer code designed to process SAP4 generated beam element data for pump or heat exchanger models. The purpose is to determine the load combination that would produce the maximum stress in a selected beam element. It is intended for use on RHR heat exchangers with four nozzles or core spray pumps with two nozzles.

3.9.1.2.5.3 Effects of Flange Joint Connections/FTFLG

The flange joints connecting the pump bowl castings are analyzed using FTFLG program. This program uses the local forces and moments determined by SAP4 to perform flat flange calculations in accordance with the rules set forth in ASME Appendix II and ASME Section III.

3.9.1.2.6 Seismic Category I Items Other than NSSS

A list of computer programs used in the non-NSSS system components is provided in Table 3.9-3. This list consists of computer programs developed and/or owned by Bechtel, and of computer programs that are recognized and widely used in industry.

The Bechtel developed and/or owned computer programs are documented, verified, and maintained by Bechtel, and meet the requirements of 10CFR50, Appendix B. A brief description of each of these Bechtel programs is provided below.

3.9.1.2.6.1 ME101, Linear-Elastic Analysis

ME101 is a finite-element computer program that performs linear-elastic analysis of piping systems using standard beam theory techniques. The input data format is specifically designed for pipe stress engineering. ME101 performs a thorough check of the input prior to analysis. In addition, the program automatically modifies the geometry to improve the finite-element model.

The output may be used directly for piping design, for conformation to Code, and for other regulatory requirements. Both ASME Section III and ANSI B31.1 piping code editions are incorporated in ME101 to the extent of computing flexibility factors, stress intensification factors, and stresses.

ME101 performs static and dynamic load analysis of piping systems, effective weight calculations, and ASME Section III, Class 2 and 3, and ANSI B31.1 Code stress checks.

Static analysis considers one or more of the following: thermal expansion, dead weight, uniformly distributed loads, and externally applied forces, moments, imposed displacements and rotations, individual force loads, static seismic (uniform directional acceleration) loads, or seismic anchor movement analysis.

Dynamic analysis is based on the standard normal superposition techniques. The input excitation may be in the form of seismic response spectra or time-dependent loading functions. In the single or multiple response spectrum analysis, the user may request modal synthesis by SRSS method or by Regulatory Guide 1.92 closely spaced mode 10% (equation 4) method. ME101 can consider further differential damping for large and small pipe according to Regulatory Guide 1.61. Various methods of eigenvalue solution are available. Determinant search or subspace iteration considers all data points as mass points. In the time history analysis, the excitation may be in the form of arbitrary nodal forces, support displacements, rotations, or support accelerations that are not necessarily in phase.

ME101 checks stresses from design loads versus allowable stresses according to ASME/ANSI Code equations. The user may request design load checks for sustained loads, occasional loads, multimode thermal expansion and pipe break, except for time history load cases.

The ME101 restraint load summary report prints the support load results from several load cases together in the same report, except for time history load cases.

The general loading combinations capability for ME101 can combine the results of several load cases together, according to certain algebraic rules, to form a new load case. The new load case resulting from this may be used in stress comparisons or restraint load summaries, except for time history load cases. ME101 has the capability of saving load case results on a tape and using these results in late runs for stress checks, restraint load summary reports, and general loading combinations, except for time history load cases.

For piping configurations with optional node numbering, ME101 generates isometric plots. The user may obtain plots on ZETA or CALCOMP plotters on a Tektronix 4014 graphics terminal, or on a RMS-600 printer/plotter.

ME101 uses out-of-core techniques for both static and response spectra analysis and has no practical limitations to the number of equations or band width. However, the use of very large

systems may become prohibitive due to cost of computation. The maximum number of mode shapes allowable for response spectra analysis is currently 125.

This program considers the zero period acceleration effect in seismic response analysis. It accepts coordinate and key-word data in English or metric units.

The ASME Benchmark Problem 1 demonstrates the solution for natural frequencies of a three-dimensional structure, as described in Reference 3.9-4.

Natural frequencies, in Hertz, from ME101 and Reference 3.9-4, are as follows:

Mode	Reference 3.9-4	ME101
1	110	112
2	117	116
3	134	138

A total of 26 test problems were used for the verification of the ME101 results. These verification problems have been compared against one of the following:

a. ME632, Computer Program, "Seismic Analysis of Piping Systems", VERB MODB, 1976 Bechtel International Corporation, San Francisco, CA.

b. "Pressure Vessel and Piping 1972 Computer Programs Verification", ASME.

c. Hand Calculations

d. EDS Superpipe, EDS Nuclear, San Francisco, CA.

e. NUPIPE-IIM, Nuclear Services Corporation Piping Analysis Program, Campbell, CA.

f. TPIPE, A Computer Program for Analysis of Piping Systems, PMB Systems Engineering, San Francisco, CA.

g. ADINA, A Computer Program, Massachusetts Institute of Technology, Boston, MA.

h. MSC/NASTRAN Program, McNeal Schwendler Corporation, Los Angeles, CA.

i. EASE2 Program, Engineering/Analysis Corporation, San Francisco, CA.

j. ANSYS, Swanson Analysis System, Inc., 1975, Elizabeth, PA.

The J1 version of ME101 also includes seven NRC benchmarked problems, as referenced in NUREG/CR-1677, dated August 1980.

ME-101 was also validated with the four benchmarked problems (using the multiple response spectrum/independent support motion method) that were transmitted from M. Hartzman (NRC) to G. Wang (Bechtel) on August 10, 1983. The results and comparisons of the problems using ME-101 were transmitted to M. Hartzman (NRC) from T.J. McDonald (Bechtel) on December 15, 1983.

The ME-101 MRS/ISM methodology was again validated with four multiple response spectrum problems, as referenced in NUREG/ CR-1677, Volume II, dated August 1985.

3.9.1.2.6.2 ME632, Piping System Analysis

Program Description

ME632 performs stress analyses of three-dimensional piping systems. The effects of thermal expansion, uniform load of the pipe, pipe contents and insulation, concentrated loads, movements of the piping system supports, and other external loads, such as wind and snow, may be considered. The input data format is specifically designed for pipe stress engineering, and the English system of units is used. A thorough checking of the input has been coordinated in the program.

The output may be used directly for piping design, and for conformation to code and other regulatory requirements. Piping codes, the ASME B&PV code, the B31.1 code, and the B31.3 code have been incorporated into the program to the extent of computing flexibility factors, stress intensification factors, and stresses.

A response spectrum analysis may be performed to analyze the effect of earthquake forces on the piping system; transient effects of water hammer, steam hammer, or other impulsive types of dynamic loading are also handled by the program. A plot of piping geometry and/or response spectrum curves may be obtained to verify the accuracy of the model.

Program Version and Computer

The current UNIVAC version of ME632 is being used by Bechtel.

Extent of Application

ME632 is a piping program developed by Bechtel. Its development began in 1970, and it is being continuously supported by Bechtel. It has been used by various Bechtel projects.

Test Problems

The ASME Benchmark Problem No. 1 demonstrates the solution for natural frequencies of a three-dimensional structure, as described in Reference 3.9-4.

The following table lists the natural frequencies from ME632 and Reference 3.9-4:

Natural Frequency Comparison, Hz

Mode No.	Reference 3.9-4	ME 632
1	110	111
2	117	116
3	134	137

3.9.1.2.6.3 ME912, Thermal-Stress

Program Description

Finite-difference representation of the heat diffusion equation is used for the pipe or component wall section in contact with fluid of specified temperature and flow rate time histories. The program is quasi-two-dimensional, so that reduction of severity of a given transient with distance from inlet is accounted for.

Thermal properties of water, and stainless and carbon steel are built in the program. Film transfer coefficients for water are computed by the program for each time step and pipe section. For other fluids such as steam, the program is used on a one-dimensional basis with user-supplied film coefficients. Sequential computations are done for pipe lengths of different diameters or wall thicknesses. Fluid outlet temperature data from one pipe length are stored for use as the inlet to the next pipe length downstream. Average temperature differences, T_a - T_b, are thus calculated for structural discontinuity.

Program Version and Computer

The ME912 program has been used by Bechtel on various Bechtel projects. A Univac 1110 computer is used to run the ME912 program.

Extent of Application

The ME912 program was developed from References 3.9-7, 3.9-8, and 3.9-9 by Bechtel. The ME912 program has been extensively used since 1975 for nuclear Class 1 component design on the Fast Flux Test Facility project.

Test Problem

For local gradients, the program has been compared with analytical flat plate data of Reference 3.9-8, and numerical results by in-house program ME643. The results are acceptable. Table 3.9-4 shows the comparison of ME912 with ME643 and analytical results from Reference 3.9-8. For axial variations of fluid and wall temperatures, the program agrees closely with the analytical solution of Reference 3.9-9.

The ME643 program was developed from References 3.9-11 and 3.9-12 by Bechtel.

The results of ME643 transient temperature responses on both inside and outside surfaces of a sample pipe are compared with Chart 36 of Reference 3.9-13, and plotted in Figure 3.9-1.

3.9.1.2.6.4 ME913, Nuclear Class 1 Piping Stress Analysis

Program Description

ME913 can determine stress intensity levels for Class 1 nuclear power piping components, equations 9 through 14 of subarticle NB-3650, "Analysis of Piping Components", ASME Section III.

Prior to using this program, the following information external to the program is required:

a. Piping configuration

b. Piping and piping component properties

c. Moment reactions due to:

   1. Thermal expansion loads

   2. Weight loads

   3. Dynamic loads

d. The thermal response of the piping system due to the specified transients is:

   ΔT_1, ΔT_2 and the (T_a-T_b) values for the key points during system life.

Program Version and Computer

The current ME913 version is being used by Bechtel. A Univac 1100 computer is used to run the ME913 program.

Extent of Application

ME913 is the revised and expanded version of the LOTEMP program, originally developed by Bechtel, and made available for use through the CDC 6600 computer. The LOTEMP program has been extensively used by the Bechtel Fast Flux Test Facility Systems Analysis Group since 1972, in the preliminary design of Fast Flux Test Facility Class 1 piping. The ME913 program has been used to analyze nuclear Class 1 piping for Bechtel nuclear power plant projects.

Test Problems

The Grand Gulf Project feedwater line was selected as a test problem. Hand calculations of a selected component in the piping system were performed in accordance with the sample problem (Reference 3.9-14). The results were compared with the computer output for code equations 9 through 14 in ME913. Table 3.9-5 shows the comparison between the ASME sample problem (Reference 3.9-14) and ME913 results.

3.9.1.2.6.5 NE452, Submerged Steam Line Reflood Analysis

Program Description

NE452 is used to analyze reflood transient in steam relief valve discharge lines that discharge to a water pool and are equipped with a vacuum relief valve. The code models the effect of the vacuum relief valve (considering both the air flow and the valve dynamics) on the line reflood phenomenon by calculating the dynamics of the slug motion of the reflooding water. The slug motion is affected by the steam condensation on the surface of the reflooding water and by the presence of noncondensable air admitted by the vacuum relief valve.

The output (predicted maximum reflood) can be used in relief line clearing transient analysis codes (such as NE805, discussed in Section 3.9.1.2.6.6) to determine pipe run forces. NE452, together with NE805, can be used for vacuum relief valve sizing.

Program Version and Computer

The current NE452 version is being used by Bechtel. A UNIVAC 1100 computer is used to run the NE452 program.

Extent of Application

Development of the NE452 program began in 1977 and is being continuously supported by Bechtel. It has been used for various Bechtel nuclear power plant projects.

Test Problems

The NE452 program was verified against PBAPS and Monticello ramshead and Mark I T-quencher test data. It has also been verified against Karlstein Mark II T-quencher and Caorso X-quencher test data. The predicted results agreed reasonably well with test data.

3.9.1.2.6.6 NE805, Relief Valve Clearing Analysis

Program Description

NE805 is a computer code that analyzes transients in discharge lines of changing cross-sectional area following a relief valve opening. The code predicts the time-dependent forces on the various pipe segments of the relief valve discharge line. It models the steam flow through the relief valve and the steam/air flows in the line. It also models the water flow in the submerged part of the line. The options for the exit device are a straight pipe, a ramshead, or a quencher model in the reservoir. The quencher model considers sequential uncovering of the quencher holes during air/water clearing. NE805 uses the method of characteristics and allows for heat transfer through the pipe wall. It calculates flow parameters, pressure, velocity, and density as functions of time and the distance along the discharge line. Using these calculated values, the code computes the dynamic forcing functions induced on various pipe segments of the relief valve discharge line.

The force output can be used directly for piping stress analysis in codes such as ME101, described in Section 3.9.1.2.6.1.

NE805 generates plots of flow parameter time histories and/or force time histories, an option specified by the user. The plots are obtained by CALCOMP 1036 plotter.

Program Version and Computer

The current UNIVAC version of NE805 is being used by Bechtel. A UNIVAC 1100 computer is used to run the NE805 program.

Extent of Application

NE805 was developed by Bechtel. Its development began in 1975 and is being continuously supported by Bechtel. It has been used by various Bechtel projects.

Test Problems

The NE805 program has been verified against Monticello Mark I T-quencher test, Karlstein Mark II T-quencher test, and Caorso X-quencher test. Comparison with test data was found to be reasonable.

3.9.1.2.6.7 ANSYS

Refer to Section 3.8.7.10

3.9.1.2.6.8 ME210 - Local Stress in Cylindrical Shells Due to External Loads

This standard presents a method of analyzing and determining local stresses in cylindrical shells due to external moments and forces acting on rigid attachments of circular or rectangular shape. This program is based on a paper "Local Stresses in Spherical and Cylindrical Shells Due to External Loadings" by Wichman, Hopper, and Mershon, published in Welding Research Council Bulletin No. 107, August 1965 and March 1979 Revision. Values from Bijlaard curves are obtained by interpolation procedures.

This program also calculates piping stress intensity due to internal pressures and moments in accordance with the pressure and moment stress calculations specified in equation 9 and equation 10 of ASME Section III, NB-3650. The local stress intensity and piping stress intensity are summed and printed out if the required information for piping stress calculation is specified in the input. If no information for piping stress calculation is given, only the local stresses including primary plus secondary stress intensity and primary membrane stress intensities are printed out.

3.9.1.2.6.9 ME602 - Spectra Merging and Simplified Seismic Analysis

ME602 performs the seismic analysis of small diameter piping systems (2 inch and under) using the modified response spectrum method described in BP-TOP-1, Revision 3. The program generates a set of tables of seismic spans, support reactions, and stresses for various pipe sizes.

This program performs response spectrum curve merging along with the calculation of the seismic span. The program can also be used independently for the sole purpose of merging spectrum curves and storing the combined spectrum data for ME101 analysis. A neutral plot file of the "RAW" or "COMBINED" spectrum curves can be generated for plotting on RMS, TEKTRONIX, CALCOMP, or any neutral file compatible plotter.

3.9.1.2.6.10 ME351 - Pipe Rupture Analysis Program

This program performs nonlinear elastic-plastic analysis of three-dimensional piping systems subjected to concentrated static or dynamic time history forcing functions. These forces may result from fluid jet thrust at the location of a postulated rupture of high energy piping. PIPERUP is an adaptation of the finite-element method to the specific requirements of pipe rupture analysis. Straight and curved beam (elbow) elements are used to mathematically represent the piping, and axial and rotational springs are used to represent restraints. The stiffness characteristics of piping and restraints can reflect elastic/linear strain hardening material properties, and gaps between piping and restraints can be modeled.

3.9.1.2.7 Computer Programs Used for Component Supports

A list of computer programs used in pipe support analysis is provided in Table 3.9-3. The list consists of computer programs developed and/or owned by Bechtel, and computer programs that are recognized and widely used in the industry.

The Bechtel developed and/or owned computer programs are documented, verified, and maintained by Bechtel and meet the requirements of 10CFR50, Appendix B. A brief description of each of these programs is provided below.

3.9.1.2.7.1 CE050 - BOLTS

BOLTS is an interactive program for determining the loads on concrete expansion anchors used for baseplates with symmetrical bolt patterns. The program incorporates the effects of plate flexibility, bolt stiffness, and attachment size. BOLTS is particularly well suited for the evaluation of baseplate expansion anchors commonly used in pipe, conduit, HVAC, cable tray, and such other small equipment supports.

3.9.1.2.7.2 ME150 - FAPPS - Frame Analysis for Pipe Supports

ME150 is an interactive program for the analysis and design of pipe support frames. It has built-in standard frames and the capability to design any other nonstandard ones. It optimizes member sizes, welds, and embedments based on various user-specified design criteria.

3.9.1.2.7.3 ME225 - Anchor Plate

ME225 presents a method of designing plate-type piping anchors. It determines thickness of anchor plate, thickness of guide plate, weld joining the plate and process pipe, weld joining the supporting structure, and take out dimension of anchor plate and guide plate.

3.9.1.2.7.4 ME035 - BASEPLATE

ME035 analyzes baseplate-type structural supports. It assumes a flexible plate resting on a nonlinear foundation. It gives concrete stresses, bolt factors of safety, and weld forces. It can analyze baseplates with variable thickness with multiple columnlike attachments.

3.9.1.2.7.5 ME226 - PICLAMP

PICLAMP will design the components of six special cases of pipe support clamps. It computes the minimum required thickness at two critical sections of the clamp. It also calculates the stress in the clamp studs. It computes the stresses in the stanchion and baseplate, when applicable, and the minimum weld size based on the stress. It also computes certain clamp dimensions and the total weight of the clamp and its associated hardware.

3.9.1.2.7.6 ME425 - STAND

STAND will design and evaluate pipe support base plates with concrete anchor bolt assemblies. Plates can be of arbitrary geometry anchored with bolts that can be located in a random pattern.

3.9.1.2.7.7 ME120 - WELD

The program presents a method of determining fillet weld sizes for connecting structural members. It accepts five different types of structural shapes and analyzes for 2-weld to 16-weld configurations. It is based on the approach described in "Design of Welded Structures" by O.W. Blodgett and "Solutions to Design of Weldments" by O.W. Blodgett.

3.9.1.2.7.8 ME152 - SMAPPS

SMAPPS analyzes and designs commonly used standard frames for pipe support including associated welds and baseplates with anchors for AISC and ASME Section III, Subsection NF requirements, as well as project deflection/stiffness requirements.

SMAPPS provides the benefits of a structural frame analysis program and the simplicity of pre-engineering standards. SMAPPS provides margin factors for frame, welds, and baseplate with anchors that minimize the need for re-evaluation of pipe support due to load changes and as-built reconciliation.

3.9.1.2.7.9 CE-901 - ICES STRUDL II

STRUDL is a broad, extensive, and general program for solving problems in structural engineering.

3.9.1.2.7.10 ME153 - MAPPS

MAPPS is a miscellaneous application program for pipe supports which enables the user to access any or all of the following pipe support analysis computer programs within the same run:

- Uniform weld
- Nonuniform welded
- Beta angle
- Clip angle
- Bolt spacing
- Anchor plate
- Local effects
- Clamp (PI clamp)

3.9.1.3 Experimental Stress Analysis

When experimental stress analysis is used in lieu of analytical methods for seismic Category I ASME Code items, the applicable ASME Code requirements for experimental testing of the specific component are applied. If testing is required for seismic Category I non-ASME code items, consideration is given to size effects, dimensional tolerances, and material properties of the tested

part to ensure that the test results are a conservative representation of the load-carrying capability of the item installed at LGS.

3.9.1.3.1 Experimental Stress Analysis of NSSS Seismic Category I Items

No experimental stress analysis methods are used.

3.9.1.3.2 Seismic Category I Items Other Than NSSS

No experimental stress analysis methods are used.

3.9.1.4 Considerations for the Evaluation of Faulted Conditions

All seismic Category I equipment is evaluated for the faulted loading conditions. However, emergency stress limits rather than faulted stress limits are used in many cases. The following paragraphs in this section show examples of the treatment of faulted conditions for the major components on a component-by- component basis. Additional discussion of faulted analysis can be found in Sections 3.9.3 and 3.9.5, and Table 3.9-6. These analyses are based on the power rerate analysis, and do not reflect the use of GE13 and GE14 fuel. The impact of GE13 fuel is documented in Reference 3.9-28. The impact of GE14 fuel is documented to be bounded by GE13 fuel in Reference 3.9-34. The impact of the MUR power uprate on GE14 fuel is evaluated in Reference 3.9-31 and Reference 3.9-32. Reference 3.9-33 identifies new design basis values for Fuel Lift Margin and Control Rod Guide Tube Lift Forces under MUR conditions. Additional analyses which consider the use of GNF2 fuel are documented in Reference 3.9-35. The GNF2 fuel is demonstrated to be bounded by the analyses in Reference 3.9-33.

Analyses were performed which considered the use of GNF3 fuel. Reference 3.9-39 identified new design basis values for the reactor internal pressure differences for unbounded reactor internals. The GNF3 analyses also identified a new design basis value for maximum Control Rod Guide Tube Lift force.

Sections 3.9.2.2 and 3.7 discuss the treatment of dynamic loads resulting from the postulated seismic and hydrodynamic events. Section 3.9.2.5 discusses the dynamic analysis of loads on the reactor internals under faulted conditions including additional blowdown forces. Deformations under faulted conditions have been evaluated in critical areas, and no cases have been identified where design limits, such as clearance limits, are violated.

Elastic-plastic analysis has not been used in evaluating LGS seismic Category I systems and components for compliance with service Level D Limits. The stress levels of these components are below the ASME allowable stress.

3.9.1.4.1 Control Rod Drive System Components

3.9.1.4.1.1 Control Rod Drives

The ASME Section III Code components of the CRD have been analyzed for faulted conditions shown in Section 3.9.1.1.1. The loading criteria, calculated, and allowable stresses for various operating conditions are summarized in Table 3.9-6(u).

The design adequacy of non-ASME code components of the CRD has been verified by analysis and extensive testing programs on component parts, specially instrumented prototype drives, and production drives. The testing included postulated abnormal events, as well as the service life cycle listed in Section 3.9.1.1.1. The following three types of tests were performed:

a. A test was conducted with the lower CRD flange oscillating with a 2 inch peak-to-peak displacement. No adverse effects were observed during the normal continuous drive-in or jog operation.

b. To simulate the seismic interaction, the core plate and top guide structures of the test vessel were displaced relative to the CRD housing centerline. The results showed no effect in CRD performance.

c. The test vessel fuel channels were deflected to simulate the seismic interactions. The test was performed with fuel channel deflections up to 1.5 inches, which are greater than the expected deflection values. Because the CRD and control rod were not permanently deformed, the drive operability was maintained.

The load criteria, calculated, and allowable stresses for various operating conditions is summarized in Table 3.9-6(v) including the results of the New Loads Adequacy Evaluation program.

3.9.1.4.1.2 Hydraulic Control Unit

The HCU was analyzed for the faulted condition. The seismic and hydrodynamic loads adequacy was demonstrated by test and analysis. The results show peak dynamic loads of 6.2 g (vertical) at the natural frequency of 8-12 Hz and 6 g (horizontal) at a natural frequency of 3-4 Hz. For comparison, the capability of the HCU to withstand loading is 15 g (vertical) at 8-12 Hz, 7 g (horizontal) at 3-4 Hz, and 9 g (horizontal z displacement) at 3-4 Hz.

In addition, a detailed analysis was performed to confirm that the test-mounting configuration is applicable to the LGS unique field installation.

The analysis of the HCU under faulted condition loads establishes the structural integrity of the system.

3.9.1.4.1.3 CRD Housing

The SSE is classified as a faulted condition; however, in the CRD housing analysis, the SSE event is treated as an emergency condition. The calculated and allowable stresses at various loading conditions are given in Table 3.9-6(v).

3.9.1.4.2 Standard Reactor Internal Components

3.9.1.4.2.1 Control Rod Guide Tube

The maximum calculated stress on the control rod guide tube occurs in the base during a faulted condition. In accordance with ASME Section III, the faulted limit is 2.4 S_m, where S_m = 16,000 psi at 575°F. The analysis and limiting stresses are summarized in Table 3.9-6(aa).

3.9.1.4.2.2 Incore Housing

The maximum calculated stress on the incore housing occurs at the outer surface of the vessel penetration during a faulted condition. The maximum allowable stress for the elastic analysis used is 2.4 S_m (39,948 psi), which bounds the calculated stress as given in Table 3.9-6(ab).

3.9.1.4.2.3 Jet Pump

The elastic analysis for the jet pump faulted conditions shows that the maximum stress is due to diffuser impulse loading during a pipe rupture and blowdown. The maximum allowable for this condition, in accordance with ASME Section III, is 3.6 S_m (60,840 psi). Table 3.9-6(w) summarizes the results of the analysis.

3.9.1.4.2.4 Low Pressure Coolant Injection Coupling

The maximum stress during a faulted condition on the LPCI coupling occurs at the "Bellows" (a purchased component designed to GE requirements for 120 normal operating condition cycles and 10 SSE cycles). Table 3.9-6(y) shows that calculated stresses are within allowable limits.

3.9.1.4.2.5 Orificed Fuel Support

Due to its complex configuration, a series of vertical and horizontal load tests were performed on the orificed fuel support to verify the design. The results show that the seismic and hydrodynamic loading is below the allowable limit with an average safety margin of 1.21 for normal and upset and 1.26 for faulted conditions.

3.9.1.4.3 Reactor Pressure Vessel Assembly

The RPV assembly was evaluated using elastic analysis methods for faulted conditions. Table 3.9-6(f) lists the calculated and allowable stresses for the various loading combinations.

3.9.1.4.4 Core Support Structure

The evaluations for faulted conditions for the core support structure are discussed in Section 3.9.5. The calculated and allowable stresses are summarized in Table 3.9-6(b).

3.9.1.4.5 Main Steam Isolation, Recirculation Gate, and MSRVs

Tables 3.9-6(g), 3.9-6(h), and 3.9-6(j) provide a summary of the analysis for the MSRVs, MSIVs, and recirculation gate valves, respectively.

Standard design rules, as defined in applied codes, are utilized in analyzing pressure boundary components of Class 1 active valves. Conventional, elastic stress analysis is used to evaluate components not defined in the code. The code allowable stresses are applied to determine acceptability of structure under applicable loading conditions, including faulted condition.

3.9.1.4.6 Main Steam and Recirculation Piping

For main steam and recirculation system piping, elastic analysis methods are used to evaluate faulted loading conditions. The allowable stresses using elastic techniques are obtained from the ASME Section III, Appendix F, "Rules for Evaluation of Faulted Conditions" (these are above

elastic limits). Additional information for the main steam, recirculation piping, and pipe-mounted equipment is contained in Tables 3.9-6(d) and 3.9-6(e), respectively.

3.9.1.4.7 NSSS Pumps, Heat Exchangers, and Turbines

The recirculation, ECCS, RCIC, and SLC pumps, RHR heat exchangers and RCIC turbine are analyzed for the faulted loading conditions identified in Section 3.9.1.1. In all cases, stresses are within the elastic limits. The analytical methods, stress limits, and allowable stresses are discussed in Sections 3.9.2.2a and 3.9.3.1.

3.9.1.4.8 Control Rod Drive Housing Supports

Design adequacy of the CRD housing supports is shown by comparing the static and dynamic loads to the original design loads. The comparison, summarized in Table 3.9-6(z), shows that the hydrodynamic loads combined with other loads are less than the design load capability of the CRD housing supports.

3.9.1.4.9 Fuel Storage Racks

All analyses related to the Fuel Storage Racks are provided in UFSAR Section 9.1.

3.9.1.4.10 Fuel Assembly (Including Channel)

GE/GNF BWR fuel assembly (including channel) design bases, analytical methods, and evaluation results, including those applicable to the faulted conditions are contained in References 3.9-16 and 3.9-17. Evaluations specific to the LGS fuel assemblies have been performed in accordance with the methodology presented in Reference 3.9-17. The resulting acceleration profiles and fuel lift gap are summarized in Table 3.9-6(x).

3.9.1.4.11 Refueling Equipment

Refueling and servicing equipment which is important to safety is classified under essential components, per the requirements of 10CFR50, Appendix A. This equipment and other equipment whose failure would degrade an essential component is defined in Section 9.1 and is classified as seismic Category I. These components are subjected to an elastic dynamic finite-element analysis to generate loadings. This analysis utilizes appropriate seismic floor response spectra, and combines loads at frequencies up to 33 Hz for seismic and up to 100 Hz for hydrodynamic loads, in three directions. Imposed stresses are generated and combined for normal, upset, and faulted conditions. Stresses are compared, depending on the specific safety class of the equipment, to allowables of Industrial Codes, ASME, ANSI or Industrial standards, or AISC. Loading conditions, acceptance criteria, calculated and allowable stresses are shown in Table 3.9-6(s).

3.9.1.4.12 Seismic Category I Items Other than NSSS

The stress allowables for statically applied loads, of ASME Section III, Appendix F, Winter 1972, are used for code components. For noncode components, allowables are based on tests or accepted standards consistent with those in Appendix F of the code.

Dynamic loads for components loaded in the elastic range are calculated using dynamic load factors, time history analysis, or any other method that assumes the elastic behavior of the component.

The limits of the elastic range are defined in paragraph 1323 of Appendix F for the code components. The local yielding due to stress concentration is assumed not to affect the validity of the assumptions of elastic behavior. The stress allowables of Appendix F for elastically analyzed components are used for code components. For noncode components, allowables are based on tests or accepted material standards consistent with those in Appendix F for elastically analyzed components.

The methods used in evaluating the pipe break effects are discussed in Section 3.6.

3.9.2 DYNAMIC TESTING AND ANALYSIS

3.9.2.1a Piping Vibration, Thermal Expansion, and Dynamic Effects Testing for NSSS Piping

The test program is divided into three phases: piping vibration, thermal expansion, and dynamic effects.

3.9.2.1a.1 Piping Vibration

3.9.2.1a.1.1 Preoperational Vibration Testing of Recirculation Piping

The purpose of the preoperational vibration test phase is to verify that operating vibrations in the recirculation piping are within acceptable limits. This phase of the test uses visual observation and manual measurements by hand-held vibrograph to supplement remote measurements. If, during steady-state operation, visual observation indicates that vibration is significant, measurements are made with a hand-held vibrograph. Visual observations, and manual and remote measurements are made during the following steady-state conditions:

a. Recirculation pumps minimum flow

b. Recirculation pumps at 50% of rated flow

c. Recirculation pumps at 75% of rated flow

d. Recirculation pumps at 100% of rated flow

3.9.2.1a.1.2 Preoperational Vibration Testing of Small Attached Piping

During visual observation of each of the above test conditions (a. through d.), special attention is given to small attached piping and instrument connections to ensure that they are not in resonance with the recirculation pump motors or flow-induced vibrations. If the operating vibration acceptance criteria are not met, corrective action, such as modification of supports, is taken.

3.9.2.1a.1.3 Startup Vibration Testing of Main Steam Recirculation and RCIC Piping

The purpose of this phase of the program is to verify that the main steam, recirculation, and RCIC piping are within acceptable limits. The main steam and recirculation piping are instrumented with

transducers to measure temperature, thermal movement, and vibration deflections. Because of limited access due to high radiation levels, no visual observation is required during this phase of the test. Remote measurements are made during the following steady-state conditions:

a. Main steam flow at 25% of rated

b. Main steam flow at 50% of rated

c. Main steam flow at 75% of rated

d. Main steam flow at 100% of rated

3.9.2.1a.1.4 Operating Transient Loads on Main Steam and Recirculation Piping

The purpose of the operating transient test phase is to verify that pipe stresses are within code limits. The amplitude of displacements and the number of cycles per transient of the main steam and recirculation piping are measured, and the displacements are compared with the acceptance criteria. The deflections are correlated with stresses to verify that pipe stresses remain within code limits. Remote vibration and deflection measurements are taken during the following transients:

a. Recirculation pump starts

b. Recirculation pump trip at 100% of rated flow

c. Turbine stop valve closure at 100% power

d. Manual discharge of each SRV at 1000 psig, and at planned transient tests that result in SRV discharge

3.9.2.1a.2 Thermal Expansion Testing of Main Steam and Recirculation Piping

The thermal expansion preoperational and startup testing program verifies that normal thermal movement occurs in the piping systems, and is performed through the use of potentiometer sensors. The main purpose of this program is to ensure the following:

a. The piping system is free to expand and move without unplanned obstruction or restraint in the x, y, and z directions, during system heatup and cooldown.

b. The piping system does "shake down" after a few thermal expansion cycles.

c. The piping system is working in a manner consistent with the assumption of the NSSS stress analysis

d. There is adequate agreement between calculated and measured displacements.

e. Thermal displacements are consistent and repeatable during heatup and cooldown of the NSSS systems.

Thermal expansion displacement limits are established prior to the start of piping testing. These are compared with the actual measured displacements to determine the acceptability of the actual motion. If the measured displacement does not vary by more than the specified tolerance from the

acceptance limit, the piping system is responding in a manner consistent with predictions, and is therefore acceptable. Two levels of displacement limits are established to check the systems, as discussed in Section 3.9.2.1a.4.

3.9.2.1a.3 Dynamic Effects Testing of Main Steam and Recirculation Piping

To verify that snubbers adequately perform their intended function during plant operation, a dynamic testing program is planned, as part of the normal startup operation testing. The main purpose of this program is to ensure the following:

a. The vibration levels from the various dynamic loadings during transient and steady-state conditions are below the predetermined acceptable limits.

b. Due to underestimating the dynamic effects caused by cyclic loading during plant transient operations, long-term fatigue failure does not occur.

This dynamic testing is to account for the acoustic wave due to the SRV lifts (RV1), SRV load resulting from air clearing (RV2), and turbine stop valve closure load. The maximum stresses developed in the piping by the RV1, RV2, and turbine stop valve closure transients analysis are used as a basis for establishing criteria which assures proper functioning of the snubbers. If field measurements exceed criteria limits, this may indicate that the snubbers are not operating properly. If field measurements are within criteria limits, it is assumed that the snubbers are functioning properly. Sample production snubbers of each size (i.e. 10 kips, 20 kips, 50 kips, etc.) will also be qualified and tested for design and faulted condition loadings, prior to shipment to field. Snubbers will be tested to allow free piping movements at low velocity. During plant startup, the snubbers will be checked for improper settings and checked for any evidence of oil leak.

The criteria for vibration displacements is based on the assumed linear relationship between displacements, snubber loads and magnitudes of applied loads, for any function and response of the system. Thus the magnitudes of limits of displacements, snubber loads, and nozzle loads are all proportional. Maximum displacements (Level 1 limits) are established to prevent the maximum stress in the piping systems from exceeding the normal and upset primary stress limits, and/or the maximum snubber load from exceeding the maximum load to which the snubber has been tested.

Based on the above criteria, Level 1 displacement limits are established for all instrumented points in the piping system. These limits will be compared with the field measured piping displacements. Method of acceptance is as explained in Section 3.9.2.1a.4.

3.9.2.1a.4 Test Evaluation and Acceptance Criteria for Main Steam and Recirculation Piping

The piping response to test conditions is considered acceptable if the organization responsible for the stress report reviews the test results, and determines that the tests verify that the piping responded in a manner consistent with the predictions of the stress report, and/or that the tests verify that piping stresses are within code limits (ASME Section III, NB-3600). Acceptable deflection limits are determined after the completion of the piping systems stress analysis and are provided in the startup test specifications.

To ensure test data integrity and test safety, criteria have been established to facilitate assessment of the test while it is in progress. These criteria, designated Level 1 and Level 2, are described in the following paragraphs.

3.9.2.1a.4.1 Level 1 Criteria

Level 1 establishes the maximum limits for the level of pipe motion which, if exceeded, makes a test hold or termination mandatory.

If the Level 1 limit is exceeded, the plant will be placed in a satisfactory hold condition, and the responsible piping design engineer will be advised. Following resolution, applicable tests must be repeated to verify that the requirements of the Level 1 limits are satisfied.

3.9.2.1a.4.2 Level 2 Criteria

If the Level 2 criteria are satisfied for both steady-state and operating transient vibrations, there will be no fatigue damage to the piping system due to steady-state vibration, and all operating transient vibrations are bounded by the values in the stress report.

Exceeding the Level 2 specified pipe motion requires that the responsible piping design engineer be advised. Plant operating and startup testing plans would not necessarily be altered. Investigations of the measurements, criteria, and calculations used to generate the pipe motion limits would be initiated. An acceptable resolution must be reached by all appropriate and involved parties, including the responsible piping design engineer.

Detailed evaluation is needed to develop corrective action or to show that the measurements are acceptable. Depending on the nature of such resolution, the applicable tests may or may not be repeated.

3.9.2.1a.4.3 Acceptance Limits

For steady-state vibration, the piping break stress due to vibration only (neglecting pressure) will not exceed 10,000 psi for Level 1 criteria and 5,000 psi for Level 2 criteria. These limits are below the piping material fatigue endurance limits as defined in Design Fatigue Curves in appendix I of ASME code for 10^6 cycles.

For operating transient vibration, the piping bending stress (zero to peak) due to operating transient only will not exceed 1.2 S_m or pipe support loads will not exceed the Service Level D ratings for Level 1 criteria. The 1.2 S_m limit ensures that the total primary stress including pressure and dead weight will not exceed 1.8 S_m, the new Code Service Level B limit. Level 2 criteria are based on pipe stresses and support loads not to exceed design basis predictions. Design basis criteria require that operating transients stresses and loads not to exceed any of the Service Level B limits including primary stress limits, fatigue usage factor limits, and allowable loads on snubbers.

3.9.2.1a.5 Corrective Actions for Main Steam and Recirculation Piping

During the course of the tests, the remote measurements are regularly checked to determine compliance with Level 1 criteria. If trends indicate that Level 1 criteria may be violated, the measurements are monitored at more frequent intervals. The test is held or terminated as soon as Level 1 criteria are violated. As soon as possible after the test hold or termination, the following corrective actions are taken:

a. Installation Inspection: A walkdown of the piping and suspension is made to identify any obstruction or improperly operating suspension components. Snubbers are located close to the midpoint of the total travel range at the operating temperature. Hangers are in their operating range between the hot and cold settings. If vibration exceeds the criteria, the source of the excitation must be identified to determine if it is related to equipment failure. Action is taken to correct any discrepancies before repeating the test.

b. Instrumentation Inspection: The instrumentation installation and calibration is checked, and any discrepancies are corrected. Additional instrumentation is added, if necessary.

c. Repeat Test: If actions a. or b. identify discrepancies that could account for failure to meet Level 1 criteria, the test is repeated.

d. Resolution of Findings: If the Level 1 criteria are violated on the repeat test, or no relevant discrepancies are identified in a. or b., the organization responsible for the stress report reviews the test results and the criteria to determine if the test can be safely continued.

If the test measurements indicate failure to meet Level 2 criteria, the following corrective actions are taken after completion of the test:

a. Installation Inspection: A walkdown of the piping and suspension is made to identify any obstruction or improperly operating suspension components. Snubbers are located close to the midpoint of the total travel range at the operating temperature. Hangers are in their operating range between the hot and cold settings. If the vibration exceeds limits, the source of the vibration must be identified. Actions, such as suspension adjustment, are taken to correct any discrepancies.

b. Instrumentation Inspection: The instrumentation installation and calibration are checked, and any discrepancies are corrected.

c. Repeat Test: If a. or b. above identify a malfunction or discrepancy that could account for failure to comply with Level 2 criteria, and appropriate corrective action is taken, the test may be repeated.

d. Documentation of Discrepancies: If the test is not repeated, the discrepancies found under actions a. or b. above are documented in the test evaluation report and correlated with the test condition. The test is not considered complete until the test results are reconciled with the acceptance criteria.

3.9.2.1a.6 Measurement Locations for Main Steam and Recirculation Piping

Remote vibration measurements during initial startup will be made for each of the main steam lines and recirculation lines. The locations of the measurements will be described in the startup test specification.

During preoperational testing of recirculation piping, visual observation and manual measurements by hand-held vibrograph are made to supplement the remote measurements.

3.9.2.1b Piping Vibration, Thermal Expansion, and Dynamic Effects Testing of Non-NSSS Piping

The dynamic effects on all safety-related ASME Class 1, 2, and 3 piping systems, including their supports and restraints, are considered as required by NB-3622.3, NC-3622, and ND-3622 of ASME Section III. The structural and functional integrity of each piping system under postulated seismic events is verified by dynamic analysis only. Piping systems having significant anticipated transient loads, caused by main stop valve closure or relief valve discharge for example, are analyzed for time-dependent forces. In addition, piping steady-state vibration and dynamic transient tests will be performed as summarized below, to ensure that:

a. Excessive steady-state vibration is not present in the piping that would result in piping stresses and restraint loads above the allowables

b. The piping is adequately restrained to withstand the dynamic transient loads.

The power ascension tests performed for each non-NSSS piping system are provided in Table 3.9-7. The table also describes the systems as to ASME Code class, high energy or moderate energy piping designation, and seismic category.

The startup test program specifications describe in detail the piping that is instrumented for remote monitoring of vibrations and thermal expansion and the piping that is accessible for preoperational or startup walkdown testing by test personnel. The test criteria limit the permissible pipe vibratory stress to the allowable limits prescribed in the industry standard for startup testing of nuclear power systems, ANSI/ASME OM3.

The LGS startup testing program requires that the following conditions be demonstrated in accordance with Regulatory Guide 1.70:

a. Thermal expansion is free from significant and unacceptable restraint not accounted for in the design.

b. Piping vibration is within acceptable limits for long-term vibratory stress.

c. Dynamic transient response of the piping is compared to the design analysis expected values. If those values are exceeded, the test results are compared with the maximum that would be allowed under the ASME Code stress limits.

Cognizant design personnel familiar with the systems to be tested participate in the development of test procedures, and in the evaluation of the test results. The data acquired from the tests are compared with the anticipated results to determine the acceptability of the total system response. Refer to STP-17, STP-33 and STP-36 in Table 14.2-3 for these startup test program procedures.

Test specifications governing the scope of startup testing of BOP piping were prepared and were intended to be the repository for all primary information relating to the scope, objectives, methods, instrumentation, measurements, and criteria for evaluation of the test results. The BOP piping systems are categorized in terms of the following:

a. Test environment (hot deflection, steady-state vibration or dynamic transient response).

b. Test measurements (remotely monitored, visual or none required due to small expected response to test environment).

c. The appropriate testing phase (preoperational or power ascension).

Piping thermal expansion tests are performed for the safety-related piping systems with normal operating temperatures exceeding 300°F. Safety-related piping systems with normal operating temperatures less than 300°F do not have significant thermal expansion to warrant these tests. Engineering review of all seismic Category I piping systems, including their supports, and restraints or snubbers, was performed after completion of construction and prior to fuel load. This ensures that no restraint of normal thermal movement occurs due to interferences and obstructions, and that the support and restraints are in accordance with the design intent. For those systems receiving thermal expansion tests, pipe movements are monitored to ensure that no restraint of normal thermal movement occurs at locations other than at the designed restraint locations.

By monitoring the thermal movement, the thermal expansion test program verifies that the free thermal expansion of piping systems takes place at the snubbers. Performance of the snubbers designed for transient loads, such as those resulting from main stop valve closure or MSRV discharge, are verified by measuring the load in the snubber during the dynamic transient tests. The snubbers are qualified by dynamic testing for cyclic loading as described in Section 3.9.3.5.2.

The acceptance criterion for thermal expansion tests and dynamic transient tests is that the measured pipe displacements, accelerations, dynamic pressures, or restraint loads are below the calculated or design values.

3.9.2.1b.1 Piping Dynamic Transient Tests

During the power ascension, the piping dynamic transient tests identified in Table 3.9-7 are performed. The following modes are considered:

a. Main steam piping outside the containment for main steam turbine stop valve trip at 25%, 75% (Unit 1 only), and 100% power. Main Steam Turbine trip test for Unit 2 at 100% power will be performed during commercial operation of that Unit.

b. Main steam bypass piping for the turbine stop valve closure

c. MSRV discharge piping for the MSRV opening

d. HPCI turbine steam supply piping for HPCI turbine trip.

e. Feedwater piping for reactor feed pump trip/coastdown

f. Feedwater heater drain piping for dump and drain valve actuation (Unit 1 only)

g. Moisture separator drain piping for flashing during normal operation and moisture separator depressurization (Unit 1 only).

From past experience, the dynamic transients in other piping systems are not significant.

Dynamic transient analysis of the subject lines is performed to determine the response of the piping system and the restraint loads. During the test the accelerations of the pipe, loads in the snubbers and restraints and the pressure at representative locations will be measured as required.

The acceptance criterion for this test is that the measured response of the piping system, the snubber, and restraint loads are below the design values. When the measured response exceeds the calculated response, or restraint loads, detailed evaluation of the design will be made to determine the acceptability.3.9.2.1b.2 Piping Steady-State Vibration Testing

The piping systems identified in Table 3.9-7 are tested for steady-state vibration during preoperational test programs or during power ascension. The following operating modes are considered:

a. RHR pump operation

b. HPCI pump and turbine operation

c. RCIC pump and turbine operation

d. Core spray pump operation

e. Main steam

f. Feedwater

g. RWCU

In addition, during the system walkdown, upon initial startup or power escalation, any abnormal vibrations of other systems observed are reviewed and instrumented, if necessary, to determine the acceptability of such vibration.

All safety-related process piping systems and safety-related instrument lines are included in the vibration monitoring program (Table 3.9-7). A vibration monitoring test specification is prepared to categorize the requirements for the testing program. Safety-related systems are categorized as follows:

a. Systems or portions of systems having no flow within a significant portion of their lines; for those system, no testing is required.

b. Systems with flow:

- Accessible lines (including attached instrument lines) monitored visually or with hand-held instruments.

- Inaccessible lines other than instrumentation lines will be monitored by remote instrumentation.

- Inaccessible instrument lines.

The inside containment instrumentation lines listed below that are inaccessible for visual inspection during power ascension testing will be included in the vibration monitoring program:

- RPV level indicator instrumentation lines

- Main steam instrumentation lines used for monitoring main steam flow

- RCIC steam supply instrument lines used for monitoring steam flow
- CRD lines
- Main steam sample lines.

The vibration monitoring program for the above lines consists of walkdown by stress analysts experienced in vibration assessment prior to power ascension testing. The review is to include proper restraining of the lines near the vibration source, at elbows and bends, and at the concentrated masses. Prior to walkdown, the stress engineer will review the mode shapes and piping analytical responses to normal and upset conditions. Any lines found to be inadequately restrained, resulting in the potential for excessive vibration, will be evaluated on a case-by-case basis to assess the impact on plant safety that could result from operation of the lines. The evaluation will identify the mode(s) of operation of such lines that cause the excessive vibration. Corrective action to prevent excessive vibration will be taken prior to operating any lines in the operating mode(s) that cause excessive vibration.

Steady-state vibration is primarily induced by the flow in the pipe and the equipment motion. In general, the nature of the steady-state vibration is not known a priori. Therefore, design engineers with stress analysis experience and with familiarity with the subject piping system observe the lines during significant modes of system operation as shown in Items a. through g. above, and classify each line as acceptable, if the vibration is not significant, or as questionable, if the vibration is significant. The lines with questionable steady-state vibration are monitored as applicable by suitable instrumentation to determine the system response.

The type of any necessary instrumentation is determined by the design engineer, so that the maximum amplitude and frequency response of the piping system can be determined. The instrumentation does not screen out the significant frequencies.

The acceptance criterion for the steady-state vibration tests is that the maximum measured amplitude of the piping vibration does not induce more stress in the pipe than the endurance limit of the material. By limiting the maximum stress in the pipe due to steady-state vibration below the allowable limits prescribed in the industry standard for startup testing of nuclear power systems (ANSI/ASME OM3), the steady-state vibration induced stress does not contribute to reducing piping fatigue life. These limits are based on the piping design fatigue curves of up to 10^6 cycles of vibration given in ASME Section III, Appendix I. To account for fatigue with higher cycles, the design fatigue strength of carbon steels will be reduced by applying a factor of 0.8 and further employing a safety factor of 1.3. Austenitic pipe steels design fatigue strength reduction factor will be 0.6, and is further reduced by employing a safety factor of 1.3. Piping stress indices (K_2C_2) and intensification factors (2i) as applicable to each particular system are also applied in accordance with the standard.

When required, additional restraints are provided to reduce the steady-state vibration, and to keep the stresses below the acceptance criteria levels. Table 3.9-7 provides a reference to the appropriate test descriptions in Chapter 14.

3.9.2.2 Dynamic Qualification of Safety-Related Mechanical Equipment

The qualification discussion in the following sections is generally divided into two types of equipment: NSSS equipment and non-NSSS equipment. The design criteria and qualification

procedures for NSSS equipment includes the effects of both seismic and hydrodynamic loads. The non-NSSS equipment qualification discussions include only seismic design criteria and qualification procedures. Refer to Appendix 3A.6.8 and 3A.7.1.7 for discussion of non-NSSS equipment subject to hydrodynamic loads. Appendix 3A.6.7 and 3A.7.1.5 contain further discussion of NSSS equipment qualification.

Safety-related NSSS and Non-NSSS mechanical equipment were reviewed to SRP 3.10 Seismic Qualification Review Team (SQRT) requirements including IEEE 344-1975 and Reg. Guides 1.100 and 1.92. The SQRT re-assessment concluded that the seismic and dynamic qualification program meets the intent of IEEE 344-1975 and Reg. Guides 1.100 and 1.92. Refer to Section 3.10.2.

3.9.2.2a Dynamic Qualification of NSSS Safety-Related Mechanical Equipment

This section describes the criteria for dynamic qualification of safety-related mechanical equipment, and the qualification testing and/or analysis applicable to this plant for all the major components, on a component-by-component basis. In some cases, a module or assembly consisting of mechanical and electrical equipment is qualified as a unit, for example, ECCS pumps. These modules are generally discussed in this section, rather than in Sections 3.10 and 3.11. Electrical supporting equipment, such as control consoles, cabinets, and panels, which are part of the NSSS, are discussed in Section 3.10. Dynamic qualification of NSSS pumps and valves is discussed in Section 3.9.3.2a.

3.9.2.2a.1 Tests and Analysis Criteria and Methods

The ability of equipment to perform its safety function during and after application of dynamic loads is demonstrated by tests and/or analysis. Selection of testing, analysis, or a combination of the two is determined by the type, size, shape, and complexity of the equipment being considered. When practical, equipment operability is demonstrated by testing. Otherwise, operability is demonstrated by analysis.

Analysis is also used to show there are no natural frequencies below 33 Hz for seismic loads and 100 Hz for hydrodynamic loads. If a natural frequency lower than these is discovered, dynamic tests may be conducted, and in conjunction with mathematical analysis, used to verify operability and structural integrity at the required dynamic input conditions.

When the equipment is qualified by dynamic testing, the response spectrum or time history of the attachment point is used in determining input motion.

Natural frequency may be determined by running a continuous sweep frequency search, using a sinusoidal steady-state input of low magnitude. Dynamic conditions are simulated by tests using random vibration input or single-frequency input (within equipment capability) at frequencies of interest. Whichever method is used, the input motion during testing envelopes the input amplitude expected during dynamic loading conditions.

Equipment having an extended structure, such as a valve operator, is analyzed by applying static-equivalent dynamic loads at the extended structure's center of gravity. In cases where the equipment's structural complexity makes mathematical analysis impractical, a test is used to determine operational capability at maximum equivalent dynamic load conditions. Pipe-mounted equipment are represented in the model used for the piping system dynamic analysis.

3.9.2.2a.1.1 Random Vibration Input

When random vibration input is used, the actual input motion envelopes the appropriate floor input motion at the individual modes. However, single-frequency input, such as sine beats, can be used, provided one of the following conditions are met:

a. The characteristics of the required input motion are dominated by one frequency.

b. The anticipated response of the equipment is adequately represented by no resonances, one resonance, or widely spaced resonances.

c. The input has sufficient intensity and duration to excite all modes to the required magnitude, so that the testing response spectra envelope the corresponding response spectra of the individual modes.

3.9.2.2a.1.2 Application of Input Motion

When dynamic tests are performed, the input motion is applied to one vertical and one horizontal axis simultaneously. However, if the equipment response along the vertical direction is not sensitive to the vibratory motion along the horizontal direction, and vice-versa, then the input motion is applied to one direction at a time. In the case of single-frequency input, the time phasing of the inputs in the vertical and horizontal directions is such that a purely rectilinear resultant input is avoided.

3.9.2.2a.1.3 Fixture Design

The fixture design simulates the actual service mounting, and causes no dynamic coupling to the equipment.

3.9.2.2a.1.4 Prototype Testing

Equipment testing is conducted on prototypes of the equipment installed in this plant.

3.9.2.2a.2 Dynamic Qualification of Specific NSSS Mechanical Components

The following sections discuss the testing or analytical qualification of NSSS equipment. Seismic and hydrodynamic qualification is also described in Sections 3.9.1.4, 3.9.3.1, and 3.9.3.2 and in Appendix 3A.6.7 and 3A.7.1.6.

3.9.2.2a.2.1 Jet Pumps

A dynamic analysis of the jet pumps was performed. The stresses resulting from the analysis are below the design allowables.

3.9.2.2a.2.2 CRD and CRD Housing

A dynamic analysis of the CRD housing (with enclosed CRD) was performed. The results of the analyses established the structural integrity of these components. Preliminary dynamic tests verified the operability of the CRD subjected to displacements resulting from a dynamic event. A simulation test, imposing a static bow in the fuel channels, was performed with the CRD functioning satisfactorily.

3.9.2.2a.2.3 Core Support (Fuel Support and Control Rod Guide Tube)

A detailed analysis imposing dynamic effects due to seismic and hydrodynamic events shows that the maximum stresses developed during these events are much lower than the maximum allowed for the component material.

3.9.2.2a.2.4 Hydraulic Control Unit

The HCU was evaluated by comparing the RRS with the TRS at mounting points through test and analysis.

3.9.2.2a.2.5 Fuel Assembly Including Channels

GE/GNF BWR fuel channel design bases, analytical methods, and evaluation results, including seismic and hydrodynamic considerations, are contained in References 3.9-16 and 3.9-17.

3.9.2.2a.2.6 Recirculation Pump and Motor Assembly

Calculations were made to assure that the recirculation pump and motor assembly is designed to withstand the specific static-equivalent seismic and hydrodynamic forces. The flooded assembly was analyzed as a free body supported by constant support hangers from the brackets on the motor mounting member, with snubbers attached to brackets located on the pump case and the top of the motor frame.

Primary stresses due to horizontal and vertical dynamic forces were considered to act simultaneously, and as a conservative measure, they were added directly. Horizontal and vertical seismic forces were applied at mass centers, and equilibrium reactions were determined for motor and pump brackets.

3.9.2.2a.2.7 ECCS Pump and Motor Assembly

The dynamic qualification of each ECCS pump and motor assembly (as a unit), while operating under faulted conditions, was met in the form of a response spectrum analysis. The maximum specified vertical and horizontal accelerations were applied, simultaneously, in the worst case combination. The results of the analysis indicate that the pumps are capable of sustaining the applicable loadings without overstressing the pump components.

A similarly designed motor was dynamically qualified by a combination of static analysis and dynamic testing. The complete motor assembly was seismically qualified by dynamic testing, in accordance with IEEE 344 (1975). The qualification test program included demonstration of startup and shutdown capabilities, as well as no-load operability during dynamic loading conditions. Refer to Section 3.10.

3.9.2.2a.2.8 RCIC Pump Assembly

The RCIC pump assembly was analytically qualified by static analysis for seismic and hydrodynamic loadings as well as the design operating loads of pressure, temperature, and external piping loads. The results of this analysis confirm that the stresses are less than the allowable.

3.9.2.2a.2.9 RCIC Turbine Assembly

The RCIC turbine was qualified for seismic and hydrodynamic loads by a combination of static analysis and dynamic testing.

The turbine assembly and its components were considered to be supported as designed, and horizontal/vertical accelerations were applied to the mass centers of gravity. The static analysis indicated that the turbine assembly is capable of sustaining the design accelerations and loadings without overstressing any components.

The complete turbine assembly was qualified by dynamic testing, in accordance with IEEE 344 (1975). The qualification test program demonstrated startup, steady-state operability, and shutdown capabilities. Refer to Section 3.10.

3.9.2.2a.2.10 SLCS Pump and Motor Assembly

The SLCS positive displacement pump and motor assembly is mounted on a common baseplate and qualified by a combination of static analysis and single-frequency testing.

The SLCS pump and motor assembly was analytically qualified by static analysis for dynamic loading, as well as for the design operating loads of pressure, temperature, and external piping loads. The results of this analysis confirm that the stresses are less than the allowable.

3.9.2.2a.2.11 RHR Heat Exchangers

A three-dimensional finite-element model of the RHR heat exchanger and its support was developed and analyzed using the response spectrum method to verify that the heat exchanger can withstand seismic and hydrodynamic loads. The same model was statically analyzed to evaluate the effect of the external piping loads and dead weight to ensure that the nozzle load criteria and stress limits were met. Critical location stresses were evaluated and found to be lower than the corresponding allowable values.

3.9.2.2a.2.12 SLCS Tank

The SLCS storage tank is a cylindrical tank, 9 feet in diameter and 12 feet high, bolted to the concrete floor. The SLCS tank was qualified by analysis for:

a. Stresses in the tank bearing plate

b. Bolt stresses

c. Sloshing loads imposed at the natural frequency of sloshing (0.58 Hz). The natural frequency of the tank is 58.8 Hz.

d. Minimum wall thickness

e. Buckling

The results confirm that the stresses at the investigated locations are below the allowable.

3.9.2.2a.2.13 Main Steam Isolation Valves

The MSIVs are qualified by dynamic testing and analysis. The dynamic characteristics of the MSIVs were modeled in the main steam piping analysis. The resulting moments and stresses from the piping interaction were below the test proven valve capability. This assured the structural integrity. The operability of the valve is demonstrated by the closure test while it was subjected to the faulted dynamic loads.

3.9.2.2a.2.14 Main Steam Relief Valves

Due to the complexity of this structure and the performance requirements of the valve, the total assembly of the MSRV (including electrical and pneumatic devices) was dynamically tested at accelerations equal to or greater than the combined SSE and hydrodynamic loading of this plant.

3.9.2.2a.2.15 HPCI Turbine

The HPCI turbine was dynamically qualified by a combination of static analysis and dynamic testing.

The turbine assembly and its components were considered to be supported as designed, and horizontal/vertical accelerations applied to the mass centers of gravity. The results of the analysis indicate that the turbine assembly is capable of sustaining the design accelerations and loadings without overstressing any components.

The complete turbine assembly was qualified by dynamic testing, in accordance with IEEE 344 (1975). The qualification test program demonstrated startup, steady-state operability, and shutdown capabilities. Refer to Section 3.10.

3.9.2.2a.2.16 HPCI Pumps

The HPCI booster pump and main pump assembly is a split body type, mounted on one common baseplate. The pump assembly was analytically qualified by three-dimensional dynamic analysis using the response spectrum modal analysis technique. Results are obtained by using acceleration forces acting simultaneously in two directions, one vertical and one horizontal.

3.9.2.2b Dynamic Qualification of Non-NSSS Safety-Related Mechanical Equipment

All non-NSSS seismic Category I equipment is designed to withstand the simultaneous horizontal and vertical accelerations caused by the OBE and the SSE, as defined herein, in conjunction with other applicable loads. Seismic Category I non-NSSS mechanical equipment and supports located in the containment, reactor enclosure, and control structure are also subjected to dynamic loads due to LOCA and MSRV discharge hydrodynamic phenomena. Appendix 3A.5.6, 3A.6.8 and 3A.7.1.7 provide a summary of the load combinations, capability assessment criteria, and methodology used to qualify the equipment to withstand these additional hydrodynamic loads in combination with seismic and all other applicable loads. The functions of instrumentation and controls, or other parts necessary for the functional requirements of the equipment, are not impaired when the equipment is subjected to these loads.

The criteria for the seismic qualifications of non-NSSS mechanical and electrical equipment, with the exception of valves and valve operators (other than relief valves), are contained in a project

specification. IEEE 344, "Seismic Qualification of Class 1E Equipment for Nuclear Power Generating Stations," is used as a supplement to the project seismic specification in some of the individual equipment specifications. Both Standard IEEE 344 and the project specification address the requirements of the demonstration of the seismic adequacy of equipment by analysis and/or tests.

Seismic qualification of non-NSSS motor and air operated valves is addressed in Section 3.9.3.2b.2, and qualification of control valves is addressed in Section 3.10.

3.9.2.2b.1 Dynamic Qualification

Seismic Category I non-NSSS mechanical equipment is qualified by any one of the following methods:

a. Dynamic analysis

b. Testing

c. Combination of analysis and testing

d. Similarity to previously tested equipment.

A list of dynamic qualification package numbers for non-NSSS safety-related mechanical equipment is provided in Table 3.9-9. The qualification packages will be maintained by the licensee in a centrally located, readably auditable permanent file.

3.9.2.2b.2 Criteria

The criteria for dynamic qualification of the equipment are given below (Refer to Appendix 3A.6.8 for the criteria for the equipment subjected to hydrodynamic loads in addition to seismic loads).

3.9.2.2b.2.1 Response Spectrum Curves

The appropriate response spectrum curves for the equipment in question are issued with the material requisition or the equipment specification, for both OBE and SSE. Response spectrum curves are based upon the seismic analysis of the supporting structure, and represent a plot of the maximum dynamic response to a family of a single-degree-of-freedom damped oscillators at a particular location within the structure. Response spectrum curves, plotted in terms of acceleration versus frequency, correspond to various locations within the buildings, and are identified with respect to the points noted on the mathematical model for each direction of vibration to be considered. This may include the vertical, as well as both the north-south and the east-west horizontal directions. In addition, each response spectrum curve corresponds to a particular damping ratio, i.e., the ratio of damping of the single-degree-of-freedom system to critical damping. See Section 3.7 for the appropriate response spectrum curves.

3.9.2.2b.2.2 Load Combinations and Allowable Stress Limits

Seismic Category I equipment is designed to withstand the more severe of the following load combinations:

a. OBE Conditions

This includes gravity loads and operating loads (or DBA loads, if applicable), including associated temperatures and pressures combined by absolute sums, with the dynamic seismic loading of the OBE.

Allowable stresses in the structural steel portions may be increased to 125% of the allowable working stress limits as set forth in ASME Section III, or other applicable industrial codes. The customary increase in normal allowable working stress due to an earthquake is used if, according to the appropriate code, it is less than 25%. Resulting deflections, misalignment or binding of parts, or effects on electrical performance (for example, contact bounce) do not prevent operation of the mechanical equipment during or after the seismic disturbance.

b. SSE Conditions

This includes gravity loads and operating loads (or DBA loads, if applicable), including associated temperatures and pressures combined by absolute sums with the dynamic seismic loading of the SSE. Allowable stresses in the structural portions may be increased to 150% of allowable working stress limits (the appropriate codes listed in a.) but may not exceed 0.9 F_y in bending, 0.85 F_y for axial tension, and 0.5 F_y in shear, where (F_y) equals the material minimum yield stress at the design temperature. For equipment designed by the maximum shear stress theory, the difference between the maximum and minimum principal stresses does not exceed 0.9 F_y. The resulting deflections, misalignment, or binding of parts, or effects on electrical performance (for example, contact bounce) do not prevent operation of the mechanical equipment during or after the seismic disturbance.

3.9.2.2b.2.3 Prevention of Overturning and Sliding

Stationary equipment is designed to prevent overturning or sliding, by using anchor bolts or other suitable mechanical anchoring devices. The effect of friction on the ability to resist sliding is neglected. The effect of upward vertical seismic loads on reducing overturning resistance is considered. Anchoring devices are designed in accordance with the requirements of a. and b. above, and the AISC Manual of Steel Construction. The proposed anchoring system is shown on the Seller's drawings, so that the Buyer can provide the proper foundation.

3.9.2.2b.2.4 Dynamic Testing

For equipment qualified by testing, seismic adequacy was established by dynamically testing the equipment in accordance with the project specifications. The equipment was tested with its mountings simulating the actual installation conditions.

3.9.2.2b.2.5 Combined Analysis and Test

Some equipment is qualified by a combination of analysis and testing procedures.

An analysis is conducted on the overall assembly to determine its stress level and the transmissibility of motion from the base of the equipment to the critical components. The critical

components are removed from the assembly and subjected to a simulation of the environment on a test table.

Testing methods are also used to aid the formulation of the mathematical model for any piece of equipment. Mode shapes and frequencies are determined experimentally and incorporated into a mathematical model of the equipment.

3.9.2.2b.2.6 Criteria for the Diesel Fuel Oil Storage Tanks

These tanks are buried below-grade under a cover of 9 feet of earth.

Tanks and tank supports are designed to withstand Cooper E80 loading, applied above 9 feet of saturated overburden. Tank walls and ends do not deflect more than 3% maximum under the most unfavorable loading conditions.

The diesel fuel oil storage tanks conform to the requirements of the UL 58 Code.

Tanks and their supports are designated seismic Category I, and are designed to resist the increased earth pressure from the OBE and the SSE.

Tanks are designed to withstand external pressure resulting from being buried in the ground when the tanks are empty. Uplift forces on buried tanks are resisted by the weight of the empty tank and the foundation mat, plus 9 feet of overburden.

The tanks were analyzed using a mathematical model considering soil/structure interaction.

3.9.2.3 Dynamic Response of Reactor Internals Under Operational Flow Transients and Steady-State Conditions

The major reactor internal components are subjected to extensive testing, coupled with dynamic system analyses, to properly describe the flow-induced vibration phenomena resulting from normal reactor operation, and from anticipated operational transients.

In general, the vibration forcing functions for operational flow transients and steady-state conditions are not predetermined by detailed analysis. Special analyses of the response signals, measured from reactor internals of similar designs, are performed to obtain the parameters that determine the amplitude and modal contributions in the vibration responses. These studies are useful for extrapolating the results from tests of internals and components of similar designs, are also performed. This vibration prediction method is appropriate where standard hydrodynamic theory cannot be applied due to the complexity of the structure and flow conditions. Elements of the vibration prediction method are outlined as follows:

a. Dynamic analysis of major components and subassemblies is performed to identify natural vibration modes and frequencies. The analysis models used for seismic Category I structures are similar to those outlined in Section 3.7.2.

b. Data from previous plant vibration measurements are assembled and examined to identify predominant vibration response modes of major components. In general, response modes are similar, but response amplitudes vary among BWRs of differing size and design.

c. Parameters are identified which are expected to influence vibration response amplitudes among the several reference plants. These include hydraulic parameters such as velocity and steam flow rates, and structural parameters such as natural frequency and significant dimensions.

d. Correlation functions of the variable parameters are developed which, when multiplied by response amplitudes, tend to minimize the statistical variability between plants. A correlation function is obtained for each major component and response mode.

e. Predicted vibration amplitudes for components of the prototype plant are obtained from these correlation functions, based on applicable values of the parameters for the prototype plant. The predicted amplitude for each dominant response mode is stated in terms of a range, taking into account the degree of statistical variability in each of the correlations. The predicted mode and frequency are obtained from the dynamic analysis of a. above.

The dynamic modal analysis also forms the basis for interpreting prototype plant preoperational and initial startup test results (Section 3.9.2.4 below). Modal stresses are calculated, and relationships are obtained between sensor response amplitudes and peak component stresses, for each of the lower normal modes. The allowable amplitude in each mode is that which produces a peak stress amplitude of ±10,000 psi.

3.9.2.4 Confirmatory Flow-Induced Vibration Testing of Reactor Internals

The LGS reactor internals are tested in accordance with the provisions of Regulatory Guide 1.20 (Rev 2) for nonprototype Category I plants. The test procedure requires operating the recirculation system at the rated flow, with internals installed (less fuel), followed by inspection for evidence of vibration, wear, or loose parts. The test duration is sufficient to subject critical components to at least 10^6 cycles of vibration during two-loop and single-loop operation of the recirculation system. At the completion of the flow test, the vessel head and shroud head are removed. The vessel is drained, and the major components are inspected on a selected basis. The inspection covers all components which were examined on the prototype design, including the shroud, shroud head, core support structures, the jet pumps, and the peripheral CRD and incore guide tubes. Access is provided to the reactor lower plenum. The prototype reactor for LGS is the Browns Ferry-3 design docketed on July 31, 1968 (Reference 3.9-18).

Reactor internals for LGS are substantially the same as the internal design configurations which have been tested in prototype BWR/4 plants. Results of the prototype tests are presented in a Licensing Topical Report, Reference 3.9-18. This report also contains additional information on the confirmatory inspection program.

3.9.2.5 Dynamic System Analysis of the Reactor Internals Under Faulted Conditions

In order to assure that no significant dynamic amplification of load occurs as a result of the oscillatory nature of the blowdown forces (Figure 3.9-2), a comparison is made between the periods of the applied forces and the natural periods of the core support structures being acted upon by the applied forces. These periods are determined from a 12 node vertical dynamic model of the RPV and internals. In addition to the masses of the RPV and core support structures, allowance is made for the water inside the RPV.

The time-varying pressures are applied to the dynamic model of the reactor internals described above. Except for the nature and locations of the forcing functions and the dynamic model, the dynamic analysis method is identical to that described for seismic analysis, and is detailed in Section 3.7.2.1. These dynamic components are combined with other dynamic loads (including hydrodynamic and seismic) by the SRSS method. The resultant force is then combined with other steady-state and static loads on an ABS basis to determine the design load. The results of the dynamic analysis of the reactor internals are summarized in Table 3.9-6(b). These results are based on the power rerate analysis, and do not reflect the use of GE13 or GE14 fuel. The impact of GE13 fuel is documented in reference 3.9-28. The impact of GE14 fuel is documented to be bounded by GE13 fuel in Reference 3.9-24. The impact of the MUR power uprate is evaluated in Reference 3.9-31 and Reference 3.9-32. Reference 3.9-33 identifies new design basis values for Fuel Lift Margin and Control Rod Guide Tube Lift Forces under MUR conditions. Additional analyses which considered the use of GNF2 fuel are documented in Reference 3.9-35. The GNF2 fuel is demonstrated to be bonded by the analyses in Reference 3.9-33.

Analyses were performed which considered the use of GNF3 fuel. Reference 3.9-39 identified new design basis values for the reactor internal pressure differences for unbounded reactor internals. The GNF3 analyses also identified a new design basis value for maximum Control Rod Guide Tube Lift force.

3.9.2.6 Correlations of Reactor Internals Vibration Tests with the Analytical Results

Prior to initiating the instrumented vibration test program for the prototype plant, extensive dynamic analyses of the reactor and internals are performed. The results of these analyses are used to generate the allowable vibration levels during the vibration test. The vibration data obtained during the test are always analyzed in detail. The results of the data analysis, vibration amplitudes, natural frequencies, and mode shapes are then compared to those obtained from the theoretical analysis.

Such comparisons provide insight into the dynamic behavior of the reactor internals. The additional knowledge gained is utilized in the generation of the dynamic models for seismic and LOCA analyses for this plant. The models used for this plant are the same as those used for the vibration analysis of the prototype plant.

The vibration test data are supplemented by data from forced oscillation tests of reactor internal components, thereby providing the analysts with additional information concerning the dynamic behavior of the reactor internals.

3.9.3 ASME CODE CLASS 1, 2, AND 3 COMPONENTS, COMPONENT SUPPORTS, AND CORE SUPPORT STRUCTURES

3.9.3.1 Loading Combinations, Design Transients, and Stress Limits

This section delineates the criteria for selecting and defining design limits and loading combinations associated with normal operation, postulated accidents, and specified seismic and hydrodynamic events for the design of safety-related ASME Code components (except containment components, which are discussed in Section 3.8).

This section also lists the major ASME Class 1, 2, and 3 associated equipment and pressure-retaining parts and on a component-by-component basis, and identifies the applicable

loadings, calculation methods, calculated stresses, and allowable stresses. Design transients for ASME Class 2 equipment are not addressed in the section, they are covered in Section 3.9.1.1; seismic and hydrodynamic related loads are discussed in Section 3.9.2.2.

Table 3.9-6 is the major part of this section; it presents the loading combination analytical methods (by reference or example) and also the calculated stress or other design values for the most critical areas of all ASME Class 1, 2, and 3 components supports and core support structures. These values (which are based on the power rerate analysis and do not reflect the use of GE13 or GE14 fuel) are also compared to applicable code allowables. The impact of GE13 fuel is documented in Reference 3.9-28. The impact of GE14 fuel is documented to be bounded by GE13 fuel in Reference 3.9-34. The impact of the MUR power uprate is evaluated in Reference 3.9-31 and Reference 3.9-32. Reference 3.9-33 identifies new design basis values for Fuel Lift Margin and Control Rod Guide Tube Lift Forces under MUR conditions. Additional analyses which consider the use of GNF2 fuel are documented in Reference 3.9-35. The GNF2 fuel is demonstrated to be bounded by the analyses in Reference 3.9-33.

Analyses were performed which considered the use of GNF3 fuel. Reference 3.9-39 identified new design basis values for the reactor internal pressure differences for unbounded reactor internals. The GNF3 analyses also identified a new design basis value for maximum Control Rod Guide Tube Lift force.

3.9.3.1.1 Plant Conditions

All events that the plant might credibly experience during a reactor year are evaluated to establish a design basis for plant equipment. These events are divided into four plant conditions.

The plant conditions described in the following paragraphs are based on event probability (i.e., frequency of occurrence) and correlated design conditions as defined in the ASME Section III.

3.9.3.1.1.1 Normal Condition

Normal conditions are any conditions in the course of system startup; operation in the design power range; normal hot standby (with condenser available); and system shutdown other than upset, emergency, faulted, or testing.

3.9.3.1.1.2 Upset Condition

Upset conditions are any deviations from normal conditions which are anticipated to occur often enough that the design should include a capability to withstand the conditions without operational impairment. The upset conditions include those transients which result from any single operator error or control malfunction, transients caused by a fault in a system component requiring its isolation from the system, and transients due to loss of load or power. Vibratory motions due to an OBE are conservatively treated as upset. Hot standby with the main condenser isolated is an upset condition.

3.9.3.1.1.3 Emergency Condition

Emergency conditions are those deviations from normal conditions which require shutdown to correct the conditions or to repair damage in the RCPB. These conditions have a low probability of occurrence, but are included to provide assurance that no gross loss of structural integrity results as a concomitant effect of any damage developed in the system. Emergency condition events

include, but are not limited to, transients caused by one or more of the following: a multiple valve blowdown of the reactor vessel; loss of reactor coolant from a small break or crack which does not depressurize the reactor system, nor result in leakage beyond normal makeup system capacity, but which does require the safety functions of containment isolation and reactor shutdown; improper assembly of the core during refueling; or vibratory motions of an OBE in combination with associated system transients.

3.9.3.1.1.4 Faulted Condition

Faulted conditions are those combinations of conditions associated with extremely unlikely postulated events, with consequences such that the integrity and operability of the system may be so impaired that considerations of public health and safety are involved. Faulted conditions encompass events that are postulated because their consequences include the potential for releasing significant amounts of radioactive material. These postulated events are the most drastic that must be designed against, and thus represent limiting design bases. Faulted condition events include, but are not limited to, one or more of the following: a control rod-drop accident; a fuel handling accident; a main steam line break; a recirculation loop break; the combination of small break/large break accident, dynamic motion associated with an SSE and hydrodynamic, and a LOOP; or the SSE.

3.9.3.1.1.5 Correlation of Plant Conditions with Event Probability

The probability per reactor year, (P), of an event associated with the plant conditions is listed below. This correlation can be used to identify the appropriate plant condition for any hypothesized event or sequence of events.

PLANT CONDITIONS	EVENT ENCOUNTERED (Probability per reactor year)
Normal (planned)	1.0
Upset (moderate probability)	$1.0>P>10^{-2}$
Emergency (low probability)	$10^{-2}>P>10^{-4}$
Faulted (extremely low probability)	$10^{-4}>P>10^{-6}$

3.9.3.1.1.6 Regulatory Guide 1.48

Regulatory Guide 1.48 was issued after the design of this plant was established, and is therefore not used as a design basis requirement. However, the GE design basis was representative of good industry practices at the time of design, procurement, and manufacture, and is shown to be in general agreement with the guidelines of Regulatory Guide 1.48 through the use of the alternate approaches. For a comparison of NSSS compliance with Regulatory Guide 1.48, refer to Table 3.9-10. This comparison reflects general GE practice on BWR/4s and BWR/5s, and therefore is applicable to LGS.

The design limits and loading combinations for non-NSSS seismic Category I fluid systems components have been evaluated as being in conformance with Regulatory Guide 1.48, although in some cases the guidelines were not specifically a design basis.

Pump and valve operability assurance during and after design loading events, as discussed in footnotes 6 and 11 in section C of the regulatory guide, is discussed in Section 3.9.3.2b.

3.9.3.1.2 Reactor Pressure Vessel Assembly

The reactor vessel assembly consists of the RPV, RPV support skirt, shroud support, and shroud plate.

The RPV, RPV support skirt, and shroud support are constructed in accordance with ASME Section III. The shroud support consists of the shroud support plate, and the shroud support cylinder and its legs. The RPV is an ASME Class 1 component. Complete stress reports on these components have been prepared in accordance with ASME requirements. Table 3.9-6(f) provides a summary of stress criteria load combinations, calculated stress, and available stresses. The stress analyses performed for the reactor vessel assembly, including the faulted condition, were completed using elastic methods. The stress load combinations and stress analyses for core support structures and other reactor internals are discussed in Section 3.9.5.

3.9.3.1.3 Main Steam Piping

The main steam piping discussed in this paragraph includes that piping extending from the reactor pressure vessel to the outboard MSIV. This piping is designed in accordance with the ASME Section III, Class 1, Subsection NB-3650. The load combinations and stress criteria for the main steam piping and pipe-mounted equipment are shown in Table 3.9-6(d).

The rules contained in ASME Section III, Appendix F are used in evaluating faulted loading conditions, independently of all other design and operating conditions. Stresses calculated on an elastic basis are evaluated in accordance with F-1360.

3.9.3.1.4 Recirculation Loop Piping

The recirculation system piping which is bounded by the RPV nozzles is designed in accordance with the ASME Section III, Class 1, Subsection NB-3650. The load combinations and allowables for the recirculation piping and pipe-mounted equipment are shown in Table 3.9-6(e). The rules contained in ASME Section III, Appendix F are used in evaluating faulted loading conditions, independently of all other design and operating conditions. Stresses calculated on an elastic basis are evaluated in accordance with F-1360.

3.9.3.1.5 Recirculation System Valves

The recirculation system suction and discharge gate valves are designed in accordance with the ASME Section III, Class 1, Subsection NB-3600. Loading combinations and other stress analysis data are presented in Table 3.9-6(j).

3.9.3.1.6 Recirculation Pump

In the design of the recirculation pumps, the ASME Section VIII, Division 1, 1971 Edition (with latest addenda) is used as a guide in calculations made to determine the thickness of pressure-retaining parts and to size the pressure-retaining bolting. At the time the LGS recirculation pump

was procured, ASME Section III design rules for pumps were under development. The New Loads Adequacy Evaluation has demonstrated that the design meets ASME Section III requirements.

The pump vendor's calculations for the design of the pressure- containing components include the determination of minimum wall thickness and allowable stress and pressures. Loading conditions and stress information of those calculations are shown in Table 3.9-6(i).

Load, shear, and moment diagrams were constructed to scale, using live loads, dead loads, and calculated snubber reactions. Combined bending, tension and shear stresses were determined for each major component of the assembly, including the pump driver mount, motor flange bolting, and pump case.

The maximum combined tensile stress in the cover bolting was calculated using tensile stress from design pressure.

Combined primary stresses did not exceed 150% of the Code allowable stress shown in ASME Section VIII, 1971 Edition.

These methods and calculations demonstrate that the pump will maintain pressure integrity.

3.9.3.1.7 SLCS Tank

The ASME Code allowable stress limits for the faulted category are 1.2 S_m for general membrane, and 1.8 S_m for bending plus local membrane.

The SLCS tank is designed in accordance with ASME Section III. A summary of the design calculations and stress criteria used is shown in Table 3.9-6(m).

3.9.3.1.8 RHR Heat Exchangers

The RHR heat exchangers are designed in accordance with ASME Section III. The loading combinations and stress analyses for the RHR heat exchangers are given in Table 3.9-6(o).

3.9.3.1.9 RCIC Turbine

Although not under the jurisdiction of the ASME Code, the RCIC turbine is designed and fabricated following the basic guidelines for an ASME Section III, Class 2 component.

Operating conditions for the RCIC turbine include:

a. Surveillance Testing - Periodic operation with the reactor pressure at 1000 psia, nominal, and saturated temperature; and turbine exhaust pressure at 25 psia, peak, and saturated temperature.

b. Auto-Startup - 30 cycles per year with the reactor pressure at 1150 psia, nominal, and saturated temperature; and turbine exhaust pressure at 25 psia, peak, and saturated temperature.

Design conditions for the RCIC turbine include:

a. Turbine Inlet - 1250 psig at saturated temperature

b. Turbine Exhaust - 165 psig at saturated temperature

Table 3.9-6(q) contains a summary of the loading conditions, stress criteria, calculated stresses and allowable stresses of the RCIC turbine.

3.9.3.1.10 RCIC Pump

The RCIC pump has been designed and fabricated to the requirements for an ASME Section III, Class 2 component.

The RCIC pump is surveillance tested in conjunction with the RCIC turbine. An operational test is performed, in which the RCIC pump takes condensate from the CST, and discharges back to the CST at the design flow through a closed test loop.

Design conditions for the RCIC pump include:

a. Required NPSH - 20 feet

b. Total head - High speed 2800 feet
Low speed 525 feet

c. Pump capacity - 625 gpm

d. Normal ambient operating temperature - 60°F to 100°F

e. Normal plus upset conditions which control the pump design include:

1. Design pressure 1500 psig

2. Design temperature 40°F - 140°F

3. OBE(1) ½ of SSE

Table 3.9-6(r) contains a summary of the loading conditions, stress criteria, calculated and allowable stresses for the RCIC pump components.

3.9.3.1.11 ECCS Pumps

The RHR and core spray pumps are designed in accordance with ASME Section III. The stress criteria and calculated and allowable stresses are summarized in Table 3.9-6(n).

Design conditions for the RHR and core spray pumps are as follows:

	RHR	Core Spray
a. Design pressure		
1. Suction	220 psig	125 psig

2.	Discharge	500 psig	500 psig
b.	Design Temperature	40-360°F	40-212°F

3.9.3.1.12 SLCS Pump

The SLCS pumps are designed and fabricated following the requirements for an ASME Section III, Class 2 component.

The SLCS pumps and motors are functionally tested by pumping demineralized water through a closed test loop.

Design conditions for each SLCS pump include:

a.	Flow rate	43 gpm
b.	Available NPSH	12.9 psi @ 110°F
c.	Maximum operating discharge pressure	1220 psig

---

(1) Combine with hydrodynamic loads of Table 3.9-6.

d. Ambient conditions:

1.	Temperature	65°F - 106°F
2.	Relative Humidity	20% - 95%

e. Normal plus upset conditions which control the pump design include:

1.	Design pressure	1400 psig
2.	Design temperature	150°F
3.	OBE	½ of SSE

f. Faulted or emergency conditions include:

1.	Design pressure		1400 psig
2.	Design temperature		150°F
3.	SSE(1)		
		horizontal	1.5 g
		vertical	0.14 g

A summary of loading combinations, stress criteria, and calculated and allowable stresses for the SLCS pump is contained in Table 3.9-6(l).

3.9.3.1.13 MSIVs and MSRVs

The MSIVs and MSRVs are designed in accordance with ASME Section III, NB-3500 for safety Class 1 components.

Load combination, analytical methods, calculated stresses, and allowable limits are shown for the MSRVs and MSIVs in Tables 3.9-6(g) and 3.9-6(h) respectively.

3.9.3.1.14 HPCI Turbine

Although not under the jurisdiction of the ASME Code, the HPCI turbine is designed and fabricated following the basic guidelines for an ASME Section III, Class 2 component.

Operating conditions for the HPCI turbine include:

a. Surveillance Testing - Periodic operation with the reactor pressure at 1000 psia, nominal, and saturated temperature; and the turbine exhaust pressure at 65 psia, peak, and saturated temperature.

---

(1) Combine with hydrodynamic loads from Table 3.9-6.

b. Auto-Startup - 30 cycles per year with the reactor pressure at 1150 psia, nominal, and saturated temperature; and turbine exhaust pressure at 65 psia, peak, and saturated temperature.

Design conditions for the HPCI turbine include:

a. Turbine Inlet - 1250 psig at 575°F

b. Turbine Exhaust - 200 psig at 382°F

A summary of loading conditions, stress criteria, and calculated and allowable stresses for the HPCI turbine components is shown in Table 3.9-6(k).

3.9.3.1.15 HPCI Pump

The HPCI pump is designed and fabricated following the requirements for an ASME Section III, Class 2 component.

The HPCI pump is surveillance tested together with the HPCI turbine (Section 3.9.3.1.14). An operational test is performed in which the HPCI pump takes condensate from the CST, and discharges at the design flow rate back to the CST through a closed test loop.

Design conditions for the HPCI pump include:

REACTOR CONDITION(2,3)

			1	2	3
a.	Required NPSH (feet)		21	21	21
b.	Total head -	High speed (feet)	3030	850	700
		Low speed (feet)	525	525	525
c.	Constant flow rate (gpm)		5600	5600	3750

d. Normal ambient operating temperature - 60°F to 100°F

e. Normal plus upset conditions which control the pump design include:

1.	Design pressure	1500 psig
2.	Design temperature	40°F - 140°F
3.	OBE(1)	½ of SSE

A summary of calculated stresses, allowable stresses, criteria and loading conditions for critical components is provided in Table 3.9-6(t).

---

(1) Combine with hydrodynamic loads from Table 3.9-6.

(2) Reactor Conditions 1 and 2 refer to the range of reactor pressures within which the rated performance of the HPCI pump is guaranteed. This range is bounded by 1156 psia (saturation pressure, Condition 1) and 215 psia. Condition 3 refers to the 100 psig pump interlock point, and is the corresponding pump performance obtained from manufacturer's input.

(3) The HPCI design basis is that it must be capable of injecting design rated flow into the reactor vessel at a maximum reactor pressure equal to the lowest SRV nominal setpoint, plus the allowable setpoint tolerance. References 3.9-26 and 3.9-27 re-evaluated HPCI system operation at the maximum reactor pressure of 1205 psig (lowest SRV setpoint, 1170 psig, plus 3% setpoint tolerance). It was concluded that maintaining the currently rated turbine speed of 4190 rpm at 1205 psig would result in a maximum rated flow rate of 5400 gpm. Reference 3.9-27 performed a conservative analysis that demonstrated a reduced flow rate of 5000 gpm between reactor pressures of 1182 and 1205 psig is adequate for all design basis requirements of the HPCI system.

3.9.3.1.16 RWCU System

The requirements of ASME Section III, Class 3 components are used as guidelines in evaluating the RWCU system pump and heat exchangers. The loading combinations, stress criteria, calculated and allowable stresses are summarized in Tables 3.9-6(p) and 3.9-6(c), respectively.

3.9.3.1.17 Non-NSSS ASME Code Constructed Items

The design loading combinations, categorized by plant operating conditions, identified as normal, upset, emergency, or faulted for Non-NSSS ASME code constructed items, are presented in Table 3.9-11.

The design criteria and stress limits associated with each of the plant operating conditions for each type of ASME code constructed items are presented in Tables 3.9-12 through 3.9-18.

The component operating condition is the same as the plant operating condition, except that the emergency or faulted plant condition is considered normal for a pump or valve whose function must be ensured during an emergency or faulted plant condition.

3.9.3.2a NSSS Pump And Valve Operability Assurance

The NSSS active pumps and valves are listed in Table 3.9-19.

Active mechanical equipment classified as seismic Category I is designed to function during the life of the plant, under postulated plant conditions. Equipment with faulted condition functional requirements includes "active" pumps and valves in fluid systems such as the ECCS. ("active" equipment performs a mechanical motion to accomplish a safety function.)

Operability is ensured by satisfying the requirements of the following programs. Safety-related valves are qualified by prototype testing and/or analysis; and safety-related active pumps are qualified by analysis and/or testing with suitable stress limits and nozzle loads. The content of these programs is detailed below.

3.9.3.2a.1 ECCS Pumps

All active pumps are qualified for operability by first being subjected to rigid tests, before and after installation in the plant. The in-shop tests include hydrostatic tests of pressure-retaining parts at 125% of the design pressure; seal leakage tests; and performance tests, while the pump is operated with flow, to determine total developed head, minimum and maximum head, and NPSH requirements. Bearing temperatures (except water-cooled bearings) and vibration levels are also monitored during these operating tests. Both are below specified limits. After the pump is installed in the plant, it undergoes cold hydrotests, functional tests, and the required periodic inservice inspection and operation. These tests demonstrate reliability of the pump for the design life of the plant.

In addition to these tests, the safety-related active pumps are analyzed for operability during a faulted condition to ensure that the pump will not be damaged during the seismic and hydrodynamic event, and that the pump will continue operating despite the faulted loads.

3.9.3.2a.1.1 Analysis of Loading, Stress, and Acceleration Conditions

In order to avoid damage during the faulted plant condition, the stresses caused by the combination of normal operating loads, SSE, and dynamic system loads are limited to the material elastic limit, as indicated in Section 3.9.3.1 and Table 3.9-6. A three-dimensional finite-element model of the pump/motor and supports was developed using the response spectrum method of dynamic analysis. The average membrane stress (δ_m) for the faulted condition loads is maintained at 1.2 S_m, or approximately 0.75 δ_y (δ_y = yield stress); the maximum stress in local fibers (δ_m plus bending stress (δ_b)) is limited to 1.8 S_m, or approximately 1.1 δ_y.

The maximum dynamic nozzle loads were also considered in an analysis of the pump supports to ensure that a system misalignment will not occur.

A dynamic analysis was performed to determine the magnitude of the seismic loading from the applicable floor response spectra. An analysis was made to ensure that faulted condition nozzle loads and dynamic accelerations would not impair the operability of the pumps during or following the faulted conditions. Pump components having a natural frequency above 33 Hz are considered rigid. This frequency is considered sufficiently high to avoid problems with amplification between the component and structure for all seismic areas.

If the natural frequency is below 33 Hz, an analysis is performed to determine the amplified input accelerations necessary to perform the static analysis. The adjusted accelerations are determined using conservatisms contained in the horizontal and the vertical accelerations used for rigid structures. The static analysis is performed using the adjusted accelerations and must meet the same stress limit criterion stated in Table 3.9-6.

These analyses, with the conservative loads stated and with the restrictive stress limits of Table 3.9-6 as allowables, assure that critical parts of the pump are not damaged during the faulted condition, and that, therefore, the reliability of the pump for postfaulted condition operation will not be impaired by a hydrodynamic or seismic event.

3.9.3.2a.1.2 Pump Operation During and Following Faulted Condition Loading

Active pump/motor rotor combinations are designed to rotate at a constant speed under all conditions. Motors are designed to withstand short periods of severe overload. The high rotary inertia in the operating pump rotor and the nature of the random shot-duration loading characteristics of the seismic and hydrodynamic events prevents the rotor from becoming seized. The dynamic loadings cause a slight increase, if any, in the torque (i.e., motor current) necessary to drive the pump at constant design speed. Therefore the pump does not shut down during the faulted condition but operates at the design speed despite the faulted loads.

The functional ability of the active pumps after a faulted condition is assured, since only normal operating loads and steady-state nozzle loads exist at this time. For the active pumps, the faulted condition is greater than the normal condition due to seismic and hydrodynamic loads on the equipment and the increase in nozzle loads from the SSE on the connecting pipe. The SSE event is infrequent and of short duration compared to the design life of the equipment. Because it is demonstrated that the pumps would not be damaged during the faulted condition, the postfaulted condition operating loads are less than the normal plant operating limits. This is assured by requiring that the imposed nozzle loads (steady-state loads) for normal conditions and postfaulted conditions are limited by the normal condition nozzle loads. The postfaulted condition ability of the pumps to function under these applied loads is proven during the normal operating plant conditions.

3.9.3.2a.2 SLCS Pump and Motor Assemblies and RCIC Pump Assembly

These equipment assemblies are small, compact, rigid assemblies, with natural frequencies greater than 100 Hz. With this fact verified, each equipment assembly is dynamically qualified by static analysis only. This static qualification verifies operability under seismic and hydrodynamic conditions, and ensures that structural loading stresses are within code limitations.

3.9.3.2a.3 RCIC Turbine

Refer to Section 3.9.2.2a.2.9 and Table 3.9-6(q).

3.9.3.2a.4 ECCS Motors

Qualification of the Class 1E motors used for the ECCS motors is in compliance with IEEE 323 (1971). The qualification of all motor sizes is based on completion of a type test, followed with review and comparison of design and material details and seismic analysis of production units, ranging from 500 Bhp to 3500 Bhp, with the motor used in the type test. All manufacturing, inspection, and routine tests by motor manufacturer on production units are performed on the test motor.

The type test was performed on a 1250 hp vertical motor, in accordance with IEEE 323 (1971). First normal operation during the design life was simulated; then the motor was subjected to a number of seismic events; and then subjected to the abnormal environmental conditions possible during and after a LOCA. The type test plan was as follows:

a. Thermal aging of the motor electrical insulation system (which is a part of the stator only) was based on extrapolation, in accordance with the temperature life of the characteristic curve from IEEE 275 (1966) for the insulation type used on the ECCS motors. The amount of aging equals the total estimated operation days of maximum insulation surface temperature.

b. Radiation aging of the motor electrical insulation equals the maximum estimated integrated gamma dose during normal and abnormal conditions.

c. The normal induced current vibration effect on the insulation system was simulated by a 1.5 g horizontal vibration acceleration for one hour at current frequency.

d. Motor bearings were selected and their operating life established on the basis of bearing manufacturer's tests and operating data using the loads calculated to act on the bearings.

e. The dynamic load-deflection analysis on the rotor-shaft, performed to ensure adequate rotation clearance, is verified by static loading and deflection of the rotor for the type test motor.

f. Dynamic loading aging and testing were performed on a biaxial test table in accordance with IEEE 344 (1971). During this type test, the shake table was activated, simulating the maximum design limit of the SSE and hydrodynamic loads with motor starts and operation combination, as may possibly occur during the life of the plant. Refer to Section 3.10.

g. An environmental test simulating a LOCA condition was performed for 100 days with the test motor fully loaded, simulating pump operation. The test consists of startup and six hours of operation at 212°F ambient temperature, and a 100% steam environment. After 1 hour standstill in the same environment, another startup and operation of the test motor was followed by sufficient operation at high humidity and temperature. This was based on extrapolation in accordance with the temperature life characteristic curve from IEEE 275 (1966) for the insulation type used on the ECCS motors.

3.9.3.2a.5 HPCI Pump

Operability of the HPCI pump assembly is demonstrated by a combination of analytical stress calculations, pump manufacturer's operating experience, and testing. The stress definitions and the allowable stress criteria are based on the ASME Section III. The code is directly applicable to the stamped pressure boundary components of the pump.

The witnessed hydrostatic and performance tests, as performed at the pump manufacturer's plant, demonstrate that the pump as designed meets the ASME Code requirements and the parameters of the design specification.

A dynamic analysis was performed by the pump manufacturer. A static analysis was performed for dead weight and nozzle loads. Dynamic analysis was used for the SSE loading condition.

Rotating parts are verified by analysis to ensure no contact with the stationary parts, except at engineered wear points, therefore, continued operation during and after an SSE is assured because the calculated stresses and deformations are less than the prescribed limits.

3.9.3.2a.6 NSSS Valves

3.9.3.2a.6.1 Class 1 Active Valves

The Class 1 active valves are the MSIVs and the MSRVs and SLCS valves. Each of these valves is designed to perform its mechanical motion in conjunction with a design basis accident. Dynamic qualification for operability is unique for each valve type; therefore, each method of qualification is detailed individually below.

3.9.3.2a.6.1.1 Main Steam Isolation Valve

The MSIVs were evaluated for operability during a dynamic loading event by analysis and test as follows:

a. The valve body was designed in accordance with ASME Section III, Class 1, which limits deformations in the operating area of the valve body to those within the elastic limit of the material by limiting pressure and pipe reaction input loads (including seismic and hydrodynamic), thereby ensuring no interference with valve operability.

b. The complete valve topworks, including the bonnet and a simulated stem of a similar design MSIV, was dynamically tested for upset loads and faulted load. The test sample was subjected to 30 seconds of bi-directional random frequency input for each test event. There were a total of 10 upset test events and 2 faulted test events. Valve closure was simulated half way through the testing duration during each event. After the complete test program, there was no significant change to the valve closure rate.

To ensure that design limits were not exceeded for both piping input loads and actuator dynamic loads, the MSIV was mathematically modeled in the main steam line system analysis. The valve dynamic characteristics were modeled in the overall steam line analysis. Pipe anchors and restraints are applied as required to limit pipe system resonance frequencies and amplified accelerations to within acceptable limits for the MSIVs. Details concerning the analysis of these valves is given in Table 3.9-6(h).

The MSIV operability during LOCA conditions is demonstrated as defined in report APED-5750 (March 1969). The test specimen is a 20 inch valve representative in design to the MSIVs. Operability during seismic acceleration is addressed in Section 3.9.2.2a.

3.9.3.2a.6.1.2 Main Steam Relief Valves

The MSRVs were evaluated for operability during seismic and hydrodynamic events. Structural integrity of the configuration during a seismic event was demonstrated by both code analysis and dynamic testing.

a. Each valve was designed for maximum moments which may be imposed on it when installed in service. These moments result from the dead weight, hydrodynamic, and seismic loading of both the valve and the connecting pipe, thermal expansion of the connecting pipe, and reaction forces from valve discharge.

b. Dynamic tests were performed on the LGS MSRV configuration. The tests validated the design static analysis and determined that the equipment remains functional during application of the specified "g" loads.

A mathematical model of this valve was included in the overall main steam line system analysis, along with the MSIVs, to ensure that design limits were not exceeded.

The MSRV analytical qualification results are shown in Table 3.9-6(g).

3.9.3.2a.6.1.3 Explosive Valves

The SLCS explosive valves are qualified to IEEE 344 (1975). The generic qualification test demonstrated the absence of natural frequencies below 35 Hz and the ability to remain operable after the application of horizontal dynamic loading equivalent to 6.5 g and a vertical dynamic loading equivalent to 4.5 g at 33 Hz. In addition, analysis shows that there are no natural frequencies below 100 Hz.

3.9.3.2a.6.2 Class 2 and 3 Active Valves

3.9.3.2a.6.2.1 Gate/Globe Valves

Class 2 active gate/globe valves provided by GE include five RHR valves, one HPCI valve, one RCIC valve, and three core spray valves; all valves are motor-operated. There are no Class 3 active valves in the GE scope of supply. The gate/globe valves are generically qualified by testing valves that are typical of the valves supplied by GE. Operability is ensured by testing under the maximum capability static load which envelopes the static design basis load. These tests ensure operability during and after the design basis load. The actuators are qualified to IEEE 382 (1972), up to levels that exceed the design loadings.

3.9.3.2a.6.2.2 Check Valves

GE provides one swing-check valve and one stop-check valve which are Class 2 active in each of the HPCI and RCIC systems. In addition, GE provides six Class 2 check valves for the RHR system and two Class 2 check valves for the core spray system. Operability of check valves is assured by performing design calculations and by providing sufficient structural margins so that

movement of the disc/hinge pin is not impaired under any loading conditions. There are no Class 3 active valves in the GE scope of supply.

3.9.3.2b Non-NSSS Pump and Valve Operability Assurance

3.9.3.2b.1 Pumps

The following pumps are active pumps:

a. Diesel oil transfer pumps

b. RHRSW pumps

c. ESW pumps

d. Control room chilled water pumps

e. Safeguard piping fill pumps.

The safeguard piping fill pumps are Class 2. All the remaining pumps are Class 3.

Safety-related active pumps are subjected to stringent tests both prior to and after installation in the plant. The in-shop tests include: hydrostatic tests of pressure-retaining parts to 150% of the design pressure; seal leakage tests at the same pressure used in the hydrostatic tests; and performance tests which are conducted while the pump is operated with flow to determine total developed head, minimum and maximum head, NPSH requirements, and other pump/motor properties. Bearing temperatures and vibration levels are also monitored during these operating tests. Both are shown to be within the limits specified by the manufacturer. After the pump is installed at the plant, it undergoes startup tests and required inservice inspection and operation.

In addition to these tests, the active pumps are qualified for operation during and after a faulted condition. That is, safety-related active pumps are qualified for operability during an SSE condition by assuring that the pump will not be damaged during the seismic event, and that the pump will continue operating despite the SSE loads. (Refer to 3A.7.1.7 for pumps subjected to hydrodynamic loads.)

In order to meet the first criterion, that the pump will not be damaged during the seismic event, the pump manufacturer is required to determine by test or dynamic analysis whether the lowest natural frequency of the pump is greater than 33 Hz. The pump, when having a natural frequency above 33 Hz, is considered essentially rigid. This frequency is considered sufficiently high to avoid problems with amplification between the component and structure for all seismic areas. A static shaft deflection analysis of the rotor is performed with the conservative SSE accelerations of 1.5 times the applicable floor acceleration. The deflections determined from the static shaft analysis are compared to the allowable rotor clearances.

If the lowest natural frequency is found to be below 33 hertz, the equipment is considered flexible. If flexible, the equipment is analyzed using the response spectrum modal analysis technique. The frequencies and mode shapes are determined in the vertical and horizontal directions. The loads due to the excitation of each mode and the loads due to the accelerations in the three orthogonal

directions are added using the square root of the sum of the squares method. Coupling effects are included in the mathematical model.

In order to avoid damage to the pumps during the faulted plant condition, the stresses caused by the combination of normal operating loads, SSE, and dynamic system loads are limited. The maximum seismic nozzle loads are also considered in an analysis of the pump supports to assure that a system misalignment cannot occur. Performance of these analyses, based upon conservative loads and restrictive stress limits, assures that critical parts of the pump will not be damaged during the faulted condition and, therefore, that the reliability of the pump for postfaulted condition operation will not be impaired by the seismic events.

The second criterion necessary to assure operability is that the pump will function throughout the SSE. The pump/motor combination is designed to rotate at a constant speed under all conditions unless the rotor becomes completely seized, i.e., with no rotation. Typically, the rotor can be seized five full seconds before a circuit breaker, used to prevent damage to the motor, opens to stop the pump. However, the high rotary inertia in the operating pump rotor and the nature of the random, short duration loading characteristics of the seismic event prevent the rotor from becoming seized. Actually, the seismic loadings cause only a slight increase, if any, in the torque, i.e., motor current, necessary to drive the pump at the constant design speed. Therefore, the pump will not shut down during the SSE and will operate at the design speed despite the SSE loads.

To complete the seismic qualification procedures, the pump motor and all appurtenances vital to the operation of the pump are independently qualified for operation during the maximum seismic event as discussed in Section 3.10.

From this regimen, it is concluded that the safety-related pump/motor assemblies will not be damaged and will continue to operate under SSE loadings and, therefore, will perform their intended functions. These proposed requirements take into account the complex characteristics of the pump and are sufficient to demonstrate and assure the seismic operability of the active pumps.

The functional ability of active pumps after a faulted condition is assured since only operating loads and steady-state nozzle loads exist. Since it is demonstrated that the pumps would not be damaged during the faulted condition, the postfaulted operating loads will be limited to the normal plant operating loads. This is assured by requiring that the imposed nozzle loads (steady-state loads) for normal conditions and postfaulted conditions are limited by the magnitudes of the normal condition nozzle loads. The postfaulted ability of the pumps to function under these applied loads is proved during the normal operating plant conditions for active pumps.

3.9.3.2b.2 Valves

The active valves are tabulated in Reference 3.9-25. Those active valves which are supplied by the NSSS vendor are identified. See Section 3.9.3.2a for a discussion of operability assurance of these valves.

Safety-related active valves are subjected to a series of stringent tests prior to service, and during the plant life. Before installation, the following tests are performed: the shell hydrostatic test, in accordance with ASME Section III requirements; back-seat and main-seat leakage tests; the disc hydrostatic test; functional tests which verify that the valve opens and closes within the specified time limits; and the operability qualification of motor operators for the environmental conditions over the installed life (i.e., aging, radiation, accident environment simulation, etc.), in accordance with

IEEE 382 (1972). After installation, cold hydrostatic tests, functional tests (in accordance with the requirements of Chapter 14), and periodic inservice operation (in accordance with the requirements of Chapter 16) are performed to verify and ensure the functional ability of the valve.

The valves are designed using either stress analyses, or the pressure-containing minimum wall thickness requirements. For all active valves with extended topworks, an analysis is also performed for static-equivalent SSE loads applied at the extended structure's center of gravity. The maximum stress limits allowed in the analyses demonstrate structural integrity, and are equal to the limits recommended by the ASME for the particular ASME class of valve analyzed. Limits for each of the loading combinations are presented in Tables 3.9-13 and 3.9-18.

In addition to these tests and analyses, a representative valve of each design type is tested to verify operability during a simulated seismic event by demonstrating operational capabilities within the specified limits. The qualification testing procedures are described below.

The valve is mounted in a manner that conservatively represents typical valve installations. The valve unit includes the actuator and all appurtenances normally attached to the valve in service. The operability of the valve during an SSE is demonstrated by satisfying the following criteria. (Refer to Appendix 3A.7.1.7 for valves subjected to hydrodynamic loads.)

a. All the active valves with topworks are basically designed to have a first natural frequency greater than 33 Hz. This may be shown by suitable testing or analysis. Regardless of value, the first natural frequency of the topworks is modeled into the piping analysis for determination of maximum accelerations.

b. While in the shop and installed in a suitable test rig, the extended topworks of the valve are subjected to a statically applied equivalent seismic load. The load (the specified g-force times the weight of the topworks) is applied at the center of gravity of the topworks, in the direction of the weakest axis of the yoke. The design pressure of the valve is simultaneously applied to the valve during the static load tests.

c. The valve is then operated at the minimum specified actuation supply voltage or pressure, with the equivalent seismic static load applied. The valve must perform its safety-related function within the specified operating time limits.

d. Motor operators are qualified as operable during and after the SSE prior to their installation on the valve, as discussed in Section 3.10.2.2.

The equivalent seismic static load, which is used for the static valve qualification, is the maximum load which the valve is designed to withstand. The piping designer must maintain the motor operator accelerations to these levels.

The valve is leak tested following the test described above, to show that the valve has not been damaged. The leak rates must not exceed the original allowable leakage rate specified for the valve.

The above factory testing program applies only to valves with overhanging structures, e.g., the motor operator or air actuator assembly. The testing is conducted on a representative number of valves. According to the size and pressure rating, valves from each of the primary safety-related design types, e.g., motor- operated gate valves, are tested. Valves that cover the range of sizes in service are qualified by tests, and the results are used to qualify all valves within the intermediate

range of sizes, as shown in Table 3.9-20. Stress analyses are used to support the interpolation. Because of their simple characteristics, check and other compact valves are not adversely affected by seismic acceleration. Check valves have no extended structures to distort the valves and cause malfunctions. Check valve discs are designed to allow sufficient clearance around the disc to prevent binding or interference due to distortions from nozzle or other imposed loads. They are qualified by a combination of the following factory tests and analysis:

a. Stress analysis of critical areas and parts for SSE loads in accordance with the allowable specified in Tables 3.9-13 and 3.9-18

b. In-shop hydrostatic test

c. In-shop seat leakage test

d. Periodic valve exercise and inspection to ensure the functional ability of the valve in accordance with the requirements of Chapter 16

A study was also performed that considered a feedwater pipe rupture outside containment to assure that the feedwater isolation check valves can perform their function following a postulated pipe break of the feedwater line outside containment. Analysis of a full circumferential break showed that the check valve inside containment (one of 3 feedwater PCIV's that are check valves) would close rapidly because of flow reversal in the pipe between the reactor and break location just outside containment. This results in a pressure surge of 2780 psia between the valve and reactor. It was determined that the piping and valves could adequately sustain this pressure.

To determine the capability of the check valve seat to withstand the initial impact caused by rapid closure and to sustain the pressure surge that follows, an estimate of check valve seat energy absorption capability was made for a postulated feedwater pipe break accident occurring upstream of the containment isolation valves. The basis for the seat stress calculation was for a valve disk closing velocity of 100 rad/sec and a pressure break in the pipe of 2780 psia.

The valve seat was assumed to consist of an assembly of six discrete, bilinear, elastic-plastic elements. The analysis assumed that the disc kinetic energy at impact equals work done in terms of seat under load, or area under the seat load-displacement curve. Valve seat yield strength was based on its being stressed to 50% of yield at a design pressure of 2132 psi. The load-displacement curve was constructed using Roark's stiffness equations for an annular plate loaded at the inner radius and fixed at the outer radius. Failure was assumed to occur at a ductility ratio of 30.

The analysis indicated that all of the seat elements reach yield, but none reach ultimate strain or fail. Effects not included that are believed to make the analysis conservative are:

a. No credit was taken for disc deformation and energy absorption

b. No credit was taken for hinge deformation and energy absorption

c. No credit was taken for valve body deformation and energy absorption

d. Hinge friction was omitted

e. No strain hardening or rate of strain effects in the seat were included.

The water hammer effects on the closed seat were determined. It was shown that the natural frequency of the combined valve seat stiffness and disc mass was much larger than the frequency of the pressure pulse, so that the effective pressure that the seat must withstand is only the peak pressure in the water hammer surge. The seat is able to withstand this maximum pressure.

Results of this analysis show that, although the conditions of a hypothetical pipe rupture on the feedwater check valves are severe, the valves should remain together at impact and are capable of withstanding 2800 psi. The valve seat should yield at disc impact but not fail, and the water hammer pressure pulse following closure will not cause failure.

An additional confirmatory analysis was also conducted which used a simplified model of single-phase, liquid flow from the reactor vessel to the pipe break, with the check valve disk being closed by drag forces.

Results of this simplified analysis indicate that the check valve disk closes in approximately 70 msec, with a closing velocity at impact of approximately 65 rad/sec. The peak pressure at the closed disk is estimated to be 2157 psi for a finite valve closure time of 70 msec. The precise pressure at valve closure cannot be predicted rigorously by the simplified method used in this study.

The results of this study confirmed the validity of the original design analysis and are consistent with the results of the analysis done for SSES and in particular for the Atwood Morrill check valves.

Operability testing is also not performed for relief valves. Due to the particular, simple characteristics of these SRVs, they are qualified by a combination of the following tests and analyses:

a. Stress analysis, including seismic loads where applicable

b. In-shop hydrostatic test

c. In-shop seat leakage test

d. Performance tests

e. Periodic in situ valve inspection as applicable and periodic valve removal, refurbishment, performance testing and reinstallation

The above testing and analysis is sufficient to ensure the functional capability of the valve.

During a seismic event, it is anticipated that the seismic acceleration imposed upon the valve may cause it to open momentarily and discharge under system conditions that otherwise would not result in valve opening, but this is considered to be of no real safety or other consequence.

Using the methods described, all the safety-related active valves in the systems are qualified for operability during a seismic event. These methods conservatively simulate the seismic event and ensure that the active valves perform their safety-related functions when necessary.

3.9.3.3 Design and Installation of Pressure Relief Devices

3.9.3.3.1 Main Steam Relief Valves (NSSS)

Lifting of an MSRV results in a transient that produces momentary unbalanced forces acting on the discharge piping system from the time the MSRV opens, until a steady discharge flow from the RPV to the suppression pool is established. This period includes clearing the water slug from the end of the discharge piping submerged in the suppression pool. Pressure waves traveling through the discharge piping following the relatively rapid opening of the MSRV cause the MSRV discharge piping to vibrate. This in turn produces forces that act on the main steam piping.

The analysis of the relief valve discharge transient consists of a step-wise time history solution of the fluid flow equation, to generate a time history of the fluid properties at numerous locations along the pipe. The fluid transient properties are calculated based on the maximum set pressure specified in the steam system specification, and the value of ASME flow rating increased by a factor to account for the conservative method of establishing the rating. Simultaneous discharge of all valves is assumed in the analysis, because simultaneous discharge is considered to induce maximum stress in the piping. Reaction loads on the pipe are determined at each location corresponding to the position of an elbow. These loads are composed of pressure times area, momentum change, and fluid friction terms. Figure 3.9-3 shows a set of fluid property and pipe section load transients typical of those produced by relief valve discharge.

The method of analysis applied to determine piping system response to MSRV operation is time history integration. The forces are applied at locations on the piping system where the fluid flow changes direction, thus causing momentary reactions. The resulting loads on the MSRV, the main steam line, and the discharge piping are combined with loads due to other effects, as specified in Section 3.9.3.1. The code stress limits corresponding to load combination classifications of normal, upset, emergency, and faulted, are applied to the main steam lines and MSRV discharge piping.

In addition, a series of water discharge tests of SRVs used in BWRs was conducted to demonstrate the operational adequacy of the SRV and SRV discharge piping integrity for expected operating conditions for transients and accidents. The tests were performed to satisfy requirements of NUREG-0737, Item II.D.1.

The tests were run at the Wyle Laboratories test facility in Huntsville, Alabama. The facility included a steam and water supply system, the test SRV mounted on a representative steam line, and a representative SRV discharge line routed to a pool of water. Opening and closing of the SRVs were monitored. Fluid conditions and flows were measured, as were strains, accelerations, temperatures, and pressures in the SRV and associated piping.

The water discharge test conditions simulated the alternate shutdown cooling condition, which is an operating condition which is considered in the design evaluation of many BWR plants. The results show that all of the tested SRVs opened and closed on command for all water tests. The measured SRV discharge line loads for water discharge were significantly less than those for the high pressure steam discharge condition for which the piping is designed. LGS specific analyses have been performed (Reference 3.9-22) to establish RPV temperature and pressure conditions where initiation of alternate shutdown cooling will result in acceptable SRV discharge line loads. Alternate shutdown cooling is manually initiated only.

The tests and analyses as described in NEDE-24988-P (Reference 3.9-15) verify the adequacy of SRV operation and the integrity of the SRV discharge piping under expected liquid discharge conditions, and satisfy requirements of NUREG-0737, Item II.D.1.

A basis for concluding that the test results presented in NEDE-24988-P on SRV testing are applicable to LGS is described in the following paragraphs:

a. The SRV discharge piping configuration at LGS uses a T-quencher at the discharge pipe exit. The average length of the 14 SRV discharge line is 132 feet of 12 inch diameter pipe, and the submergence length in the suppression pool is approximately 18'-6". The SRV test program used a ramshead at the discharge pipe exit, a pipe length of 112 feet, a diameter of 10 inches, and a submergence length of approximately 13 feet. Loads on valve internals in the LGS configuration are within acceptable limits for the following reasons:

   1. No dynamic mechanical load originating at the T-quencher is transmitted to the valve in the LGS configuration because there is at least one anchor point between the valve and the T-quencher.

   2. The length of the first segment of piping downstream of the SRV in the test facility was selected to result in the test program having a bounding dynamic mechanical load on the valve. The LGS SRV discharge line piping configuration differs from the test facility in that the first line segment does not terminate in a 90° elbow, and the pipe size increases in the first segment. An assessment of the LGS configuration has confirmed that the mechanical loads imposed on the LGS valves by the low pressure water flow are enveloped by the high pressure steam loads.

   3. Dynamic hydraulic loads (back pressure) are experienced by the valve internals in the LGS configuration. The back pressure loads may be either transient back pressures occurring during valve actuation or steady-state back pressures occurring during steady-state flow following valve actuation.

      The key parameters affecting the transient back pressures are the fluid pressure upstream of the valve, the valve opening time, the fluid inertia in the submerged SRV discharge line 0, and the SRV discharge line air volume. Transient back pressures increase with higher upstream pressure, shorter valve opening times, greater line submergence, and smaller SRV discharge line air volume. An evaluation of these differences has confirmed that the test facility and the LGS configuration have comparable back pressures. The maximum transient back pressure occurs with high pressure steam flow conditions. The transient back pressure for the alternate shutdown cooling mode of operation is always much less than the design for steam flow conditions because of the lower upstream pressure and the longer valve opening time.

      The steady-state back pressure in the test program was maximized by using an orifice plate in the SRV discharge line above the water level and before the ramshead. The orifice was sized to produce a back pressure greater than that calculated for any of the LGS SRV discharge lines.

An additional consideration in the selection of the ramshead for the test facility was to allow more direct measurement of the thrust load in the final pipe segment. The use of a T-quencher in the test program would have required quencher supports that would unnecessarily obscure accurate measurement of the pipe thrust loads.

The differences in the line configuration between the LGS plant and the test program as discussed above result in loads on the LGS valve internals that are within acceptable limits.

b. The LGS SRV discharge lines are supported by a combination of snubbers, rigid supports, and spring hangers. These supports were designed to accommodate combinations of loads resulting from piping, dead weight, thermal conditions, seismic and suppression pool hydrodynamic events, and a high pressure steam discharge transient. Each SRV discharge line at LGS has 2 to 5 spring hangers, all of which are located in the drywell. The test facility configuration utilized no spring hangers.

   The dynamic load effects on the piping and supports of the test facility due to the water discharge events (the alternate shutdown cooling mode) were found to be significantly lower than corresponding loads resulting from the high pressure steam discharge event. As stated in Reference 3.9-15, this finding is considered generic to all BWRs because the test facility was designed to be prototypical of the features pertinent to this issue. Furthermore, assessment of a typical LGS SRV discharge line configuration has confirmed the applicability of the generic statement to LGS. LGS specific analysis for acceptable alternate shutdown cooling initiating conditions has been performed (Reference 3.9-22).

   During the water discharge transient, there will be significantly lower dynamic loads acting on the snubbers and rigid supports than during the steam discharge transient. This will more than offset the small increase in the dead load on these supports due to the weight of the water during the alternate shutdown cooling mode of operation. Therefore, design adequacy of the snubbers and rigid supports is assured because they are designed for the larger steam discharge transient loads.

   The design adequacy of the spring hangers with respect to the increased dead load due to the weight of the water during the liquid discharge transient has been addressed. As was discussed with respect to snubbers and rigid supports, the dynamic loads resulting from liquid discharge during the alternate shutdown cooling mode of operation are significantly lower than those from the high pressure steam discharge. The spring hangers have been reviewed for the deflections resulting from the steam discharge dynamic event and were found to be acceptable. In addition, the spring hangers have been evaluated for the increased dead load due to a water-filled condition. Both the spring hangers and piping stresses were acceptable. Furthermore, the effects of the water dead weight load does not affect the ability of SRVs to open to establish the alternate shutdown cooling path because the loads occur in the SRV discharge line only after valve opening.

c. The purpose of the SRV test program was to demonstrate that the SRV will open and reclose under all expected flow conditions. The expected valve operating conditions were determined through the use of analyses of accidents and anticipated operational occurrences referenced in Regulatory Guide 1.70 (Rev 2). Single failures were applied

to these analyses so that the dynamic forces on the SRVs would be maximized. Test pressures were the highest predicted by conventional safety analysis procedures. The BWROG, in their enclosure to the September 17, 1980 letter from D.B. Waters (BWROG) to R.H. Vollmer (NRC), identified 13 events that may result in liquid or two-phase SRV inlet flow that would maximize the dynamic forces on the SRV. These events were identified by evaluating the initial events described in Regulatory Guide 1.70 (Rev 2), with and without the additional conservatism of a single active component failure or operator error postulated in the event sequence. It was concluded from this evaluation that the alternate shutdown cooling mode is the only expected event that will result in liquid at the valve inlet. Consequently, this was the event simulated in the SRV test program. This conclusion and the test results applicable to LGS are discussed below.

The 13 events and the plant specific features that mitigate these events are summarized in Table 3.9-32. Of these 13 events, only nine are applicable to LGS because of its design and specific plant configuration. Four events (5, 6, 10 and 13) are not applicable to LGS for the reasons listed below:

1. Events 5 and 10 are not applicable because LGS does not have a high pressure core spray system.

2. Event 6 is not applicable because LGS does not have RCIC head sprays.

3. Event 13 is not applicable because large breaks will not be isolated at LGS.

For the nine remaining events, the LGS specific features, such as trip logic, power supplies, instrument line configuration, alarms and operator actions, have been compared to the base case analysis presented in the BWROG submittal of September 17, 1980. The comparison has demonstrated that, in each case, the base case analysis is applicable to LGS because the base case analysis does not include any plant features that are not already present in the LGS design. For these events, Table 3.9-32 demonstrates that the LGS specific features are included in the base case analysis presented in the BWROG submittal of September 17, 1980. It is seen from Table 3.9-32 that all plant features assumed in the event evaluation are also existing features in the LGS plant. All features included in this base case analysis are similar to plant features in the LGS design. Furthermore, the time available for operator action is expected to be longer in the LGS plant than in the base case analysis for each case where operator action is required due to the conservative nature of the base case analysis.

Event 7, the alternate shutdown cooling mode of operation, is the only expected event that will result in liquid or two-phase fluid at the SRV inlet. Consequently, this event was simulated in the BWR SRV test program. In LGS, the event involves flow of subcooled water (approximately 31°F subcooled) at a pressure of approximately 156 psig. The SRV inlet fluid conditions tested in the BWROG SRV test program, as documented in Reference 3.9-15, are 15°F to 50°F subcooled liquid at 20 psig to 250 psig. These fluid conditions envelope the conditions expected to occur at LGS in the alternate shutdown cooling mode of operation.

As discussed above, the BWROG evaluated transients including single active failures that would maximize the dynamic forces on the SRVs. As a result of this evaluation, the

alternate shutdown cooling mode is the only expected event involving liquid or two-phase flow. Consequently, this event was tested in the BWR SRV test program. The fluid conditions and flow conditions tested in the BWROG test program conservatively envelope the LGS plant specific fluid conditions expected for the alternate shutdown cooling mode of operation (Reference 3.9-22).

d. The flow coefficient, C_v, for the Target Rock SRV used in LGS was determined in the generic SRV test program (Reference 3.9-15). The average flow coefficient calculated from the test results for the Target Rock valve is reported in table 5.2-1 of Reference 3.9-15. This test value has been used by the licensee to confirm that the liquid discharge flow capacity of the LGS SRVs will be sufficient to remove core decay heat when injected into the RPV in the alternate shutdown cooling mode. The C_v of the valve determined in the SRV test demonstrates that the LGS SRVs are capable of returning sufficient flow to the suppression pool to accommodate injection by the RHR or core spray pump.

   If it were necessary to place the LGS plant in the alternate shutdown cooling mode, the operator would ensure that adequate core cooling was being provided by monitoring the following parameters: RHR or core spray flow rate, reactor vessel pressure, and reactor vessel temperature.

   The flow coefficient for the Target Rock valve reported in Reference 3.9-15 was determined from the SRV flow rate when the valve inlet was pressurized to approximately 250 psig. The valve flow rate was measured with the supply line flow venturi upstream of the steam chest. The C_v for the valve was calculated using the nominal measured pressure differential between the valve inlet (steam chest) and 3 feet downstream of the valve and the corresponding measured flow rate. Furthermore, the test conditions and test configuration were representative of LGS plant conditions for the alternate shutdown cooling mode, e.g., pressure upstream of the valve, fluid temperature, friction losses, and liquid flow rate. Therefore, the reported C_v values are appropriate for application to the LGS plant.

3.9.3.3.2 Design and Installation Details for Mounting of Pressure Relief Devices in ASME Class 1, 2, and 3 Systems (Non-NSSS)

The design of the pressure-relieving devices can be grouped into two categories: open discharge and closed discharge.

a. Open Discharge

   There are no open discharge pressure-relieving devices with limited runs of discharge piping mounted on ASME Code Class 1, 2, and 3 systems.

b. Closed Discharge

   A closed discharge system is characterized by piping between the valve and a tank, or some other terminal end. Under steady-state conditions, there are no net unbalanced forces. The initial transient response and resulting stresses are determined by using either a time history computer solution, or a conservative equivalent static solution. In

calculating initial transient forces, pressure and momentum terms are included. Water slug effects are also considered.

Time history dynamic analysis is performed for the discharge piping and its supports. The effect of the loading on the header is also considered. The design load combinations for a given transient are shown in Table 3.9-11, and the design criteria and stress limits are shown in Tables 3.9-12 and 3.9-16.

3.9.3.4 Component Supports Furnished with the NSSS

3.9.3.4.1 Piping

Hangers are designed in accordance with ANSI B31.7. In general, the load combinations for the various operating conditions correspond to those used to design the supported pipe. Design transient cyclic data are not applicable to hangers because no fatigue evaluation is necessary to meet the code requirements. All hangers are designed, fabricated, and assembled so that they cannot become disengaged by the movement of the supported pipe or equipment after they are installed. The design load on hangers is the load caused by dead weight. The hangers are calibrated to ensure that they support the design load at both their hot and cold load settings. Hangers provide a specified down travel and up travel in excess of the specified thermal movement. Visual inspection and acceptance of pipe supports are performed in accordance with NCIG-01 requirements (Reference 3.9-10).

For pipe supports, reactions produced by primary and secondary pipe loads are categorized as primary. The primary and secondary loads are summed and compared to the load rating to ensure that the rating is not exceeded. Because no distinction is made between primary and secondary loads, and load rated components are designed to primary limits or qualified by testing, the supports meet primary stress criteria for primary and secondary loads combined.

Required load capacity and snubber location for NSSS piping systems are determined by GE as a part of the NSSS piping system design and analysis scope. However, design, installation and inspection of snubbers are included in the non-NSSS scope (Section 3.9.3.5).

The entire piping system, including valves and the suspension system between anchor points, is mathematically modeled for complete structural analysis. In the mathematical model, the snubbers are modeled as springs with a given stiffness depending on the snubber size. The analysis determines the forces and moments acting on each component and the forces acting on the snubbers due to all dynamic loading conditions defined in the piping design specification. The design load on snubbers includes those loads caused by seismic forces (OBE and SSE), system anchor movements, and reaction forces caused by relief valve discharge, turbine stop valve closure, and other hydrodynamic forces (SRV, LOCA, annulus pressurization).

The assessment of all affected piping including their supports and structural modifications necessitated by reconciliation of the suppression pool hydrodynamic loads have been completed.

The snubber location and loading direction are decided by estimation so that the stresses in the piping system have acceptable values. The snubber locations and direction are refined by performing the computer analysis on the piping system as described above.

The spring constant required by the suspension design specification for a given load capacity snubber is compared against the spring constant used in the piping system model. If the spring

constants are not in agreement, they are brought into agreement, and the system analysis is redone to confirm the snubber loads.

If the stiffness of the backup structure for the snubber is not large compared to that of the snubbers, the reduced effective snubber stiffness (spring constant) is used in the analysis to account for backup structure flexibility.

Snubber design is discussed in Section 3.9.3.5.2.

3.9.3.4.2 NSSS Floor-Mounted Equipment (Pumps, Heat Exchangers, and RCIC and HPCI Turbines)

The ECCS pumps, RCIC and SLCS pumps, RHR heat exchanger, and RCIC and HPCI turbines are analyzed to verify the adequacy of their support structure under various plant operating conditions. In all cases, the stress loads in the critical support areas are within ASME Code allowables. The assessment of all affected equipment including their supports and structural modifications necessitated by reconciliation of the suppression pool hydrodynamic loads have been completed. The loading conditions, stress criteria, and allowable and calculated stresses in the critical support areas are summarized in Tables 3.9-6(k), 3.9-6(l), 3.9-6(m), 3.9-6(n), 3.9-6(o), 3.9-6(q), 3.9-6(r), and 3.9-6(t).

3.9.3.4.3 Supports for ASME Code Class 1, 2, and 3 Active Components

ASME Code Class 1, 2, and 3 active components are either pumps or valves. Because valves are supported by piping and are not tied to building structures, pipe design criteria govern.

Seismic Category I active pump supports are qualified for seismic and hydrodynamic loads by testing when the pump supports along with the pumps are fulfilling the following conditions:

a. Simulate actual mounting conditions

b. Simulate all static and dynamic loadings on the pump

c. Monitor pump operability during testing

d. Normal operation of the pump during and after the test indicates that the supports are adequate; any deflection or deformation of the pump supports that precludes the operability of the pump is not accepted.

e. Supports are inspected for structural integrity after the test; any cracking or permanent deformation is not accepted.

Seismic and hydrodynamic qualification of component supports by analysis is generally accomplished as follows:

a. Stresses at all support elements and parts such as pump holddown, baseplate holddown bolts, pump support pads, pump pedestal, and foundation are checked to be within the allowable limits as specified in ASME Subsection NF.

b. For normal and upset plant conditions, the deflections and deformations of the supports are assured to be within the elastic limits and not exceed the values permitted by the designer based on design verification tests to ensure the operability of the pumps.

c. For emergency and faulted plant conditions, the deformations must not exceed the values permitted by the designer to ensure operability of the pumps.

3.9.3.4.4 RPV Support Skirt

The permissible compressive load on the reactor vessel support skirt cylinder (modeled as plate and shell type component support) is limited by the design specification to 90% of the load which produces yield stress, divided by the safety factor for the condition being evaluated. The effects of fabrication and operational eccentricity are included. The safety factor for faulted conditions is 1.125.

An analysis of RPV support skirt buckling for faulted conditions shows that the support skirt has the capability to meet ASME Section III, paragraph F-1370(c), faulted condition limits of 0.67 times the critical buckling strength of the support at temperature. The faulted condition analyzed included the compressive loads due to the design basis maximum earthquake, the overturning moments and shears due to the jet reaction load resulting from a severed pipe, and the compressive effects on the support skirt due to the thermal and pressure expansion of the reactor vessel.

Subsequently, based on currently defined faulted condition loads, the maximum compressive stress in the support skirt including axial and bending loads in less than the faulted condition allowable of appendix F (paragraph F-1325) determined by the methods of ASME Section III, NB 3133.6. (Axial loads include weight, fuel interaction, seismic SSE, and the maximum of condensation oscillation, chugging and vent clearing due to a LOCA. Bending loads include seismic SSE and jet reaction, jet impingement, and annulus pressurization due to a LOCA.) The loading criteria, stress criteria, calculated and allowable stresses are summarized in Table 3.9-6(f).

3.9.3.4.5 Bolting Stress Limits (NSSS)

3.9.3.4.5.1 Component Support Bolting

The support bolting of the RWCU pump that is not essential to safety is designed for the effects of pipe load and SSE load to the requirements of ASME Section III, Appendix XVII. The stress limits of 0.41 S_y for tension and 0.15 S_y for shear are used.

For RCIC/SLCS pumps and RCIC turbine, the equipment-to-base plate bolting satisfies the following design criteria: For normal and upset conditions, 1.0S is used for primary membrane and 1.5S for primary membrane plus bending, where (S) is the allowable stress limit from ASME Section III, Appendix I, table I-7.3. For emergency and faulted conditions, stresses shall be less than 1.2 times the allowable limits for "normal and upset" given above.

There are no flange-type connections in pipe mounted component supports.

3.9.3.4.5.2 Piping Supports and Pipe-Mounted Equipment (Valves and Pump) Supports

The hanger type supports (including clamps) and their bolting are designed in accordance with the requirements of ANSI B31.7. The allowable stress limit for the bolting is equal to or less than the yield strength of the bolt material at temperature.

3.9.3.5 Component Supports Not Furnished with the NSSS

3.9.3.5.1 Design Basis

ASME Section III, Subsection NF, is used for the design and installation of the CRD piping supports and TIP piping supports. For the remainder of the non-NSSS portion of the LGS design and installation, Subsection NF is not used. The codes used instead are ANSI B31.7 for nuclear class piping and ANSI B31.1 for non-nuclear class piping. Visual inspection and acceptance of non-Subsection NF pipe supports are performed in accordance with NCIG-01 requirements (Reference 3.9-10). For a graphical definition of jurisdictional boundaries between pipe supports and supporting structures, refer to Figures 3.9-9 and 3.9-10.

The design loading combinations for supports for ASME Class 1, 2 and 3 components, categorized with respect to plant operating conditions identified as normal, upset, emergency, and faulted are given in Table 3.9-21. This table also provides the stress limits for each plant operating condition. The loads imposed on the ASME Class 1, 2 and 3 active valves and pumps are limited to values below the code allowable loads to ensure operability of the active components by the design of the supports. The supports are designed to remain elastic under the maximum loads. The minor local deformations associated with the elastic deformation of the support will not impair operability of the active components.

3.9.3.5.2 Snubbers

Snubbers are used in seismic Category I systems. The load ratings of the snubbers are appropriate for the design conditions and load combinations.

3.9.3.5.2.1 Analytical Methods

The methodology used for the stress analysis of seismic Category I, 2½ inches and larger piping systems is as follows:

a. For systems designed to seismic and hydrodynamic loads, the flexibility of the pipe supports are considered in the piping stress analysis. A stiffness tolerance criteria is used to facilitate support design and installation.

b. For systems designed to seismic loads, only the supports are considered as rigid members in the piping stress analysis model and are designed such that their fundamental frequencies in the direction of the applied load is within the rigid range of the seismic response spectra.

3.9.3.5.2.2 Snubber Design Specification

Snubbers for LGS are used to arrest shock due to seismic and other dynamic transient events. Under such applications, the snubbers will be subjected to a limited number of load cycles. Snubbers are not designed for vibration control. Therefore, no fatigue evaluation has been performed.

The purchase specification of new shock suppressors (snubbers) covers the following criteria for supplier's performance qualification tests and load tests. End clearance and lost motion are not considered in the piping stress analysis. Instead, linear average snubber stiffness is used in combination with that of the snubber support structure.

Mechanical Snubbers

a. The friction resistance of the suppressor to normal pipe movement shall be a maximum of 1% of the service level A rated load of the unit or 5 lb, whichever is greater.

b. The suppressor shall limit the acceleration of the pipe to a maximum of 0.02 g when subjected to any load up to the normal rated load.

   Based on experience from other plants, the activation threshold has been shown to be above the thermal growth rate of the piping systems.

c. The total lost movement at the suppressor shall not exceed ±0.040 inches due to any applied dynamic cycle load from 3-33 cps up to the rated load at the unit.

d. The suppressor shall be designed for an exposure to a temperature of room temperature (65° to 70°F) prior to initial startup and 200°F during continuous operations and to a radiation dose of $6.4x10^7$ rads during the life of the plant. Functioning of the shock suppressor under 340°F temperature for a short duration under rated load shall be demonstrated.

Hydraulic Snubbers

a. The friction resistance of the snubbers rated at 20 kips or greater shall have a friction resistance to normal movement of less than or equal to one percent of the service level A rated load. Snubbers rated at less than 20 kips shall have a friction resistance to normal movement of less than or equal to two percent of the rated load.

b. Activation of the snubber shall be defined as the velocity at which the snubber begins to support load, and restricts movement to the maximum bleed rate of the snubber. The activation velocity may be referred to as the lock-up velocity or activation velocity interchangeably. These requirements shall be satisfied under both tension and compression. The activation velocity of new snubbers at room temperature (65 to 75°F) shall be greater than or equal to 4.72 IPM and less than or equal to 14.17 IPM for all sizes.

c. The bleed rate shall be defined as that velocity at which the snubber will move under constant rated loads after the activation velocity has been reached and the control valves have closed. These requirements shall be satisfied under both tension and compression. The bleed velocity for the new snubbers at room temperature (65 to 75°F) shall be greater than or equal to 0.47 IPM and less than or equal to 4.72 IPM for all sizes.

d. The snubber shall be designed to withstand the normal environmental conditions inside the drywell of -0.5 to 2.0 psig, 160°F (based on Drywell Air Cooling System Design Bases described in Section 9.4.5.2), 40 to 90% relative humidity, and a radiation dose of 6.4×10^7 rads during the life of the plant. This bounding radiaton dose may be reduced by component or model specific evaluations of normal and design basis accident radiation environments.

3.9.3.5.2.3 Snubber Performance Test

A production test is required to be performed on each unit.

a. Check unit to confirm that it operates freely over the total stroke.

b. Measure and record the force required to initiate motion over the stroke in tension and compression.

c. On units which allow movement after the initial suppression of load, determine that the maximum allowable acceleration (mechanical snubbers) or velocity (hydraulic snubbers) is not exceeded. This requirement must be met in both tension and compression at room temperature.

d. Measure and record lost motion of the snubber mechanism (mechanical snubbers only).

Qualification tests are to be performed on randomly selected production models. These tests are used to demonstrate the required load performance (load rating) and specified displacement when subjected to dynamic load cycling. Also included in these tests are low temperature, high temperature, humidity, radiation and faulted load conditions.

Preinstallation, installation and postinstallation inspections of snubbers are performed before a preoperational test. Additional inspections are required if more than 6 months have elapsed between the last inspection and initial system power operation (Section 3.9.3.5.2.4).

Steady state vibration conditions will be identified during the preoperational test program. Snubbers have not been used to control steady state vibration. If the snubbers are used to correct such conditions, they will be evaluated for acceptability under those conditions.

In addition, the snubber inservice inspection program ensures that any potential malfunction due to fatigue-type failure will be detected.

3.9.3.5.2.4 Snubber Preservice Examination

Preservice examination of snubbers should be performed after installation, but not more than six months prior to initial system preoperational testing.

The mechanical snubber examination is described as follows. The objective is to verify adequate preservice examination to mechanical snubbers on all safety-related systems. The prerequisites of all preinstallation, installation, and postinstallation inspections have been performed on mechanical snubbers by designated inspection organizations. Verify through document review that all inspection activities have been completed, verified, and signed. Reviews will be made by systems and additional visual inspections will be made if original inspections are performed more than 6 months prior to initial power operation of the system.

The preservice examination should as a minimum verify the following:

a. There are no visible signs of damage or impaired operability as a result of storage, handling or installation.

b. The snubber location, orientation, position setting, and configuration (attachments, extensions, etc.) are according to design drawings and specifications.

c. Snubbers are not seized, frozen, or jammed.

d. Adequate swing clearance is provided to allow snubber movement.

e. Structural connections such as pins, fasteners, and other connecting hardware such as lock nuts, tabs, wire, and cotter pins are installed correctly.

If the period between the initial preservice examination and initial power operation exceeds 6 months, re-examination of items a. and d. shall be performed. Snubbers which are installed incorrectly or otherwise fail to meet the above requirements must be repaired or replaced and re-examined in accordance with the above criteria.

3.9.3.5.3 Struts

The design load on struts includes those loads caused by dead weight, thermal expansion, primary dynamic forces, (i.e., OBE and SSE), system anchor displacements, and reaction forces caused by relief valve discharge, turbine stop valve closure, etc.

For pipe supports, reactions produced by primary and secondary pipe loads are categorized as primary. The primary and secondary loads are summed and compared to the load rating to ensure that the rating is not exceeded. Because no distinction is made between primary and secondary loads, and load rated components are designed to primary limits or qualified by testing, the supports meet primary stress criteria for primary and secondary loads combined.

3.9.3.5.4 Bolting Stress Limits (Non-NSSS)

The bolting used in pipe support components is designed to an allowable stress equal to or less than the yield strength of the bolt material at temperature.

For flanged connections, the bolt allowables used in the piping are ASME Section III, 1979 Summer Addenda, Sections NB, NC and ND for Class 1, 2, and 3, respectively.

3.9.4 CONTROL ROD DRIVE SYSTEM

The discussion in this Section includes the CRDM, the HCU, the condensate supply system, and the scram discharge volume, and extends to the coupling interface with the control rods.

3.9.4.1 Descriptive Information on CRD System

Descriptive information on the CRD system is contained in Section 4.6.

3.9.4.2 Applicable CRD System Design Specifications

The CRD system is designed to meet the functional design criteria as outlined in Section 4.6, and consists of the following:

a. Locking piston CRD

b. HCU

c. Hydraulic power supply (pumps)

d. Interconnecting piping

e. Flow and pressure and isolation valves

f. Instrumentation and electrical controls

Those components of the CRD forming part of the primary pressure boundary are designed according to ASME Section III.

The quality group classification of the CRD hydraulic system is outlined in Table 3.2-1; and the components are designed according to the codes and standards governing the individual quality groups.

Pertinent aspects of the design and qualification of the CRD components are discussed in the following locations: transients in Section 3.9.1.1, faulted conditions in Section 3.9.1.4, and dynamic testing in Section 3.9.2.2a.

3.9.4.3 Design Loads, Stress Limits, and Allowable Deformation

The ASME Code components of the CRD system are evaluated analytically, and the design loading conditions, stress criteria, calculated stresses, and allowable stresses are summarized in Tables 3.9-6(u) and 3.9-6(v). For the noncode components, experimental testing is used to determine the CRD performance under all possible conditions, as described in Section 3.9.4.4.

Deformation is not a limiting factor in the analysis of the CRD components based on the results of the numerous tests performed on the drive.

3.9.4.3.1 CRD Housing Supports

The CRD housing support system functions are described in Section 4.6.1.3.

The AISC Manual of Steel Construction, "Specification for the Design, Fabrication, and Erection of Structural Steel for Buildings," was used in designing the CRD housing support system. However, to provide a structure that absorbs as much energy as practical without yielding, the allowable tension and bending stresses used were 90% of yield and the shear stress used was 60% of yield. The design stresses are 1.5 times the AISC allowable stresses (60% and 40% of yield, respectively).

The CRD housing supports are designed as seismic Category I equipment. Loading conditions and examples of stress analysis results and limits are given in Table 3.9-6(z).

3.9.4.4 CRD Performance Assurance Program

The CRD test program consists of the following tests:

a. Development tests

b. Factory quality control tests

c. 5 year maintenance life tests

d. 1.5x design life tests

e. Operational tests

f. Acceptance tests

g. Surveillance tests

All of the above tests except c. and d. are discussed in Section 4.6.3. Tests c. and d. are discussed below:

Test c. - 5 Year Maintenance Life Tests

Four CRDs are normally picked at random from the production stock each year, and subjected to various tests under simulated reactor conditions and 1/6 of the cycles specified in Section 3.9.1.1.

Upon completion of the test program, CRDs must meet, or surpass, the minimum specified requirements.

Test d. - 1.5x Design Life Tests

When a significant design change is made to the components of the drive, the drive is subjected to a series of tests equivalent to 1.5 times the life test cycles specified in Section 3.9.1.1.

Two CRDs underwent such testing in 1976. Upon completion of the test program, these CRDs met or surpassed the minimum specified requirements.

3.9.5 REACTOR PRESSURE VESSEL INTERNALS

This section identifies and discusses the structural and functional integrity of the major RPV internals.

3.9.5.1 Design Arrangements

The core support structures and RPV internals (exclusive of fuel, control rods, CRDs, and incore nuclear instrumentation) are identified below:

Core Support Structures

Shroud

Shroud support

Core support plate and holddown bolts

Top guide (including bolts and keepers)

CRD housing

Fuel supports

Control rod guide tubes

Reactor Internals

*Jet pump assemblies and instrumentation

*Feedwater spargers

Vessel head spray nozzle (Removed-Unit 1. Never installed-Unit 2)

Differential pressure and liquid control lines

Incore flux monitor guide tubes

*Initial startup neutron sources

*Surveillance sample holders

Core spray lines and spargers

*Incore instrument housings

LPCI coupling

*Steam dryer

*Shroud head and steam separator assembly

*Guide rods

CRD thermal sleeves

* = Nonsafety class component

A general assembly drawing of the important reactor components is shown in Figure 3.9-4.

The floodable inner volume of the RPV can be seen in Figure 3.9-5. This is the volume inside the core shroud up to the level of the jet pump suction inlet.

The design arrangement of the reactor internals, such as the jet pumps, steam separators and guide tubes, is such that one end is unrestricted, and thus free to expand.

The LPCI couplings incorporate sleeves to allow free thermal expansion.

3.9.5.1.1 Core Support Structures

The core support structures consist of those items listed in Section 3.9.5.1. These structures form partitions within the reactor vessel, to sustain pressure differentials across the partitions, to direct the flow of the coolant water, and to laterally locate and support the fuel assemblies. Figure 3.9-5 shows the reactor vessel internal flow paths.

3.9.5.1.1.1 Shroud

The shroud support and shroud make up a stainless steel cylindrical assembly that provides a partition to separate the upward flow of coolant through the core, from the downward recirculation flow. This partition separates the core region from the downcomer annulus, thus providing a floodable region following a recirculation line break. The volume enclosed by this assembly is characterized by three regions. The upper portion surrounds the core discharge plenum, which is bounded by the shroud head on top and the top guide's grid plate below. The central portion of the shroud surrounds the active fuel, and forms the longest section of the assembly. This section is bounded at the top by the grid plate and at the bottom by the core plate. The lower portion, surrounding part of the lower plenum, is welded to the RPV shroud support.

3.9.5.1.1.2 Shroud Support

The shroud support is designed to support the shroud, and to support and locate the jet pumps. The shroud support provides an annular baffle between the RPV and the shroud. The jet pump discharge diffusers penetrate the shroud support to introduce the coolant to the inlet plenum below the core.

3.9.5.1.1.3 Shroud Head and Steam Separator Assembly

This component is not a core support structure. It is discussed here to describe coolant flow paths in the RPV. The shroud head and steam separator assembly is bolted to the top of the shroud, forming the top of the core discharge plenum. This plenum provides a mixing chamber for the steam-water mixture before it enters the steam separators. Individual stainless steel axial flow steam separators are attached to the top of standpipes that are welded into the shroud head. The steam separators have no moving parts. In each separator, the steam-water mixture rising through the standpipe passes vanes that impart a spin that establishes a vortex, separating the water from the steam. The separated water flows from the lower portion of the steam separator into the downcomer annulus.

3.9.5.1.1.4 Core Support Plate

The core support plate is a circular stainless steel plate with bored holes, which is stiffened with a rim and beam structure. The plate provides lateral support and guidance for the control rod guide tubes, incore flux monitor guide tubes, peripheral fuel supports, and startup neutron sources. The last two items are supported vertically by the core support plate.

The entire assembly is bolted to a support ledge on the lower portions of the shroud.

3.9.5.1.1.5 Top Guide

The top guide is formed by a series of stainless steel beams joined at right angles to form square openings, and fastened to a peripheral rim. Each opening provides lateral support and guidance

for 4 fuel assemblies, or in the case of peripheral fuel, for less than 4 fuel assemblies. Sockets are provided in the bottom of the beam intersections to anchor the incore flux monitors and startup neutron sources. The rim of the top guide rests on a ledge between the upper and central portions of the shroud. The top guide has alignment pins that engage and bear against slots in the shroud which are used to correctly position the assembly before it is secured. Lateral restraint is provided by wedge blocks between the top guide and the shroud wall.

3.9.5.1.1.6 Fuel Supports

The fuel supports, shown in Figure 3.9-6 are of two basic types; peripheral supports, and four-lobed orificed fuel supports. The peripheral fuel support is located at the outer edge of the active core, and is not adjacent to control rods. Each peripheral fuel support holds one fuel assembly, and contains a single orifice assembly designed to ensure proper coolant flow to the peripheral fuel assembly. Each four-lobed orificed fuel support holds four fuel assemblies, and is provided with four orifice plates to ensure proper coolant flow distribution to each rod-controlled fuel assembly. The four-lobed orificed fuel supports rest in the top of the control rod guide tubes, which are supported laterally by the core plate. The control rods pass through slots in the center of the four-lobed orificed fuel support. A control rod and the four adjacent fuel assemblies represent a core cell (Section 4.1.2).

3.9.5.1.1.7 Control Rod Guide Tubes

The control rod guide tubes, located inside the vessel, extend from the top of the CRD housings, and up through holes in the core plate. Each tube is designed as the guide for a control rod, and as the vertical support for a four-lobed orificed fuel support piece and the four fuel assemblies surrounding the control rod. The bottom of the guide tube is supported by the CRD housing, which in turn transmits the weight of the guide tube, fuel support, and fuel assemblies to the reactor vessel bottom head. A thermal sleeve is inserted into the CRD housing from below, and is rotated to lock the control rod guide tube in place. A key is inserted into a locking slot in the bottom of the CRD housing to hold the thermal sleeve in position.

3.9.5.1.1.8 Jet Pump Assemblies

The jet pump assemblies are not core support structures, but are discussed here to describe coolant flow paths in the vessel. The jet pump assemblies are located in two semicircular groups in the downcomer annulus, between the core shroud and the reactor vessel wall. The design and performance of the jet pumps are covered in detail in References 3.9-19 and 3.9-20. Each stainless steel jet pump consists of driving nozzles, a suction inlet, a throat or mixing section, and a diffuser (Figure 3.9-7). The driving nozzle, suction inlet, and throat are joined together as a removable unit, and the diffuser is permanently installed. High pressure water from the recirculation pumps is supplied to each pair of jet pumps through a riser pipe welded to the recirculation inlet nozzle thermal sleeve. A riser brace consists of cantilever beams welded to a riser pipe and to pads on the reactor vessel wall.

The nozzle entry section is connected to the riser by a metal-to-metal, spherical-to-conical seal joint. Firm contact is maintained by a holddown clamp. The throat section is supported laterally by a bracket attached to the riser. There is a slip-fit joint between the throat and diffuser. Some jet pumps have been equipped with a clamp on this slip-fit joint to dampen vibration forces. Some jet pumps have been equipped with an anti-vibration solution between the restrainer bracket and inlet mixer to dampen vibration forces. The diffuser is a gradual conical section, changing to a straight cylindrical section at the lower end.

The licensee will reduce the preload on the beams from 30 kips to 25 kips in accordance with GE recommendations. This increases the expected life of the beams to 19-40 years. Inservice inspection of the jet pump holddown beam will be performed to detect cracking. Inspection frequencies will be based on a lead-plant experience and GE testing, and will be such that any crack initiation will be detected prior to beam failure.

3.9.5.1.1.9 Steam Dryers

The steam dryer assembly is not a core support structure. It is discussed here to describe coolant flow paths in the vessel. The steam dryers remove moisture from the wet steam leaving the steam separators. The extracted moisture flows down the dryer vanes to the collecting troughs, then flows through tubes and into the downcomer annulus. A skirt extends from the bottom of the dryer vane housing to the steam separator standpipe, below the water level. This skirt forms a seal between the wet steam plenum and the dry steam flowing from the top of the dryers to the steam outlet nozzles.

The steam dryer and shroud head are positioned in the vessel during installation with the aid of vertical guide rods. The dryer assembly rests on steam dryer support brackets attached to the reactor vessel wall. Upward movement of the dryer assembly, which may occur under accident conditions, is restricted by steam dryer holddown brackets attached to the reactor vessel top head.

3.9.5.1.1.10 Feedwater Spargers

The feedwater nozzle and sparger design follows the resolution presented in Reference 3.9-6. These components are not core support structures. They are discussed here to describe flow paths in the vessel. The feedwater spargers are stainless steel headers located in the mixing plenum above the downcomer annulus. A separate sparger is fitted to each feedwater nozzle, and is shaped to conform to the curvature of the vessel wall. Sparger end brackets are pinned to vessel brackets to support the spargers. Feedwater flow enters the center of the spargers, and is discharged radially inward, mixing the cooler feedwater with the downcomer flow from the steam separators and steam dryer, before it contacts the vessel wall.

The feedwater also serves to condense the steam in the region above the downcomer annulus, and to subcool the water flowing to the jet pumps and recirculation pumps.

3.9.5.1.1.11 Core Spray Lines

This component is not a core support structure. It is discussed here because the core spray lines are the means for directing flow to the core spray nozzles, which distribute coolant during accident conditions.

Two core spray lines enter the reactor vessel through the two core spray nozzles. The lines divide immediately inside the reactor vessel. The two halves are routed to opposite sides of the reactor vessel, and are supported by clamps attached to the vessel wall. The lines are then routed downward into the downcomer annulus, passing through the upper shroud immediately below the flange. The flow divides again as it enters the center of the semicircular sparger, which is routed halfway around the inside of the upper shroud. The two spargers are supported by brackets designed to accommodate thermal expansion. The line routing and supports are designed to accommodate differential movement between the shroud and vessel. The other core spray line is identical, except that it enters the opposite side of the vessel, and the spargers are at a slightly

different elevation inside the shroud. The correct spray distribution pattern is provided by a combination of distribution nozzles pointed radially inward and downward from the spargers (Section 6.3).

3.9.5.1.1.12 Head Cooling Spray Nozzle (Removed)

This component is not a core support structure.

The head cooling spray nozzle (component B11-D072) was mounted on a short length of pipe and a flange, which was bolted to a mating flange (RPV Nozzle N6A) on the reactor vessel head. The piping supplying coolant to the nozzle has been disconnected, partially removed and the remainder abandoned in place in Unit 1 and was never installed in Unit 2. The head cooling spray nozzle in Unit 1 was removed with the discontinued piping and never installed in Unit 2. RPV Nozzle N6A is empty and blind flanged in both units.

3.9.5.1.1.13 Differential Pressure Line

This component is not a core support structure. It is discussed here to describe the coolant flow paths in the reactor vessel. The differential pressure line senses the differential pressure across the core support plate (Section 7.7). This line enters the reactor vessel at a point below the core shroud, as two concentric pipes. In the lower plenum, the two pipes separate. The inner pipe terminates inside the lower shroud support, with a capped, perforated length below the core support plate. This section of pipe was formerly utilized as the liquid control sprager but now is only used to sense the pressure below the core support plate. The outer pipe terminates open-ended immediately above the core support plate, and senses the differential pressure across the core support plate and the fuel support assemblies.

3.9.5.1.1.14 Incore Flux Monitor Guide Tubes

This component is not a core support structure, but is discussed here to describe the coolant flow paths in the reactor vessel. Incore flux monitor guide tubes provide a means of positioning fixed detectors in the core, as well as providing a path for calibration monitors (TIP system).

The incore flux monitor guide tubes extend from the top of the incore flux monitor housing (Section 5.3) in the lower plenum, to the top of the core support plate. The power range detectors for the PRNM System units, and the dry tubes for the SRM and IRM detectors are inserted through the guide tubes. A latticework of clamps, tie bars, and spacers give lateral support and rigidity to the guide tubes. The bolts and clamps are welded, after assembly, to prevent loosening during reactor operation.

3.9.5.1.1.15 Surveillance Sample Holders

This component is not a core support structure. It is discussed here to describe the coolant flow paths in the reactor vessel. The surveillance sample holders are welded baskets containing impact and tensile specimen capsules (Section 5.3). The baskets hang from the brackets that are attached to the inside wall of the reactor vessel, and extend to mid-height of the active core. The radial positions are chosen to expose the specimens to the same environment and maximum neutron fluxes experienced by the reactor vessel itself, while avoiding jet pump removal interference or damage.

3.9.5.1.1.16 Low Pressure Coolant Injection Lines

This component is not a core support structure, but is discussed here to describe the coolant flow paths in the reactor vessel. Four LPCI lines penetrate the core shroud through separate LPCI nozzles. Coolant is discharged inside the core shroud.

3.9.5.1.1.17 Startup Neutron Sources

The startup neutron sources are held in place by spring pressure between the top of the core support and the bottom of the top guide. For Unit 1, each source consists of two irradiated antimony rods within a single beryllium cylinder. Both the antimony and the beryllium are encased in stainless steel tubes. For Unit 2, californium is used; it is also encased in stainless steel tubes. The design provides for a sufficient source of neutrons present in the core to ensure that the core neutron flux is continuously detectable by installed neutron monitors and to ensure that significant changes in core reactivity are readily detectable by installed neutron flux instrumentation.

3.9.5.2 Design Loading Conditions

3.9.5.2.1 Events to be Evaluated

Examination of the spectrum of conditions that the safety design basis must satisfy by core support structure and ESF components reveals four significant faulted events:

a. Recirculation line break: a break in a recirculation line between the reactor vessel and the recirculation pump suction

b. Steam line break accident: a break in one main steam line between the reactor vessel and the flow restrictor. This accident results in significant pressure differentials across some of the structures within the reactor.

c. Earthquake: subjects the core support structures and reactor internals to significant forces as a result of ground motion.

d. SSE/relief valve discharge: SRV discharge in combination with SSE.

Analysis of other conditions existing during normal operation, abnormal operational transients, and accidents shows that the loads affecting the core support structures and other ESF reactor internals are less severe than these three postulated events. The faulted conditions for the RPV internals are discussed in Section 3.9.1.4. Loading combination and analysis for the RPV internals are discussed in Section 3.9.3.1, and Tables 3.9-2 and 3.9-6. These results are based on the power rerate analysis and do not reflect the use of GE13 or GE14 fuel; the impact of GE13 fuel is documented in Reference 3.9-28. The impact of GE14 fuel is documented to be bounded by GE13 fuel in Reference 3.9-34. The impact of the MUR power uprate is evaluated in Reference 3.9-31 and Reference 3.9-32. Reference 3.9-33 identifies new design basis values for Fuel Lift Margin and Control Rod Guide Tube Lift Forces under MUR conditions. Additional analyses which consider the use of GNF2 fuel are documented in Reference 3.9-35. The GNF2 fuel is demonstrated to be bounded by the analyses in Reference 3.9-33.

Analyses were performed which considered the use of GNF3 fuel. Reference 3.9-39 identified new design basis values for the reactor internal pressure differences for unbounded reactor internals. The GNF3 analyses also identified a new design basis value for maximum Control Rod Guide Tube Lift force.

3.9.5.2.2 Pressure Differential During Rapid Depressurization

A digital computer code is used to analyze the transient conditions within the reactor vessel following the recirculation line break accident and the steam line break accident. The analytical model of the vessel consists of nine nodes, connected to the necessary adjoining nodes by flow paths having the required resistance and inertial characteristics. The program solves the energy and mass conservation equations for each node, giving the depressurization rates and pressure in the various regions of the reactor. Figure 3.9-8 shows the nine reactor nodes. The computer code used is the GE Short-Term Thermal-Hydraulic Model, described in Reference 3.9-21. This model is approved for use in ECCS conformance evaluation under 10CFR50, Appendix K. In order to adequately describe the blowdown pressure effect on the individual assembly components, three features are included in the model that are not applicable to the ECCS analysis and are, therefore, not described in Reference 3.9-21. These additional features are discussed below:

a. The liquid level in the steam separator region, and in the annulus between the dryer skirt and the pressure vessel, is tracked to more accurately determine the flow and mixture quality in the steam dryer and in the steam line.

b. The flow path between the bypass region and the shroud head is more accurately modeled, since the fuel assembly pressure differential is influenced by flashing in the guide tubes and in the bypass region for a steam line break. In the ECCS analysis, the momentum equation is solved in this flow path; but its irreversible loss coefficient is conservatively set at an arbitrary low value.

c. The enthalpies in the guide tubes and the bypass region are calculated separately, since the fuel assembly ΔP is influenced by flashing in these regions. In the ECCS analysis, these regions are lumped.

3.9.5.2.3 Recirculation Line and Steam Line Break

3.9.5.2.3.1 Accident Definition

Both a recirculation line break (the largest liquid break) and an inside steam line break (the largest steam break) are considered in determining the design basis accident for the ESF reactor internals. The recirculation line break is the same as the design basis LOCA described in Section 6.3. A sudden, complete circumferential break is assumed to occur in one recirculation loop. The resulting pressure differentials on the reactor internals and core support structures are in all cases less than for the main steam line break.

The analysis of the steam line break assumes a sudden, complete circumferential break of one main steam line, between the reactor vessel and the main steam line restrictor. A steam line break upstream of the flow restrictors produces a larger blowdown area, and thus a faster depressurization rate, than a break downstream of the restrictors. A larger blowdown area results in greater pressure differentials across the reactor internal structures.

The steam line break accident produces significantly higher pressure differentials across the reactor internal structures than does the recirculation line break. This results from the higher reactor depressurization rate associated with the steam line break. Therefore, the steam line break is the DBA for internal pressure differentials.

3.9.5.2.3.2 Effects of Initial Reactor Power and Core Flow

The maximum internal pressure loads can be considered to be composed of two parts: steady-state and transient pressure differentials. For a given plant, the core flow and the core power are the two major factors which influence the reactor internal pressure differentials. The core flow essentially affects only the steady-state part. For a fixed power, the greater the core flow, the larger the steady-state pressure differentials. The core power affects both the steady-state and the transient parts. As the power is decreased, there is less voiding in the core, and consequently the steady-state core pressure differential is less. However, less voiding in the core also means that less steam is generated in the RPV, thus increasing the depressurization rate and the transient part of the maximum pressure load. As a result, the total loads on some components are higher at low power.

To ensure that the calculated pressure differences bound those which are expected if a steam line break should occur, an analysis is conducted at a low power, high recirculation flow condition, in addition to the standard safety analysis condition at high power-rated recirculation flow. The power chosen for analysis is the minimum value permitted by the recirculation system controls at rated recirculation drive flow (that is, the drive flow necessary to achieve rated core flow at rated power).

This condition maximizes those loads which are inversely proportional to power. It must be noted that this condition, while possible, is unlikely, because the reactor generally operates at or near full power; and because high core flow is neither required, nor desirable at such a reduced power condition.

3.9.5.2.4 Seismic and Hydrodynamic Loads

The seismic and hydrodynamic loads acting on the structures within the reactor vessel are based on a dynamic analysis, as described in Section 3.7. Seismic analysis is performed by coupling the lumped-mass model of the reactor vessel and internals (Section 3.7), with the building model to determine the acceleration, force, and moment time histories in the reactor vessel and internals. This is accomplished by using the modal superposition method. Acceleration response spectra are also produced for subsystem analysis of selected components.

3.9.5.3 Design Bases

3.9.5.3.1 Safety Design Bases

The reactor core support structures and internals meet the following safety design bases:

a. Core support structures are arranged to provide a floodable volume, in which the core can be adequately cooled in the event of a breach in the nuclear system process barrier, external to the reactor vessel.

b. Deformation is limited to ensure that the control rods and the core standby cooling systems can perform their safety functions.

c. Mechanical design of applicable structures ensures that safety design bases a. and b., above, are satisfied so that the safe shutdown of the plant and removal of decay heat are not impaired.

3.9.5.3.2 Power Generation Design Bases

The reactor core support structures and internals are designed to the following power generation design bases:

a. They provide the proper coolant distribution during all anticipated normal operating conditions up to full power operation of the core without fuel damage.

b. They are arranged to facilitate refueling operations.

c. They are designed to facilitate inspection.

3.9.5.3.3 Design Loading Categories

Loading combinations for the core support structures are shown in Table 3.9-26. The basis for determining faulted loads on the reactor internals is shown for seismic and hydrodynamic loads in Section 3.7, and for pipe rupture loads in Sections 3.9.5.2.3 and 3.9.5.3.4. Table 3.9-6(b) gives analytical methods and allowable and calculated stresses for typical core support structures and reactor internal components.

Stress intensity and other design limits are discussed in Section 3.9.5.3.5. The core support structures which are fabricated as part of the RPV assembly are discussed in Section 3.9.1.3.

LGS reactor internals were designed and procured prior to the issuance of ASME Section III, Subsection NG. However, an earlier draft of the ASME Code was used as a guide in the design of the reactor internals. These criteria are presented in this section and were used in lieu of Subsection NG. Subsequent to the issuance of Subsection NG, comparisons were made to ensure that the pre-NG design meets the equivalent level of safety as presented by Subsection NG.

The design requirements for equipment classified as "other internals," e.g., steam dryers and shroud heads, are specified by the designer with appropriate consideration of the intended service of the equipment and expected plant and environmental conditions under which it operates. Where possible, design requirements are based on applicable industry codes and standards. If these are not available, the designer relies on accepted industry or engineering practices.

3.9.5.3.3.1 Reactor Core Support and Internals Structural Margin Evaluations

The analyses of conditions found during inspections of reactor internal and core support structures use approved industry codes and standards as described in the LGS Inservice Inspection Program, references 5.2-10 and 5.2-11. These analyses are performed as described in the above referenced Sections except that limit load, linear elastic (LEFM), and elastic-plastic (EFPM) fracture mechanic methods may be used as discussed in Tables 3.9-23, 3.9-24, 3.9-28, and 3.9-30.

Neutron fluence is evaluated when the irradiation induced changes in the material fracture toughness properties are judged to be significant. These material properties include yield and ultimate tensile strengths, uniform elongation and upper-shelf Charpy energy. The trends in these properties as a function of fluence level are reviewed to determine a fluence value above which the use of LEFM or EPFM techniques would be necessary and to determine the appropriate flaw growth rate to be used in the structural margin analyses. The fluence calculations use the methodology discussed in Section 4.3.2.8.

a. The design loads for the LGS Unit 1 and Unit 2 core shroud horizontal welds H1 through H8 have been calculated and are documented in reference 3.9-29. The loads and their combinations are based on power rerate and new loads design adequacy evaluations as discussed in reference 3.9-23. The effects of additional loads from GE13 fuel design (reference 3.9-28), fuel lift loads, and increased core flow (3% noise) beyond power rerate and the new loads programs are included in the updated core shroud loads and analysis. The impact of GE14 fuel is documented to be bounded by GE13 fuel in Reference 3.9-34. Reference 3.9-33 identifies new design basis values for Fuel Lift Margin and Control Rod Guide Tube Lift Forces under MUR conditions. Additional analyses which consider the use of GNF2 fuel are documented in Reference 3.9-35. The GNF2 fuel is demonstrated to be bounded by the analyses in Reference 3.9-33. Analyses were performed which considered the use of GNF3 fuel. Reference 3.9-39 identified new design basis values for the reactor internal pressure differences for unbounded reactor internals. The GNF3 analyses also identified a new design basis value for maximum Control Rod Guide Tube Lift force.

b. Design loads for GNF3 fuel are documented in Reference 3.9-37 for LGS Unit 1 and 2 core shroud horizontal welds H1 through H7.

Reference 3.9-30 was prepared in response to Generic Letter (GL) 94-03, Intergranular Stress Corrosion Cracking of Core Shrouds in Boiling Water Reactors, which required a plant specific safety assessment supporting continued operation of core shrouds. The report provides accident loading information applicable to LGS Unit 1 and Unit 2, as well as the safety assessment for postulated through-wall flaws at core shroud horizontal welds H1 through H7. The analysis considers both normal plant operations and limiting abnormal operational occurrences. It provides information on the plant response i.e., control rod insertion and ECCS injection, to postulated Main Steam Line Break (MSLB) and Recirculation Line Break (RLB), including a coincident Safe Shutdown Earthquake (SSE). The overall conclusion concerning plant safety is that the core shroud is an extremely flaw tolerant core support structure such that the probability is a very small that flawed welds would result in shroud separation under any desgn basis operational event.

The design requirements for equipment classified as "other internals," e.g., steam dryers and shroud heads, are specified by the designer with appropriate consideration of the intended service of the equipment and expected plant and environmental conditions under which it operates. Where possible, design requirements are based on applicable industry codes and standards. If these are not available, the designer relies on accepted industry or engineering practices.

3.9.5.3.4 Response of Internals Due to Inside Steam Break Accident

The maximum pressure loads acting on the reactor internal components result from an inside steam line break; on some components the loads are maximum when operating at the minimum power associated with the maximum core flow. This is substantiated by the analytical comparison of liquid versus steam breaks, and by the investigation of the effects of core power and core flow.

It has also been pointed out that it is possible but not probable that the reactor is operating at the rather abnormal condition of minimum power and maximum core flow. More realistically, the reactor is at or near a full power condition, and thus the maximum pressure loads acting on the internal components would be less.

3.9.5.3.5 Stress, Deformation, and Fatigue Limits for ESF Reactor Internals (Except Core Support Structure)

Elastic displacement is considered in the design of reactor internal components in which deflection can affect control rod insertability. Plastic deformation will not occur in any permanent core support structure component of the reactor vessel. Radiation-induced deformation can occur in the fuel channel over the core life. These effects are considered in control rod insertability tests. No fatigue analysis is required under the faulted conditions due to the low encounter frequency of faulted events and the low number of cycles. The forcing functions applicable to the reactor internals are discussed in Section 3.9.2.5. The stress, deformation, and fatigue limits are given in Table 3.9-6(b).

3.9.5.3.6 Stress, Deformation, and Fatigue Limits for Core Support Structures

The stress, deformation, and fatigue limits are given in Table 3.9-6(f).

3.9.6 Inservice Testing Of Pumps And Valves

Inservice testing of pumps and valves is accomplished in accordance with the requirements of 10CFR50.55a, using the date of commercial operation for determining test intervals.

The Preservice Testing Program included provisions for design and access to enable the operational readiness testing of pumps and valves, and was required to comply, as a minimum, with the 1971 Edition of Section XI of the ASME B&PV Code, including the winter of 1972 Addenda (this being in effect 6 months prior to the LGS construction permit date of June 1974). That publication did not include requirements for preservice testing of pumps and valves to ensure operational readiness. The requirements for inservice testing of pumps and valves were added as Subsections IWV and IWP to the ASME B&PV Code, Section XI, Summer 1973 Addenda, effective December 30, 1973. The Preservice Testing Program for assessing operational readiness of pumps and valves was conducted, however, to the extent practical within design limitations, to comply with the 1980 Edition of ASME Section XI, with addenda through Winter 1981.

Inservice testing of pumps and valves to ensure operational readiness for the first 120-month interval was performed in accordance with the requirements of 10CFR50.55a and met, to the extent practical within design limitations, the requirements of the Code in effect 12 months prior to the date of commercial operation. The first 120-month interval for Unit 2 was required to comply with the 1986 Edition of ASME Section XI. As permitted by 10CFR50.55a, the Unit 1 IST Program was updated to comply with the 1986 Edition of ASME Section XI. Subsequently, NRC authorized a one-time extension of the first 120-month interval for Unit 1, resulting in both Units being on concurrent intervals.

During the second and successive 120-month intervals, inservice testing of pumps and valves to ensure operational readiness shall be performed in accordance with the requirements and limitations specified in 10CFR50.55a. Detailed information regarding current Code requirements, component selection, testing requirements, Code Class, and deviations from referenced Code requirements is provided in Reference 3.9-25.

There is a Risk Informed Categorization and Treatment Program at Limerick which is based on 10 CFR 50.69. This regulation provides an alternative approach for establishing requirements for treatment of SSCs using a risk-informed method of categorizing SSCs according to their

safety significance. Specifically, for SSCs categorized as low safety significant, alternate treatment requirements may be implemented rather than treatments chosen by the inservice testing of pumps and valves program. Refer to Section 13.5.5 for further information.

S. BECHTEL CRITERIA FOR BOP PIPING

1.	½ SSE Cycles (OBE)	Condition - Upset
	Expected number of equivalent ½ SSE in life of pipe system	5
	Average duration of strong motion vibration ½ SSE	15 sec
	Average number of maximum seismic load cycles of pipe system for each ½ SSE	10
	Total lifetime number of maximum seismic load cycles of piping system	50
2.	SSE Cycles (Design Basis Earthquake)	Condition - Faulted
	Expected number of equivalent SSE in life of pipe system	1
	Average duration of strong motion vibration SSE	15 sec

Table 3.9-1 (Cont'd)

T. GENERAL ELECTRIC CRITERIA FOR NSSS PIPING

1.	½ SSE Cycles (OBE)	Condition - Upset
	Expected number of equivalent ½ SSE in life of pipe system	1
	Average duration of strong motion vibration ½ SSE	30 sec
	Average number of maximum seismic load cycles of pipe system for each ½ SSE	10
	Total lifetime number of maximum seismic load cycles of piping system	10
2.	SSE Cycles (Design Basis Earthquake)	Condition - Faulted
	Expected number of equivalent SSE in life of pipe system	1
	Average duration of strong motion vibration SSE	30 sec
	Average number of maximum seismic load cycles of pipe system for each SSE	1
	Total lifetime number of maximum seismic load cycles of piping system	1
3.	Turbine Stop Valve(14) Closure	Condition - Upset 120 cycles
4.	Relief Valve Lift Cycles(14) (at 3 cycles per actuation)	Condition - Upset 34,200 cycles

Table 3.9-1 (Cont'd)

(1) After temperature is raised to 100°F, reactor pressure is increased to 1250 psig and then decreased to 0 psig.
(2) Reactor pressure increases from 0 to 1000 psig at rate of temperature increase.
(3) Reactor pressure remains at 1000 psig.
(4) Reactor pressure increases to 1125 psig all relief valves open. Pressure decreases to 240 psig and then increases to 1000 psig.
(5) Reactor pressure decreases to 240 psig and then increases to 1000 psig.
(6) Reactor pressure decreases from 1000 psig to 0 psig.
(7) 5 step changes to 100°F and back during cooldown.
(8) Reactor pressure increases to 1180 psig. All relief valves open. Pressure decreases to 1125 psig and relief valves close. RCIC initiates and pressure decreases to 875 psig. RCIC trips off on high level and pressure increases to 1125. One relief valve opens and then closes as pressure decreases at rate of 100°F/hr.
(9) Reactor pressure increases to 1350 psig. All relief valves and safety valves open. Pressure decreases to 240 psig.
(10) Reactor pressure decreases to 0 psig with one relief valve or safety valve open.
(11) Reactor pressure decreases with auto-blowdown relief valves open to 35 psig.
(12) Reactor pressure increases to 1000 psig as temperature increases.
(13) Reactor pressure decreases from 1000 psig to 35 psig in 15 seconds.
(14) Not applicable to recirculation piping due to negligible effect.
(15) Temperature rates are informational only and approximated.

Table 3.9-2

PLANT EVENTS

EVENT NO.		NO. OF CYCLES
	NORMAL, UPSET, AND TESTING CONDITIONS	
1.	Bolt-up[1]	123
2.	Design hydrostatic test	130
3.	Startup (100° F/hr heatup rate)[2]	120
4.	Daily reduction to 75% power[1]	10,000
5.	Weekly reduction to 50% power[1]	2,000
6.	Control rod pattern change[1]	400
7.	Loss of feedwater heaters	80
8.	OBE event at rated operating conditions	10/50[3]
9.	Scram:	
	a. Turbine-generator trip, feedwater on, isolation valves stay open	40
	b. Other scrams	140
10.	Reduction to 0% power, hot standby, shutdown (100 ° F/hr cooldown rate)[2]	111
11.	Unbolt	123
12.	Pre-op blowdown	10
13.	Loss of RWCU	240
14.	MSRV actuations	7700
15.	SLCS Operation	10

Table 3.9-2 (Cont'd)

EVENT NO.		NO. OF CYCLES
	EMERGENCY CONDITIONS	
16.	Scram:	
a.	Reactor overpressure with delayed scram, feedwater stays on, isolation valves stay open	1(4)
b.	Loss of feedwater pumps, isolation valves closed	5
c.	Automatic Blowdown	1(4)
d.	Single safety or relief valve blowdown	8
17.	Improper start of cold recirculation loop	1(4)
18.	Sudden start of pump in cold recirculation loop	1(4)
19.	Improper startup with reactor drain shut off	1(4)
	FAULTED CONDITION	
20.	SSE at rated operating conditions	1(4)
21.	Pipe rupture and blowdown	1(4)

(1) Applies to RPV only.
(2) Bulk average vessel coolant temperature change in any 1-hour period.
(3) An environmental fatigue calculation provides the basis for reduced OBE cycle limits for the following piping systems: RHR Return and Supply piping – 20 cycles; Recirculation Drain piping – 20 cycles; Core Spray piping – 40 cycles (Unit 1), 30 cycles (Unit 2); and Reactor Recirculation piping – 30 cycles. All other piping has a limit of 50 OBE cycles. These administrative transient cycle limits are imposed to meet License Renewal Commitment T04740.
(4) The annual encounter probability of the one cycle events is $<10^{-2}$ for emergency and $<10^{-4}$ for faulted events.

Table 3.9-6

LOADING COMBINATIONS, STRESS LIMITS, AND ALLOWABLE STRESSES

The following is a list of the tables that give the design loading combinations, allowable stresses, and calculated stresses for the major mechanical safety-related components in the plant and referenced in Section 3.9.

3.9-6(a)	Load Combinations and Acceptance Criteria for ASME Class 1, 2, and 3 NSSS Piping, Equipment, and Supports
3.9-6(b)	Reactor Internals and Associated Equipment
3.9-6(c)	RWCU Heat Exchangers
3.9-6(d)	Class 1 Main Steam Piping and Pipe-mounted Equipment
3.9-6(e)	Class 1 Recirculation Loop Piping and Pipe-mounted Equipment
3.9-6(f)	RPV and Shroud Support Assembly
3.9-6(g)	Main Steam Relief Valves
3.9-6(h)	Main Steam Isolation Valve
3.9-6(i)	Recirculation Pump
3.9-6(j)	Reactor Recirculation System Gate Valves
3.9-6(k)	HPCI Turbine
3.9-6(l)	SLCS Pump
3.9-6(m)	SLCS Tank
3.9-6(n)	ECCS Pumps
3.9-6(o)	RHR Heat Exchanger
3.9-6(p)	RWCU Pump
3.9-6(q)	RCIC Turbine
3.9-6(r)	RCIC Pump

Table 3.9-6 (Cont'd)

3.9-6(s)	Reactor Refueling and Servicing Equipment
3.9-6(t)	HPCI Pump
3.9-6(u)	Control Rod Drive
3.9-6(v)	CRD Housing
3.9-6(w)	Jet Pumps
3.9-6(x)	Fuel Assembly (Including Channel)
3.9-6(y)	LPCI Coupling
3.9-6(z)	RPV Support Equipment; CRD Housing Support
3.9-6(aa)	Control Rod Guide Tube
3.9-6(ab)	Incore Housing

Table 3.9-6(a)

LOAD COMBINATION AND ACCEPTANCE CRITERIA FOR
ASME CLASS 1, 2, AND 3 NSSS PIPING, EQUIPMENT, AND SUPPORTS

LOAD COMBINATION	DESIGN BASIS	EVALUATION BASIS	SERVICE LEVEL
N + $SRV_{(ALL)}$	Upset	Upset	(B)
N + OBE	Upset	Upset	(B)
N + OBE + $SRV_{(ALL)}$	Emergency	Upset	(B)
N + SSE + $SRV_{(ALL)}$	Faulted	Faulted	(D)(1)
N + SBA + SRV	Emergency	Emergency	(C)(1)
N + SBA + $SRV_{(ADS)}$	Emergency	Emergency	(C)(1)
N + SBA/IBA + OBE + $SRV_{(ADS)}$	Faulted	Faulted	(D)(1)
N + SBA/IBA + SSE + $SRV_{(ADS)}$	Faulted	Faulted	(D)(1)
N + LOCA(2) + SSE	Faulted	Faulted	(D)(1)

LOAD DEFINITION LEGEND

N	-	Normal loads (e.g., weight, pressure, temperature, etc)
OBE	-	Operational basis earthquake loads
SSE	-	Safe shutdown earthquake loads
SRV	-	Safety/relief valve discharge induced loads from two adjacent valves (one valve actuated when adjacent valve is cycling)
SRV_{ALL}	-	Loads induced by actuation of all 14 safety/relief valves that activate within milliseconds of each other (e.g., turbine trip operational transient)

Table 3.9-6(a) (Cont'd)

SRV_{ADS}	-	Loads induced by the actuation of all 5 safety/relief valves associated with automatic depressurization system that actuate within milliseconds of each other during the postulated small or intermediate size pipe rupture.
LOCA	-	Loss-of-coolant accident associated with the postulated pipe rupture of large pipes (e.g., main steam, feedwater, recirculation piping)
$LOCA_1$	-	Pool-swell drag/fallback loads on piping and components located between the main vent discharge outlet and the suppression pool water upper surface
$LOCA_2$	-	Pool-swell impact loads on piping and components located above the suppression pool water upper surface
$LOCA_3$	-	Oscillating pressure induced loads on structures and equipment during condensation oscillation
$LOCA_4$	-	Oscillating pressure induced loads on structures and equipment during chugging
$LOCA_5$	-	Building motion induced loads from main vent air clearing
$LOCA_6$	-	Vertical and horizontal loads on main vent piping
$LOCA_7$	-	Annulus pressurization loads
SBA	-	Abnormal transients associated with a small break accident
IBA	-	Abnormal transients associated with an intermediate break accident.

(1) All ASME Class 1, 2 and 3 piping that are required to function for safe shutdown under the postulated events are designed to meet the requirements described in NEDO-21985.

(2) The most limiting case of load combinations among $LOCA_1$ through $LOCA_7$.

Table 3.9-6(b)

REACTOR INTERNALS AND ASSOCIATED EQUIPMENT

ASME SECTION III, SUBSECTION NG PRIMARY STRESS LIMIT CRITERIA	LOAD CASE NUMBER[1]	PRIMARY STRESS TYPE	ALLOWABLE STRESS (psi)	MAXIMUM CALCULATED STRESS[3] (psi)
TOP GUIDE - HIGHEST STRESSED BEAM				
MATERIAL 304 S.S.				
A. NORMAL AND UPSET CONDITION:				
$P_m \leq S_m$	Normal and Upset Condition Loads:	Primary membrane	16,900	1,889
S_m = 16,900 @ 550 ^{o} F	1. Normal loads 2. Upset pressure 3. OBE 4. SRV			
$P_L + P_b \leq 1.5\ S_m$		Primary membrane plus bending	25,350	17,735
1.5 S_m = 25,350 @ 550 ^{o} F				
B. EMERGENCY CONDITION:				
$P_m \leq 1.5\ S_m$	Emergency Condition Loads:	Primary membrane	25,350	326
1.5 S_m = 25,350 @ 550 ^{o} F	1. Normal loads 2. Upset pressure 3. Chugging 4. SRV_1			
$P_L + P_b$ 2.25 S_m		Primary membrane plus bending	38,025	12,192
2.25 S_m = 38,025 @ 550 ^{o} F[2]

ASME SECTION III, SUBSECTION NG PRIMARY STRESS LIMIT CRITERIA	LOAD CASE NUMBER[1]	PRIMARY STRESS TYPE	MAXIMUM ALLOWABLE STRESS (psi)	CALCULATED STRESS[3] (psi)
DIFFERENTIAL PRESSURE AND LIQUID CONTROL LINES				
MATERIAL: 304 S.S.				
A. NORMAL AND UPSET CONDITION:				
$P_m \leq S_m$ S_m = 16,950 @ 550°F	Normal and Upset Condition Loads: 1. OBE 2. SRV			
$P_L + P_b \leq 3\ S_m$ $3\ S_m$ = 50,850 @ 550°F		Primary membrane plus bending plus secondary membrane	49,200	8,654
B. EMERGENCY CONDITION:				
$P_m \leq S_m$ S_m = 16,950 @ 550°F	Emergency Condition Loads: 1. OBE 2. SRV			
$P_L + P_b \leq 2.25\ S_m$ $2.25\ S_m$ = 37,120 @ 550°F[2]		Primary membrane plus bending	36,900	8,654
C. FAULTED CONDITION:				
$P_m \leq S_m$ S_m = 16,950 @ 550°F	Faulted Condition Loads: 1. Annulus pressurization 2. SSE			
$P_L + P_b \leq 3.6\ S_m$ $3.6\ S_m$ = 61,020 @ 550°F[2]		Primary membrane plus bending plus secondary membrane	59,040	15,106

(1) Load cases are defined in Table 3.9-6.
(2) Value of S_m or S_y is shown depending on the controlling criteria (e.g., 1.8 S_m or 1.5 S_y for B)
(3) The loads listed here are associated with the operating level of 3458 MWt. Per Reference 3.9-32, the loads on the differential pressure and liquid control lines are bounding at MUR power uprate condition; the loads on the top guide and core plate are increased but within the allowable limits. Increased loads due to the revised Fuel Lift Margin and CRGT lift forces under MUR conditions are addressed in Reference 3.9-33.

$P_L + P_b \leq 3.6\ S_m$		Primary membrane plus bending	72,000	30,260
$3.6\ S_m$ = 72,000 @ 575°F[2]				
D. MAXIMUM CUMULATIVE USAGE FACTOR: 0.192[5] at Stub tube				

(1) Load cases are defined in Table 3.9-6.
(2) Value of S_m or S_y is shown depending on the controlling criteria (e.g., 1.8 S_m or 1.5 S_y for B).
(3) Maximum calculated values are based on design loads because they are greater than new loads.
(4) The loads here correspond to the operating power level of 3458 MWt. Per Reference 3.9-31, the loads for the vessel support skirt, feedwater nozzle and the CRD penetration are not changed as a result of MUR power uprate. Per Reference 3.9-32, the loads on the shroud support are bounding at MUR power uprate condition.
(5) Numerical values can be found in Reference 3.9-38. Per Reference 3.9-38, these values are based off CLTP of 3515 MWt.

Table 3.9-6(g)

MAIN STEAM SAFETY/RELIEF VALVES (PILOT-OPERATED)
(ASME SECTION III, 1968, Including Addenda through Summer 1970)

Topic	Method of Analysis	Target Rock 9867F Analysis	Allowable Value	Calculated
1. Body inlet and outlet flange stresses Note, Topics 1 and 2: Design Pressures: P_d = 1250 psig (inlet) P_b = 500 psig (outlet) Analyses include applied moments of M = 409,000 in-lb (inlet) and M = 372,000 in-lb (outlet) Actual tested capability (including accelerations and moments) is as described in Topic No. 11. The analyses also include consideration of seismic, operational, and flow reaction forces. Allowable vs. tested capabilities are provided in Topic No. 12	$S_H = \frac{fM_o}{Lg^2B} + \frac{PB}{4g_o} < 1.5\ S_m$ $S_R = \frac{(4te/3+1)M_o}{Lt^2B} < 1.5\ S_m$ $S_T = \frac{YM_o}{t^2B} - Z\ S_R < 1.5\ S_m$ where: S_H = Longitudinal "hub" wall stress, psi S_R = Radial "flange" stress, psi S_T = Tangential "flange" stress, psi Body Material: A105 Grade II S_m = 19,400 psi (500°F, equivalent inlet and outlet temperature)	P_D (Target Rock) = P (codes)	1.5 S_m = 29,100 psi	Inlet: S_H = 27,656 psi S_R = 15,295 psi S_T = 14,257 psi Outlet: S_H = 15,591 psi S_R = 23,614 psi S_T = 557 psi

Table 3.9-6(g) (Cont'd)

Topic	Method of Analysis	Target Rock 9867F Analysis	Allowable Value	Calculated
2. Inlet and outlet stud area requirements	Total cross-sectional area excees the greater of: $Am_1 = \frac{Wm_1}{S_b}$, or $Am_2 = \frac{Wm_2}{S_a}$,	$Am_1 = \frac{Wm_1}{S_b}$ $Am_2 = \frac{Wm_2}{S_a}$ *	Inlet: Am_1 (>Am_2) = 8.15 in^2 Outlet: Am = 5.39 in^2	Inlet: A_b (actual area) = 13.85in^2 Outlet: A_b = 9.68 in^2
	where: Am_1 = total required bolt (stud) area for operating condition Am_2 = total required bolt (stud) area for gasket seating	Bolting Material: SA193 Grade B7 *Where AM (required minimum) is the greater of Am_1 and Am_2; and A_b (actual bolt area) must exceed Am.		
3. Body Wall thickness	1. Valve Wall Thickness Criterion:	Section at inlet:		t_{ACT} = 1.098 in.
	$t_{min.} < t_A$ where: $t_{min.}$ = minimum calculated thickness requirement, including corrosion allowance. t_A = Actual wall thickness (NOTE: This $t_{min.}$ is t_m per notation of the codes.)	$t_{RQD} < t_{ACT}$ Section at middle of body $t_{RQD} < t_{ACT}$ [c] Section at outlet: $t_{RQD} < t_{ACT}$ Section at neck: $t_{RQD} < t_{ACT}$	t_{RQD} = 0.7 in Actual thickness greater than t_m at the section under consideration.	t_{ACT} [c] = 0.805 in. t_{ACT} = 1.359 in. t_{ACT} = 0.953 in.

Table 3.9-6(g) (Cont'd)

Topic	Method of Analysis	Target Rock 9867F Analysis	Allowable Value	Calculated
3. (Cont'd)	Cycle Rating: Thermal $I_t = \Sigma \frac{N_{ri}}{N_i}$ Fatigue Na > 2,000 cycles, as based on S_a, where S_a is defined as the larger of $S_p = (2/3)Q_p + \frac{P_{eb}}{2}$ $_1$ $+ Q_T + 1.3Q_T$ $_2$ $_1$ or $S_P = 0.4\ Q_p + \frac{K(P_{eb}+2Q_T)}{2}$ $_2$ $_2$ where: Sp = Fatigue stress intensity at [1] inside surface of crotch psi Sp = Fatigue stress intensity [2] outside surface of crotch psi	$I_t = \Sigma \frac{N_{ri}}{N_i}$ (i = 1, 2 & 3) Na ≥ 2,000 cycles as based on $S_A = S_p$ ($>S_p$), where S_A (Target $_2$ $_3$ Rock) = S_a (codes) { Uses same notation as codes }	I_t (max.) ≤ 1.0 Na ≥ 2,000 cycles	I_t = 0.518 Na (based on S_p) $_2$ = 1.5×10^5 cycles ∴ satisfies criterion

MAIN STEAM ISOLATION VALVE

(UNIT 1)

CRITERIA	METHOD OF ANALYSIS	ALLOWABLE STRESS, (psi) MINIMUM THICKNESS (in), OR MINIMUM AREA (in^2)	CALCULATED STRESS, (psi) ACTUAL THICKNESS (in), OR MINIMUM AREA (in^2)
Design of Pressure-Retaining Parts	All references are made to ASME Code for Pumps and Valves for Nuclear Power, dated November 1968. Reference the same code for explanation of the symbols used.		
Body Minimum Wall Thickness	Reference Article 452.1b(2), Nonstandard Pressure - Rated Value. Table NB 451.4 For design condition of 1,250 psig and 575°F. The primary service rating = 655 based on a core diameter of 23 in		
	t_m = 1.925 in (including a corrosion allowance of 0.12 in).	1.925 in	1.9375 in
Body Shape Rules	Reference Article 452.2, Body Shape Rules		
Radius of Crotch	Reference Article 452.2a(1), Radius of Crotch. Criterion: $r_2 \geq 0.3\ t_m$; r_2 = 1.0 in, t_m = 1.925 (0.3 · 1.925) = 0.578 <1.0; criterion satisfied.	0.578 in	1.0 in
Out of Roundness	Reference Article 452.2e. Since no ovality was built into the valve body, the requirements of this article are satisfied.	Not applicable	Not applicable
Flat wall Limitation	Reference Article 452.2g, Flat Wall Limitation. Since no flat sections were built into the valve body design, the requirements of this article are satisfied.	Not applicable	Not applicable
Primary Crotch Stress Due to Internal Pressure	Reference Article 452.3 Criterion: $P_m = (A_f/A_m + 0.5)\ P_s < S_m$		
	where A_f = 504 in^2, A_m = 58 in^2, P_s = 1,375 psig, P_m = 12,650 psi, S_m = 19,400 psi; since $S_m > P_m$ criterion satisfied.	19,400 psi	12,650 psi
Valve Body Secondary Stress	Reference Article 452.4		
Primary Plus Secondary Stress Due to Internal Pressure	Reference Article 452.4a $Q_p = C_p\ (r_i/t_e + 0.5)\ P_s\ C_a$		
	where C_p = 3, r_i = 11.625 in, P_s = 1,375 psi, t_e = 2.75 for wye-type valve C_a = 1.33 ---> Q_p = 25,965 psi		

Table 3.9-6(h) (Cont'd)

(Unit 1)

CRITERIA	METHOD OF ANALYSIS	ALLOWABLE STRESS, (psi) MINIMUM THICKNESS (in), OR MINIMUM AREA (in^2)	CALCULATED STRESS, (psi) ACTUAL THICKNESS (in), OR MINIMUM AREA (in^2)
Secondary Stress Due to Pipe Reaction	Reference Article 452.4b, figures 452.4b(3), 452.4b(4), 452.4b(5)		
Direct or Axial Load Effect	$P_{ed} = F_d S/G_d$ where S = 30,750, F_d = 30 in^2, G_d = 183 in^2	19,400 psi	5,040 psi
	---> P_{ed} = 5,040 psi		
Bending Load Effect	$P_{eb} = C_b F_b S/G_b$ where S = 30,750, F_b = 340 in^3,		
	i.d. = 23.25 in, r_i = 11.625, t_e = 2.75, $\bar{Y}$ = 13.90 in as t_e/r = .197 > .19 ---> C_b = 1		
	$G_b = I/(r_i + t_e)$ where I = 15,028 in^4, r_i = 11.625 in,		
	t_e = 2.75 in ---> G_b = 1052 in^3		
	---> P_{eb} = 9,940 psi	19,940 psi	9,940 psi
Torsion Load Effect	Reference Article 452.4b		
	$P_{et} = 2 F_b S/G_t$ where F_b = 340 in^3, S = 30,750 psi		
	G_t = 2,162 in^3	19,400 psi	9,670 psi
	P_{et} = 9,670 psi		

Table 3.9-6(h) (Cont'd)

(Unit 1)

CRITERIA	METHOD OF ANALYSIS	ALLOWABLE STRESS, (psi) MINIMUM THICKNESS (in), OR MINIMUM AREA (in^2)	CALCULATED STRESS, (psi) ACTUAL THICKNESS (in), OR MINIMUM AREA (in^2)
Thermal Secondary Stress at Crotch Region	Reference Article 452.4C, figures 452.4C(4), 452.4C(3), 452.4C(5) $Q_T = Q_{T_1} + Q_{T_2}$ where $Te_1 = 3$ in, $Q_T = 1{,}100$ psi $Q_{T_2} = C_6C_2\Delta T_2$ where $C_2 = .21$, $C_6 = 220$, and $T_2 = 5.6$ $Q_{T_2} = 260$ psi, $Q_T = 1{,}360$ psi Criterion: $S_N = Q_{P_2} + P_e = 2Q_T \leq 3 S_m$ where $Q_p = 25{,}965$, $P_e = 9{,}940$, $Q_T = 1360$ as $38{,}625 \leq 58{,}200$; criterion satisfied	58,200 psi	38,625 psi
Normal Duty Valve Fatigue Requirements	Reference Article 452.5, figure 452.5(a) Criterion $N_a \geq 2{,}000$ cycles $S_{p_1} = 2/3\ Q_p + P_{eb}/2_2 + Q_{T_1} + 1.3\ Q_T$, $S_{p_2} = 0.4\ Q_p + (K/2)_2 (P_{eb} + 2Q_T)$ where $Q_p = 25{,}965$, $P_{eb} = 9{,}940$ K-2, $Q_{T_1} = 1{,}160$, $Q_{T_2} = 260$ psi $\rightarrow S_{p_1} = 23{,}970$, $S_{p_2} = 20{,}845$, S_a equal to the larger of S_{p_1} and S_{p_2} $\rightarrow S_a = 23{,}970$ psi $\rightarrow$ $N_a = 55{,}000 \geq 2{,}000$; criterion satisfied		

Table 3.9-6(h) (Cont'd)

(Unit 1)

CRITERIA	METHOD OF ANALYSIS	ALLOWABLE STRESS, (psi) MINIMUM THICKNESS (in), OR MINIMUM AREA (in^2)	CALCULATED STRESS, (psi) ACTUAL THICKNESS (in), OR MINIMUM AREA (in^2)
Cyclic Loading Requirements at Valve Crotch	Reference Article 454 Thermal Transients Not Excluded by Code Criterion: $?(N_{fi}/N_i) < 1$ Calculate the fatigue usage factor (I_t) as follows: S_n Max = $Q_p + P_{eb} + C_6 (C_3 + C_4) \Delta T_f$ max ---> S_n max = 105,810 psi for ΔT_{fi} = 90, N_{fi} = 120, N_i = 2,700 N_{fi}/N_i = 0.044 for ΔT_{fi} = 122, N_{fi} = 10, N_i = 1,600 N_{fi}/N_i = 0.006 for ΔT_{fi} = 342, N_{fi} = 8, N_i = 55 N_{fi}/N_i = 0.143 -->$I_t = ?(N_{fi}/N_i)$ = 0.196 < 1; criterion satisfied		

Table 3.9-6(h) (Cont'd)

(Unit 1)

CRITERIA	METHOD OF ANALYSIS	ALLOWABLE STRESS, (psi) MINIMUM THICKNESS (in), OR MINIMUM AREA (in^2)	CALCULATED STRESS, (psi) ACTUAL THICKNESS (in), OR MINIMUM AREA (in^2)
Disk Design Calculation	From Reference 3.9-5, Pages 198, 200, 201 Disk design conditions, P_S = 1,250 psi at 575°F, S_m = 17,800 psi at 600°F		
	Case No. 13: $S_t = \frac{3W}{4mt^2 (a^2-b^2)} [a^4 (3m + 1) + b^4 (m - 1) -$ $4m\, a^2b^2 - 4(m + 1)\, a^2b^2 (1n(a/b))]$ where W = 1,250 psi, m = 10/3, t = 5.625 in, a = 10.75 in, b = 1.75 in, $S_{t_{13}}$ = 10,354 psi		
	Case No. 14: $S = \frac{3W}{2\pi mt^2} \frac{[2a^2 (m + 1)}{a^2 - b^2} 1n(a/b) + (m - 1)]$ where W = 59,044 lb_f, t = 5.625 in, m = 10/3, a = 10.75 in, b = 1.75 in, $S_{t_{14}}$ = 4,943 psi	17,800 psi	15,297 psi
	Case No. 21: $S_r = \frac{3W}{4t^2} \frac{[4a^4(m + 1) 1n(a/b)\, a^4(m + 3) + b^4(m - 1) + 4a^2b^2]}{a^2(m + 1) + b^2(m - 1)}$ where W = 1,250, m = 10/3, t = 3.125 in, a = 10.75 in, b = 7.25 in --> $S_{r_{21}}$ = 5760 psi		
	Case No. 22: $S_r = \frac{3W}{2t^2} \frac{[2a^2(m + 1) 1n(a/b) + a^2(m - 1) - b^2(m - 1)]}{a^2(m + 1) + b^2(m - 1)}$ where W = 1,250, m = 10/3, t = 3,125, a = 10.75, b = 7.25 --> $S_{r_{22}}$ = 10,740 psi		
	Total stress = $S_{r_{21}} + S_{r_{22}}$ = 16,500 psi, allowable stress = 17,800 psi	17,800 psi	16,500 psi

Table 3.9-6(h) (Cont'd)

(Unit 1)

CRITERIA	METHOD OF ANALYSIS	ALLOWABLE STRESS, (psi) MINIMUM THICKNESS (in), OR MINIMUM AREA (in^2)	CALCULATED STRESS, (psi) ACTUAL THICKNESS (in), OR MINIMUM AREA (in^2)
Tensile Stress at Thread Relief Valve Stem	Valve open $S_A = F/A_t$ where F = 31,586 lbs, A_t = 1,956 in^2, S_{max} = 16,148 psi		
	Valve Closed F = 46,342 lbs S_{max} = 23,692 psi	30,600 psi	23,692 psi
Bonnet Design Calculations Including Seismic Accelerations For SSE	Paragraph UG-34c(2) on ASME Code Section VIII		
Minimum Thickness	$P_{fd} = P + P_{eg}$, $P_{eg} = \frac{16M}{\pi G^3} + \frac{4F}{\pi G^2}$		
	where M = 1,292,000 in-lbs, F = 53,739 lbs, G = 24.75 in		
	P_{eg} = 546 psi, P_{fd} = 1,796 psi		
	$t = d\left(\frac{CR}{1.5S} + \frac{1.78\ W\ hg}{1.5\ S_d{}^3}\right)^{1/2}$		
	where C = 0.3, P_{fd} = 1,459 psi, S = 17,800 psi, hg = 2.625 in, W = 1,120,000 lbs, d = 24.75 in -->t = 4.503 in, t = 4.503 + 0.120 = 4.623 in (corrosion allowance is 0.120 in)	4.623 in	5.344 in
Reinforcement	Reference paragraph I-704.41(c) of USAS B31-7 to account for the opening for stem in the bonnet Required reinforcement d x t x 0.5 = $(d_3t_3 = d_4t_4)/2$ d_3 = 1.875, t_4 = 2.223, t_3 = 2.875, d_4 = 3 Reinforcement = 6.030 in^2 required = 6.6126 in^2 available	6.030 in^2	6.6126 in^2
Bonnet Studs Design Calculation	Reference Article E-1000 Bolt used 20 pieces of 2.652 in^2/bolts Total bolt area = 53.04 in^2		
Normal Operation	1. Pressure stress at Operating Condition $S_1 = W_{m1}/A_b$ = 21,116 psi where W_{m1} = 1,120,000 lbs and A_b = 53.04 in^2	27,700 psi	21,116 psi

Table 3.9-6(h) (Cont'd)

(Unit 1)

CRITERIA	METHOD OF ANALYSIS	ALLOWABLE STRESS, (psi) MINIMUM THICKNESS (in), OR MINIMUM AREA (in^2)	CALCULATED STRESS, (psi) ACTUAL THICKNESS (in), OR MINIMUM AREA (in^2)
	2. Gasket load at ambient condition with no internal pressure $S_2 = W_{m2}/A_b$ = 2,019 psi where W_{m2} = 107,065 lb_f and A_b = 53.04 in^2 Maximum tensile stress = 21,116 psi Thermal-stress is assumed negligible because the coefficients of thermal expansion of bonnet place and stud are the same.	35,000 psi	2,019 psi
Body Flange Design Calculations	Reference paragraph I-704.5.1 of USAS B 317 Total flange moment under operating conditions $M_O = M_D + M_G + M_T$ $M_D = H_D h_D$, $H_D = 0.785 B^2P$, $h_D = R + 0.591$ where B = 21.75, P = 1,796 psi --> H_D = 667,290 lb_f, h_D = 2.813 in, M_D = 1,877,000 in-lbs $M_G = H_G h_g$, $H_G = W - H$, $h_G = \frac{C-G}{2}$ where W is the higher of W_{m1} and W_{m2} W_{m1} = 1,120,000 lbs W_{m2} = 107,065 lbs H_G = 256,392 lbs, h_G = 2.625 in -->M_G = 673,000 in-lbs $M_T = H_T h_T$ H_T = 196,775 lbs, h_T = 3.375 in, M_T = 664,000 in-lb_f M_o = 3,214,000 in-lbs Total flange moment under gasket seating condition $M_o = W(C-G)/2$, $W = S_a(A_m + A_b)/2$ where C = 30 in, A_b = 53.04 in^2, G = 24.75 in, A_m = 32.857 in^2, s_a = 35,000 psi at 100°F --->W = 1,503,193 lbs ---> M_o = 3,945,895 in-lbs

RECIRCULATION PUMP

STRESS OR CRITERIA	METHOD OF ANALYSIS	ANALYTICAL RESULTS	ALLOWABLE / ACTUAL THICKNESS
1. Casing Minimum Wall Thickness	$t = \frac{PR}{SE - 0.6P} + C$		
A. Loads: Normal and upset condition Design pressure and temperature	where: t = minimum required thickness, in P = design pressure, psig R = maximum internal radius, in S = allowable working stress, psi E = joint efficiency C = corrosion allowance, in	t = 2.69 in	S_{allow} = 15,075 psi t_{act} = 3.00 in
B. Primary membrane stress limit Allowable working stress per ASME Section III, Class 1			
2. Casing Cover Minimum Thickness			
A. Loads: Normal and upset condition Design pressure and temperature	Bending Stress S_B max. = $\frac{KQa^2}{h^2}$	S_B max = 5950 psi	$S_{B\ allow}$ = 15,075 psi t_{act} = 7 in

Table 3.9-6(i) (Cont'd)

CRITERIA	METHOD OF ANALYSIS	ANALYTICAL RESULTS	ALLOWABLE STRESS OR ACTUAL THICKNESS
B. Primary membrane stress limit Allowable working stress per Section III, Class 1	where: Q = design pressure a = outer radius b = inner radius a = K = 0.711 b h = thickness		
	Shear Stress S_S max = F/A_S	S_S max = 3380 psi	$S_{S_{allow}}$ = 8750 psi
	where: F = force A_S = area		t_{act} = 3.5 in
3. Pump Discharge Nozzle Stress (Pressure Pending, Axial and Torsional)	Pressure $P_P = \frac{SEt}{R + 0.6t}$	P_P = 1594 psi P_{eb} = 18,500 psi	1.5 S_m = 28,837 psi (S_m = 19,225 psi)
	where: S = allowable stress E = joint efficiency t = thickness R = inside radius P_P = pressure load		
A. Loads: Normal and upset condition Design pressure and temperature piping reaction during normal operation	Bending $P_{eb} = \frac{C_b F_b S}{G_b}$	P_{ed} = 7670 psi P_{et} = 16,000 psi	

Table 3.9-6(i) (Cont'd)

CRITERIA	METHOD OF ANALYSIS	ANALYTICAL RESULTS	ALLOWABLE STRESS OR ACTUAL THICKNESS
B. Combined Stress limit: 1.5 S_m per ASME Code for Pumps and Valves for Nuclear Power Class I	Axial $P_{ed} = \frac{F_d S}{G_d}$ Torsional $P_{et} = \frac{2F_b S}{G_t}$		
4. Cover and Seal Flange Bolt Areas A. Loads: Normal and upset condition Design pressure and temperature Design gasket load B. Bolting Stress Limit Allowable working stress per ASME Section III, Class C	Bolting loads, areas and stresses shall be calculated in accordance with "Rules for bolted Flange Connections" - ASME Section VIII, Paragraph UA-49.	Cover Flange Bolts S_{act} = 19,050 psi A_m = 90.2 in^2 Seal Flange Bolts S_{act} = 18,000 psi A_m = 9.85 in^2	S_{allow} = 20,000 psi A_{act} = 101.0 in^2 S_{allow} = 20,000 psi A_{act} = 11.1 in^2

Table 3.9-6(i) (Cont'd)

CRITERIA	METHOD OF ANALYSIS	ANALYTICAL RESULTS	ALLOWABLE STRESS OR ACTUAL THICKNESS
5. Cover Clamp Flange Thickness A. Loads: Normal and upset condition Design pressure and temperature Design gasket load Design bolting load B. Tangential Flange Stress Limit Allowable working stress per ASME Section III, Class C	Flange thickness and stress shall be calculated in accordance with "Rules for Bolted Flange Connections" - ASME Section VIII, Paragraph UA-49.	Flange Thickness and Stress t = 8.9 in	t_{act} = 9.25 in S_{allow} = 17,500 psi
6. Seal Compartment Wall Thickness A. Loads: Normal and upset condition Design pressure and temperature B. Primary membrane stress limit Allowable working stress per ASME Section III, Class C	$t = \frac{PR}{SE - 0.6P} + C$ where: t = minimum required thickness, in P = design pressure, psig R = maximum internal radius, in S = allowable working stress, psi E = joint efficiency C = corrosion allowance, in	t = 0.741	S_m = 15,075 psi t_{act} = 1.375 in

Table 3.9-6(i) (Cont'd)

CRITERIA	METHOD OF ANALYSIS	ANALYTICAL RESULTS	ALLOWABLE STRESS OR ACTUAL THICKNESS
7. Stresses Due to Seismic Loads A. Loads: Operation pressure and temperature SSE horizontal seismic force = 2.27 g SSE vertical seismic force = 1.39 g B. Combined Stress Limit: Yield stress per ASME Section VIII	The flooded pump-motor assembly shall be analyzed as a free body supported by constant support hangers from the pump brackets. Horizontal and vertical seismic forces shall be applied at mass center of assembly and equilibrium reactions shall be determined for the motor and pump brackets. Load, shear, and moment diagrams shall be constructed using live loads, dead loads, and calculated snubber reactions. Combined bending tension and shear stresses shall be determined for each major component of the assembly including motor support barrel, bolting and pump casing. The maximum combined tensile stress in the cover bolting shall be calculated using tensile stresses determined from loading diagram plus tensile stress from operating pressure.	Motor Bolt Tensile Stress S_{act} = 22,471 psi Pump Cover Bolt Tensile stress S_{act} = 19,417 psi Motor Support Barrel Combined Stress S_{act} = 3307 psi	 S_{allow} = 30,800 psi S_{allow} = 32,000 psi S_{allow} = 22,400 psi

(Unit 2)

COMPONENT/ LOADS/ DESIGN	DESIGN PROCEDURE	REQUIRED DESIGN VALUE[2]	ACTUAL DESIGN VALUE[2]
Stresses in Stem			
Not applicable, valve is passive			
Disc Analysis			
Loads: Maximum differential pressure			
Maximum stress in the disc	Calculate maximum stress according to table 10 of Reference 3.9-5	$S_{max} < 1.5\ S_m$ (500°F) = 28,500	S_{max} = 22,885 psi
Yoke and Yoke Connections			
Loads: Stem operational load	Calculate stresses in the yoke and yoke connections to acceptable structural analysis methods.		
Tensile stress in yoke legs bolts		$S_{max} \leq S_m$ = 28,800 psi (500°F)	S_{max} = 3,716 psi
Stress of yoke legs		$S_{max} \leq 1.5\ S_m$ = 19,400 psi (500°F)	S_{max} = 5,145 psi
Stress of yoke-bonnet connection		$S_{max} \leq S_m$ = 19,225 psi (575°F)	S_{max} = 5,741 psi

Table 3.9-6(j) (Cont'd)

(Unit 2)

COMPONENT/ LOADS/ DESIGN	DESIGN PROCEDURE[1]	REQUIRED DESIGN VALUE[2]	ACTUAL DESIGN VALUE[2]
IV. 28" SUCTION VALVE			
Body and Bonnet			
Loads: Design pressure, design temperature pipe reaction thermal effects	System requirement not specified	1,275 psi 575°F	1,275 psi 575°F
Pressure rating, psi	Used ASME Section III Figure NB-3545.1-2	p_r = 668	p_r = 668
Minimum wall thickness, inches	Used ASME Section III Para NB-3542	$t_m \geq$ 1.7724 in	t_m = 2.0 minimum
Primary membrane stress, psi	Used ASME Section III Para NB-3545.1	$P_m \leq S_m$ (500°F) = 19,600 psi	P_m = 9,275 psi
Secondary stress due to pipe reaction	Used ASME Section III Para NB-3545.2(b)(1) (S = 30,000 psi)	$P_e < 1.5\ S_m$ (500°F) 1.5 (16,800) = 25,200 psi	P_{ed} = 5,318 psi P_{eb} = 11,980 psi P_{et} = 11,575 psi P_e = 11,980 psi
Primary plus secondary stress due to internal pressure	Used ASME Section III Para NB-3545.2(a)(1)	$S_n \leq 3\ S_m$ (500°F) = 58,800	Q_p = 20,580 psi
Thermal secondary stress	Used ASME Section III Para NB-3545.2	$S_n \leq 3\ S_m$ (500°F) = 58,800	Q_t = 5,489 psi

Table 3.9-6(j) (Cont'd)

(Unit 2)

COMPONENT/ LOADS/ DESIGN	DESIGN PROCEDURE(1)	REQUIRED DESIGN VALUE(2)	ACTUAL DESIGN VALUE(2)
Sum of primary plus secondary stress	Used ASME Section III Para NB-3545.2	$S_n \leq 3\ S_m$ (500?F) = 58,800	$S_n = Q_p + P_e + 2Q_t$ = 43,538 psi
Fatigue Requirements	Used ASME Section III Para NB-3545.3	$N_a \geq 2{,}000$ cycles	$N_a > 10^6$ cycles
Cyclic rating	Used ASME Section III Para NB-3550	$I_t \leq 1$	$I_t = 0.00274$
Body-to-Bonnet Bolting			
Loads: Design pressure and temperature, gasket loads, stem operational load, seismic load (SSE)	Used ASME Section III Para NB-3647.1		
Bolt area	Used ASME Section III Para NB-3647.1	$A_b \geq 37.53$ in^2 $S_b \leq 27{,}975$ psi (575°F)	$A_b = 55.86$ in^2 $S_b = 19{,}283$ psi
Body flange stresses	Used ASME Section III Para NB-3647.1		
Operating condition	Used ASME Section III Para NB-3647.1	$S_H \leq 1.5\ S_m$(575°F) = 28,838 psi $S_R \leq 1.5\ S_m$(575°F) = 19,225 psi $S_T \leq 1.5\ S_m$(575°F) = 19,225 psi	$S_H = 24{,}264$ psi $S_R = 6{,}476$ psi $S_T = 8{,}364$ psi
Gasket seating condition	Used ASME Section III Para NB-3647.1	$S_H \leq 1.5\ S_m$(100°F) = 30,000 psi $S_R \leq 1.5\ S_m$(100°F) = 30,000 psi $S_T \leq 1.5\ S_m$(100°F) = 30,000 psi	$S_H = 28{,}945$ psi $S_R = 10{,}253$ psi $S_T = 13{,}619$ psi

Tensile stress in yoke legs bolts		$S_{max} \leq S_m$ (500°F) = 28,800 psi	S_{max} = 3,877 psi
Stress at yoke legs		$S_{max} \leq 1.5\ S_m$ (500°F) = 19,400 psi	S_{max} = 5,378 psi
Stress at yoke-bonnet connection		$S_{max} \leq S_m$ (575°F) = 19,225 psi	S_{max} = 6,004 psi

---

(1) ASME Section III refers to 1968 Edition of ASME B&PV Code.

(2) Terms used are defined as follows:

A_b	=	actual total cross-sectional area of bolts at root of thread or section of least diameter under stress, in^2	
I_t	=	thermal cyclic index for a particular valve application	
N_a	=	permissible number of complete startup/shutdown cycles at 100°F/hour fluid temperature change rate	
p_r	=	primary pressure rating, lb	
P_e	=	largest value among P_{eb}, P_{ed}, P_{et}, psi	
P_{eb}	=	secondary stress in crotch region of valve body caused by bending of connected standard pipe, psi	
P_{ed}	=	Secondary stress in crotch region of valve body caused by direct or axial load imposed by connected standard	piping, psi
P_{et}	=	secondary stress in crotch region of valve body caused by twisting of connected standard pipe, psi	
P_m	=	general primary-membrane stress intensity at crotch region, psi	
Q_p	=	sum of primary-plus-secondary stresses at crotch resulting from internal pressure, psi	
Q_T	=	thermal-stress in crotch region resulting from 100°F/hour fluid temperature change rate, psi	
S_b	=	allowable bolt stress at design temperature, psi	
S_B	=	bending stress, psi	
S_H	=	calculated longitudinal stress in hub, psi	
S_m	=	design stress intensity, psi	
S_{max}	=	maximum stress, psi	
S_n	=	sum of primary-plus-secondary stress intensities at crotch region resulting from 100?F/hour temperature change rate,	psi
S_R	=	calculated radial stress in flange, psi	
S_s	=	shear stress due to operator torque, psi	
S_t	=	stress due to operator thrust, psi	
S_T	=	tangential stress in flange, psi	
t_m	=	minimum body wall thickness, in	

Table 3.9-6(k)

HPCI TURBINE

CRITERIA/COMPONENT	LOADING CONDITION	STRESS TYPE	ALLOWABLE STRESS (PSI)	CALCULATED STRESS (PSI)
PRESSURE BOUNDARY CASTINGS				
Allowable stresses based on ASME Section III. Pressure boundary castings for Type SA216-WCB				
	For normal condition: Design pressure Design temperature Inlet and exhaust nozzle loads			
1. Stop Valve (100% radiograph)		General membrane	8,975	17,500
2. Turbine inlet (high pressure)		General membrane	6,550	14,000
3. Turbine wheel case (low pressure)		General membrane	6,000	14,000
	For upset, Emergency, or faulted condition: Design pressure Design temperature Controlling combination of OBE, SSE, SRV, & LOCA Inlet and exhaust nozzle loads			
1. Stop valve (100% radiograph)		General membrane	17,700	19,250
2. Turbine inlet (high pressure)		General membrane	15,250	15,400
3. Turbine wheel case (low pressure)		General membrane	13,690	15,400
PRESSURE BOUNDARY BOLTING				
Allowable stresses are based on ASME Section III, for pressure boundary bolting for Type SA193-B7				
	For normal condition: Design pressure Design temperature Inlet and exhaust nozzle loads			

Table 3.9-6(k) (Cont'd)

CRITERIA/COMPONENT	LOADING CONDITION	STRESS TYPE	ALLOWABLE STRESS (PSI)	CALCULATED STRESS (PSI)
PRESSURE-CONTAINING BOLTS				
Stop valve		Tensile	17,600	25,000
Turbine flange		Tensile	18,290	25,000
	For upset emergency, or faulted condition: Design pressure Design temperature Controlling combination of OBE, SSE, SRV, & LOCA Inlet and exhaust nozzle loads			
PRESSURE-CONTAINING BOLTS				
Stop valve		Tensile	17,950	25,000
Turbine flange		Tensile	18,655	25,000
	For faulted condition: Design pressure Design temperature Combination (ABS) of SSE, SRV, & LOCA Inlet and exhaust nozzle loads			
Turbine shaft stress		Bending	12,850 psi	45,000 psi
Turbine shaft deflection	-		0.032 inch	0.125 inch
Thrust bearing load		Force	4,600 lb_f	5,600 lb_f
Journal bearing load		Force	5,020 lb_f	19,500 lb_f
Pedestal bolts, coupling end		Tension	28,740 lb	31,100 lb
Taper pins, coupling end		Shear	39,110 lb	42,050 lb
Guide block weld, governor end		Shear	43,550 lb	43,650 lb

SLCS PUMP

Criteria/Loading		Component	Limiting Stress Type	Allowable Stress (psi)	Calculated Stress (psi)
Based on ASME Section III.					
Pressure Boundary Parts:					
1. Fluid Cylinder - SA182-F304,	S_y = 30,000 psi				
2. Discharge valve stop, stuffing box and cylinder head extension SA479-304,	S_y = 30,000 psi				
3. Discharge valve cover, cylinder head and stuffing box flange plate, SA285, Grade C	S_y = 30,000 psi				
4. Stuffing box gland, ASTM A461, Grade 630	S_y = 90,000 psi				
5. Studs, SA193-B7,	S_y = 105,000 psi				
6. Dowel pins(2) alignment, SAE4140,	S_y = 117,000 psi				
7. Studs, cylinder tie, SA193-B7,	S_A = 25,000 psi				
8. Pump holddown bolts, SAE Grade 1	T_A = 15,000 psi Q_A = 12,000 psi				
9. Power frame, foot area, cast iron,	S_A = 15,000 psi				
10. Motor holddown bolts, SAE Grade 1	T_A = 15,000 psi Q_A = 12,000 psi				
11. Motor frame foot area, cast iron,	S_A = 15,000 psi				

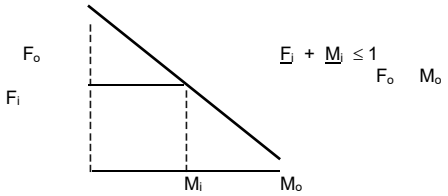
Table 3.9-6(l) (Cont'd)

Criteria/Loading	Component	Limiting Stress Type	Allowable Stress (psi)	Calculated Stress (psi)
Normal and Upset Condition Loads:				
1. Design pressure	1. Fluid Cylinder	General membrane	17,800	
2. Design temperature	2. Discharge valve stop	General membrane	17,800	(3)
3. Operating basis earthquake	3. Cylinder head extension	General membrane	17,800	
4. Nozzle loads(1)	4. Discharge valve cover	General membrane	17,800	
5. Thermal expansion	5. Cylinder head	General membrane	17,800	
6. SRV	6. Stuffing box flange plate	General membrane	17,800	
7. Dead weight	7. Stuffing box gland	General membrane	35,000	
	8. Cylinder head studs	Tensile	25,000	
	9. Stuffing box studs	Tensile	25,000	
Emergency or Faulted Condition:				
1. Design pressure	1. Fluid cylinder	General membrane	21,360	4,450
2. Design temperature	2. Discharge valve stop	General membrane	21,360	13,600
3. Weight of structure	3. Cylinder head extension	General membrane	21,360	13,600
4. Thermal expansion	4. Discharge valve cover	General membrane	21,360	8,150
5. Safe shutdown earthquake	5. Cylinder head	General membrane	21,360	8,150
6. LOCA	6. Stuffing box flange plate	General membrane	21,360	10,390
7. Nozzle loads	7. Stuffing box gland	General membrane	42,000	11,420
	8. Cylinder head studs	Tensile	25,000	18,820
	9. Dowel pins(2)	Shear only(2)	23,400	19,400
	10. Studs, cylinder tie	Tensile(2)	25,000	24,750
	11. Pump holddown bolts	Shear	12,000	7,560
	12. Pump holddown bolts	Tensile	15,000	9,950
	13. Power frame-foot area	Shear	15,000	1,850
	14. Power frame-foot area	Tensile	15,000	11,390
	15. Motor holddown bolts	Shear	12,000	3,470
	16. Motor holddown bolts	Tensile	15,000	5,660
	17. Motor frame-foot area	Shear	15,000	2,550
	18. Motor frame-foot area	Tensile	15,000	4,125

Table 3.9-6(l) (Cont'd)

Criteria/Loading	Component	Allowable Loads [5] (lb, ft-lb)	Calculated Loads (lb,ft-lb)
Normal and Upset Condition Loads:			
1. Design pressure	Suction	F_o = 730	F_i = 571
2. Design temperature	Nozzle	M_o = 282	M_i = 218
3. Weight of structure			
4. Thermal expansion	Discharge	F_o = 350	F_i = 138
5. Operating basis earthquake	Nozzle	M_o = 69	M_i = 38
6. SRV			
Emergency or Faulted Condition Loads:			
1. Design pressure	Suction	F_o = 730	F_i = 620
2. Design temperature	Nozzle	M_o = 282	M_i = 228
3. Weight of structure			
4. Thermal expansion	Discharge	F_o = 350	F_i = 170
5. Safe shutdown earthquake	Nozzle	M_o = 67	M_i = 46
6. LOCA			

---



(1) Nozzle loads produce shear loads only.
(2) Dowel pins take all shear.
(3) Calculated stresses for emergency or faulted condition are less than the allowable stresses for the normal and upset condition loads, therefore the normal and upset condition is not evaluated.
(4) Operability: The sum of the plunger and rod assembly, pounds mass times 1.75, acceleration is much less than the thrust loads encountered during normal operating conditions. Therefore, the loads during the faulted condition have no significant effect on pump operability.

Table 3.9-6(l) (Cont'd)

(5) Allowable nozzle load criteria:

Units: Forces - lb
Moments - ft-lb

The allowable combinations of forces and moments are as follows:

$$\frac{F_i}{F_o} + \frac{M_i}{M_o} \leq 1$$

where:

F_i = Largest absolute value of the three actual external orthogonal forces (F_x, F_y, F_z) that may be imposed by the interface pipe.

M_i = Largest absolute value of the three actual external orthogonal moments (M_x, M_y, M_z) permitted from the interface pipe when they are combined simultaneously for a specific condition.

F_o = Allowable value of F_i when all moments are zero.

M_o = Allowable value of M_i when all forces are zero.

Table 3.9-6(m)

3. Nozzle Loads		See (a) and (b) below	See (c) below
Design pressure and temperature			
Dead weight, thermal expansion and SSE	Primary local membrane stress less than 1.8 ASME Section VIII allowable.		

a) Maximum allowable piping loads for faulted conditions (including SSE) shall not exceed the following relationship for each nozzle:

$$\frac{F_{ix}}{F_{ox}} + \frac{F_{iy}}{F_{oy}} + \frac{F_{iz}}{F_{oz}} \leq 1 \quad \text{and} \quad \frac{M_{ix}}{M_{ox}} + \frac{M_{iy}}{M_{oy}} + \frac{M_{iz}}{M_{oz}} \leq 1$$

where F_i (lbs) is the maximum piping load imposed on each nozzle in the x, y and z direction and M_i (lb-ft) is the maximum moment imposed on each nozzle in the x, y and z directions.

b) Allowable design basis limits (forces F_{ox}, F_{oy}, F_{oz} and Moments M_{ox}, M_{oy}, M_{oz}) for nozzles N1, N2, N3, and N4:

	N1 (Channel inlet)	N2 (Channel outlet)	N3 (Shell inlet)	N4 (Shell outlet)
F_{ox}	11,395 lb	11,395 lb	44,143 lb	26,692 lb
F_{oy}	25,621 lb	25,621 lb	19,630 lb	26,692 lb
F_{oz}	25,621 lb	25,621 lb	44,143 lb	11,871 lb
M_{ox}	65,926 lb-ft	65,926 lb-ft	21,839 lb-ft	12,230 lb-ft
M_{oy}	8,537 lb-ft	8,537 lb-ft	113,596 lb-ft	12,230 lb-ft
M_{oz}	8,537 lb-ft	8,537 lb-ft	21,839 lb-ft	68,680 lb-ft

Note: The calculated loads in (c) below that exceed these allowable loads have been evaluated and are acceptable.

Table 3.9-6(o) (Cont'd)

(Unit 1)

CRITERIA		METHOD OF ANALYSIS		ALLOWABLE STRESS OR MINIMUM THICKNESS REQUIRED	ACTUAL[2] STRESS OR MINIMUM THICKNESS REQUIRED
c)[1]					
F_{ox}	6,367 lb	6,822 lb	6,638 lb	1,101 lb	
F_{oy}	4,442 lb	8,034 lb	10,370 lb	2,526 lb	
F_{oz}	4,836 lb	1,818 lb	11,327 lb	8,178 lb

Loads: Faulted			
Design pressure and temperature, dead weight, nozzle loads, SSE.	Principal stress	19,250 psi	12,080 psi

(1) The actual nozzle loads are provided by AE and are used to calculate the actual stresses.

(2) The "actual" stresses tabulated were calculated using the "maximum" nozzle loads that the RHR Heat Exchanger can withstand without exceeding the allowable stress.

(3) The "actual" stresses tabulated were calculated using the "actual" nozzle loads supplied by the AE for the Limerick 2 RHR Heat Exchanger.

Table 3.9-6(p)

RWCU PUMP

Following is a summary of the design calculations on the RWCU pump (B, C only):

Pump Part[1]	CALCULATED STRESS (psi)	ALLOWABLE STRESS (psi)
Casing wall	10,820	12,814
Cover bolting	20,000	25,000
Pedestal bolt (shear)	18,015	44,000
Motor Part[2]		
Motor foot bolts (shear)	174	60,000
Pump pedestal bolt (shear)	194	60,000
Foundation bolting	230	60,000

Following is a summary of the design calculations on the “A” RWCU pumps:

Part(1)	Calc. Stress (psi)	Allowable Stress (psi)
Pump Suction Nozzle	12,774 (U1) 1,582 (U2)	15,000
Pump Discharge Nozzle	12,824 (U1) 1,546 (U2)	17,500
Motor Case Outlet Nozzle	5,995 (U1) 5,995 (U2)	17,500
Motor Case Inlet Nozzle	5,997 (U1) 5,997 (U2)	17,500
Pump Support Flange Bolts (shear)	3,437 (U1) 3,325 (U2)	25,833 (U1) 11,800 (U2)
Pump Case/Motor Case Studs	23,229 (U1) 23,229 (U2)	25,000

Table 3.9-6(q) (Cont'd)

(Unit 2)

CRITERIA/LOADING	COMPONENT	ALLOWABLE LOAD CRITERIA[4]	CALCULATED CRITERIA[4]
Nozzle Load Definition:			
Turbine vendor and GE have defined allowable nozzle loads for the turbine assembly. The above calculated stresses assume these allowable nozzle loads have been satisfied.			
Normal Condition Loads:			
1. Design pressure 2. Design temperature 3. Weight of structure 4. Thermal expansion	Inlet Nozzle	$F = \frac{2620-M}{3}$	F = 563 lb M = 575 ft-lb
	Exhaust Nozzle	$F = \frac{6000-M}{3}$	F = 324 lb M = 1,748 ft-lb
Upset, Emergency, and Faulted Condition Loads:			
1. Design pressure 2. Design temperature 3. Weight of structure 4. Thermal expansion 5. Controlling combination of SSE, SRV, and LOCA	Inlet Nozzle	$F = \frac{7500-M}{3.75}$	F = 1,518 lb M = 1,137 ft-lb
	Exhaust Nozzle	$F = \frac{8500-M}{0.34}$, but less than 7000 lb	F = 1,016 lb M = 3,030 ft-lb

_____

(1) Calculated stresses for the faulted condition are lower than the allowable stresses for the normal condition, therefore the normal condition is not evaluated.

(2) Operability: Analysis indicated that shaft deflection with faulted loads is 0.014 inch; which is fully acceptable; and maximum bearing load with faulted condition is 80% of allowable.

(3) 100% radiograph

(4) F = resultant force (lb); M = resultant moment (ft-lb).

Table 3.9-6(r)

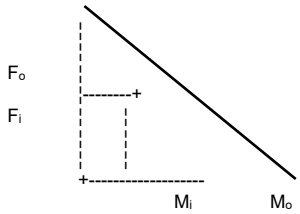
RCIC PUMP

CRITERIA/LOADING		COMPONENT	LIMITING STRESS TYPE	ALLOWABLE STRESS (PSI)	CALCULATED STRESS (PSI)
Pressure boundary stress limits of the various components for the RCIC pump assembly are based on ASME Section III, for pressure boundary parts at 140°F.					
1. Forged barrel, SA105 Grade II	S_y = 36,000 psi				
2. End cover plates, SA105 Grade II	S_y = 36,000 psi				
3. Nozzle connections, SA105 Grade II	S_y = 36,000 psi				
4. Aligning pin, SA105 Grade II	S_y = 36,000 psi				
5. Closure bolting, SA193-87	S_y = 105,000 psi				
6. Pump holddown bolting, SA449	S_y = 81,000 psi				
7. Taper pins, SA108 Grade B1112	S_y = 75,000 psi				
Normal and Upset Condition Loads:					
1. Design pressure		1. Forged barrel	General membrane[1]		
2. Design temperature		2. Nozzle reinforcement	Tensile shear		
3. Operating basis earthquake		3. Alignment pin	Tensile		
4. Suction nozzle loads		4. Taper pins			
5. Discharge nozzle loads		5. Pump holddown bolts			
6. Thermal expansion					
7. SRV					
8. Dead weight					
Emergency or Faulted Condition Loads:					
1. Design pressure		1. Forged barrel	General membrane	17,500	7,792
2. Design temperature		2. Nozzle reinforcement at barrel	General membrane	26,250	8,680
3. Safe shutdown earthquake		3. Alignment pin	Shear	18,000	2,465
4. Suction nozzle loads		4. Taper pins (bearing housing)		15,000	2,520
5. Discharge nozzle loads		5. Pump holddown bolts	Tension	48,000	37,196
6. Thermal expansion					
7. LOCA					
8. Dead weight					

Table 3.9-6(r) (Cont'd)

CRITERIA/LOADING	COMPONENT	ALLOWABLE LOADS[4] (lb, ft-lb)	CALCULATED LOADS (lb, ft-lb)
Normal and Upset Condition Loads:			
1. Design pressure	Suction	F_o = 1940	F_i = 1173
2. Design temperature	Nozzle	M_o = 2950[3]	M_i = 2555
3. Weight of structure			
4. Thermal expansion	Discharge	F_o = 3715	F_i = 913
5. Operating basis earthquake	Nozzle	M_o = 4330	M_i = 1193
6. SRV			
Emergency or Faulted Condition Loads:			
1. Design pressure	Suction	F_o = 2325	F_i = 1033
2. Design temperature	Nozzle	M_o = 2950	M_i = 2438
3. Weight of structure			
4. Thermal expansion	Discharge	F_o = 4450	F_i = 1061
5. Safe shutdown earthquake	Nozzle	M_o = 5200	M_i = 1751
6. LOCA			

(1) Calculated stresses for emergency or faulted condition are less than the allowable for normal plus upset condition.



(2) Operability static analysis for emergency or faulted condition shows that the maximum shaft deflection is 0.0044 inch with a 0.0055 inch allowable, shaft stresses are 5602 psi with 32,000 psi allowable, drive end bearing loads are 45 lb with 7670 lb allowable, and thrust end bearing loads are 1462 lb with 17,200 lb allowable.

(3) This allowable moment was determined by analytical qualification which exceeds the Code-determined allowable.

Table 3.9-6(r) (Cont'd)

(4) Allowable nozzle load criteria:
Units: Forces - lb
Moments - ft-lb

The allowable combinations of forces and moments are as follows:

$$\frac{F_i}{F_o} + \frac{M_i}{M_o} \leq 1$$

where:

F_i = Largest absolute value of the three (F_x, F_y, F_z) that may be imposed by actual external orthogonal forces the interface pipe.

M_i = Largest absolute value of the three actual external orthogonal moments (M_x, M_y, M_z) permitted from the interface pipe when they are combined simultaneously for a specific condition.

F_o = Allowable value of F_i when all moments are zero.

M_o = Allowable value of M_i when all forces are zero.

REACTOR REFUELING AND SERVICING EQUIPMENT

The information on this page has been deleted.

Table 3.9-6(s) (Cont'd)

The information on this page has been deleted.

Table 3.9-6(s) (Cont'd)

ACCEPTANCE CRITERIA	LOADING	PRIMARY STRESS TYPE	ALLOWABLE STRESS (psi)	CALCULATED STRESS (psi)
FUEL PREPARATION MACHINE				
The allowable axial plus bending loads stresses are based on manual of steel construction, 1980, 8th edition				
F_y = 35,000 psi				
F_u = 38,000 psi				
For normal condition:(2)	For normal condition:	Axial load	23,100	4,441
S_{limit} = 0.66 F_y	1. Static	plus bending		
For emergency condition:(2)	For emergency condition:	Axial load	30,800	27,619
S_{limit} = 0.88 F_y	1. Static 2. OBE 3. LOCA 4. SRV	plus bending		
For faulted condition:(2)	For faulted condition:	Axial load	30,800	30,118
S_{limit} = 0.88 F_y	1. Static 2. SSE 3. LOCA 4. SRV	plus bending		

Table 3.9-6(s) (Cont'd)

ACCEPTANCE CRITERIA	LOADING	PRIMARY STRESS TYPE	ALLOWABLE STRESS (psi)	CALCULATED STRESS (psi)
REFUELING PLATFORMS				
The allowable axial plus bending loads stresses are based on ASME Section III, Subsection NA				
For type				
S_u = 58,000 psi				
S_y = 36,000 psi				
For normal condition: $S_{limit} = S_m = 0.66\ S_y$	For normal condition: 1. Static loads	Axial load plus bending	23,760	6,366 (3)
For upset condition: $S_{limit} = 0.9\ S_y$	For upset condition: 1. Static 2. OBE 3. LOCA 4. SRV	Axial load plus bending	31,680	31,552 (3)
For faulted condition: $S_{limit} = 0.7\ S_u$	For faulted condition: 1. Static 2. SSE 3. LOCA 4. SRV	Axial load plus bending	40,600	32,455 (3)

(1) Pins in shear are limiting factor for horizontal loads applied to all rack castings. Allowable S_s assumed @ 50% allowable stress.
(2) The allowable stresses are shape dependent; therefore, these factors apply only at the location of the calculated stress.
(3) Calculated stresses shown on this table are based on conservative set of spectra, and pre-upgrade conditions. Calculation LS-0266 demonstrates on a comparative basis that these stresses bound the stresses in the upgraded configuration.

Dowel Pins (Booster) (Shear)		F_o, M_o Actual	30,880 21,498	42,000 33,600
Dowel Pins (Main) (Shear)		F_o, M_o Actual	38,488 23,451	42,000 33,600

(1) Eight anchor bolts, each carries the stresses for both units mounted on a common base-plate.

(2) The allowable stress values for bolts are 0.5 S_u, and 0.4 S_u for pins where F_o, M_o criteria are used. For actual nozzle loads, the stress limits are based on ASME Section III at 140°F.

Table 3.9-6(u)

CONTROL ROD DRIVE (INDICATOR TUBE)

CRITERIA	LOADING	PRIMARY STRESS TYPE	ALLOWABLE STRESS (psi)	CALCULATED STRESS[2] (psi)
Allowable primary membrane stress plus bending stress plus bending is based on ASME Section III for type 316 stainless steel @ 250°F S_m = 20,000 psi				
For normal and upset condition: S_{allow} = 50,000 psi	For normal and upset condition: 1. Normal loads[1]	Primary membrane plus bending	50,000	45,500
For emergency condition: S_{allow} = 50,000 psi	For emergency condition: 1. Dynamic P 2. OBE 3. SRV	primary membrane plus bending	50,000	45,500
For faulted condition: S_{allow} = 59,900 psi	For faulted condition: 1. Dynamic P 2. SSE 3. LOCA 4. SRV	Primary membrane plus bending	59,900	46,600

[1] Normal loads include pressure, temperature, weight and mechanical loads.
[2] The loads listed here correspond to the operating power level of 3458 MWt. Per Reference 3.9-31, the loads are not changed for the MUR power uprate conditions.

Table 3.9-6(v)

CRD HOUSING[1]

CRITERIA	LOADING	PRIMARY STRESS TYPE	ALLOWABLE STRESS (psi)	CALCULATED STRESS[2] (psi)
Primary Stress Limit - The allowable primary membrane stress is based on ASME Section III, for Class 1 vessels, stainless steel.				
For normal and upset condition: $S_{limit} = 1.0\ S_m$ = 16,660 psi @ 575?F	Normal and upset condition loads: 1. Design pressure 2. Stuck rod scram loads 3. OBE, with housing lateral support installed 4. SRV 5. Hydraulic line loads	Maximum membrane stress intensity occurs at the tube-to-tube weld near the center of the housing for normal, upset, emergency, and faulted conditions.	16,660	11,900
For faulted conditions:	Faulted conditions loads: 1. Design pressure 2. Stuck rod scram loads 3. SSE, with housing lateral support installed 4. Annulus pressurization 5. LOCA 6. Hydraulic line loads		59,760	25,850

[1] Analyzed to emergency conditions limits
[2] The loads listed here correspond to the operating power level of 3458 MWt. Per Reference 3.9-32, the loads are bounding for the MUR power uprate condition.

Table 3.9-6(w)

JET PUMPS

Criteria	Loading Combinations	Stress Type	Allowable Stress (psi)	Calculated Stress[1] (psi)
Primary membrane plus bending stress based on ASME Section III				
For service levels A and B (normal and upset) condition: For type 304SS @ 550°F S_m = 16,900 psi S_{limit} = 3.0 S_m psi	Normal and Upset Condition Loads: 1. Pressure 2. Weight 3. Clamping force 4. OBE 5. Vibration force 6. Thermal loads 7. SRV_{ALL}	Primary membrane plus bending plus secondary	50,700	18,185
For service level C (emergency) condition: For type 304SS @ 550°F S_m = 16,900 psi S_{limit} = 2.25 S_m psi	Emergency Condition Loads: 1. Pressure 2. Weight 3. Clamping force 4. Chugging 5. SRV_{ALL}	Primary membrane plus bending	38,025	10,702
For service level D (faulted) condition: For type 304SS @ 550°F S_m = 16,900 psi S_{limit} = 3.6 S_m psi	Faulted Condition Loads: 1. Pressure (internal) 2. Pressure (external) 3. Weight 4. Clamping force 5. Shock wave loads 6. SSE 7. Annulus pressurization 8. Jet reaction	Primary membrane plus bending	60,840	46,788

[1] The loads listed here correspond to the operating power level of 3458 MWt. Per Reference 3.9-32, the loads are bounding for the MUR power uprate condition.

Table 3.9-6(x)

FUEL ASSEMBLY (INCLUDING CHANNEL)[1][2][3]

Acceptance Criteria	Loading	Primary Load Type	Calculated Peak Acceleration	Evaluation Basis Acceleration
Acceleration Envelope	Horizontal Direction: Peak Pressure SSE Annulus Pressurization	Horizontal Acceleration	2.45 g	[5]
	Vertical Direction: Peak Pressure SSE Safety/Relief Valve Chugging	Vertical Accelerations	3.7 g	[5]

(1) Evaluation basis accelerations and evaluations are contained in NEDE-21175-3-P.

(2) The calculated maximum fuel assembly gap opening for the most limiting load combination is <0.01 inch based on the methodology contained in NEDE-21175-3-P.

(3) The fatigue analysis indicates that the fuel assembly has adequate fatigue capability to withstand the loadings resulting from multiple SRV actuations and the OBE + SRV event.

(4) This value is determined using the methodology contained in NEDE-21175-3-P.

(5) These are bounding values from GNF2 and GNF3. The evaluation basis accelerations are proprietary and bound the calculated values. For GNF3, these are found in Reference 3.9-36 and for GNF2, these are found in Reference 3.9-35.

Table 3.9-6(y)

HIGHEST STRESSED REGION ON THE LPCI COUPLING (ATTACHMENT RING)

Criteria	Loading Combinations	Stress Type	Allowable Stress (psi)	Calculated Stress[1] (psi)
Primary membrane plus bending stress based on ASME Section III NG-3000 for type CF3				
For service levels A and B (normal & upset) condition: $S_{limit} = 1.5\ S_m$ psi S_m = 16,900 psi @ 550°F	Normal and Upset Condition Loads: 1. Normal loads 2. Upset pressure 3. OBE 4. SRV	Primary membrane + bending	25,350	12,000
For service level C (emergency) condition: $S_{limit} = 2.25\ S_m$ S_m = 16,900 psi @ 550°F	Emergency Condition Loads: 1. Normal loads 2. Emergency pressure 3. Chugging 4. SRV	Primary membrane + bending	38,025	21,100
For service level D (faulted) condition: $S_{limit} = 3.6\ S_m$ S_m = 16,900 psi @ 550°F	Faulted Condition Loads: 1. Normal loads 2. Faulted pressure 3. Annulus pressurization 4. SSE	Primary membrane + bending	60,840	28,000

[1] The loads listed here correspond to the operating power level of 3458 MWt. Per Reference 3.9-32, the loads are bounding for the MUR power uprate condition.

Table 3.9-6(z)

REACTOR VESSEL SUPPORT EQUIPMENT:
CRD HOUSING SUPPORT

CRITERIA	LOADING	LOCATION	ALLOWABLE STRESS (psi)	CALCULATED STRESS (psi)
Primary Stress Limit				
AISC specification for the design, fabrication, and erection of structural steel for buildings	Faulted condition loads 1. Deadweight 2. Impact force from failure of a CRD housing	Beams (top chord) Beams (bottom chord)	33,000 33,000 33,000 33,000	f_a = 12,200 f_b = 16,500 f_a = 10,300 f_b = 11,700
For normal and upset condition: $f_a = 0.60\ f_y$ (tension) $f_b = 0.60\ f_y$ (bending) $f_v = 0.40\ f_y$ (shear) For faulted conditions: f_a limit = 1.5 f_a (tension) f_b limit = 1.5 f_b (bonding) f_v limit = 1.5 f_v (shear) f_y = material yield strength	(Deadweights and earthquake loads are very small compared to jet forces.)	Grid structure	41,500 27,500	f_b = 40,700 f_v = 11,100

Table 3.9-6(aa)

CONTROL ROD GUIDE TUBE

Criteria	Loading	Primary Stress Type	Allowable Stress (psi)	Calculated Stress[1] (psi)
Control Rod Guide Tube Primary stress limit - The allowable primary membrane stress plus bending stress is based on ASME Section III for type 304 stainless steel tubing.		Maximum stress occurs in the guide tube base		
For normal and upset conditions: 1.5 S_m = 1.5x16,000 psi = 24,000 psi	Upset condition loads 1. dead weight 2. external pressure 3. lateral flow impingement 4. OBE + SRV_{max} 5. scram	$P_m + P_b$	24,000	14,820
For emergency condition: 2.25 S_m = 36,000 psi	Emergency condition loads: 1. dead weight 2. external pressure 3. lateral flow impingement 4. SRV_{ADS} + CHUG	$P_m + P_b$	36,000	20,920
For faulted condition: 2.4 S_m = 38,400 psi	Faulted condition loads: 1. dead weight 2. external pressure 3. lateral flow impingement 4. SSE + SRV_{LSPA} + BCO	$P_m + P_b$	38,400	33,230

(1) The loads are calculated in Reference 3.9-32.

Table 3.9-6(ab)

INCORE HOUSING

Criteria	Loading	Primary Stress Type	Allowable Stress (psi)	Calculated Stress[1] (psi)
Primary Stress Limit - The allowable primary membrane stress is based on ASME Section III for Class 1 vessels for type 304 stainless steel.				
For normal, upset and emergency condition: $S_{limit} = 1.0\ S_m$ = 16,660 psi at 575°F	Service Level C (Emergency) condition loads 1. Design pressure 2. Design basis earthquake 3. SRV	Maximum membrane stress intensity occurs at the outer surface of the vessel penetration.	16,660	13,850
For faulted condition: $S_{limit} = 2.4\ S_m$	Faulted condition loads: 1. Faulted pressure 2. LOCA 3. SRV 4. SSE	Maximum membrane stress intensity occurs at the outer surface of the vessel penetration.	39,984	21,225

(1) The loads listed here correspond to the operating power level of 3458 MWt. Per Reference 3.9-32, the loads are bounding for the MUR power uprate condition.

Table 3.9-7 (Cont'd)

(1) Code(s): ASME III B&PV Code, -1, -2 or -3: Denotes nuclear Class 1, 2, or 3 piping;
B 31.1: Denotes ANSI B 31.1, Code for Pressure Piping;
SC I, II, or IIA: Denotes seismic Category I, II, or IIA;
HE: Denotes high energy piping system, i.e., pressure ≥275 psi or temperature ≥200°F during normal plant operation;
ME: Denotes moderate energy piping system.

(2) Thermal expansion test for the indicated systems corresponds to test description STP-17 in Table 14.2-3.

(3) Dynamic transient test for the indicated systems corresponds to test description STP-36 in Table 14.2-3. Main steam turbine trip test for Unit 2 (ref. Startup Test STP-36) at 100% power level will be performed during commercial operation of that Unit.

(4) Steady-state vibration tests for the indicated systems corresponds to test description STP-33 Table 14.2-3.

Instrument lines connected to process pipes on which steady-state vibration testing is performed are evaluated on the following basis;
a) for accessible lines; visually monitored
b) for inaccessible lines; instrument lines are monitored, inspected, and measured in accordance with startup test specification for BOP piping as committed in SSER-2.

(5) N/A: Denotes not applicable. Test is not performed for the following reason:
a) For thermal expansion tests: The system is not safety-related or the normal operating temperature < 300°F;
b) For dynamic transient test: The system is not safety-related or does not experience any significant transients;
c) For steady-state vibration tests: The system is not safety-related or no significant vibration is expected.

	F	NPC + SSE + DSL	1.0 P_r 11/	12.a	NPC + SSE + DSL	σ_m = 1.2 S[(a)(b)]	NC/ND 362	Structural integrity under its peak transient conditions was justified under applicable provisions of B31.1 (1967). This valve fully meets the load combination and acceptance criteria of Table 3.9-6.

(1) Numerical indicators (e.g. 1/) in the Regulatory Guide portion of the table correspond to footnotes of Regulatory Guide 1.48.
Alphabetical indicators in the LGS portion of table (or comparative column) correspond to the following:

(a) In addition to compliance with the design limits specified, assurance of operability under all design loading combinations shall be in accordance with Section 3.9.3.2.

(b) The design limit for local membrane stress intensity or primary membrane plus primary bending stress intensity is 150% of that allowed for general membrane (except as limited to 2.45 for inactive components under faulted condition).

(c) When selecting plant events for evaluation, the choice of the events to be included in each plant condition is selected based on the probability of occurrence of the particular load combination. The combination of loads are those identified in Table 3.9-2.

UPC = Upset Plant Conditions
NPC = Normal Plant Conditions
EPC = Emergency Plant Conditions
DSL = Dynamic System Loading
SSE = Safe Shutdown Earthquake

(d) Inactive limits may be used since operability will be demonstrated in accordance with Section 3.9.3.2.

(2) U = Upset
E = Emergency
F = Faulted

Table 3.9-11

DESIGN LOADING COMBINATIONS FOR ASME CODE
CLASS 1, 2, AND 3 NON-NSSS COMPONENTS(2)

CONDITION		DESIGN LOADING COMBINATIONS(1)
Design		PD
Normal		PD + DW
Upset	(a)	$PO + DW + (OBE^2 + SRV_x^2)^{1/2}$
	(b)	$PO + DW + (RVC^2 + OBE^2)^{1/2}$
	(c)	PO + DW + FV
	(d)	PO + DW + OBE + RVO
Emergency	(a)	$PO + DW + (OBE^2 + SRV^2_{ADS} + SBA^2)^{1/2}$
	(b)	$PO + DW + (FV^2 + OBE^2)^{1/2}$
Faulted	(a)	$PO + DW + (OBE^2 + SRV^2_{ADS} + IBA^2)^{1/2}$
	(b)	$PO + DW + (SSE^2 + SRV^2_{ADS} + IBA^2)^{1/2}$
	(c)	$PO + DW + (SSE^2 + DBA^2)^{1/2}$

where:

PD = design pressure
PO = operating pressure
DW = dead weight
OBE = operating basis earthquake (inertia portion)
SSE = safe shutdown earthquake (inertia portion)
SRV_x = loads due to SRV blow, axisymmetric or asymmetric
SRV_{ADS} = loads due to automatic depressurization SRV blow, axisymmetric
SBA = small break accident
IBA = intermediate break accident
DBA = design basis accident
FV = transient response of the piping system associated with fast valve closure (transients associated with valve closure times less than 5 seconds are considered)
RVC = transient response of the piping system associated with relief valve opening in a closed system
RVO = sustained load or response of the piping system associated with relief valve opening in an open system or last segment of the closed system with steady-state load

Table 3.9-11 (Cont'd)

SBA, IBA, and DBA include all event induced loads, as applicable, such as chugging, condensation oscillation, pool swell, drag loads, annulus pressurization, etc.

(1) As required by the appropriate subsection (ie, NB, NC, or ND, of ASME Section III, Division I), other loads, such as thermal transient, thermal gradients, and anchor point displacement portion of the OBE or SRV, are considered in addition to the primary stress-producing loads listed.

(2) Table 3.9-6 lists the load combinations for ASME Code Class 1, 2, and 3 NSSS piping, equipment, and supports.

Table 3.9-12

DESIGN CRITERIA FOR ASME CLASS 1 NON-NSSS PIPING

CONDITION	SERVICE LEVEL	APPLICABLE CODE PARAGRAPH[1][2]	PRIMARY STRESS LIMITS
Design	-	NB-3221 and NB-3652	1.5 S_m
Normal	A	NB-3222 and NB-3653	1.5 S_m
Upset	B	NB-3223 and NB-3654	1.8 S_m and 1.5 S_y
Emergency	C	NB-3224 and NB-3655	2.25 S_m and 1.85 S_y
Faulted	D	NB-3225 and NB-3656	3.0 S_m

(1) As specified by ASME Section III, 1977 Edition through Summer 1979 Addenda.
(2) Functional capability of essential piping is assured in accordance with NEDO-21985, September 1978.

Table 3.9-13

DESIGN CRITERIA FOR NON-NSSS ASME CODE CLASS 1 VALVES

CONDITION	STRESS LIMITS
Design	NB-3521(1)
Normal and upset	NB-3200 or NB-3500(1) (Standard Design Rules)
Emergency(2)	NB-3526(3)
Faulted(2)	NB-3527(3)

(1) As specified by ASME Section III, 1971 through Winter 1972 Addenda.

(2) Where valve function must be ensured (active valve) during the emergency or faulted conditions, the specified emergency or faulted condition for the plant shall be considered the normal condition for the valve.

(3) As specified by ASME Section III, 1971, through Winter 1973 Addenda.

Table 3.9-14

DESIGN CRITERIA FOR NON-NSSS ASME CODE CLASS 2 AND 3
VESSELS DESIGNED TO NC-3300 AND ND-3300

CONDITION	STRESS LIMITS[1]
Design and normal	The vessel shall conform to the requirements of NC-3300 and ND-3300.
Upset, emergency, and faulted	The vessel shall conform to the requirements of ASME Code Case 1607-1.

(1) As specified by ASME Section III, 1971 through Winter 1972 Addenda.

Table 3.9-15

DESIGN CRITERIA FOR NON-NSSS ASME CODE CLASS 2 VESSELS
DESIGNED TO ALTERNATE RULES OF NC-3200

CONDITION	STRESS LIMITS[1][2]
Design and normal	The vessel shall conform to the requirements of NC-3200.
Upset[3]	$P_e \leq 3\ S_m$
	$P_m \leq 1.1\ S_m$
	$(P_m \text{ or } P_L) + P_b \leq 1.65\ S_m$
Emergency	$P_m \leq$ greater of $1.2\ S_m$ or $1.0\ S_y$
	$(P_m \text{ or } P_L) + P_b \leq$ greater of
	$1.8\ S_m$ or $1.5\ S_y$
Faulted[4]	$P_m \leq 2.0\ S_m$
	$(P_m \text{ or } P_L) + P_b \leq 2.4\ S_m$

(1) Definition of symbols:

P_m = General primary membrane stress intensity. This stress intensity is derived from the average value across the solid section under consideration. Excludes discontinuities and concentrations. Produced only by pressure and other mechanical loads.

P_L = Local primary membrane stress intensity. Same as P_m except that discontinuities are considered.

P_b = Primary bending stress intensity. Component of primary stress intensity proportional to distance from centroid of solid section. Excludes discontinuities and concentrations. Produced only by pressure and other mechanical loads.

P_e = Secondary stress intensity range. Developed by constraint of adjacent parts or by self-constraint of a structure. Considers discontinuities but not concentrations. Produced by mechanical loads and by thermal expansion.

Table 3.9-15 (Cont'd)

S_m = Design stress intensity value, ASME Section III, Appendix I, Table I-1.0.

S_y = Yield strength value, ASME Section III, Appendix I, Table I-2.0.

(2) These limits do not take into account either local or general buckling that might occur in thin-wall vessels. Such buckling shall be considered for upset conditions, but need not be considered for emergency or faulted conditions unless required by the design specification.

(3) Fatigue analysis requirements of NC-3219 and Appendix XIV are considered.

(4) As an alternative to satisfying these limits, the faulted condition stress limits of Appendix F may be applied provided that a complete analysis in accordance with NC-3211.1(c) is performed.

Table 3.9-16

DESIGN CRITERIA FOR NON-NSSS ASME CLASS 2 AND 3 PIPING

CONDITION	APPLICABLE CODE PARAGRAPH[1][2]	PRIMARY STRESS LIMITS
Design:		
Sustained Loads	NC, ND 3652.1	1.0 S_h
Occasional Loads	NC, ND 3652.2	1.2 S_h
Normal & Upset	NC, ND 3652.2 & 3611	1.2 S_h
Emergency	NC, ND 3611	1.8 S_h
Faulted	Code Case 1606	2.4 S_h

(1) As specified by ASME Code Section III, 1971 through Winter 1972 Addenda except the following:

Nuclear Class 2 and 3 flanges are analyzed in accordance with ASME Section III 1977 edition through 1979 Summer Addenda.

(2) Functional capability of essential piping is assured in accordance with NEDO-21985, September 1978.

[1] Test data acquired for a qualified valve may be used to qualify valves of the same type that fall within the range of sizes permitted by this table, provided geometric similarity is maintained and supporting stress calculations are provided. If the qualified valve is larger than 36 inch nominal diameter, extrapolation may be made to valves whose nominal size does not vary more than 25% from that of the qualified valve.

Table 3.9-21

DESIGN LOADING COMBINATIONS FOR SUPPORTS FOR ASME CODE CLASS 1, 2, AND 3 COMPONENTS

CONDITION STRESS[2][3]	DESIGN LOADING COMBINATIONS[1]	ALLOWABLE
Hydrostatic Test	a) HTDW	0.8 S_y
Normal and Upset	a) DW + TH + $(OBE^2 + SRV_x^2)^{1/2}$	S_h
	b) DW + TH + $(RVC^2 + OBE^2)^{1/2}$	
	c) DW + TH + FV	
	d) DW + TH + OBE + RVO	
Emergency	a) DW + TH + $(OBE^2 + SRV^2_{ADS} + SBA^2)^{1/2}$	1.8 S_h
	b) DW + TH + $(OBE^2 + FV^2)^{1/2}$	
Faulted	a) DW + TH + $(SSE^2 + SRV^2_{ADS} + IBA^2)^{1/2}$	0.9 S_y
	b) DW + TH + $(OBE^2 + SRV^2_{ADS} + IBA^2)^{1/2}$	
	c) DW + TH + $(SSE^2 + DBA^2)^{1/2}$	

where:

HTDW = piping dead weight due to hydrostatic test

TH = reaction of the support due to thermal expansion of the pipe

S_y = yield stress

S_h = allowable stress per ANSI B31.1

See Table 3.9-11 for additional nomenclature.

---

(1) Loads due to OBE, SSE, SRV_x, SRV_{ADS}, SBA, IBA, and DBA include both the inertia portion and the anchor motion portion when the response spectra method is used. The loads from the inertia portion and anchor motion are combined by the SRSS method.

(2) The allowable stress shall be limited to 2/3 of the critical buckling stress.

(3) Snubbers, compensating starts, and struts comply with all the requirements of ASME Section III, Subsection NF; they are not commercially available to meet the requirements of ANSI B31.1.

Table 3.9-22

FATIGUE LIMIT
(FOR SAFETY CLASS REACTOR INTERNAL STRUCTURES ONLY)

Summation of fatigue damage usage with design and operation loads following Miner hypotheses [1]

CUMULATIVE DAMAGE IN FATIGUE	LIMIT FOR SERVICE LEVELS A AND B (NORMAL AND UPSET) DESIGN CONDITIONS
Design fatigue cycle usage from analysis using the method of ASME Code	$\leq$1.0

(1) M.A. Miner, "Cumulative Damage in Fatigue," Journal of Applied Mechanics, 12, (67), pp. A159-164, (September 1945).

Table 3.9-23

CORE SUPPORT STRUCTURES
STRESS CATEGORIES AND LIMITS OF STRESS INTENSITY FOR SERVICE LEVELS A AND B (NORMAL AND UPSET) CONDITIONS

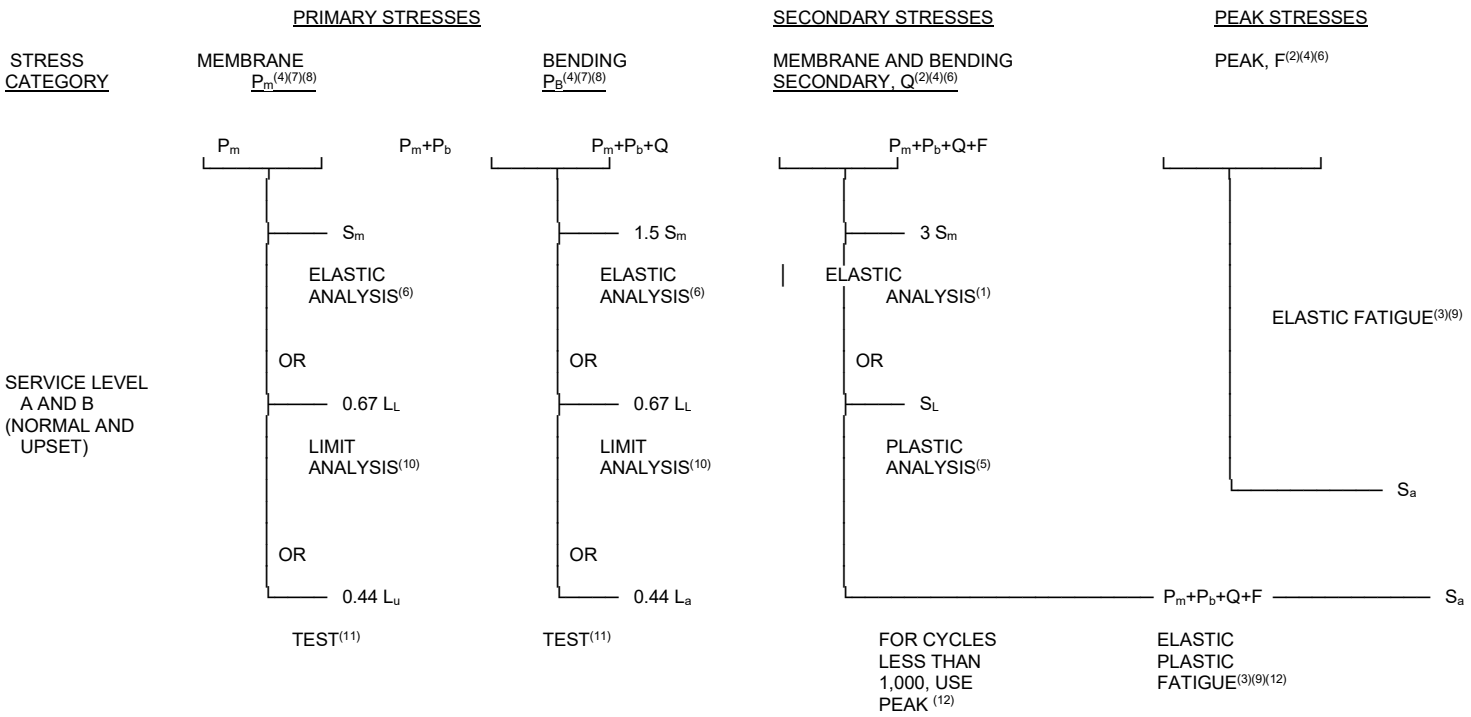

Table 3.9-23 (Cont'd)

---

(1) This limitation applies to the range of stress intensity. When the secondary stress is due to a temperature excursion at the point at which the stresses are being analyzed, the value of S_m shall be taken as the average of the S_m values tabulated in tables I-1.1, I-1.2, and I-1.3 of ASME Section III for the highest and the lowest temperature of the metal during the transient. When part of the secondary stress is due to mechanical load, the value of S_m shall be taken as the S_m value for the highest temperature of the metal during transient.

(2) The stresses in Category Q are those parts of the total stress which are produced by thermal gradients, structural discontinuities, etc, and do not include primary stresses which may also exist at the same point. It should be noted, however, that a detailed stress analysis frequently gives the combination of primary and secondary stresses directly and, when appropriate, this calculated value represents the total of $P_m + P_b + Q$ and not Q alone. Similarly, if the stress in Category F is produced by a stress concentration, the quantity F is the additional stress produced by the notch, over and above the nominal stress. For example, if a plate has a nominal stress intensity, $P_m = S$, $P_b = O$, $Q = O$ and a notch with a stress concentration K is introduced, then $F = P_m (K-1)$ and the peak stress intensity equals $P_m + P_m (K-1) = KP_m$.

(3) S_a is obtained from the fatigue curves, figures I-9.1 and I-9.2 of ASME Section III. The allowable stress intensity for the full range of fluctuation is $2 S_a$.

(4) The symbols P_m, P_b, Q, and F do not represent single quantities, but rather sets of six quantities representing the six stress components σ_t, σ_1, σ_r, γ_{tl}, γ_{lr}, γ_{rt}.

(5) S_L denotes the structural action of shakedown load as defined in paragraph NB 3213.18 of ASME Section III calculated on a plastic basis as applied to a specific location on the structure.

(6) The triaxial stresses represent the algebraic sum of the three primary principal stresses ($\sigma_1 + \sigma_2 + \sigma_3$) for the combination of stress components. Where uniform tension loading is present, triaxial stresses are limited to $4 S_m$.

(7) For configurations where compressive stresses occur, the stress limits shall be revised to take into account critical buckling stresses (see paragraph NB-3211(c) of ASME Section III). For external pressure, the permissible "equivalent static" external pressure shall be as specified by the rules of paragraph NB-3133 of ASME Section III. Where dynamic pressures are involved, the permissible external pressure shall be limited to 25% of the dynamic instability pressure.

(8) When loads are transiently applied, consideration should be given to the use of dynamic load amplification, and possible change in modulus of elasticity.

(9) In the fatigue data curves, where the number of operating cycles are less than 10, use the S_a value for 10 cycles; where the number of operating cycles are greater than 10^6, use the S_a value for 10^6 cycles.

Table 3.9-23 (Cont'd)

(10) L_L is the lower bound limit load with yield point equal to 1.5 S_m (where S_m is the tabulated value of allowable stress at temperature as contained in ASME Section III). The "lower bound limit load" is here defined as that produced from the analysis of an ideally plastic (nonstrain hardening) material where deformations increase with no further increase in applied load. The lower bound load is one in which the material everywhere satisfies equilibrium and nowhere exceeds the defined material yield strength using either a shear theory or a strain energy of distortion theory to relate multiaxial yielding to the uniaxial case.

(11) For service levels A and B (normal and upset) conditions, the limits on primary membrane plus primary bending need not be satisfied in a component if it can be shown from the test of a prototype or model that the specified loads (dynamic or static-equivalent) do not exceed L_u, where L_u is the ultimate load or the maximum load to load combination used in the test. In using this method, account shall be taken of the size effect and dimensional tolerances which may exist between the actual part and the test part, or parts, as well as differences which may exist in the ultimate strength or other governing material properties of the actual part and the tested part to assure that the loads obtained from the test are a conservative representation of the load-carrying capability of the actual component under the postulated loading for service level A and B (normal and upset) conditions.

(12) The allowable value for the maximum range of this stress intensity is 3 S_m except for cyclic events which occur less than 1000 time during the design life of the plant. For this exception, in lieu of meeting the 3 S_m limit, an elastic-plastic fatigue analysis in accordance with ASME Section III may be performed to demonstrate that the cumulative fatigue usage attributable to the combination of these low events, plus all other cyclic events, does not exceed a fatigue usage value of 1.0.

			OR			
			KS_E	STRESS RATIO ANALYSIS[8]		

Table 3.9-24 (Cont'd)

(1) The symbols P_m, P_b, Q, and F do not represent single quantities, but rather sets of six quantities representing the six stress components σ_t, σ_l, σ_r, γ_{tl}, γ_{lr}, γ_{rt}.

(2) For configurations where compressive stresses occur, stress limits shall be revised to take into account critical buckling stresses. For external pressure, the permissible "equivalent static" external pressure shall be taken as 150% of that permitted by the rules of paragraph NB-3133 of ASME Section III. Where dynamic pressures are involved, the permissible external pressure shall satisfy the preceding requirements or be limited to 50% of the dynamic instability pressure.

(3) The triaxial stresses represent the algebraic sum of the three primary principal stresses ($\sigma_1 + \sigma_2 + \sigma_3$) for the combination of stress components. Where uniform tension loading is present, triaxial stresses should be limited to 6 S_m.

(4) L_L is the lower bound limit load with yield point equal to 1.5 S_m (where S_m is the tabulated value of allowable stress at temperature as contained in ASME Section III). The "lower bound limit load" is here defined as that produced from the analysis of an ideally plastic (nonstrain hardening) material where deformations increase with no further increase in applied load. The lower bound load is one in which the material everywhere satisfies equilibrium and nowhere exceeds the defined material yield strength using either a shear theory or a strain energy of distortion theory to relate multiaxial yielding to the uniaxial case.

(5) S_u is the ultimate strength at temperature. Multiaxial effects on ultimate strength shall be considered.

(6) This plastic analysis uses an elastic-plastic evaluated nominal primary stress. Strain hardening of the material may be used for the actual monotonic stress-strain curve at the temperature of loading or any approximation to the actual stress-strain curve which everywhere has a lower stress for the same strain as the actual monotonic curve may be used. Either the shear or strain energy of distortion flow rule shall be used to account for multiaxial effects.

(7) For service level C (emergency) conditions, the stress limits need not be satisfied if it can be shown from the test of a prototype or model that the specified loads (dynamic or static-equivalent) do not exceed 60% of L_e, where L_e is the ultimate load or the maximum load or load combination used in the test. In using this method, account shall be taken of the size effect and dimensional tolerances which may exist between the actual part and the tested part or parts as well as differences which may exist in the ultimate strength or other governing material properties of the actual part and the tested parts to assure that the loads obtained from the test are a conservative representation of the load-carrying capability of the actual component under postulated loading for service level C (emergency) conditions.

(8) Stress ratio is a method of plastic analysis which uses the stress ratio combinations (combination of stresses that consider the ratio of the actual stress to the allowable plastic or elastic stress) to compute the maximum load a strain hardening material can carry. K is defined as the section factor; $S_e \leq 2\ S_m$ for primary membrane loading.

(9) Where deformation is of concern in a component, the deformation shall be limited to two-thirds the value given for service level C (emergency) conditions in the Design Specification.

(10) When loads are transiently applied, consideration should be given to the use of dynamic load amplification and possible change in modulus of elasticity.

Table 3.9-25

MAXIMUM PRESSURE DIFFERENTIALS ACROSS REACTOR VESSEL INTERNALS DURING A STEAM LINE BREAK

Reactor Component	Pressure Differential(psid)[3] Case 1[1]	Case 2[2]
Core Plate and Guide Tube	24.5	24.5
Shroud Support Ring and Lower Shroud	48	49.0
Upper Shroud	28.0[4][5]	29.0[4][6]
Average Channel Wall (Bottom)	13.1	10.6
Top Guide	2.4	3.6[4][5]

Table 3.9-26

CORE SUPPORT STRUCTURE DESIGN LOADING
CONDITIONS AND COMBINATIONS

OPERATING CONDITION AND STRESS LIMITS	SERVICE LEVEL	DESIGN LOADINGS CONDITIONS AND COMBINATIONS
Normal and Upset	A and B	$N + A_D$ and $N + U$
Emergency	C	N and R, or other conditions which have a 40 year encounter probability from 10^{-1} to 10^{-3}
Fault	D	N and A_m and $\overline{R}$ or other conditions which have a 40 year encounter probability from 10^{-3} to 10^{-6}

where:

N	=	service level A (normal) loads
U	=	service level B (upset) loads excluding earthquake
A_D	=	½SSE including any associated transients.
A_m	=	SSE
R	=	automatic blowdown or equivalent auxiliary pipe rupture loading (pipe rupture loadings are not directly considered on piping itself because this is handled by a failure mode analysis)
$\overline{R}$	=	primary loadings which result from rupture of a main steam line or a recirculation line

Table 3.9-27

DEFORMATION LIMIT
(FOR REACTOR INTERNAL STRUCTURES ONLY)

EITHER ONE OF (NOT BOTH)		GENERAL LIMIT
a.	$\left[\frac{\text{Permissible deformation, DP}}{\text{Analyzed deformation causing loss of function, DL}}\right]$	$\leq \frac{0.9}{SF_{min}}$
b.	$\left[\frac{\text{Permissible deformation, DP}}{\text{Experiment deformation causing loss of function, DE}}\right]^{(1)}$	$\leq \frac{1.0}{SF_{min}}$

where:

DP = permissible deformation under stated conditions of service levels A, B, C or D (normal, upset, emergency or faulted)

DL = analyzed deformation which could cause a system loss of function(2)

DE = experimentally determined deformation which could cause a system loss of function

SF_{min} = minimum safety factor

(1) Equation b is not used unless supporting data are provided to the NRC by GE.

(2) "Loss of function" can only be defined quite generally until attention is focused on the component of interest. In cases of interest, where deformation limits can affect the function of equipment and components, they are specifically delineated. From a practical viewpoint, it is convenient to interchange some deformation condition at which function is assured with the loss of function condition if the required safety margins from the functioning conditions can be achieved. Therefore, it is often unnecessary to determine the actual loss of function condition because this interchange procedure produces conservative and safe designs. Examples where deformation limits apply are: CRD alignment and clearances for proper insertion, core support deformation causing fuel disarrangement or excess leakage of any component.

Table 3.9-28

PRIMARY STRESS LIMIT
(FOR SAFETY CLASS REACTOR INTERNAL STRUCTURES ONLY)

ANY ONE OF (NO MORE THAN ONE REQUIRED)		GENERAL LIMIT
a.	$\left[\frac{\text{Elastic evaluated primary stresses, PE}}{\text{Permissible primary stresses, PN}}\right]$	$\leq \frac{2.25}{SF_{min}}$
b.	$\left[\frac{\text{Permissible load, LP}}{\text{Largest lower bound limit load, CL}}\right]$	$\leq \frac{1.5}{SF_{min}}$
c.	$\left[\frac{\text{Elastic evaluated primary stresses, PE}}{\text{Conventional ultimate strength at temperature, US}}\right]$	$\leq \frac{0.75}{SF_{min}}$
d.	$\left[\frac{\text{Elastic – plastic evaluated nominal primary stress, EP}}{\text{Conventional ultimate strength at temperature, US}}\right]$	$\leq \frac{0.9}{SF_{min}}$
e.	$\left[\frac{\text{Permissible load, LP}}{\text{Plastic instability load, PL}}\right]^{(1)}$	$\leq \frac{0.9}{SF_{min}}$
f.	$\left[\frac{\text{Permissible load, LP}}{\text{Ultimate load from fracture analysis, UF}}\right]^{(1)}$	$\leq \frac{0.9}{SF_{min}}$
g.	$\left[\frac{\text{Permissible load, LP}}{\text{Ultimate load or loss of function load from test, LE}}\right]^{(1)}$	$\leq \frac{1.0}{SF_{min}}$

Table 3.9-28 (Cont'd)

where:

PE = primary stresses evaluated on an elastic basis. The effective membrane stresses are to be averaged through the load-carrying section of interest. The simplest average bending, shear or torsion stress distribution which will support the external loading will be added to the membrane stresses at the section of interest.

PN = permissible primary stress levels under service levels A or B (normal or upset) conditions under ASME Section III.

LP = permissible load under stated conditions of service levels A, B, C, or D (emergency or faulted).

CL = lower limit load with yield point equal to 1.5 S_m where S_m is the tabulated value of allowable stress at temperature of the ASME Section III Code or its equivalent. The "lower bound limit load" is here defined as that produced from the analysis of an ideally plastic nonstrain hardening material where deformations increase with no further increase in applied load. The lower bound load is one in which the material everywhere satisfies equilibrium and nowhere exceeds the defined material yield strength using either a shear theory or a strain energy of distortion theory to relate multiaxial yield to the uniaxial case.

US = conventional ultimate strength at temperature or loading which would cause a system malfunction, whichever is more limiting.

EP = elastic-plastic evaluated nominal primary stress. Strain hardening of the material may be used for the actual monotonic stress-strain curve at the temperature of loading or any approximation to the actual stress-strain curve which everywhere has a lower stress for the same strain as the actual monotonic curve may be used. Either the shear or strain energy of distortion flow rule may be used.

PL = plastic instability load. The "plastic instability load" is defined here as the load at which any load- bearing section begins to diminish its cross-sectional area at a faster rate than the strain hardening can accommodate the loss in area. This type analysis requires a true stress-true strain curve or a close approximation based on monotonic loading at the temperature of loading.

Table 3.9-28 (Cont'd)

UF = ultimate load from fracture analyses. For components which involve sharp discontinuities (local theoretical stress concentration <3) the use of a "fracture mechanics" analysis where applicable utilizing measurements of plane strain fracture toughness may be applied to compute fracture loads. Correction for finite plastic zones and thickness effects as well as gross yielding may be necessary. The methods of linear-elastic stress analysis may be used in the fracture analysis where its use is clearly conservative or supported by experimental evidence. Examples where "fracture mechanics" may be applied are for fillet welds or end of fatigue life crack propagation.

LE = ultimate load or loss of function load as determined from experiment. In using this method, account shall be taken of the dimensional tolerances which may exist between the actual part and the tested part or parts as well as differences which may exist in the ultimate tensile strength of the actual part and the tested parts. The guide to be used in each of these areas is that the experimentally determined load shall use adjusted values to account for material property and dimension variations, each of which has no greater probability than 0.1 of being exceeded in the actual part.

SF_{min} = minimum safety factor

(1) Equations e., f., and g. are not used unless supporting data are provided to the NRC by GE.

Table 3.9-29

BUCKLING STABILITY LIMIT
(FOR SAFETY CLASS REACTOR INTERNAL STRUCTURES ONLY)

ANY ONE OF (NO MORE THAN ONE REQUIRED)	GENERAL LIMIT
a. $\left[\frac{\text{Permissible load, LP}}{\text{Service level A (normal) permissible load, PN}}\right]$	$\leq \frac{2.25}{SF_{min}}$
b. $\left[\frac{\text{Permissible load, LP}}{\text{Stability analysis load, SL}}\right]$	$\leq \frac{0.9}{SF_{min}}$
c. $\left[\frac{\text{Permissible load, LP}}{\text{Ultimate buckling collapse load from test, SE}}\right]$(1)	$\leq \frac{1.0}{SF_{min}}$

where:

LP = permissible load under stated conditions of service levels A, B, C or D (normal, upset emergency or faulted)

PN = applicable service level A (normal) permissible load

SL = stability analysis load. The ideal buckling analysis is often sensitive to otherwise minor deviations from ideal geometry and boundary conditions. These effects shall be accounted for in the analysis of the buckling stability loads. Examples of this are ovality in externally pressurized shells or eccentricity on column members.

SE = ultimate buckling collapse load as determined from experiment. In using this method, account shall be taken of the dimensional tolerances which may exist between the actual part and the tested part. The guide to be used in each of these areas is that the experimentally determined load shall be adjusted to account for material property and dimension variations, each of which has no greater probability than 0.1 of being exceeded in the actual part.

SF_{min} = minimum safety factor

(1) Equation c. is not used unless supporting data are provided to the NRC by GE.

	OR	OR		
	$0.8\ L_F$ TESTS[7][11]	KS_F STRESS-RATIO ANALYSIS[8]		
	OR			
	S_F STRESS-RATIO ANALYSIS[8]			

Table 3.9-30 (Cont'd)

(1) The symbols P_m, P_b, Q, and F do not represent single quantities, but rather sets of six quantities representing the six stress components δ_t, δ_l, δ_r, γ_{tl}, γ_{tr}, γ_{rl}.

(2) When loads are transiently applied, consideration should be given to the use of dynamic load amplification and possible changes in modulus of elasticity.

(3) For configurations where compressive stresses occur, stress limits take into account critical buckling stresses. For external pressure the permissible "equivalent static" external pressure shall be taken as 2.5 times that given by the rules of paragraph NB-3133 of ASME Section III. Where dynamic pressures are involved, the permissible external pressure satisfies the preceding requirements or be limited to 75% of the dynamic instability pressure.

(4) L_L is the lower bound limit load with yield point equal to 1.5 S_m (where S_m is the tabulated value of allowable stress at temperature as contained in ASME Section III). The "lower bound limit load" is defined as that produced from the analysis of an ideally plastic (nonstrain hardening) material where deformations increase with no further increase in applied load. The lower bound load is one in which the material everywhere satisfies equilibrium and nowhere exceeds the defined material yield strength using either a shear theory or a strain energy of distortion theory to relate multiaxial yielding to the uniaxial case.

(5) S_u is the ultimate strength at temperature. Multiaxial effects on ultimate strength are considered.

(6) This plastic analysis uses an elastic-plastic evaluated nominal primary stress. Strain hardening of the material may be used for the actual monotonic stress-strain curve at the temperature of loading or any approximation to the actual stress-strain curve which everywhere has a lower stress for the same strain as the actual monotonic curve may be used. Either the maximum stress or strain energy of distortion flow rule shall be used to account for multiaxial effects.

(7) For service level D (fault) conditions, the stress limits need not be satisfied if it can be shown from the test of a prototype or model that the specified loads (dynamic or static-equivalent) do not exceed 80% of L_F, where L_F is the ultimate load or load combination used in the test. In using this method, account is taken of the size effect and dimensional tolerances, as well as differences which may exist in the ultimate strength or other governing material properties of the actual part and the tested parts, to assure that the loads obtained from the test are a conservative representation of the load-carrying capability of the actual component under postulated loading for service level D (fault) condition.

(8) Stress ratio is a method of plastic analysis which uses the stress ratio combinations (combination of stresses that consider the ratio of the actual stress to the allowable plastic or elastic stress) to compute the maximum load a strain hardening material can carry. K is defined as the section factor; S_f is the lesser of 2.4 S_m or 0.75 S_u for primary membrane loading.

(9) Where deformation is of concern in a component, the deformation is limited to 80% of the value given for service level D (fault) conditions in the Design Specifications.

(10) 0.7 S_u per ASME Section III Appendix F.

(11) Same as ASME Section III Appendix F.

(12) 3.6 S_m per ASME Section III Appendix F.

3.10 QUALIFICATION OF SEISMIC CATEGORY I INSTRUMENTATION AND ELECTRICAL EQUIPMENT

The dynamic qualification criteria applicable to the seismic Category I instruments, electrical equipment, and their supports are provided in this section. The methods and procedures used to qualify them are also discussed. Seismic Category I instruments, equipment, and supporting structures are identified in Table 3.2-1.

3.10.1 DYNAMIC QUALIFICATION CRITERIA

The seismic Category I instruments and electrical equipment are designed to withstand the effects of the SSE defined in Section 3.7 and the hydrodynamic loads discussed in Section 3.9 and Appendix 3A.4 through 3A.7 without functional impairment.

The qualification discussion covered in the following sections is generally divided into two types of equipment: NSSS equipment and non-NSSS equipment.

The following design criteria and qualification procedures for NSSS equipment include the effects of both seismic and hydrodynamic loads. The non-NSSS equipment qualification discussions include only seismic design criteria and procedures. Refer to Appendix 3A.6.8 and 3A.7.1.7 for non-NSSS equipment subjected to hydrodynamic loads. Appendix 3A.6.7 and 3A.7.1.6 contain further discussion of NSSS equipment qualification.

There is a Risk Informed Categorization and Treatment Program at Limerick which is based on 10 CFR 50.69. This regulation provides an alternative approach for establishing requirements for treatment of SSCs using a risk-informed method of categorizing SSCs according to their safety significance. Specifically, for SSCs categorized as low safety significant, alternate treatment requirements may be implemented rather than treatments chosen by the seismic qualification program. Refer to Section 13.5.5 for further information.

3.10.1.1 Dynamic Loading Design Criteria (NSSS Equipment)

The criterion used in the design and subsequent qualification of all Class 1E instruments and electrical equipment supplied by GE is as follows: "The Class 1E equipment shall be capable of performing all safety-related functions during (1) normal plant operation, (2) anticipated transients, (3) DBAs, and (4) postaccident operation while being subjected to, and after the cessation of, the accelerations resulting from the SSE and hydrodynamic loads at the point of attachment of the equipment to the building or supporting structure."

The criteria for each of the devices used in the Class 1E systems depend on the use in a given system; for example, a relay in one system may have as its safety function to de-energize and open its contacts within a certain time, while in another system it must energize and close its contacts. Since GE supplies many devices for many applications, the approach taken was to test the device in the worst case configuration. In this way, the capability of protective action initiation and the proper operation of safety-related circuits is assured.

From the basic input ground motion data, a series of response curves at various structure elevations is developed after the building layout is completed. Standard requirement levels that meet or exceed the maximum expected unique plant information are included in the purchase specifications for seismic Category I equipment. Suppliers of equipment such as batteries and racks, instrument racks, control consoles, etc., are required to submit test data, operating

experience and/or calculations to substantiate that their components, systems, etc will not suffer loss of function during or after dynamic loadings. The magnitude and frequency content of the loadings which each component will experience are determined by its specific location within the plant. All Class 1E equipment will be evaluated for the capability of performing its safety function during and after dynamic loading combinations given in Table 3.9-6.

3.10.1.2 Dynamic Loading Design Criteria (Non-NSSS Equipment)

The seismic Category I instruments and electrical equipment is the equipment that is designed to maintain its functional capability and/or to maintain the pressure boundary integrity during and after an SSE and at least 5 OBEs. (Refer to Appendix 3A.6.8 for criteria for equipment subjected to hydrodynamic loads.)

Seismic Category I equipment is designed to withstand the more severe of the following load combinations:

a. OBE Conditions:

The load combinations include gravity loads and operation loads (or LOCA loads, if applicable) including associated temperatures and pressures, combined with the seismic loading of an OBE.

Stresses in the structural steel portions may be increased to 125% of the allowable working stress limits accepted as good practice as set forth in the appropriate design standards; that is, AISC Manual of Steel Construction, ASME B&PV Code, ANSI B31.1 and B31.7 codes for pressure piping, or other equivalent industrial codes. The resulting deflections do not prevent continuous normal operation of the equipment during and after the seismic disturbance.

b. SSE Conditions:

The load combinations include gravity loads and operating loads (or LOCA loads, if applicable) including associated temperatures and pressures combined with the seismic loading of the SSE. Stresses in the structural portions may be increased to 150% of code allowable working stress limits but are not to exceed 0.9 F_y in bending, 0.85 F_y for tension, and 0.5 F_y in shear, where (F_y) equals the material yield stress at the design temperature. The resulting deflections will not prevent the operation of the equipment during and after the seismic disturbance.

The performance requirements of the seismic Category I items and their respective supports are structural as well as functional. Where applicable, the structural requirements are in accordance with AISC "Specifications for the Design, Fabrication, and Erection of Structural Steel for Buildings," adopted February 12, 1969, or similar codes applicable for other construction materials.

The structural requirements for electrical and instrumentation equipment and systems that are required to maintain pressure boundary integrity are in accordance with the ASME Section III.

3.10.2 METHODS AND PROCEDURES FOR QUALIFYING ELECTRICAL EQUIPMENT AND INSTRUMENTATION

Seismic Category I instruments and electrical equipment are qualified according to the criteria discussed in Section 3.10.1 by the methods and procedures described in this section. The qualification methods and procedures are discussed in two parts: NSSS and non-NSSS equipment; both of which were re-assessed to SRP 3.10 Seismic Qualification Review Team (SQRT) requirements including IEEE 344-1975, and Reg. Guides 1.10 and 1.92. The SQRT re-assessment concluded that the seismic and dynamic qualification program meets the intent of IEEE 344-1975 and Reg. Guides 1.100 and 1.92.

3.10.2.1 Methods and Procedures for Qualifying NSSS Electrical Equipment and Instruments (Excluding Motors and Valve-Mounted Equipment)

3.10.2.1.1 Methods of Showing NSSS Equipment Compliance with IEEE 344 (1975) and Regulatory Guide 1.100

Originally, NSSS equipment were qualified to IEEE 344 (1971), which was the plant commitment, and as such did not demonstrate compliance with Regulatory Guide 1.100 and other SQRT criteria. However, a re-assessment of all NSSS equipment qualifications to NEDE-24788 "SQRT Technical Approach" ensures an adequate degree of equipment conformance to IEEE 344-1975 and Regulatory Guides 1.100 and 1.92 requirements which represents an acceptable basis for qualifying the equipment.

GE-supplied Class 1E equipment meets the requirement that the dynamic qualification should demonstrate the capability to perform the required function during and after the dynamic event. Both analysis and testing were used, but most equipment was tested. Analysis was primarily used to determine the adequacy of mechanical strength (mounting bolts, etc) after operating capability was established by testing.

a. Analysis

GE-supplied Class 1E equipment performing primarily a mechanical safety function (pressure boundary devices, etc) was analyzed, since the passive nature of its critical safety role usually made testing impractical. Analytical methods sanctioned by IEEE 344 (1971) were used in such cases and were re-evaluated to IEEE 334 (1975) criteria with satisfactory results. Table 3.10-1 shows which items were qualified by analysis.

b. Testing

GE-supplied Class 1E equipment having primarily an active electrical safety function was tested in compliance with IEEE 344 (1971), section 3.2 and were re-evaluated to IEEE 344 (1975) criteria with satisfactory results.

Available documentation verifies that the dynamic qualification of GE-supplied Class 1E equipment is in accordance with the requirements of IEEE 344 (1975).

3.10.2.1.2 Testing Procedures for Qualifying NSSS Electrical Equipment and Instruments (Excluding Motors and Valve-Mounted Equipment)

The test procedure requires that the device be mounted on the table of the vibration machine in a manner similar to how it is normally installed. The device is tested in the operating states as if it were performing its Class 1E functions and these states are monitored before, during, and after the test to assure proper function and absence of spurious function. In the example of a relay, both

energized and de-energized states and normally open and normally closed contact configurations are tested if the relay is used in those configurations in its Class 1E functions.

The dynamic excitation is a single-frequency test in which the applied vibration is a sinusoidal table motion at a fixed peak acceleration and a discrete frequency at any given time. The vibratory excitation is applied in three orthogonal axes individually, with the axes chosen as those coincident with the most probable mounting configuration.

The first step is to search for resonances in each axis. This is done because resonances cause amplification of the input vibration and are the most likely cause of malfunction. The resonance search is usually run at low acceleration levels (0.2 g) to avoid damaging the test sample in case a severe resonance is encountered. The resonance search is run in accordance with IEEE 344; if the device is large enough, the vibrations are monitored by accelerometers placed at critical locations, from which resonances are determined by comparing the acceleration level with that at the table of the vibration machine. If the devices are either too small for an accelerometer, have their critical parts in an inaccessible location, or have critical parts that would be adversely affected by the mounting of an accelerometer, the vibrations are monitored at the closest location.

Following the frequency scan and resonance determination, the devices are tested to determine their malfunction limit. This test is a necessary adjunct to the assembly test, as shown later. The malfunction limit test is run at each resonant frequency as determined by the frequency scan. In this test, the acceleration level is gradually increased until either the device malfunctions or the limit of the vibration machine is reached. If no resonances are detected (as is usually the case), the device is considered to be rigid (all parts move in unison), and the malfunction limit is therefore independent of frequency. To achieve maximum acceleration from the vibration machine, rigid devices are malfunction tested at the upper test frequency because that allows the maximum acceleration to be obtained from deflection-limited machines.

The summary of the tests on the devices used in Class 1E applications given in Table 3.10-1 includes the "qualification" limit for each device tested.

The above procedures are required of purchased devices, as well as of those made by GE. Vendor test results are reviewed, and, if unacceptable, the tests are repeated either by GE or by the vendor. If the vendor tests are adequate, the device is considered qualified to the limits of the test.

3.10.2.1.3 Qualification of Valve-Mounted Equipment

The piping analysis establishes the response spectra, the power spectral density function or time history characteristics, and develops horizontal and vertical accelerations for the pipe-mounted equipment. Class 1E MOV actuators are qualified in accordance with IEEE 382 (1972).

The SRV, including the electrical components mounted on the valve, is subjected to a dynamic test. This testing is described in Sections 3.9.2.2a.2.14 and 3.9.3.1.13.

3.10.2.1.4 Qualification of NSSS Motors

The seismic qualification of the ECCS motors is discussed in Section 3.9.2.2a.2.7 in conjunction with the ECCS pump and motor assembly. The seismic qualification of the SLCS pump motor is discussed in Section 3.9.2.2a.2.10 in conjunction with the SLC pump motor assembly.

3.10.2.2 Methods and Procedures for Qualifying Non-NSSS Instruments and Electrical Equipment

In regard to compliance with Regulatory Guide 1.100, the analysis and testing for the seismic qualification of non-NSSS Class 1E instruments and electrical equipment required to function during and after an SSE are in compliance with IEEE 344 (1971) for components purchased before issuance of IEEE 344 (1975) and are in compliance with IEEE 344 (1975) for components purchased after its issuance. In addition, all non-NSSS instruments and controls were re-evaluated to IEEE 344 (1975) and Reg. Guide 1.100 requirements (SQRT requirements) and found satisfactory.

Pipe-mounted instrumentation is qualified by analysis and/or testing to the acceleration levels allowed for piping systems. These levels include gravity and operation loading, as well as loading that is due to seismic excitation. Passive instruments that must only maintain mechanical and pressure boundary integrity are tested to the acceleration levels of the response spectra for the area in which they are to be installed.

Seismic Category I equipment is shown to be capable of withstanding the horizontal and vertical accelerations of five OBEs and one SSE by one of the following methods: dynamic analysis; dynamic testing; or a combination of dynamic analysis and testing. (Refer to Appendix 3A.7.1.7 for qualification methods for equipment subjected to hydrodynamic loads.)

3.10.2.2.1 Dynamic Analysis

For the analysis, equipment is idealized as a system of lumped masses and springs for which frequencies and mode shapes are determined for vibration in the vertical direction and two orthogonal horizontal directions. For each direction of vibration, the spectral accelerations per mode are obtained from the appropriate spectrum response curve corresponding to the location and damping of the equipment. Seismic loading in terms of inertia forces, moments, and shears is determined for each direction using the spectrum response method summing the absolute values per mode. If the orientation of the equipment is not designated, the horizontal seismic loading is taken as the maximum loading (worst case) obtained using each horizontal direction of vibration and the appropriate horizontal spectrum response curve(s). If the frequencies of all equipment modes (determined by either analysis or testing) are greater than the frequency of the appropriate spectrum response curve at which the acceleration is constant in the rigid (high frequency) range, the seismic loading consists of the static loading corresponding to that acceleration level.

If the equipment damping is unknown, the following values shall be used:

a. OBE - ½% damping

b. SSE - 1% damping

In lieu of determining the vibrational frequencies of equipment, the seismic loading of structurally simple equipment (that can be adequately represented as a single mass and spring) consists of a static load corresponding to 1.5 times the peak acceleration of the appropriate response spectrum curve. Total seismic loading consists of both the vertical seismic loading and the maximum horizontal seismic loading applied to the equipment simultaneously.

Where equipment must meet IEEE 344 (1975), the dynamic analysis is in accordance with section 5 of IEEE 344 (1975). Equipment qualified by analysis to IEEE 344 (1971) were re-evaluated to IEEE 344 (1975) criteria and found satisfactory.

3.10.2.2.2 Dynamic Tests

In lieu of performing a dynamic analysis, seismic adequacy is established by providing dynamic test or previous dynamic environmental (performance) data that demonstrate that the equipment meets the seismic design criteria as defined in this section. The previous data include at least one of the following:

a. Recent test data acquired from dynamic tests of equipment

b. Dynamic test data from previously tested comparable equipment

c. Performance data from equipment that, during normal operating conditions, is subjected to dynamic loads equal to or greater than those defined in this section

3.10.3 METHODS AND PROCEDURES OF ANALYSIS OR TESTING OF SUPPORTS OF ELECTRICAL EQUIPMENT AND INSTRUMENTATION

3.10.3.1 Dynamic Analysis Testing Procedures And Restraint Measures For NSSS Equipment Supports (Other Than Motors And Valve-Mounted Equipment)

Some GE-supplied Class 1E devices are qualified by analysis only (Table 3.10-1). Analysis is used for passive mechanical devices and sometimes is used in combination with testing for larger assemblies containing safeguard devices. For instance, a test may be run to determine if there are natural frequencies in the equipment within the critical frequency range. If the equipment is determined to be free of natural frequencies, then it is assumed to be rigid and a static analysis is performed. If the equipment has natural frequencies in the critical frequency range, then calculations of transmissibility are performed and responses to varying input accelerations are determined to see whether Class 1E devices mounted in the assembly would operate without malfunctioning. In general, the testing of Class 1E equipment is accomplished using the following procedure.

Assemblies (i.e., control panels) containing devices that have had dynamic loading malfunction limits established are tested by mounting the assembly on the table of a vibration machine, in a manner similar to that in which it is to be mounted when in use, and vibration testing the assembly by running a low level resonance search. As with the devices, the assemblies are tested in the three major orthogonal axes. The resonance search is run in the same manner as described for devices. If resonances are present, the transmissibility between the input and the locations of each Class 1E device is determined by measuring the accelerations at each device location and calculating the magnification between it and the input. Once known, the transmissibilities could be used analytically to determine the response at any Class 1E device location for any given input. It is assumed that the transmissibilities are linear as a function of acceleration, even though they actually decrease as acceleration is increased; therefore, this is a conservative assumption. As long as the device input accelerations are determined to be below their malfunction limits, the assembly is considered a rigid body with a transmissibility equal to 1, so that a device mounted on it is limited directly by the assembly input acceleration.

Since control panels and racks constitute the majority of seismic Category I electric assemblies supplied by GE, the qualification testing of these is discussed in more detail. There are basically four generic panel types: vertical board; instrument rack; local rack; and NEMA-12 enclosures. One or more of each type is tested using the above procedures.

Figures 3.10-1 through 3.10-4 illustrate the four basic panel types referenced above and show typical accelerometer locations. The status of the dynamic tests on the Class 1E panels supplied by GE for LGS is summarized in Table 3.10-2.

The full acceleration level tests described above disclose that most of the panel types have more than adequate mechanical strength and that a given panel design acceptability is just a function of its amplification factor and the malfunction levels of the devices mounted in it. Subsequent panels are therefore tested at lower acceleration levels, and the transmissibilities are measured to the various devices as described above. By dividing the devices' malfunction levels by the panel transmissibility between the device and the panel input, the panel qualification level can be determined. Several high level tests have been run on selected generic panel designs to assure the conservatism in using the transmissibility analysis described.

3.10.3.2 Non-NSSS Equipment Supports

Analyses or tests are performed for all supports of electrical equipment and instruments, such as switchgear, battery racks, instrument racks, control consoles, cabinets, and panels to ensure their structural capability to withstand seismic excitation.

The following bases are used in the seismic design and analysis of seismic Category I instrument tubing supports:

a. All instrument tubing supports are qualified by analysis, using the response spectrum method described in Section 3.10.2.2.1.

b. Analysis and design of seismic restraint measures for instrument tubing supports are based on combined limiting values for static load, span length, and computed seismic response.

c. Maximum stress is limited to 90% of minimum yield stress.

d. The seismic Category I instrument tubing systems are supported so that the allowable stresses permitted by ASME Section III are not exceeded when the tubing is subjected to the loads specified in Section 3.9 for Class 2 and 3 piping.

For field-mounted instruments, the following are applicable. (Refer to Appendix 3A.7.1.7 for instrument supports subjected to hydrodynamic loads.)

a. The mounting structures for seismic Category I instruments have a fundamental frequency of 33 Hz or higher (rigid range), which corresponds to the maximum floor acceleration. Therefore the ZPA for the installation is applicable.

b. The stress level in the mounting structure does not exceed the material allowable stress when the mounting structure is subjected to the maximum acceleration level for its location, in combination with other design loads.

3.10.4 OPERATING LICENSE REVIEW

3.10.4.1 NSSS Equipment

3.10.4.1.1 NSSS Control and Electrical Equipment (Other Than Motors and Valve-Mounted Equipment)

The qualification test plans and results for safety-related panels and control equipment within the NSSS scope of supply are maintained as follows:

a. Proprietary documents will be maintained by GE in a centrally located, readily auditable, permanent file.

b. Nonproprietary summary documents will be maintained by the licensee in a centrally located, readily auditable, permanent file.

If equipment fails to pass the tests, it is rejected. In some cases, equipment that fails one test is modified or repaired to meet the performance requirements and is retested. If the retested equipment passes the latter test, it may be used in a Class 1E application.

Table 3.10-1 lists the NSSS control devices by item number and vendor. The table also gives the corresponding acceleration levels for the devices used in Class 1E applications. The acceleration level shown in the right columns of Table 3.10-1 is the acceleration at which either the device malfunctioned or the limit of the vibration machine was reached.

3.10.4.1.2 NSSS Motors

Qualification test results for the ECCS motors are discussed in Section 3.9.2.2a.2.7 in conjunction with the ECCS pump and motor assembly. Qualification test results for the SLCS motor are discussed in Section 3.9.2.2a.2.10 in conjunction with the SLCS pump motor assembly.

3.10.4.1.3 Valve-Mounted Equipment

The SRVs, including the electrical components mounted on the valves, are subjected to dynamic tests. The results of these tests are discussed in Sections 3.9.2.2a.2.14 and 3.9.3.1.13, and are maintained in the same manner as discussed in Section 3.10.4.1.1.

3.10.4.2 Non-NSSS Equipment

A list of dynamic qualification packages for non-NSSS safety-related instruments and electrical equipment is given in Table 3.10-3. The qualification packages will be maintained by the licensee in a centrally located, readily auditable permanent file.

3.11 ENVIRONMENTAL DESIGN OF ELECTRICAL EQUIPMENT

This description provides a summary of the information addressed and substantiated in the separate Environmental Qualification Report (Section 1.1). The EQR identifies and documents the licensee's program for the environmental qualification of safety-related electric equipment installed in the LGS, in accordance with 10CFR50.49.

3.11.1 ENVIRONMENTAL DESIGN CRITERIA FOR ELECTRICAL EQUIPMENT

All safety-related equipment must be capable of performing its safety function and/or remaining in a safe mode under all conditions postulated to occur during its installed life. This requirement is embodied in GDC 1, 2, 4, and 23 of 10CFR50, Appendix A, in Criterion III and Criterion XI of 10CFR50, Appendix B, 10CFR50.55a(h), which incorporates by reference IEEE 279 (1971), "Criteria for Protection Systems for Nuclear Power Generating Stations," and in 10CFR50.49.

The NRC has issued definitive criteria in NUREG-0588, "Interim Staff Position on Environmental Qualification of Safety-Related Electrical Equipment", which contains the following criteria:

a. Category I, for plants whose construction permit SERs were issued after July 1, 1974, incorporates and supplements IEEE 323 (1974).

b. Category II, for plants whose construction permit SERs were issued before July 1, 1974, incorporates and supplements IEEE 323 (1971) unless the operating license applicant's record indicates that IEEE 323 (1974) is to be used, in which case Category I criteria are applicable.

The LGS construction permit SER was issued in June 1974, therefore, NUREG-0588 Category II criteria are applicable.

In February 1980 and June 1982, the NRC requested that the licensee perform a review of their environmental qualification program for safety-related equipment to identify the degree to which the program complied with the regulatory criteria. The EQR has been developed to provide detailed information on the LGS EQ program. The following sections provide a summary of the information contained in the EQR including mild environment qualification.

There is a Risk Informed Categorization and Treatment Program at Limerick which is based on 10 CFR 50.69. This regulation provides an alternative approach for establishing requirements for treatment of SSCs using a risk-informed method of categorizing SSCs according to their safety significance. Specifically, for SSCs categorized as low safety significant, alternate treatment requirements may be implemented rather than treatments chosen by the environmental qualification program. Refer to Section 13.5.5 for further information.

3.11.2 EQUIPMENT REQUIRING ENVIRONMENTAL QUALIFICATION

The list of equipment that is included in the environmental qualification program was established by considering those systems which are required to mitigate the consequences of a LOCA or HELB. This list also includes certain postaccident monitoring equipment. This list specifically includes the equipment required to achieve or support (1) emergency reactor shutdown, (2) containment isolation (3) reactor core cooling, (4) containment heat removal, (5) core residual heat removal, and (6) prevention of significant release of radioactive material to the environment.

Subsequent to identifying the equipment requiring qualification, equipment locations are identified using design drawings and are verified, where practicable, by field inspection. Equipment locations are identified by architectural room numbers with defined boundaries.

3.11.3 ENVIRONMENTAL SERVICE CONDITIONS

Environmental conditions have been determined for normal, abnormal, and accident conditions.

All areas inside containment and rooms containing high energy lines or post-LOCA recirculatory fluid lines outside of containment are considered to be harsh environments.

3.11.3.1 Environmental Conditions During Normal Plant Operation

Redundant plant HVAC systems are designed to maintain the temperature and humidity within the normal limits which are shown in the EQR. Section 9.4 describes the HVAC system.

The TID for normal operation for 40 years of equipment life have been calculated assuming a 100% load factor and rated power. The doses are based on the design radiation source terms of the radiation sources within each plant area.

Aging effects on all equipment are considered in the qualification program to conform to the requirements of section 4 of NUREG-0588. Components susceptible to aging effects are identified, and refurbishment and/or replacement is incorporated into the LGS Preventive Maintenance/Surveillance Program. Known susceptibility to aging degradation, results of inspections and manufacturer's recommendations are factored into the Maintenance/Surveillance Program.

Effects of known normal vibratory loads on equipment are considered in the EQ program when significant.

3.11.3.2 Accident Environmental Conditions

Operability duration requirements have been determined based on the length of time the equipment must maintain its ability to perform its safety function.

The primary containment time-dependent pressure and temperature profiles for the spectrum of postulated LOCAs and main steam line breaks have been generated using NRC approved methodology.

Temperature and pressure conditions resulting from a HELB outside containment have been determined using plant specific profiles. These profiles bound accident environments caused by other events. Sections 3.6 and 9.4 describe the analyses used in generating these profiles. Additional information is contained in the EQR.

Post-LOCA radiation doses inside primary and secondary containments were calculated in accordance with NUREG-0737, item II.B.2. The source terms are consistent with those specified in NUREG-0588 and NUREG-0737. Additional information is contained in Section 1.13.

Dynamic qualification of equipment due to seismic and hydrodynamic loads from SRV and LOCA is addressed in Section 3.10 and Appendix 3A.7.1.7.

The potential for submergence of equipment inside and outside containment is identified. Identified equipment is either qualified for submergence or analyzed to ensure both that it completes its function prior to submergence and that failure after submergence is acceptable. If these conditions cannot be met, the equipment will be relocated above flood level.

LGS has the capability of water spray actuation to mitigate the effects of a LOCA. Although no credit for spray actuation has been taken in determining temperature/pressure conditions inside containment, equipment inside containment is evaluated for the effects of spray.

Synergistic effects, where known, are considered. Specifically, where a supplier has identified synergisms or where the licensee is aware of synergistic effects for a particular component, it has been addressed. Appropriate documentation is included in the qualification file.

Margins appropriate to account for unquantified uncertainties in the effects of production variations and/or inaccuracies in test instruments are included in the qualification program.

3.11.4 QUALIFICATION TESTING AND ANALYSIS OF EQUIPMENT

All qualification testing and analysis of safety-related electrical equipment is performed according to the appropriate NUREG-0588 guidelines. Sequential testing and analysis or a combination thereof is performed for all electrical equipment. Analyses, performed on a case-by-case basis, have been conducted using approved methodologies to provide adequate justification.

3.11.5 METHODOLOGY FOR EVALUATING ENVIRONMENTAL QUALIFICATION TO SERVICE CONDITIONS

A comparison of environmental qualification to equipment service conditions is performed for all equipment located in harsh environmental zones. The equipment is evaluated for the 40 year normal environment and accident environments resulting from the spectrum of LOCAs and HELBs inside and outside containment. A point-by-point comparison is made between service condition parameters and qualified levels.

In addition, reviews and analyses were completed to ensure that the equipment tested was either identical or similar to the installed plant equipment.

3.11.6 MAINTENANCE/SURVEILLANCE PROGRAM

A Maintenance/Surveillance Program has been developed to encompass vendor prescribed maintenance procedures and periodic inspections of equipment to ensure that degradation is not occurring sooner than predicted. The program requires replacement of subcomponents (e.g., seals, gaskets, etc) at predetermined intervals to maintain the designated life. In addition, the program encompasses procedures to ensure that the environment is maintained relatively clean to avoid the possible adverse effects of dust.

3.11.7 REPLACEMENT PARTS PROGRAM

Safety-related equipment and spare and replacement parts are being ordered to meet or exceed the original specifications. For replacement parts being procured from the original specification and which are identical to the originally supplied equipment, a certificate of conformance is considered sufficient documentation to support qualification. However, if identical replacement parts are not available, environmental qualification for the new replacement parts will be demonstrated.

3.11.8 MILD ENVIRONMENT QUALIFICATION

Mild environment qualification is not included in the EQ program. A mild environment is an environment that would at no time be significantly more severe than the environment that would occur during normal plant operation, including anticipated operational occurrences.

3.12 CONTROL OF HEAVY LOADS

3.12.1 Introduction/Licensing Background

Site Licensing documentation is discussed in Section 1.12 (Subsection A-36) of the LGS UFSAR. Section 1.12 states "requirements for heavy loads, NUREG-0612, were addressed in the initial operating license review." Section 1.12 mentions a submittal dated August 13, 1984, which includes Bechtel Revision 3 of the LGS Overhead Handling Systems Review Final Report. Limerick Generating Station, Limerick Units 1 and 2, Overhead Handling Systems Review Final Report, Bechtel Revision 6/PECO Revision 1 (SDOC M-038-00008), August 1989 is incorporated in the LGS UFSAR as reference 9.1-1. The report summarizes the site correspondence to and from the NRC with respect to GL 81-07 and GL 85-11. Licensee submittal dated May 10, 1996, in response to NRC Bulletin 96-02 determines that at the time, NUREG-0612, Phase I commitments were being effectively implemented at LGS.

3.12.2 Safety Basis

UFSAR Section 1.12 (Subsection A-36) provides documentation of the site's compliance with Phase I of NUREG-0612 and Overhead Handling Systems Review Final Report (Reference 9.1-1) provides documentation that the site utilizes a single failure proof crane for RPVH/specified lifts and performed load drop analysis that demonstrates the fuel in the RPV will not be damaged and by providing electrical or mechanical interlocks on the crane to prevent travel of crane over spent fuel pool.

3.12.3 Scope of Heavy Load Handling Systems

The scope of load handling systems is documented in tabular form in M-038-00008 (Reference 9.1-1).

3.12.4 Control of Heavy Loads Program

3.12.4.1 Commitments in Response to NUREG-0612, Phase I Elements

The station is committed to NUREG-0612, Phase I elements as summarized in section 1.12 (Subsection A-36) of the LGS UFSAR. Detailed information is documented in M-038-00008 (Reference 9.1-1).

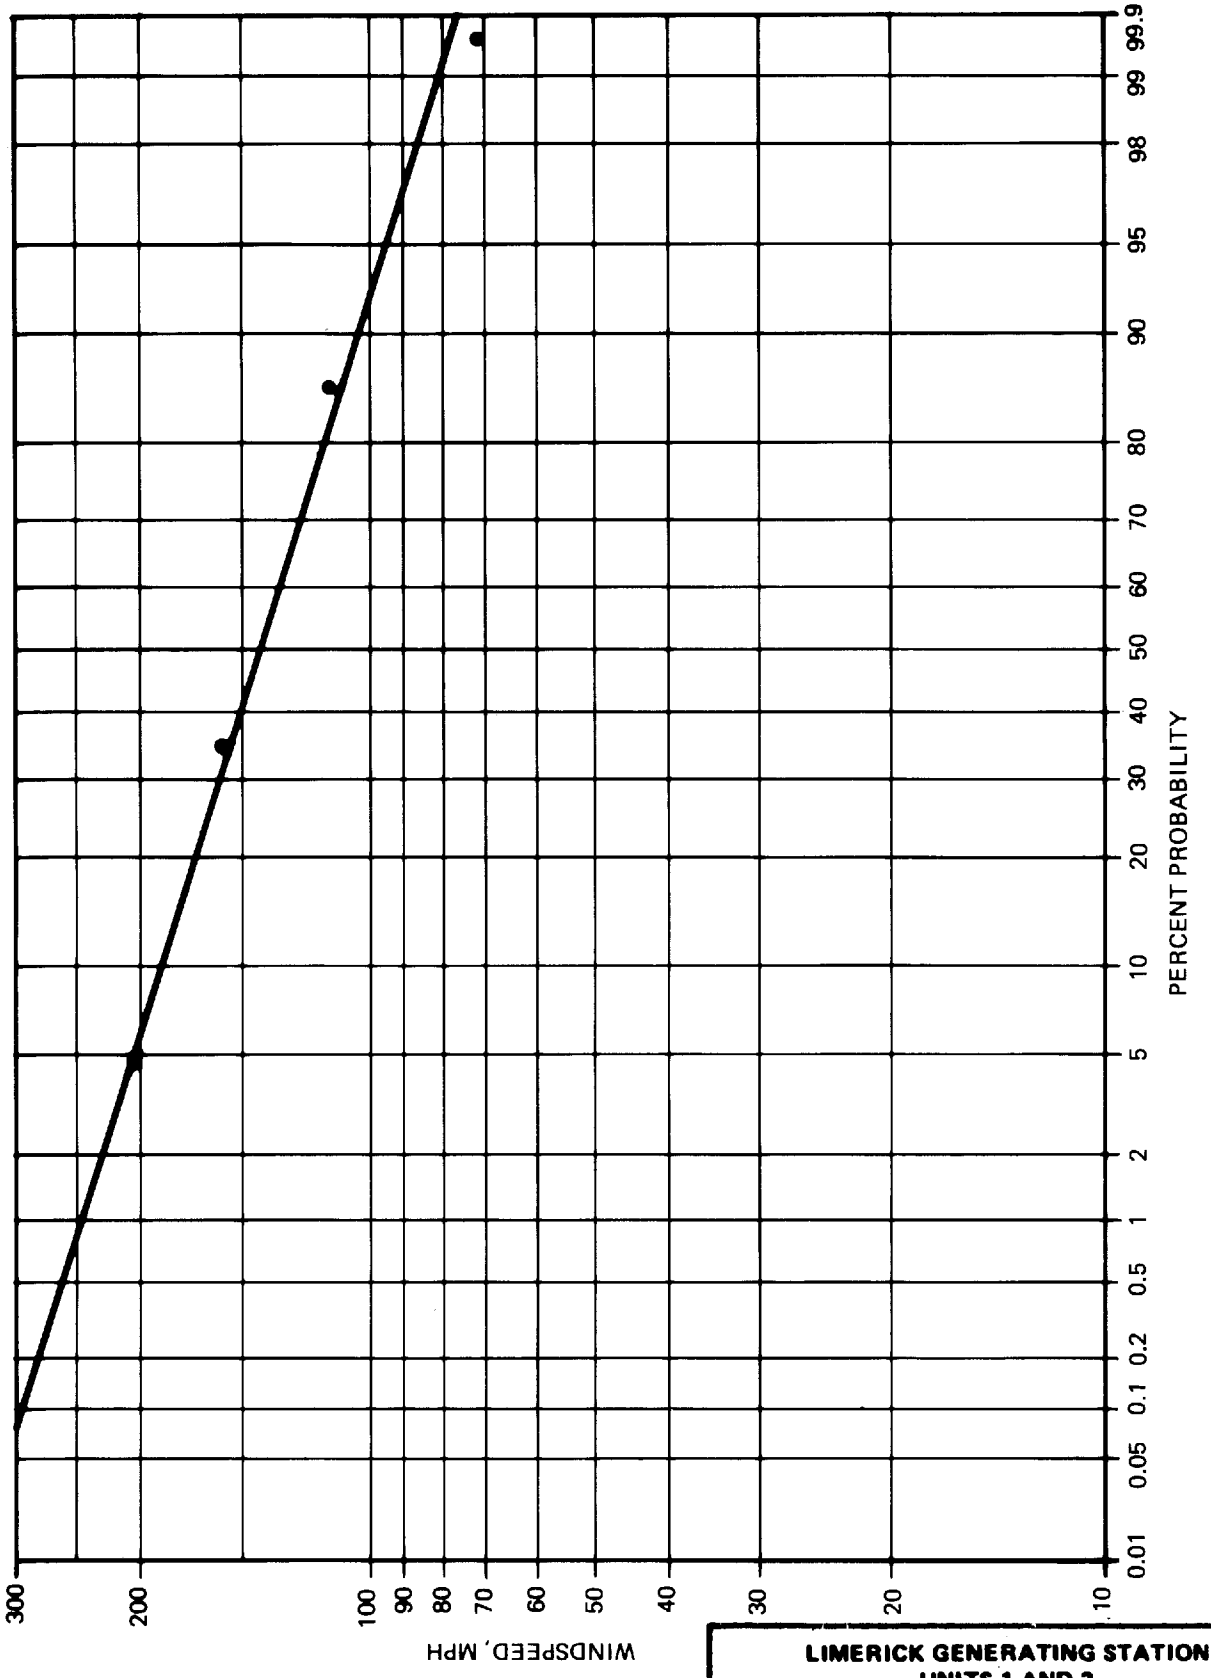
3.12.4.2 Reactor Pressure Vessel Head (RPVH) Lifting Procedures

The LGS UFSAR documents a single failure proof crane to be utilized to perform RPV head lifts in UFSAR Section 9.1.5 and is also documented further in reference 9.1- 1 (SDOC M-038-00008). In addition, the strong back/carousel used as a special lifting device for this evolution is single failure proof per UFSAR Section 9.1.4.2.5.8.

This safety basis (single failure proof lift for RPVH) is reflected in procedures M-041-200 (Reactor Pressure Vessel Disassembly) and M-041-400 (Reactor Pressure Vessel Reassembly).

3.12.4.3 Single Failure Proof Cranes for Spent Fuel Casks

The spent fuel cask will be equipped with lifting lugs and yoke(s) which are single failure proof and compatible with the single failure proof reactor enclosure crane and main hook, thus precluding a cask-drop due to a single failure (UFSAR section 15.7.5). Refer to Section 9.1.5 for a description of the reactor enclosure crane and the interlocks that prevent moving the crane over the fuel pool in the absence of specific action by the crane operator to allow such movement.

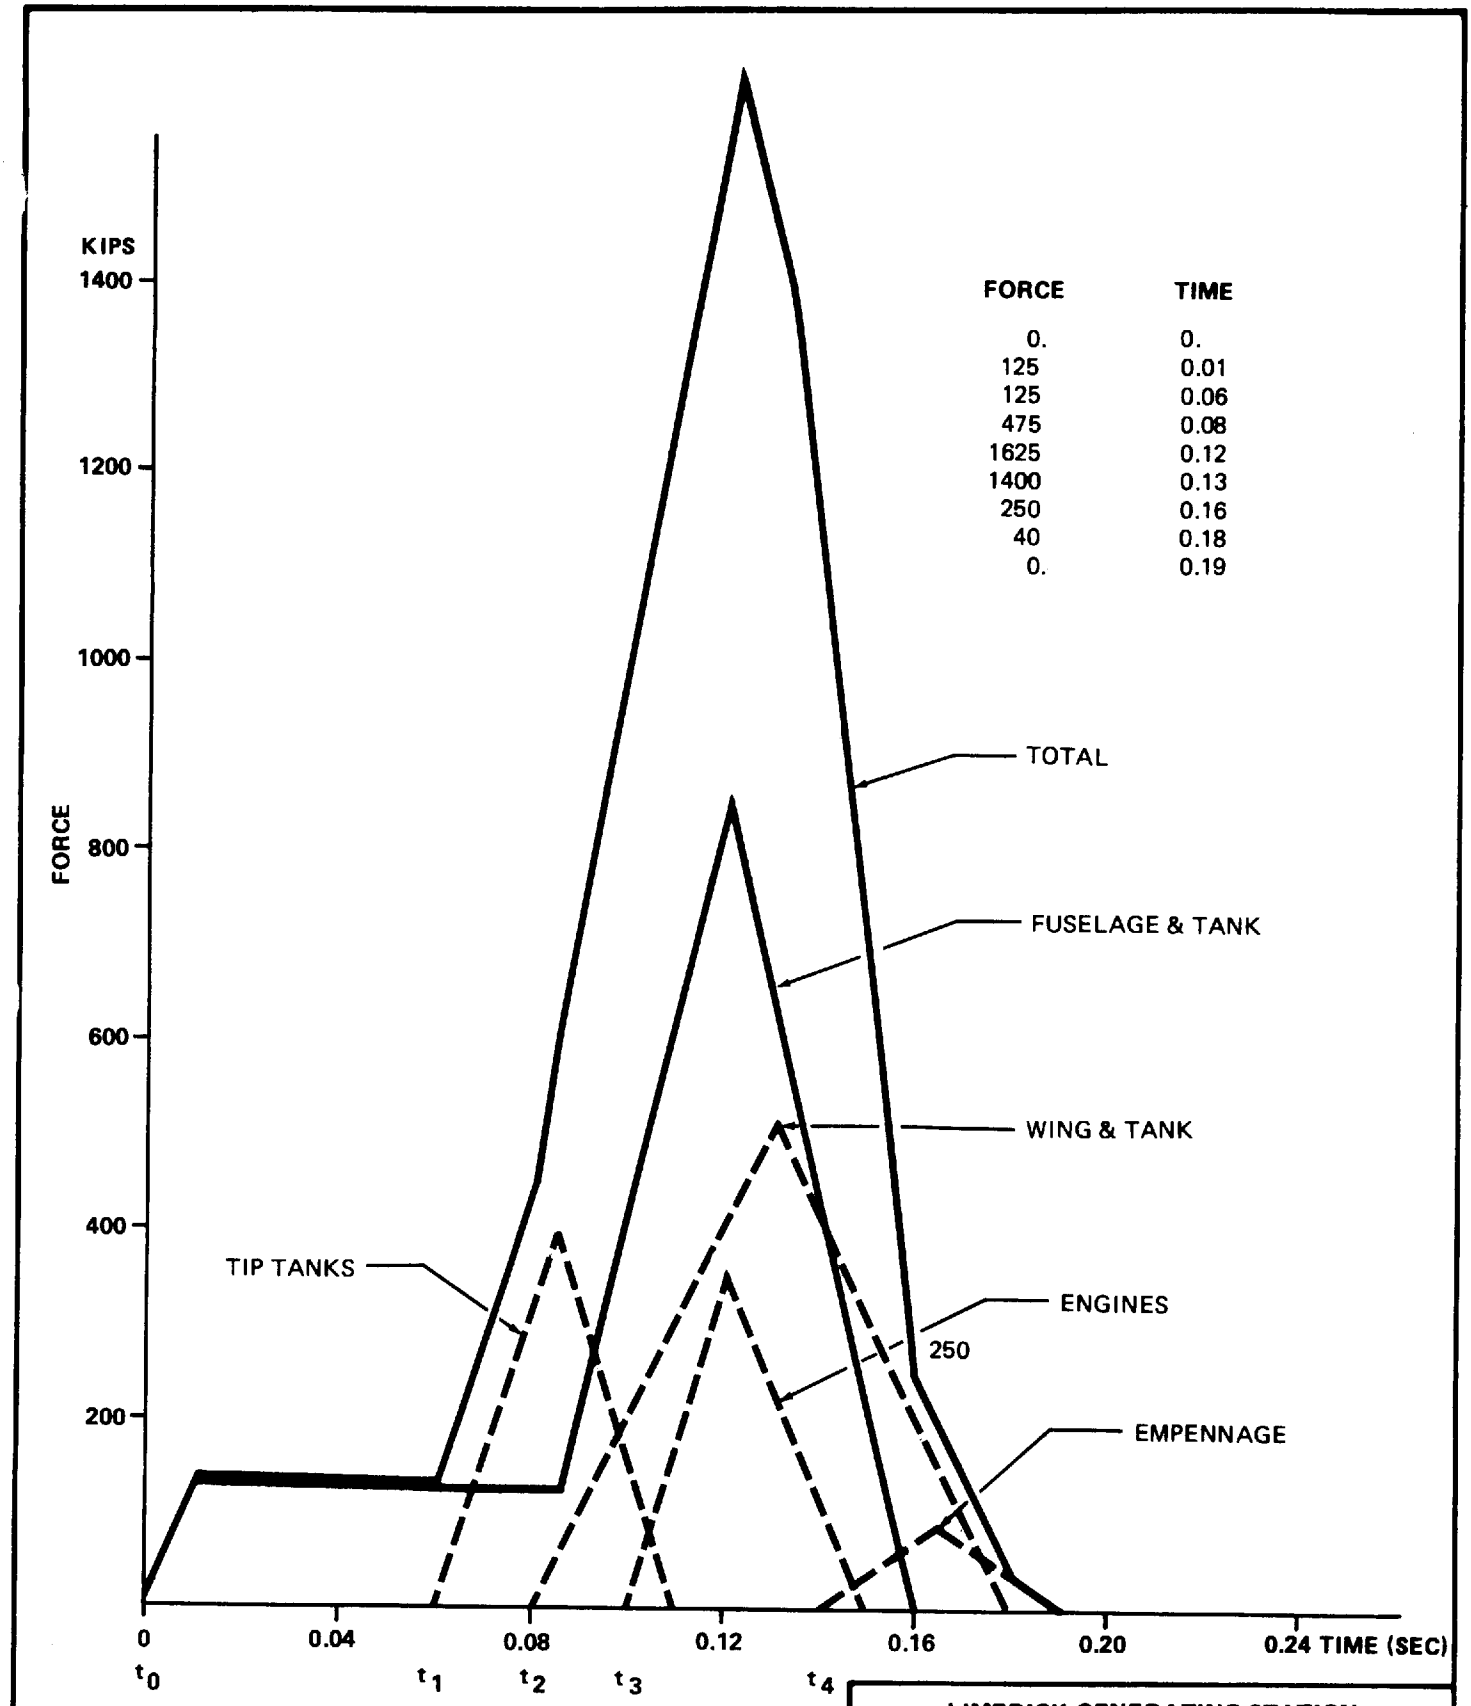


3.12.5 Safety Evaluation

The basis for the site's conclusion that the existing heavy loads program is compliant with the NUREG-0612, Phase 1 requirements is documented in UFSAR Section 1.12 under the heading of "Implementation and Status Summary." This section states, "the requirements for heavy loads, NUREG-0612, were addressed in the initial operating license submittal and Unit I Operating License NPF-27 License Condition 2.C(19)." This demonstrates that the LGS heavy loads program is compliant with the appropriate regulations, codes, and standards.

Reference 9.1 1 documents, that in the event of postulated load drops, the consequences are acceptable, as demonstrated by load drop analyses. Restrictions on load height, weight, medium under the load and safe paths are reflected in plant procedures.

Reference 9.1-1 documents that when using single failure proof cranes or equivalent to perform heavy loads lifts, the risk of a load drop is extremely unlikely and acceptably low.



Detailed review of load handling systems as documented in Reference 9.1-1 (SDOC M-038-00008) provides sufficient documentation (along with controls required by station rigging procedures) that heavy load lifts are done safely.

NOTES

1. CALCULATED STRESSES FOR THE NODE POINTS SHOWN IN THIS FIGURE ARE LISTED IN TABLE 3.6-20

2. THE FOLLOWING SYMBOLS ARE USED TO INDICATE BREAK LOCATIONS:

   (TE) – TERMINAL END BREAK

   (IB) – INTERMEDIATE BREAK

   (C) – CIRCUMFERENTIAL BREAK

   (L) – LONGITUDINAL BREAK

3. STRUCTURES AND DEVICES THAT ACT AS RESTRICTIONS TO PIPE MOVEMENT FOLLOWING A PIPE BREAK ARE DESIGNATED BY THE FOLLOWING SYMBOLS:

   – PIPE WHIP RESTRAINT

   – BUMPER-TYPE RESTRAINT

   – ANCHOR

4. (M) – PIPING DOWNSTREAM OF VALVE 2027 IS MODERATE-ENERGY.

TABLE OF CONTENTS

3A.1 GENERAL INFORMATION

3A.1.1 Purpose of Report
3A.1.2 Background
3A.1.3 Mark II Containment Program
3A.1.4 Plant Description
3A.1.41 Primary Containment
3A.1.4.1.1 Penetrations
3A.1.4.1.2 Internal Structures

3A.2 SUMMARY

3A.2.1 Load Definition Summary
3A.2.1.1 SRV Load Definition Summary
3A.2.1.2 LOCA Load Definition Summary

3A.2.2 Design Assessment Summary
3A.2.2.1 Containment Structure, Reactor Enclosure, and Control Structure Assessment Summary
3A.2.2.1.1 Containment Structure Assessment Summary
3A.2.2.1.2 Reactor Enclosure and Control Structure Assessment Summary
3A.2.2.2 Containment Submerged Structures Assessment Summary
3A.2.2.3 BOP Piping Systems Assessment Summary
3A.2.2.4 NSSS Assessment Summary
3A.2.2.4.1 Introduction
3A.2.2.4.2 Design Assessment Results
3A.2.2.5 BOP Equipment Assessment Summary
3A.2.2.6 Electrical Raceway System Assessment Summary
3A.2.2.7 HVAC Duct System Assessment Summary
3A.2.2.8 Suppression Pool Temperature Assessment Summary
3A.2.2.9 Wetwell-to-Drywell Vacuum Breaker and Downcomer Capping Assessment Summary

3A.3 SRV DISCHARGE AND LOCA TRANSIENT DESCRIPTION

3A.3.1 Description of Safety/Relief Valve Discharge
3A.3.1.1 Causes of SRV Discharge
3A.3.1.2 Description of the SRV Discharge Phenomena and SRV Loading Cases

TABLE OF CONTENTS (cont'd)

3A.3.2 Description of Loss-of-Coolant Accident
3A.3.2.1 Small Break Accident
3A.3.2.2 Intermediate Break Accident
3A.3.2.3 Design Basis Accident

3A.4 LOAD DEFINITION

3A.4.1 Main Steam Safety/Relief Valve Discharge Load Definition (Proprietary - See Appendix 3B)
3A.4.2 LOCA Load Definition
3A.4.2.1 LOCA Loads Associated with Pool-Swell
3A.4.2.1.1 Wetwell/Drywell Pressures During Pool-Swell
3A.4.2.1.2 Submerged Boundary Loads During Vent Clearing
3A.4.2.1.3 LOCA Jet Loads
3A.4.2.1.4 Boundary Loads During Pool-swell
3A.4.2.1.5 Pool-Swell Asymmetric Air Bubble Load
3A.4.2.1.6 Pool-Swell Impact Load
3A.4.2.1.7 LOCA Air Bubble Submerged Structure Load
3A.4.2.1.8 Pool-Swell Drag Load
3A.4.2.1.9 Pool-Swell Fallback Load
3A.4.2.2 Condensation Oscillations and Chugging Loads
3A.4.2.2.1 Containment Boundary Loads Due to Condensation Oscillations
3A.4.2.2.2 Pool Boundary Loads Due to Chugging
3A.4.2.2.3 Downcomer Lateral Loads
3A.4.2.2.4 Multiple Vent Lateral Loads
3A.4.2.2.5 Submerged Structure Loads Due to Condensation Oscillation and Chugging
3A.4.2.3 Secondary Loads
3A.4.2.3.1 Downcomer Friction Drag Loads
3A.4.2.3.2 Sonic Waves
3A.4.2.3.3 Compressive Wave
3A.4.2.3.4 Fallback Loads on Submerged Boundaries
3A.4.2.3.5 Vent Clearing Loads on the Downcomers
3A.4.2.3.6 Postpool-Swell Waves
3A.4.2.3.7 Seismic Slosh
3A.4.2.3.8 Thrust Loads
3A.4.2.4 Long-Term LOCA Loads
3A.4.2.4.1 Design Basis Accident Transients
3A.4.2.4.2 Intermediate Break Accident Transients
3A.4.2.4.3 Small Break Accident Transients
3A.4.2.5 LOCA Loading Histories for LGS Containment Components
3A.4.2.5.1 LOCA Loads on the Containment Wall and Pedestal
3A.4.2.5.2 LOCA Loads on the Basemat and Liner Plate
3A.4.2.5.3 LOCA Loads on the Drywell and Drywell Floor
3A.4.2.5.4 LOCA Loads on the Columns
3A.4.2.5.5 LOCA Loads on the Downcomers
3A.4.2.5.6 LOCA Loads on the Downcomer Bracing
3A.4.2.5.7 LOCA Loads on the Wetwell Piping

TABLE OF CONTENTS (cont'd)

3A.5 LOAD COMBINATIONS FOR STRUCTURES, PIPING, AND EQUIPMENT

3A.5.1 Introduction
3A.5.2 Load Combinations for Concrete Design in Containment, Reactor Enclosure, and Control Structure
3A.5.3 Structural Steel and ASME Class MC Steel Components Load Combinations
3A.5.4 Liner Plate Load Combinations
3A.5.5 Downcomer Load Combinations
3A.5.6 Piping, Quencher, and Quencher Support Load Combinations
3A.5.6.1 Load Considerations for Piping Inside the Drywell
3A.5.6.2 Load Considerations for Piping Inside the Wetwell
3A.5.6.3 Quencher and Quencher Support Load Considerations
3A.5.6.4 Load Considerations for Piping in the Reactor Enclosure
3A.5.7 NSSS Load Combinations
3A.5.8 BOP Equipment Load Combinations
3A.5.9 Electrical Raceway System Load Combinations
3A.5.10 HVAC Duct System Load Combinations

3A.6 DESIGN CAPABILITY ASSESSMENT CRITERIA

3A.6.1 Introduction
3A.6.2 Containment, Reactor Enclosure, and Control Structure Capability Assessment Criteria
3A.6.2.1 Containment Structure Capability Assessment Criteria
3A.6.2.2 Reactor Enclosure and Control Structure Capability Assessment Criteria
3A.6.3 Structural Steel and ASME Class MC Steel Component Capability Assessment Criteria
3A.6.4 Liner Plate Capability Assessment Criteria
3A.6.5 Downcomer Capability Assessment Criteria
3A.6.6 BOP Piping, Quencher, and Quencher Support Capability Assessment Criteria
3A.6.7 NSSS Capability Assessment Criteria
3A.6.8 BOP Equipment Capability Assessment Criteria
3A.6.8.1 Analysis
3A.6.8.2 Testing
3A.6.8.3 Combined Analysis and Test
3A.6.9 Electrical Raceway System Capability Assessment Criteria
3A.6.10 HVAC Duct System Capability Assessment Criteria

3A.7 DESIGN ASSESSMENT

3A.7.1 Assessment Methodology
3A.7.1.1 Containment, Reactor Enclosure, and Control Structure Assessment Methodology
3A.7.1.1.1 Containment Structure
3A.7.1.1.2 Reactor Enclosure and Control Structure
3A.7.1.2 Structural Steel and ASME Class MC Steel Components Assessment Methodology
3A.7.1.2.1 Suppression Chamber Columns
3A.7.1.2.2 Downcomer Bracing
3A.7.1.2.3 ASME Class MC Steel Components

TABLE OF CONTENTS (cont'd)

3A.7.1.3 Liner Plate Assessment Methodology
3A.7.1.4 Downcomer Assessment Methodology
3A.7.1.4.1 Structural Model
3A.7.1.4.2 Loads
3A.7.1.4.3 Analysis
3A.7.1.4.4 Design Assessment
3A.7.1.4.5 Fatigue Evaluation of Downcomers in Wetwell Air Space
3A.7.1.5 BOP Piping and SRV Systems Assessment Methodology
3A.7.1.5.1 Fatigue Evaluation of MSRV Discharge Lines in Wetwell Air Volume

APPENDIX 3A- DESIGN ASSESSMENT REPORT

3A.1 GENERAL INFORMATION

3A.1.1 PURPOSE OF REPORT

The purpose of this Design Assessment Report is to present evidence that the Limerick Generating Station design margins are adequate if the plant should be subjected to the recently defined thermohydrodynamic loads that result from SRV operations and/or discharges during a LOCA in a GE boiling water reactor.

3A.1.2 BACKGROUND

The history of the recently defined Mark II thermohydrodynamic loading issue is based on two distinctive events. First, in April 1972, at the German AEG-Kraftwerk Union Wurgassen Nuclear Plant, a BWR SRV was opened during startup testing and failed to close. The reactor remained at full pressure, and the valve discharged reactor steam into the containment suppression chamber until the suppression pool water heated from just above ambient to almost 170°C (in approximately 30 minutes). Pulsating condensation developed and large impulsive forces with substantial underpressure amplitudes acted upon the containment, eventually causing leakage from the bottom liner plate. Therefore, concern was expressed that the structural integrity of other BWR pressure containment systems could be sensitive to SRV induced dynamic loads. The Nuclear Regulatory Commission issued Bulletin 74-14 to all BWR owners on November 14, 1974, to alert them to the potential problems of condensation instability (Wurgassen effect) due to SRV operation. The NRC requested verification that BWR suppression pools had been designed to withstand loads similar to those being experienced.

Secondly, in January 1975, GE-NEPD identified the dynamic loading conditions due to LOCA hydrodynamic phenomena that result from vent clearing and pool-swell. These loads had not been fully considered in the design criteria of Mark II BWR containments.

It became evident that a complex technical issue existed for all Mark II plants. PECo took part in the formation of a unified utility group to address the matter. A Mark II BWR containment owners group was formed in June 1975 to define the suppression pool dynamic loads and to explore ways to assess their impact. As the direct result of action taken by the Mark II containment owners organization, a generic Dynamic Forcing Function Information Report was issued jointly by GE-NEPD and Sargent and Lundy for the Mark II owners in September 1975 (Section 3A.1.3).

3A.1.3 MARK II CONTAINMENT PROGRAM

PECo is a member of the Mark II owners group that was formed in June 1975 to define and investigate the dynamic loads due to SRV discharge and LOCA. The methods for calculating these hydrodynamic loads are described in the DFFR (Reference 3A-1). The DFFR also specifies load combinations for plant design assessment. The methods provided in the DFFR are based on a combination of analytical models, test data, and engineering judgment. The methods and information provided are sufficient for use in a conservative evaluation of the design adequacy of Mark II structures and components.

The Mark II Owners Group Containment Program concentrated initially on the tasks required for the licensing of the lead-plants (Zimmer, LaSalle, and Shoreham). This Lead-Plant Program established interim bounding loads appropriate for the anticipated life of each of the lead-plants. The NRC

acceptance criteria for the lead-plant LOCA and SRV load definitions are described in NUREG-0487 (Reference 3A-2) and NUREG-0487 Supplements 1 and 2 (References 3A-3 and 3A-4, respectively).

The remainder of the Mark II Owners Group Program concentrated on the tasks required to license the long-term plants, which include LGS. The NRC acceptance criteria for the long-term plant LOCA and SRV load definitions are described in NUREG-0808 (Reference 3A-5) and NUREG-0802 (Reference 3A-6), respectively. The objectives of the Long-Term Program were (a) to provide justification, by tests and analyses, for refinement of selected lead-plant bounding loads, and (b) to provide additional confirmation of certain loads used in the Lead-Plant Program.

As a task separate from the Mark II Owners Group Program, a Mark II SRV discharge Line T-quencher device and load specification was developed in 1978 by Kraftwerk Union for Pennsylvania Power and Light for use in the Susquehanna Steam Electric Station. The T-quencher provides a reduction in the containment wall loads as compared to the loads generated by the original Ramshead quencher design. The T-quencher also promotes effective heat transfer and condensation of discharge steam in the suppression pool. PECo decided to use the same T-quencher design for LGS. Following this decision, KWU compared the LGS and SSES SRV-related parameters and concluded that the same load specification could be used by PECo for the LGS containment analysis. The LGS and SSES SRV-related parameters are compared in Table 3B-1.

The quencher load specification was submitted to the NRC by PP&L in April 1978. In addition, a full-scale SSES unique unit cell test (Section 3B.8) was performed by KWU in 1979. This test verifies KWU's design approach for the quencher load specification used for LGS.

Table 3A-1 provides a summary of the LGS licensing basis as a result of the Mark II Containment Program.

Table 3A-2 presents a summarizing review of the LGS suppression pool dynamic loadings. This is achieved by comparing the NRC Acceptance Criteria with the LGS plant unique position.

3A.1.4 PLANT DESCRIPTION

The LGS, Units 1 and 2, is located on the east bank of the Schuylkill River in Limerick Township of Montgomery County, Pennsylvania, approximately 1.7 miles southeast of the limits of the Borough of Pottstown and approximately 20.7 miles northwest of the Philadelphia city limits. Each of the LGS units employs a GE BWR designed to operate at a rerated core thermal power of 3515 MWt.

3A.1.4.1 Primary Containment

The containment is a reinforced concrete structure consisting of a cylindrical suppression chamber beneath a truncated conical drywell. Figures 3A-1 and 3A-2 show the cross-section of the containment and suppression chamber (including pedestal), respectively. The conical portion of the primary containment (drywell) encloses the reactor vessel, reactor coolant recirculation loops, and associated components of the RCS. The drywell is separated from the wetwell, i.e., the pressure-suppression chamber and pool, by the drywell floor, also named the diaphragm slab. The cone and cylinder form a structurally integrated reinforced concrete vessel, lined with steel plate and closed at the top of the drywell with a steel domed head. The carbon steel liner plate is anchored to the concrete by structural steel members embedded in the concrete and welded to the liner plate.

The entire containment is structurally separated from the surrounding reactor enclosure except at the base foundation slab (a reinforced concrete mat, top lined with a carbon steel liner plate) where a seismic gap filled with rodofoam is provided between the two adjoining foundation slabs. The containment structure dimensions and parameters are listed in Tables 3A-3 and 3A-4.

Major systems and components in the containment include the vent pipe system (downcomers) connecting the drywell and wetwell, vacuum relief system, containment cooling system, and MSRV discharge piping and associated quencher components. Figure 3A-3 shows the locations and orientation of the quenchers and discharge piping.

3A.1.4.1.1 Penetrations

Services and communications between the inside and the outside of the containment are performed through penetrations. Basic penetration types include pipe penetrations, electrical penetrations, and access hatches (equipment hatches, personnel lock, suppression chamber access hatches, and CRD removal hatch). Each penetration consists of a pipe sleeve with an annular ring welded to it. The ring is embedded in the concrete wall and provides an anchorage for the penetration to resist normal operating and accident loads. The pipe sleeve is also welded to the containment liner plate to provide a leak-tight penetration.

3A.1.4.1.2 Internal Structures

The internal structures consist of reinforced concrete and structural steel and have the major functions of supporting and shielding the rector vessel, supporting the piping and equipment, and forming the pressure-suppression boundary. These structures include the diaphragm slab, the reactor pedestal (a concentric cylindrical reinforced concrete shell resting on the containment base foundation slab and supporting the reactor vessel; Figure 3A-2 shows pedestal cross-section), the reactor shield wall, the suppression chamber columns (hollow steel pipe columns supporting the diaphragm slab), the drywell platforms, the seismic trusses, the quencher supports, and the reactor steam supply systems supports.

3A.2 SUMMARY

3A.2.1 LOAD DEFINITION SUMMARY

3A.2.1.1 SRV Load Definition Summary

Hydrodynamic loads resulting from SRV actuation fall into two categories: loads on the SRV system itself (the discharge line and the discharge quencher device), and the loads on the suppression pool walls and submerged structures.

Loads on the SRV system during SRV actuation include loads on the SRV piping due to effects of steady back pressure, transient water slug clearing, and SRV line temperature. Determination of loading on the quencher body, arms, and support is based on transients resulting from valve opening (water clearing and air clearing), valve closing, and operation of an adjacent quencher.

Air clearing loads are examined for four loading cases: symmetric (all-valve) SRV actuation, asymmetric adjacent SRV actuation, single SRV actuation, and automatic depressurization system (ADS-five valve) actuation. Dynamic forcing functions for loading of the containment walls, pedestal, basemat, and submerged structures are developed using techniques discussed in Section 3B.4.1 and 3A.11. Loads on the SRV system due to SRV actuation are discussed in Section 3B.4.1.3, and

loads on suppression pool walls and submerged structures due to SRV actuation are discussed in Section 3B.4.1.4. A full-scale, unit cell test program was conducted at the KWU laboratories to verify these SRV loading specifications. These tests are described in Section 3B.8.

Adjacent structures indirectly affected by SRV loads include the reactor enclosure, control structure, and associated equipment and components. The assessment methodology used in determining the SRV load effect on these adjacent structures is described in Section 3A.7.1.1.2.

3A.2.1.2 LOCA Load Definition Summary

The spectrum of LOCA-induced loads acting on the LGS containment structure is characterized by LOCA loads associated with pool-swell and condensation oscillation and chugging, as well as long-term and secondary LOCA loads.

The LOCA loads associated with pool-swell result from short duration transients and include downcomer clearing loads, water jet loads, pool-swell impact and drag loads, poll fallback drag loads, pool-swell air bubble loads, and loads due to drywell and wetwell temperature and pressure transients. Techniques used to evaluate these loads are described in Section 3A.4.2.1.

Condensation oscillations result from mixed flow (air-steam) and pure steam flow effects in the suppression pool. Chugging loads result from low mass flux pure steam condensation. The load definitions from these phenomena are contained in Section 3A.4.2.2.

Long-term LOCA loads result from those wetwell and drywell pressure and temperature transients associated with DBAs, IBAs, and SBAs. Their load definitions are contained in Section 3A.4.2.4.

Structures directly affected by LOCA loads include the drywell walls and floor, wetwell walls, RPV pedestal, basemat, liner plate, columns, downcomers, downcomer bracing system, and wetwell piping. Their loading conditions are described in Section 3A.4.2.5.

Adjacent structures indirectly affected by LOCA loads include the reactor enclosure, control structure, and associated equipment and components. The assessment methodology used in determining the LOCA load effect on these adjacent structures is described in Section 3A.7.1.1.2.

3A.2.2 Design Assessment Summary

Design assessment of the LGS structures and components is achieved by analyzing the response of the structures and components to the load combinations explained in Section 3A.5. In Section 3A.7, predicted stresses and responses (from the loads defined in Sections 3A.4 and 3B.4 and combined as described in Section 3A.5) are compared with the applicable code allowable values identified in Section 3A.6.

3A.2.2.1 Containment Structure, Reactor Enclosure, and Control Structure Assessment Summary

3A.2.2.1.1 Containment Structure Assessment Summary

The primary containment walls, base slab, diaphragm slab, reactor pedestal and reactor shield are analyzed for the effects of SRV and LOCA in accordance with Table 3A-14. The ANSYS finite-element program is used for the dynamic analysis of structures.

Response spectra curves are developed at various locations within the containment structure to assess the adequacy of components. Stress resultants due to dynamic loads are combined with

other loads in accordance with Table 3A-14 to evaluate rebar and concrete stresses. Design safety margins are defined by comparing the actual concrete and rebar stresses at critical sections with the code allowable values. The assessment methodology of the containment structure is given in Section 3A.7.1.1.1.

The containment mode shapes, modal frequencies, and hydrodynamic response spectra are given in Section 3A.9.

The results of the structural assessment of the containment structure are given in Section 3A.12.

3A.2.2.1.2 Reactor Enclosure and Control Structure Assessment Summary

The reactor enclosure and control structure are assessed for the effects of SRV and LOCA loads in accordance with Table 3A-14 and Table 3A-15.

Pressure time histories in the wetwell are used to investigate the reactor enclosure and control structure response to SRV and LOCA loads. Maximum time history force responses and broadened response spectra curves are approximately used to assess the adequacy of associated structural components. The assessment methodology of the reactor enclosure and control structure is presented in Section 3A.7.1.1.2.

The mode shapes, modal frequencies, and hydrodynamic response spectra of the reactor enclosure and control structure are presented in Section 3A.10.

The results of the structural assessment are summarized in Section 3A.13.

3A.2.2.2 Containment Submerged Structures Assessment Summary

Load combinations for the downcomer bracing and suppression chamber columns are presented in Table 3A-15. Load combinations for the downcomers are presented in Table 3A-17. The hydrodynamic design assessment methodology for the downcomers, bracing, and columns is presented in Sections 3A.7.1.2 and 3A.7.1.4. The results of the analysis are presented in Section 3A.12.

The suppression pool liner plate loads are combined in accordance with Table 3A-14. Results from the analysis indicated that no structural modification is required (Sections 3A.7.1.3 and 3A.7.2.1.5).

3A.2.2.3 BOP Piping Systems Assessment Summary

Containment and reactor enclosure BOP piping systems were analyzed by the methods presented in Section 3A.7.1.5. The load combinations for piping are described in Table 3A-18. The results of the analysis are presented in Section 3A.14.

3A.2.2.4 NSSS Assessment Summary

3A.2.2.4.1 Introduction

GE performed a design assessment of LGS Unit 1 to demonstrate that the NSSS piping and safety-related equipment and associated supports have sufficient capability to accommodate combinations of seismic and hydrodynamic loadings. The scope of the evaluation included the RPV, RPV internals and associated equipment, main steam and recirculation piping, and GE-supplied floor-mounted

equipment, pipe-mounted equipment, and control and instrumentation equipment and all associated supports.

The methodologies described in Section 3A.7.1.6 were used to perform the evaluation. Load combinations and acceptance criteria listed in Table 3A-19 were used for the evaluation of ASME Class 1, 2 and 3 piping, equipment, and supports.

3A.2.2.4.2 Design Assessment Results

The results of the assessment have demonstrated that the NSSS piping and safety-related equipment have sufficient capability to accommodate combinations of seismic and hydrodynamic loadings for the normal, upset, emergency and faulted conditions.

Detailed results of the NSSS piping and major safety-related equipment evaluations are given in Sections 3.9 and 3.10.

3A.2.2.5 BOP Equipment Assessment Summary

Safety-related BOP equipment in the containment, reactor enclosure, and control structure are assessed by the methods contained in Section 3A.7.1.7. Loads are combined as shown in Table 3A-20.

3A.2.2.6 Electrical Raceway System Assessment Summary

The electrical raceway system located in the containment, reactor enclosure, and control structure is assessed for load combinations in accordance with Table 3A-21. The assessment methodology and analysis results are presented in Section 3A.7.1.8.

3A.2.2.7 HVAC Duct System Assessment Summary

The HVAC duct system located in the containment, reactor enclosure, and control structure is assessed for load combinations in accordance with Table 3A-22. The assessment methodology and analysis results are presented in Section 3A.7.1.9

3A.2.2.8 Suppression Pool Temperature Assessment Summary

SPTMS design criteria and adequacy assessment, analysis of suppression pool temperature response to SRV discharge, and analysis of the suppression pool local-to-bulk temperature difference (ΔT) are presented in Section 3A.15.

3A.2.2.9 Wetwell-to-Drywell Vacuum Breaker and Downcomer Capping Assessment Summary

The assessment of the wetwell-to-drywell vacuum breakers to adequately withstand the dynamic effects of pool-swell and chugging is summarized in Section 3A.16. The design assessment of the downcomer capping arrangement is also summarized in Section 3A.16.

3A.3 SRV DISCHARGE AND LOCA TRANSIENT DESCRIPTION

3A.3.1 DESCRIPTION OF SAFETY/RELIEF VALVE DISCHARGE

LGS is equipped with a safety/relief system that condenses reactor steam in a suppression chamber pool. By this arrangement, reactor steam is conducted to the wetwell via fast-acting SRVs and quencher-equipped discharge lines. This section discusses the causes of SRV discharge, describes the SRV discharge process, and identifies the resultant SRV discharge actuation cases. Section 3B.4.1 presents a quantitative description of specific SRV-related loads.

3A.3.1.1 Causes of SRV Discharge

During certain reactor operating transients, the SRVs may be actuated (by pressure, by electrical signal, or by operator action) for rapid relief of pressure in the RPV. The following reactor operating transients have been identified as those which may result in SRV actuation:

a. Turbine-generator trip (with bypass or without)

b. MSIV closure

c. Loss of condenser vacuum

d. Feedwater controller failure - maximum demand

e. Pressure regulator failure - closed

f. Generator load rejection (with and without bypass)

g. Loss of ac or auxiliary power

h. Loss of feedwater flow

i. Trip of two recirculation pumps

j. Recirculation flow control failure - decreasing flow

k. Inadvertent safety/relief valve opening

l. Control rod withdrawal error

m. ATWS

n. Failure of shutdown cooling

A description of these transients is provided in Chapter 15.

3A.3.1.2 Description of the SRV Discharge Phenomena and SRV Loading Cases

Before an individual SRV opens, the water level in the discharge line is approximately equal to the water level in the pool. As a valve opens, steam flows into the discharge line air space between the valve and the water column and mixes with the air. Because the downstream portion of the discharge line contains a water slug, the pressure inside the line increases. The increased pressure expels the water slug from the SRV discharge line and quencher. The magnitude of the water clearing pressure is primarily influenced by the steam flow rate through the valve, the degree to which entering steam

is condensed along the discharge line walls, the volume of the discharge line airspace, and the volume of the water slug to be accelerated.

The clearing of water is followed by an expulsion of the enclosed air-steam. The exhausted gas forms an oscillating systems with the surrounding water, where the gas acts as the spring and the water acts as the mass. This oscillating system is the source of short-term air clearing loads.

As the air-steam mixture oscillates in the pool, its also rises because of buoyancy and eventually breaks through the pool water surface, at which time air clearing loads cease. When all the air leaves the safety/relief system, steam flows into the suppression pool through the quencher holes and condenses. The LGS quencher design ensures stable condensation even with elevated pool water temperature.

The SRV actuation cases resulting from the transients listed in Section 3A.3.1.1 are classified as being bounded by one of the following cases:

a. Symmetric all-valve, or abnormal operating transient discharge

b. Asymmetric discharge

c. Single valve discharge

d. ADS discharge

The symmetric discharge case is classified as the type of SRV discharge that would follow rapid isolation of the vessel from the turbine such as turbine trip, closure of all MSIVs, loss of condenser vacuum, etc. As pressure builds up following isolation of the vessel, the SRVs actuate sequentially according to the pressure setpoints of the valves. This may or may not result in actuation of all the SRVs, but for conservatism in loading considerations, all valves are assumed to actuate simultaneously.

Asymmetric discharge is defined as the firing of the SRVs for the three adjacent quencher devices which results in the greatest asymmetric pressure loading on the containment. This situation is hypothesized when, following a reactor scram and isolation of the vessel, decay heat raises vessel pressure so that low setpoint valves actuate. If, during this time of discharge of decay heat energy, manual actuation of the two other adjacent SRVs that comprise the asymmetric case is assumed, this actuation would result in the maximum asymmetric pressure load on the containment.

The single valve discharge case is classified as the firing of the SRV which gives the single largest hydrodynamic load. Transients that could potentially initiate such a case are an inadvertent SRV discharge or DBA. Refer to Section 3A.3.2.3 for a discussion of the latter possibility.

The ADS discharge is defined as the simultaneous actuation of the five SRVs associated with the ADS. Figure 3A-3 shows the location of the quencher devices associated with the ADS valves. The ADS is assumed to actuate during an IBA or SBA. (The IBA and SBA are described in Sections 3A.3.2.2 and 3A.3.2.1, respectively.) The effects of an increased suppression pool temperature (resulting from steam condensation during the LOCA transient) and increased suppression chamber pressure (resulting from clearing of the drywell air into the pool during the transient) are considered in the calculation of pressure loadings for the ADS discharge case.

Section 3A.4.1.4.2 describes the loads resulting from symmetric, asymmetric, single valve, and ADS discharge transients.

3A.3.2 Description Of Loss-Of-Coolant Accident

This event involves the postulation of a spectrum of piping breaks inside the containment varying in size, type, and location. For the analysis of hydrodynamic loadings on the containment, the postulated LOCA event is identified as a SBA, and IBA, or a DBA.

3A.3.2.1 Small Break Accident

This section discusses the containment transient associated with small primary system blowdowns. The primary system ruptures in this category are those ruptures that will not result in reactor depressurization from either loss of reactor coolant or automatic operation of the ECCS equipment, i.e., those ruptures with a break size less than 0.1 ft^2.

The following sequence of events is assumed to occur. With the reactor and containment operating at the maximum normal conditions, a small break occurs that allows blowdown of reactor steam or water to the drywell. The resulting pressure increase in the drywell leads to high drywell pressure signal that scrams the reactor and activates the containment isolation system. The drywell pressure continues to increase at a rate dependent upon the size of the steam leak. The pressure increase lowers the water level in the downcomers. At this time, air and steam enter the suppression pool at a rate dependent upon the size of the leak. Once all the drywell air is carried over to the suppression chamber, pressurization of the suppression chamber ceases and the system reaches an equilibrium condition. The drywell contains only superheated steam, and continued blowdown of reactor steam condenses in the suppression pool. The principal loading condition in this case is the gradually increasing pressure in the drywell and suppression pool chamber and the loads related to the condensation of steam at the end of the vents.

3A.3.2.2 Intermediate Break Accident

This section discusses the containment transient associated with intermediate primary system blowdowns. This classification covers breaks for which the blowdown will result in limited reactor depressurization and operation of the ECCS, i.e., the break size is equal to slightly greater than 0.1 ft^2.

Following the break, the drywell pressure increases at approximately 1.0 psi/sec. This drywell pressure transient is sufficiently slow so that the dynamic effect of the water in the vents is negligible and the vents will clear when the drywell-to-suppression chamber differential pressure is equal to the hydrostatic pressure corresponding to the vent submergence. The resulting pressure increase in the drywell will lead to a high drywell pressure signal that will scram the reactor and activate the containment isolation system. Approximately 5 seconds after the 0.1 ft^2 break occurs, air, steam, and water will be condensed, and the air will rise to the suppression chamber free space. The continual purging of drywell air to the suppression chamber will result in a gradual pressurization of both the wetwell and drywell. The ECCS will be initiated by the break and will provide emergency cooling of the core. The operation of these systems is such that the reactor will be depressurized in approximately 600 seconds. This will terminate the blowdown phase of the transient. The principal loading condition in this case will be gradually increasing pressure in the drywell and suppression chamber and the loads related to the condensation of the steam at the end of the vents.

3A.3.2.3 Design Basis Accident

An occurrence of events that could result in a DBA (instantaneous rupture of main steam or recirculation line) is a remote possibility. Because such an accident provides an upper limit estimate to the resultant effects for this category of pipe breaks, it is evaluated without causes being identified. For LGS, an assumed instantaneous double-ended rupture of a recirculation line causes the maximum drywell pressure and therefore the governing LOCA hydrodynamic loads.

The sequence of events immediately following the rupture of a recirculation line has been determined. A drywell high pressure signal is almost instantaneously sensed, initiating a scram and containment isolation and signaling the HPCI, CS and LPCI to start. The flow in both sides of the break will accelerate to the maximum allowed by the critical flow considerations. In the side adjacent to the suction nozzle, the flow will correspond to critical flow in the pipe cross-section. In the side adjacent to the injection nozzle, the flow will correspond to critical flow at the 10 jet pump nozzles associated with the broken loop. In addition, the cleanup line cross-tie will add to the critical flow area. This high rate of flow out of the ruptured recirculation line results in a drywell pressure rise of approximately 42.1 psig in 8.7 seconds (Table 6.2-5A and Figure 6.2-3A).

This rapid increase in drywell pressure accelerates the water initially in the containment vent system out through the vents. Immediately following vent water clearing, a coalescing air-steam bubble starts to form at the downcomer exits. Initially, the bubble pressure is essentially equal to the current drywell pressure. As the flow of air-steam from the drywell becomes established in the vent system, the initial vent exit bubble expands, thus accelerating upward the suppression pool water above the vent exits. The steam fraction of the flow is condensed, but continued injection of drywell air and expansion of the air bubble results in a rapid rise in the suppression pool surface known as pool-swell.

Following the pool-swell and fall back, there is a period of high steam flow rate through the containment vent system. For large primary system ruptures, reactor blowdown and, therefore, vent steam condensation last for approximately 40 seconds (approximately 60 seconds for MSLB; see Tables 6.2-10 and 6.2-11).

Shortly after a DBA, the ECCS pumps (HPCI, CS, and LPCI) automatically start pumping CST water or suppression pool water in to the RPV. Within 70 seconds, all ECCS pumps are at rated flow (Table 6.3-2). This floods the reactor core until water starts to cascade into the drywell from the break. The time at which this occurs would depend upon break size and location. Because the drywell would be full of steam at the time of vessel flooding, the sudden introduction of cold water causes steam condensation and drywell depressurization. When the drywell pressure falls below the suppression chamber pressure, the drywell vacuum relief system is actuated and air from the suppression chamber enters the drywell. Eventually, sufficient air returns to the drywell to equalize the pressures. Similarly, small differential pressures between the drywell and the suppression chamber can be produced if the containment spray system is actuated, condensing steam in the drywell.

Following the vessel flooding and drywell/suppression chamber pressure equalization phase of the accident, suppression pool water will be continuously recirculated through the core by the ECCS pumps. The energy associated with the core decay heat will result in a slow heatup of the suppression pool. The suppression pool temperature is controlled by the RHR heat exchangers. The capacity of these heat exchangers is such that the maximum suppression pool temperature increase is reached after several hours. The suppression pool can experience a peak temperature of 205°F under worst case conditions (Table 6.2-5A). The post-LOCA containment heatup and pressurization transient is terminated when the RHR heat exchangers reduce the pool temperature and containment pressure to nominal values.

The primary loads on the containment generated by a DBA are the pressure build-ups in the drywell and suppression chamber, and loads resulting from various modes of steam condensation at the vent ends. The high rate of system depressurization resulting from a DBA militates against the firing of an SRV; however, for conservatism, SRV discharges are considered coincident with the DBA for containment structural loading purposes (Table 3A-14).

3A.4 LOAD DEFINITION

3A.4.1 MAIN STEAM SAFETY/RELIEF VALVE DISCHARGE LOAD DEFINITION (PROPRIETARY - SEE APPENDIX 3B)

3A.4.2 LOCA Load Definition

Sections 3A.4.2.1 and 3A.4.2.2 discuss the numerical definition of loads resulting from a LOCA in the LGS containment. The LOCA loads are divided into four groups:

a. Short-term LOCA loads associated with pool-swell (Section 3A.4.2.1)

b. Condensation oscillation and chugging loads (Section 3A.4.2.2)

c. Secondary loads (Section 3A.4.2.3)

d. Long-term LOCA loads (Section 3A.4.2.4)

The application of these loads to the various components and structures on the LGS containment is discussed in Section 3A.4.2.5.

3A.4.2.1 LOCA Loads Associated with Pool-Swell

NOTE: The load definition defined in Section 3A.4.2.1 for the LOCA loads associated with pool swell is historical and is based on original design basis conditions. Section 6.2.1.8 discusses the methods and results used for current plant conditions. However, the short-term containment response conditions with power rerate are within the conditions used to define the pool swell loads. The initial drywell pressurization rate used to define the pool swell load is negligibly affected by rerated power. The short-term containment response conditions for vent flow rate and pool temperature are negligibly affected by power rerate. Therefore, the LOCA load definition for loads associated with pool swell is not affected by power rerate.

In the first few seconds following a postulated LOCA, a mixture of air and steam is carried through the containment downcomers into the suppression pool. The loads associated with the transfer of the air-steam mixture are referred to as pool-swell loads. A description of the LOCA/pool-swell transient is given in Section 3A.3.2.3. The LOCA loads associated with pool-swell are listed in Table 3A-5.

3A.4.2.1.1 Wetwell/Drywell Pressures During Pool-Swell

The drywell pressure transient used for the pool-swell portion of the LOCA transient ($\leq$2.0 sec) is tabulated in Table 3A-6. This drywell pressure transient includes the blowdown effects of pipe inventory and reactor subcooling and is the highest possible drywell pressure case for pool-swell. This drywell pressure transient is calculated using the method documented in Reference 3A-7.

The short-term wetwell pressure transient due to pool-swell is calculated by applying the pool-swell model contained in Reference 3A-8 and section 4.2.2 of Reference 3A-1. Input used for calculation of the LGS unique pool-swell transient is shown in Table 3A-7.

The short-term wetwell pressure transient calculated with the pool-swell code is shown in Figure 3A-6. The short-term wetwell pressure peak is 53.644 psia (38.944 psig).

3A.4.2.1.1.1 Differential Pressure Load on Diaphragm Floor

A vertical load on the diaphragm floor will occur because of the pressure difference between the drywell and the wetwell airspace. Normally, the net load acts downward, although an upward load my occur due to rapid pressurization of the wetwell airspace during the pool-swell transient. A value of 5.5 psid will be used as a design value for the upward load on the diaphragm floor in Mark II containments, as recommended in Reference 3A-5 and section 4.2.5.2 of Reference 3A-1.

3A.4.2.1.2 Submerged Boundary Loads During Vent Clearing

The submerged jet formed by the expulsion of the water leg in the downcomers creates a vent clearing load on the basemat and the submerged wetwell walls. This loading is defined by Reference 3A-9 as a 24 psi overpressure statically applied with hydrostatic pressure to surfaces below the vent exit, linearly attenuating to zero at the pool surface (Figure 3A-4). This load is applied during vent clearing as required by section 2.1.2.1 of Reference 3A-5.

3A.4.2.1.3 LOCA Jet Loads

The LOCA jet formed by the expulsion of the water leg in the downcomers also imposes jet loads and induced drag loads on structures in the paths and in the vicinity of the jet respectively. The direct jet loads is calculated based on a simple stoppage of momentum [Ref. 3A.10]:

$$F = KA_lV^2/2g_c,$$

where V is the jet velocity, A_l is the intercepted jet area normal to the jet direction, and K = 2 for structures which fully or partially intercepts the jet. The induced drag loads are caused by the induced velocity and acceleration fields created by the passing jets in the suppression pool.

The original methodology employed to predict the drag forces is contained in Reference 3A-10 (often called the Moody jet model) and is an analytical representation of an unsteady water jet discharging into a suppression pool. The jet is made up of constant velocity fluid particles traveling at the speed at which they exited the discharge pipe. The jet front is described as the locus of points through which a particle overtakes the one exiting immediately before it. No velocities or accelerations are defined in the fluid external to the jet.

Reference 3A-2, subsection III.D.1.a, proposed that velocity and acceleration be predicted throughout the pool using the potential function of a sphere at the jet front. A modification of the load calculated at jet impingement was also required. The acceptance criteria was a simple method to determine a bounding jet load for all structures below the downcomer exits.

The Moody jet model was clearly derived from jets with constant or linearly increasing acceleration. However, the vent clearing transients predicted for Mark II plants typically have an increase in acceleration greater than linear. Strict application of Reference 3A-10 leads to unrealistic mathematical results. Two interpretations of the results are possible depending on the time base employed. Examining the jet in "real-time" (Reference 3A-10), a jet can be seen with two independent fronts traveling at different speeds at different locations which coincide only at the point of jet dissipation. On the other hand, if the "exit-time" (τ) is used as a basis, the jet reverses and moves backward in both space and "real-time" before dissipation. Clearly neither of these observations is of much use in calculating loads on structures.

To overcome the difficulties of using this model, an alternative methodology has been formulated. The jet front will be described by the motion of the particle having traveled the farthest at any instant in time. This will be identical to the Moody jet motion for jets with linearly increasing acceleration but will yield a single continuous velocity and acceleration time history even if the acceleration increases more rapidly.

A sphere is then placed at the jet front generating a potential flow described by the following function:

$$\varphi = \frac{-3}{8\pi} U_j V_w \frac{\cos\theta}{r^2} \qquad \text{(EQ. 3A-1)}$$

where:

(r, θ) = spherical coordinates from the sphere center to some position in the suppression pool with θ measured from the jet direction

U_j = the velocity of the sphere determined by the velocity of the particle having traveled the farthest at the instant in the time the draft forces are being computed

V_w = the initial volume of water in the vent.

The local velocity (U_∞) and acceleration ($\mathring{U}_\infty$) are then calculated from the above relation by the methods of Reference 3A-10. Once the local velocity and acceleration are known, the drag forces are computed from Reference 3A-11 as follows:

$$F_A = \frac{\mathring{U}_{\infty n} \nu \rho}{g_c} \qquad \text{(EQ. 3A-2)}$$

$$F_S = \frac{C_D A_X U^2_{\infty n} \rho}{2 g_c}$$

where:

F_A = the acceleration drag

$\mathring{U}_{\infty n}$ = the local acceleration field normal to the structure

ν = the acceleration drag volume for flow normal to the structure

ρ = the fluid density

F_S = the standard drag

C_D = the drag coefficient for flow normal to the structure

A_x = the projected structure area normal to $U_{\infty n}$

$U_{\infty n}$ = the local velocity field normal to the structure.

When the jet is predicted to dissipate, the sphere is traveling at the final jet velocity at the point of maximum jet penetration. This condition is used as the final load calculation point. The final jet velocity is that of the jet front just before the last particle leaving the vent reaches the jet front. The velocity of the last particle is disregarded.

The largest induced water jet drag loads on affected components are given in Table 3A-8 for the original plant operating conditions.

For power rerate plant conditions, the increase in drywell pressurization rate and maximum vent velocity is 2% or less. The LOCA jet loads are controlled by the drywell pressure history and vent clearing velocities up to the time of vent clearing. There is sufficient conservatism in the methodology used to calculate the original LOCA jet loads and margin to design limits in the resulting component stress calculations to accommodate this increase in LOCA jet loads. Therefore, power rerate does not impact the pool swell design loads which occur up to the time of vent clearing.

3A.4.2.1.4 Boundary Loads During Pool-swell

During the pool-swell transient, the high pressure air bubble that forms in the vicinity of the vent exit creates an increase in pressure on all suppression pool boundaries below the vent exit as well as those walls with which it is in direct contact. Boundaries that are between the bubble location and the point of maximum pool elevation also experience increased pressure loads corresponding to the increased pressure in the wetwell airspace, as well as the hydrostatic contribution of the water slug.

Reference 3A-1, section 4.2.5, and Reference 3A-5, section 2.1.2.5, describe the methodology for specification of these boundary loads. The pool-swell analytical model is used to determine the maximum values of bubble pressure and wetwell airspace pressure. The analysis takes the maximum pool elevation as 1.5 times the initial submergence. Using this data, a static loading is applied to the containment structure as follows:

a. For the basemat - uniform pressure equal to the maximum bubble pressure superimposed on the hydrostatic load corresponding to a submergence from vent exit to the basemat

b. For the containment walls below the vent exit - maximum bubble pressure plus hydrostatic head corresponding to vertical distance from vent exit.

c. For the containment walls between the vent exit and maximum pool elevation - linear variation between maximum bubble pressure and maximum wetwell airspace pressure.

d. For the containment walls above maximum pool elevation - maximum wetwell airspace pressure.

The pressure distribution used for the LGS analysis is shown in Figure 3A-5 for the original plant operating conditions.

The original pool swell boundary loads calculations were reassessed for power rerate conditions. The original calculations for both the maximum calculated bubble pressure and peak wetwell pressure assume no credit for bubble breakthrough which occurs when the wetwell pressure exceeds the drywell pressure by about 2.5 psi.

The highest wetwell pressure for power rerate shown in Table 6.2-5A (39.0 psig or 53.7 psia) is essentially the same as the original peak wetwell pressure value of 53.64 psia shown in figure 3A-5. The maximum pool swell elevation of 19.51 ft is valid for Power Rerate operation. The peak bubble pressures at the time of peak pool swell are about six (6) psi lower than that was assumed in the original calculations (48.25 psia). If credit was taken for bubble breakthrough, the bubble pressure at breakthrough would be about 12 psi lower than the 48.25 psia in the original calculations. In addition, the containment design is based on the design pressure of 55 psig (69.7 psia) and that the boundary loads during pool swell are not the governing load for the design of the containment walls,

basemat, or liners. Therefore, there is sufficient conservatism in the original calculation of the boundary loads during pool swell to accommodate Power Rerate operation.

3A.4.2.1.5 Pool-Swell Asymmetric Air Bubble Load

The methodology used in Section 3A.4.2.1.4 assumes that the air flow rate in each downcomer is equal, leading to a symmetric loading of the containment boundary. Concern has been expressed (Reference 3A-2, subsection III.B.3.e) that circumferential variations in the downcomer air flow rate can occur, due to drywell air-steam mixture variation, that would result in variations in the bubble pressure load on the wetwell wall. This asymmetric loading condition is calculated by statically applying the maximum air bubble pressure, obtained from the PSAM computer code, to half of the submerged boundary and statically applying the hydrostatic pressure of the water column to the other half of the submerged boundary. The pressure load on the basemat and wetwell walls below the vent exit is the sum of the air pressure and the hydrostatic pressure. For the portion of the wall above the vent exit, the pressure increase due to the air bubble is linearly attenuated from the bubble pressure at the vent exit to zero at the pool surface. This increase is then added to the local hydrostatic pressure to obtain the total pressure. The time period of application of the load is from the termination of vent clearing until the maximum swell height is reached.

These loading conditions are conservative with respect to the NRC's long-term criteria for asymmetric bubble loads (Reference 3A-5, Appendix A).

3A.4.2.1.6 Pool-Swell Impact Load

As the pool rises during pool-swell, structures located between the initial suppression pool surface and the peak pool-swell height are subject to the pool-swell impact load. The pool-swell maximum elevation is determined by the pool-swell analytical model with polytropic exponent of 1.2 for wetwell air compression to a maximum swell height which is the greater of 1.5 times the maximum vent submergence or the elevation corresponding to the drywell floor uplift pressure of 2.5 psid (References 3A-1 and 3A-5). For LGS, Reference 3A-1 separates all impacted structures into two classes:

a. Impact loads on small structures (one dimension < 20 in)

b. Impact loads on large structures (both dimensions > 20 in). These structures are treated on a case-by-case basis.

Pool-swell impact loads on small structures are determined as specified in Reference 3A-5, Appendix A.

The PSAM computer runs summary is provided on Figures 3A-6 through 3A-10for the original plant operating conditions. These graphs present various pool-swell plant unique characteristics, including pressure-time, ΔP-time, velocity-time, velocity-height, and height-time parameters. The pool swell response was reanalyzed assuming power rerate plant operating conditions. This analysis showed that the peak pool velocity and pool swell height is insensitive to changes in the plant operating conditions. Therefore, the original pool swell impact load definition remains bounding for power rerate operation.

3A.4.2.1.7 LOCA Air Bubble Submerged Structure Load

During the drywell air purge phase of a LOCA, an expanding bubble is created at the downcomer exits. These rapidly expanding bubbles create three-dimensional velocity and acceleration fields.

To determine the drag loads, the system was modeled acoustically by the inhomogeneous wave equation (Reference 3A-14). A bubble source was developed from 4T test data and qualitative information. Table 3A-9 presents major LOCA air bubble loads for the original plant operating conditions. The LOCA air bubble response was reanalyzed assuming power rerate plant operating conditions. This analysis showed that the drywell pressurization rate is insensitive to changes in the plant operating conditions. Therefore, the original LOCA air bubble submerged structure load definition remains bounding for power rerate operation.

3A.4.2.1.8 Pool-Swell Drag Load

Subsequent to bubble contact, all bubbles are assumed to coalesce into a blanket of air, and the pool-swell drag loads are due to the slug of water rapidly accelerating upward. The loads act in the vertical direction only (except for lift forces that act in the transverse direction to the flow). The one-dimensional pool-swell model is used to predict the velocity and acceleration at the structure location. As recommended in References 3A-5 and 3A-2 and consistent with section 3A.4.2.3.5 of Reference 3A-1, the velocity is increased by 10% for additional conservatism to account for possible bubble asymmetry. Once the flow field is known, the drag forces are calculated by the methods of Section 3A.11. This methodology conservatively estimates a standard drag coefficient for unsteady flow. This drag load applies to any structure located between the elevation of the vent exit and the peak pool-swell height. The duration of the drag load begins when the vent clears, except for structures that are originally not submerged. For structures that are not submerged, the drag load duration is based on the slug transient time (Reference 3A-12, pp. 4-78, step 3). Friction drag forces on vertical piping, downcomers, and columns are given in Table 3A-10 for the original plant operating conditions. The pool swell response was reanalyzed assuming power rerate plant operating conditions. This analysis showed that the peak pool velocity and pool swell height is insensitive to changes in the plant operating conditions. Therefore, the original pool swell impact load definition remains bounding for power rerate operation.

3A.4.2.1.9 Pool-Swell Fallback Load

After the termination of pool-swell, the slug of water falls under the influence of gravity, causing drag forces on structures located between the peak pool-swell height and the vent exit. The motion of water is described by the following equations:

$$H(t) = H_{max} - \tfrac{1}{2}gt^2 \qquad \text{(EQ. 3A-3)}$$

$$V_{FB}(t) = gt$$

$$\dot{V}_{FB} = g$$

where:

- g = the acceleration of gravity
- $H(t)$ = the height above initial water level at time (t)
- H_{max} = the maximum swell height
- t = the time (starting with t = 0) at maximum swell height

The drag load is then calculated from the methods of Section 3A.11. The loading stops when H(t) has fallen below the structure or when H(t) has returned to the normal water level, whichever is calculated to occur first.

The pool-swell fallback analysis of piping that has interference effects was performed by using the FORCE II computer code. The results indicate that the interference effects increase the vertical load component by a maximum of 16%, depending on the elevation.

3A.4.2.2 Condensation Oscillations and Chugging Loads

Condensation oscillation and chugging loads follow the pool-swell loads in time. There are basically three loads in this secondary time period, i.e., from about 4-60 seconds after the break. Condensation oscillation is broken down into two phenomena, a mixed flow regime and a steam flow regime. The mixed flow regime is a relatively high mass flux phenomenon that occurs during the final period of air purging from the drywell to the wetwell when the mixed flow through the downcomer vents contains some air as well as steam. The steam flow portion of the condensation oscillation phenomena occurs after all the air has been carried over to the wetwell and a relatively high intermediate mass flux of pure steam flow is established.

Chugging is a pulsating condensation phenomenon that can occur either following the intermediate mass flux phase of a LOCA or during the class of smaller postulated pipe breaks that result in steam flow through the vent system into the suppression pool. A necessary condition for chugging to occur is that only pure steam flows from the LOCA vents. Chugging imparts a loading condition to the suppression pool boundary and all submerged structures.

3A.4.2.2.1 Containment Boundary Loads Due to Condensation Oscillations

The containment boundary loads due to condensation oscillation are based on direct application of pressure measurements in the drywell and the suppression pool from the full-scale 4TCO tests, as described in section 4.3 of Reference 3A-1, and Reference 3A-13.

The basic condensation oscillation load is a bounding load for any condensation oscillation condition expected during a hypothetical LOCA in the plant. All 28 of the 4TCO test runs were analyzed to determine the bounding time periods. The criterion for the selection of these time periods was to bound the maximum power spectral density values observed at the bottom center pressure throughout the condensation oscillation period in all runs - in any 2.048 second block for all frequencies from 0-60 Hz - in approximately 0.5 Hz increments. The selected time periods were independently confirmed to be bounding by the amplified response spectra analysis (Reference 3A-13, Appendix A).

The pressure response spectrum envelope for the time periods selected is shown in Figure 3A-11; the spatial pressure distribution is shown in Figure 3A-12. The drywell pressure histories for the time periods defined in Reference 3A-13 are applied uniformly throughout the drywell.

3A.4.2.2.2 Pool Boundary Loads Due to Chugging

The Mark II generic chugging load definition was developed by applying the acoustic chugging methodology described in Reference 3A-14 to the chugging data base provided by the Mark II 4T Condensation Oscillation (4TCO) Test Program (Reference 3A-15). The definition of a chugging load starts with the identification of steam-bubble collapse as the fundamental excitation mechanism. The collapse produces acoustic responses in the suppression pool and the vents. The combined excitation of the suppression pool and vent response is characterized as a time-varying volumetric point source in the acoustic model. Point sources for the 4TCO facility are inferred from 4TCO wall pressures via the 4TCO acoustic model. These point sources can be applied to an acoustic model of the Mark II suppression pool because the bubble collapse and vent response in Mark II are correctly simulated by the prototypical 4TCO geometry and blowdown conditions. The multivent effects of variation in chug strength and chug time among vents are incorporated in the Mark II application (Reference 3A-16).

Seven large (key) chugs from the 4TCO data base were used to develop design sources to be applied to the acoustic model of the LGS containment. These design sources are to be applied desynchronized, using the set of chug start times having the smallest variance in one-thousand Monte Carlo trails drawn from a uniform distribution of start times having a width of 500 milliseconds. The chug start times are randomly assigned to the vents in the Mark II containment.

The observation of vent desynchronization has been verified by determining the time delay between individual bubble collapses in the full-scale, 7 vent tests conducted by the Japan Atomic Energy Research Institute. Conservatism is ensured by applying to the Mark II plant models a minimum estimate of the time window within which the individual bubble collapses must occur.

Two cases of source application are specified: symmetric and asymmetric. The symmetric case is defined as the desynchronized application of each of the design sources in turn, at every vent exit location in the LGS pool. The definition of the asymmetric case starts with the identification of a design moment axis which divides the suppression pool into two halves. Adjustment factors are applied to the design sources to raise their strength on one side of the pool and lower their strength on the other side. This procedure and its rationale are described in Reference 3A-16.

3A.4.2.2.3 Downcomer Lateral Loads

During chugging and condensation oscillation, a downcomer will experience intermittent lateral loading. However, the 4TCO tests (Reference 3A-15) have shown that the magnitude of the lateral loading in a Mark II facility during the condensation oscillation phase is relatively small compared to chugging-induced lateral loads. The chugging lateral load may be the result of asymmetric steam-bubble collapse or the result of the impact on the vent caused by rapidly inflowing water. In either case, the loads occur near the downcomer exit and have been observed to be impulsive in nature and random in both magnitude and direction. The stochastic nature of the loads appears unaffected by the proximity of other structures such as containment walls or another downcomer as close as three vent diameters away. The duration of an individual lateral load is typically less than 10 ms half sine wave. The single vent, lateral load specification for LGS consists of a static-equivalent load of 10 kips and 6 ms for low intensity chugs, 30 kips and 3 ms for the high intensity chugs, and 65 kips and 3 ms for the low probability, very high intensity chugs (Figure 3A-13). This 65,000 lbf load (Reference 3A-5) corresponds to the maximum load implied by extrapolation in the cold pool tests of GKM II data with an exceedance of 0.1 per LOCA.

3A.4.2.2.4 Multiple Vent Lateral Loads

Test data observations indicate that chugging forces on a single downcomer occur periodically in random directions for short time durations. The probability that the number of downcomers loaded with the maximum force in a particular time interval in the same direction is extremely small. Nonetheless, there is a small but finite probability that some fraction of the downcomers may experience a fraction of the load acting in the same direction at the same time.

The methodology used for driving the lateral loads on the various downcomer group combinations that will result in a conservative assessment is described in Reference 3A-5. The results indicate that a probability level of 10^{-4} for exceeding an impulse in 265 chugs is adequate for determining the total load on a group of downcomers. Phasing between vents is completely neglected. These two factors result in a conservative methodology for multiple vent lateral loads. The value of 265 chugs was reached based on consideration of a range of small liquid breaks (Reference 3A-2).

3A.4.2.2.5 Submerged Structure Loads Due to Condensation Oscillation and Chugging

Condensation oscillation and chugging create velocity and acceleration fields in the suppression pool that cause submerged structure drag loads. The pressure distributions corresponding to sources from the GE 700 series (Reference 3A-16) are computed at several elevations (nodes) around the submerged structure using IWEGS/MARSOFT (for condensation oscillation) and IWEGS/MARS-P (for chugging). These pressure responses around the body of each level are then spatially integrated to obtain the dynamic load due to fluid motion (force per unit length).

$$F = \int Pds \qquad \text{(EQ. 3A-4)}$$

where p is the fluid pressure acting on an area increment ds = nds, n being the inward-pointing normal unit vector at ds. The submerged structure load is equal to double the dynamic load due to the effect of the hydrodynamic mass. Table 3A-11 provides a summary of maximum force per unit length on various submerged structures for condensation oscillation and chugging phases.

3A.4.2.3 Secondary Loads

The previous sections have identified and specified loading methodologies that result in significant containment dynamic loads. In addition, several pool dynamic loads can occur that are considered secondary when compared to the previous loads or because the containment and related equipment response is small when subjected to them. The following sections identify the secondary loads and the load criteria to be applied to the LGS containment.

3A.4.2.3.1 Downcomer Friction Drag Loads

Friction drag loads are experienced internally by the downcomers during vent clearing and subsequent air or steam flow. In addition, the downcomers experience an external drag load during pool-swell. Using standard drag force calculation procedures, these loads are determined to be 0.6 kips and 0.3 kips per downcomer, respectively, and are not considered in the structural evaluation of the containment.

3A.4.2.3.2 Sonic Waves

Immediately following the postulated instantaneous rupture of a large primary system pipe, a sonic wave front is created at the break location and propagates through the drywell to the vent system. This load has been determined to be negligible and, therefore, none is specified.

3A.4.2.3.3 Compressive Wave

The compression of the air in the drywell and vent system causes a compressive wave to be generated in the downcomer water legs. This compressive wave propagates through the pool and causes a differential pressure loading on the submerged structures and on the wetwell wall. This load has been evaluated and is considered negligible.

3A.4.2.3.4 Fallback Loads on Submerged Boundaries

During fallback, water hammer type loads could exist if the water slug remained intact during this phase. However, available test data indicate that this does not occur, and the fallback process

consists of a relatively gradual setting of the pool water to its initial level as the air bubble percolates upward. This is based on visual observations during the EPRI tests (Reference 3A-17) as well as indirect evidence provided by an examination of pool bottom pressure forces from the 4T, EPRI, foreign licensee, and Marviken tests. Thus, these loads are small and will not be considered.

3A.4.2.3.5 Vent Clearing Loads on the Downcomers

The expulsion of the water leg in the downcomers at vent clearing creates a transient water jet in the suppression pool. This jet formation may occur asymmetrically leading to lateral reaction loads on the downcomer. However, this load is bounded by the load specification during chugging and will not be considered for containment analysis.

3A.4.2.3.6 Postpool-Swell Waves

Following the pool-swell process, continued flow through the vent system generates random pool motion. The pool motion creates waves that have potential loading impingement effects on the LGS wetwell wall and internal components. In accordance with the response to Question M020.8 documented in Appendix A of the DFFR, Revision 3 (June 1978), this load is considered negligible when compared to the other design basis loads.

3A.4.2.3.7 Seismic Slosh

The computer code SOLA-3D was used to estimate the suppression pool seismic slosh hydrodynamic loads. The results indicate the seismic slosh loads in the plant are much less that the LOCA chugging loads or the SRV air clearing bubble oscillation loads (on the order of a few psi at a relatively low frequency depending on location and direction).

The maximum wave (sloshing) height is 1.6 feet. The nodal force close to the pool bottom oscillates between 112 kips to 88 kips (including static load). Therefore, the bottom pressure rises to about 1.2 psi above the static pressure due to sloshing. The dominant frequency of the sloshing motion is 0.1 Hz, whereas the dominant frequency of the seismic acceleration is about 2 Hz.

3A.4.2.3.8 Thrust Loads

Thrust loads are associated with the rapid venting of air and/or steam through the downcomers. To determine this load, a momentum balance for a control volume consisting of the drywell, diaphragm floor, and vents is taken. Results of the analysis indicate that the load reduces the downward pressure differential on the diaphragm.

3A.4.2.4 Long-Term LOCA Loads

The LOCA causes pressure and temperature transients in the drywell and wetwell due to mass and energy released from the line break. The drywell and wetwell pressure and temperature time histories are required to establish the structural loading conditions in the containment because they are the basis for other containment hydrodynamic phenomena. The response must be determined for a range of parameters such as break size, reactor pressure, and containment initial conditions.

3A.4.2.4.1 Design Basis Accident Transients

The DBA LOCA for LGS is conservatively estimated to be a 3.538 ft^2 break of the recirculation line. This transient results in the maximum drywell pressure and therefore governs the LOCA

hydrodynamic loads. The LGS unique assumptions and input for the analysis are given in Section 6.2.1. Drywell and wetwell pressure and temperature responses are shown in Figures 3A-14 and 3A-15. This description of the transient does not include the effect of reactor subcooling.

3A.4.2.4.2 Intermediate Break Accident Transients

The worst case intermediate break for LGS is a 0.1 ft^2 break of a liquid line. The drywell and wetwell pressure and temperature responses are shown in Figures 3A-16 and 3A-17. This description of the transient does not include the effect of reactor subcooling.

3A.4.2.4.3 Small Break Accident Transients

Plant unique SBA data for LGS is not available. The wetwell and drywell pressure and temperature transients for a typical Mark II containment are used to estimate the LGS containment response to these accidents. These curves are shown in Figure 3A-18 (extracted from Reference 3A-12).

3A.4.2.5 LOCA Loading Histories for LGS Containment Components

The various components directly affected by LOCA loads are shown schematically in Figure 3A-19. These components may in turn load other components as they respond to the LOCA loads. For example, lateral loads on the downcomer vents produce minor reaction loads in the drywell floor from which the downcomers are supported. The reaction load in the drywell floor is an indirect load resulting from the LOCA and is defined by the appropriate structural model of the downcomer/drywell floor system. Only the direct loading situations are described in detail here. Table 3A-12 is a LOCA load chart for LGS. This chart shows which LOCA loads directly affect the various structures. Details of the loading time histories are discussed below.

3A.4.2.5.1 LOCA Loads on the Containment Wall and Pedestal

Figure 3A-20 shows the LOCA loading history for the LGS containment wall and the RPV pedestal. The wetwell pressure loads apply to the unwetted elevations in the wetwell; addition of the appropriate hydrostatic pressure is made for loads on the wetted elevations. Condensation oscillation and chugging loads are applied to the wetted elevations in the wetwell only. The pool-swell air bubble load applies to the wetwell boundaries as shown in Figures 3A-11 and 3A-12.

3A.4.2.5.2 LOCA Loads on the Basemat and Liner Plate

Figure 3A-21 shows the LOCA loading history for the LGS basemat and liner plate. Wetwell pressures are applied to the wetted and unwetted portions of the liner plate as discussed in Section 3A.4.2.5.1. The downcomer water jet impacts the basemat line plate as does the pool-swell air bubble load. Chugging and condensation oscillation loads are applied to the wetted portion of the liner plate.

3A.4.2.5.3 LOCA Loads on the Drywell and Drywell Floor

Figure 3A-22 shows the LOCA loading history for the LGS drywell and drywell floor. The drywell floor undergoes a vertically applied, continuously varying differential pressure, the upward component of which is especially prominent during pool-swell when the wetwell airspace is highly compressed.

3A.4.2.5.4 LOCA Loads on the Columns

Figure 3A-23 shows the LOCA loading history for the LGS columns. Pool-swell drag and fallback loads are minor because the column surface is oriented parallel to the pool-swell and fallback velocities. The pool-swell air bubble, condensation oscillations, and chugging will provide loads on the submerged (wetted) portion of the columns.

3A.4.2.5.5 LOCA Loads on the Downcomers

Figure 3A-24 shows the LOCA loading history for the LGS downcomers. The downcomer clearing load is a lateral load applied at the downcomer exit (in the same manner as the chugging lateral load) plus a vertical thrust load. Pool-swell drag and fallback loads are minor because the downcomer surfaces are oriented parallel to the pool-swell and fallback velocities. The pool-swell air bubble load is applied to the submerged portion of the downcomer as are the chugging and condensation oscillation loads.

3A.4.2.5.6 LOCA Loads on the Downcomer Bracing

Figure 3A-25 shows the LOCA loading history for the LGS downcomer bracing system. This system is not subject to impact loads because it is submerged at el 203'-5". As a submerged structure, it is subject to pool-swell drag, fallback, and air bubble loads. Condensation oscillations and chugging at the vent exit will also load the bracing system both through downcomer reaction (indirect load) and directly through the hydrodynamic loading in the suppression pool.

3A.4.2.5.7 LOCA Loads on the Wetwell Piping

Figure 3A-26 shows the LOCA loading history for piping in the LGS wetwell. Because the wetwell piping occurs at a variety of elevations in the LGS wetwell, sections may be completely submerged, partially submerged, or initially uncovered. Piping may occur parallel to pool-swell and fallback velocities, as with the main steam safety/relief piping. For these reasons, there are a number of potential loading situations that arise, as shown in Table 3A-13. In addition, the pool-swell air bubble load applies to the submerged portion of the wetwell piping as do the condensation oscillation and chugging loads.

3A.5 LOAD COMBINATIONS FOR STRUCTURES, PIPING, AND EQUIPMENT

3A.5.1 INTRODUCTION

To verify the adequacy of mechanical and structural design, it is necessary first to define the load combinations to which structures, piping, and equipment may be subjected. In addition to the loads due to pressure, weight, thermal expansion, seismic, and fluid transients, hydrodynamic loads resulting from LOCA and SRV discharge are also considered in the design of structures, piping, and equipment in the drywell and suppression pool. This chapter specifies how the LOCA and SRV discharge hydrodynamic loads will be combined with the other loading conditions. For the load combinations discussed in this chapter, seismic and hydrodynamic responses are combined by the methods specified in Reference 3A-1, section 5.1.2.

3A.5.2 LOAD COMBINATIONS FOR CONCRETE DESIGN IN CONTAINMENT, REACTOR ENCLOSURE, AND CONTROL STRUCTURE

The loads on the containment, its concrete internals (i.e., RPV pedestal, diaphragm slab), reactor enclosure, and control structure are combined to assess the structural integrity in accordance with

the design load combinations given in Table 3A-14. The factored load approach is used in the assessment of the concrete structural components. The load factors adopted are based on the degree of certainty and probability of occurrence for the individual loads as discussed in Reference 3A-1, section 5.1.2.

The LOCAs are characterized by several phenomena that result in nonconcurrent loadings on the structures. Time sequences of occurrence of the various time-dependent loads, as shown in figures 5-5 through 5-20 of Reference 3A-1, are taken into account to determine the most critical loading conditions.

3A.5.3 STRUCTURAL STEEL AND ASME CLASS MC STEEL COMPONENTS LOAD COMBINATIONS

The load combinations for structural steel in the containment, reactor enclosure, and control structure are given in Table 3A-15. These combinations apply to the suppression chamber steel columns, the downcomer bracing, and miscellaneous structural steel within the containment, reactor enclosure, and control structure.

The LOCAs are characterized by several phenomena that result in nonconcurrent loadings on the structures. Time sequences of occurrence of the various time-dependent loads, as shown in figures 5-5 through 5-20 in Reference 3A-1, are taken into account to determine the most critical loading conditions.

The load combinations for the ASME Class MC steel components in the concrete containment are given in Table 3A-16. These combinations apply to the drywell head assembly, equipment hatches, personnel lock, suppression chamber access hatches, CRD removal hatch and piping and electrical penetrations.

3A.5.4 LINER PLATE LOAD COMBINATIONS

The liner plate and its anchorage system, being an integral part of the containment system, is assessed for the same load combinations listed in Table 3A-14. However, for the liner system, the load factors are taken as unity and the acceptance criteria are specified in Section 3A.6.4.

The LOCAs are characterized by several phenomena that result in nonconcurrent loadings on the structures. Time sequences of occurrence of the various time-dependent loads, as shown in figures 5-5 through 5-20 in Reference 3A-1 are taken into account to determine the most critical loading conditions.

3A.5.5 DOWNCOMER LOAD COMBINATIONS

Load combinations and stress allowables for the downcomers are given in Table 3A-17. These load combinations are based in the load combinations given in table 5-2 of Reference 3A-1.

The LOCAs are characterized by several phenomena that result in nonconcurrent loadings on the structures. Time sequences of occurrence of the various time-dependent loads, as shown in figures 5-5 through 5-20 in Reference 3A-1, are taken into account to determine the most critical loading conditions.

3A.5.6 PIPING, QUENCHER, AND QUENCHER SUPPORT LOAD COMBINATIONS

LOCA loads considered on piping systems include pool-swell impact loads, pool-swell drag loads, downcomer water jet loads, pool-swell air bubble loads, fallback drag loads, condensation oscillation loads, chugging loads, and inertial loading due to the acceleration of the containment structure produced by LOCA loads. Loads due to SRV discharge on piping systems include water clearing loads, air clearing loads, fluid transient loads on SRV discharge piping, reaction forces at the quencher, and inertial loading due to the acceleration of the containment structure produced by SRV discharge loads.

The load combinations and stress limits for piping systems are given in Table 3A-18.

3A.5.6.1 Load Considerations for Piping Inside the Drywell

Piping systems inside the drywell are subjected to inertial loading due to the acceleration of the containment produced by LOCA and SRV discharge loads in the wetwell. The SRV discharge piping in the drywell is also subjected to fluid transient forces due to SRV discharge.

3A.5.6.2 Load Considerations for Piping Inside the Wetwell

All piping in the wetwell is subject to the inertial loading due to LOCA and SRV discharge.

Drag and impact loads due to LOCA and SRV discharge on individual pipes in the wetwell depend on the physical location of the piping. Other SRV discharge and LOCA loads applicable to piping in the wetwell are discussed in the paragraphs that follow.

Piping systems located below the suppression chamber water level are shown on Figures 3A-27 and 3A-28. In addition to the inertial loads, these piping systems are subjected to SRV air bubble and LOCA air bubble loads, condensation oscillation loads, and chugging loads. The SRV piping, quencher, and quencher support are also subject to fluid transient forces due to SRV discharge. Piping systems located within the jet impingement cone of the downcomer are also subjected to downcomer water jet loads.

Piping systems within the pool-swell zone are shown on Figures 3A-28, 3A-29, and 3A-30. All horizontal runs of these pipes are above the suppression chamber water level. The following loads, in addition to the inertial loads, act on these systems:

a. The horizontal runs of pipe below el 225'-8", experience pool-swell impact, pool-swell drag, and fallback drag loads.

b. The vertical portions of pipe in the water below el 225'-8" experience pool-swell drag and fallback drag loads.

3A.5.6.3 Quencher and Quencher Support Load Considerations

The quencher and quencher supports are subjected to the following hydrodynamic loads in addition to the pressure, weight, thermal, and seismic loads:

a. Unbalanced loads on the quencher due to SRV water clearing and air clearing transients, irregular condensation, and steady-state blowdown.

b. Drag loads due to SRV discharge and LOCA.

c. SRV piping end loads.

d. Inertial loading due to the acceleration of he containment produced by SRV discharge and LOCA.

3A.5.6.4 Load Considerations for Piping in the Reactor Enclosure

The effects of the inertial loading due to acceleration of the containment produced by SRV discharge and LOCA loads are evaluated for this piping.

3A.5.7 NSSS LOAD COMBINATIONS

Load combinations and acceptance criteria for ASME Class 1, 2, and 3 NSSS piping, equipment, and supports are provided in Table 3A-19.

3A.5.8 BOP EQUIPMENT LOAD COMBINATIONS

Safety-related equipment located within the primary containment, reactor enclosure, and control structure are assessed for the governing load combinations shown in Table 3A-20.

3A.5.9 ELECTRICAL RACEWAY SYSTEM LOAD COMBINATIONS

Load combinations for the electrical raceway system are given in Table 3A-21.

3A.5.10 HVAC DUCT SYSTEM LOAD COMBINATIONS

Load combinations for the HVAC duct system are given in Table 3A-22.

3A.6 DESIGN CAPABILITY ASSESSMENT CRITERIA

3A.6.1 INTRODUCTION

The criteria by which the design capability is determined are discussed in this chapter. Design of the LGS is assessed as adequate when the design capability of the structures, piping, and equipment is greater then the loads (including LOCA and SRV discharge) to which the structures piping and equipment are subjected. Loading combinations are discussed in Section 3A.5. The margins by which design capabilities exceed these loads are discussed in Section 3A.7.

3A.6.2 CONTAINMENT, REACTOR ENCLOSURE, AND CONTROL STRUCTURE CAPABILITY ASSESSMENT CRITERIA

3A.6.2.1 Containment Structure Capability Assessment Criteria

The acceptance criteria detailed in Section 3.8.1.5 have been used to assess the structural integrity of the containment and internal structures. No changes are made in these acceptance criteria when the effects of the dynamic SRV discharge and LOCA loads are included.

3A.6.2.2 Reactor Enclosure and Control Structure Capability Assessment Criteria

The acceptance criteria for seismic Category I structures presented in Section 3.8.4.5 have been used to assess the structural integrity of the reactor enclosure, control structure, and their

components. No changes are made in these acceptance criteria when the effects of the dynamic SRV discharge and LOCA loads are included.

3A.6.3 STRUCTURAL STEEL AND ASME CLASS MC STEEL COMPONENT CAPABILITY ASSESSMENT CRITERIA

The allowable stresses for structural steel in the containment, reactor enclosure, and control structure are given in Table 3A-15. These criteria apply to the suppression chamber steel columns, the downcomer bracing, and miscellaneous structural steel within the containment, reactor enclosure, and control structure.

The allowable stresses for ASME Class MC steel components in the concrete containment are given in Table 3A-16. These allowable stresses apply to the drywell head assembly, equipment hatches, personnel lock, suppression chamber access hatches, and piping and electrical penetrations.

3A.6.4 LINER PLATE CAPABILITY ASSESSMENT CRITERIA

The strains in the liner plate and anchorage system (welds and anchors) from self-limiting loads such as dead load, creep, shrinkage, and thermal effects are limited to the allowable values specified in table CC-3720-1 of Reference 3A-18. The displacements of the liner anchorage are limited to the displacement values of table CC-3730-1 of Reference 3A-18.

Stresses in the liner plate and anchorage system (welds and anchors) from mechanical loads such as SRV discharge and chugging are checked according to Reference 3A-19. Specifically, primary plus secondary membrane plus bending stresses are checked according to subsection NE-3222.2. Fatigue strength evaluation is based on subsection NE-3222.4. Allowable design stress intensity values, design fatigue curves, and material properties that are used conform to subsection NA, Appendix I.

The capacity of the liner plate anchorage is limited by the concrete pull-out to the service load allowable for concrete as specified in Reference 3A-20.

3A.6.5 DOWNCOMER CAPABILITY ASSESSMENT CRITERIA

The allowable stresses for the downcomers are given in Table 3A-17. These allowable stresses are in accordance with subsection NE of Reference 3A-19. As permitted by subsection NE-1120 for MC components, the downcomers are analyzed in accordance with subsection NB-3650 of Reference 3A-19. However, the lower allowable stresses, S_m, from table I-10.1 for MC components, are used when performing the analysis.

3A.6.6 BOP PIPING, QUENCHER, AND QUENCHER SUPPORT CAPABILITY ASSESSMENT CRITERIA

BOP piping systems in the containment and reactor enclosure are analyzed in accordance with ASME Section III, Division 1 (1971 Edition with Addenda through Winter 1972 for Class 2 and 3 piping, and 1977 Edition through Summer 1979 Addenda for Class 1 piping and Class 2 and 3 flanges), subsections NB-3600, NC-3600, and ND-3600, and ANSI B31.1 (Power Piping Code) for the loading described in Table 3A-18. In addition to these code requirements, when piping is required to deliver rated flow during or following an emergency or faulted event, the functional capability requirement shall be met for the load combinations with the event.

The quencher and quencher support are designed in accordance with ASME Section III, Division 1 (1977 Edition with Addenda through Summer 1979), subsections NC-3200 and NF-3000, respectively, for the loading discussed in Section 3A.5.6.3.

3A.6.7 NSSS CAPABILITY ASSESSMENT CRITERIA

The capability assessment criteria used for the evaluation of NSSS piping systems, RPV, RPV supports, RPV internals and floor-mounted equipment are shown in Table 3A-19. Table 3A-19 is in agreement with a conservative general interpretation of the NRC technical position, "Stress Limits for ASME Class 1, 2 and 3 Components and Component Supports of Safety-Related Systems and Core Support Structures Under Specific Service Loading Combinations".

Peak response due to related dynamic loads postulated to occur in the same time frame but from different events are combined by the SRSS method. A discussion of this load combination technique is given in Reference 3A-24.

3A.6.8 BOP EQUIPMENT CAPABILITY ASSESSMENT CRITERIA

All BOP equipment is required to withstand the dynamic loads resulting from seismic and hydrodynamic loads (SRV, SBA, IBA, and DBA) as follows:

a.	OBE alone	½% damping
b.	SSE alone	1% damping
c.	Combination of seismic and hydrodynamic loads	2% damping

Cases a and b are discussed in Section 3.7.3. Case c is considered in accordance with the load combinations shown in Table 3A-20. The adequacy of the qualification is verified by the following methods:

a. Analysis

b. Testing

c. Combination of analysis and testing

3A.6.8.1 Analysis

Safety-related equipment located in the primary containment, reactor enclosure, and control structure are analyzed to satisfy load combinations 1a, 1b, 2, 3d, and 3e of Table 3A-20. The maximum load effects result from simultaneous excitation in all three principal directions for all combinations involving dynamic loads as detailed in Section 3A.7.1.7.4.1.3.

3A.6.8.2 Testing

When safety-related equipment is qualified by testing, the TRS is to envelope the RRS for load combinations 1b, 3e, and 4 of Table 3A-20. The minimum test sequence is to perform five runs for load combination 1b, followed by one run of load combination 3e. The input motion for load combination 3e is such that the TRS generated for 2% damping envelopes the RRS for load

combination 4. Qualification is achieved if the equipment does not fail or malfunction during the test. Operability is verified before and after the test sequence. Active components required to function during a dynamic event are also verified during the test.

3A.6.8.3 Combined Analysis and Test

Some equipment is qualified by a combination of analysis and testing procedures.

An analysis is conducted on the overall assembly to determine its stress level and the transmissibility of motion from the base of the equipment to the critical components. The critical components are removed from the assembly and subjected to a simulation of the environment on a test table.

Testing methods are used to aid the formulation of the mathematical model for any piece of equipment. Mode shapes and frequencies are determined experimentally and incorporated into a mathematical model of the equipment. The model and subsequent analysis will meet the requirements of Section 3A.7.1.7.4.1.

3A.6.9 ELECTRICAL RACEWAY SYSTEM CAPABILITY ASSESSMENT CRITERIA

The allowable stresses for the electrical raceway system are given in Table 3A-21.

3A.6.10 HVAC DUCT SYSTEM CAPABILITY ASSESSMENT CRITERIA

The allowable stresses for the miscellaneous steel for the HVAC duct system are given in Table 3A-22.

3A.7 DESIGN ASSESSMENT

3A.7.1 ASSESSMENT METHODOLOGY

Loads on LGS structures, piping, and equipment are defined in Sections 3A.4 and 3B.4. The methods by which these loads are combined are discussed in Section 3A.5. The criteria for establishing design capability are stated in Section 3A.6.

This section describes the assessment methodology used in the final evaluation of structures, piping, and equipment.

3A.7.1.1 Containment, Reactor Enclosure, and Control Structure Assessment Methodology

3A.7.1.1.1 Containment Structure

3A.7.1.1.1.1 Hydrodynamic Loads

3A.7.1.1.1.1.1 Structural Models

The dynamic analysis for the structural response of the containment and internal structures due to the SRV discharge loads and LOCA loads is performed using the finite-element method. The ANSYS (Section 3.8.7) finite-element computer program was chosen for the transient dynamic analysis. Figure 3A-31 shows the ANSYS finite-element model. The concrete containment walls, slabs, RPV, RPV pedestal, and shield wall are modeled with shell elements. The refueling bellows

and stabilizer truss are modeled with spar elements. The RPV internals are modeled with beam elements. The suppression pool fluid mass is modeled with lumped-mass elements. The ANSYS model includes a total of 797 elements and 206 dynamic degrees of freedom.

The soil-structure interaction is taken into consideration by modelling the soil using a series of discrete springs and dampers in three directions as shown in Figure 3A-31. The properties of the discrete springs and dampers are calculated based on the formulae for lumped-parameter foundations found in Reference 3A-21.

3A.7.1.1.1.1.2 Damping

a. Structural Damping

The equations of motion for a discrete structure must include a term to account for viscous damping that is linearly proportional to the velocity. The equations of motion for a damped system are:

$$[M]\{\ddot{r}\} + [C]\{\dot{r}\} + [K]\{r\} = \{R(t)\} \qquad \text{(EQ. 3A-5)}$$

where [C] is the viscous damping matrix.

A viscous damping matrix of the form

$$[C] = \alpha [M] + \beta [K] \qquad \text{(EQ. 3A-6)}$$

was used (Reference 3A-22) where α and β are proportionality constants that relate damping to the velocity of the nodes and the strain rates, respectively. This damping matrix leads to the following relation between α and β and the damping ratio of the ith mode C_i:

$$C_i = \alpha/2\omega_i + \beta\omega_i/2 \qquad \text{(EQ. 3A-7)}$$

where ω is the natural circular frequency of the ith mode. For the usual case of only structural damping, $\alpha = 0$ and therefore $\beta = 2C_i/\omega_i$.

Because only a single value of β is permitted in the ANSYS input, the most dominant natural frequency of the structure is selected for the computation of β (Reference 3A-23).

A value of β equal to 0.00063 is used in the ANSYS model which corresponds to structural modal damping of approximately 4% of critical at 20 Hz which is the most dominant natural frequency of the structure.

Figure 3A-32 shows modal damping ratio versus modal frequency for structural stiffness-proportional damping.

b. Soil Springs and Radiation Damping

The elastic half-space theory as described by Reference 3A-21 was used to compute the values of the spring constants and dampers in the horizontal, vertical, and rocking directions (K_H, K_V, K_ψ, C_H, C_V, C_ψ).

The following parameters are used to represent the rock foundation:

G = Shear modulus of foundation medium
= 1.154×10^3 KSI

ν = Poisson's ratio of foundation medium
= 0.3

ρ_s = Material density of foundation medium
= 0.00481 k-sec^2/ft^4

V_S = Shear-wave velocity
= 6180 ft/sec

From which we get the following:

K_H = 3.37×10^6 k/in

C_H = 1.57×10^4 k-sec/in

K_V = 3.96×10^6 k/in

C_V = 2.72×10^4 k-sec/in

K_ψ = 9.5×10^{11} k-in/Rad

C_ψ = 2.29×10^9 k-in-sec/Rad

The above-lumped foundation springs and dampers were then distributed to every node on the basemat according to the tributary area.

3A.7.1.1.1.1.3 Fluid-Structure Interaction

The ANSYS finite-element model with appropriate fluid-structure coupling was developed for the analysis of the containment structure. The water mass constitutes only 1/7 of the total mass of the reinforced concrete structure. The model used considers fluid-structure coupling by lumping the water mass in the suppression pool at each node of the wetted surface. The weighted area approach was considered to determine the fluid mass at each node of the suppression pool.

3A.7.1.1.1.1.4 Supplementary Computer Programs

Supplementary computer programs were used for preprocessing and postprocessing of data generated for or by the ANSYS computer program.

Preprocessing programs called PREPRC1, PREPRC2, and PREPRC3 were developed to convert the SRV, condensation oscillation, and chugging pressure time histories into force time histories, respectively, acting at the associated nodes of the ANSYS model. The programs write the nodal force time histories onto a file for processing by ANSYS.

A postprocessor program was developed to calculate the nodal acceleration time history. This program is called DISQGE. It reads the structural response displacement time histories generated

from ANSYS (displacement pass option), scans for the maximum displacements, and generates the acceleration time histories using the Fast Fourier Transformation method.

Bechtel in-house computer program MSPEC was used to compute the ARS obtained from DISQGE. The program also performs plotting and broadening of the spectrum.

A computer program ENVELOP was developed to envelope response spectra obtained from MSPEC.

Computer program SCALE was developed to scan the maximum absolute stresses generated by ANSYS (stress pass option). An explanation of SCALE is given in Section 3A.7.1.1.1.1.6.2.

Verification of PREPRC1, PREPRC2, PREPRC3, DISQGE, ENVELOP, and SCALE are available for review.

3A.7.1.1.1.1.5 Load Application

3A.7.1.1.1.1.5.1 SRV Discharge Loads

The SRV discharge load used in the analyses was taken from the KWU load report (Reference 3B-2). The analyses were done for KWU SRV pressure traces 35, 76, and 82. Axisymmetric and asymmetric pressure distributions were considered. Section 3B.4.1 contains a detailed SRV load definition. The load definition takes into account the variation in pressure amplitude and frequency in the input forcing functions by applying a change of key frequencies in the assumed range of 55% to 125% of original frequency content (included are 55%, 67%, 87%, 100%, and 125% of the original frequencies) and a pressure multiplier of 1.5 to each input load trace. A total of 15 axisymmetric load traces and 15 asymmetric load traces were used in the analyses.

3A.7.1.1.1.1.5.2 LOCA-Related Loads

The main LOCA loads that significantly affect the dynamic analysis are condensation oscillation and chugging loads.

Because CO and chugging are sequential nonsimultaneous events, formulation of the LOCA load is conservatively accomplished by enveloping the CO and chugging results obtained from dynamic analyses.

The CO analysis was performed for two cases: the basic CO case and the CO-ADS case. Both CO and CO-ADS load definitions are based on direct application of measured pressure data from the 4TCO facility, a BWR Mark II prototypical unit cell used to produce expected bounding CO load data (Reference 3A-1). The CO load case is related to the basic CO load that covers all LOCA blowdown conditions resulting in CO, whereas the CO-ADS load case is data associated with the combination of CO and ADS events. Both events (CO and CO-ADS) produce wall pressure loading of axisymmetric nature. The wetwell pressure load vector was appropriately applied to the ANSYS model for a dynamic analysis. Also considered in the analysis is associated drywell pressure load defined in Reference 3A-1, based on a direct application of the measured drywell acoustic pressure time histories. A total of 17 time segments of CO and two time segments of CO-ADS are considered in the analysis.

The LGS Mark II chugging load pressure transients were calculated by Bechtel proprietary computer code IWEGS/MARS-P using GE700 series CHUG source data supplied by GE (Reference 3A-1).

The source data were based on measured data from 4TCO test facility, a BWR Mark II prototypical unit cell used to simulate the chugging loads during a postulated Mark II LOCA. A total of 14 chugging time histories are considered in the chugging analyses.

3A.7.1.1.1.1.6 Analysis

3A.7.1.1.1.1.6.1 Response Spectra Generation

Acceleration time histories, maximum structural displacements and accelerations, and broadened ARS are developed for the analysis of piping, equipment, and NSSS systems. Gross acceleration time histories are generated at the interface between pedestal and diaphragm slab, the stabilizer location at the containment wall, the top of drywell at the refueling bellows, and at the interface between wetwell wall and base slab.

The maximum containment response to SRV axisymmetric loads is obtained by enveloping the ARS of the 15 axisymmetric SRV cases. Likewise, the response spectra for the 15 asymmetric SRV cases are enveloped.

The maximum containment response to the condensation oscillation loads is obtained by enveloping the ARS of the 17 CO segments. Likewise, the response spectra of the two CO-ADS segments are enveloped.

The maximum containment response to the chugging loads is obtained by enveloping the ARS of the 14 chugging cases.

Enveloped floor response spectra of 8 damping values, between 0.5% and 20% of critical are generated. For clarity, these 8 enveloped floor spectra are grouped into two separate plot sets of 4 dampings each. The low damping plot sets, furnished in Section 3A.9, include damping ratios of ½%, 1%, 2%, and 5% of critical. The high damping plot sets include damping ratios of 7%, 10%, 15%, and 20% of critical. Floor response spectra of high damping values (i.e., greater than 7% critical) are generated for application to systems and components where larger system or material damping values are justified. Reference 3A-31 provides an example of such an application. The spectra are broadened by ±15% to account for the uncertainties in the structural modeling techniques and material properties.

3A.7.1.1.1.1.6.2 Stress Analysis

The ANSYS computer program (stress pass option) is used to compute the force and moment resultants due to SRV and LOCA-related loads. A postprocessor program called SCALE is used to scan for the maximum absolute values of forces and moments in the circumferential and meridional directions.

The forces and moments due to chugging and condensation oscillation loads are considered for the load combinations including the LOCA loads. The governing forces and moments from the six different frequencies are used in the stress analysis.

3A.7.1.1.1.2 Seismic Loads

Seismic loads constitute a significant loading in the structural assessment. The same seismic loads as those used in the initial building design are used. In that design, a dynamic analysis was made using discrete mathematical idealization of the entire structure using lumped masses. The resulting

axial forces, moments, and shear forces at various levels due to OBE and SSE are used (Section 3.7). The effects of the seismic overturning moment and vertical accelerations are converted into forces at the elements.

3A.7.1.1.1.3 Static and Thermal Loads

The loads under consideration are the static loads (dead load and accident pressure) and temperature loads (operating and accident temperature) which are all axisymmetrical.

a. To analyze the above static loads, an in-house computer program, FINEL (Section 3.8.7), is used. Moments, axial forces, and shear forces are computed by FINEL in an uncracked axisymmetric finite-element containment model.

b. The operating and accident temperature gradients are computed using ME 620 (Section 3.8.7) computer program (Bechtel program).

c. The results from a, b, and the hydrodynamic/seismic analysis are combined and applied to a containment element. The element contains data relative to rebar location, direction, and quantity and concrete properties. Within that wall element, force equilibrium and strain compatibility between the rebar and concrete is established by allowing the concrete to crack in tension. In this way, the stresses in the rebar and concrete are determined. The program used for this analysis is called CECAP (Section 3.8.7).

3A.7.1.1.1.4 Load Combinations

All load combinations from equations 1 through 7a as presented in Table 3A-14 have been analyzed.

The reversible nature of the structural responses due to the pool dynamic loads and seismic loads is taken into account by considering the peak positive and negative magnitudes of the response forces and maximizing the total positive and negative forces and moments governing the design.

Seismic and pool dynamic load effects (SRV and LOCA) are combined by conservatively summing the peak responses of each load by the absolute sum method. Even though the SRSS method is more appropriate because the peak effects of all loads may not occur simultaneously (Reference 3A-24), the conservative absolute sum method is used in the design assessment of the containment and internal concrete structures to expedite licensing.

3A.7.1.1.1.5 Design Assessment

Material stresses at the critical sections in the primary containment and internal concrete structure are analyzed using the CECAP computer program. Critical sections for bending moment, axial force and shear in three directions are located throughout the containment structure. Liner plate is not considered as a structural element. The CECAP program considers concrete cracking in the analysis of reinforced concrete sections. CECAP uses an iterative technique to obtain stresses considering redistribution of forces due to cracking and, in the process, it reduces the thermal-stresses due to the relieving effect of concrete cracking. The program is also capable of describing the spiral and transverse reinforcement stresses directly. The input data for the program consists of the uncracked forces, moments and shears calculated by FINEL, ANSYS, and seismic analysis. The loads are then combined in accordance with Table 3A-14 with appropriate load factors. The stress margins are calculated in Section 3A.7.2.

3A.7.1.1.2 Reactor Enclosure and Control Structure

3A.7.1.1.2.1 Hydrodynamic Loads

3A.7.1.1.2.1.1 Load Definitions

The reactor enclosure and control structure were analyzed for both the SRV discharge load and the LOCA condensation oscillation and chugging loads. Description of the different load cases are presented in Section 3A.7.1.1.1.1.5.

3A.7.1.1.2.1.2 Hydrodynamic Analysis Models

For the hydrodynamic loads described in Section 3A.7.1.1.2.1.1, different mathematical models are constructed for the determination of the reactor enclosure and control structure hydrodynamic responses. The mathematical models are presented in detail in the following sections and are summarized in Table 3A-23.

3A.7.1.1.2.1.2.1 SRV Analysis Models

The reactor enclosure and control structure were modeled to simulate global structural response during SRV actuation. Included in the analyses were an axisymmetric model for axisymmetric SRV loads and flexible base vertical, N-S, and E-W stick models for the asymmetric SRV loads. The latter uses the ANSYS containment finite-element model response as input. The mathematical models and analysis procedures are described below.

3A.7.1.1.2.1.2.1.1 Axisymmetric SRV Analysis Model

An axisymmetric model, based on Bechtel proprietary code CE971-FESS, was created to generate vertical response data for the NSSS new loads' structure and equipment adequacy assessment. The axisymmetric model has been closely correlated with in-plant test data (Reference 3A-25).

The model represents a containment system, adjacent structure (including reactor enclosure and control structure), and the soil medium as shown in Figure 3A-33. Figure 3A-38 shows a mass-proportional and stiffness-proportional damping simulation. The containment system and soil medium were modeled as FESS axisymmetric finite-elements, whereas the adjacent structure was simulated by a coupled stick model. Altogether, the model has a combination of 673 dynamic degrees of freedom.

The model was modified to simulate as-built conditions (i.e., concrete aging effect, etc.) and normal plant operating conditions (i.e., RPV mass, etc.) for generation of response data used for associated equipment adequacy evaluation. The analytical elements have the material properties as shown in Table 3A-31.

3A.7.1.1.2.1.2.1.2 Asymmetric SRV Analysis Models

Analysis models for the asymmetric load include the combined use of the ANSYS finite-element containment model response as input to the flexible base vertical, N-S horizontal and E-W horizontal stick models of the reactor enclosure and control structure. The ANSYS containment model is shown in Figure 3A-31, and the stick models are shown in Figures 3A-34 and 3A-35. The stick model damping uses the composite damping method (Reference 3A-21).

The vertical stick model was taken from the verified axisymmetric (FESS) coupled model. This model has 46 dynamic degrees of freedom. The flexible base was simulated by a soil spring and a damper as recommended in the Bechtel design guide (Reference 3A-21).

The N-S and E-W analytical stick models were similar to those used in the seismic analyses. Each stick model has 12 dynamic degrees of freedom.

Input load data were taken from associated ANSYS containment analysis output data. This includes use of a vertical input time history at the adjacent structure base equal to an average vertical response acceleration time history (from ANSYS) at the containment wall base, multiplied by an attenuation factor and use of horizontal input acceleration time history at the adjacent structure base equal to the gross motion generated from the associated containment ANSYS output data.

3A.7.1.1.2.1.2.2 CO Analysis Model

The reactor enclosure and control structure were modeled to simulate global structural response due to CO loads. Included in the analyses were an axisymmetric model for basic CO load case and CO-ADS load case, as was used in the axisymmetric SRV analysis described in Section 3A.7.1.1.2.1.2.1.1.

3A.7.1.1.2.1.2.3 CHUG Analysis Models

The reactor enclosure and control structure were modeled to simulate global structural response during various CHUG events. Included in the time history analyses were flexible base stick models presented in Section 3A.7.1.1.2.1.2.1.2, which use the ANSYS containment model response as input for the CHUG asymmetric loads, and an axisymmetric model for the CHUG equivalent axisymmetric loads. The mathematical models and analytical procedures are described below.

3A.7.1.1.2.1.2.3.1 CHUG Asymmetric Analysis Models

Analysis models for the CHUG asymmetric loads, as were used for SRV asymmetric loads, include the combined use of the ANSYS finite- element containment model response as input to the flexible base vertical, N-S horizontal and E-W horizontal stick models of the reactor enclosure and control structure. The ANSYS containment model is shown in Figure 3A-31, and the stick models are shown in Figures 3A-34 and 3A-35. The stick model damping used the composite damping method (Reference 3A-21).

The vertical stick model used was taken from the verified axisymmetric (FESS) coupled model. This model has 46 dynamic degrees of freedom. The flexible base was simulated by a soil spring and damper as recommended in the Bechtel design guide (Reference 3A-21).

The N-S and E-W analytical stick models were the same as were used in the seismic analyses. Each stick model has 12 dynamic degrees of freedom.

Input load data were taken from associated ANSYS containment analysis output data. This includes the use of a vertical input time history at the reactor enclosure and control structure base equal to an average vertical response acceleration time history (from ANSYS) at the containment wall base, multiplied by an attenuation factor, and the use of horizontal input acceleration time history at the reactor enclosure and control structure base equal to the gross motion generated from the associated containment ANSYS output data (no attenuation factor being used).

3A.7.1.1.2.1.2.3.2 CHUG Axisymmetric Analysis Model

An axisymmetric model, based on Bechtel proprietary code CE971-FESS, was created to generate vertical response data for the NSSS new loads' structure and equipment adequacy assessment.

Similar to the axisymmetric SRV analysis model (Section 3A.7.1.1.2.1.2.1.1) and the axisymmetric CO analysis model (Section 3A.7.1.1.2.1.2.2), CHUG axisymmetric analysis model represents a containment system, an adjacent structure (including reactor enclosure and control structure), and the soil medium as shown in Figure 3A-33. The containment system and soil medium were modeled as FESS axisymmetric finite-elements, whereas the adjacent structure was simulated by a coupled stick model. The model has a combination of 673 dynamic degrees of freedom. The model was modified to simulate as-built conditions (i.e., concrete aging effect, etc.) and normal plant operating conditions (i.e., RPV mass, etc.), for generation of response data used for associated equipment adequacy evaluation.

The analytical elements have the material properties as shown in Table 3A-31.

3A.7.1.1.2.1.2.4 Control Structure Floor/Local Models

Based on the excitation source at floor-wall junctions, analytical models for the selected floors were constructed to generate floor vertical response. Each floor considered was as a finite-element model, with boundaries at walls simulated by clamped edges. Along the line of symmetry (N-S direction), symmetric boundary conditions were imposed in the construction of a "half-model" for the transient analyses, i.e., SRV and CHUG loads.

To deal with dynamic problems of larger load duration, i.e., CO, CO-ADS, and seismic loads, a "quarter-model" was formed by taking a symmetric line in the E-W direction of the "half-model". Symmetric boundary were imposed similarly.

The half-model (Figure 3A-36) consists of 42 model nodes and 30 quadrilateral elements. By choosing five dynamic degrees of freedom to each interior node and three DDOF to each symmetric node, the model has 115 DDOF. Similarly, the quarter-model has 9 model nodes and 4 quadrilateral elements (Figure 3A-37), with 12 DDOF selected for analysis.

All floor models considered have identical nodal coordinates and similar model material properties (i.e., equivalent floor element thickness and mass density to take into account the beam-slab system action).

Floor-supporting steel girders have contributed a substantial portion of equivalent floor element thickness calculated for the beam-slab system. The contribution of the girders are different in magnitude, depending upon girder size and junction with or without shear connectors. The floors, except that of el 269' (control room), were built with shear connectors. The floor model at el 269' (control room) was verified by data correlation/ comparison with an in-plant test.

In addition, the models were modified to simulate as-built conditions (e.g., concrete aging effect, etc). To deal with seismic events, the models were further modified to consider cracking effects.

Floor model material properties are shown in Table 3A-24.

3A.7.1.1.2.1.3 Hydrodynamic Analysis

3A.7.1.1.2.1.3.1 Analysis Procedures

3A.7.1.1.2.1.3.1.1 Axisymmetric Analysis Procedure

The axisymmetric analysis general procedure is to perform a time history analysis using equivalent axisymmetric input forcing vectors described in Sections 3A.7.1.1.1.1.5.1 and 3A.7.1.1.1.1.5.2, using Bechtel proprietary code CE971-FESS. ARS data are generated using the acceleration response time histories obtained from the time history analysis using Bechtel proprietary code CE789-MSPEC. All associated ARS data are enveloped, widened ±15%, and plotted, using Bechtel proprietary codes ENVLPS and MSPEC.

3A.7.1.1.2.1.3.1.2 Asymmetric Analysis Procedure

The general analytical procedure for asymmetric analysis consists of generating input load vectors to ANSYS model from appropriate use of the load definition and applying ANSYS transient response for asymmetric loadings to adjacent structure decoupled stick models (N-S, E-W, and vertical). A transient analysis is performed using decoupled BSAP stick models for each load case. The ARS data are generated using the response acceleration time histories and Bechtel proprietary code CE789-MSPEC. All associated ARS data are enveloped, widened ±15%, and plotted.

3A.7.1.1.2.1.3.1.3 Floor/Local Model Analysis Procedure

The floor model analysis general procedure is to perform a time history analysis using input forcing vectors taken from the output of stick model analyses described in Sections 3A.7.1.1.2.1.3.1.1 and 3A.7.1.1.2.1.3.1.2 and using the model according to Bechtel proprietary code CE800-BSAP. ARS data are developed using the acceleration response time histories and Bechtel proprietary codes CE789-MSPEC and ENVLPS.

3A.7.1.1.2.1.3.2 Generation of Response Data

3A.7.1.1.2.1.3.2.1 Acceleration Response Spectra Data

3A.7.1.1.2.1.3.2.1.1 SRV ARS Data

Two sets of ARS data were generated. One set is for SRV axisymmetric analysis and the other set is for SRV asymmetric analysis. The ARS data, enveloped from associated data and broadened ±15% at peak frequencies, represent global response, applicable to structural assessment and NSSS equipment (or other safety-related equipment) adequacy evaluations located at or near the adjacent structure walls and/or columns. The ARS at selected typical locations on the reactor enclosure and control structure are presented in Section 3A.10.

3A.7.1.1.2.1.3.2.1.2 CO ARS Data

Two sets of ARS data are generated. One set is for basic CO load case analysis and the other set is for the CO-ADS load case. Again, the ARS data, enveloped from associated data and broadened ±15% at all peak frequencies, represent global response. The data are applicable to structure and/or equipment adequacy assessment located at or near the adjacent structure walls and/or columns. The ARS at selected locations are presented in Section 3A.10.

3A.7.1.1.2.1.3.2.1.3 CHUG ARS Data

Two sets of broadened ARS data are presented in Section 3A.10 for appropriate use in structure and equipment adequacy assessment. Set one is for CHUG asymmetric analysis case, and set two is for the CHUG equivalent axisymmetric analysis case.

The ARS data for the CHUG asymmetric case were developed and plotted similar to the SRV asymmetric analysis case. The data plots include the broadened ARS data in the three global directions (vertical, N-S, and E-W axes).

The CHUG asymmetric vertical ARS data provide responses for the applicable areas for the NSSS equipment adequacy assessment. The N-S and E-W ARS data apply to all NSSS equipment situated in any location of the reactor enclosure and control structure.

The ARS data for CHUG equivalent axisymmetric analysis cases were developed and plotted similar to SRV axisymmetric analysis cases.

Again, the data represent only global response, applicable to the NSSS equipment adequacy evaluations located at or near the adjacent structure walls and/or columns. Local/floor models are required for generating vertical ARS data for some floor-mounted equipment.

3A.7.1.1.2.1.3.2.1.4 Hydrodynamic Local ARS Data

The local ARS data in the control structure were generated based on the floor/local model analytical procedure described in Sections 3A.7.1.1.2.1.2.4 and 3A.7.1.1.2.1.3.1.3. The data was broadened ±15 percent at all peaks of the data enveloped from associated dynamic events.

The hydrodynamic events considered in the enveloping were SRV, CHUG, CO (basic), and CO-ADS.

The hydrodynamic local ARS data are used for the structures, components, and floor-mounted equipment where the global ARS data are not applicable.

3A.7.1.1.2.2 Seismic Loads

The seismic analysis methodology is discussed in Section 3.7.2.1. A seismic local model (Section 3A.7.1.1.2.1.2.4) was developed to generate local ARS data for the floors of the control structure.

3A.7.1.1.2.3 Static Loads

The static loads are discussed in Section 3.8.4.3.

3A.7.1.1.2.4 Load Combinations

All individual loads for concrete structures are combined with the appropriate load factors, as shown in Table 3A-14, for analysis of all loading combinations.

Steel structures are checked for the load combinations listed in Table 3A-15.

3A.7.1.1.2.5 Design Assessment

Critical sections for bending moment, axial force, and shear in all three directions are located throughout the reactor enclosure and control structure. Design capability at the critical sections is

determined, and then the design capability is compared with the actual forces and moments acting on the sections under all the load combinations. This comparison yields design margins. The design margins are discussed in Section 3A.7.2.

3A.7.1.2 Structural Steel and ASME Class MC Steel Components Assessment Methodology

3A.7.1.2.1 Suppression Chamber Columns

There are 12 suppression chamber columns, which are 42 inch diameter pipe with 1¼ inch wall thickness. The columns are attached at the underside of the diaphragm slab at el 234'-2" and at the basemat at el 181'-11".

3A.7.1.2.1.1 Structural Models

The columns were independently analyzed for static and dynamic loads. The analytical methods used for nonhydrodynamic loads such as dead, live, pressure, temperature, seismic, and pipe rupture loads are described in Section 3.8.3.4.5.

To deal with dynamic effects from seismic and hydrodynamic events, two analytical approaches were used. The ANSYS containment model (Section 3A.7.1.1.1), in which the columns were also modeled, was used for LOCA load cases. For seismic and SRV loads, the BSAP beam model (Figure 3A-44) was used. The beam model has 13 beam elements and 14 nodes, with effective water mass in the submerged portion. The column ends were modeled as clamped edges.

3A.7.1.2.1.2 Loads

The columns, partially submerged in the suppression pool, are subjected to direct pressure loads from air bubble oscillation, etc, and inertia loads due to building response (or movement) from dynamic loads (seismic and hydrodynamic). Thermal loads are induced due to the rise of temperature during hydrodynamic LOCA events.

3A.7.1.2.1.2.1 SRV Discharge Loads

The SRV discharge pressure time histories are considered as acting on the submerged portions of the columns.

The inertia forces from building response due to SRV discharge load are included by using the response spectra shown in Section 3A.9.

3A.7.1.2.1.2.2 LOCA-Related Loads

The manner in which the LOCA-related loads are applied to the column is the same as described for SRV loads in Section 3A.7.1.2.1.2.1.

3A.7.1.2.1.2.3 Seismic Loads

The seismic loads on the column were obtained by response spectrum method. The response spectra used are developed for OBE and SSE as described in Section 3.7.

3A.7.1.2.1.2.4 Static Load

Static loads, including dead load and thermal load, were considered in the column analysis.

3A.7.1.2.1.2.5 Load Combinations

The load combinations and allowable stresses are in accordance with Section 3A.5.3. The peak dynamic responses due to the seismic and pool dynamic load effects are combined by the SRSS method. The resulting combined dynamic loads are combined with the static loads by the absolute sum technique.

3A.7.1.2.1.2.6 Design Assessment

The combined stresses due to axial force and bending moment were calculated and compared with allowable stresses.

3A.7.1.2.2 Downcomer Bracing

The following covers the methodology used in the assessment of the bracing system at el 203'-5" in the primary containment suppression pool.

3A.7.1.2.2.1 Bracing System Description

The downcomer bracing system is designed as a two-dimensional truss system to provide horizontal support for 87 downcomers, 14 MSRV discharge lines, and other miscellaneous piping in the suppression pool. The bracing system is supported vertically by the 87 downcomers and at 12 anchor points around the RPV pedestal wall. The bracing system is made of stainless steel members connected to carbon steel collars at the downcomers and embedment plates at the pedestal wall by high strength stainless steel bolts. The bracing members consist of 10 inch and 12 inch diameter schedule 160 pipe sections, and 3¼ inch end connection plates. The bracing system is designed in accordance with Reference 3A-30.

The bracing system layout and typical connection details are shown in Figures 3A-39 and 3A-40. The mathematical model used in the bracing system is presented in Figure 3A-396.

3A.7.1.2.2.2 Loads

The bracing system is assessed for all plant operation induced loads described below. The basis for all hydrodynamic loads considered in the analysis is presented in Section 3A.4 and 3B.4.

3A.7.1.2.2.2.1 SRV Discharge Loads

Discharge through the SRV discharge pipe creates horizontal as well as vertical loading on the bracing system due to unbalanced pressures. The horizontal (lateral) load is considered as acting on the downcomers and the SRV discharge pipes. The vertical load is considered acting on the bracing members alone. These loads are applied to the bracing system by considering them as equivalent static loads using a dynamic magnification factor which is obtained from the dynamic analysis of the downcomer, as described in Section 3A.7.1.4.

The SRV discharge also induces hydrodynamic forces in the containment structure. Inertial forces of the bracing system, due to the response of the containment structure, are considered using hydrodynamic response spectra of the containment structure shown in Section 3A.9.

The lateral loads and the containment structure response form the complete SRV discharge load set on the bracing system.

3A.7.1.2.2.2.2 LOCA-Related Loads

LOCAs are characterized by several phenomena that result with nonconcurrent loadings on the bracing system as described in Section 3A.4.2. These hydrodynamic loads induce accelerations of the containment structure, which in turn induce additional loads on the bracing system. These loads are obtained from the hydrodynamic ARS shown in Section 3A.9.

In addition, the LOCA event induces lateral forces on the submerged portion and tip of downcomers. The loads include drag loads, pressure loads, and chugging tip load. The hydrodynamic analysis of a single downcomer for the lateral loads is presented in Section 3A.7.1.4. The resulting reaction forces at the bracing support are applied as equivalent static load in accordance with section 3.1 of Reference 3A-26.

3A.7.1.2.2.2.3 Seismic Loads

The forces due to the seismic accelerations of the downcomers, the SRV lines, and the bracing members are obtained by analysis of these structures using the response spectra developed for OBE and SSE as described in Section 3.7.2.

3A.7.1.2.2.2.4 Static Loads

The dead load of the bracing members is considered with allowance for buoyancy.

3A.7.1.2.2.2.5 Thermal Load

The operating and accident temperature considered is 90°F and 210°F, respectively. The reference temperature of the system is assumed to be 60°F.

3A.7.1.2.2.2.6 Load Combinations

The load combinations and allowable stresses are described in Table 3A-15. Although the loads on the bracing system under consideration act in random horizontal directions, each individual load is applied on the system in the worst possible direction to find the maximum resultant forces.

3A.7.1.2.2.3 Design Assessment

The two-dimensional truss model of the bracing system is analyzed for the static, thermal, and equivalent static hydrodynamic loads using the computer program STRUDL. The ASME truss model is analyzed for the containment structure inertia response due to seismic and hydrodynamic events using the computer program ANSYS. The bracing member forces calculated above for the various loading conditions are combined by the SRSS method and assessed in accordance with the loading combinations and stress allowables specified in Table 3A-15.

3A.7.1.2.3 ASME Class MC Steel Components

The ASME Class MC steel components include suppression chamber access hatch, equipment hatch, equipment hatch/personnel airlock, refueling head and CRD removal hatch. Details of these components are shown in Figures 3.8-31 through 3.8-34. All of these components were reevaluated

for additional loads due to Mark II hydrodynamic effects (SRV and LOCA) by Chicago Bridge and Iron Company under subcontract from Bechtel. The refueling head and the equipment hatch/personnel airlock were analyzed using Chicago Bridge and Iron computer program E0781. This computer program calculates the stresses and displacements in thin wall elastic shells of revolution when subjected to static edge, surface, and/or temperature loads with an arbitrary distribution over the surface of the shell. The other components (CRD removal hatch, suppression chamber access hatch, and equipment hatch) were reassessed using manual computations in accordance with the load combinations and allowable stresses shown in Table 3A-16.

An analysis, using the ANSYS 5.7, was performed by Structural Integrity Associates to reduce the Unit 2 drywell head bolt preload, (See Section 3A.7.2.1.9.1).

3A.7.1.2.3.1 Loads

Loads considered in the assessment of the components included dead load, live load, design accident pressure and thermal load, external pressure load, and jet load resulting from postulated pipe rupture as discussed in Section 3.8.2.3. Equivalent static loads were considered for the seismic load and Mark II hydrodynamic loads using appropriate peak spectral accelerations.

3A.7.1.2.3.2 Load Combinations

Load combinations and allowable stresses used in the re-assessment are given in Table 3A-16. Loads due to SRV, seismic, and LOCA events were combined using the SRSS technique.

3A.7.1.2.3.3 Design Assessment

The resultant membrane stresses, surface stresses, shear stresses and stress in welds were evaluated against allowable stresses given in Table 3A-16 for all components. The preloads and maximum stresses in connecting bolts were also assessed. Relative deflections and rotations were examined at locations where leak-tightness is required. The assessment results for the components are discussed in Section 3A.7.2.

3A.7.1.3 Liner Plate Assessment Methodology

Section 3.8.1.1.2 provides a description of the containment liner plate and its anchorage system.

The analysis and design of the liner plate anchorages for nonhydrodynamic loads is in accordance with Reference 3A-27.

In the assessment of the concrete-backed liner plate and anchorages for hydrodynamic pressure loads, the controlling load on the liner plate and anchorage system is that due to the net negative pressure load if present. The net negative pressure load is determined from the dynamic negative pressure due to SRV actuation and/or LOCA chugging minus the static positive pressure due to the wetwell hydrostatic pressure and/or LOCA wetwell pressure. Figures 3A-41 and 3A-42 describe the loads on the suppression chamber liner plate for the normal and abnormal load conditions.

For the normal condition, the hydrostatic pressure on the basemat liner is 10.4 psi (positive) and the maximum negative pressure due to the actuation of all SRVs is 7.8 psi (negative). The distribution of these pressures on the suppression chamber wall is shown in Figure 3A-41. The maximum net pressure is 2.6 psi (positive).

For the abnormal condition, the combined pressure distribution due to hydrostatic, LOCA wetwell pressure, SRV, and chugging loads is shown in Figure 3A-42. The total positive pressure on the basemat linear is 35.4 psi which consists of 10.4 psi (positive) from hydrostatic pressure plus 25.0 (positive) from a small or intermediate break LOCA. The total cyclic pressure on the basemat liner is 17.6 psi (negative) due to the axisymmetric chugging and SRV loads. Although the maximum negative pressures due to SRV actuation and chugging are combined for conservatism, it is recognized that the probability of these two phenomena producing peak negative pressures at the same time is very low.

The assessment of the liner plate is contained in Section 3A.7.2.1.5.

3A.7.1.4 Downcomer Assessment Methodology

3A.7.1.4.1 Structural Model

There are 87, 24 inch OD, steel pipe downcomers running vertically down from the diaphragm slab. The downcomers are embedded in the diaphragm slab and extend downward to el 193'-11", which is approximately 12 feet below high water level, as shown in Figure 3A-2. All downcomers are supported laterally at el 203'-5" by the downcomer bracing system. Any vertical loads are transmitted by the bracing system to the downcomers and therefore to the diaphragm slab.

The structural model considers the downcomer as a vertical pipe fixed at the underside of the diaphragm slab with a spring in the horizontal direction at bracing level. This model is shown in Figure 3A-43. The inertial effect of the water in the submerged portion of the downcomer (12 feet) was approximated by the addition of a equivalent mass of water lumped at the appropriate nodal points. The model is evaluated for three spring values for a representative support stiffness provided by the bracing system to the downcomers. The bracing spring is set to 50 k/in, 350 k/in, and 15000 k/in to represent the tangential mode, the radial mode, and rigid response of the bracing system.

3A.7.1.4.2 Loads

The downcomer is subjected to static and dynamic loads due to normal, upset, emergency, and faulted conditions. Loading cases and combinations are described in Table 3A-17. The basis for all hydrodynamic loads considered in the analysis is presented in Section 3A.4 and 3B.4.

3A.7.1.4.3 Analysis

Downcomers are analyzed for the specified loading conditions using the Bechtel computer program BSAP. The downcomers are analyzed for both the hydrodynamic loads acting directly on the submerged portions and the inertial forces due to containment responses to the hydrodynamic and seismic loads.

The hydrodynamic load analyses, due to SRV discharge and LOCA- related loads acting on the submerged portion of the downcomers, are performed using the mode-superposition time history technique. The seismic and hydrodynamic load analyses, due to containment responses, are performed using the response spectrum analysis procedure. Damping values used are equal to 2% of critical for OBE and SRV loads, and 7% of critical for SSE and LOCA loads.

3A.7.1.4.4 Design Assessment

The resultant stresses in the downcomers due to the load combinations described in Table 3A-17 are compared with the allowable stresses in accordance with the criteria given in Reference 3A-19.

3A.7.1.4.5 Fatigue Evaluation Of Downcomers In Wetwell Air Space

A fatigue analysis of the downcomers was conducted in accordance with ASME Section III, Division 1 (1979 Summer Addendum), subsection NB-3650. Only that portion of the downcomer in the air space of the suppression chamber need be evaluated for fatigue. Figures 3A-394 and 3A-395 show the number of cycles considered and the load histogram, respectively.

3A.7.1.5 BOP Piping and SRV Systems Assessment Methodology

BOP piping and SRV systems were analyzed for the load combinations described in Table 3A-18 using Bechtel computer program ME101. This program is described in Section 3.9. Hydrodynamic load considerations are provided in Section 3A.5.6. Static and dynamic analysis of the piping and SRV systems are performed as described in the paragraphs below.

Static analysis techniques are used to determine the stresses due to steady-state loads and/or dynamic loads having equivalent static loads.

Response spectra at the piping anchors are obtained from the dynamic analysis of the containment subjected to LOCA and SRV loading. Piping systems are then analyzed for these response spectra following the method described in Reference 3A-28. Alternatively, the multiple response spectra/independent support motion method of analysis may be used where distinct response spectra are applied to the piping system attachment points.

Time history dynamic analysis of the SRV discharge piping subjected to fluid transient forces in the pipe due to relief valve opening is performed using Bechtel computer code ME101.

3A.7.1.5.1 Fatigue Evaluation of MSRV Discharge Lines in Wetwell Air Volume

In an effort to evaluate the steam bypass potential arising from a failure of the MSRV discharge line in the wetwell air space, a complete fatigue analysis has been performed. Specifically, structural analyses of the MSRV discharge lines from the diaphragm

slab penetration to the quencher was performed. Fatigue evaluations of flued head penetration, elbows, tees, taper transitions, and anchors were done. This analysis considered the cyclic loading acting on the MSRV discharge lines and is in accordance with the applicable portions of ASME Code. This evaluation is considered supplemental and does not displace the original design basis for these lines as set forth in the appropriate UFSAR sections.

3A.7.1.5.1.1 Loads and Load Combinations Used for Assessment

The MSRV discharge lines are subject to numerous dynamic and hydrodynamic loads from normal, upset, and LOCA-related plant operating conditions. For purposes of fatigue evaluation, the following loads are included: (1) significant thermal and pressure transients, (2) cyclic loads due to hydrodynamic effects including MSRV actuations, CO and chugging, and (3) seismic effects. The determination of load combinations as well as number and duration of each event is obtained from the applicable sections of Reference 3A-1 and the UFSAR.

3A.7.1.5.1.2 Acceptance Criteria

The design rules, as set forth in ASME Section III, subsection NB, were used for the fatigue assessment.

3A.7.1.5.1.3 Methods of Analysis

The MSRV discharge lines in the wetwell air volume were analyzed for the appropriate load combinations and their associated number of cycles. The combined stresses and corresponding equivalent stress cycles were computed to obtain the fatigue usage factors in accordance with the equations of subsection NB-3600 of the ASME Code.

3A.7.1.5.1.4 Results and Design Margins

The cumulative usage factors for flued head, elbows, tees, tapered transitions, and anchors are summarized in Table 3A-27.

3A.7.1.6 NSSS Assessment Methodology

Safety-related NSSS piping and equipment located within the containment, reactor enclosure, and control structure are subjected to hydrodynamic loads due to SRV and LOCA discharge effects principally originating in the suppression pool of the containment structure. The NSSS piping and equipment are assessed to verify their adequacy to withstand these hydrodynamic loads in combination with seismic and all other applicable loads in accordance with the load combinations given in Table 3A-23.

The structural system responses for the SRV and LOCA suppression pool hydrodynamic phenomena are generated by Bechtel using defined forcing functions. These structural system responses are transmitted to GE in the form of (1) broadened response spectra and (2) acceleration time histories at the pedestal to diaphragm floor intersection and at the stabilizer elevation.

The response spectra for piping attachment points on the RPV, shield wall and pedestal complex (above the pool area) are generated by GE, based on the acceleration time histories supplied by Bechtel, using a detailed lumped-mass beam model for the reactor pressure vessel internals, including a representation of the structure. For the assessment of the NSSS primary piping (main steam and recirculation), a combination of GE and Bechtel developed response spectra are used as input responses for all attachment points of each piping system. For the assessment of the NSSS floor-mounted equipment, except the RPV, the broadened response spectra supplied directly by Bechtel are used.

The acceleration time histories and the detailed RPV and structure lumped-mass beam model are used to generate the forces and moments acting on the RPV supports and internal components. These forces and moments are used for the GE assessment of RPV supports and internals.

The structural system response to the LOCA-induced annulus pressurization transient asymmetric pressure buildup in the annular region between the biological shield wall and RPV is based on pressure time histories supplied by Bechtel. These pressure time histories are combined with jet reaction, jet impingement, and pipe whip restraint loads for the assessment. A time history analysis is performed resulting in accelerations, forces and moment time histories as well as response spectra at the piping attachment points on the RPV, shield wall, pedestal, RPV supports, and external components.

3A.7.1.6.1 NSSS Qualification Methods

3A.7.1.6.1.1 NSSS Piping

The NSSS piping stress analyses are conducted to consider the secondary dynamic responses from: (1) the original design basis loads including seismic vibratory motions, (2) the structural system feedback loads from the suppression pool hydrodynamic events, and (3) the structural system loads from the LOCA-induced annulus pressurization from postulated feedwater and recirculation pipe breaks.

Lumped-mass models are developed by GE for the NSSS primary piping systems, main steam, and recirculation. These lumped-mass models include the snubbers, hangers, and pipe-mounted valves and represent the major BOP branch piping connected to the main steam and recirculation systems. Amplified response spectra for all attachment points within the piping system are applied; i.e., distinct acceleration excitations are specified at each piping support and anchor point. The detailed models are analyzed independently to determine the piping system resulting loads (shear and moments) for:

a. Each design basis load which includes pressure, temperature, weight, seismic events, etc.

b. Bounding suppression pool hydrodynamic event

c. Annulus pressurization dynamic effects on the unbroken piping system.

In addition, the end reaction forces and/or accelerations for the pipe mounted/connected equipment (valves and nozzles) are simultaneously calculated.

The piping stresses from the resulting loads (shears and moments) for each load event are determined and combined in accordance with the load combinations given in Table 3A-19. These

stresses are calculated at geometrical discontinuities and compared to ASME code allowable determined stresses (ASME Section III, NB-3650) for the appropriate loading condition to ensure design adequacy. Fatigue usage is calculated for the range of stress between all operating and upset events and summed to ensure that the fatigue usage factor is less than one.

3A.7.1.6.1.2 Valves

The reaction forces and/or accelerations acting on the pipe-mounted equipment when combined in accordance with the required load combinations are compared to the valve allowables to assure design adequacy. The RCPB valves are qualified for operability during seismic and hydrodynamic loading events by both analysis and test.

3A.7.1.6.1.3 Reactor Pressure Vessel, Supports, and Internal Components

The bounding load combinations for seismic, hydrodynamic, and annulus pressurization forces are established within each service condition category (upset, emergency, and faulted).

The loads for these bounding load combinations are compared to the design basis loads originally used to establish the component design. When the calculated bounding loads are less than the design basis loads, the component design is deemed adequate. When the calculated loads are greater than the design basis loads, the new stresses are calculated and are compared to the code allowable stresses. When the calculated stresses are below the code allowable stresses, the design is deemed adequate. If the increased stresses are above the code allowable stresses, the specific load combination is identified and a more refined stress analysis is performed, if possible, to demonstrate the component design adequacy.

In certain cases, component test results are combined with analyses to assess component adequacy. Fatigue evaluations of the RPV, supports, and internal components are also conducted for SRV cyclic duty loads. The equipment is analyzed for fatigue usage due to SRV load cycles based on the loading during the SRV events. SRV fatigue usage factors are calculated and combined with all other upset condition usage factors to obtain a cumulative fatigue usage factor.

3A.7.1.6.1.4 Floor-Mounted Equipment

3A.7.1.6.1.4.1 Qualification Methods

The adequacy of the design of the equipment is assessed by one of the following methods:

a. Dynamic analysis

b. Testing

c. Combination of testing and analysis

The choice depends on function, type, size, shape, and complexity of the equipment and the reliability of the qualification method.

In general, the requirements outlined in IEEE 344 (1975) are followed for the qualification of equipment. See Section 3.10.

3A.7.1.6.1.4.1.1 Dynamic Analysis

3A.7.1.6.1.4.1.1.1 Methods and Procedures

The dynamic analysis of various equipment is classified into three groups according to the relative rigidity of the equipment based on the magnitude of the fundamental natural frequency described below.

a. Structurally simple equipment - comprises equipment that can be adequately represented by frame-type structures consisting of members physically similar to beams and columns.

b. Structurally rigid equipment - Comprises that equipment whose fundamental frequency is:

   1. Greater than 33 Hz for the consideration of seismic loads, and,

   2. Greater than the zero period acceleration frequency of the suppression pool hydrodynamic load RRS.

c. Structurally complex equipment - Comprises equipment that cannot be classified as structurally simple or structurally rigid.

The appropriate response spectra for specific equipment are obtained from the response spectra for the floor at which the equipment is located in a building for OBE, SSE, and hydrodynamic loads. This includes the vertical as well as both the N-S and E-W horizontal directions. For equipment that is structurally simple, the dynamic loading (either seismic or hydrodynamic) consists of a static load corresponding to the equipment weight times the acceleration selected from the appropriate response spectrum. The acceleration selected corresponds to the equipment natural frequency, if the equipment natural frequency is known. If the equipment natural frequency is not known, the acceleration selected corresponds to the maximum value of the response spectra, which is multiplied by a static coefficient of 1.5 to take into account the effects of both multifrequency excitation and multimode response.

For equipment that is structurally rigid, the seismic load consists of a static load corresponding to the equipment weight times the acceleration at 33 Hz, selected from the appropriate response spectrum. The hydrodynamic loading consists of a static load corresponding to the equipment weight times the acceleration at the zero period acceleration, selected from the appropriate response spectrum.

The analysis of structurally complex equipment uses an idealized mathematical model which predicts the dynamic properties of the equipment. A dynamic analysis is performed using any standard analysis procedure. An acceptable alternative method of analysis is by static coefficient analysis for verifying structural integrity of frame-type structures that can be represented by a simple model. No determination of natural frequencies is made, and the response of the equipment is assumed to be the peak of the response spectrum. This response is multiplied by a static coefficient to take into account the effects of both multifrequency excitation and multimode response. The static coefficient used for structurally complex equivalent is justified and is consistent with Regulatory Guide 1.100 guidelines.

3A.7.1.6.1.4.1.2 Testing

Dynamic adequacy for some equipment is established by providing dynamic test data instead of performing dynamic analysis. Such data must conform to one of the following:

a. Performance data of equipment that has been subjected to equal of greater dynamic loads (considering appropriate frequency range) than those to be experienced under the specified dynamic loading conditions.

b. Test data from comparable equipment previously tested under similar conditions that has been subjected to equal or greater dynamic loads than those specified.

c. Actual testing of equipment in operating conditions simulating, as closely as possible, the actual installation, the required loadings and load combinations.

The equipment to be tested is mounted in a manner that simulates the actual service mounting. Sufficient monitoring devices are used to evaluate the performance of the equipment. With the appropriate test method selected, the equipment is considered to be qualified when the TRS envelopes the RRS and the equipment does not malfunction or fail. A new test does not need to be conducted if equipment requires only minor modifications such as additional bracings or change in switch model, etc, and if proper justification is given to show that the modifications would not jeopardize the strength and function of the equipment.

3A.7.1.6.1.4.1.3 Combined Analysis and Testing

This method has not been used in the NSSS piping and safety-related equipment adequacy evaluations.

3A.7.1.7 BOP Equipment Assessment Methodology

Safety-related equipment located within the containment, the reactor enclosure, and the control structure are subjected to hydrodynamic loads due to SRV and LOCA (SBA, IBA, and DBA) discharge effects principally originating in the suppression pool of the containment structure. The equipment and equipment supports are assessed to verify their adequacy to withstand these hydrodynamic loads in combination with seismic and all other applicable loads in accordance with the load combinations given in Table 3A-20. In addition, safety-related active pumps and valves located within the containment, the reactor enclosure, and the control structure are qualified for operability during seismic and hydrodynamic events.

3A.7.1.7.1 Dynamic Loads

3A.7.1.7.1.1 SRV Discharge Loads

Loadings associated with the axisymmetric and asymmetric SRV discharges are described in Sections 3A.3, 3A.4, and 3B.4. ARS at the various elevations where the equipment are located have been generated for all appropriate pressure history traces (Figures 3B-25 through 3B-27) for damping values of ½%, 1%, 2%, and 5%.

3A.7.1.7.1.2 LOCA-Related Loads

Loadings associated with a LOCA are described in Sections 3A.3, 3A.4 and 3B.4. The various LOCA loadings considered include condensation oscillation and chugging (Section 3A.4.2.2). ARS at

various elevations where the equipment are located have been generated for the above LOCA loads for damping values of ½%, 1%, 2%, and 5%.

3A.7.1.7.1.3 Seismic Loads

The details of seismic input and seismic loads are discussed in Section 3.7. The effects of both the OBE and SSE are considered. These loads are provided in the form of ARS at each floor for damping values of ½%, 1%, 2%, and 5% for each of N-S, E-W and vertical directions.

3A.7.1.7.2 Load Combinations

Seismic, SRV, and LOCA loads have been combined for various load combinations in accordance with Table 3A-20 at all floor elevations. For the same equipment located at various elevations, the combined response spectra are enveloped into a single curve for a damping value of 2%. Such enveloped curves are generated for each of the N-S, E-W, and vertical directions.

3A.7.1.7.3 Other Loads

In addition to hydrodynamic and seismic loads, other loads such as dead loads, live loads, operating loads, pressure loads, thermal loads, nozzle loads and equipment piping interaction loads, as applicable, are also considered.

3A.7.1.7.4 Qualification Methods

The adequacy of the design of the equipment is assessed by one of the following:

a. Dynamic analysis

b. Testing

c. Combination of testing and analysis.

The choice is based on the practicality of the method depending upon function, type, size, shape, complexity, and nonlinear effects of the equipment and the reliability of the qualification method.

In general, the requirements outlined in Reference 3A-29 are followed for the qualification of equipment.

3A.7.1.7.4.1 Dynamic Analysis

3A.7.1.7.4.1.1 Methods and Procedures

The dynamic analysis of various equipment is classified into three groups according to the relative rigidity of the equipment based on the magnitude of the fundamental natural frequency described below:

a. Structurally simple equipment - comprised of that equipment which can be adequately represented by one degree of freedom system.

b. Structurally rigid equipment - Comprised of that equipment whose fundamental frequency is:

1. Greater than 33 Hz for the consideration of seismic loads, and,

2. Greater than 100 Hz for the consideration of hydrodynamic loads.

c. Structurally complex equipment - Comprised of that equipment which cannot be classified as structurally simple or structurally rigid.

When the equipment is structurally simple or rigid in one direction but complex in the other, each direction may be classified separately to determine the dynamic loads.

The appropriate response spectra for specific equipment are obtained from the response spectra for the elevation at which the equipment is located in a building for OBE, SSE, and hydrodynamic loads. This includes the vertical as well as both the N-S and E-W horizontal directions.

For equipment that is structurally simple, the dynamic loading (either seismic or hydrodynamic) consists of a static load corresponding to the equipment weight times the acceleration (in "g's") selected from the appropriate response spectrum. The acceleration selected from the response spectrum corresponds to the equipment's natural frequency, if the equipment's natural frequency is known. If the equipment's natural frequency is not known, the acceleration selected corresponds to the maximum "g" value of the response spectra.

For equipment that is structurally rigid, the seismic load consists of a static load corresponding to the equipment weight times the acceleration at 33 Hz, selected from the appropriate response spectrum and the hydrodynamic loading consists of a static load corresponding to the equipment weight times the acceleration at 100 Hz, selected from the appropriate response spectrum.

For the analysis of structurally complex equipment, the equipment is idealized by a mathematical model that adequately predicts the dynamic properties of the equipment, and a dynamic analysis is performed using any standard analysis procedures such as response spectrum modal analysis or a time history analysis. The responses of interest such as deflection, stress, acceleration, etc., are determined by combining each modal response considering all significant modes by the SRSS. The absolute sum of similar effects is considered for closely spaced in-phase modes. Closely spaced modes are those with frequencies differing by 10% or less.

An acceptable alternative method of analysis is by static coefficient analysis for verifying structural integrity of frame-type structures such as members physically similar to beams and columns that can be represented by a simple model. No determination of natural frequencies is made, and the response of the equipment is assumed to be the peak of the response spectrum at damping values in accordance with Section 3A.7.1.7.4.1.2. This response is then multiplied by a static coefficient of 1.5 to take into account the effects of both multifrequency excitation and multimode response.

For nonlinear analysis that may be necessary to account for the nonlinear material properties or the geometry-related nonlinearities, the analysis will include a detailed justification for the approach used for the qualification. Alternatively, the testing method of qualification is used where the effects of nonlinearities are to be considered.

3A.7.1.7.4.1.2 Appropriate Damping Values

The following damping values are used for the design assessment:

a.	Load combinations involving OBE but not hydrodynamic loads	½%
b.	Load combinations involving SSE but not hydrodynamic loads	1%
c.	Load combinations involving hydrodynamic loads, or seismic and hydrodynamic loads	2%

Higher damping values may be used where justified.

3A.7.1.7.4.1.3 Three Components of Dynamic Motions

The responses such as internal forces, stresses, and deformations at any point from the three principal orthogonal directions of the dynamic loads are combined as follows.

The response value used shall be the maximum value obtained by adding the response due to vertical earthquake with the larger value of the responses due to one of the horizontal earthquakes by the ABS method.

For the other dynamic loads, the response value shall be obtained by combining the response due to three orthogonal directions of an individual load by the SRSS method.

3A.7.1.7.4.2 Testing

Qualification by testing is used in cases where operability requires verification and the effects of nonlinearities have to be considered. For these instances, dynamic adequacy is established by providing dynamic test data. Such data must conform to one of the following:

a. Performance data of equipment that has been subjected to equal or greater dynamic loads (considering appropriate frequency range) than those to be experienced under the specified dynamic loading conditions.

b. Test data from comparable equipment previously tested under similar conditions that has been subjected to equal or greater dynamic loads than those specified.

c. Actual testing of equipment in operating conditions simulating, as closely as possible, the actual installation, the required loadings and load combinations.

A continuous sinusoidal test, sine beat test, or decaying sinusoidal test is used when the applicable floor acceleration spectrum is a narrow band response spectrum. Otherwise, random motion test (or equivalent) with broad frequency content is used.

The equipment to be tested is mounted in a manner that simulates the actual service mounting. Sufficient monitoring devices are used to evaluate the performance of the equipment. With the appropriate test method selected, the equipment is considered to be qualified when the TRS envelopes the RSS and the equipment does not malfunction or fail. A new test does not need to be conducted if equipment requires only minor modifications such as additional bracings or change in switch model, etc, and if proper justification is given to show that the modifications would not jeopardize the strength and function of the equipment.

3A.7.1.7.4.3 Combined Analysis and Testing

There are several instances where the qualification of equipment by analysis alone or testing alone is not practical or adequate because of its size, or its complexity, or large number of similar configurations. In these instances, a combination of analysis and testing is the most practical. The following are general approaches:

a. An analysis is conducted on the overall assembly to determine its stress level and the transmissibility of motion from the base of the equipment to the critical components. The critical components are removed from the assembly and subjected to a simulation of the environment on a test table.

b. Experimental methods are used to aid in the formulation of the mathematical model for any piece of equipment. Mode shapes and frequencies are determined experimentally and incorporated into a mathematical model of the equipment.

3A.7.1.8 Electrical Raceway System Assessment Methodology

3A.7.1.8.1 General

The analysis and design of supports of electrical raceway systems for nonhydrodynamic loads are in accordance with Reference 3A-32. SRV discharge and LOCA loads are considered similar to seismic loads by using appropriate floor response spectra for the hydrodynamic loads. A damping value of 3% critical is used for all raceway systems for the normal load condition involving SRV discharge loading only. The damping ratios used for the electrical raceway assessment are in accordance with Reference 3A-32. For the abnormal/extreme load condition, a damping value of 10% of critical is used for cable tray support systems; 7% damping for conduit and wireway gutter trapeze-type support systems; 5% damping for conduit and wireway gutter nontrapeze-type support systems. These damping values are based on the results of the Cable Tray and Conduit Raceway Seismic Test Program (Reference 3A-31).

The cable tray system damping is substantially greater than that of bolted steel structures due to the cable motion within the trays. The test program demonstrated that cable tray system damping is, in general, much higher than 10%, and damping values up to 50% were reported. The damping values recommended in Reference 3A-32, and shown in Figure 3A-45, are based on the lower bound values developed from the test program. An unloaded tray will have an associated lower bound damping value of about 7% as shown in Figure 3A-45.

Analysis using 10% damping for a fully loaded tray system under the abnormal/extreme load conditions is conservative and will envelop an analysis of an unloaded tray with a 7% damping ratio for the following reasons:

The frequency shift resulting from reduced mass in a relatively unloaded tray may result in either higher of lower response, depending on the individual response spectrum. However, when the combined effects of frequency shift, reduced damping, and lower weights are considered, the result will be a more conservative design. For example, consider the comparison of accelerations, weights, and resulting seismic forces for fully loaded and unloaded trays shown in Table 3A-26. A fully loaded tray typically weighs approximately eight times more than an empty tray. The maximum acceleration for the unloaded tray case (at 7% damping) is four times that for the fully loaded tray case (at 10% damping) assuming that frequency shift, due to the reduced mass of the unloaded tray, results in the maximum

increase in acceleration. In calculating the resulting seismic forces for both cases, it is apparent that the loaded tray case yields the higher seismic load.

In addition, based on a random sampling of cable tray supports and conservatively assuming a fully loaded tray and peak acceleration, approximately 75% of the sampled members have a stress margin of 30% or more. The remaining 25% of the members are within allowable stress limits.

LGS cable tray systems are similar to those tested in Reference 3A-32, i.e., the trays are of the same material and of similar construction, and the hangers and installation are similar in construction and design. Therefore, the dynamic behavior of LGS tray systems will parallel the dynamic behavior of the tested tray systems.

For conduit systems, the test program demonstrates that, at the abnormal/extreme load condition, the damping value equals 7% of critical. This damping value is consistent with Regulatory Guide 1.61 recommended values for bolted steel structures. Therefore, 7% damping is used for conduit with trapeze-type support systems, and a more conservative 5% damping is used for conduit with nontrapeze-type support systems.

Wireway gutters were not tested; however, the manner in which they are constructed (with more bolted connections and more cables than conduit) provides more damping mechanisms than those present in conduit systems. Therefore, it is conservative to use the conduit system damping value.

3A.7.1.8.2 Loads

3A.7.1.8.2.1 Static Loads

The static loads are the dead loads and live loads. For cable trays, the weight of the cable plus tray is considered to be 36 lb/ft (except unique situations where heavier weights are considered) and a concentrated live load of 200 lb applicable at any point on the cable tray span is used.

3A.7.1.8.2.2 Seismic Loads

The details of the seismic motion input are discussed in Section 3.7. The effects of the OBE and the SSE are considered.

For the normal load condition, involving SRV discharge loading, a damping value equal to 3% of critical is used for all raceway systems. The SRV load is considered similar to an OBE load; therefore, a 3% damping value is considered conservative because 4% damping is recommended by Regulatory Guide 1.61 for bolted steel structures for the OBE loading.

3A.7.1.8.2.3 Hydrodynamic Loads

The details of the axisymmetric and asymmetric SRV discharge loads as well as LOCA loads including condensation oscillation and chugging are discussed in Sections 3A.4 and 3B.4.

The enveloped ARS at each floor for N-S, E-W, and vertical directions have been generated and widened by ±15%. These curves form the basis for the hydrodynamic load assessment of the electrical raceway system. Examples of the response spectrum curves for the containment and reactor and control enclosures are presented in Sections 3A.9 and 3A.10.

3A.7.1.8.3 Analytical Methods

Electrical raceway systems are modeled as a three-dimensional dynamic system consisting of several consecutive supports complete with raceways and longitudinal and transverse bracing. The cable tray properties are determined from the load-deflection tests. Member joints are modeled as spring elements having rotational stiffness with known spring values as determined from the test results.

Composite spectra are developed by enveloping the floor response spectra after broadening by ±15% for critical floors for seismic, SRV, and LOCA loading conditions. The design spectrum is obtained by adding these response spectra curves by either the SRSS method or the ABS method. A frequency variation of ±20% is used to further broaden the spectrum at the fundamental frequency of the electrical raceway system. The composite response spectra curves are obtained for vertical and two horizontal directions.

Modal and response spectrum analyses are performed using the Bechtel Structural Analysis Program (BSAP), which is a general purpose finite-element computer program. The total response due to the dynamic loads is calculated by determining the absolute sum of the vertical response and only the larger response of the two horizontal responses.

Dead and live load stresses are determined from a static analysis of a plane frame model using the BSAP computer program or hand calculation, and these results are combined with those from the response spectrum analysis. For normal load conditions, SRV discharge stresses are proportioned from the response spectrum analysis of SSE plus SRV discharge plus LOCA loads according to their spectral acceleration ratios at the fundamental frequencies. Several different support types that are widely used have been analyzed by these methods.

An alternative method for analyzing other support types uses hand calculations by a response spectrum analysis technique. The support may be idealized as a single degree of freedom system. In general, the maximum peak spectral accelerations were used in the analysis. In some cases where the stresses are critical, a more refined value for the acceleration response was used corresponding to the computed system fundamental frequency and considering a frequency variation as explained earlier in this section. The total response due to the dynamic loads is calculated by determining the absolute sum of the vertical response and only the larger response of the two horizontal responses. The member stresses are kept within the elastic limit.

3A.7.1.9 HVAC Duct System Assessment Methodology

The SRV discharge and LOCA loads are considered similar to seismic loads by using appropriate floor response spectra generated for the CO, chugging, and SRV loads described in Sections 3A.4 and 3B.4.

A damping value of 5% of critical is used for load combinations involving SSE, SRV discharge, and LOCA loads, while a damping value of 3% of critical is used for load combinations involving OBE and/or SRV discharge loads. For a discussion of the seismic and hydrodynamic loads input for HVAC duct system assessment, refer to Sections 3A.7.1.8.2.2 and 3A.7.1.8.2.3, respectively. The HVAC duct system has been analyzed by determining the fundamental frequencies of the system in three directions. The inertia forces are determined from the composite spectra to establish member forces and moments due to hydrodynamic as well as seismic loads.

3A.7.2 DESIGN CAPABILITY MARGINS

This section describes the design margins for structures, piping, and equipment resulting from the LGS design assessment which uses the methods of Section 3A.7.1.

3A.7.2.1 Stress Margins

Stresses at the critical sections for all of the structures, piping, and equipment described in Section 3A.7.1 are evaluated for the loading combinations presented in Section 3A.5.

The stress margin (SM) in percent is defined as follows:

$$SM = (1 - SR) \times 100$$

where SR represents the stress ratio. SR is calculated by dividing the factored stress ($C_n f_n$) by the associated stress allowable (F_n) or, mathematically,

$$SR = \Sigma (C_n f_n / F_n) \qquad \text{(EQ. 3A-8)}$$

3A.7.2.1.1 Containment Structure

The detailed results from the structural assessment of the containment structure are summarized in Section 3A.12.1. Figure 3A-362 shows the design sections in the basemat, shield walls, containment walls, reactor pedestal, and the diaphragm slab that were considered in the structural assessment. Figures 3A-363 through 3A-386 give the calculated maximum design stresses for the load combinations listed in Table 3A-14.

Both rebar stresses and concrete stresses are calculated based on the applicable load combination equations. The stresses in the drywell wall are calculated at design sections 1 to 5 and are tabulated in Figures 3A-363 through 3A-366. The stresses in the wetwell wall are calculated at design sections 6 to 11 and are tabulated in Figures 3A-367 through 3A-370. The stresses in the shield wall are calculated at design sections 12 and 13 and are tabulated in Figures 3A-371 and 3A-372, respectively. The RPV pedestal stresses are calculated at design sections 14 to 20 and are tabulated in Figures 3A-373 through 3A-377. The stresses in the diaphragm slab are calculated at design sections 21 to 25 and are tabulated in Figures 3A-378 through 3A-381. The stresses in the basemat are calculated at design sections 26 to 30 and are tabulated in Figures 3A-382 through 3A-386.

The containment assessment is summarized as follows:

a. The calculated stress level is very low for load combination equation 1 (an operating condition), i.e., rebar stresses are far less than 20 ksi.

b. The maximum rebar stress is predicted as 53.9 ksi at design sections 6 and 11, located in the wetwell vertical direction. The magnitude is within the rebar stress allowable ($0.9 F_y = 54$ ksi).

c. In general, rebar stresses and concrete compressive stresses are within stress allowables.

3A.7.2.1.2 Reactor Enclosure and Control Structure

Results of the structural assessment of the reactor enclosure and control structure are summarized in Section 3A.13. Figures 3A-398 through 3A-418 show the selected structural elements and sections where stresses were calculated.

Section 3A.13 contains tabulations of predicted stresses, stress allowables, and design margins for critical loading combinations considered. The sections selected for assessment were considered to be the most critical based on previous seismic calculations.

The critical load combinations are tabulated considering critical locations/sections related to reactor enclosure and control structure shear walls, foundations, floor slabs and supporting steel, steel platforms, and floor support columns.

Emphasis is placed on margins of principal resisting structural elements, with reinforcing bar stresses for reinforced concrete structures and axial and/or bending stresses for steel structures.

Also included in Section 3A.13 are diagrams of axial forces, N-S shear forces, N-S overturning moments, E-W shear forces, E-W overturning moments for reactor enclosure and control structure as shown in Figures 3A-419 through 3A-428.

The reactor enclosure floor system stress margins were calculated for both slabs and floor support steel beams, including floors at el 201', 217', 253', 283', 313', 333', and 352'. Calculated slab stress levels were generally governed by either equation 1 or 7a of Table 3A-14. The highest reinforcing bar stress was found at the floor of el 253', having a stress intensity of 51.26 ksi and an associated stress margin of approximately 5%. Figure 3A-429 shows rebar stresses and related stress margins of the aforementioned floors. In addition, the stresses and related stress margins of floor support steel beams are presented in Figure 3A-430. The governing equations were equations 1 and 7 of Table 3A-15. Stress levels were generally low.

In the case of reactor enclosure support columns, load combination 7 of Table 3A-15 governs the column stress interaction. Stress interaction calculations were performed and show that columns were generally understressed (Figure 3A-431). The column at column lines 30.5 and E of el 217' to el 253' has a fully stressed situation.

The reactor enclosure shear wall sections close to the base (el 177') were assessed as shown in Figure 3A-432. The highest stress conditions occurred in the walls of column lines 14.1 (west wall) and 31.9 (east wall) due to shearing effect at the base. The corresponding stress margin was approximately 1%.

The floor system of the control structure, including the concrete slabs and their supporting steel beams, are shown in Figure 3A-406 through 3A-414, while the stress margins are listed in Figures 3A-433 and 3A-434.

In general, none of those selected critical sections were found overstressed in the control structure. All concrete floors were assessed. The concrete slabs are governed by the normal load conditions, equation 1 of Table 3A-14. The steel floor beams supporting the concrete slabs are governed by the abnormal extreme environmental load conditions, equation 7 of Table 3A-14. Generally, the concrete slabs have a higher stress margin than the supporting steel beams.

For the control structure shear walls, the stress levels are critical in the walls close to the base due to seismic loads. The stress margins for the shear walls at column lines 19.4 and 26.6, as shown in

Figure 3A-435, were found most critical under the abnormal extreme environmental load condition including DBE and seismic torsional effects.

The steel platforms at el 313', el 322', el 340', and el 350' were also assessed. The dynamic loads applied on the steel frames which support the platforms were found less significant than the normal loads. All the steel frames are governed by the normal load condition, equation 2 of Table 3A-15, with its associated allowable stresses. Those assessed steel members are shown in Figures 3A-415 through 3A-418. As demonstrated in Figure 3A-436, steel frames are generally understressed.

3A.7.2.1.3 Suppression Chamber Columns

The column vibration mode shapes are calculated using computer program BSAP. The mode shapes are shown in Figure 3A-387. The equivalent water mass is equal to the column volume.

The stresses at the top and bottom of the suppression chamber columns were calculated and combined in accordance with the load combinations shown in Table 3A-15. The maximum stresses in the column are governed by load combination equation 7. The maximum stresses in the column (42 inch diameter pipe), top anchorage, and bottom anchorage are shown in Figure 3A-388. The lowest stress margin in the column structure is 10%.

3A.7.2.1.4 Downcomer Bracing

The bracing member forces and the corresponding design margins due to the governing load combinations are given in Figure 3A-397 for the critical bracing members.

3A.7.2.1.5 Liner Plate

For the normal and abnormal conditions, the liner plate system does not experience any net negative pressures as demonstrated in Figures 3A-41 and 3A-42. There is a large stress margin because the liner plate is designed for resisting a large suction (i.e., 5 psi negative).

3A.7.2.1.6 Downcomers

The downcomer vibration mode shapes are calculated for the modal analyses using computer program BSAP. The mode shapes are shown in Figures 3A-389 through 3A-391, for the three representative bracing system spring stiffnesses. The equivalent water mass included in the model is equal to the downcomer volume.

The downcomers were assessed in accordance with ASME Section III, Division 1, subsection NB-3652, using load combinations in Table 3A-17. Stresses and design margins are given in Figure 3A-392.

Downcomer fatigue at three critical locations were also checked. Loads are combined by the absolute sum method. Figure 3A-393 shows the fatigue usage factors at these critical locations, computed in accordance with ASME Section III, Division 1, subsection NB-3650 (1979 Summer Addenda). Downcomers are adequate for fatigue considerations.

3A.7.2.1.7 Electrical Raceway System

The electrical raceway system was analyzed using the load combinations in Table 3A-21 in accordance with the methodology described in Section 3A.7.1.8. The stress margins were found to

be most critical under the abnormal/extreme load condition. Stresses are below allowable stress levels for all members of the electrical raceway system.

3A.7.2.1.8 HVAC Duct System

The HVAC duct system was analyzed using the load combinations in Table 3A-22 in accordance with the methodology described in Section 3A.7.1.9. The stress margins were found to be most critical under the abnormal/extreme load condition. Stresses are below allowable stress levels for all members of the HVAC duct system.

3A.7.2.1.9 ASME Class MC Steel Components Margins

3A.7.2.1.9.1 Refueling Head And Flange

The refueling head and flange were found to have no stresses exceeding the specified allowable limits.

The leak-tightness of the flanged joint is investigated for the combined effect of temperature, pressure, seismic, SRV, LOCA and jet forces. Vertical separation at the flange faces is prevented by providing sufficient bolt preload to offset uplift due to the applied loads. Similarly, relative horizontal movement between the flange faces is prevented by the bolt preload induced frictional forces. For Unit 1 a preload of 157k per bolt is required to maintain leak-tightness at the flange joint. For Unit 2 a preload of 130k per bolt is required to maintain leak-tightness at the flange joint. (The Unit 2 preload is based on an analysis performed by Structural Integrity Associates.)

3A.7.2.1.9.2 Suppression Chamber Access Hatch, CRD Removal Hatch, and Equipment Hatch

For these components, the analysis by Chicago Bridge and Iron Company indicated that there are no stresses in excess of the specified allowable limits when considering the additional hydrodynamic loading.

3A.7.2.1.9.3 Equipment Hatch/Personnel Airlock

The equipment hatch with personnel airlock has been assessed for hydrodynamic and seismic loads. Modifications to some cap screws of the attachment brackets are required to accommodate the additional hydrodynamic loading. The equipment hatch with personnel airlock and all related components are within the specified allowable limits.

3A.7.2.1.10 BOP Piping and MSRV Systems Margins

As described in Section 3A.7.1.5, all seismic Category I BOP piping components and their supports located inside the containment, reactor enclosure, and control structure have been included in the design assessment and have been analyzed for seismic and hydrodynamic loads. The loads from the analyses are combined as described in Table 3A-18. Additional supports and modification of existing supports where required to accommodate the hydrodynamic and seismic loads for some piping systems have been completed.

Stresses and stress margins for selected BOP piping systems are summarized in Section 3A.14. The stress reports for the evaluation of the BOP piping will be available for NRC review.

3A.7.2.1.11 BOP Equipment Margins

All seismic Category I BOP equipment and their supports have been included in the design assessment and analyzed for hydrodynamic and seismic loads (Section 3A.7.1.7) via the LGS SQRT

program. Structural modifications necessitated by the addition of suppression pool hydrodynamic loads have been completed. For each piece of BOP equipment, a five page SQRT summary form has been prepared documenting the re-evaluation of the equipment.

3A.7.2.1.12 NSSS Margins

Safety-related NSSS piping, equipment and their supports have been assessed for hydrodynamic and seismic loads. Detailed results of the evaluation are given in Sections 3.9 and 3.10. Structural modifications necessitated by addition of suppression pool hydrodynamic loads have been completed. In addition, GE has prepared Seismic Qualification Reevaluation Program forms, NSSS Loads Adequacy Evaluation Program Summary reports, and design stress reports to document the assessment of seismic and hydrodynamic loads on NSSS piping, safety-related equipment and all related supports. These forms and reports will be available for NRC review.

3A.7.2.2 Acceleration Response Spectra

3A.7.2.2.1 Containment Structure

The method of analysis and load description for the ARS generation are outlined in Section 3A.7.1.1.1.6.1. From a review of the ARS curves for the containment structure, the maximum spectral accelerations are tabulated for 1 percent damping of critical. For SRV and LOCA loads, the maximum spectral accelerations are presented in Table 3A-25.

The hydrodynamic ARS of the containment structure are presented in Section 3A.9.2.

3A.7.2.2.2 Reactor Enclosure and Control Structure

The method of analysis and load applications for the computation of the hydrodynamic ARS in the reactor enclosure and the control structure are described in Section 3A.7.1.1.2. The response spectra of the reactor enclosure and the control structure are shown in Section 3A.10.

3A.8 MARK II T-QUENCHER VERIFICATION TEST (PROPRIETARY – SEE APPENDIX 3B)

3A.9 CONTAINMENT MODE SHAPES AND HYDRODYNAMIC RESPONSE SPECTRA

3A.9.1 CONTAINMENT MODE SHAPES

The containment model is shown in Figure 3A-46. Figure 3A-47 shows containment frequencies from the modal analysis with water mass included as discussed in Section 3A.7.1.1.1.3. Containment mode shapes are shown in Figures 3A-48 through 3A-70, covering mode shapes 1 through 23.

3A.9.2 CONTAINMENT HYDRODYNAMIC RESPONSE SPECTRA

This section shows examples of the horizontal and vertical response spectra curves of the containment structure due to LOCA and SRV loading. Four spectral damping values, i.e., 0.005, 0.01, 0.02, and 0.05, are shown on each group of curves. The structural model of the containment is shown on Figure 3A-46. The modal frequencies and mode shapes are shown on Figures 3A-47 through 3A-70. The broadened response spectrum curves, shown on Figures 3A-71 through 3A-150, are submitted as representative examples of the containment structure response spectra. The loads under consideration are SRV and LOCA.

The KWU SRV loads consist of 3 pressure time histories. Five different time factors are applied to each pressure time history to account for possible variations in the frequency content. Therefore, a total of 15 axisymmetric and 15 asymmetric SRV load cases were analyzed.

The LOCA loads considered include 17 segments of CO, 2 segments of condensation oscillation with ADS (CO-ADS), and 14 cases of chugging.

Enveloped and broadened ARS at selected nodes for the respective hydrodynamic loads are included in this report. The locations of the selected nodes are shown on Figure 3A-46. The hydrodynamic response spectra included at the selected nodes are shown on Figures 3A-71 through 3A-86 for SRV axisymmetric load, on Figures 3A-87 through 3A-102 for SRV asymmetric load, on Figures 3A-103 through 3A-118 for CO load, on Figures 3A-119 through 3A-134 for CO-ADS load, and on Figures 3A-135 through 3A-150 for chugging load. However, the chugging response spectra presented is the envelope spectra of all nodal points at the same elevation and radius. Therefore, the chugging spectra consist of representative spectra at containment locations with the same elevation and radius as the labeled nodal points on Figure 3A-46.

3A.10 REACTOR ENCLOSURE AND CONTROL STRUCTURE MODE SHAPES AND HYDRODYNAMIC RESPONSE SPECTRA

3A.10.1 REACTOR ENCLOSURE AND CONTROL STRUCTURE MODE SHAPES

The reactor enclosure and control structure horizontal mathematical stick model (for N-S and E-W directions) is shown in Figure 3A-35. Mode frequencies and participation factors are shown in Figure 3A-151. Representative vibration mode shapes that have significant participation are plotted in Figures 3A-152 and 3A-153.

The reactor enclosure and control structure vertical mathematical decoupled stick model is shown in Figure 3A-34. Mode frequencies and participation factors are shown in Figure 3A-154. Representative vibration mode shapes that have significant participation are plotted in Figures 3A-155 to 3A-163.

The control structure floor vertical "half-model" is shown in Figure 3A-36. Mode frequencies and participation factors for a typical local floor model at el 269' in the control structure are shown in Figure 3A-164. Representative vibration mode shapes that have significant participation are plotted in Figures 3A-165 to 3A-168.

3A.10.2 REACTOR ENCLOSURE AND CONTROL STRUCTURE HYDRODYNAMIC ACCELERATION RESPONSE SPECTRA

This section shows representative examples of the horizontal and vertical response spectra curves of the structure due to LOCA and SRV loading. Five special damping values, i.e., 0.005, 0.01, 0.02, 0.03 and 0.05, are shown on each group of curves. The response spectra presented in this section are at representative locations of the building models (Figures 3A-33 to 3A-35).

The SRV loads are defined by KWU from measured pressure traces. Figures 3A-169 to 3A-226 show broadened response spectra for the SRV loads, considering both asymmetric and axisymmetric cases.

The LOCA loads consist of chugging and condensation oscillation. The chug loads were generated form the improved Mark II chugging load definition based on GE 700 series design sources. The source data were based on 4TCO test data. Figures 3A-227 to 3A-284 show broadened response spectra curves for chugging, considering both asymmetric and axisymmetric cases. The CO loads were generated from GE's generic 4TCO test data. Figures 3A-285 to 3A-352 show broadened response spectra curves for CO-Basic and CO-ADS (axisymmetric only).

The seismic loads are described in Section 3.7.

3A.11 SUBMERGED STRUCTURE METHODOLOGY

3A.11.1 INTRODUCTION

The Mark II suppression pool is expected to experience fluid motion as a result of SRV actuation and postulated LOCA. The velocity and acceleration fields will cause drag loads on structures submerged in the pool. These loads have been calculated in the past by assuming the existence of a uniform flow field and applying steady-state standard and acceleration drag coefficients. The NRC Lead Plan Acceptance Criteria, NUREG-0487, (Reference 3A-2) pointed out that this method might not be conservative under certain flow conditions and for certain structure geometries. This section explains the methods used by the lead-plants and LGS to ensure that the design loads are conservative.

Section 3A.11.2 presents a method of evaluating the correction to both standard and acceleration drag coefficients in unsteady flow and a method to evaluate the transverse (lift) force in this flow. Sections 3A.11.3 and 3A.11.4 describe the effect of neighboring structures on the submerged structure drag loads. This method provides modified drag coefficients for the range of geometries existing in Mark II plants.

Section 3A.11.5 presents the results of sensitivity studies that verify the adequacy of the nodalization used in predicting loads. These studies show that increasing the number of points at which loads are calculated will not make significant changes in the result.

All of the drag coefficients used for submerged structure load calculations for each particular accident condition were determined directly from the data that are presented in the references listed in Section 3A.17 and 3B.17. In addition, all modifications made to the drag coefficients describing the effects of neighboring structures and unsteady flow were based on actual data listed in these references. The theory provided in this section is used as background information and provides support to the load calculations performed on this plant. The theory presented also addresses the concerns raised in NUREG-0487.

3A.11.2 DRAG AND LIFT COEFFICIENTS FOR UNSTEADY FLOW

3A.11.2.1 General Considerations

Drag and lift loads on submerged structures in the suppression pool due to the LOCA charging air bubble, pool-swell, fallback, and the SRV air bubble are considered. In calculating these loads on submerged structures, acceleration and standard drag and lift coefficients are used whenever they are applicable to a specific situation. The effects of unsteady flow on the above mentioned coefficients are treated in this section, and interference effects,

if present, are addressed in Sections 3A.11.3 and 3A.11.4. The steady-state drag coefficients are corrected appropriately to include the effects of unsteady flow.

Because the majority of the available data for unsteady flow have been developed for a cylinder, the discussion provided herein is in terms of a cylinder. The structures in the LGS suppression pool are all analyzed as cylinders. If differently shaped structures were present, a cylinder with an equivalent diameter would be used for calculations. This approach is conservative for drag load calculations, with the possible exception of the prediction of initiation of vortex shedding. Lift forces due to vortex shedding on sharp-edged structures are calculated conservatively based on available data.

Possible shapes of submerged structures in a Mark II suppression pool include circular cylinders, box beams, and I-beams. Equivalent diameters can easily be determined for these structures.

First, to determine the unsteady effects on a submerged structure, a circular cylinder with an equivalent diameter is considered. Then, for the appropriate literature, the drag coefficient due to unsteady flow for cylinders are determined, and a drag coefficient multiplier is calculated as the ratio of the unsteady drag coefficients to the steady-state drag coefficients. Finally, these multipliers are applied to the steady-state drag coefficients of the particular submerged structure of interest. However, in computing the loads, the actual dimensions of the structure are used in order to properly determine the loads.

An equivalent diameter is determined by circumscribing a circle about any structure (Reference 3A-33). For a cylinder, the equivalent diameter is equal to the diameter of the cylinder.

If a box beam is considered, its equivalent diameter is:

$$D_{EQ} = \sqrt{a^2 + b^2} \qquad \text{(EQ. 3A-9)}$$

where:

a = height of box beam
b = width of box beam

For an I-beam, the equivalent diameter is:

$$D_{EQ} = \sqrt{a^2 + b^2} \qquad \text{(EQ. 3A-10)}$$

where:

a = depth of I-beam flange
b = width of I-beam flange

The nondimensional numbers on which drag coefficients depend are based on the equivalent diameter. They are:

$$\text{Reynolds number} - Re = \frac{U_m D_{EQ}}{\nu} \qquad \text{(EQ. 3A-11)}$$

$$\text{Period parameter} - K = \frac{U_m T}{D_{EQ}} \quad \text{(EQ. 3A-12)}$$

$$\text{Strouhal number} - S = \frac{f D_{EQ}}{U_m} \quad \text{(EQ. 3A-13)}$$

where:

U_m = maximum velocity at the location of the loaded structure during the transient

D_{EQ} = equivalent diameter

T = period of flow oscillation

f = vortex shedding frequency

ν = kinematic viscosity.

To properly determine the effect of unsteady flow, a drag coefficient multiplier is defined as the ratio of the unsteady to steady-state drag coefficients:

$$f_d = \frac{C_{D1}}{C_D} \quad \text{(EQ. 3A-14)}$$

$$f_m = \frac{C_{M1}}{C_M} \quad \text{(EQ. 3A-15)}$$

where:

C_D = steady-state standard drag coefficient

C_{D1} = unsteady standard drag coefficient

C_M = steady-state acceleration drag coefficient

C_{M1} = unsteady acceleration drag coefficient

f_d = standard drag coefficient multiplier

f_m = acceleration drag coefficient multiplier.

These factors are based on drag coefficients for circular cylinders. Once they are determined for cylinders using the appropriate data, the factors are applied to the steady-state drag coefficients for the particular structure of interest. These steady-state drag coefficients are described in Reference 3A-33. The factors are applied in the following manner:

$$C_{D3} = f_d C_{D2} \quad \text{(EQ. 3A-16)}$$

$$C_{M3} = f_m C_{M2} \qquad \text{(EQ. 3A-17)}$$

where:

C_{D2} = steady-state standard drag coefficient for the particular submerged structure

C_{D3} = corrected unsteady standard drag coefficient

C_{M2} = steady-state acceleration drag coefficient for the particular submerged structure

C_{M3} = corrected unsteady acceleration drag coefficient.

The lift coefficients are determined using the actual lift data for the specific structure analyzed for the applicable transient conditions.

However, if submerged structures of unique shapes are encountered in the suppression pool, they need to be considered on a plant unique basis.

Finally, when all the coefficients are determined, the standard and acceleration drag forces are calculated based on the corrected drag coefficients and the actual structure dimensions. The sum of these forces is the in-line force.

The transverse force consists only of lift. The following equations present the contributions of the standard and acceleration drag forces to the in-line force:

$$F_S = \frac{C_{D3} \; A \; \rho \; U(t) \left| U(t) \right|}{2 \; g_c} \qquad \text{(EQ. 3A-18)}$$

$$F_A = \frac{C_{M3} V_S \rho \dot{U}(t)}{g_c} \qquad \text{(EQ. 3A-19)}$$

$$F_{IN-LINE} = F_S + F_A \qquad \text{(EQ. 3A-20)}$$

where:

F_S = standard drag force

F_A = acceleration drag force

$F_{IN-LINE}$ = total in-line force

C_{D3} = corrected unsteady standard drag coefficient

C_{M3} = corrected unsteady acceleration drag coefficient

A = projected area of submerged structure

V_S = volume of submerged structure

ρ = fluid density

$U(t)$ = velocity in the in-line direction

$\mathring{U}(t)$ = acceleration in the in-line direction.

g_c = gravitational acceleration

The determination of the lift force is considered separately in each of the following sections.

3A.11.2.2 LOCA Charging Air Bubble

The LOCA charging air bubble is considered to be a nonoscillatory accelerating flow. It is readily observed from the velocity and acceleration time histories of the transient (Figures 3A-353 and 3A-354) that the transient exhibited an increasing velocity and high positive values of acceleration. In addition, the fluid flow never reverses and the acceleration is nearly constant. This is true for all locations in the suppression pool. Comparing typical velocity time histories (Figure 3A-353) to acceleration time histories (Figure 3A-354), one can observe that the acceleration is the major contributor to the drag load because the velocity is small. The velocity and acceleration time histories were generated using the LOCA charging air bubble model described in Reference 3A-33.

The geometric configuration that was used to determine the LOCA charging air bubble transient on a submerged structure is shown in Figures 3A-355 and 3A-356. A 36° segment of a typical Mark II suppression pool was used, which contained 10 downcomers. The LOCA charging air bubbles were used at these downcomer histories on a vertical submerged structure in the pool.

For this transient, Reference 3A-34 is used in determining the standard and acceleration drag coefficients, which are conservatively taken as 1.2 and 2.0, respectively.

Due to the low velocities and small duration of this transient, lift due to vortex shedding is not present. In Reference 3A-34, the author indicates that for unsteady flow, no lift force due to vortex shedding is present for small-period parameters. In addition, the author states that for a fluid starting from rest, vortex shedding is to be present.

With the information in Reference 3A-34, it was determined that the time required for separation to occur was longer than the duration of the LOCA charging air bubble transient. Therefore, lift due to unsteady flow effects is not considered for this transient.

3A.11.2.2.1 Lift Due to Vortex Shedding

According to Reference 3A-34, the separation necessary for vortex shedding to be present does not occur until a fluid has moved a distance:

$$S = 0.293D \qquad \text{(EQ. 3A-21)}$$

where:

S = traveled distance

D = cylinder diameter

The authors also state in Reference 3A-34 that:

$$S = \tfrac{1}{2}Vt \qquad \text{(EQ. 3A-22)}$$

where:

V = velocity

t = time for separation to occur

Assuming a representative case for LOCA charging air bubble velocity in a Mark II suppression pool, the maximum pipe diameter required for separation to occur can be determined. A linear velocity increase from 0.0 ft/sec to 3.0 ft/sec was assumed to closely resemble the actual transient velocity with a transient duration of 60 msec. Integrating the velocity, a traveled distance (S) of 0.09 foot was determined. Using the above mentioned equations, the traveled distance translates to a maximum pipe diameter of 3½ inches. In other words, for a pipe with a diameter of 3½ inches that experienced a velocity transient increasing linearly form 0.0 ft/sec to 3.0 ft/sec, separation would occur at 60 msec. This is the time when the LOCA charging air bubble transient has ended.

Following this procedure for other piping within the suppression pool experiencing the LOCA charging air bubble transient, it can be concluded that lift due to vortex shedding is not present and does not need to be considered for Mark II pool geometries.

3A.11.2.3 Pool-Swell

Pool-swell is regarded as being an oscillatory flow, with the pool-swell duration considered to be the half period of the flow field. This flow is exhibited by experimental data, namely, the EPRI and 4T tests. For Reynolds numbers in the subcritical region, the drag coefficients are determined from Reference 3A-35. These drag coefficients are dependent only on the period parameter. However, if the Reynolds number is in the supercritical region ($>4x10^5$), the steady-state standard drag coefficient reduces from 1.2 to 0.71 (Reference 3A-36). To determine the unsteady standard and acceleration drag coefficients for flow at the supercritical Reynolds numbers, Reference 3A-37 is used, which correlates the Reynolds number, period parameter, and the pipe roughness to both the standard and acceleration drag coefficients. The correlations for smooth pipes are used because these correlations best represent the structures within the Mark II suppression pool.

In addition, lift due to vortex shedding is considered. Reference 3A-38 provides the necessary information to determine lift loads. As before, the lift coefficient is based on the period parameter and

the Reynolds number where both are evaluated at the maximum velocity observed in the transient. Moreover, the vortex shedding frequency must also be defined. Reference 3A-37 provides a correlation of the relative frequency, f_r, to the period parameter and the Reynolds number evaluated at the maximum velocity.

$$f_r = \frac{f_v}{f_w} \qquad \text{(EQ. 3A-23)}$$

where:

f_r = relative frequency

f_v = vortex shedding frequency

f_w = oscillating fluid frequency

However, if the relative frequency falls out of the range shown in figure 21 of Reference 3A-37, Reference 3A-38 indicates that a Strouhal number of 0.3 should be used at high Reynolds numbers.

When determining the lift force due to vortex shedding, the maximum amplitude is based on the maximum velocity that the structure sees (Reference 3A-38):

$$F_L = \frac{C_L \; A \; \rho \; U_m^2 \; \sin 2 \; \pi f_v t}{2 g_c} \qquad \text{(EQ. 3A-24)}$$

where:

F_L = lift force (transverse to flow direction)

C_L = lift coefficient

A = projected area of structure

g_c = gravitational acceleration

ρ = fluid density

U_m = maximum in-line velocity the structure observes

f_v = vortex shedding frequency

t = time

The vortex shedding frequency is specified from the correlation mentioned previously. With the maximum amplitude and frequency, the lift force is defined. The lift force varies with time and is sinusoidal in nature for viscous lift.

In this case, the acceleration drag force considers the effect of gravity and is determined in the following manner:

$$F_A = \frac{V_S \rho \ C_{M3} \ \dot{U}(t)}{g_c} \qquad \text{(EQ. 3A-25)}$$

where:

F_A = acceleration drag force

V_S = volume of submerged structure

C_{M3} = corrected unsteady acceleration drag coefficient

$\mathring{U}(t)$ = acceleration in the in-line direction.

3A.11.2.4 Fallback

Fallback is considered to be a constantly accelerating flow. It is assumed that fallback behaves as a falling water slug. For this case, the standard and acceleration drag coefficients are determined from Reference 3A-34. As with pool-swell, the lift coefficients due to vortex shedding are also determined. The lift coefficient is given by Reference 3A-39 as CL = 1.0 for Karman vortices. To determine the vortex shedding frequency, Reference 3A-39 indicates that a Strouhal number of 0.22 should be used. This is also substantiated by Reference 3A-40. The force is then determined as:

$$F_L = \frac{C_L \ \Delta\rho \ U_m^2 \ \sin 2\pi ft}{2g_c} \qquad \text{(EQ. 3A-26)}$$

In this case, the acceleration drag force is determined in the following manner:

$$F_A = \frac{C_H \ g \ V_S \ \rho}{g_c} \qquad \text{(EQ. 3A-27)}$$

where:

C_H = hydrodynamic mass coefficient ($C_H = C_M - 1$).

3A.11.2.5 SRV Air Bubbles

SRV air bubbles are considered to be of oscillatory nature. Reference 3A-35 is used to determine the unsteady standard and acceleration drag coefficients. These drag coefficients are based on the period parameter evaluated at the maximum velocity. However, if the unsteady drag coefficients are less than the steady-state drag coefficients, then the steady-state coefficients are used for load determination. If any lift is present, Reference 3A-35 is used, which also bases the lift coefficients on the period parameter. This reference mentions that no lift is present for period parameters less than 5. The drag loads are determined as described in Section 3A.11.2.1.

3A.11.3 INTERFERENCE EFFECTS ON ACCELERATION DRAG

When submerged structures are closely located in a flow field, they can interfere with one another, affecting the acceleration drag. The proximity effect can be accounted for by either (a) using actual data that is presented in References 3A-44, 3A-46, and 3A-47, (b) performing a detailed analysis, or (c) applying a conservative factor of 4 on the acceleration drag. For LGS, actual data that are presented in References 3A-44, 3A-46, and 3A-47 were used to determine the interference effects on acceleration drag.

A detailed method is presented in the following sections for determining interference effects of nearby cylinders and/or a boundary on the acceleration drag for circular cylinders and is based on References 3A-41 through 3A-46.

According to the method, the interference effect between any two stationary cylinders can be completely determined by six force coefficients that are functions solely of the radius ration and the relative spacing. For the case of more than two cylinders, the total proximity effect on a given cylinder may be approximately obtained simply by superimposing each interference effect between cylinder pairs.

3A.11.3.1 Method of Analysis

The following assumptions are considered in the method:

a. Two-dimensional potential flow without separations and wakes is considered.

b. The velocity and acceleration in the flow field are the same as those seen locally by the submerged structure (cylinder).

c. The containment and pedestal walls are considered as plane boundaries.

d. Coordinate system

+x : radially outward from reactor pressure vessel centerline.

+y : vertically upward.

+z : by right-hand rule parallel to the plane boundary.

Origin: at the center of cylinder in question.

3A.11.3.2 Two Stationary Cylinders (Real Cylinders)

If the pth cylinder is isolated in a free stream, the hydrodynamic (acceleration drag) force per unit length of the cylinder is:

$$F_{po} = 2 \rho \pi A_p^2 \dot{U}_{\infty n} \qquad \text{(EQ. 3A-28)}$$

where:

F_{po} = acceleration drag force per unit length

ρ = fluid density

A_p = radius of pth cylinder

$\mathring{U}_{\infty n}$ = acceleration normal (in-line) to p^{th} cylinder

When the nth cylinder is in the vicinity of the pth cylinder, the change in the force of the pth cylinder, ΔF_{pn}, is:

$$\Delta F_{pn} = \rho \pi A_p^2 |\mathring{U}_{\infty n}| \{ (C_1 - 1)\exp(i\alpha_1) - C_2\exp[i(2\beta_{pn} - \alpha_1)] \}$$

$$+ \rho A_p |U_{\infty n}|^2 \{ (C_3 + C_4)\exp(i\beta_{pn}) - C_5\exp[i(3\beta_{pn} - 2\alpha_2)]$$

$$-C_6\exp(i(2\alpha_2 - \beta_{pn})] \} \qquad \text{(EQ.3A-29)}$$

where:

$U_{\infty n}$ = velocity normal (in-line) to the pth cylinder

α_1 = angle of acceleration with respect to z-axis

α_2 = angle of velocity with respect to z-axis

β_{pn} = angle between the line through centers of cylinders and the z-axis.

$$C_1 = 1 + 2 \sum_{j=1}^{\infty} b_{1,2j+1}$$

$$C_2 = 2 \left(\frac{A_n}{A_p}\right)^2 \sum_{j=1}^{\infty} b_{1,2j+1}$$

$$C_3 = 4\pi \sum_{k=1}^{\infty} \sum_{j=1}^{\infty} \frac{b_{1,2k-1} b_{2,2j}}{\left(\frac{L_{pn}}{A_p} - q_{1,2k-1} - \frac{A_n}{A_p} q_{2,2j}\right)^3}$$

$$C_4 = 4\pi \left(\frac{A_n}{A_p}\right)^4 \sum_{k=1}^{\infty} \sum_{j=1}^{\infty} \frac{b_{1,2k-1} b_{2,2j-1}}{\left(\frac{L_{pn}}{A_p} - q_{1,2k-1} - \frac{A_n}{A_p} q_{2,2j-1}\right)^3}$$

$$C_5 = 4\pi \left(\frac{A_n}{A_p}\right)^2 \sum_{k=1}^{\infty} \sum_{j=1}^{\infty} \frac{b_{1,2k-1} b_{2,2j-1}}{\left(\frac{L_{pn}}{A_p} - q_{1,2k-1} - \frac{A_n}{A_p} q_{2,2j-1}\right)^3}$$

$$C_6 = 4\pi \left(\frac{A_n}{A_p}\right)^2 \sum_{k=1}^{\infty} \sum_{j=1}^{\infty} \frac{b_{1,2k}\, b_{2,2j}}{\left(\frac{L_{pn}}{A_p} - q_{1,2k} - \frac{A_n}{A_p} q_{2,2j}\right)^3}$$

where:

$b_{1,1} = 1$

$b_{2,1} = 1$

$b_{1,m} = b_{2,m-1}\, q_{1,m}^2$ for $m \geq 2$

$b_{2,m} = b_{1,m-1}\, q_{2,m}^2$ for $m \geq 2$

in which:

$q_{1,1} = 0,$

$q_{2,1} = 0,$

$q_{1,j} = \frac{A_p}{L_{pn} - A_n q_{2,j-1}}$ for $j \geq 2,$

$q_{2,j} = \frac{A_n}{L_{pn} - A_p q_{1,j-1}}$ for $j \geq 2,$

A_n = radius of the nth cylinder

L_{pn} = distance between the centers of cylinders

3A.11.3.3 Stationary Cylinders Near a Plane Boundary (Real and Imaginary Cylinders)

A single stationary cylinder in a uniform stream, $U_{\infty n}$, is hydrodynamically equivalent to a cylinder moving at a speed $-U_{\infty n}$ in a still fluid, except that the former cylinder experiences an extra force, $\rho\pi A_p^2 \dot{U}_{\infty n}$, from the pressure field that has been created to provide the fluid acceleration $(\dot{U}_{\infty n})$. This is also true for any number of cylinders if the cylinders move together.

When a cylinder is moving in a arbitrary direction (on a line or on a curve) with respect to the plane boundary, it can be considered as two equal cylinders moving symmetrically with respect to the plane boundary because the plane acts as a perfect reflector (mirror) of the hydrodynamic pressure. A similar argument can be applied to multiple cylinders.

Based on the above discussion, the plane boundary can be removed and replaced by an imaginary cylinder of the same size as the original (real) cylinder and the plane boundary away from the original cylinder. Similarly, multiple imaginary cylinders can be obtained by reflecting those multiple real cylinders near the plane boundary.

Now if the nth imaginary cylinder is in the proximity of the pth cylinder, the change in the hydrodynamic force of the pth cylinder (ΔF_{pn}) can be derived from Reference 3A-41 and is:

$$\Delta F_{pn} = \rho\pi A_p^2 |U_{\infty n}| \{ (C_1 - 1)\exp(i\alpha_1) - C_2\exp[i(\alpha_1 + 2\beta_{pn})] \}$$

$$+ \rho A_p |U_{\infty n}|^2 \{ (C_3 + C_4)\exp(i\beta_{pn}) - C_5\exp(i3\beta_{pn}) - C_6\exp(-i\beta_{pn}) \}$$

(EQ. 3A-30)

where:

C_1 through C_6 are the same as described earlier.

3A.11.3.4 Total Acceleration Drag Force

Summing up each effect from all the surrounding N real and imaginary cylinders, the force on the pth cylinder is approximately given as:

$$F_p = F_{po} + \sum_{\substack{n=1 \\ n\neq p}}^{n} \Delta F_{pn} = 2\rho\pi A_p^2 \dot{U}_{\infty n} + \sum_{\substack{n=1 \\ n\neq p}}^{n} \Delta F_{pn} \quad \text{(EQ. 3A-31)}$$

or:

$$F_p = C_m \rho\pi A_p^2 |\dot{U}_{\infty n}| + C_v \rho A_p |U_{\infty n}|^2 \quad \text{(EQ. 3A-32)}$$

where:

C_m = acceleration drag coefficient

C_v = convective force coefficient

3A.11.3.5 Practical Application

When the increase in force on the pth cylinder arising from interference effects is calculated, only those real and imaginary cylinders that have a significant contribution should be considered. Significant contributions to the summation equations presented in Section 3A.11.3.4 arise only from those cylinder pairs within a gap distance of 3D, where D is the larger diameter of the pair being considered.

If the flow is omnidirectional during a specific transient, a magnification factor K_M may be obtained from the maximum $|C_m|$ that is determined in the range of $0° \leq \alpha_1 \leq 180°$. This is performed to account for the interference effect on the acceleration drag. Similarly, to account for the lift force, the maximum $|C_v|$ can be determined by varying α_2 in the range of $0° \leq \alpha_2 \leq 180°$. Then the maximum lift coefficient is combined with the standard drag coefficient, C_D, by the SRSS to include the lift force due to the proximity effect.

The acceleration and drag forces are determined as follow:

$$|F_{Ap}| = \frac{2K_M \rho \pi A_p^2 |\ddot{U}_{\infty n}|}{g_c} \quad \text{(EQ. 3A-33)}$$

$$|F_{sp}| = \sqrt{C_D^2 + |C_L|^2}\ \frac{\rho A_p |U_{\infty n}| U_{\infty n}}{2g_c} \quad \text{(EQ. 3A-34)}$$

where:

F_{Ap} = acceleration drag per unit length on p^{th} cylinder

K_M = $|C_m|/2$ magnification factor and $|C_m|$ is the maximum acceleration drag coefficient

ρ = fluid density

A_p = radius of pth cylinder

$\dot{U}_{\infty n}$ = acceleration in the normal (in-line) direction to the cylinder

$U_{\infty n}$ = velocity in the normal (in-line) direction to the cylinder

C_D = standard drag coefficient

$|C_L|$ = maximum lift coefficient

F_{sp} = standard drag per unit length on the pth cylinder.

The directions of the acceleration and standard drags are the same as those without the interference effect.

However, if the flow field is well defined and the direction of flow known, then the actual acceleration drag and lift coefficients are used. In this case, the lift force is applied in the transverse direction. The equations used are then:

$$F_{Ap} = \frac{2C_m \rho \pi A_p^2 \ddot{U}_{\infty n}}{g_c} \quad \text{(EQ. 3A-35)}$$

$$F_{Lp} = \frac{C_L\ \rho A_p |U_{\infty n}| U_{\infty n}}{2g_c} \quad \text{(EQ. 3A-36)}$$

where:

C_m = acceleration drag coefficient determined through the analysis

C_L = lift coefficient determined through the analysis

F_{Lp} = lift force in the transverse direction

3A.11.3.6 Model/Data Comparisons

The method has been tested numerically as well as experimentally, and the results (Figure 3A-357) indicate excellent agreement with both known numerical values (References 3A-41, 3A-42, and 3A-44) and experimental data (References 3A-43 and 3A-45).

3A.11.4 INTERFERENCE EFFECTS ON STANDARD DRAG

When submerged structures are located closely together in a flow field, they can interfere with one another, causing an effect on the standard drag. Actual data presented in the references can be used, a detailed analysis can be used, or a factor of four can be applied to the standard drag force. For LGS, actual data that are presented in Reference 3A-49 were used to determine the interference effects on standard drag.

Three technical papers (References 3A-48, 3A-49, and 3A-50) have described this phenomenon and presented experimental data on interference effects. Most of the data presented in these references are applicable to interference between two cylinders.

Reference 3A-49 has presented some data for three cylinders whose axes are co-planar. Cylinder spacing, Reynolds number, and the angle between flow direction and the plane containing cylinder axes were varied in the above investigations. In many instances the data obtained from the above references can be applied directly to Mark II suppression pool conditions.

A procedure has been developed to use the above data for interference between more than two cylinders. The results have been compared with measured data of three cylinders and are found to be conservative.

3A.11.4.1 Interference Between Two Cylinders of Equal Diameter

As indicated by the data given in References 3A-48, 3A-49, and 3A-50, the interference between two parallel cylinders alters the flow direction drag and also induces a lift force normal to flow direction. For two cylinders of equal diameter, the interference effect on drag forces is small, and in most cases negative (i.e., the drag is reduced due to interference). The lift force, however, is not always insignificant.

The following bounding values for interference between two cylinders of equal diameter can be used without any further detailed analysis. A bounding value of C_D for a Reynolds number greater than 8,000 and a S/d ratio greater than 0.2 is 1.4, and the bounding value for C_L is 1.0.

3A.11.4.2 Interference Between More than Two Cylinders of Equal Diameter

To evaluate the drag coefficient of a cylinder that is interfered by more than one cylinder, the maximum of C_{Do}, C_{Di}, and $D_{Di,j}$ should be used.

$$C_{Di} - C_{Do} = \sum_{\substack{j=1 \\ j \neq 1}}^{n} (C_{Di,j} - C_{Do}) \qquad \text{(EQ. 3A-37)}$$

where:

C_{Di} = standard drag coefficient for the ith cylinder

C_{D0} = standard drag coefficient for a single cylinder without any interference

$C_{Di,j}$ = drag coefficient of ith cylinder when it is interfered by Cylinder j alone.

Figure 3A-358 illustrates an arrangement of cylinders. The standard drag coefficient of Cylinder 1 would be:

$$C_{D_1} = C_{D_0} + (C_{D_{1/2}} - C_{D_0}) + (C_{D_{1/3}} - C_{D_0}) + (C_{D_{1/4}} - C_{D_0})$$

From this, the maximum value of C_{D_1}, C_{D_0}, $C_{D_{1/2}}$, and $C_{D_{1/4}}$ would be used for the standard drag coefficient.

To evaluate the lift coefficient, the maximum of C_{Li} and $C_{Li,j}$ should be used:

$$C_{Li,j} = \sum_{\substack{j=1 \\ j \neq 1}}^{n} \qquad \text{(EQ. 3A-38)}$$

where:

C_{Li} = lift coefficient of ith cylinder

$C_{Li,j}$ = lift coefficient of ith cylinder when it is interfered by Cylinder j alone.

From Figure 3A-358, the lift coefficient would be determined in the following manner:

$$C_{Li} = C_{L_{1,2}} + C_{L_{1,3}} + C_{L_{1,4}} \qquad \text{(EQ. 3A-39)}$$

The maximum value of C_{L_1}, $C_{L_{1,2}}$, $C_{L_{1,3}}$, and $C_{L_{1,4}}$ would be used for the lift coefficient.

The above described method yielding interference on standard drag between more than two cylinders of equal diameter (bounding procedure) is illustrated in the following examples:

Example 1

Consider the three cylinder arrangement shown in Figure 3A-359.

Let $\frac{S}{d} = 1$, $\theta = 60°$, and $Re = 2.78 \times 10^4$

For this arrangement:

$C_{D_{1,2}}$ = Drag coefficient of Cylinder 1 when interfered by Cylinder 2 only.

$= \quad 1.01$ (S/d = 1)

$C_{D_{1,3}} = \quad 1.02$ (S/d = 3)

$C_{D0} = \quad 1.16$ [Reference 3A-36, p. 341]

$C_{Di} - C_{D_0} = (C_{D_{1,2}} - C_{D_0}) + (C_{D_{1,3}} - C_{D_1})$

$= \quad 0.37$

$\therefore$ Maximum of C_{Di}; $C_{D_{1,2}}$; $C_{D_{1,3}}$; C_{D_0} is 1.16

$\therefore$ Use $C_D = 1.16$

From measurements (Reference 3A-49):

$C_D = \quad 0.97$, which is less than the calculated drag coefficient.

Example 2

Consider the three cylinder side-by-side arrangement shown in Figure 3A-360.

Let S/d = 1 and Re = 2.78×10^4

$C_{D_{1,2}} = 1.03$(S/d = 1)

$C_{D_{1,3}} = 1.05$ (S/d = 3)

$C_{D_o} = 1.16$

$\therefore C_{D_1} - 1.16 = 1.03 - 1.16 + 1.05 - 1.16$

or $C_{D_1} = 0.92$

Maximum of C_{D_o} ; C_{D_1} ; $C_{D_{1,2}}$; $C_{D_{1,3}}$ is 1.16

Use $C_D =$ 1.16

The measured value is 0.98, which is less than the calculated value.

3A.11.4.3 Drag on Small Cylinder Upstream of Large Cylinder

Figure 3A-361 presents the flow around cylinders of unequal diameters.

The coordinates of point A (center of smaller cylinder) are (-a,b). Let R and R_1 be the radii of larger and smaller cylinders, respectively. The velocity potential of flow around the larger cylinder in the absence of smaller cylinder is

$$\phi = Ux\left(1 + \frac{R^2}{x^2 + y^2}\right)$$

where:

ϕ = velocity potential

U = free stream velocity

R = radius of large cylinder.

If u and v are the x and y components of velocity at point "A" (smaller cylinder absent) then,

$$u = U\left[1 + R^2\left\{\frac{b^2 - a^2}{\left(a^2 + b^2\right)^2}\right\}\right] \qquad \text{(EQ. 3A-40)}$$

and

$$v = \frac{2ab\ R^2\ U}{\left(a^2 + b^2\right)^2} \qquad \text{(EQ. 3A-41)}$$

where:

u = the velocity parallel to the free stream velocity at the centerline of the smaller cylinder

v = the velocity perpendicular to the free stream velocity at the centerline of the smaller cylinder.

To use the above velocity correction, it is more convenient to increase the standard drag coefficient and use the corrected standard drag coefficient with the free stream velocity. The standard drag force on the smaller cylinder with interference present is:

$$F_1 = \frac{C_D\ \rho\ A\left(u^2 + v^2\right)}{2g_c} \qquad \text{(EQ. 3A-42)}$$

where:

F_1 = standard drag force with interference

C_D = standard drag coefficient

ρ = fluid density

A = projected area of smaller cylinder.

The direction of flow is:

$$\beta = \tan^{-1}\left(\frac{v}{u}\right)$$

The standard drag force without interference is:

$$F = \frac{C_D \rho A U^2}{2g_c} \qquad \text{(EQ. 3A-43)}$$

where:

F = standard drag force without interference

U = free stream velocity.

The ratio of the two standard drag forces yields the following expression for the correction of the standard drag coefficients:

$$\frac{C_D \text{ (interference)}}{C_D \text{ (without interference)}} = m^2 + n^2 \qquad \text{(EQ. 3A-44)}$$

where:

$$m = 1 + R^2\left\{\frac{b^2 - a^2}{(a^2 + b^2)^2}\right\}$$

$$n = \frac{2ab\ R^2}{(a^2 + b^2)^2}$$

If the determined ratio of the standard drag coefficients is less than 1, then a ratio of 1 is used. However, if the determined ratio is greater than 1, then the determined ratio is used.

The standard drag force on the smaller cylinder is then determined by:

$$F_1 = \frac{C_D \rho A U |U|}{2g_c} \qquad \text{(EQ. 3A-45)}$$

where:

F_1 = standard drag force on smaller cylinder

C_D = the corrected standard drag coefficient for interference

U = free stream velocity in the in-line direction.

The lift force on the smaller cylinder is determined in the same manner as was the standard drag force:

$$\frac{C_L \text{ (interference)}}{C_L \text{ (without interference)}} = m^2 + n^2 \qquad \text{(EQ. 3A-46)}$$

where m and n are the same as previously described. Once again, if the determined ratio is less that 1, then the ratio of 1 is used. However, if the determined ratio is greater than 1, then the determined ratio is used. The lift force is then determined by:

$$F_L = \frac{C_L \rho A U |U|}{2g_c} \qquad \text{(EQ. 3A-47)}$$

where:

F_L = lift force

C_L = corrected lift coefficient for interference.

The lift force is applied in the transverse direction to the resultant flow.

3A.11.4.4 Standard Drag on Smaller Cylinder Downstream of Large Cylinder

If the smaller cylinder is located downstream of the larger cylinder, then the lift and standard drag coefficients are evaluated corresponding to S/d (where S is the distance between the cylinder surfaces and d is the diameter of the cylinders) ratios of for both cylinders, assuming equal diameters. The coefficients are first determined by assuming both cylinders are equal to the diameter of the smaller cylinder, and then assuming booth cylinders are equal to the diameter of the larger cylinder. When determining the coefficients, the centerline distance between the two submerged structures is maintained at the actual distance.

Afterwards, the larger coefficients are used for determining submerged structure loads. In addition, if the lift and standard drag coefficients are less than the coefficients without interference, then the coefficients without interference are used.

3A.11.4.5 Standard Drag on the Large Cylinder

The method described in Section 3A.11.4.4 is used to determine the standard drag and lift on the large cylinder.

3A.11.4.6 Structures of Noncircular Cross-Section

The methodology of determining an equivalent diameter described in Section 3A.11.4.2 is used to determine the coefficients due to interference effects.

3A.11.4.7 Interference Between Nonparallel Cylinders

To estimate the interference effects between nonparallel structures, the lift and standard drag coefficients are determined by assuming that the structures are parallel. The distance used between them would be the minimum distance between the two structures. In the same manner, the larger coefficients of either with or without interference effects are chosen for submerged structure load determination.

3A.11.5 FLOW BLOCKAGE EFFECTS OF DOWNCOMER BRACING

The downcomer bracing is a flow restriction that increases the fluid velocity and acceleration during pool-swell. As a result, the standard drag, acceleration drag, and lift loads on structures in the pool-swell zone are higher than those which would exist if no downcomer bracing was present. Although the pool-swell loads are not design-controlling criteria, the load calculations were adjusted for blockage effects by introducing a multiplicative factor to the fluid velocity and acceleration.

A method of correction has been developed based on References 3A-51 and 3A-52. A multiplicative factor has been determined based upon Maskell's paper (Reference 3A-52).

$$\frac{C_{Dm}}{C_{Df}} = 1 + n\, C_{Df}\ S/C \qquad \text{(EQ. 3A-48)}$$

where:

C_{Dm} = modified drag coefficient of structures in the pool-swell zone

C_{Df} = steady flow, free steam drag coefficient

n = blockage factor

S = total blocked area

C = unrestricted flow area.

The value of the blockage factor, n, depends upon the structure's geometry. The blockage ratio varies from 0.96 to 2.77 for structures with aspect ratios, AR, from ∞ to 1.0, respectively. Maskell (Reference 3A-52) recommends a blockage factor of 2.5 for bluff bodies, and this value is considered conservative for the suppression pool bracing system.

The unrestricted flow area, C, is the pool surface area minus the area of the columns, downcomers and MSRV lines. THe blocked area, S, includes all the flanges and members of the bracing system. The drag coefficient used on the right side of Equation 3A-48 is the steady flow, free stream drag coefficient of the particular structure being analyzed.

Equation 3A-48 can be rearranged to obtain

$$C_{Dm} = \left(1 + n\ C_{Df}\ \frac{S}{C} \right) C_{Df} \qquad \text{(EQ. 3A-49)}$$

$$= f\ C_{Df}$$

where (f) is defined as the blockage correction factor. Because (f) is proportional to the drag coefficients, and therefore to the square of the velocity, the fluid velocity and acceleration are multiplied by the square root of (f). For consistency, the same multiplicative factor is used for the velocity and acceleration.

As a result, the pool-swell loads are calculated by the following equations:

Standard Drag Load: $F_X = \frac{1}{2} \rho (\sqrt{f}\ V)^2 C_D A$ (EQ. 3A-50)

Acceleration Drag Load: $F_A = \rho(\sqrt{f}\ a) C_m V_s$ (EQ. 3A-51)

Lift Load: $F_L = \frac{1}{2} \rho (\sqrt{f}\ V)^2 C_L A$ (EQ. 3A-52)

where:

ρ = fluid density

f = blockage correction factor

V = fluid velocity

C_D = standard drag coefficient which accounts for any interference effects

A = projected cross-sectional area of the structure

C_L = lift coefficient

a = fluid acceleration

C_m = inertial coefficient

V_S = structure's volume.

3A.12 CONTAINMENT AND SUBMERGED STRUCTURE - STRUCTURAL DESIGN ASSESSMENT

3A.12.1 CONTAINMENT STRUCTURE - STRUCTURAL DESIGN ASSESSMENT

Figure 3A-362 indicates the containment structural elements and cross-sections where stresses are determined, and Figures 3A-363 through 3A-386 contain a tabulation of the predicted stresses and allowable stresses for each loading combination considered.

Load Combinations, taken from Table 3A-14, are tabulated to cover all of the critical sections in the containment concrete structures. Load combination equation 2 for all sections and equations 1 and/or 3 and 6 for some sections are not executed because they do not represent the governing cases.

3A.12.2 SUBMERGED STRUCTURE - STRUCTURAL DESIGN ASSESSMENT

The submerged structures in the suppression chamber include the diaphragm slab support columns, the downcomer bracing system, and the downcomers. The bracing system and the columns are assessed in accordance with Table 3A-15. In the column assessment, the dynamic loads are combined by the SRSS method and then combined with the static loads using the absolute sum procedure. In the assessment of the downcomer bracing system, all loads are combined using the absolute sum method. For both the downcomer bracing system and the columns, equation 7 of Table 3A-15 is the most critical combination.

The natural vibration frequencies and shapes of the suppression chamber columns are presented in Figure 3A-387, and the assessment results are summarized in Figure 3A-388. Bolt stresses are not shown in the bottom anchorage because the design is more critical at the connecting flange, which yields a design margin of 10%.

The natural vibration frequencies and mode shapes of the downcomers are presented in Figures 3A-389 through 3A-391. Downcomer design margins are provided in Figure 3A-392. Fatigue usage factors, fatigue cycles, and fatigue histogram are provided in Figures 3A-393, 3A-394 and 3A-395, respectively.

The downcomer bracing system mathematical model is shown in Figure 3A-396, and the design margins for the most critical member in each quadrant are summarized in Figure 3A-397.

3A.13 REACTOR ENCLOSURE AND CONTROL STRUCTURE - STRUCTURAL DESIGN ASSESSMENT

Figure 3A-398 presents the reactor enclosure and control structure general floor plan at el 177' to aid in the location of wall marks.

Figures 3A-399 through 3A-418 identify and locate the selected critical structural elements where stresses are assessed in the reactor enclosure and control structure.

Figures 3A-419 through 3A-428 present diagrams of combined vertical (axial) forces, N-S and E-W shear forces, and N-S and E-W overturning moments, based on the dynamic portion of the load combinations specified in Tables 3A-14 and 3A-15.

Figures 3A-429 through 3A-436 contain tabulations of predicted stresses, stress allowables, and/or stress margins for the reactor enclosure and control structure floor slabs, floor support steel, and shear walls.

3A.14 BOP PIPING DESIGN ASSESSMENT

Table 3A-27 provides maximum cumulative fatigue usage factors for the MSRV discharge lines in the wetwell airspace. Table 3A-28 summarizes the stresses and stress margins for selected BOP piping systems.

The stress reports for the evaluation of the BOP piping will be available for NRC review.

3A.15 SUPPRESSION POOL TEMPERATURE DESIGN ASSESSMENT

3A.15.1 SUPPRESSION POOL TEMPERATURE MONITORING SYSTEM

3A.15.1.1 Suppression Pool Temperature Monitoring System Design Criteria

The SPTMS monitors the suppression pool temperature during normal plant operations and after transient or accidents. Operator monitoring of pool temperature is required to ensure that the suppression pool is operated within the allowable temperature limits set forth in the LGS Technical Specifications. Operation of the pool within the Technical Specifications will provide assurance that the suppression pool temperature will be maintained within the limits specified in NUREG-0783. Section 3A.15.1.1.4 describes the Technical Specification temperature alarm setpoints for pool operation.

The SPTMS is designed in conformance with the acceptance criteria specified in NUREG-0487 (Reference 3A-56) and NUREG-0783 (Reference 3A-58).

3A.15.1.1.1 Sensor Locations

The suppression pool temperature is redundantly monitored by two divisionalized systems. Eight dual element RTDs are provided for each system and are evenly distributed around the pool to provide a reasonable measure of the bulk water temperature. The eight monitoring locations and individual RTD identifications are shown in Figure 3A-437.

The sensors are located at a depth of 4'-4" below the minimum Technical Specification pool water level. This depth ensures a conservative measurement of bulk temperature because the hottest water will rise to the pool surface. This depth also provides adequate sensor submergence to preclude the possibility of sensor uncovery during an accident or transient.

3A.15.1.1.2 Safety Evaluation

The indication of suppression pool temperature in the control room is required to ensure that the plant is always operating within the Technical Specification limits. Manual operator action is required to maintain the plant within the Technical Specifications. Suppression pool temperature is also required for postaccident monitoring. These functions are safety-related.

The system design conforms to all applicable criteria for physical separation, redundancy and divisionalization. Physical and electrical separation is provided for the safety-related instrumentation. The safety-related instrumentation is powered from divisionalized Class 1E power sources.

The suppression pool temperature sensors are qualified to seismic Category I and Class 1E criteria and are energized from onsite emergency power supplies.

A CF Card located on the recorder records the average temperature, the individual temperature, and the current date and time. The data saved on a CF card can be converted by data conversion software to Lotus 1-2-3, Excel, or ASCII format file, facilitating processing on a PC. The Viewer software allows a PC to display waveforms on its screen and to print out waveforms. Trending information may also be printed at the Operator's request. Alarm conditions are printed along with the temperature. This function is not safety-related.

3A.15.1.1.3 Equipment Design

The signals from the redundant sensors are processed by two independent divisionalized recorders located on a main control room cabinet. The recorders convert the RTD signals into degrees Fahrenheit and compute the average of the eight temperatures. The average value is displayed by the recorders and on the remote indicators located at the main control board. A keypad located on the microprocessor allows the operator to display any individual temperature input.

The SPTMS trouble alarm located in the main control room is generated if the calculated average temperature exceeds any of the four distinct high temperature setpoints that are stored in the microprocessors. (Section 3A.15.1.1.4 provides details on the temperature alarm setpoints.) Also, appropriate high temperature status lights are initiated on the associated recorder and remote indicator. Electrically isolated outputs interface with the SPTMS trouble alarm located in the main control room.

The SPTMS trouble alarm is also initiated if one of the RTDs fails or if non-Class 1E power to the cabinet cooling fans is lost. A keypad allows the operator to remove a failed RTD from the calculated average.

Both elements of each dual element RTD are wired out through containment penetrations. One element of each RTD is connected to the associated recorder inputs. This design provides the capability to easily connect the backup RTD elements in case of a failure, with the exception of the backup RTD elements for TE41-101D and H.

For temperature elements TE41-101D and H only, the second dual element is used for providing suppression pool temperature indication at the remote shutdown panel. This is an independent Division 1 loop to provide the operator with suppression pool water temperature indication when the main control room is inaccessible (Method R shutdown as described in (Appendix 9A).

A CF Card located on the recorder records the average temperature, the individual temperature, and the current date and time. The data saved on a CF card can be converted by data conversion software to Lotus 1-2-3, Excel, or ASCII format file, facilitating processing on a PC. The Viewer software allows a PC to display waveforms on its screen and to print out waveforms. Trending information may also be printed at the Operator's request. Alarm conditions are printed along with the temperature.

Output signals are provided to interface with other plant information systems including a signal to the PMS computer. The recorder has a self checking diagnostic system that provides an alarm if a failure is detected in any critical part of the system.

3A.15.1.1.4 Alarm Setpoints

The SPTMS provides alarm at four pool temperature setpoints (95°F, 105°F, 110°F, and 120°F) to provide assurance that the suppression pool will be maintained within the temperature limits defined in NUREG-0783. Section 3A.15.2 describes these pool temperature limits and provides LGS analysis for suppression pool temperature response to SRV discharge. This analysis demonstrates the adequacy of these alarm setpoints with regard to alerting the operator to maintain the pool temperature below the NUREG-0783 limit. The alarm setpoints are based on Reference 3A-53 and are defined as follows:

a. 95°F: maximum allowable pool temperature for continuous power operation without suppression pool cooling

b. 105°F: maximum allowable pool temperature during testing at power which adds heat to the pool.

c. 110°F: manual reactor scram setpoint

d. 120°F: manual reactor depressurization setpoint.

3A.15.1.2 SPTMS Adequacy Assessment

As mentioned in Section 3A.15.1.1, the selection of the SPTMS sensor locations conforms with the acceptance criteria specified in NUREG-0487 (Reference 3A-56) and NUREG-0783 (Reference 3A-58). Section 3A.15.1.2 provides data for confirming the adequacy of the SPTMS sensor locations shown on Figure 3A-437, in predicting the bulk pool temperature.

The following assessment is based on a SPTMS sensor location of 2' below minimum Technical Specification water level. Subsequent to the assessment, the sensors were relocated at 4'-4" below the minimum Technical Specification water level to be below the resultant post-LOCA water level.

A sensitivity study as to the effect of the lower SPTMS sensor elevation on the following assessment was performed and the differences were negligible. Therefore, the following assessment, which was originally performed corresponding to SPTMS sensor elevation of 2' below the minimum Technical Specification water level, remains as an adequate representation of the SPTMS prediction capability.

In lieu of conducting LGS unique confirmatory in-plant tests of SRV discharges, analyses were performed using the KFIXTM computer code. KFIXTM is a three-dimensional thermal-hydraulic computer code which was developed to provide an analytical tool for predicting the thermal mixing and temperature response in the LGS suppression pool resulting from SRV actuation. The calculated results from the KFIXTM code have been verified against LaSalle and Caorso SRV extended blowdown in-plant test data. The KFIXTM code verification and methodology have been provided to the NRC (Reference 3A-54).

Section 3A.15.1.2.1 describes the scenarios that were analyzed for assessment of the LGS SPTMS. These scenarios are also used in Section 3A.15.3 to assess the adequacy of the suppression pool local-to-bulk temperature difference (ΔT). Sections 3A.15.1.2.1.1 and 3A.15.1.2.1.2 describe the initial/operating conditions and KFIXTM modeling, respectively. The calculated temperature time histories for the individual SPTMS sensors are discussed in Section 3A.15.1.2.2 The arithmetic average values among these sensors are presented in Section 3A.15.1.2.3. Conclusions of the SPTMS adequacy assessment are provided in Section 3A.15.1.2.4.

3A.15.1.2.1 Stuck Open Relief Valve Scenarios

The KFIXTM code is employed for the simulation of three SORV scenarios to predict the LGS suppression pool thermal mixing and temperature response.

To parallel the scenarios chosen in the LaSalle in-plant tests, two single SORV blowdown scenarios under conditions of high reactor pressure and relatively low pool temperature were selected. This analysis quantifies the thermal mixing effectiveness in the pool due to the large momentum associated with the heated fluid jet induced by high reactor pressure steam discharges through the quencher.

The third scenario considers a single SORV blowdown scenario under conditions of low reactor pressure and high pool temperature. This analysis quantifies the thermal mixing effectiveness in the pool even under conditions of reduced fluid jet momentum associated with steam discharges under low reactor pressure.

The LGS SRV set pressures are provided in Table 3A-3. The associated quencher orientations are shown in Figure 3A-3. Among the 14 SRVs, the two with designations of L and H, which are located along the outer and inner quencher circles, respectively, were selected for the high reactor pressure

analysis because these valves have the lowest set pressure values among those on the corresponding quencher circles. SRV-H was chosen for the low reactor pressure analysis. Quenchers H and L have off-radial orientations of 30° and 10° in the counterclockwise direction, respectively. Discharge associated with the end gap of Quencher H is towards the containment wall, while discharge associated with the end cap of Quencher L is towards the pedestal. Figures 3A-438 and 3A-441 show these quencher configurations in the KFIXTM models.

In the KFIXTM code, the LGS suppression pool is subdivided into a large number of computational cells which is on the order of 5500. Among these computational cells, the containment walls, major submerged structures and boundaries are treated as obstruction (or fictitious) cells, the containment walls, major submerged structures, and boundaries are treated as obstruction (or fictitious) cells while the remainder are called fluid cells. The governing conservation equations are solved with respect to the fluid cells. Fluid cells which contain the quencher discharge areas are called special cells. Additional source terms are included in the conservation equations in these special cells to account for the steam blowdown precess. The source terms are derived from various operating conditions, i.e., the reactor pressure, the SRV steam flow rate, the geometrical data of the quencher, and the quencher orientation. Geometrical data of the Mark II T-quencher is provided in Section 3B.4.1.

3A.15.1.2.1.1 Initial and Operating Conditions

The initial and operating conditions pertinent to the high and low reactor pressure SORV scenarios are tabulated below:

Parameter	High Reactor Pressure Analysis	Low Reactor Pressure Analysis
Reactor vessel pressure	1025 psia	90 psia
SRV steam flow rate	239.6 lb_m/sec	21 lb_m/sec
Suppression pool initial water depth	22 ft	23 ft
Initial pool temperature	95° F	199° F
Duration of blowdown	10 minutes or longer	20 minutes or longer

The 1025 psia reactor pressure corresponds to the nominal pressure in the RPV steam dome at 105% of nuclear boiler rated steam flow. The 90 psia reactor pressure corresponds to the lowest pressure just prior to clearing the shutdown cooling pressure interlock. The SRV flow rates correspond to the nominal flow rates adjusted to the specified reactor pressures.

The high pressure analysis initial pool water depth (22 feet) corresponds to the low pool level (Figure 3A-2). The initial pool temperature (95°F) corresponds to the maximum operating temperature without suppression pool cooling.

The low pressure analysis initial pool water depth (23 feet) corresponds to the normal pool level. The normal water level was chosen in lieu of the low level to account for the additional water condensed from the incoming SRV steam during reactor depressurization to 90 psia.

The low pressure analysis initial pool temperature corresponds to the highest temperature at a reactor pressure of 90 psia. From LGS analysis of suppression pool temperature response to SRV discharge presented in Section 3A.15.2, a pool temperature of 199°F exists at 90°F and 10^4 seconds into the transient (Figure 3A-456, Case 3.a).

The blowdown durations selected for the high and low pressure SORV scenarios allow the pool temperature to reach a quasi-steady rate of increase.

In addition to the above initial and operating conditions, several conservative assumptions are made in the high and low reactor pressure analyses. For example, the water in the pedestal is neglected, no RHR operation is considered, the initial pool motion is assumed to be stagnant, and containment wall boundaries are treated adiabatically.

3A.15.1.2.1.2 Geometrical Modeling

The plan and section views of the mesh systems used in the KFIXTM model to simulate the SRV-H and SRV-L blowdown scenarios are shown in Figures 3A-438 through 3A-442. The mesh compositions associated with each scenario are summarized as follows:

Parameter	SRV-H Blowdown (High Reactor Pressure)	SRV-L Blowdown (High Reactor Pressure)	SRV-H Blowdown (Low Reactor Pressure)
Total Cell Number	11x12x39=5148	12x12x40=5760	11x12x39=5148
Grid size variation along radial direction (ΔR)	2 ft to 4.076 ft	2 ft to 3.5 ft	2 ft to 4.076 ft
Grid size variation along Circumferential direction ($\Delta\phi$)	7° to 11.5°	5.5° to 11.5°	7° to 11.5°
Grid size variation along Vertical direction (ΔZ)	2.333 ft to 2.695 ft	2.333 ft to 2.695 ft	2.333 ft to 2.841 ft

The following KFIXTM geometrical modeling aspects apply to the mesh system summarized above and shown in Figures 3A-438 through 3A-442:

- Variable grid sizes are used in the mesh systems. Note that finer mesh sizes in the vicinity of the quencher allow KFIXTM to more accurately predict the pool response in the local region.

- Because the pool normal water level (23') was used in analyzing the SRV-H scenario under the low reactor pressure condition in comparison with the minimum level (22') associated with the high pressure case, the grid sizes along the vertical direction for the low pressure case have to be slightly expanded to account for the additional one foot of water.

- The free surface at the top of the suppression pool is calculated by tracing the surface waves kinematically.

- Because the SPTMS sensors are not located at cell centers, the calculated SPTMS temperatures are interpolated or extrapolated from the temperature values defined at the neighboring cell centers in the code calculations.

- The suppression chamber columns are modeled as stacks of obstruction cells which conservatively approximate the circular cross-section of the actual columns.

- The two T-quencher arms are modeled by means of two special cells separated by an obstruction cell representing the quencher hub/assembly.

- The size of the special cells (i.e., fluid cells which contain the quencher discharge arms) are chosen to be comparable with those used in the LaSalle simulation runs for verifying the KFIXTM code (Reference 3A-54).

- A greater number of fluid cells are needed to model the SRV-L blowdown scenario than that needed for the SRV-H blowdown scenario. This is due to the fact that a better resolution with respect to the outer quenchers (e.g., Quencher L) generally requires more cells in the cylindrical coordinates (compare Figures 3A-438 and 3A-441).

- The obstruction effects of the downcomers are neglected to simplify the geometrical modeling. The downcomers have neglected obstruction effects on SPTMS sensor predictions because of their relative distance from the sensor locations.

3A.15.1.2.2 Individual SPTMS Sensor Predictions

The SPTMS sensor identifications and locations are shown in Figure 3A-437. The SPTMS sensor locations can be classified into two categories: 1) four dual element sensors mounted on columns with approximate azimuthal locations of 0°, 90°, 180°, and 270°, (i.e., TE 101/103-B, D, F, & H); and 2) four dual element sensors mounted on the containment wall with approximate azimuthal locations of 45°, 135°, 225°, and 315° (i.e., TE 101/103-A, C, E, & G).

The calculated sensor predications for each SORV blowdown scenario are shown in Figures 3A-443 through 3A-448 and are discussed in the following sections. The four temperature traces associated with each SPTMS sensor category (as defined above) are shown in the same figure. Sensor temperature traces may vary among each other because of the relative distances between the active quenchers and the various sensor locations. Only division TE 101 predictions are provided. Temperature traces of redundant Division TE 103 are not presented because they are nearly identical. Also shown on these figures is the analytical bulk pool temperature trace which provides a measure of how close the individual sensor predicts the bulk temperature. The bulk pool temperature is calculated by KFIXTM an is based on a mass-energy balance assuming that the pool is a uniform heat sink.

3A.15.1.2.2.1 SRV-H Blowdown Under High Reactor Pressure

Figures 3A-443 and 3A-444 show the KFIXTM calculated temperature time histories of the SPTMS sensors mounted on the columns and the containment wall, respectively, resulting form the SRV-H blowdown under the high reactor pressure condition.

Time delays, or response times, exist before the SPTM sensors start sensing the heat-up process in the suppression pool. These time delays result from the considerable vertical elevation difference between the sensors and the active quencher (i.e., 16.5 feet). However, within this short time delay period, the pool will experience only minor bulk heat-up. Figures 3A-443 and 3A-444 show a bulk pool heat-up on the order of $3^{O}F$ during a response time ranging from 1-1.5 minutes.

3A.15.1.2.2.2 SRV-L Blowdown Under High Reactor Pressure

Figures 3A-445 and 3A-446 show the KFIXTM calculated temperature time histories of the SPTMS sensors mounted on the columns and the containment wall, respectively, resulting form the SRV-L blowdown under the high reactor pressure condition. The response times range from about 0.5-1 minute.

3A.15.1.2.2.3 SRV-H Blowdown Under Low Reactor Pressure

Figures 3A-447 and 3A-448 show the KFIXTM calculated temperature traces of the SPTMS sensors mounted on the columns and the containment wall, respectively, resulting from the SRV-H blowdown under the low reactor pressure condition. The response times range from 1.5-3 minutes.

Note that Figures 3A-447 and 3A-448 show that the time scale (abscissa) is compressed in comparison to the high pressure cases to accommodate the longer transient (approximately 25 minutes). The temperature scale (ordinate) is stretched to suit the milder temperature variation resulting form a smaller SRV steam flow rate associated with low reactor pressure condition. Note also that the elevated pool temperature reflects the assumption of RHR system not in operation (i.e., no pool cooling or shutdown cooling) during the SORV transient analysis.

3A.15.1.2.3 Average SPTMS Sensor Prediction

The arithmetic average values of the eight traces for the three blowdown cases are presented in Figures 3A-449, 3A-450, and 3A-451. Also shown on these figures are the corresponding analytical bulk pool temperatures (based on a pool mass-energy balance) and code predicted overall average temperatures. The KFIXTM predicted overall average temperature is defined as the average of the entire set of computational fluid cells in the LGS pool model.

In principle, the predicted overall average temperature should adhere closely to the bulk pool temperature to warrant a global calculation. However, due to the accumulated errors in the numerical computation spanning a large number of computational cycles (on the order of 10,000 for the present calculations), the overall average temperature may deviate slightly from the bulk pool temperature.

Figure 3A-449 provides the average SPTMS sensor prediction resulting form SRV-H blowdown under high reactor pressure. The response time is approximately 45 seconds. The SPTMS overpredicts the bulk pool temperature by approximately $1.7^{O}F$. The bulk pool temperature and overall average temperature traces are nearly identical, reflecting the adequacy of the overall energy conservation equations in the suppression pool model.

Figure 3A-450 provides the average SPTMS sensor prediction resulting for SRV-L blowdown under high reactor pressure. The response time is about 25 seconds. The SPTMS overpredicts the bulk pool temperature by approximately 2°F. The bulk pool temperature and the overall average temperature traces are nearly identical.

Figure 3A-451 provides the average SPTMS sensor prediction resulting from SRV-H blowdown at low reactor pressure. The response time is about 60 seconds. Both the SPTMS and overall average temperature prediction diverge from and underpredict (by about 1°F) the analytical bulk pool temperature. The apparent inaccuracy in the overall average and SPTMS temperature predictions are due to inherent interpolation errors associated with the large variations in subcooled water properties at elevated pool temperatures amplified by the large number of computational cycles in the code. Regardless of these apparent inaccuracies, the fact that the SPTMS adheres closely to the overall average temperature implies that the in-plant SPTMS sensor average reading will closely follow the actual suppression pool bulk temperature.

Note that the elevated pool temperature shown in Figure 3A-451 reflects the assumption of RHR system not in operation (i.e., no pool cooling or shutdown cooling) during the SORV transient analysis.

3A.15.1.2.4 Conclusion

In light of the code results presented in the preceding sections, it can be concluded that the SPTMS sensor locations are adequate in predicting the bulk pool temperature. The temperature traces indicate that short response times exist for the heated fluid, induced by the quencher discharge at the low pool elevation to rise near the top of the suppression pool where the SPTMS sensors are located. The SPTMS sensor average conservatively overpredicts the pool bulk temperature by 1.7°F to 2°F for the high reactor pressure blowdown scenario.

For the low pressure blowdown scenario, the calculated results for the SPTMS adequately predict the calculated overall average temperature. Because the calculated overall average temperature slightly deviates from the bulk temperature by about 1°F, it is concluded that the code calculated results for the SPTMS predict the bulk pool temperature with an accuracy of 1°F for the low reactor pressure/high pool temperature scenario.

Based on the sensitivity study discussed in Section 3A.15.1.2 to ascertain the effect of lowering the sensors from the original 2' to 4'-4" below the minimum Technical Specification water level, it was concluded that the foregoing results provide an adequate representation of the SPTMS prediction capability.

The SPTMS will adequately monitor the suppression pool bulk temperature in accordance with the requirements of NUREG-0487 (Reference 3A-56) and NUREG-0783 (Reference 3A-58).

3A.15.2 SUPPRESSION POOL TEMPERATURE RESPONSE TO SRV DISCHARGE

The information presented in Section 3A.15.2 is based on the original design basis conditions. The local pool temperature limit for SRV discharge is specified in NUREG-0783 because of concerns resulting from unstable condensation observed at high pool temperatures in plants without quenchers. Reference 3A-62 provides justification for elimination of this limit for plant with quenchers on the SRV discharge lines. Because LGS has quenchers, no evaluation of this limit is necessary, as stated in Supplement 1 of Reference 3A-63. However, the limiting case presented in Section 3A.15.2 (Case 3.a) was reanalyzed at the current plant conditions using the methodology and inputs described in Section 6.2.1.8. The results of this analysis were found to be acceptable.

3A.15.2.1 Introduction

In late 1974, the NRC alerted the BWR Owners to the potential for severe vibratory loads on the containment structure due to SRV discharge at elevated suppression pool temperature (Reference 3A-55). This phenomenon, or condensation instability, was associated with certain SRV discharge device configurations and occurred above given threshold values of pool temperature and steam mass flux. While the condensation instability phenomenon described above has never been exhibited for quencher devices, even in large-scale tests where local temperatures approached saturation, the NRC (Reference 3A-56) has taken the position that a local pool temperature limit of 200°F "will provide additional conservatism and will ensure that unstable steam condensation will not occur with a quencher device" and that "applicants will have to provide plant unique analyses for pool temperature responses to transients involving SRV operations to demonstrate that the plants will operate within the limit of 200°F."

The Mark II Owners Group subsequently prepared a generic report, the "White Paper" (Reference 3A-57), which was used by the utilities, including PECo, as a guideline for plant unique analyses. In conjunction with the development of this report, the Mark II Owners Group proposed alternative suppression pool temperature limits. These alternative acceptance criteria were subsequently accepted by the NRC for plants using the generic Mark II T-Quencher design. The alternative pool temperature limits are defined in NUREG-0783 (Reference 3A-58) as follows:

a. For all plant transients involving SRV operations during which the steam flux through the quencher perforations exceeds 94 lb_m/ft^2-sec, the suppression pool local temperature shall not exceed 200°F.

b. For all plant transients involving SRV operations during which steam flux through the quencher perforations is less than 42 lb_m/ft^2-sec, the suppression pool local temperature shall be at least 20°F subcooled. This is equivalent to a local temperature of 210°F with quencher submergence of 14 feet.

c. For plant transients involving SRV operations during which the steam flux through the quencher perforations exceeds 42 lb_m/ft^2-sec but is less than 94 lb_m/ft^2-sec, the suppression pool local temperature can be established by linearly interpolating the local temperatures established under items a and b above.

The following presentation of the suppression pool temperature analysis for LGS conforms with NUREG-0783 in terms of the pool temperature limit acceptance criteria, assumptions, and pool heatup events required for analysis.

3A.15.2.2 Events for the Analysis of Pool Temperature Transients

The following events have been analyzed on the basis of mass and energy balance on the suppression pool during SRV blowdown. The results of the pool temperature transients demonstrate the history of the pool bulk temperature of for all the events analyzed. Assumptions for the events are discussed in Section 3A.15.2.3. The associated peak pool temperatures calculated for each event are summarized in Table 3A-30.

3A.15.2.2.1 Event 1: Stuck Open SRV at Power Operation

SORV at power cases are analyzed to demonstrate that the spurious opening of an SRV during normal power operation will not result in high pool temperatures.

Two cases of SORV at power are considered separately:

Case 1.a: Single failure of one RHR heat exchanger

Case 1.b: Initiation of the MSIV closure signal at the time of scram and subsequent unavailability of main condenser.

3A.15.2.2.2 Event 2: SRV Discharge Following Isolation/Scram

Isolation/scram cases are analyzed to demonstrate that the loss of the main condenser by the sudden closure of the MSIVs and subsequent scram, SRV openings at set pressure, and manual depressurization will not result in high pool temperature.

Two single failures are considered separately:

Case 2.a: Single failure of one RHR heat exchanger

Case 2.b: Failure of an SRV to reclose (SORV)
(Note: Case 2.b is not required by NUREG-0783 but is presented to maintain consistency with the "White Paper: cases.)

3A.15.2.2.3 Event 3: SRV Discharge Following a Small Break Accident

SBA cases are analyzed to demonstrate that SRV discharge required to depressurize the reactor coolant system following a small break will not result in high pool temperatures. As a result of continued flow through the break, peak pool temperature is not reached until after SRV discharge has terminated.

Two cases of SBA are considered separately:

Case 3.a: Single failure of one RHR heat exchanger

Case 3.b: Loss of shutdown cooling
(Note: Case 3.b is not required by NUREG-0783 but is presented to maintain consistency with the "White Paper" cases.)

3A.15.2.3 Assumptions Used in the Analysis

3A.15.2.3.1 General Assumptions

The following general assumptions and initial conditions have been used for all transients. Table 3A-29 summarizes the values for important system characteristics and input parameters listed below.

a. Power level, decay heat standard, RHR heat exchanger capability (considering design fouling factors), and suppression pool initial temperature (maximum Technical Specification temperature of continuous power operation without pool cooling) are consistent with those used for the analysis of containment pressure and temperature response to a LOCA.

b. The service water temperature is characterized as a transient starting at 88°F (Technical Specification limit for average spray pond temperature).

c. The initial water level of the suppression pool is at the minimum level in the Technical Specifications.

d. MSIV closure is complete 3.5 seconds after the isolation signal (t=0) for transients where isolation occurs.

e. The water volume within the reactor vessel pedestal is not included in the calculation of pool temperature response.

f. To maximize heat addition to the pool, feedwater at the temperature in excess of instantaneous pool temperature is assumed to maintain RPV level rather than CST inventory via RCIC and HPCI. Feedwater injection is terminated when additional feedwater will ultimately result in cooling the pool. (Note: This requirement is more conservative than the NUREG-0783 assumption that "feedwater pumps supply feedwater to the reactor until the feed pumps trip on an automatic signal.") HPCI (From the suppression pool) and CRD (from the CST) systems provide vessel makeup after all the hot feedwater is expended. CRD flow was used for all cases except SBA with one RHR.

g. Offsite power is not available for isolation/scram and SBA events or where MSIV closure is assumed, except SBA Case 3.b Offsite power is available for Case 3.b; however, Case 3.b is conservative due to the conservatism associated with feedwater addition (see assumption "f" above) and the unavailability of the main condenser. Also, Case 3.b is not the controlling event for calculation of peak pool temperature (Table 3A-30).

h. HPCI system is terminated at or before a pool temperature of 170°F.

i. A single electrical division failure may result in the unavailability of RHR shutdown cooling and one loop of RHR pool cooling. The assessment of this single failure assumption on suppression pool temperature response to SRV discharge is provided in Section 3A.15.2.3.2.3.1.

j. The calculation of mass and energy release to the suppression pool due to SRV discharge follows the methodology described in Reference 3A-59.

k. There are no heat losses to the containment atmosphere and structures.

l. The RHR operates in the suppression pool cooling mode 10 minutes after the high pool temperature alarm (95°F).

m. All transients involving one RHR heat exchanger operation assume a minimum controlled depressurization rate and employ a rapid transfer (16 minutes, without flush) from pool cooling to shutdown cooling using the available RHR heat exchanger when the reactor pressure reaches the permissive value (89.7 psia). Shutdown cooling is not used in the analyses for those transients having both RHR trains available.

n. In accordance with the LGS Technical Specifications, manual depressurization at a rate of 100°F/hour begins at a pool temperature of 120°F unless the depressurization rate for the event itself (e.g., SORV, SBA) exceeds the required rate at that time. Manual depressurization is terminated upon initiation of shutdown cooling.

o. SRV flow rate = 122.5% of ASME rated.

3A.15.2.3.2 Assumptions for Specific Events

This section describes the specific assumptions used for the events described in Section 3A.15.2.2. Operator actions are also described for justification of the assumptions.

3A.15.2.3.2.1 Event 1: SORV at Power

This initiating event postulates that an SRV is inadvertently actuated while the plant is operating at power. Following actuation, the SRV fails to reseat and remains open throughout the transient. As a result of this malfunction, steam from the primary systems is discharged through the SRV and released to the suppression pool.

Two independent systems will generate alarms and displays in the control room so as to give the operator immediate and unambiguous indications of an SORV. First, the SRVPI system (Section 7.6.1.5.1) provides positive indication and alarm of SRV position through the use of acoustic sensors (two per valve) which detect noise generated by steam flow through an open SRV. Secondly, the SPTMS will indicate a rise in the suppression pool temperature and alert the operator to initiate corrective action. A control room alarm is generated when the average pool temperature increases to 95°F, 105°F, 110°F, and 120°F. Further details of the SPTMS are provided in Section 3A.15.1.

In accordance with the EOPs, the operator will manually scram the reactor prior to suppression pool temperature reaching 110°F by turning the mode switch to "shutdown" if the SRV cannot be reclosed immediately.

For analysis purposes, it is conservatively assumed that manual scram does not occur until the Technical Specification limit on pool temperature for power operation is reached (110°F).

Case 1.a: Single Failure - One RHR Heat Exchanger Unavailable

- Manual scram at pool temperature = 110°F.
- Offsite power is available.
- One RHR system is placed in pool cooling mode 10 minutes after the SORV.
- The MSIVs remain open because the mode switch has been taken out of the "run" position.
- Following scram, the reactor steam generation will decrease so that the TCV will mechanistically close as the RPV pressure drops, thus isolating the turbine from the reactor. The turbine bypass valves are also mechanistically closed. The SJAE will continue to maintain vacuum in the main condenser.
- The operator manually depressurizes the reactor by reestablishing the main condenser as a heat sink through the main turbine bypass system. It is assumed that the operator will manually open the turbine bypass valve 20 minutes after scram.
- The main condenser is available using full bypass capacity until the reactor vessel pressure permissive for RHR shutdown cooling is reached (89.7 psia).

- RHR out of pool cooling when pressure permissive for RHR shutdown cooling is reached; 16 minute delay for RHR transfer to shutdown cooling.

Case 1.b: Single Failure - Spurious Main Steam Line Isolation at Scram

- Manual scram at pool temperature - 110°F
- Nonmechanistic main steam line isolation occurs at scram (t = 0)
- LOOP
- Two RHR systems are placed in the pool cooling mode 10 minutes after the SORV.
- When the pool temperature = 120°F, the operator begins manual depressurization to maintain 100°F/hour cooldown rate by opening additional SRVs as needed.
- RHR shutdown cooling is not initiated.

3A.15.2.3.2.2 Event 2: SRV Discharge Following Isolation/Scram

Case 2.a: Single Failure - One RHR Heat Exchanger Unavailable

- Nonmechanistic main steam line isolation and automatic scram at t=0
- LOOP
- One RHR system placed in pool cooling mode 10 minutes after the event.
- When the pool temperature = 120°F, the operator begins manual depressurization at a rate of 100°F/hour by opening SRVs as needed.
- RHR out of pool cooling when pressure permissive for RHR shutdown cooling is reached; 16 minute delay for RHR transfer to shutdown cooling.

Case 2.b: Single Failure - SORV

- Nonmechanistic main steam line isolation and automatic scram at t=0.
- SORV occurs at t=0
- LOOP
- Two RHR systems are placed in the pool cooling mode 10 minutes after the event.
- When the pool temperature = 120°F, the operator begins manual depressurization to maintain 100°F/hour cooldown rate by opening additional SRVs as needed.
- RHR shutdown cooling is not initiated.

3A.15.2.3.2.3 Event 3: SRV Discharge Following SBA

Case 3.a: Single Failure - One RHR Heat Exchanger Unavailable

- Automatic scram on high drywell pressure at t=0.
- Nonmechanistic main steam line isolation at t=0.
- LOOP
- One RHR system is placed in the pool cooling mode 10 minutes after event.
- When the pool temperature = 120°F, the operator begins manual depressurization at a rate of 100°F/hour by opening SRVs as needed.
- Automatic RHR switch-over to the LPCI system mode on LPCI initiation signal. (LPCI signal occurs at (a) low reactor level or (b) high drywell pressure combined with low reactor pressure.) The operator manually converts back to the pool cooling mode in 10 minutes.
- RHR out of pool cooling when pressure permissive for RHR shutdown cooling is reached; 16 minute delay for RHR transfer to shutdown cooling.

Case 3.b: Single Failure - Shutdown Cooling Unavailable

- Automatic scram on high drywell pressure at t=0.
- Nonmechanistic main steam line isolation at t=0.
- Offsite power is available.
- Two RHR systems are placed in the pool cooling mode 10 minutes after event.
- When the pool temperature = 120°F, the operator begins manual depressurization at a rate of 100°F/hour by opening SRVs as needed.
- Automatic RHR switch-over to the LPCI system mode on LPCI initiation signal. The operator manually converts back to the pool cooling mode in 10 minutes.
- RHR shutdown cooling is not initiated. The operator will ultimately reach cold shutdown by establishing the alternate shutdown cooling path as outlined in Section 15.2.9.

3A.15.2.3.2.3.1 SRV Discharge Following SBA: Single Electrical Division Failure

In response to NUREG-0783, sections 5.7.1(8) and 5.7.2.3(2), LGS has evaluated the effect of a most limiting single failure on the suppression pool peak temperature. It was concluded that a worst case single failure of an electrical division power source may result in the unavailability of RHR shutdown cooling and one loop of RHR pool cooling. However, the peak pool temperature resulting from this single failure will be bounded by the peak temperature calculated for limiting SBA Case 3.a when taking credit for manual operator action to regain the lost loop of pool cooling.

Approximately 2½ hours are available to the operator for manual realignment of affected valves to obtain additional pool cooling capability from the second RHR heat exchanger. This available time

is conservatively derived from the pressure-temperature time history for comparable Case 3.a (Figure 3A-456). Limiting Case 3.a is similar to the single electrical division failure case because only one loop of RHR pool cooling is available during the depressurization phase of the event.

The time is based on the conservative assumption that LOOP (and subsequent operator awareness of loss of both RHR shutdown cooling and one loop of pool cooling) occurs at a pool temperature of 120°F (Technical Specification limit for manual depressurization). From Figure 3A-456 (Case 3.a), the pool temperature reaches 120°F at approximately 1000 seconds. The time available for manual operator action after t=1000 seconds without the pool exceeding the peak calculated temperature is limited to the same point in time in Case 3.a where shutdown cooling was initiated (89.7 psia), i.e, approximately 10,000 seconds. Therefore, the total time available based on limiting Case 3.a is approximately 9,000 seconds or 2½ hours.

A study of required manual operator actions has concluded that a second RHR heat exchanger could be available in the pool cooling mode in less than 2½ hours (the time when Case 3.a peak pool temperature is reached). The pool temperature will decrease following the initiation of the second RHR loop in the pool cooling mode because the heat removal rate of both RHR exchangers will exceed the heat addition rate to the pool at this time in the
event.

Because the RHR shutdown cooling mode is not initiated, the operator will ultimately reach cold shutdown by establishing the alternative shutdown cooling path as outlined in Section 15.2.9. The heat addition rate to the pool resulting from this alternate path of shutdown cooling will be controlled to preclude the possibility of additional pool heatup.

If manual operator actions are required in case of a worst case single electrical division failure, the plant operator could actually reduce the blowdown rate to extend the time before the peak pool temperature is reached. This scenario allows additional time for operator actions and would result in a peak pool temperature which is lower than Case 3.a.

3A.15.2.4 Analysis Results and Conclusions

Table 3A-30 lists the peak bulk suppression pool temperatures that were calculated using the GE computer code HEX for the scenarios described in Sections 3A.15.2.2 and 3A.15.2.3. Figures 3A-452 through 3A-457 provide plots of the suppression pool temperature and the respective reactor pressure versus time.

As stated earlier, the pool temperatures summarized in Table 3A-30 represent "bulk" temperatures, i.e., they were calculated assuming a homogeneously mixed suppression pool. In reality, pool mixing will not be perfect and differences will exist between the "local" temperature of the water in the immediate vicinity of the quencher and the calculated "bulk" temperature. However, because of the special design features of quenchers and their predominantly radial orientation in the suppression pool to optimize pool thermal mixing (Figure 3A-3), the local-to-bulk ΔT is expected to be small and not exceed the value that was previously derived for ramshead discharge devices in Mark I plants (10°F, Reference 3A-56). This number has been verified to be conservative for LGS using in-plant tests and analysis (Section 3A.15.3).

The suppression pool temperature limits defined in NUREG-0783 and listed in Section 3A.15.2.1 are specified in terms of "local" pool temperature and quencher mass flux criteria. Because Figures 3A-452 through 3A-457 specify the LGS time histories in terms of "bulk" pool temperature and reactor pressure, it is necessary to convert the NUREG-0783 local pool temperature limit criteria to

bulk pool temperature and reactor pressure criteria. Applying a local-to-bulk ΔT of 10°F as described above and calculating the LGS reactor pressures corresponding to steam fluxes of 42 lb_m/ft^2 sec and 94 lb_m/ft^2 sec, respectively, a bulk suppression pool temperature limit curve is developed. These curves are shown on Figures 3A-452 through 3A-457 and demonstrate that the LGS suppression pool temperatures due to SRV discharge comply with the temperature limits defined in NUREG-0783.

3A.15.3 SUPPRESSION POOL LOCAL-TO-BULK TEMPERATURE DIFFERENCE ADEQUACY ASSESSMENT

3A.15.3.1 Introduction

NUREG-0783 (Reference 3A-58) defines the suppression pool temperature limits for steam discharges through the Mark II T-quenchers (e.g., those used in the LGS suppression pool). These limits stem from the NRC's concern that, for certain combinations of pool temperatures and quencher mass fluxes, the steam condensation in the vicinity of the quencher exit may lead to higher vibratory loads on the submerged structures within the suppression pool. These pool temperature limits depend on the quencher steam mass flux and the saturation temperature at the quencher centerline submergence. The NUREG-0783 local pool temperature limits are expressed in terms of a local pool temperature. According to NUREG-0783, the local pool temperature is defined as the average water temperature in the vicinity of the quencher discharge device and represents the relevant temperature which controls the condensation process occurring at the quencher exit.

To confirm that LGS will not exceed the pool temperature limits stipulated in NUREG-0783 for all design basis scenarios which involve T-quencher operation, the LGS mass and energy analysis has been performed as reported in Section 3A.15.2. The analysis calculates a bulk pool temperature, defined as the pool temperature obtained by an energy balance on the pool assuming the pool acts as a uniform heat sink (i.e., no thermal stratification).

If ideal pool mixing would occur during steam discharges through the quenchers, the bulk temperature calculated by the mass and energy analysis would become the local pool temperature, and could be used directly to confirm that the LGS suppression pool will not exceed the NUREG-0783 temperature limits. In reality, thermal stratification occurs in the suppression pool, resulting in higher values of local pool temperature in comparison with the bulk pool temperature. The difference between these two temperatures in the local-to-bulk pool temperature difference (ΔT). Therefore, once the LGS unique local-to-bulk ΔT is determined, it can be used with the results of the mass and energy analysis (Section 3A.15.2) to confirm that the LGS suppression pool conforms to the local pool temperature criteria provided in NUREG-0783.

In conjunction with the SPTMS adequacy assessment provided in Section 3A.15.1.2, the KFIXTM code is used to calculate the local-to-bulk ΔT in the LGS suppression pool for the SORV blowdown scenarios described in Section 3A.15.1.2.1. Sections 3A.15.1.2.1.1 and 3A.15.1.2.1.2. provide the initial/operating conditions and KFIXTM geometrical models associated with these scenarios, respectively. Summarizing, these scenarios consist of two single SORV blowdowns under the high reactor pressure condition (SRV-H and SRV-L) and one single SORV blowdown under the low reactor pressure condition (SRV-H).

The two conditions of high and low reactor pressures correspond to the early and late stages of the SORV transient, respectively. The magnitude of the local-to-bulk ΔT gains significance at the later stages of the transient due to the smaller margin between the elevated bulk pool temperature and NUREG-0783 pool temperature limits. The results from the KFIXTM analysis, to be delineated in

the following sections, indicate that the low reactor pressure analysis yields a lower local-to-bulk ΔT than that associated with the high pressure analysis.

NUREG-0783 provides a specific definition of local pool temperature stated as follows:

> "To define the local pool temperature, a qualitative picture of the flow pattern during quencher discharge can be evolved by a combination of physical reasoning and experimental evidence...., it is apparent that the temperature which controls the condensation process (that is, the "local" temperature) is best characterized by that which would occur at a point directly above and below the quencher arms (perhaps one or two arms diameters distant), with the former providing a more conservative measure of this parameter."

Based on this definition, the local pool temperature can be calculated for both the high and low reactor pressure cases by mass averaging the temperature traces from the four fluid cells located directly above and below the two special cells representing the quencher arms. From Figures 3A-439, 3A-440, and 3A-442, the distances from the centers of these four cells to the centerline of the quencher arm varies from 2.333' to 2.47', or approximately twice the quencher arm diameter. The distances from the centers of these four cells to the top or bottom surface of the quencher arm is about 1½ times the quencher arm diameter. Thus, the methodology for calculating the local temperature conforms to the NUREG-0783 criteria.

Sections 3A.15.3.2, 3A.15.3.3, and 3A.15.3.4 discuss the KFIXTM calculated local and bulk pool temperature traces and corresponding local-to-bulk ΔTs for the SORV scenarios. Concluding remarks regarding the LGS local pool temperature and the related NUREG-0783 pool temperature limits are presented in Section 3A.15.3.5.

3A.15.3.2 SRV-H Blowdown Under High Reactor Pressure

Figure 3A-458 shows that the quasi steady-state local-to-bulk ΔT is about 8.6°F for SRV-H blowdown under high reactor pressure. The calculation of the local temperature is described in Section 3A.15.3.1. The bulk pool temperature is calculated by KFIXTM and is based on a mass-energy balance assuming that the pool is a uniform heat sink.

3A.15.3.3 SRV-L Blowdown Under High Reactor Pressure

Figure 3A-459 illustrates that the predicted local pool temperature follows the bulk pool temperature closely for SRV-L blowdown under high reactor pressure (i.e., local-to-bulk ΔT is minimal). The favorable thermal mixing characteristics associated with this analysis result from the combination of the quencher location (outer ring) and its orientation.

3A.15.3.4 SRV-H Blowdown Under Low Reactor Pressure

Section 3A.15.3.2 shows that a peak local-to-bulk ΔT of approximately 8.6°F is calculated for the high reactor pressure and relatively low pool temperature conditions. At this time in the transient, the steam flux through the active quencher is greater than 94 lb_m/ft^2 sec. As discussed in Section 3A.15.2.1, the NUREG-0783 local pool temperature limit at this flux is 200°F. Because the bulk pool temperature is much lower than 200°F at high reactor pressures (Figures 3A-452 through 3A-457), the local-to-bulk ΔT is relatively unimportant at these conditions.

As the reactor depressurizes and SRV flow rate decreases, the momentum transfer to the pool (i.e., pool mixing) decreases. The bulk pool temperature continues to increase and the local-to-bulk ΔT

gains significance. Therefore, the KFIXTM code is used to quantify the local-to-bulk ΔT calculated earlier is conservative with respect to the low reactor pressure ΔT.

Figure 3A-460 shows the bulk temperature trace along with the code predicted local temperature trace and overall average temperature trace (of all fluid cells) for SRV-H blowdown under low reactor pressure. The slight deviations between the bulk pool temperature and the KFIXTM predicted overall average temperature are due to the minor inaccuracies of KFIXTM temperature predications under low reactor pressure and elevated pool temperature conditions (Section 3A.15.1.2.3). Regardless of the apparent inaccuracy, the local pool temperature adheres closely to the overall average temperature and the local-to-bulk ΔT for the low pressure scenario is both minimal and bounded by the ΔT for the high pressure scenario.

3A.15.3.5 Conclusion

The local pool temperature limits stipulated in NUREG-0783 have been restated in Section 3A.15.2.1. Figures 3A-452 to 3A-457 plot these pool temperature limits relative to the bulk temperature time histories for the six mass and energy cases described in Section 3A.15.2.2. The local temperature limits have been converted to bulk limits by applying a local-to-bulk ΔT equal to 10°F. A local-to-bulk ΔT of 10°F was previously derived for ramshead discharge devices in Mark I plants (Reference 3A-56). Figures 3A-452 to 3A-457 indicate that adequate margin exists between the NUREG-0783 local limits (converted to bulk limits by 10°F ΔT) and the calculated bulk temperatures from the mass and energy analyses. The minimum margin occurs for Case 3.a near the end of the transient at low reactor pressure when the maximum bulk temperature peaks at 202°F (Figure 3A-456).

The peak calculated local-to-bulk ΔT has been established to be 8.6°F for SRV-H blowdown under high reactor pressure (Section 3A.15.3.2) and is adequately bounded by 10°F ΔT. In addition, the results of the low reactor pressure analysis (Section 3A.15.3.4) confirm that the low reactor pressure ΔT is much lower than the high pressure ΔT. Therefore, LGS has demonstrated that the NUREG-0783 maximum local pool temperature specification will not be exceeded.

3A.16 WETWELL-TO-DRYWELL VACUUM BREAKER AND DOWNCOMER CAPPING ADEQUACY ASSESSMENT

3A.16.1 INTRODUCTION

In April 1981, the ACRS expressed concern regarding the potential pool bypass from a stuck open wetwell-to-drywell vacuum breaker. This concern stems from the fact that following the onset of a LOCA about 20 seconds into the transient, the chugging phenomenon takes place. This rapid steam condensation will cause repeated and strong dynamic under and overpressure conditions in the downcomer. As a result of this pressure variation, the vacuum breaker attached to the downcomer may open.

Because chugging is a repetitive phenomenon, the vacuum breaker may be called on to function in a cyclic manner during these intermittent steam condensation events. These potential opening and closing impact loads could exceed the original design basis of the vacuum breakers. Failure of a vacuum breaker to close during this time could result in steam bypass of the suppression pool and subsequent pressurization of the wetwell air space, thus jeopardizing the integrity of the containment.

In July 1981, the NRC staff was informed that the Mark II owners who have vacuum breakers attached to the downcomer were conducting a joint qualification test program to demonstrate the

operability of the vacuum breaker under this intermittent steam condensation loading. The Mark II owners also identified the potential adverse effect of pool-swell on the performance of vacuum breakers. Because the wetwell air space will pressurize during the pool-swell event, the resulting differential pressure will cause the vacuum breaker to cycle open and then cycle closed when he pool falls back to the normal water level. The potential opening and closing impact load could exceed the potential opening and closing impact load could exceed the original design basis of the vacuum breakers.

3A.16.2 DESIGN ASSESSMENT

3A.16.2.1 Vacuum Breaker Cycling During Pool-Swell

To qualify the LGS vacuum breakers to withstand the dynamic effects of pool-swell, design modifications to the vacuum breakers have been implemented based on results from the Anderson Greenwood Company vacuum breaker test program. The modifications and test program results have been transmitted to the NRC (References 3A-60 and 3A-61).

3A.16.2.2 Vacuum Breaker Cycling During Chugging

To qualify the LGS vacuum breakers to withstand the dynamic effects of chugging, the four downcomers on which the wetwell-to-drywell vacuum breakers are counted have been capped. Capping the downcomers will eliminate the dynamic under and overpressures caused by the sudden steam condensation at the downcomer exit and eliminate the vacuum breaker cyclic actuation due to chugging phenomena. The locations of these capped downcomers are shown in Figure 3A-461.

3A.16.2.2.1 Downcomer Capping Design Assessment

3A.16.2.2.1.1 Downcomer Modifications

Figure 3A-462 shows a configuration of a modified downcomer with vacuum breaker (typical of four). The modifications include installation of a cap, a 3 inch drain line, and a 1 inch weir at the drywell entrance of the downcomer.

The capping design incorporates a 3 inch Schedule 160 drain line. Water motion in the 3 inch drain line has been modeled. As a result of this work, the drain has been extended 9'-7¾" above the downcomer exit plane. This extended length will prevent water from streaming into the downcomer during the rapid drywell depressurization caused by the gross chugging at the downcomer exits. In addition, to prevent water from exiting the drain line during the chugging/CO phase of a LOCA, the drain line is extended 4 feet below the downcomer exit plane. Therefore, potential chugging/CO dynamic loading phenomena at the drain exit are precluded.

The addition of a 1 inch weir at the drywell entrance of each capped downcomer is designed to limit the maximum ECCS flow into these downcomers during the recirculation mode after a LOCA. The 3 inch drain line is capable of passing this limited flow of ECCS water while preventing the downcomers from being filled to the vacuum breaker elevation.

3A.16.2.2.1.2 Containment Evaluation

Capping 4 out of 87 downcomers requires an evaluation to determine its effect on the containment design basis LOCA loading conditions and safety margins. To resolve this concern, Bechtel's computer program COPDA was used to evaluate the drywell conditions based on 83 and 87 downcomers, respectively. The results indicate that there is no significant change in either drywell

pressure and temperature or steam blowdown rate through the downcomers for the capped and uncapped situations.

Based on this analysis, capping 4 out of 87 downcomers will have no adverse effects on the LGS containment safety margins resulting from design basis LOCA loads, as defined in Section 3A.4.2, including pool-swell loads, containment functional pressure, submerged structure loads, boundary loads, and asymmetric effects.

Table 3A-2

COMPARISON OF LGS LICENSING BASIS WITH NRC ACCEPTANCE CRITERIA

Load or Phenomenon	NRC Acceptance Criteria	Criteria Source	LGS Position
I. LOCA-Related Hydrodynamic Loads			
A. Submerged Boundary Loads During Vent Clearing	24 psi overpressure added to local hydrostatic pressure below vent exit (walls and basemat) – linear attenuation to pool surface	NUREG-0487 Supplement 1	Acceptable
B. Pool-swell Loads			
1. Pool-swell Analytical Model			
a. Air Bubble Pressure	Calculated by the pool swell analytical model (PSAM) used in calculation of submerged boundary loads.	NUREG-0487	Acceptable
b. Pool-swell Elevation	Use PSAM with polytropic exponent of 1.2 to a maximum swell height which is the greater of 1.5x vent submergence or the corresponding to the drywell floor uplift ΔP = 2.5 psid.	NUREG-0808	Acceptable. Used NUREG-0487, Supplement 1

Table 3A-2 (Cont'd)

Load or Phenomenon	NRC Acceptance Criteria	Criteria Source	LGS Position
c. Pool-swell Velocity	Velocity history vs. pool elevation predicted by the PSAM used to compute impact loading on small structures and drag on gratings between initial pool surface and maximum pool elevation and steady-state drag between vent wxit and maximum pool elevation. Analytical velocity variation is used up to maximum velocity. Maximum velocity applies thereafter up to maximum pool-swell. PSAM predicted velocities multiplied by a factor of 1.1.	NUREG-0808	Acceptable. Used NUREG-0487. PSAM calculated velocity without 1.1 multiplier However multiplied by 1.1 when used in force code.
d. Pool-swell Acceleration	Acceleration predicted by the PSAM. Pool acceleration is used in the calculation of acceleration loads on submerged components during pool-swell.	NUREG-0487	Acceptable
e. Wetwell Air Compression	Wetwell air compression is calculated by PSAM consistent with maximum pool-swell elevation calculated in B.1.b above.	NUREG-0487 Supplement 1	Acceptable. Maximum pool-swell elevation calculated in accordance with NUREG-0487, Supplement 1.
f. Drywell Pressure	Methods of NEDM-10320 and NEDO-20533 Appendix B. Used in PSAM to calculate pool-swell loads.	NUREG-0487	Acceptable.

Table 3A-2 (Cont'd)

Load or Phenomenon	NRC Acceptance Criteria	Criteria Source	LGS Position
2. Loads on Submerged Boundaries	Maximum bubble pressure predicted by the PSAM added uniformly to local hydrostatic pressure below vent exit (walls and basemat) – linear attenuation to pool surface. Applied to walls up to maximum pool-swell elevation.	NUREG-0487	Acceptable
3. Impact Loads			
a. Small Structures	1.35 x Pressure-Velocity correlation for pipes and I-beams based on PSTF impulse data and flat pool assumption. Variable pulse duration.	NUREG-0808	Acceptable
b. .Large Structures	None – Plant unique laod where applicable.	NUREG-0487	Not Applicable. No large structures.
c. Grating	Pool-swell drag vs. grating area correlation and pool velocity vs. elevation. Pool velocity from the PSAM. Pool-swell drag multiplied by dynamic laod factor.	NUREG-0808	Acceptable
4. Wetwell Air Compression			
a. Wall Loads	Direct application of the PSAM calculated pressure due to wetwell compression.	NUREG-0487	Acceptable

Table 3A-2 (Cont'd)

Load or Phenomenon	NRC Acceptance Criteria	Criteria Source	LGS Position
b. Diaphragm Upward Loads	5.5 psid diaphragm loadings only.	NREG-0808	Acceptable. Calculated diaphragm uplift ΔP = 10.6 psid (Figures 3A-6 and 3A-7) Design diaphragm uplift ΔP = 20 psid.
5. Asymetric LOCA Pool	Use 20 percent of maximum bubble pressure statiscally applied to ½ of the submerged boundary.	NUREG-0808	Acceptable
C. Steam Condensation and Chugging Loads			
1. Downcomer Lateral Loads			
a. Single Vent Loads (24 in.)	Dynamic load to end of vent. Half sine wave with a duration of 3-6 ms and corresponding maximum amplitudes of 65-10 k-lb_f.	NUREG-0808	Acceptable
b. Multiple Vent Loads (24 in.)	Prescribed variation of load per vent vs. number of vents. Determined from single vent dynamic load specification and multivent reduction factor.	NUREG-0808	Acceptable
c. Single/Mulitple vent loads (28 in)	Multiply basic vent loads by factor f = 1.34	NUREG-0808	Not Acceptable

Table 3A-2 (Cont'd)

Load or Phenomenon	NRC Acceptance Criteria	Criteria Source	LGS Position
2. Submerged Boundary Loads			
a. High/Medium Steam Flux Condensation Oscillaiton Load	Bounding CO pressure histories observed in 4TCO tests. In-phase application.	NUREG-0808	Acceptable
b. Low Steam Flux Chugging Load	Conservative set of 10 sources derived from 4TCO tests. Applied to plants using the IEWGS/MAPS acoustic model. Source desynchronization of 50 ms or alternate load using 7 sources derived from 4TCO key chugs without averaging.	NUREG-0808	Acceptable
- Symmetric Load	All vents use source of equal strength for each of the sources.		
- Asymmetric Load Case	Source strengths $S\pm = S(1\pm\alpha)$ applied to all vents on + and – side of containment. Sources based on the symmetric sources. Asymmetric parameter α based on rms moment method of interpreting experimental 4TCO single vent and JAERI multivent data.		

Table 3A-2 (Cont'd)

Load or Phenomenon	NRC Acceptance Criteria	Criteria Source	LGS Position
II. SRW Related Hydrodynamic Loads			
A. Pool Temperature Limits	For plants using a discharge device with the exact hole pattern as described in the SSES DAR Section 4.1, the following limits shall apply:	NUREG-0783	
	1. For all plant transients involving SRV operations during which steam flux exceeds 94 lb_m/ft^2-sec, the local pool temperature shall not exceed 200°F.	NUREG-0783	Acceptable
	2. For all plant transients involving SRV operations during which steam flux is less than 42 lb_m/ft^2-sec, the local pool temperature shall be at least 20°F subcooled. This is equivalent to a temperature of 210°F with quencher submergence of 14 feet.	NUREG-0783	Acceptable

Table 3A-2 (Cont'd)

Load or Phenomenon	NRC Acceptance Criteria	Criteria Source	LGS Position
	3. For all plant transients involving SRV operations during which steam flux is between 42 lb_m/ft^2-sec and 94 lb_m/ft^2-sec, the local pool temperature can be determined by linear interpolation between the temperatures defined in items 1 and 2 above.	NUREG-0783	Acceptable
B. Evaluation of Air Cleaning Load Definition Procedures	The T-quencher load specification described in section 4.1 of the SSES DAR may be applied for evaluation of SRV containment boundary pressure loads with the following restrictions:	NUREG-0802	Acceptable
	1. All valves load case The DLV and DLWL combinations must lie below the limit line of figure A.1 defined in the criteria where: a. DLV shall be equal to the arithmetic average of all discharge line volumes (m^3)	NUREG-0802	Acceptable

Table 3A-2 (Cont'd)

Load or Phenomenon	NRC Acceptance Criteria	Criteria Source	LGS Position
	b. DLW shall be equal to the quencher submergence at high water level (m).		
	2. ADS Load Case The DLV and DLWL combinations must lie below the limit line of figure A.2 defined in the criteria where: a. DLV shall be equal to the arithmetic average of all ADS discharge line volumes (m^3) b. DLWL shall be equal to the differences between the plant downcomer exit elevation and the quencher center line elevation (m)	NUREG-0802	Acceptable
	3. Frequency Range For the single valve and asymmetric load cases, the time-wise compression of the design pressure signatures shall be increased to provide an overall dominant frequency range that extends to 11 Hz.	NUREG-0802	Acceptable (Section 3B.4.1.4.1)

Table 3A-2 (Cont'd)

Load or Phenomenon	NRC Acceptance Criteria	Criteria Source	LGS Position
	4. Vertical Pressure Distribution The maximum pressure amplitudes shall be applied uniformly to the containment and pedestal walls up to an el 2.5' above the quencher centerline followed by linear attenuation to zero at pool surface.	NUREG-0802	Acceptable
C. T-Quencher Tie-Down Loads	The T-Quencher load specification described in SSES DAR section 4.1.2, as interpreted in sections 2.2.3 and 2.3.3 of NUREG-0802, may be applied for evaluation of quencher and quencher support.	NUREG-0802	Acceptable
D. SRV Boundary Loads	The acceptance criteria specified in NUREG-0802. Appendix A (A.1.1 through A.1.7), are recommended for plants following the "alternate" load methodology (i.e., T-Quencher load specification described in SSES DAR section 4.1)	NUREG-0802	Acceptable Section 3B.4.1.1.1 demonstrates the acceptability of using the SSES SRV load specification for LGS.

Table 3A-2 (Cont'd)

Load or Phenomenon	NRC Acceptance Criteria	Criteria Source	LGS Position
III. LOCA/SRV Submerged Structure Loads			
A. LOCA Downcomer Jet Load	Alternate methodology presented in Zimmer DAR may be applied.	NUREG-0487 Supplement 1	Acceptable
B. SRV T-Quencher Jet	SRV T-quencher jet loads may be neglected betond a 5 ft cylindrical zone of influence. Cyliner should be extended 10 hole diameters on the arm with holes in the end cap.	NUREG-0487	Acceptable
C. LOCA Air Bubble Drag Loads	Calculate based on methods described in NEDE-21471 subject to the following constraints and modifications:	NUREG-0487	Applying plant unique methodology defined in Section 3A.4.2.1.5
	1. To account for bubble asymmetry, accelerations and velocities shall be increased 10 %.	NUREG-0487	Acceptable
	2. For standard drag in accelerating flow fields, use draft coefficients presented in Zimmer FSAR Attachement 1.k with following modifications:	NUREG-0487 Supplement 1	Acceptable

Table 3A-2 (Cont'd)

Load or Phenomenon	NRC Acceptance Criteria	Criteria Source	LGS Position
	a. Use $C_H = C_m^{-1}$ in the F_A formula b. For noncylindrical structures, use lift coefficient for appropriate shape or $C_L = 1.6$ c. The standard drag coefficient for pool-swell and SRV oscillating bubbles should be based on data for structures with sharp edges.		
	3. For equivalent uniform flow velocity and acceleration calculations, structures are segmented into small sections such that $1.0 \leq L/D \leq 1.5$. The loads are then applied to the geometric center of each segment. This approach, as presented in Zimmer FSAR Attachment 1.k. may be applied.	NUREG-0487 Supplement 1	Acceptable
	4. A detailed methodology on the approach for considering effects as presented in Zimmer FSAR Attachment 1.k may be applied.	NUREG-0487 Supplement 1	Acceptable

Table 3A-2 (Cont'd)

Load or Phenomenon	NRC Acceptance Criteria	Criteria Source	LGS Position
	5. Formula 2-23 of NEDE-21739 shall be modified by replacing M_H by ρ_{FB} V_A where V_A is obtained from tables 2-1 & 2-2.	NUREG-0487	Acceptable
D. SRV Air Bubble Drag Load	No criteria specifiec for T-quencher		Applying plant unique methodology defined in Section 3B.4.1.4 and applying the Mark II Submerged structure load methodology for SRV - bubbles described in Section 3A.11
E. Steam Condensation Drag Load	No criteria specifiec		Applying plant unique methodology defined in Section 3A.4.2
IV. Secondary Loads			
1. Sonic Wave Load	Negligible Load	NUREG-0487	Acceptable
2. Comprehensive Wave Load	Negligible Load	NUREG-0487	Acceptable
3. Fallback Load on Submerged Boundary	Negligible Load	NUREG-0487	Acceptable
4. Thrust Load	Negligible Load	NUREG-0487	Acceptable
5. Friction Load on Submerged Boundary	Negligible Load	NUREG-0487	Acceptable
6. Vent Clearing Loads	Negligible Load	NUREG-0487	Acceptable

Table 3A-2 (Cont'd)

Load or Phenomenon	NRC Acceptance Criteria	Criteria Source	LGS Position
7. Postswell Wave Load	Methodology for establishing loads resulting from postswell waves to be evaluated on a plant unique basis	NUREG-0487	Load is negligible when compared to design basis loads (Section 3A.4.2.3.6)
8. Seismic Slosh Load	Methodology for establishing loads resulting from seismic slosh to be evaluated on a plant unique basis	NUREG-0487	Load is negligible when compared to design basis loads (Section 3A.4.2.3.7)
V. Confirmatory In-plant Tests of SRV Discharge			
A. SRV Load Specification	In the event that an applicant cannot demonstrated to the staff's satisfaction, equivalence in any of the areas cited in acceptance criteria A.1.1 through A.1.7 of confirmatory testing may be employed to demonstrate the applicability of the acceptance criteria for individual plants. Such testing if proposed should conform to the guidelines set down in NUREG-0763	NUREG-0802 Appendix A	Acceptable. No In-plant test is required. Section 3B>4.1.1.1 demonstrates the acceptability of using SSES SRV load specification for LGS.
B. Pool Temperature Specification (Thermal Mixing)	The acceptability of the safety/relief valve in-plant confirmatory test program shall be based on conformance guidelines specified in sections 6, 7, and 8 of NUREG-0763. I f the applicant/licensee elects not to perform the SRV in-plant tests, justification should be provided following the guidelines specified in section 4 of NUREG-0763.	NUREG-0763	Acceptable. The LGS pool thermal mixing capability has been adequately demonstrated by in-plant testing at LaSalle and analysis (Sections 3A.15.1.2 and 3A.15.3).

SHORT-TERM LOCA LOADS ASSOCIATED WITH POOL-SWELL

Load
1. Wetwell/drywell pressures during pool-swell
2. Pool-swell impact loads
3. Pool-swell drag loads
4. Downcomer clearing loads
5. Downcomer water jet load
6. Pool-swell air bubble load
7. Pool-swell fallback load

Table 3A-6

SHORT-TERM DRYWELL PRESSURES DURING POOL-SWELL

Time (sec)	Pressure (psia)
0.0000[1]	36.11
0.0600	36.29
0.1000	36.82
0.1200	37.08
0.1600	37.57
0.2000	38.04
0.2400	38.49
0.2800	38.91
0.3200	39.30
0.3600	39.67
0.4000	40.01
0.5000	40.75
0.6000	40.75
0.7000	41.39
0.8000	42.07
0.9000	42.80
1.0000	43.56
1.1000	44.603
1.2000	45.36
1.3000	46.08
1.4000	46.75

(1) Represents the beginning of the pool-swell phase, which starts 0.7107 seconds after the break.

NOTE: The information presented in this table is historical and is based on the original design basis conditions. The initial drywell pressurization rate is negligibly affected by the current plant conditions. The results presented here reasonably represent the general characteristics of the drywell pressure response.

Table 3A-7

LGS PLANT UNIQUE POOL-SWELL CODE INPUT DATA

Downcomer area (each)	2.95 ft^2
Suppression pool free surface area (outside pedestal)	4973.89 ft^2
Maximum downcomer submergence	12.25 ft
Downcomer loss coefficient (without exit loss)	1.23
Number of downcomers	87
Initial wetwell pressure	15.45 psia
Wetwell free air volume	149,425 ft^3
Vent clearing time	0.7107 sec
Slug velocity in downcomer at vent clearing	3.096 ft/sec
Initial drywell temperature	135°F
Initial drywell relative humidity	0.20
Downcomer friction coefficient, f	0.0115 (nominal)
Bubble initialization parameter (nominal)	50

NOTE: The information presented in this table is based on the original design basis conditions. Refer to Table 6.2.4A for input values used in the containment analyses for the current plant conditions.

Table 3A-8

INCLUDED LOCA WATER JET DRAG LOADS

Largest vertical downward force density acting on RHR pump suction line strainer	49 psi
Largest horizontal force density acting on RHR pump suction line strainer	29 psi
Largest vertical force on closest MSRV discharge line (distance = 2 ft)	1207 lb/ft
Largest horizontal force on closest MSRV discharge line (distance = 2 ft)	1394 lb/ft

NOTE: The information presented in this table is pertains to the original design basis. At current plant conditions, the LOCA water jet loads are approximately 2% higher than the load values shown in the table. However, margin between the design limits and the resulting component stress calculations exists to accommodate the increase in the LOCA jet loads.

Table 3A-9

POOL-SWELL AIR BUBBLE LOADS

Water volume in downcomers	3142.16 ft^3
Pool surface area (outside pedestal)	4973.89 ft^2
Maximum pool-swell after water discharge	18.88 ft
Height of downcomer water in the pool	7.58 in (0.632 ft)
Maximum pool-swell height (18.88 ft + 0.632 ft)	19.51 ft
Basemat hydrostatic pressure	10.51 psig
Downcomer tip hydrostatic pressure	5.20 psig
Maximum air bubble pressure	48.25 psia
Maximum pressure at basemat	58.76 psia
Maximum pressure at downcomer tip	48.25 psia
Maximum pool-swell inside the pedestal	212'-9" (6.62 ft above the high water level)

NOTE: The information presented in this table is based on the original design basis conditions. Refer to Sections 3A.4.2.1.4 and 3A.4.2.1.7 for the air bubble loads evaluation at the current operating conditions.

Table 3A-10

POOL-SWELL WATER FRICTION DRAG LOADS

Friction drag loads on columns	
Number of columns	12
Surface area per column	214.55 ft^2
Friction force for 12 columns	5098 lb_f
Shear stress	0.01375 lb/in^2
Friction drag load on downcomers	
Number of downcomers	87
Surface area of downcomer	122.6 ft^2
Frictional drag coefficient	0.00216
Friction force for 87 downcomers	2112.2 lb
Friction drag load on MSRV pipes	1806 lb
Air friction drag inside downcomers	303 lb
Downcomer bracing fallback loads	
Vertical load (12" nominal diameter)	3720 lb/ft
Horizontal load (12" nominal diameter)	2823 lb/ft
Vertical load (10" nominal diameter	2616 lb/ft
Horizontal load (10" nominal diameter	2046 lb/ft

NOTE: The information presented in this table is based on the original design basis conditions. Refer to Section 3A.4.2.1.8 for the pool swell drag load evaluation at the current operating conditions.

Table 3A-11

MAXIMUM LOAD ON SUBMERGED STRUCTURES

Submerged Structure	Max CO Load (lb/in)	Max Chugging Load (lb/in)
MSRV Discharge Line	3.8	24.0
Downcomer	22.0	41.0
Bracer	0.8	10.2
Core spray discharge line	0.22	6.6
HPCI discharge line	22.0	22.0
RHR discharge line	2.2	16.0
Column	51.6	190.0

13	Wetwell/drywell P and T during SBA

Table 3A-13

WETWELL PIPING LOCA LOADING SITUATIONS

Piping Configuration	LOCA Load to be Applied
1. Completely Submerged	
(a) vertical	skin drag load only (C_f)
(b) horizontal	drag load (C_D)
2. Partially Submerged	
(a) vertical	skin drag load only (C_f)
3. Initially Uncovered	
(a) vertical	skin drag load only (C_f)
(b) horizontal	impact load, then drag load (C_D)

Table 3A-14

LOAD COMBINATIONS FOR CONCRETE DESIGN IN CONTAINMENT, REACTOR ENCLOSURE, AND CONTROL STRUCTURES
(CONSIDERING HYDRODYNAMIC LOADS)

Equation	Load Condition	D	L	P_o	T_o	R_o	E_o	E_{ss}	P_B	P_A	T_A	B_A	R_V	SRV	AOT[1]	ADS	ASYM	Single Valve	LOCA[3]

Table 3A-14 (Cont'd)

Load Description

D	=	Dead Loads
L	=	Live Loads
P_o	=	Operating Pressure Loads
T_o	=	Operating Temperature Loads
R_o	=	Operating Pipe Reactions
SRV	=	Safety Relieve Valve Loads
E_o	=	Operating Basis Earthquake
E_{ss}	=	Safe Shutdown Earthquake
P_B	=	SBA or IBA (LOCA) Pressure Load
B_A	=	Pipe Break Temperatures Reaction Loads
P_A	=	DBA (LOCA) Pressure Load
T_A	=	Pipe Break temperature Load
R_V	=	Reaction and jet forces associated with the pipe break
AOT	=	Abnormal Operating Transient
ADS	=	Automatic Depressurization System
ASYM	=	Asymmetric

(1) For columns designated AOT, ADS, ASYM, and Single Valve, only one of the four possible columns may be included in the load combination for any one equation. For example, in Equation 1, either AOT or ASYM may be considered with the other loads but not both AOT and ASYM simultaneously.

(2) X indicates applicability for the designated load combination.

(3) LOCA includes chugging, condensation oscillation, and large air bubble loads.

Table 3A-15

LOAD COMBINATIONS AND ALLOWABLE STRESSES FOR
STRUCTURAL STEEL COMPONENTS
(Suppression Chamber Columns, Downcomer Bracing,
and Reactor Enclosure Structural Steel)

Equation	Condition	Load Combination	Allowable Stress
1	Normal w/o Temp.	$D+L+P_o+SRV$	F_s
2	Normal w/ Temp.	$D+L+P_o+T_o+SRV$	F_s
3	Normal/ Severe	$D+L+P_o+T_o+E+SRV$	$1.25\ F_s$
4	Normal/ Extreme	$D+L+P_o+T_o+E'+SRV$	(1)
5	Abnormal	$D+L+P+(T_o+T_a)+R+SRV+LOCA$	(1)
6	Abnormal/ Severe	$D+L+P+(T_o+T_a)+R+E+SRV+LOCA$	(1)
7	Abnormal/ Extreme	$D+L+P+(T_o+T_a)+R+E'+SRV+LOCA$	(1)

(1) In no case shall the allowable stress exceed $0.90\ F_y$ in bending, $0.85\ F_y$ in axial tension or compression, and $0.50\ F_y$ in shear. Where the design is governed by requirements of stability (local or lateral buckling), the actual stress shall not exceed $1.5\ F_s$.

Table 3A-15 (Cont'd)

Notations:

F_s	=	Allowable stress according to the AISC, "Specification for the Design, Fabrication, and Erection of Structural Steel for Building," dated 1969, Part 1
F_y	=	Minimum specified yield strength
D	=	Dead load
L	=	Live load
T_o	=	Thermal effects during normal operating conditions including temperature gradients and equipment and pipe reactions
T_a	=	Added thermal effects (over and above operating thermal effects) that occur during a design accident
P_o	=	Operating Pressure Load
P	=	Design basis accident pressure load
R	=	Local force or pressure on structure due to postulated pipe rupture including the effects of steam/water jet impingement, pipe whip, and pipe reaction
E	=	Load due to operating basis earthquake
E'	=	Load due to safe shutdown earthquake
SRV	=	Safety relief valve loads
LOCA	=	Loads due to loss-of-coolant accident conditions (chugging, condensation oscillation, or large air bubble loads)

Table 3A-16

LOAD COMBINATIONS AND ALLOWABLE STRESSES FOR
ASME CLASS MC COMPONENTS

The drywell head assembly, equipment hatches, personnel lock suppression chamber access hatches, CRD removal hatch, and piping and electrical penetrations are designed for the following loading combinations and allowable stresses:

Equation	Condition	Load Combination	Stress Limits
1	Normal	D+L+1.15P	1.15 times ASME Section III, Class B
2	Normal	$D+L+T_A+P$	ASME Section III, Class B
3	Emergency	$D+L+T_A+P+H_A+R+E$	ASME Section III, Summer 1970 Addenda, Figure N-414
4	Faulted	$D+L+T_A+P+H_A+R+E'$	ASME Section III, Summer 1970 Addenda, Figure N-414
5	Normal w/Temp.	$D+L+T_o$ +SRV	ASME Section III, Class MC Components
6	Abnormal/ Severe	$D+L+T_A+P+H_A+R+E$ +SRV+LOCA	ASME Section III, Fig. NB-3224-1 for "Emergency Conditions"
7	Abnormal/ Extreme	$D+L+T_A+P+H_A+R+E'$ +SRV+LOCA	ASME Section III, Fig. NB-3225-1 for "Faulted Conditions"

Definitions

D = Dead load

L = Live Load

T_o = Thermal effects due to temperature gradient through the wall, under operating conditions

T_A = Thermal effects due to temperature gradient through the wall, under accident conditions

P = Design basis accident pressure load

Table 3A-16 (Cont'd)

R	=	Steam/water jet forces or reactions resulting from the rupture of process piping
E	=	Load due to the operating basis earthquake
E'	=	Load due to the design basis earthquake
B	=	Hydrostatic loading due to postaccident flooding of the primary containment to the level of the reactor core
H_A	=	Force on the structure due to thermal expansion of pipes, under accident conditions
SRV	=	Safety/relief valve loads
LOCA	=	Loads due to loss-of-coolant accident conditions (chugging, condensation oscillation, annulus pressurization or large air bubble loads)

Table 3A-17

LOAD COMBINATIONS AND ALLOWABLE STRESSES FOR DOWNCOMERS

Equation	Condition	Load Combination	Allowable Stress
1	Upset	$D+P_o+SRV_{ALL}$	1.5 S_m
2	Emergency	$D+P_o+SRV_{ALL}+E$	2.25 S_m
3	Emergency	$D+P_{SBA}+SRV_{ADS}+E+LOCA(SBA)$	2.25 S_m
4	Faulted	$D+P_o+SRV_{ALL}+E'$	3 S_m
5	Faulted	$D+P_{IBA}+SRV_{ADS}+E+LOCA(IBA)$	3 S_m
6	Faulted	$D+P_{SBA}$ (or P_{IBA}) $+SRV_{ADS}+E'+LOCA(SBA \text{ or } IBA)$	3 S_m
7	Faulted	$D+P_A+E'+LOCA(DBA)$	3 S_m

Notations:

S_m = Maximum allowable stress

D = Dead weight of the downcomer

P_o = Pressure differential between drywell and suppression chamber during normal operating condition

P_{SBA} = Pressure differential between drywell and suppression chamber during SBA.

P_{IBA} = Pressure differential between drywell and suppression chamber during IBA.

P_A = Pressure differential between drywell and suppression chamber during DBA.

SRV_{ALL} = Dynamic lateral pressure and inertia load due to the discharge of all 14 safety/relief valves simultaneously.

Table 3A-17 (Cont'd)

SRV_{ADS} = Dynamic lateral pressure and inertia load due to the discharge of all 5 ADS safety/relief valves simultaneously.

E = Load due to operating basis earthquake

E' = Load due to safe shutdown earthquake

LOCA = Loads due to chugging, condensation oscillation, or air bubble loads. The governing applicable loading case should be considered. The loads should include:

1. Lateral load at the tip of the downcomer
2. Horizontal and vertical inertial loads
3. Submerged structure loads

Table 3A-18

LOAD COMBINATIONS AND STRESS LIMITS FOR BOP PIPING SYSTEMS

Equation	Condition	Load Combination	Stress Limit
1	Design	PD	NB-3652 NC-3600, ND-3600
2	Normal	PD + DW	NB-3654, NC-3600, ND-3600
3	Upset	(a) $PO+DW+(OBE^2+SRV_x^2)^{1/2}$ (b) $PO+DW+(RVC^2+OBE^2)^{1/2}$ (c) PO+DW+FV (d) PO+DW+OBE+RVO	NB-3654, NC-3600, ND-3600
4	Emergency	(a) $PO+DW+(OBE^2+SRV_{ADS}^2+SBA^2)^{1/2}$ (b) $PO+DW+(FV^2+OBE^2)^{1/2}$	NB-3655, NC-3600, ND-3600
5	Faulted	(a) $PO+DW+(OBE^2+SRV_{ADS}^2+IBA^2)^{1/2}$ (b) $PO+DW+(SSE^2+SRV_{ADS}^2+IBA^2)^{1/2}$ (c) $PO+DW+(SSE^2+DBA^2)^{1/2}$	NB-3656 ASME Code Case 1606

Notations:

PD = Design pressure

PO = Operating pressure

DW = Dead weight

OBE = Operating basis earthquake (inertia portion)

SSE = Safe shutdown earthquake (inertia portion)

SRV_x = Loads due to safety/relief valve blow, axisymmetric or asymmetric

Table 3A-18 (Cont'd)

SRV_{ADS}	=	Load due to automatic depressurization SRV blow, axisymmetric
SBA	=	Small break accident(1)
IBA	=	Intermediate break accident(1)
DBA	=	Design basis accident(1)
FV	=	Transient response of the piping system associated with fast valve closure (transients associated with valve closure times less than 5 seconds are considered)
RVC	=	Transient response of the piping system associated with relief valve opening in a closed system
RVO	=	Sustained load or response of the piping system associated with relief valve opening in an open system or last segment of the closed system with steady-state load

(1) SBA, DBA, and IBA include all event-induced loads, as applicable, such as chugging, condensation oscillation, pool-swell, annulus pressurization, etc.

Table 3A-19

LOAD COMBINATIONS AND ACCEPTANCE CRITERIA FOR
ASME CLASS 1, 2, AND 3 NSSS PIPING, EQUIPMENT, AND SUPPORTS

LOAD COMBINATION	DESIGN BASIS	EVALUATION[3] BASIS	SERVICE LEVEL
N + $SRV_{(ALL)}$	Upset	Upset	(B)
N + OBE	Upset	Upset	(B)
N + OBE + $SRV_{(ALL)}$	Emergency	Upset	(B)
N + SSE + $SRV_{(ALL)}$	Faulted	Faulted	(D)[1]
N + SBA + SRV	Emergency	Emergency	(C)[1]
N + SBA + $SRV_{(ADS)}$	Emergency	Emergency	(C)[1]
N + SBA/IBA + OBE + $SRV_{(ADS)}$	Faulted	Faulted	(D)[1]
N + SBA/IBA + SSE + $SRV_{(ADS)}$	Faulted	Faulted	(D)[1]
N + LOCA[2] + SSE	Faulted	Faulted	(D)[1]

LOAD DEFINITION LEGEND

N - Normal loads (e.g., weight, pressure, temperature, etc)

OBE - Operating basis earthquake loads

SSE - Safe shutdown earthquake loads

SRV - Safety/relief valve discharge induced loads from two adjacent valves (one valve actuated when adjacent valve is cycling)

SRV_{ALL} - Loads induced by actuation of all 14 safety/relief valves that activate within milliseconds of each other (e.g., turbine trip operational transient)

SRV_{ADS} - Loads induced by the actuation of all 5 safety/relief valves associated with automatic depressurization system that actuate within milliseconds of each other during the postulated small or intermediate size pipe rupture.

LOCA - Loss-of-coolant accident associated with the postulated pipe rupture of large pipes (e.g., main steam, feedwater, recirculation piping)

Table 3A-19 (Cont'd)

$LOCA_1$ - Pool-swell drag/fallback loads on piping and components located between the main vent discharge outlet and the suppression pool water upper surface

$LOCA_2$ - Pool-swell impact loads on piping and components located above the suppression pool water upper surface

$LOCA_3$ - Oscillating pressure induced loads on submerged piping and components during condensation oscillations

$LOCA_4$ - Building motion induced loads from chugging

$LOCA_5$ - Building motion induced loads from main vent air clearing

$LOCA_6$ - Vertical and horizontal loads on main vent piping

$LOCA_7$ - Annulus pressurization loads

SBA - Abnormal transients associated with a small break accident

IBA - Abnormal transients associated with an intermediate break accident.

---

(1) All ASME Class 1, 2 and 3 piping that are required to function for safe shutdown under the postulated events are designed to meet the requirements described in NEDO-21985 (Sept. 1978).

(2) The most limiting case of load combinations among $LOCA_1$ through $LOCA_7$.

(3) Evaluation basis in accordance with NRC requirements.

Table 3A-20

LOAD COMBINATIONS AND DAMPING VALUES FOR SAFETY-RELATED BOP EQUIPMENT IN THE PRIMARY CONTAINMENT, REACTOR ENCLOSURE, AND CONTROL STRUCTURES

Equation	Condition	Load Combination	Damping(1)
1	Upset	a. $N+[OBE^2 + SRV^2]^{1/2}$	2%
		b. N+OBE	0.5%
2	Emergency	a. $N+[OBE^2 + SRV^2 + SBA^2]^{1/2}$	2%
3	Faulted	a. $N+[OBE^2 + SRV^2 + IBA^2]^{1/2}$	2%
		b. $N+[SSE^2 + SRV^2 + IBA^2]^{1/2}$	2%
		c. $N+[SSE^2 + DBA^2]^{1/2}$	2%
		d. Envelope of a, b & c	2%
		e. N+SSE	1%
4	Worst	a. Envelope of 1a, 2 and 3d	2%

Notations:

N = Normal loads (dead weight + operating temp + operating pressure, etc.

OBE = Operating basis earthquake loads

SSE = Safe shutdown earthquake loads

SRV = Safety/relief valve discharge loads

SBA = Small break accident loads

IBA = Intermediate break accident loads

DBA = Design basis accident loads

(1) Where justified, a higher damping value may be used.

Table 3A-21

LOAD COMBINATIONS AND ALLOWABLE STRESSES FOR ELECTRICAL RACEWAY SYSTEM

Equation	Condition	Load Combination	Allowable Stress
1	Normal	D+L+SRV	F_s
2[1]	Normal/Severe	D+E	[2]
3	Abnormal/Extreme	D+E'+SRV+LOCA	[2,3]

Notations:

F_s = Allowable stress for normal condition

D = Dead weight of raceway and cables

L = A 200 lb concentrated live load is applied at any point on cable trays only between supports

E = Load due to operating basis earthquake

E' = Load due to safe shutdown earthquake

SRV = Safety/relief valve loads

LOCA = Loss-of-coolant accident loads

F_y = Minimum specified yield strength

Table 3A-21 (Cont'd)

(1) Applies only to connections for fatigue considerations.

(2) The following equation is applicable for connections:

$$\frac{5n_{EQ}}{N_{OBE}} + \frac{n_{EQ}}{N_{SSE}} \leq 1.0$$

where:

n_{EQ} = Total number of load/stress cycles per earthquake.

N_{OBE} = Allowable number of load/stress cycles per OBE event.

N_{SSE} = Allowable number of load/stress cycles per SSE event.

Allowable shear and normal loads on proprietary connection fittings shall be determined from the manufacturer's data or from code allowable stresses, whichever is applicable and as provided by Specification C-98.

(3) In no case shall the allowable stress exceed 0.90 F_y in bending, 0.85 F_y in axial tension or compression, and 0.50 F_y in shear. Where the design is governed by requirements of stability (local or lateral buckling), the actual stress shall not exceed 1.5 F_s.

Table 3A-22

LOAD COMBINATIONS AND ALLOWABLE STRESSES FOR HVAC DUCT SYSTEMS

DUCTS

Equation	Condition	Load Combination	Allowable Stress
1	Normal	D+L+SRV	F_s
2	Normal	$D+P_M$+SRV	F_s
3	Abnormal	$D+P_T$	1.25 F_s
4	Normal/Severe	$D+P_M$+E	1.25 F_s
5	Normal/Severe	$D+P_M$+E+SRV	1.25 F_s
6	Normal	D+Po	F_s
7	Normal/Severe	D+Po+E	1.25 F_s
8	Normal/Extreme	D+Po+E'	(2)
9	Normal/Extreme	$D+P_M$+E'+SRV	(2)
10	Normal/Abnormal	$D+P_O+P_A$+E'+SRV+LOCA	(2)
11	Normal/Abnormal	When protection against tornado depressurization is required:	
		$D+P_O+W_D$+SRV+LOCA	(2)
12	Extreme/Abnormal	For ducts inside drywell of containment, the following additional load combination is also applicable:	
		$D+H_A+P_O+P_A$+E'+SRV+LOCA	(2)

Table 3A-22 (Cont'd)

DUCT SUPPORTS

Equation	Condition	Load Combination	Allowable Stress
1	Normal	D+L+SRV	F_s
2	Normal/Severe	D+E	1.25 F_s (1)
3	Normal/Severe	D+E+SRV	1.25 F_s
4	Extreme/Abnormal	D+E'+SRV+LOCA	(2)

Notations:

D = Dead load

L = Live load

P_O = Duct normal operating pressure load

P_T = Duct test pressure load

P_A = Design basis accident pressure load

P_M = Duct maximum operating pressure load, excluding P_A & P_T, e.g., fan cutoff pressure load

E = Load due to operating basis earthquake

E' = Load due to safe shutdown earthquake

W_D = Tornado depressurization load

H_A = Forces due to thermal expansion of HVAC ducts under accident conditions

SRV = Safety/relief valve loads

LOCA = Loss-of-coolant accident loads

F_s = Allowable stress for steel, governed by AISI or AISC Codes, as applicable

F_y = Yield strength for steel (ASTM specification minimum)

Table 3A-22 (Cont'd)

(1) This value shall be F_s for transverse and longitudinal bracing and their connections.

(2) In no case shall be allowable stress exceed 0.90 F_y in bending, 0.85 F_y in axial tension or compression, and 0.50 F_y in shear. Where the design is governed by requirements of stability (local or lateral buckling), the actual stress shall not exceed 1.5 F_s.

Flush weld for pipe anchor	0.870	1.0

Table 3A-28

SUMMARY OF BOP PIPING STRESSES

(UNIT 1)

Stress Ratio[1] = Maximum Stress / Allowable Stress

Maximum Calculated Stress (PSI)[3]

Piping System	I.C./O.C[2]	Reference Stress Calculation[4]
RWCU	I.C.	1-10-11B
	O.C.	P1-37-52
	O.C.	R1-37-53
RHR	I.C.	1-10-05
	O.C.	1-10-65B
	O.C.	P1-10-75
CS	I.C.	1-20-02
	O.C.	P1-20-54
	O.C.	P1-20-56
FPCC	I.C.	1-33-01
	I.C.	1-33-02
	O.C.	1-33-62
HPCI	I.C.	1-01-03
	O.C.	P1-10-72

Table 3A-28 (Cont'd)

SUMMARY OF BOP PIPING STRESSES
(UNIT 2)

Stress Ratio[1] = Maximum Stress / Allowable Stress

Piping System	I.C./O.C[2]	Maximum Calculated Stress (PSI)[3]	Reference Stress Calculation[4]
RWCU	I.C.		2-10-11
	O.C.		2-37-63
RHR	I.C.		2-10-05
	O.C.		2-10-84
	O.C.		2-10-83
CS	I.C.		2-20-02
	O.C.		2-20-64
	O.C.		2-20-63
FPCC	I.C.		2-33-02
	I.C.		2-33-01
	O.C		2-43-02
HPCI	I.C.		2-01-03
	O.C.		2-10-83

(1) Design Margin = 1 - Max. Stress / Allowable Stress

(2) I.C. = Inside Containment
O.C. = Outside Containment

(3) Calculated stresses are based on original analysis. Changes due to re-rate are small and stress ratios are less than 1.0. Changes due to “A” RWCU pump replacement result in stress ratios that are less than 1.0.

(4) Calculated stresses are maintained within the Reference Stress Calculation from the Table.

Table 3A-29

SYSTEM CHARACTERISTICS AND INPUT PARAMETERS

REACTOR	
Initial core power (105% Rated)	3.26×10^6 Btu/sec
Initial RPV liquid mass	608,142 lb_m
Initial RPV steam mass	24,669 lb_m
RPV and internals mass	2.772×10^6 lb_m
Initial vessel pressure	1025 psia
Initial steam flow (105% Rated)	4129 lb_m/sec
REACTOR MAKEUP	
Initial CRD flow	8.89 lb_m/sec
CRD flow after scram (P_{RPV} = 0 psig)	23.6 lb_m/sec
CRD enthalpy (from CST)	108 Btu/lb_m
Feedwater flow rate	as required to maintain RPV level

Feedwater mass/enthalpy

Mass (lb_m)	Enthalpy (Btu/lb_m)
165,385	402
256,919	342
370,885	235
359,442	156
235,746	126

HPCI "on" volume (RPV level 2)	12,675 ft^3
HPCI "off" volume (RPV level 8)	15,281 ft^3
VALVES	
MSIV closure time	3.5 sec
SRV flow rate (122.5% ASME)	390 lb_m/sec at 1500 psia
SRV setpoints	See Table 3A-29A

NOTE: The information presented in this table is based on the original design bais conditons. Refer to Section 6.2.1.8 for the initial conditions and methodology used to analyze current plant conditions.

Table 3A-29 (Cont'd)

RHR SYSTEM	
RHR heat exchanger effectiveness, K (shutdown cooling)	288.9 Btu/sec °F
RHR heat exchanger effectiveness, K (pool cooling)	288.9 Btu/sec °F
RHR flow rate in pool cooling	1390 lb_m/sec
RHR flow rate in shutdown cooling	1390 lb_m/sec
RHR pump horsepower	1250 hp/pump
RHRSW temperature	88°F at time = 0 sec 91.2°F at time = 18,000 sec 92.5°F at time = 36,000 sec
RHRSW flow rate	9000 gpm
Maximum reactor pressure for switch-over from RHR pool cooling to shutdown cooling	89.7 psia
WETWELL/SUPPRESSION POOL	
Wetwell airspace pressure	15.45 psia
Initial suppression pool water mass (at low water level, without water mass inside pedestal)	7.194×10^6 lb_m
Initial suppression pool temperature	95°F
Suppression pool temperature Technical Specification limits for:	
a. Continuous operation without suppression pool cooling	95°F
b. Continuous testing at power	105°F
c. Power operation (Scram Technical Specification temperature	110°F
d. Hot standby (Depressurization Technical Specification temperature)	120°F
Quencher submergence (at low water level)	18.5 feet

NOTE: The information presented in this table is based on the original design bais conditons. Refer to Section 6.2.1.8 for the initial conditions and methodology used to analyze current plant conditions.

Table 3A-29A

SRV SETPOINTS USED FOR SUPPRESSION POOL TEMPERATURE RESPONSE ANALYSIS

SAFETY/RELIEF VALVES

Number 14

Spring Set Pressures, Mass Flow Rates:

Valve	Set Pressure (psig)	Mass Flow (lb_m/hr) at 103% of Spring Set Pressure
A	1150	917,00
B	1150	917,000
C	1150	917,000
D	1140	909,000
E*	1140	909,000
F	1150	917,000
G	1150	917,000
H*	1130	301,500
J	1130	901,500
K*	1140	909,000
L	1130	901,500
M*	1140	909,000
N	1130	901,500
S*	1140	909,000

* ADS Valves

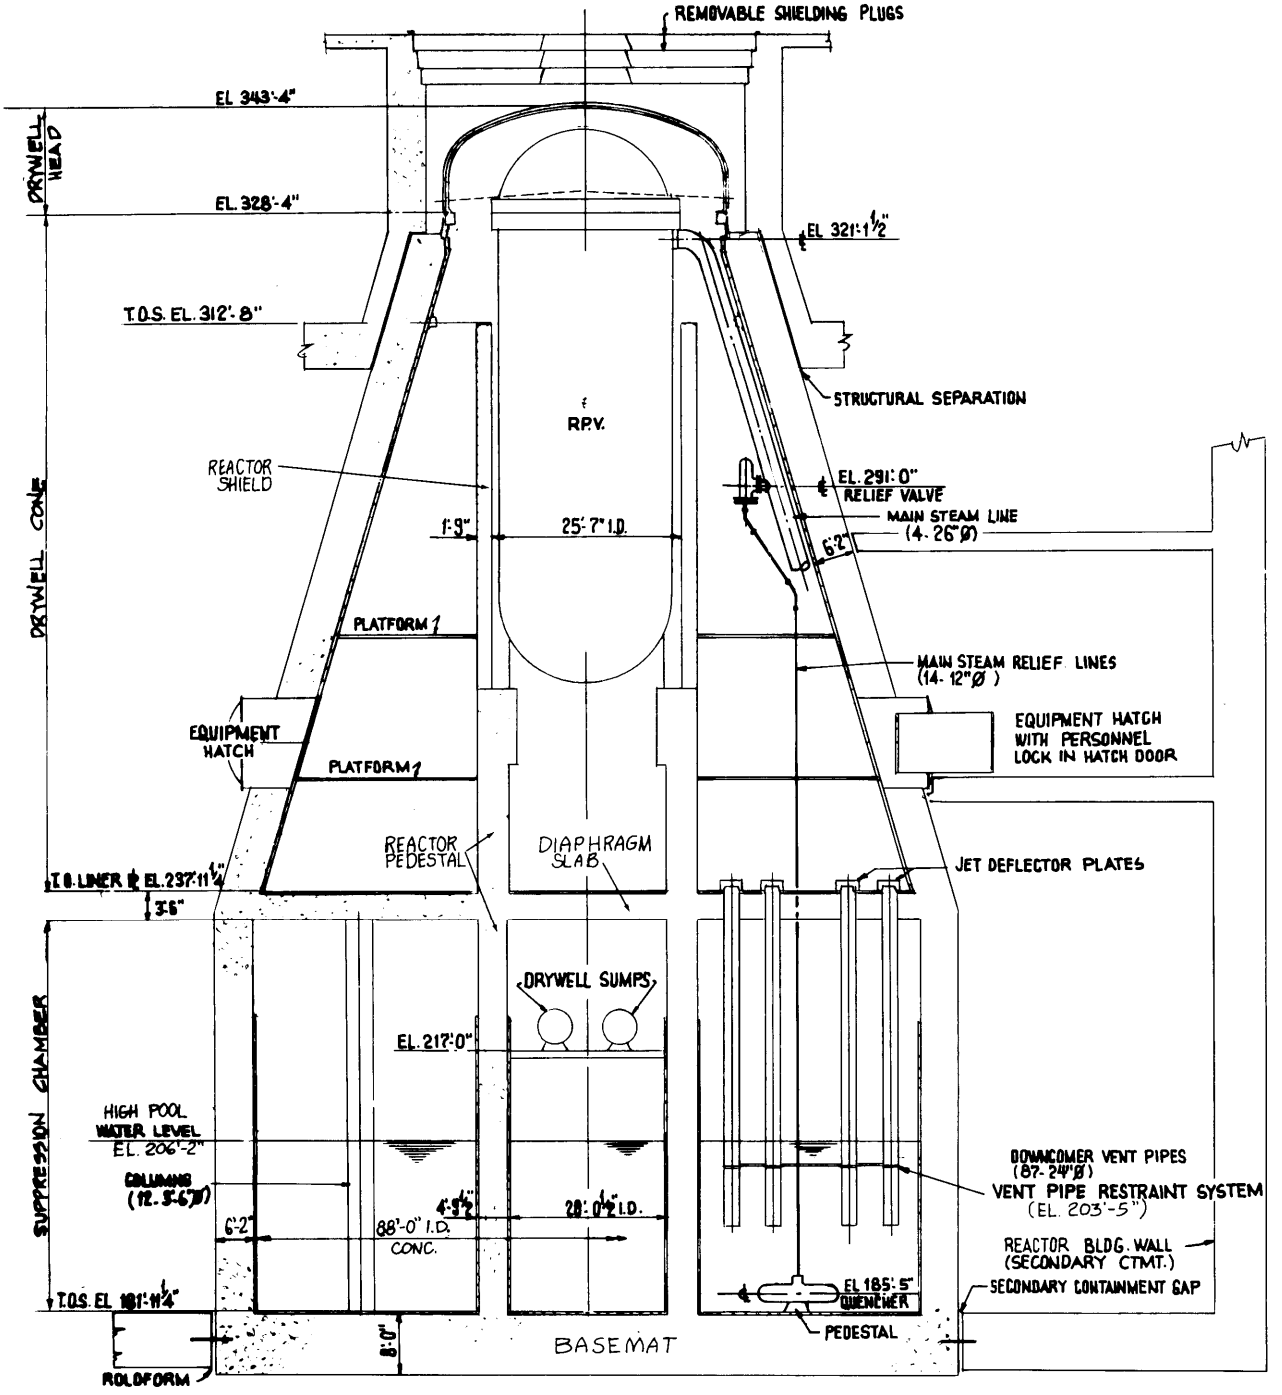
NOTE: The information presented in this table is historical and is based on the original design bais conditons. Refer to Table 3A-3 for the current SRV setpoints.

Table 3A-30

PEAK SUPPRESSION POOL TEMPERATURES[1]

EVENT	TEMPERATURE
1. SORV at Power	
Case 1.a	169°F
Case 1.b	187°F
2. Isolation/Scram	
Case 2.a	201°F
Case 2.b	183°F
3. SBA	
Case 3.a	202°F[2]
Case 3.b	182°F

(1) The information presented in this table for the suppression pool temperature response is based on the original design basis conditions. The current suppression pool temperature results are discussed in Section 3A.15.2. The results shown in this table reasonably represent the general characteristics and relative differences between the cases.



(2) The limiting case (Case 3.a) was reanalyzed for the current plant conditions and the resulting peak suppression pool temperature was 203°F.

Table 3A-31

MATERIAL PROPERTIES FOR ANALYTICAL ELEMENTS
OF THE AXISYMMETRIC SRV ANALYSIS MODEL

Element Material Type	Young's Modulus, E kip/ft^2	Material Density, ρ $kip\text{-}s^2/ft^4$	Poisson's Ratio	Shear Wave, V_s (ft/s)
Concrete	0.0936E+6*	0.00446	0.22	-
Steel	0.4176E+7	0.01524	0.33	-
Soil Medium	0.432E+6	0.00481	0.30	5950**

*The modulus represents a dynamic modulus of elasticity.
**The shear-wave velocity, V_s, is used to simulate a soil shear modulus ($G = V_s^2\rho$), equal to $0.166x10^6$ kip/ft^2.
