U.S. Nuclear Regulatory Commission
ATTN: Document Control Desk
Washington, DC 20555-0001

Limerick Generating Station, Units 1 and 2
Renewed Facility Operating License Nos. NPF-39 and NPF-85
NRC Docket Nos. 50-352 and 50-353

Subject: Submittal of Updated Final Safety Analysis Report (UFSAR), Revision 23 and Technical Specification (TS) Bases

Reference: Letter from David P. Heckler (Constellation Energy Generation, LLC- formerly Exelon Generation Company, LLC) to U.S. Nuclear Regulatory Commission – Amended Update to Updated Final Safety Analysis Report (UFSAR), Revision 20, dated April 29, 2021 (ML21138A801)

In accordance with 10 CFR 50.71(e)(4) and 10 CFR 50.4(b)(6), enclosed is Revision 23 of the Updated Final Safety Analysis Report (UFSAR) for Limerick Generating Station (LGS), Units 1 and 2. The enclosed UFSAR Revision 23 is being provided to the NRC in its entirety and constitutes a total replacement copy. In addition, as required by 10 CFR 50.71(e)(2)(ii), Attachment 1 to this letter identifies changes made under the provisions of 10 CFR 50.59, and is included in Revision 23 of the UFSAR, but not previously submitted to the NRC.

10 CFR 50.71(e)(4) stipulates that revisions to the UFSAR must reflect changes made up to a maximum of six months prior to the submittal. As a result, UFSAR Revision 23 reflects changes made up to the LGS, Units 1 and 2, UFSAR at least up to September 1, 2026. Attachment 2 of this document includes UFSAR Chapters 1 thru 17 and Appendix A.

On October 20, 2014, the NRC issued Renewed Facility Operating Licenses NPF-39 and NPF-85 for LGS, Units 1 and 2, respectively. Therefore, pursuant to the requirements of 10 CFR 54.37(b) and the guidance specified in Regulatory Issue Summary 2007-16, Revision 1, "Implementation of the Requirements of 10 CFR 54.37(b) for Holders of Renewed Licenses," the UFSAR update required by 10 CFR 50.71(e) must include any Structures, Systems, or Components (SSCs) newly identified that would have been subject to an aging management review or evaluation of time-limited aging analyses in accordance with 10 CFR 54.21. The UFSAR update must describe how the licensee will manage the effects of aging in order to effectively maintain the intended function(s) of newly-identified SSCs. An evaluation was completed to determine whether any newly-identified SSCs existed in support of submitting UFSAR Revision 23 for LGS, Units 1 and 2. This evaluation involved reviewing pertinent

documentation for the period subsequent to the last LGS biennial UFSAR revision. As a result of this review, there were no newly-identified SSCs for which aging management reviews or time-limited aging analyses would apply.

As noted in the Reference, Appendix 3B of the UFSAR contains proprietary information and will be withheld from public disclosure pursuant to 10 CFR 2.390 in Revision 23 of the LGS UFSAR. The Reference letter provides information regarding the revision history pertaining to Appendix 3B and that earlier legacy correspondence supports the submittal of the Appendix 3B information as proprietary which includes supporting affidavits. Since the Reference letter, there have been no changes to UFSAR Appendix 3B. Therefore, a proprietary version is not included in Revision 23 of the LGS UFSAR update and Appendix 3B is only included by reference.

Additionally, in accordance with the requirement of LGS, Units 1 and 2 Technical Specification (TS) 6.8.4.h.d, Constellation Energy Generation, LLC, hereby submits a complete updated copy of the Unit 1 and Unit 2 TS Bases, which includes changes through the date of this letter.

As required by 10 CFR 50.71(e)(2)(i), I certify that to the best of my knowledge, the information contained in the Attachments to this letter accurately reflects information and analyses submitted to the NRC, or prepared pursuant to the NRC requirements as described above.

If you have any questions or require further information, please contact Lane Oberembt at 267-533-5301.

Respectfully,

Para, Wendi E

Summary of UFSAR Changes

ATTACHMENT 1

10 CFR 50.71(e)(2)(ii) requires that revisions to the UFSAR include changes made under the provisions of 10 CFR 50.59, but not previously submitted to the NRC. Accordingly, the list below identifies plant changes included in Revision 23 of the Updated Final Safety Analysis Report (UFSAR) that were not previously submitted to the NRC.

Limerick Generating Station, Units 1 and 2
Summary of UFSAR Changes – Revision 23

UFSAR Change Request	Issue Report	Engineering Change Request (ECR) / Engineering Change (EC)	Description
2023-017	4504651-55	EC 640130	FPR Section 9A.6.2, Table 9A-12, and the List of Tables on page 9A.vii are being revised to include new guidance from the NRC in Reg. Guide 1.189 Revision 4. The NRC Staff has reconsidered their position concerning 3-Phase Hot Shorts, and no longer believes they need to be postulated for High/Low Pressure Interfaces. App. 9A Table of Contents change is administrative only. Table 9A-13 was previously deleted but the Table of Contents was not updated.
2024-004	4504651-70	EC 641755	Defeat trip function for Turbine Enclosure Main Steam Isolation Valve Leak Detection System High Temperature. Update Tables 5.2-7, 6.2-17 , 7.3-5 , 7.3-7 and system description in Chapter 7.
2024-005	4504651-71	N/A	Removing reference to abandoned CO2 systems in the plant (Section A.2.1.17). Removal of legacy wording regarding CO2 from Appendix A, Fire Protection AMP that was previously missed during UFSAR Change Package 2022-008 (editorial change).
2025-001	4504651-75	N/A	Update to UFSAR sections for DCWS (Drywell Chilled Water System) and RECW (Reactor Enclosure Cooling Water) to allow outboard RECW to DCWS valves to be operated in OPCONS 1, 2, & 3 as allowed by the PCIV Tech Specs.
2025-003	4504651-78	EC 642350	UFSAR Updates for Limerick Generating Station Unit 2 Cycle 19 Reload Evaluation. The proposed changes are focused on correcting typographical and editorial errors as well clarifying that only Unit 1 is operating with GNF2 fuel. Unit 2 Cycle 19 will be the first cycle operating with a full core of GNF3 fuel.
2025-004	4504651-80	EC 423388	RRP MOTOR 2A REPLACEMENT PROJECT. EC 423388 Rev 3 permanently removes the cabinet and abandons the cables that no longer used. The removed cabinet and abandoned components are no longer in use and are not part of any plant system which has design basis functions. The UFSAR markup is administrative and non-regulatory and remove unnecessary information.
2025-005	4504651-81	N/A	Incorporating changes from previously approved UFSAR Change Packages 2019-

UFSAR Change Request	Issue Report	Engineering Change Request (ECR) / Engineering Change (EC)	Description
			019 and 2023-005 that were inadvertently omitted.
2025-009	4504651-87	EC 644904	Removal of HV-011-132A and HV-011-232A from Table 9A-14 following implementation of EC 644904. EC 644904 evaluated the changes to the Emergency Service Water A/B Loop Outlet valves to prevent stem-disc separation failures.
2026-001	4504651-89	N/A	Buried and Underground Piping and Tanks License Renewal Commitment Clarification. The Buried Piping LR Commitment in the UFSAR has vague wording that led to an inaccurate interpretation of the commitment resulting in the NRC Green NCV. There is no change in the commitment requirements but this is an editorial change to help clarify requirements.
2026-003	4504651-92	EC 644570 & EC 646777	Close and Deactivate Select Post LOCA Hydrogen Recombiner (PLHR) Motor Operated Primary Containment Isolation Valves (HV-057-164 and HV-057-262, -263, -264, -269). Closing and deactivating the valves will render the valves inoperable and maintain the containment isolation requirements of GDC 56 as committed to in the UFSAR.
2026-004	4504651-93	N/A	Reference ANSI/ANS 56.8 - 2002 was adopted in License Amendment Nos. 241 and 204 SER (ML19351E376) to adopt NEI 94-01 Rev 3A. Change the reference to pretest requirements of "ANSI/ANS N56.8 - 1994" to "ANSI/ANS 56.8 - 2002".
2026-005	4504651-94	EC 647146	Unit 1 Recirculation pump discharge valve and suction valve interlock trips will be removed. EC 647146 defeats this vulnerability by disconnecting the interlock contacts and limit switches. Section 15.3.1.1.1 of the UFSAR identifies both either the suction valve or discharge valve trips (not being fully opened) as causes to trip the recirculation pump motor. Removing the aforementioned trios does not adversely affect the design function of the recirculation system as described in the UFSAR.
2026-006	4504651-95	EC 644579	UFSAR Updates for Limerick Generating Station Unit 1 Cycle 22 Reload Evaluation to remove GNF2 information as both LGS units will contain full cores of GNF3 fuel once Cycle 22 commences. Also includes grammatical corrections and editorial updates (word choice & font color), correct Reference titles and dates, remove the use of "latest approved revision" for NF related references and replace this with the correct revision number.
2026-008	4504651-97	N/A	The maximum allowable closure time for PCIVs is detailed in TRM Table 3.6.3-1. This table has the Maximum isolation time for valves associated with penetrations

ATTACHMENT 1

UFSAR Change Request	Issue Report	Engineering Change Request (ECR) / Engineering Change (EC)	Description
			231A & 213B listed as 30 seconds. UFSAR Table 6.2-17 has the isolation times for these valves listed as 20 seconds. The UFSAR should be revised to reflect the information in the TRM.
2026-010	4504651-99	N/A	UFSAR Section 2.3.1, Regional Climatology, states hourly meteorological data from the Pottstown-Limerick Airport is used to review the Site Meteorological Tower data consistency on a daily basis. This UFSAR section is being revised to clarify the current practice of utilizing the meteorological data from the Pottstown – Limerick Airport periodically throughout the month to verify consistency of the Site Meteorological Tower data. If a data discrepancy is identified, further investigation is performed and data comparison is performed more frequently.
2026-011	4974857-01	N/A	This UFSAR change (activity) revises UFSAR Section 5.4.7.1.5 to remove a reactor cavity flooded up restriction to permit bypassing the RHR shutdown cooling (SDC) mode specific automatic isolation functions sooner and for a longer duration during an outage when they are not required by Technical Specifications (TS) and corrects a grammatical error.
2026-012	4974857-02	N/A	UFSAR Chapter 12.3.4.1.3 describes ten portable local area monitors provided in addition to the installed ones. They are located on each of the two refueling bridges, the three turbine enclosure crane cabs, the east and west unit 1 and 2 turbine enclosure deep bed vessel areas, and the health physics and chemistry source storage and calibration room. UFSAR Table 12.3-7 p. 12.3-32 only lists two turbine crane monitors instead of three. All the other portable radiation monitors are correctly listed in both sections.

CHAPTER 1 - INTRODUCTION AND GENERAL DESCRIPTION OF PLANT

TABLE OF CONTENTS

1.1 INTRODUCTION

1.2 GENERAL PLANT DESCRIPTION

1.2.1 Site Characteristics
1.2.1.1 Location
1.2.1.2 Site Environs and Access
1.2.1.3 Geology
1.2.1.4 Seismology
1.2.1.5 Hydrology
1.2.1.6 Meteorology

1.2.2 Principal Design Criteria
1.2.2.1 General Design Criteria
1.2.2.2 System Design Criteria
1.2.2.2.1 Nuclear System Criteria
1.2.2.2.2 Safety-Related Systems Criteria
1.2.2.2.3 Process Control Systems Criteria
1.2.2.2.4 Power Conversion Systems Criteria
1.2.2.2.5 Electrical Power Systems Criteria
1.2.2.2.6 Auxiliary Systems Criteria
1.2.2.2.7 Radioactive Waste Management Systems Criteria
1.2.2.2.8 Shielding and Access Control Criteria
1.2.2.2.9 Fuel Handling and Storage Facilities

1.2.3 General Arrangement of Structures and Equipment

1.2.4 System Description
1.2.4.1 Nuclear System
1.2.4.1.1 Reactor Core and Control Rods
1.2.4.1.2 Reactor Vessel and Internals
1.2.4.1.3 Reactor Recirculation System
1.2.4.1.4 Residual Heat Removal System
1.2.4.1.5 Reactor Water Cleanup System
1.2.4.1.6 Nuclear Leak Detection System
1.2.4.2 Safety-Related Systems
1.2.4.2.1 Reactor Protection System
1.2.4.2.2 Neutron Monitoring System
1.2.4.2.3 Control Rod Drive System
1.2.4.2.4 Control Rod Velocity Limiter
1.2.4.2.5 Control Rod Drive Housing Supports
1.2.4.2.6 Nuclear System Pressure Relief System
1.2.4.2.7 Reactor Core Isolation Cooling System
1.2.4.2.8 Primary Containment

TABLE OF CONTENTS (cont'd)

1.2.4.2.9 Primary Containment and Reactor Vessel Isolation Control System
1.2.4.2.10 Secondary Containment
1.2.4.2.11 Main Steam Isolation Valves
1.2.4.2.12 Main Steam Line Flow Restrictors
1.2.4.2.13 Emergency Core Cooling Systems
1.2.4.2.14 Residual Heat Removal System (Containment Cooling)
1.2.4.2.15 Control Room Heating, Ventilating and Air Conditioning System
1.2.4.2.16 Reactor Enclosure Recirculation System and Standby Gas Treatment System
1.2.4.2.17 Standby AC Power Supply
1.2.4.2.18 DC Power Supply
1.2.4.2.19 Residual Heat Removal Service Water System
1.2.4.2.20 Emergency Service Water System
1.2.4.2.21 Main Steam Line Radiation Monitoring System
1.2.4.2.22 Reactor Enclosure and Refueling Area Ventilation Radiation Monitoring System
1.2.4.2.23 Remote Shutdown System
1.2.4.2.24 Standby Liquid Control System
1.2.4.2.25 Information in Section Deleted
1.2.4.2.26 Redundant Reactivity Control System
1.2.4.3 Instrumentation and Control Systems
1.2.4.3.1 Nuclear System Process Control and Instrumentation
1.2.4.3.2 Power Conversion Systems Process Control and Instrumentation
1.2.4.4 Electrical Systems
1.2.4.4.1 Transmission and Generation Systems
1.2.4.4.2 Electric Power Distribution Systems
1.2.4.5 Fuel Handling and Storage Systems
1.2.4.5.1 New and Spent Fuel Storage
1.2.4.5.2 Fuel Pool Cooling and Cleanup System
1.2.4.5.3 Fuel Handling Equipment
1.2.4.6 Cooling Water and Auxiliary Systems
1.2.4.6.1 Service Water System
1.2.4.6.2 Reactor Enclosure Cooling Water System
1.2.4.6.3 Turbine Enclosure Cooling Water System
1.2.4.6.4 Fire Protection System
1.2.4.6.5 Plant Heating, Ventilating, and Air Conditioning Systems
1.2.4.6.6 Instrument Air System
1.2.4.6.7 Clarified Water System
1.2.4.6.8 Demineralized Water Makeup System
1.2.4.6.9 Plant Equipment and Floor Drainage System
1.2.4.6.10 Process Sampling System
1.2.4.6.11 Plant Communication System
1.2.4.7 Power Conversion Systems
1.2.4.7.1 Turbine-Generator
1.2.4.7.2 Main Steam System
1.2.4.7.3 Main Condenser
1.2.4.7.4 Main Condenser Evacuation System
1.2.4.7.5 Steam Seal System
1.2.4.7.6 Turbine Bypass and Pressure Control System
1.2.4.7.7 Circulating Water System

TABLE OF CONTENTS (cont'd)

1.2.4.7.8 Condensate Cleanup System
1.2.4.7.9 Condensate and Feedwater Systems
1.2.4.7.10 Condensate and Refueling Water Storage Facilities
1.2.4.8 Radioactive Waste Systems
1.2.4.8.1 Liquid Radwaste System
1.2.4.8.2 Solid Radwaste System
1.2.4.8.3 Gaseous Radwaste System
1.2.4.9 Radiation Monitoring and Control
1.2.4.9.1 Process Radiation Monitoring
1.2.4.9.2 Area Radiation Monitors
1.2.4.9.3 Site Environs Radiation Monitors
1.2.4.10 Shielding

CHAPTER 1 - INTRODUCTION AND GENERAL DESCRIPTION OF PLANT

1.1 INTRODUCTION

This UFSAR is submitted to fulfill the requirements of 10CFR50.71(e) for Exelon's nuclear power station designated as the Limerick Generating Station, Units 1 and 2. These units hold full power utilization facility (Class 103) licenses, NPF-39 and NPF-85. These licenses were issued in August 1985 and August 1989 respectively.

LGS is located on the east bank of the Schuylkill River in Limerick Township of Montgomery County, Pennsylvania, approximately 4 river miles downriver from Pottstown, 35 river miles upriver from Philadelphia, and 49 river miles above the confluence of the Schuylkill with the Delaware River. The site contains 595 acres (423 acres in Montgomery County and 172 in Chester County).

Each of the LGS units employs a GE BWR originally designed and licensed to operate at a rated core thermal power of 3293 MWt (100% steam flow) with a corresponding gross electrical output of 1092 MWe. Approximately 37 MWe are used for auxiliary power. Subsequent to issuing the original operating licenses, LGS Units 1 and 2 were reevaluated with regard to rerating power to 3458 MWt (Rerate Power). The acceptability of the rerate evaluations stems from the fact that LGS Units 1 and 2 were originally designated for steam flow capabilities at least 5% above its original rating. In addition, improvements in the analytical techniques based on more realistic assumptions, plant performance feedback, and the latest fuel designs resulted in a significant increase in the calculated operational margins related to safety analyses. Subsequently, the core thermal power was uprated from 3458 MWt to 3515 MWt as part of the measurement uncertainty recapture power uprate (MUR PU). The existing analyses assume a 2% uncertainty in feedwater flow, which is reduced to 0.3% using leading edge ultrasonic flow meters. This is acceptable because the analyzed conditions and margins of the safety analyses are not affected by this change in FW flow measurement.

The reactor design power level used in various analyses is discussed in Section 6.3 and Chapter 15.

The containment system, designed by Bechtel Power Corporation, limits the release of radioactive materials to the environs subsequent to the occurrence of a postulated LOCA so that the offsite doses are below the values stated in 10CFR50.67. The design employs the drywell/pressure-suppression features of the BWR/Mark II containment concept. The containment consists of a dual barrier: the primary containment, and the secondary containment. The primary containment is a steel-lined reinforced concrete pressure-suppression system of the over-and-under configuration. The secondary containment is the enclosure that encloses the reactor, and its primary containment, and fuel storage areas.

Condenser cooling is provided by water circulated through natural draft cooling towers.

The LGS PSAR was submitted on February 26, 1970 (AEC Dockets 50-352 and 50-353). The construction permits, CPPR-106 and CPPR-107, were originally issued on June 19, 1974. Environmental impact is discussed in the Applicant's Environmental Report - Construction Permit Stage (Revised) dated May 1972. The Atomic Energy Commission (now Nuclear Regulatory Commission) issued the LGS Final Environmental Statement Construction Stage in November 1973.

The LGS FSAR was originally submitted on March 17, 1981 and docketed on July 27, 1981. The NRC issued its SER in August 1983 and nine supplements to NUREG-0991 through August 1989.

A discussion of environmental impact was also submitted as the EROL, and the NRC issued its LGS Final Environmental Statement Operating License Stage, NUREG-0974, in April 1984.

The LGS Unit 1 low power (5%) operating license (NPF-27) was issued on October 26, 1984 and the full power operating license (NPF-39) was issued on August 8, 1985. The LGS Unit 1 entered commercial operation on February 1, 1986.

The LGS Unit 2 was issued an operating license (NPF-83) to load fuel and conduct testing up to, but not including, initial criticality on June 22, 1989. The low power (5%) operating license (NPF-84) was issued July 10, 1989 and the full power operating license (NPF-85) was issued August 25, 1989. The LGS Unit 2 entered commercial operation on January 8, 1990. The licensee received a license amendment for a 5% increase in rated power to 3458 MWt for LGS Unit 2 on February 16, 1995 and for Unit 1 on January 24, 1996. The licensee received license amendments for an additional 1.65% increase in rated power to 3515 MWt for Unit 1 and Unit 2 on April 8, 2011.

The FSAR was prepared and submitted in accordance with 10CFR50.34(b). Its format and content are in accordance with Regulatory Guide 1.70 (Rev 3), "Standard Format and Content of Safety Analysis Reports for Nuclear Power Plants", November, 1978. Following its initial update, the UFSAR will be updated in accordance with 10CFR50.71.

The relationships of other various reports submitted by the licensee are discussed below.

As discussed in Appendix 9A, the Fire Protection Evaluation Report was prepared and submitted in response to a September 30, 1976 NRC request. Since it contains the information suggested by Regulatory Guide 1.70 to be provided in Section 9.5.1.3, the FPER, in its entirety, was incorporated into the UFSAR as Appendix 9A in accordance with 10CFR50.32. The FPER will be updated in accordance with 10CFR50.71.

As discussed in Appendix 3A, the Design Assessment Report was prepared and submitted in response to a generic industry concern of thermohydrodynamic loads resulting from SRV operations and/or discharges during a LOCA. The DAR contains considerable design information and will be updated in accordance with 10CFR50.71. Proprietary DAR information is discussed in Appendix 3B.

The Quality Assurance Program was prepared and submitted in accordance with 10CFR50.34(b). Its format and content were prepared in accordance with Regulatory Guide 1.70 (Rev 3). The Quality Assurance Program is incorporated into the UFSAR as Section 17.2 and will be updated in accordance with 10CFR50.54(a)(3) and 10CFR50.71.

In accordance with 10CFR50.34(b)(6)(v) and Regulatory Guide 1.70, the Emergency Plan, while a separate report, is referenced in Section 13.3 of the UFSAR. The Emergency Plan will be updated in accordance with 10CFR50.54(q) and 10CFR50, Appendix E.

The Security Plan was prepared and submitted in accordance with 10CFR50.34(c). It is identified as a separate report withheld from public disclosure in UFSAR Section 13.6, in accordance with Regulatory Guide 1.70 (Rev 3). The Security Plan will be updated in accordance with 10CFR50.54(p).

The Safeguards Contingency Plan was prepared and submitted in accordance with 10CFR50.34(c), and withheld from public disclosure pursuant to 10CFR2.790(d). No discussion of

this report is provided in the UFSAR, consistent with Regulatory Guide 1.70 (Rev 3). The Safeguards Contingency Plan will be updated in accordance with 10CFR50.54(p).

As discussed in Section 1.0 of the Environmental Qualification Report, the EQR was prepared and submitted in response to a May 1980 Commission Memorandum and Order (CLI 80-21). It has been revised to fulfill the requirements of 10CFR50.49. The EQR is referenced in Section 3.11 of the UFSAR but is considered to be a licensee working document and update submittals are not planned.

The EROL was prepared and submitted in accordance with 10CFR51.21. Its format and content are in accordance with Regulatory Guide 4.2 (Rev 2), "Preparation of Environmental Reports for Nuclear Power Plants", July 1976. Regulatory Guide 4.2, section 7.1, "Station Accidents Involving Radioactivity" was later superseded by the Commission's Interim Position on Accident Consideration Under NEPA (45FR40101).

As discussed in section 1.1 of the Probabilistic Risk Assessment (PRA) and the Severe Accident Risk Assessment (SARA), the PRA and SARA were prepared and submitted in response to an initial May 6, 1980 NRC request. Because they contain the information required by the NRC's Interim Position on Accident Considerations under NEPA (45FR40101), the PRA and SARA were used in the analysis performed for EROL Section 7.1, in accordance with 10CFR50.32. At the request of the NRC Limerick Project Manager, the PRA is acknowledged in UFSAR Section 15.11; it is not referenced therein. The PRA and SARA are considered to be licensee working documents and update submittals are not planned.

1.2 GENERAL PLANT DESCRIPTION

1.2.1 SITE CHARACTERISTICS

A summary of the site characteristics for LGS is provided below. Detailed discussions on the site characteristics are provided in Chapter 2 of the UFSAR.

1.2.1.1 Location

LGS is located in southeastern Pennsylvania on the Schuylkill River about 1.7 miles southeast of the limits of the Borough of Pottstown and about 20.7 miles northwest of the Philadelphia city limits. The Schuylkill River passes through the site and separates the western portion, which is located in East Coventry Township, Chester County, from the eastern portion, which is partly in Limerick Township and partly in Lower Pottsgrove Township, both in Montgomery County, Pennsylvania. All of the major plant structures are located in Limerick Township. The site location map is shown in Figure 2.1-1.

1.2.1.2 Site Environs and Access

The site is located in gently rolling countryside, traversed by numerous valleys containing small creeks or streams that empty into the Schuylkill River. Two parallel streams, Possum Hollow Run and Brooke Evans Creek, cut through the site in wooded valleys, running southwest into the Schuylkill River.

The area surrounding the site can be generally classified as rural and open. A large portion of the land is used for agricultural purposes with the remainder of the area being either vacant or woodland with scattered residences.

The main access to the plant is from U.S. Highway 422 which runs east and west about one mile north of the site. Access to the site and all activities thereon are under the control of the licensee.

1.2.1.3 Geology

The site is situated in the Triassic Lowland section of the Piedmont Physiographic Province. This section is characterized by a gently rolling land surface formed on an eroded low plateau.

The rocks in the region surrounding the site include Precambrian and Lower Paleozoic crystalline rocks and folded sedimentary strata, and essentially unfolded Triassic sedimentary rocks and igneous intrusions. The Triassic rocks belong to the Newark Group which is divided into the basal Stockton Formation and the Brunswick, Lockatong, and Hammer Creek Lithofacies.

Bedrock at the site underlies a thin cover of residual soil. The Brunswick red siltstone, sandstone, and shale is the predominant bedrock formation. Gray shale and argillite of the Lockatong Lithofacies, light gray sandstones and conglomerates of the Hammer Creek Lithofacies, and intruded diabase and associated hornfels are also found in the area. The strata exhibit gentle homoclinal dips to the north and northwest. The thickness of the Newark Group overlying the Paleozoic and Precambrian basement rocks at the site is on the order of 8000 feet.

The dominant structural feature of the region is the Regional Appalachian Orogenic Belt. This belt is marked by the northeast- southwest orientation of the axes and lineation of most of the structural features and stratigraphic contacts.

1.2.1.4 Seismology

The seismicity of the site was evaluated on the basis of historical earthquakes, damage resulting from these shocks, and the regional and local geologic structure. The site lies in a region that has experienced a moderate amount of earthquake activity. Most of the reported earthquakes have occurred in the Piedmont province. Some minor shocks have occurred in a northeast-southwest trend along the Fall Zone, the physiographic boundary between the Piedmont and the Coastal Plain to the southeast. Some scattered activity has occurred in the Coastal Plain. No recent faulting has been mapped in the area of the site.

Based on the seismic history and the geologic structure of the region, no significant earthquake ground motion is expected at the site during the life of the proposed facility. Despite this demonstrative evidence to the contrary, the remote possibility that the geologic structure in the epicentral areas of the significant regional earthquakes could exist in the site area is considered. Thus, a design basis earthquake is hypothesized equivalent to the 1871 Wilmington, Delaware earthquake (Intensity VII) near the site. Such an event is highly improbable and this hypothesis is very conservative.

The plant has the capability for safe shutdown if subjected to a peak horizontal ground acceleration at foundation level of 0.15 g. Seismic Category I structures are founded on the competent siltstone and sandstone bedrock of the Brunswick Lithofacies. Design spectra consistent with the safe shutdown earthquake are used for the dynamic analysis of the seismic Category I structures and equipment.

1.2.1.5 Hydrology

In the site area, Triassic-age siltstone, sandstone, and shale are found at shallow depths beneath a thin cover of residual soils. The residual soils are relatively impermeable. Most groundwater in the area is found in joints, fractures, and other secondary openings in the rock. The groundwater table is found at relatively shallow depths, except in the vicinity of pumping wells. Because of the limited quantities of available groundwater, surface water is the primary source of supply in the region. Groundwater accounts for only about 3% of the total industrial and commercial use in the region. However, numerous domestic wells extract small quantities of water from the Triassic strata.

A number of wells are located in the general site area. However, the geologic, hydrologic, and topographic conditions are such that the possibility of any adverse effect on these wells by operation of LGS is extremely remote.

The flows of the Schuylkill vary widely at different points along the river. This is mainly due to the varying topography and climatological and geohydrologic conditions along its course. The extreme and average daily flows as recorded at Pottstown gauging station (about 5.5 river miles upstream from the site) are:

	Flow (cfs)	Date
Minimum	87	August 13, 1930 (instantaneous)
Average	1793	October 1926-September 1969 (daily)
Maximum	95,900	June 1972 (instantaneous)

The probable maximum flood peak and stage at the plant site are estimated to be 500,000 cfs and el 174' (MSL), respectively.

The principal uses of the Schuylkill River are for municipal and industrial water supply. The river is also used for recreational fishing and boating.

1.2.1.6 Meteorology

The general climate of the site is best described as humid continental. The region is dominated by continental air masses in winter, and by alternating continental and maritime tropical air masses in the summer. The site is near the track of most eastwardly moving low pressure systems that are brought from the interior of the U.S. by the prevailing westerlies. Annual average wind speeds in the region are between 9 and 10 mph and temperatures rarely exceed 100?F or drop below 0?F. The region receives a moderate amount of precipitation which is well distributed over the year.

Five years of meteorological data collected on the site have verified that the general regional conditions do exist at the site and that no unusual meteorological conditions prevail.

1.2.2 PRINCIPAL DESIGN CRITERIA

The principal criteria for design, construction, and testing of LGS are summarized below. Specific criteria, codes, and standards are addressed in Sections 3.1 and 3.2.

1.2.2.1 General Design Criteria

The LGS design conforms to the requirements given in 10CFR50, Appendix A, "General Design Criteria for Nuclear Power Plants." Specific compliance is discussed in Section 3.1.

a. The plant is designed, fabricated, erected, and operated to produce electrical power in a safe and reliable manner.

b. The plant is designed, fabricated, erected, and operated in such a way that the release of radioactive materials to the environment does not exceed the limits and guideline values of applicable government regulations pertaining to the release of radioactive materials for normal operations, and for abnormal transients and accidents. Safety-related systems are designed to permit safe plant operation and to accommodate postulated accidents without endangering the health and safety of the public.

1.2.2.2 System Design Criteria

1.2.2.2.1 Nuclear System Criteria

a. The fuel cladding is designed to retain integrity, so that any failures are within acceptable limits, as a radioactive material barrier for the design power range and for any abnormal transient.

b. Those portions of the nuclear system that form part of the nuclear system process barrier are designed to retain integrity as a radioactive material barrier during normal operation and following abnormal operational transients and accidents.

c. Heat removal systems are provided to remove heat generated in the reactor core for the full range of normal operational conditions from shutdown to design power,

and for any abnormal operational transient. Heat removal systems are provided to remove decay heat generated in the core under remote circumstances where the normal operational heat removal systems become inoperative. The capacity of such systems is adequate to prevent fuel cladding damage.

d. The reactor core and reactivity control systems are designed so that control rod action is capable of bringing the core subcritical and maintaining it so, even with the rod of highest reactivity worth fully withdrawn and unavailable for insertion.

e. Backup reactor shutdown capability is provided independent of normal reactivity control provisions. This backup system has the capability to shut down the reactor from any operating condition, and subsequently to maintain the shutdown condition.

f. The nuclear system is designed so there is no tendency for divergent oscillation of any operating characteristics through hardware and administrative controls, considering the interaction of the nuclear system with other appropriate plant systems.

g. The reactor core is designed so that its nuclear characteristics do not contribute to a divergent power transient through hardware and administrative controls .

1.2.2.2.2 Safety-Related Systems Criteria

1.2.2.2.2.1 General

a. Safety systems act in response to abnormal operational transients so that fuel cladding retains its integrity as a radioactive material barrier to keep any failures within acceptable limits.

b. Safety systems and ESF act to ensure that no damage to the nuclear system process barrier results from internal pressures caused by abnormal operational transients or accidents.

c. Where positive, precise actions are immediately required in response to accidents, these actions are automatic and require no decision or manipulation of controls by operations personnel.

d. Essential safety actions are carried out by equipment of sufficient redundancy and independence so that no single failure of active components prevents the required actions. For systems or components to which IEEE 279 and/or IEEE 308 are applicable, single failures of passive electrical components are considered as well as single failures of active components in recognition of the higher anticipated failure rates of passive electrical components relative to passive mechanical components.

e. Features of the station that are essential to the mitigation of accident consequences are designed, fabricated, and erected to quality standards that reflect the importance of the safety function to be performed.

f. The design of safety systems and ESF includes allowances for environmental phenomena at the site.

g. Provision is made for control of active components of nuclear safety systems and ESF from the control room.

h. Safety systems and ESF are designed to permit demonstration of their functional performance requirements.

1.2.2.2.2.2 Containment and Isolation Criteria

a. A primary containment is provided to completely enclose the reactor vessel. It is designed to act as a radioactive material barrier during accidents that release radioactive material into the primary containment. It is possible to test the primary containment integrity and leak-tightness at periodic intervals.

b. A secondary containment that completely encloses both the primary containment and fuel storage areas is provided and designed to act as a radioactive material barrier.

c. The primary and secondary containments, in conjunction with other ESF, act to prevent radioactive material released from the containment volumes from exceeding the guideline values of applicable regulations.

d. Provisions are made for the removal of energy from within the primary containment as necessary to maintain the integrity of the containment system following accidents that release energy to the primary containment.

e. Piping that both penetrates the primary containment structure and could serve as a path for the uncontrolled release of radioactive material to the environs is automatically isolated whenever such uncontrolled radioactive material release is threatened. Such isolation is effected in time to prevent radiological effects from exceeding the guideline values of applicable regulations.

1.2.2.2.2.3 Emergency Core Cooling Systems Criteria

a. The ECCS is provided to prevent excessive fuel clad temperature as a result of a LOCA.

b. The ECCS provides for continuity of core cooling over the complete range of postulated break sizes in the nuclear system process barrier.

c. The ECCS is diverse, reliable, and redundant.

d. Operation of the ECCS is initiated automatically when required, regardless of the availability of offsite power supplies and the normal generating system of the plant.

1.2.2.2.3 Process Control Systems Criteria

1.2.2.2.3.1 Nuclear System Process Control Criteria

a. Control equipment is provided for recirculation flow control to allow the operator to respond manually to load changes.

b. It is possible to manually control the reactor power level.

c. Control of the nuclear system is possible from a single location.

d. Nuclear system process controls are arranged to allow the operator to rapidly assess the condition of the nuclear system and to locate process system malfunctions.

e. Interlocks or other automatic equipment are provided as a backup to procedural controls to avoid conditions requiring the actuation of nuclear safety systems or ESF.

f. If the control room is inaccessible, it is possible to bring the reactor from power range operation to a cold shutdown condition by manipulation of controls and equipment that are available outside of the control room.

1.2.2.2.3.2 Power Conversion Systems Process Control and Instrumentation Criteria

a. Controls are provided to maintain temperature and pressure to below design limitations. These systems result in a stable operation and response for all allowable variations.

b. Controls and instrumentation are designed to provide equipment protection, indication, and alarm in the event of power conversion system trouble.

c. Control of the power conversion system is possible from locations accessible during normal operation.

d. Controls are provided to ensure adequate cooling of power conversion system equipment.

e. Controls are provided to ensure adequate condensate purity.

f. Controls are provided to regulate the supply of water so that adequate reactor vessel water level is maintained.

1.2.2.2.3.3 Electrical Power Systems Process Control Criteria

a. Controls are provided to ensure that sufficient electrical power is provided for startup, normal operation, and to attain prompt shutdown and continued maintenance of the station in a safe condition.

b. Control of the electrical power system is possible from locations accessible during normal operation.

1.2.2.2.4 Power Conversion Systems Criteria

a. The power conversion system components are designed to produce electrical power from the steam coming from the reactor, condense the steam into water, and return the water to the reactor as heated feedwater, with a major portion of its gases and particulate impurities removed.

b. The power conversion system components are designed to ensure that fission products or radioactivity associated with the steam and condensate are safely contained inside the system or are released under controlled conditions in accordance with waste disposal procedures and the plant Technical Specifications.

1.2.2.2.5 Electrical Power Systems Criteria

a. The station electrical power systems are designed to efficiently deliver the electrical power generated.

b. Sufficient normal and standby auxiliary sources of electrical power are provided to attain prompt shutdown and continued maintenance of the station in a safe condition. The capacity of the power sources is adequate to accomplish all required ESF under postulated DBA conditions.

1.2.2.2.6 Auxiliary Systems Criteria

a. Fuel handling and storage facilities are designed to prevent criticality and to maintain adequate shielding and cooling for spent fuel.

b. Multiple independent station auxiliary systems are provided for the purpose of cooling and servicing the station, the reactor, and the station containment systems under various normal and abnormal conditions.

c. Auxiliary systems that are not required to effect safe shutdown of the reactor or maintain it in a safe condition are designed so that a failure of these systems does not prevent the essential systems from performing their design functions.

1.2.2.2.7 Radioactive Waste Management Systems Criteria

a. Gaseous, liquid, and solid waste management facilities are designed so that the discharge of radioactive effluents and offsite shipment of radioactive materials are made in accordance with applicable regulations.

b. The waste management systems, design includes means of informing station operations personnel whenever operational limits on the release of radioactive material are exceeded.

1.2.2.2.8 Shielding and Access Control Criteria

a. Radiation shielding is provided, and access control patterns are established, to allow the operating staff to control radiation doses within the limits of applicable regulations in any mode of normal station operation.

b. The control room is shielded against radiation and has suitable environmental control so that occupancy under DBA conditions is possible.

1.2.2.2.9 Fuel Handling and Storage Facilities

Fuel handling and storage facilities are located in the refueling area (Zone III) of the secondary containment and are designed to preclude criticality and to maintain adequate shielding and cooling for spent fuel.

1.2.3 GENERAL ARRANGEMENT OF STRUCTURES AND EQUIPMENT

The principal structures are listed below:

a. Main power block comprised of the following:
    1. Two reactor enclosures with common refueling area
    2. Two turbine enclosures with common operating floor
    3. One control structure with common control room
    4. Two diesel generator enclosures
    5. One radwaste enclosure
    6. One chemistry laboratory expansion
    7. One administration building
    8. One auxiliary boiler enclosure
    9. One warehouse and shop
b. One circulating water pump structure
c. Two cooling towers with two acid/chlorine enclosures and a common valve and meter pit
d. One spray pond and spray pond pump structure
e. One Schuylkill pump structure
f. One Perkiomen pump structure
g. One water treatment enclosure
h. One fuel oil pump structure
i. One sewage treatment plant

The arrangement of structures on the site is shown in drawing C-2. The general arrangements for the major power block structures and the spray pond pump structure are shown in drawings M-110, M-111, M-112, M-113, M-114, M-115, M-116, M-117, M-118, M-119, M-120, M-121,M-122, M-123, M-124, M-125, M-126, M-127, M-128, M-129, M-130, M-131, M-132, M-133, M-134, M-135, M-136, M-137, M-138, M-140, M-141, M-142, M-143, M-144, M-145, M-146, M-388, M-389, and M-390. The layout of piping and equipment within the reactor enclosure and primary containment is shown in drawings M-206, M-207, M-208, M-209, M-210, M-211, M-213, M-215, M-217, M-218, M-219, M-220, M-221, M-222, M-223, M-225, M-226, M-227, M-228, M-229, M-230, M-231, M-232, M-234, M-235, M-236, M-237, M-238, M-239, M-240, M-241, M-242, M-246, M-288, M-289, M-290, M-291, M-292, M-293, M-295, M-296, M-297, M-298, M-299, M-300, M-301, M-302, M-303, M-305, M-306, M-307, M-308, M-309, M-310, M-311, M-312, M-313, M-316, M-317, M-318, M-319, M-320, M-321, M-322, M-323, and M-326.

1.2.4 SYSTEM DESCRIPTION

A summary of the systems provided for LGS is provided below.

1.2.4.1 Nuclear System

The nuclear system includes a single-cycle, forced circulation, GE BWR producing steam for direct use in the steam turbine. A heat balance showing the major parameters of the nuclear system for the rated power condition is shown in Figure 1.2-84.

1.2.4.1.1 Reactor Core and Control Rods

The fuel for the reactor core consists of slightly enriched uranium dioxide pellets contained in sealed Zircaloy-2 fuel rods. These fuel rods are assembled into individual fuel assemblies. Gross control of the core is achieved by movable, bottom-entry control rods. The control rods are of cruciform shape and are dispersed throughout the lattice of fuel assemblies. The rods are controlled by individual hydraulic systems.

1.2.4.1.2 Reactor Vessel and Internals

The reactor vessel contains the core and supporting structure; the steam separators and dryers; the jet pumps; the control rod guide tubes; distribution lines for the feedwater, and core spray; the incore instrumentation; and other components. The main connections to the vessel include the steam lines, the coolant recirculation lines, the feedwater lines, the CRD and nuclear instrumentation housings, and the ECCS lines.

The reactor vessel is designed and fabricated in accordance with applicable codes for a pressure of 1250 psig. The nominal operating pressure is 1060 psia in the steam space above the separators. The vessel is fabricated of carbon steel and is clad internally with stainless steel (except for the top head which is not clad).

The reactor core is cooled by demineralized feedwater that enters the lower portion of the core and is heated as it flows upward around the fuel rods. The steam leaving the core is dried by steam separators and dryers located in the upper portion of the reactor vessel. The steam is then directed to the turbine through four main steam lines. Each steam line is provided with two isolation valves in series, one on each side of the primary containment barrier.

1.2.4.1.3 Reactor Recirculation System

The reactor recirculation system consists of two recirculation pump loops external to the reactor vessel. These loops provide the piping path for the driving flow of water to the reactor vessel jet pumps that provide a continuous internal circulation path for the major portion of the core coolant flow. Each loop has one motor-driven recirculation pump. Recirculation pump speed can be varied to allow some control of reactor power level through the effects of coolant flow rate on moderator void content.

1.2.4.1.4 Residual Heat Removal System

The RHR system consists of pumps, heat exchangers, and piping that fulfill the following functions:

a. Removal of decay and sensible heat during and after plant shutdown

b. Injection of water into the reactor vessel following a LOCA, to reflood the core independent of other core cooling systems. This is discussed Section 1.2.4.2.13.

c. Removal of heat from the primary containment following a LOCA to limit the increase in primary containment pressure. This is accomplished by cooling and

recirculating the suppression pool water (containment cooling) and by spraying the drywell and suppression pool air spaces (containment spray) with suppression pool water.

1.2.4.1.5 Reactor Water Cleanup System

A RWCU system is provided to clean up the reactor cooling water, to reduce the amounts of activated corrosion products in the water, and to remove excess reactor coolant from the nuclear system under controlled conditions.

1.2.4.1.6 Nuclear Leak Detection System

The nuclear leak detection and monitoring system consists of temperature, pressure, flow, and fission product sensors with associated instrumentation and alarms. This system detects and annunciates leakage in the following systems:

a. Main steam lines

b. RWCU system

c. RHR system

d. RCIC system

e. Feedwater system

f. ECCS systems

g. Miscellaneous systems

Small leaks generally are detected by monitoring the temperature, radiation levels, and drain sump fill-up and pump-out rates. Large leaks are also detected by changes in reactor water level and changes in flow rates in process lines.

1.2.4.2 Safety-Related Systems

Safety-related systems provide actions necessary to assure safe shutdown, to protect the integrity of radioactive material barriers, and/or to prevent the release of radioactive material in excess of allowable dose limits. These systems can be components, groups of components, systems, or groups of systems. ESF systems are included in this category. ESF systems function to mitigate the consequences of DBAs.

1.2.4.2.1 Reactor Protection System

The RPS initiates a rapid, automatic shutdown (scram) of the reactor. This action is taken in time to prevent excessive fuel cladding temperatures and any nuclear system process barrier damage following abnormal operational transients. The RPS overrides all operator actions and process controls.

1.2.4.2.2 Neutron Monitoring System

Those portions of the NMS that are part of the RPS are safety-related. The IRM and APRM monitor neutron flux via incore detectors and provide scram logic inputs to the RPS to initiate a scram in time to prevent excessive fuel clad damage as a result of overpower transients (Upscale neutron flux), upscale simulated thermal power, and OPRM upscale are conditions that provide scram logic signals.

1.2.4.2.3 Control Rod Drive System

When a scram is initiated by the RPS, the CRD system inserts the negative reactivity necessary to shut down the reactor. Each control rod is controlled individually by a hydraulic control unit. When a scram signal is received, high pressure water from an accumulator for each rod forces each control rod rapidly into the core.

1.2.4.2.4 Control Rod Velocity Limiter

A control rod velocity limiter is a part of each control rod and limits the velocity at which a control rod can fall out of the core should it become detached from its CRD. The rate of reactivity insertion resulting from a rod-drop accident is limited by this feature. The limiters contain no moving parts.

1.2.4.2.5 Control Rod Drive Housing Supports

CRD housing supports are located underneath the reactor vessel near the control rod housings. The supports limit the travel of a control rod in the event that a control rod housing is ruptured. The supports prevent a nuclear excursion as a result of a housing failure, thus protecting the fuel barrier.

1.2.4.2.6 Nuclear System Pressure Relief System

A pressure relief system, consisting of SRVs mounted on the main steam lines, prevents excessive pressure inside the nuclear system during operational transients or accidents.

1.2.4.2.7 Reactor Core Isolation Cooling System

The RCIC system provides makeup water to the reactor vessel whenever the vessel is isolated from the main condenser and feedwater system. The RCIC system uses a steam-driven turbine-pump unit and operates automatically in time, and with sufficient coolant flow, to maintain adequate reactor vessel water level for events defined in Section 5.4.6.1.

1.2.4.2.8 Primary Containment

A pressure-suppression primary containment houses the reactor vessel, the reactor coolant recirculation loops, and other branch connections of the reactor primary system. The pressure-suppression system consists of a drywell, a pressure-suppression chamber storing a large volume of water, a connecting vent system between the drywell and the water pool, isolation valves, containment cooling systems, and other service equipment. In the event of a process system piping failure within the drywell, reactor water and steam would be released into the drywell air space. The resulting increased drywell pressure would then force a mixture of air, steam, and water through the vents into the pool of water stored in the suppression chamber. The steam would condense rapidly in the suppression pool, resulting in a rapid pressure reduction in the drywell. Air transferred from the drywell to the suppression chamber pressurizes the suppression chamber and is subsequently vented to the drywell to equalize the pressure between the two

chambers. Cooling systems remove heat from the reactor core, the drywell, and from the water in the suppression chamber, thus providing continuous cooling of the primary containment under accident conditions. Appropriate isolation valves are actuated during this period to ensure containment of radioactive materials within the primary containment.

1.2.4.2.9 Primary Containment and Reactor Vessel Isolation Control System

The primary containment and reactor vessel isolation control system automatically initiates closure of isolation valves to close off all process lines that are potential leakage paths for radioactive material to the environs. This action is taken upon indication of a potential breach in the nuclear system process barrier.

1.2.4.2.10 Secondary Containment

Any leakage from the primary containment system is contained within the secondary containment system. This system includes the SGTS and the RERS. The secondary containment system is designed to minimize the release of airborne radioactive materials, and to provide for the controlled, filtered release of the reactor enclosure atmosphere under accident conditions.

1.2.4.2.11 Main Steam Isolation Valves

Although process lines that penetrate the primary containment, and offer a potential release path for radioactive material, are provided with redundant isolation capabilities, the main steam lines, because of their large size and large mass flow rates, are given special isolation consideration. Two automatic isolation valves, each powered by both pneumatic pressure and spring force, are provided in each main steam line. These valves fulfill the following objectives:

a. To prevent excessive damage to the fuel barrier by limiting the loss of reactor coolant from the reactor vessel resulting either from a major leak from the steam piping outside the primary containment, or from a malfunction of the pressure control system, resulting in excessive steam flow from the reactor vessel

b. To limit the release of radioactive materials, by closing the nuclear system process barrier, in case of a gross release of radioactive materials from the fuel to the reactor coolant and steam

c. To limit the release of radioactive materials by closing the primary containment barrier, in case of a major leak from the nuclear system inside the primary containment.

1.2.4.2.12 Main Steam Line Flow Restrictors

A venturi-type flow restrictor is installed in each steam line. These devices limit the loss of coolant from the reactor vessel and prevent uncovering of the core before the MSIVs are closed in case of a main steam line break.

1.2.4.2.13 Emergency Core Cooling Systems

Four independent core standby cooling systems are provided to maintain fuel clad temperatures below the limits of 10CFR50.46 in the event of a breach in the RCPB that results in a loss of reactor coolant. The four core standby cooling systems are as follows:

a. High Pressure Coolant Injection System

The HPCI system provides and maintains an adequate coolant inventory inside the reactor vessel to limit fuel clad temperatures as a result of postulated small breaks in the RCPB. A high pressure system is needed for such breaks because the reactor vessel depressurizes slowly, preventing low pressure systems from injecting coolant. The HPCI system includes a turbine-driven pump powered by reactor steam. The system is designed to accomplish its function on a short-term basis without reliance on plant auxiliary power supplies other than the dc power supply.

b. Automatic Depressurization System

The ADS acts to rapidly reduce reactor vessel pressure in a LOCA situation in which the HPCI system fails to maintain reactor vessel water level. The depressurization provided enables the low pressure ECCS to deliver cooling water to the reactor vessel. The ADS uses some of the relief valves that are part of the nuclear system pressure relief system. The automatic relief valves are arranged to open on conditions indicating that both a break in the nuclear system process barrier has occurred and the HPCI system is not delivering sufficient cooling water to the reactor vessel to maintain the water level above a preselected value. The ADS will not be activated unless either the core spray or the LPCI system is operating.

c. Core Spray System

The CS system consists of two independent pump loops that deliver cooling water to spray spargers over the core. The system is actuated by conditions indicating that a breach exists in the RCPB, but water is delivered to the core only after reactor vessel pressure is reduced. This system provides the capability to cool the fuel by spraying water on the core. Either loop functioning in conjunction with the ADS or HPCI can provide sufficient fuel cladding cooling following a LOCA.

d. Low Pressure Coolant Injection

LPCI is an operating mode of the RHR system. LPCI uses the pump loops of the RHR system to inject cooling water into the reactor system. LPCI is actuated by conditions indicating a breach in the RCPB, but water is delivered to the core only after reactor vessel pressure is reduced. LPCI operation provides the capability of core reflooding following a LOCA in time to maintain the fuel cladding below prescribed temperature limits.

1.2.4.2.14 Residual Heat Removal System (Containment Cooling)

The RHR system for containment cooling is placed in operation to limit the temperature of the water in the suppression pool and of the atmospheres in the drywell and suppression chamber following a design basis LOCA, to control the pool temperature during normal operation and to reduce the pool temperature following an isolation transient. In the containment cooling mode of operation, the RHR system pumps take suction from the suppression pool and deliver the water through the RHR system heat exchangers, where cooling takes place by transferring heat to the RHR service water system. The fluid is then discharged back to the suppression pool, the drywell or suppression chamber spray headers, or to the RPV.

1.2.4.2.15 Control Room Heating, Ventilating and Air Conditioning System

The control room HVAC system provides ventilation, cooling, and control of environmental conditions in the control room areas for the safety and comfort of operating personnel during normal operations and during postulated accident conditions. The system includes air filter units used to remove contaminants that are potentially present in the air following a postulated accident before introducing the air into the control room HVAC system.

1.2.4.2.16 Reactor Enclosure Recirculation System and Standby Gas Treatment System

Both the RERS and the SGTS service the secondary containment. The recirculation system has the capability of recirculating the reactor enclosure air volume prior to its discharge via the SGTS, following a LOCA. The SGTS has the capability of maintaining a negative pressure within the reactor enclosures and the refueling area zones of the secondary containment with respect to the outside atmosphere. The air moving through the SGTS is filtered and discharged through the north exhaust stack.

1.2.4.2.17 Standby AC Power Supply

The standby ac power supply system consists of four diesel generator sets per unit. The diesel generators are sized so that any three diesels can supply all the necessary power requirements for one unit in the DBA condition. The diesel generators are designed to start and be able to accept load within 10 seconds. Four independent 4 kV ESF switchgear assemblies are provided for each reactor unit. Each diesel generator feeds an independent 4 kV bus for each reactor unit.

Each diesel generator starts automatically upon LOOP or detection of a LOCA. The necessary safety-related loads are applied in a preset time sequence. Each generator operates independently and without paralleling during a LOOP or LOCA signal.

1.2.4.2.18 DC Power Supply

Each unit is provided with two independent Class 1E 125/250V, two independent Class 1E 125V, one non-Class 1E 125/250V, and one non-Class 1E 250V DC systems. The systems are provided to supply station DC control power, DC power to diesel generators, their associated switchgear, ESF systems, and DC motor driven pumps and valves.

The Class 1E DC systems are designed to supply power adequate to satisfy the safety-related load requirements of the unit with the postulated LOOP and any concurrent signal failure in the DC system.

1.2.4.2.19 Residual Heat Removal Service Water System

The purpose of the RHRSW system is to provide a reliable supply of cooling water for heat removal from the RHR system during normal shutdown operations and under postaccident conditions. It can also supply a source of water if postaccident flooding of the primary containment is required.

The system consists of two independent loops, each of 100% capacity, supplying one RHR heat exchanger in each unit. During postaccident conditions the system uses the common spray pond as the heat sink. Interconnections are provided to allow use of a cooling tower as a heat sink during normal operations and, if conditions permit, during postaccident operation.

1.2.4.2.20 Emergency Service Water System

The purpose of the ESW system is to provide a reliable supply of cooling water to emergency equipment during LOOP and postaccident conditions.

The system consists of two independent loops. Each loop supplies corresponding safety-related equipment in each unit. The safety- related cooling loads consist of equipment room coolers, control room chillers, and the RHR pump coolers.

ESW for the diesel generators is supplied by either loop. The ESW system uses the common spray pond as a heat sink. Interconnections are provided to allow use of a cooling tower as a heat sink if conditions permit.

1.2.4.2.21 Main Steam Line Radiation Monitoring System

The MSL-RMS consists of four gamma radiation monitors located external to the main steam lines just outside of the primary containment. The monitors are designed to detect a gross release of fission products from the fuel. Upon detection of high radiation, an alarm signal is initiated by the monitors.

1.2.4.2.22 Reactor Enclosure and Refueling Area Ventilation Radiation Monitoring System

The REVE-RMS and RAVE-RMS consists of a number of radiation monitors arranged to monitor the activity level of the ventilation exhaust from the reactor enclosure and refueling area. Upon detection of high radiation, the affected area is automatically isolated and the SGTS and RERS (for reactor enclosure only) are started.

1.2.4.2.23 Remote Shutdown System

A remote shutdown panel and associated procedures are provided for each unit so that the plant can be maintained in a safe shutdown condition in the event that the control room becomes uninhabitable.

1.2.4.2.24 Standby Liquid Control System

Although not intended to provide rapid reactor shutdown, the SLCS provides a redundant, independent, and alternate way to bring the reactor subcritical and to maintain it subcritical as the reactor cools. The system makes possible an orderly and safe shutdown in the event that not enough control rods can be inserted into the reactor core to accomplish normal shutdown. The system is sized to counteract the positive reactivity effect from rated power to the cold shutdown condition. The SLCS also provides pH control for the primary containment water inventory following a LOCA.

1.2.4.2.25 Deleted.

1.2.4.2.26 Redundant Reactivity Control System

The RRCS is designed to provide a redundant and diverse method of shutting down the reactor, in the unlikely event that the RPS does not scram the reactor as a result of an anticipated operating transient. The RRCS logic is initiated when either the high reactor pressure or low reactor water

level setpoints are reached. A signal is then sent to open the ARI valves that vent the CRD scram air header to insert the control rods into the reactor. A signal is also transmitted to the RPT breakers to trip the reactor recirculation pumps to reduce the reactor power. An initiation of the RRCS logic by high reactor pressure will cause the feedwater pumps to automatically runback. If reactor power has not decreased to a predetermined level, within a specified period of time, the RRCS logic will initiate a feedwater runback and the injection of a neutron poison solution into the reactor, via the SLCS, and shut down the reactor.

The system consists of control panels, their associated ATWS detection and actuation logic, and the necessary interface logic to the recirculation system, the feedwater system, the SLCS, the RWCU system and the ARI components of the CRD system required to perform specific functions in response to an ATWS event.

1.2.4.3 Instrumentation and Control Systems

1.2.4.3.1 Nuclear System Process Control and Instrumentation

1.2.4.3.1.1 Reactor Manual Control System

The reactor manual control system provides the means by which control rods are positioned from the control room for power control. The system operates valves in the CRD hydraulic system to control rod position. Only one control rod can be manipulated at a time. The reactor manual control system includes the logic that restricts control rod movement (rod block) under certain conditions as a backup to procedural controls.

1.2.4.3.1.2 Recirculation Flow Control System

The recirculation flow control system controls the speed of the reactor recirculation pumps. Adjusting the pump speed changes the coolant flow rate through the core. This effects changes in core power level. The system is operated manually to match reactor power output to the load demand by adjusting the frequency of the electrical power supply for the reactor recirculation pumps.

1.2.4.3.1.3 Neutron Monitoring System

The NMS is a system of incore neutron detectors and electronic monitoring equipment. The system provides indication of neutron flux that can be correlated to thermal power level for the entire range of flux conditions that may exist in the core. The SRM and IRM provide flux level indications during reactor startup and low power operation. The LPRM and APRM allow assessment of local and overall flux conditions during power range operation. The TIP system provides a means to calibrate the individual LPRMs utilizing a gamma-measuring probe. The NMS provides inputs to the reactor manual control system to initiate rod blocks if preset alarm flux limits are exceeded, and inputs to the RPS to initiate a scram if trip limits are exceeded.

1.2.4.3.1.4 Refueling Interlocks

A system of interlocks, restricting the movements of refueling equipment and control rods when the reactor is in the refueling and startup modes, is provided to prevent an inadvertent criticality during refueling operations. The interlocks back up procedural controls that have the same objective. The interlocks affect the refueling platform, the refueling platform hoists, the fuel grapple, and control rods.

1.2.4.3.1.5 Reactor Vessel Instrumentation

In addition to instrumentation provided for the nuclear safety systems and ESF, instrumentation is provided to monitor and transmit information that can be used to assess conditions existing inside the reactor vessel and the physical condition of the vessel itself. The instrumentation provided monitors reactor vessel pressure, water level, temperature, internal differential pressures and coolant flow rates, and top head flange leakage.

1.2.4.3.1.6 Deleted

1.2.4.3.1.7 Plant Monitoring System

The PMS is a centralized, integrated system which performs the process monitoring and calculation that are necessary for the effective evaluation of normal and emergency power plant operation. The PMS acquires and records process data (e.g., temperatures, pressures, flows, status indicators) to produce displays, logs, and plots of current or historical plant performance which are presented to plant personnel in the plant main control room.

1.2.4.3.1.8 Rod Worth Minimizer

The RWM monitors and enforces adherence to established low power level rod insert and withdraw sequences. This function prevents the operator from establishing control rod patterns that are not consistent with the prescribed sequence by initiating the appropriate rod insert and withdraw block. When RWM is inoperable both insert and withdraw blocks are enforced unless the RWM is bypassed. The RWM enforces control rod sequences designed to limit individual control rod worths to acceptable levels as determined by the rod-drop accident design basis.

1.2.4.3.2 Power Conversion Systems Process Control and Instrumentation

1.2.4.3.2.1 Pressure Regulator and Turbine-Generator Control

The pressure regulator controls the turbine control and turbine bypass valves to maintain the nuclear system pressure essentially constant.

The turbine-generator speed-load control is set above the desired load and grid generator frequency. Load changes are made by the operator by adjusting the reactor recirculation flow control system and control rods.

The turbine-generator speed-load controls initiate rapid closure of the turbine control valves (rapid opening of the turbine bypass valves) to prevent turbine overspeed on loss of the generator electric load.

1.2.4.3.2.2 Feedwater System Control

A three-element control system regulates the feedwater system so that proper water level is maintained in the reactor vessel. Signals used by the control system are main steam flow rate, reactor vessel water level, and feedwater flow rate. The feedwater control signal is used to control the speed of the steam turbine-driven feedwater pumps.

1.2.4.3.2.3 Electrical Power System Control

Controls for the electrical power system are located in the control room to permit safe startup, operation, and shutdown of the plant.

1.2.4.4 Electrical Systems

1.2.4.4.1 Transmission and Generation Systems

Redundant sources of offsite power are provided to each unit by separate transmission lines to ensure that no single failure of any active component can prevent a safe and orderly shutdown. Each unit is provided with an independent substation, which is 220 kV for Unit 1 and 500 kV for Unit 2. The substations are connected by an autotransformer and ultimately feed into the PJM interconnection through the 220 kV and 500 kV transmission systems. Two independent offsite sources provide auxiliary power for startup and for operating the safety-related systems.

The main generator for each unit is an 1800 rpm, 3 phase, 60 Hz synchronous unit rated at 1264.97 MVA. Each generator is connected directly to the turbine shaft and is equipped with an excitation system coupled directly to the generator shaft. Power from the generators is stepped up from 22-220 kV on Unit 1 from 22-500 kV on Unit 2 by the unit main transformers and supplied by overhead lines to the 220 kV and 500 kV switchyards, respectively.

1.2.4.4.2 Electric Power Distribution Systems

The electric power distribution system includes Class 1E and non- Class 1E ac and dc power systems. The Class 1E power system supplies all safety-related equipment, while the non-Class 1E system supplies the balance of plant equipment.

The Class 1E ac system for each unit consists of four independent load groups. Two independent offsite power systems provide the normal electric power to these groups. Each load group includes a 4 kV switchgear, a 440 V load center, 440 V MCCs, and 120 V control and instrument power panels. The vital ac instrumentation and control power supply systems include battery systems and static inverters.

There are four independent diesel generator sets for each unit. Each diesel generator is provided as a standby source of power for one of the four Class 1E ac load groups in each unit. Assuming the total LOOP and failure of one diesel generator, the remaining diesel generators have sufficient capacity to operate all the equipment necessary to prevent undue risk to public health and safety in the event of a DBA on one unit and an emergency shutdown of the second unit.

The non-Class 1E ac system includes 13.2 kV switchgear, 2.3 kV switchgear, 440 V load centers, MCCs, and 120 V control and instrument power panels.

Two independent Class 1E 125 V dc batteries and two independent Class 1E 125/250 V dc batteries and associated battery chargers provide direct current power for the Class 1E dc loads of each unit. Power for non-Class 1E dc loads is supplied from 125/250 V and 250 V non-Class 1E batteries and associated battery chargers.

1.2.4.5 Fuel Handling and Storage Systems

1.2.4.5.1 New and Spent Fuel Storage

The fuel storage racks are designed to prevent load buckling and inadvertent criticality under dry and flooded conditions. Sufficient coolant and shielding are maintained to prevent overheating and excessive personnel exposure, respectively. New and spent fuel will be stored in the spent fuel pool in addition to spent fuel stored in the Independent Spent Fuel Storage Installation.

1.2.4.5.2 Fuel Pool Cooling and Cleanup System

The FPCC system is provided to remove decay heat from spent fuel stored in the fuel pool and to maintain specified water temperature, purity, clarity, and level.

1.2.4.5.3 Fuel Handling Equipment

The major fuel servicing and handling equipment includes the reactor enclosure cranes, refueling service platform, fuel and control rod servicing tools, fuel sipping and inspection devices, and other auxiliary servicing tools.

1.2.4.6 Cooling Water and Auxiliary Systems

1.2.4.6.1 Service Water System

The service water system supplies cooling water to equipment required for normal plant operation.

The system consists of three 50% capacity pumps with associated piping and valves. The cooling water supply to the pumps is taken from the cooling tower basin, while the water being returned from the system is discharged into the cooling tower.

1.2.4.6.2 Reactor Enclosure Cooling Water System

The RECW system is a closed-loop cooling water system that provides cooling water for miscellaneous reactor auxiliary plant equipment. The RECW system consists of two 100% capacity pumps, two 100% capacity heat exchangers, a head tank, chemical addition tank, associated piping, valves, and controls. One RECW pump is normally in service and the other pump is on automatic standby. During normal plant operation, heat is transferred from the RECW system to the service water system.

1.2.4.6.3 Turbine Enclosure Cooling Water System

The TECW system is a closed-loop cooling system that provides cooling water to the auxiliary plant equipment associated with the nuclear and power conversion systems in the turbine enclosure. The TECW system consists of two 100% capacity pumps, two 100% capacity heat exchangers, a head tank, chemical addition tank, and associated piping and valves. During normal plant operation, the TECW heat exchanger transfers heat from the TECW system to the service water system. One TECW pump is normally in service and the other pump is on automatic standby.

1.2.4.6.4 Fire Protection System

A fire protection system supplies fire fighting water to points throughout the plant. An automatic carbon dioxide protection system, in addition to portable fire extinguishers, is provided. An automatic halon fire protection system provides protection in the auxiliary electrical equipment room.

1.2.4.6.5 Plant Heating, Ventilating, and Air Conditioning Systems

The HVAC systems supply and circulate filtered fresh air for personnel comfort and equipment cooling.

1.2.4.6.6 Instrument Air System

The instrument air system supplies compressed air of suitable quality and pressure for power plant operation.

1.2.4.6.7 Clarified and Domestic Water Systems

The clarified and domestic water systems provide filtered, clarified water for plant and personnel use.

1.2.4.6.8 Demineralized Water Makeup System

A demineralized water makeup system is provided to furnish a supply of treated water suitable for use as makeup for the plant.

1.2.4.6.9 Plant Equipment and Floor Drainage System

The plant equipment and floor drainage system handles both radioactive and nonradioactive drains. Drains that can contain radioactive materials are pumped to the radwaste system for cleanup, reuse, or discharge. Nonradioactive drains are processed to remove oil and chemicals and then discharged to the environs.

1.2.4.6.10 Process Sampling System

The process sampling system is provided to monitor the operation of plant equipment and to provide information needed to make operational decisions.

1.2.4.6.11 Plant Communication System

The plant communication system provides communication between various plant structures and locations.

1.2.4.7 Power Conversion Systems

1.2.4.7.1 Turbine-Generator

The turbine-generator consists of the turbine, generator, exciter, controls, and required subsystems designed for a nominally rated MWe 1231.1.

The turbine is an 1800 rpm, tandem-compound, nonreheat steam turbine and an EHC system. The main turbine comprises one double-flow high pressure turbine and three double-flow low pressure turbines. Exhaust steam from the high pressure turbine passes through moisture separators before entering the three low pressure turbines.

The generator is a direct-driven, 3 phase, 60 Hz, 22,000 V, 1800 rpm, synchronous generator rated at 1265 MVA on the basis of guaranteed best turbine efficiency MW rating at an expected 0.973 power factor at 75 psig hydrogen pressure.

1.2.4.7.2 Main Steam System

The main steam system delivers steam from the nuclear boiler system via four 26 inch OD steam lines to the turbine-generator. This system also supplies steam to the SJAE, the RFPT, the main condenser hotwell at startup and low loads, and the steam seal evaporator.

1.2.4.7.3 Main Condenser

The main condenser system condenses and deaerates the exhaust steam from the main turbine and RFPT, and provides a heat sink for the turbine bypass system. The main condenser is a triple-pass, triple-pressure, deaerating-type with a reheating-deaerating hotwell and divided water boxes. The condenser consists of three sections with each section located below one of three low pressure turbines.

1.2.4.7.4 Main Condenser Evacuation System

The main condenser evacuation system removes the noncondensable gases from the main condenser. Two redundant SJAE are provided for air removal during normal operation, and one motor-driven vacuum pump is provided for air removal during startup.

1.2.4.7.5 Steam Seal System

The steam seal system provides clean, nonradioactive steam to the seals of the turbine valve packings and the turbine shaft packings. The sealing steam is supplied by the steam seal evaporator. The auxiliary boiler provides an auxiliary steam supply for startup and can be used as a backup to the steam seal evaporator, when available, during power operation.

1.2.4.7.6 Turbine Bypass and Pressure Control System

The turbine bypass and pressure control system provides control of the reactor pressure for the following operating modes:

a. During reactor heatup to rated pressure

b. While the turbine is being brought up to speed and synchronized

c. During normal power operation and transient power operation when the reactor steam generation exceeds the turbine steam requirements

d. When shutting down the reactor

1.2.4.7.7 Circulating Water System

The circulating water system is a closed-loop system designed to circulate the flow of water required to remove the heat load from the main condenser and auxiliary heat exchanger equipment and discharge it to the atmosphere through natural draft cooling towers.

1.2.4.7.8 Condensate Cleanup System

The function of the condensate cleanup system is to maintain the required purity of the feedwater to the reactor. The system consists of full flow condensate filter/demineralizers and deep bed condensate demineralizers. The condensate filter/demineralizers remove suspended solids from the condensate and feedwater streams. Downstream of and in series with the condensate filter/demineralizers, the deep bed condensate demineralizers use ion exchange resins that remove dissolved impurities from the feedwater. A bypass exists around one of the condensate filter/demineralizers to provide a means to control the iron/transition metal concentration in the reactor recirculation system. The deep bed condensate demineralizers also remove some of the radioactive material produced by corrosion as well as fission product carryover from the reactor.

1.2.4.7.9 Condensate and Feedwater Systems

The condensate and feedwater systems are designed to deliver the required feedwater flow to the reactor vessel during stable and transient operating conditions throughout the entire operating range from startup to full load to shutdown. The system operates using three condensate pumps to pump deaerated condensate from the hotwell of the main condenser through the SJAE condenser, the gland steam packing exhauster condenser, and then to the condensate cleanup system. The demineralized feedwater then flows through three parallel strings of low pressure feedwater heaters to the suction of three reactor feed pumps that deliver the feedwater through one set of three parallel high pressure heaters to the reactor.

1.2.4.7.10 Condensate and Refueling Water Storage Facilities

The condensate and refueling water storage facilities provide storage of condensate water for use in normal plant operations and refueling operations.

1.2.4.8 Radioactive Waste Systems

The radioactive waste systems are designed to confine the release of plant-produced radioactive material to well within the limits specified in 10CFR20 and 10CFR50, Appendix I. Various methods are used to achieve this end (e.g., collection, filtration, holdup for decay, dilution, and concentration). The pre-1994 10CFR20, Appendix B limits were used for the original licensing basis of the plant. Current liquid effluent releases are limited to ten-times the Effluent Concentration Limit (ECL) for each isotope specified in post-1994 10CFR20, Appendix B, Table 2, Column 2. Current gaseous and liquid effluent releases are controlled by the Radioactive Effluent Controls Program defined by the Technical Specifications.

1.2.4.8.1 Liquid Radwaste System

The liquid radwaste system collects, treats, stores, and disposes of radioactive liquid wastes. These wastes are collected in sumps and drain tanks at various locations throughout the plant and then transferred to the appropriate collection tanks in the radwaste enclosure prior to treatment, storage, and disposal. Processed liquid wastes are returned to the condensate system, packaged for offsite shipment, or discharged from the plant.

Equipment is selected, arranged, and shielded to permit operation, inspection, and maintenance within radiation allowances for personnel exposure. For example, tanks and processing equipment that will contain significant radiation sources are shielded and sumps, pumps, instruments, and valves are located in controlled access rooms or spaces. Processing equipment is selected and designed to require a minimum of maintenance.

Valving redundancy, instrumentation for detection, alarms of abnormal conditions, and procedural controls protect against the accidental discharge of liquid radioactive waste.

1.2.4.8.2 Solid Radwaste System

Solid wastes originating from nuclear system equipment are stored for radioactive decay in the fuel storage pool and prepared for reprocessing or offsite storage in approved shipping containers. Examples of these wastes are spent control rods, and incore ion chambers.

Process solid wastes are collected, dewatered, packaged, and stored in shielded compartments prior to offsite shipment. Examples of these solid wastes are filter residue, spent resins, paper, air filters, rags, and used clothing.

1.2.4.8.3 Gaseous Radwaste System

Radioactive gaseous wastes are discharged to the turbine enclosure vent via the gaseous radwaste system. This system provides hydrogen-oxygen recombination, filtration, and holdup of the offgases to ensure a low rate of release from the turbine enclosure vent.

The offgases from the main condenser are the greatest source of gaseous radioactive waste. The treatment of these gases reduces the released activity to well below permissible levels even with some defective fuel elements.

1.2.4.9 Radiation Monitoring and Control

1.2.4.9.1 Process Radiation Monitoring

Radiation monitors are provided on various lines to monitor and control radioactivity in process and effluent streams and to activate appropriate alarms and controls.

1.2.4.9.2 Area Radiation Monitors

Radiation monitors are provided to monitor for abnormal radiation at various locations in the plant. These monitors activate alarms when abnormal radiation levels are detected.

1.2.4.9.3 Site Environs Radiation Monitors

Radiation monitors are provided outside the plant structures to monitor radiation levels. These data are used for determining the contribution of plant operations to onsite and offsite radiation levels.

1.2.4.10 Shielding

Shielding is provided throughout the plant, as required, to reduce radiation levels to operating personnel and to the general public within the applicable limits set forth in 10CFR20, 10CFR50, and 10CFR50.67. It is also designed to protect certain plant components from radiation exposure resulting in unacceptable alterations of material properties or activation.

1.2.5 Control Of Unit 2 Construction Activities During Unit 1 Operation

To meet the requirements of 10CFR50.34(b)(6)(vii), an evaluation was performed which verified that safety-related structures, systems, and components of Unit 1 were protected from potential

hazards resulting from construction activities on Unit 2. This evaluation also identified the plant administrative and managerial controls required to provide assurance that technical specification limiting conditions for operation were not exceeded. Administrative and managerial controls existed in the form of design controls, procedures and training during the construction of Unit 2. The plant Technical Specifications were taken into consideration throughout the development of these controls. The Plant Operations Review Committee was not required to review the Unit 2 construction activity controls or the revisions thereto.

LGS utilizes a unitized design for safety-related structures and systems with only the following common structures and systems as exceptions: the control enclosure and supporting systems, spray pond, spray pond pumphouse and supporting systems, ESW system, RHRSW system, and SGTS. All portions of the Unit 1 systems and those common systems required for the safe operation and shutdown of Unit 1 were completed prior to Unit 1 fuel load. Unit 2 systems and structures required to assure that Unit 1 limiting conditions for operation were not exceeded had also been completed. A PAB that was maintained in accordance with an established separation program served to define the Unit 1 and common operations area. The PAB considered personnel access for both security and ALARA radiation exposure. The LGS security plan covered all aspects of Unit 1 and common security.

Administrative and managerial controls governed the activities associated with Unit 2 construction to prevent the safe operation of Unit 1 from being affected. Design controls, procedures, safety programs, or training sessions existed to ensure that the following areas were addressed during Unit 2 construction:

- Separation of Unit 1 and common safety-related systems and equipment (including those Unit 2 systems, structures, and equipment required for operation of Unit 1) from Unit 2 construction activities.

- Yard activities, such as excavation, blasting, grading, use of heavy equipment, and erection of structures, such that consideration is given to site drainage, protection of underground utilities, and Unit 1 operation.

- Maintenance of construction personnel radiation exposures as low as reasonably achievable.

- Minimizing the probability of the LOOP to Unit 1 due to Unit 2 construction activities.

- The control of the use of hazardous and toxic chemicals which may have been used during Unit 2 construction.

- The control of the use and storage of compressed gas cylinders which may have been used during Unit 2 construction such that Unit 1 was not jeopardized.

- Construction cranes were prevented from damaging Unit 1 and common structures and systems important to safety by governing placement and operation.

- Rigging and the movement of equipment was governed to ensure potential heavy load drops did not affect Unit 1 or common safe shutdown equipment.

- The safe operation of Unit 1 was maintained by considering the fire barrier, missile protection, radiation protection, pressure boundary, flood control, and security aspects of walls, ceilings and floors when construction openings were made.

- Use of safe onsite transportation and traffic practices.

- Fire protection programs were enforced and not affected by construction activities associated with Unit 2.

1.3 COMPARISON TABLES

1.3.1 COMPARISONS WITH SIMILAR FACILITY DESIGNS

This section highlights the principal design features of the plant and compares the major features with those of other BWR facilities. The design of this facility is based on proven technology attained during the development, design, construction, and operation of BWRs of similar types. The data, performance, characteristics, and other information presented here represent the original design, and licensed operating conditions.

The following tables summarize the plant design characteristics for LGS, PBAPS, SSES, and Zimmer Unit 1:

Table No.	System
1.3-1	Nuclear Steam Supply System
1.3-2	Engineered Safety Features and Auxiliary Systems
1.3-3	Power Conversion Systems
1.3-4	Containment
1.3-5	Structural Design
1.3-6	Radioactive Waste Management Systems
1.3-7	Electrical Power Systems

1.3.2 COMPARISON OF FINAL AND PRELIMINARY INFORMATION

Significant changes made in the facility design between the PSAR stage and the FSAR stage are listed in Table 1.3-8. Design changes are only those that have occurred since the last PSAR amendment. Notice of all other design changes has been given through amendments to the PSAR. Each item in Table 1.3-8 is cross-referenced to the appropriate section of the UFSAR which describes the present design.

Table 1.3-1
COMPARISON OF NUCLEAR STEAM SUPPLY SYSTEM DESIGN CHARACTERISTICS

	LGS*	SSES	ZIMMER 1	PBAPS
THERMAL AND HYDRAULIC DESIGN (Section 4.4)				
Rated power, MWt	3293	3293	2436	3293
Design power, MWt	3435	3439	2550	3440
Steam flow rate, lb/hr	14.159×10^6	13.48×10^6	10.477×10^6	13.381×10^6
Core coolant flow rate, lb/hr	100×10^6	100.5×10^6	100.5×10^6	102.5×10^6
Feedwater flow rate, lb/hr	14.127×10^6	13.44×10^6	10.447×10^6	10.447×10^6
Feedwater temperature, °F	420	383	420	376.1
System pressure, nominal in steam dome, psia	1020	1020	1020	1020
Average power density, kW/liter	48.7	48.7	50.51	50.8
Maximum linear heat generation rate, kW/ft	13.4	13.4	13.4	18.35
Average linear heat generation rate, kW/ft	5.3	5.3	5.4	7.049
Maximum heat flux, Btu/hr-ft^2	361,600	361,600	354,255	425,060
Average heat flux, Btu/hr-ft^2	144,100	143,700	144,032	163,230
Maximum uranium dioxide ($U0_2$) temperature, °F	3435	3435	3435	4430
Average volumetric fuel temperature, °F	2130	2130	2130	2780
Average fuel rod surface temperature, °F	566	566	566	560
Minimum critical power ratio (MCPR)	1.22	1.25	1.24	-
Coolant enthalpy at core inlet, Btu/lb	526.1	521.8	527.4	521.2
Core maximum exit voids within assemblies, %	77.1	76.6	75	79
Core average exit quality, % steam	14.1	13.2	13.2	13.2
Design power peaking factor(1)				
Maximum relative assembly power	1.4	1.4	1.4	1.4
Design power peaking factor(1)				
Maximum relative assembly power	1.4	1.4	1.4	1.4
Axial peaking factor	1.4	1.4	1.4	1.5
NUCLEAR DESIGN (FIRST CORE) (Section 4.3)				
Water/UO_2 volume ratio (cold, beginning of cycle [BOC])	2.74	2.80	2.55	2.43
Reactivity with strongest control rod out, k_{eff}	<0.99	<0.99	<0.99	<0.99

Table 1.3-1 (Cont'd)
COMPARISON OF NUCLEAR STEAM SUPPLY SYSTEM DESIGN CHARACTERISTICS

Recirculation pump flow rate, gpm	45,200	45,200	32,500	45,200
Number of jet pumps in reactor	20	20	20	20
MAIN STEAM LINES (Section 10.3)				
Number of steam lines	4	4	4	4
Design pressure, psig	1115	1250	1250	1115
Design temperature, °F	582	575	575	583
Pipe diameter, in	26	26	24	26
Pipe material	Carbon steel	Carbon steel	Carbon steel	Carbon steel

(1) Local and total peaking factors are not used as input to the thermal/hydraulic codes and are therefore not included here.
(2) Available values for PBAPS first core were developed on a different basis and are not directly comparable to LGS, SSES, or Zimmer 1.
(3) LGS Unit 1 will use 80 mil thick fuel channels beginning with refueling cycle 2.
LGS Unit 2 will use 80 mil thick fuel channels beginning with the initial core.

* Based on the original licensed operating conditions.

RADIOACTIVE WASTE MANAGEMENT SYSTEMS DESIGN CHARACTERISTICS

	LGS	SSES	ZIMMER 1	PBAPS
GASEOUS RADWASTE (See UFSAR Section 11.3				
Design bases, noble gases, Ci/sec	100, 000 at 30 min	100, 000 at 30 min	100, 000 at 30 min	100, 000 at 30 min
Process treatment	Recombiner and ambient charcoal delay	Recombiner and ambient charcoal delay	Chilled charcoal	Recombiner
Design condenser inleakage, cfm	75	30	12.5	54
Release point-height above ground, ft	197	201	172	500
LIQUID RADWASTE (See UFSAR Section 11.2)				
Treatment of:				
Floor drains	F, D, R	F, D, R	F, E, R	F, O
Equipment drains	F, D, R	F, D, R	F, D, R	F, D, R
Chemical drains	F, D, R	E, D concentrates to solid radwaste, distillate R	E, D concentrates to solid radwaste, distillate R	Neutralized radwaste, F, O
Laundry drains	F, O	Diluted and sent to circulating water discharge	Reverse osmosis discharge	F, O

(1) Legend:
D = demineralized
F = filtered
E = evaporator/concentrator
R = recycled, i.e., returned to condensate storage
O = discharged

Table 1.3-7

COMPARISON OF ELECTRICAL POWER SYSTEMS DESIGN CHARACTERISTICS

	LGS	SSES	ZIMMER 1	PBAPS
TRANSMISSION SYSTEM (See UFSAR Section 8.2)				
Outgoing lines, number-rating	3-500 kV 2-230 kV	1-230 kV (Unit 1) 1-500 kV (Unit 2)	3-345 kV	4.500 kV
NORMAL AUXILIARY AC POWER (See UFSAR Sections 8.2 and 8.3)				
Incoming lines, number-rating	3-500 kV 2-230 kV	2.230 kV (common to both units)	1-69 kV 1-345 kV	1-230 kV 13.8 kV
Auxiliary transformers, number	2	1 per unit	1(unit auxiliary)	2
Startup transformers, numbers	2	2 (common to both units)	2	2
Safeguard transformers, numbers	2 + 1 spare	-	-	2
STANDBY AC POWER SUPPLY (See UFSAR Section 8.3)				
Number of diesel generators	8	4 (common to both units)	3	4
Number of 4160 V shutdown buses	8	4 per unit	3	8
Number of 480 V shutdown buses	8	4 load centers and 8 MCCS per unit; 8 MCCs common to both units	8	8

Table 1.3-7 (Cont'd)

	LGS*	SSES	ZIMMER 1	PBAPS
DC POWER SUPPLY (See UFSAR Section 8.3)				
Number of 125 V or 250 V batteries	4-125 V 6-125/250 V 2-250 V	4-125 V per unit 2-250 V per unit	3-125 V 1-250 V	4-125/250 V 2-250 V
Number of 125 V buses	33	4 per unit	3	8
Number of 250 V buses	8 buses and 8 MCCs	2 load centers and 3 MCCs per unit	1	8

Table 1.3-8

SIGNIFICANT DESIGN CHANGES FROM PSAR TO FSAR

ITEM	CHANGE	REASON FOR CHANGE	UFSAR SECTION IN WHICH SUBJECT IS DISCUSSED
Nuclear fuel	The arrangement of fuel rods in each fuel bundle was changed from 7x7 to 8x8.	This change improves fuel performance by increasing safety margins.	4.2
Nuclear pressure relief system	The two safety valves were deleted and the number of relief valves was increased from 11 to 14.	This change improves the pressure suppression capability of the nuclear relief system.	5.2.2
Feedwater sparger	The design of the thermal sleeve connecting the sparger to the reactor vessel has been changed.	This change eliminated the possibility of vibration and leakage.	5.3
Reactor recirculation system	The 4 inch bypass line around the recirculation pump discharge valve has been deleted.	This changed improves the integrity and reliability of the recirculation loop.	5.4
Process sensors	The monitoring devices of process parameters have been changed (e.g., pressure, level, and flow) for the RPS and the ESF systems from process switches to transmitters and trip units.	This change improves testability.	7.2, 7.3
Main condenser low vacuum	The MSIV and main steam drain line isolation valves, rather than the turbine stop valves and turbine bypass valves, are automatically closed if there is loss of vacuum in the main condenser.	This eliminates reliance on the turbine control system for isolation of the main condenser from the main steam supply.	7.2, 7.3

Table 1.3-8 (Cont'd)

ITEM	CHANGE	REASON FOR CHANGE	UFSAR SECTION IN WHICH SUBJECT IS DISCUSSED
Standby ac power system	Bypassing of the following diesel generator trip signals, if there is a LOCA, has been added: a. Phase overcurrent b. Ground neutral overcurrent c. Ant-motoring d. Jacket coolant high temperature/low pressure e. Lube oil high temperature/low pressure	To conform with BTP ICSB 17.	
Control room HVAC system	The capability for total isolation and recirculation of control room atmosphere on toxic chemical detection signal has been added.	For conformance with Regulatory Guides 1.78 and 1.95.	6.4, 9.4.1
Reactor enclosure HVAC isolation	The requirement for complete closure of the isolation valves in the reactor enclosure normal exhaust duct before any contaminated air is released after its detection has been deleted. Isolation valves will trip in normal time on detection of airborne contamination.	The reactor enclosure normal exhaust system serves those areas of the reactor enclosure which have a low release potential. Releases of radioactivity during the short time period required for isolation valve closure would be a very small fraction of 10CFR50.67 guidelines.	9.4.2
Drywell unit coolers	Changed from two-speed to single fan motors of sufficient horsepower for LOCA operation and ILRT operation.	This change was made to obtain motors qualified for 340°F operation.	9.4.5

Table 1.3-8 (Cont'd)

ITEM	CHANGE	REASON FOR CHANGE	UFSAR SECTION IN WHICH SUBJECT IS DISCUSSED
Reactor enclosure and control structure HVAC systems	Added steam flooding isolation dampers	This prevents damage to safeguard equipment and protects personnel from pipe breaks outside containment.	9.4.2
Drywell HVAC duct-work	Added pressure relief valves	This prevents damage to ducts during LOCA pressure surge in drywell.	9.4.5
Mechanical vacuum pump	The pump exhaust was rerouted to the turbine equipment compartment exhaust duct leading to the charcoal filters and vent stack.	The charcoal filters will capture the iodine discharged from the vacuum pumps, as identified by EPRI Report NP-495.	9.4.4
Mechanical vacuum pump compartment	The room air exhaust was changed from nonfiltered to filtered exhaust.	The charcoal filters will capture iodine released to the room per EPRI Report NP-495.	9.444
Liquid Waste Management System	The radwaste evaporator system and associated equipment was not completely installed for plant operation.	Effective processing of chemical waste can be provided by the floor drain subsystem, thereby eliminating operational problems associated with evaporative processing.	11.2
Gaseous waste management system	Change the offgas treatment system from cryogenic distillation type to charcoal adsorption type.	The charcoal adsorption method provides advantages in reliability and maintainability, while limiting offsite doses to levels as low as or lower than can be achieved with the cryogenic distillation method.	11.3

Table 1.3-8 (Cont'd)

ITEM	CHANGE	REASON FOR CHANGE	UFSAR SECTION IN WHICH SUBJECT IS DISCUSSED
Solid radwaste management system	Because the evaporator was not completely installed for plant operation, a system for solidification of evaporator concentrates was also not installed.	Due to the previously described change in the liquid waste management system, the evaporator concentrates will not be produced. Dewatered resin wastes will be packaged in approved high integrity containers consistent with the requirements established by the South Carolina Department of Health and Environmental Control and will meet the intent of BTP ESTB 11-3. The vibrating hoppers were eliminated from system design because of anticipated operational problems and because they are not required for effective functioning of the solid radwaste system.	
Primary containment instrument gas system	A seismic Category I backup gas supply for operation of ADS valves has been added.	To allow for long-term operation of ADS valves to provide an alternate shutdown cooling path for conformance with Regulatory Guide 1.139. Also satisfies NUREG-0694 item.	9.3.1, 5.4.7, 1.13
Bypass leakage barrier design	Added vent lines to potential bypass leakage paths to vent to the secondary containment and added a feedwater fill system to maintain a wate seal on the feedwater lines.	To minimize leakage in order to minimize offsite doses in the event of a LOCA.	6.2.3
Residual heat removal system	Addes intertie piping and valves 'A' and 'B' and between RHR 'C' and 'D' discharge loops.	To allow use of RHR pumps 'B' and 'D' in conjunction with the RHR heat exchanger in the shutdown cooling mode for greater system flexibility during maintenance.	5.4

Table 1.3-8 (Cont'd)

ITEM	CHANGE	REASON FOR CHANGE	UFSAR SECTION IN WHICH SUBJECT IS DISCUSSED
Ultimate heat sink	Added soil-bentonite lining to the spray pond bottom and soil slopes.	To minimize construction delays in event that the potential for greater than expected seepage rates was found.	2.5, 9.2.6
Safeguard piping fill system	Provided a redundant safety-grade piping fill system.	To provide increased assurance that water hammer events will not occur during ECCS system startup.	6.3
Spent fuel pool	Added makeup water connections from the ESW System.	To provide Seismic Category I, safety-grade makeup water supply to the spent fuel pools to provide cooling in the event of loss of the spent fuel pool cooling system in conformance with Regulatory Guide 1.13.	9.1
Reactor recirculation system	Deleted recirculation loops equalizing line.	To improve the integrity and reliability of the recirculation loops.	5.4
Reactor coolant pressure boundary piping	Changed portions of the RHR LPCI, head spray, and shutdown cooling piping to type 316L stainless steel with less than 0.02% carbon. Changed recirculation loop piping to type 316K stainless steel.	To minimize potential for IGSCC.	5.2.3
Battery System	Added a non-Class IE battery to power non-Class IE dc loads.	To provide separation of Class 1E and non-Class 1E loads in conformance with Regulatory Guide 1.75	8.3

Table 1.3-8 (Cont'd)

ITEM	CHANGE	REASON FOR CHANGE	UFSAR SECTION IN WHICH SUBJECT IS DISCUSSED
Reactor enclosure recirculation system	RERS no longer recirculates air from the refueling area which is permanently separated from the reactor enclosure at el 352'. Refueling area now exhausts directly to the SGTS upon isolation.	Separation prevents the temperature and humidity of the refueling area from affecting the reactor enclosure below through RERS mixing, reduces the time for drawdown of the reactor enclosure by eliminating the possibility of mixing airborne activity through reactor enclosure 1, the refueling area, and reactor enclosure 2 following a LOCA.	9.4.2.1
Redundant Reactivity Control System	Added RRCS	To reduce the possibility of an ATWS event and the automatically mitigate the consequences of an ATWS event by independently monitoring the RPV dome pressure and water level and automatically initiating the ARI, RPT, SLCS flow and feedwater runback.	7.6.1.8 & 7.6.2.8
Alternate rod insertion	Added ARI solenoid valves to the scram valve pilot air header.	To provide independent solenoid valves to bleed air from the scram valve pilot air header on low water level or high dome pressure in the RPV when detected by the RRCS to increase the reliability of control rod insertion.	4.6.1.2.5.4
Recirculation Pump Trip	Added redundant trip breakers to the power supply to each reactor recirculation pump motor.	To trip the reactor recirculation pump motors in the event of high dome pressure or low water level in the RPV, and thereby reduce the reactor power level in the event of an ATWS.	7.1 & 7.6

Table 1.3-8 (Cont'd)

ITEM	CHANGE	REASON FOR CHANGE	UFSAR SECTION IN WHICH SUBJECT IS DISCUSSED
HPCI Flow Split	Added a cross connection so that HPCI flow is injected to the RPV through both the core spray and feedwater spargers.	To ensure adequate mixing of SLCS flow injected into the RPV.	6.3.2.2.1
Standby Liquid Control System	Added a third SLCS pump & explosive valve.	To permit increased SLCS maintenance flexibility.	9.3.5
Reactor Building Recirculation System	Added REPS Vent.	This vent is needed to allow simultaneous SGTS operation to the reactor enclosure and refueling area. The SGTS duct is seal welded to ensure RERS prefiltration after the RERS fan starts.	
Standby Gas Treatment System	SGTS filters have 8 inch deep charcoal adsorber with and assigned efficiency of 99.0% for removal of inorganic iodines.	The 8 inch deep SGTS charcoal adsorber provides a residence time 0.68 seconds after drawdown. This is sufficient to meet the filtering efficiency specified in table 2 of Regulatory Guide 1.52 (Rev 2).	6.5.1.1.2
Reactor Recirculation Pump Motor Power Supply	Both of the Unit 1 Recirculation Pump Motors Power Supplies have been changed from a Motor-Generator (MG) Set to an Adjustable Speed Drive (ASD).	The ASD is more reliable and efficient than the MG Set for controlling Reactor Recirculation Pump speed.	Table 1.3-8, 1.10-1, Table 3.2-1, Sect. 3.8.4.1.8, Sect. 4.4.3.3.2, 4.4.3.5, Table 5.2-3, Sect. 5.4.1.3, Table 5.4-1, Sect. 7.1.1.2, Table 7.1-1, Sect. 7.7.1.3.1.1, 7.7.1.3.2, 7.7.1.3.3.2.1, 7.7.1.3.3.3, 7.7.1.3.3.4, 7.7.1.3.3.4.3, 7.7.1.3.3.4.4, 7.7.1.3.3.4.5, 7.7.1.3.3.4.6, 7.7.1.3.3.4.7, 7.7.1.3.3.4.8, 7.7.1.3.3.5, 7.7.1.3.5.1, 7.7.1.3.5.2, 7.7.2.3.1, 7.7.2.3.3, Fig. 7.7-7, Sect. 8.1.6.1.12, Fig. 8.1-4, Table 8.3-28, Table 8.3-29,

Table 1.3-8 (Cont'd)

ITEM	CHANGE	REASON FOR CHANGE	UFSAR SECTION IN WHICH SUBJECT IS DISCUSSED
Reactor Recirculation Pump Motor Power Supply	Recirculation Pump Motor Power Supply has been changed from a Motor-Generator (MG) Set to an Adjustable Speed Drive (ASD) for Unit 2. The Unit 1 MG sets replacement was performed previously.	The ASD is more reliable and efficient to improve system response to perturbations and transients. In addition, the ASD units are designed to be tolerant to single failures	Sect. 9.4.4.1, 9.4.4.2.4, 9.5.1.2.3.2, 9.5.1.2.9, 9.5.1.2.12, Sect. 9A.2.3, 9A.2.12, 9A.5.8.12, Table 9A-1, Fig. 9A-8, Sect. 15.3.1.1.1, 15.3.2.1.1, 15.3.2.2.3, 15.3.2.3.3, 15.4.5.1.1, 15.4.5.2.1, 15.4.5.3.2, 15.9.6.3.3 Table 1.3-8, 1.10-1, Table 3.2-1, Sect. 3.8.4.1.8, Sect. 4.4.3.3.2, 4.4.3.5, Sect. 5.4.1.3, Table 5.4-1, Sect. 7.1.1.2, Table 7.1-1, Sect. 7.7.1.3.1.1, 7.7.1.3.2.1, 7.7.1.3.2.2, 7.7.1.3.3.2.1, 7.7.1.3.3.3.1, 7.7.1.3.3.3.2, 7.7.1.3.3.4.1, 7.7.1.3.3.4.2, 7.7.1.3.3.4.3, 7.7.1.3.3.4.4, 7.7.1.3.3.4.5, 7.7.1.3.3.4.6, 7.7.1.3.3.4.7, 7.7.1.3.3.4.8, 7.7.1.3.3.5, 7.7.1.3.5.1, 7.7.1.3.5.2, 7.7.2.3.1, 7.7.2.3.3, Fig. 7.7-7.1. 1.4 IDENTIFICATION OF AGENTS AND CONTRACTORS

1.4.1 APPLICANT

Exelon Generation Company, LLC (EGC) is the sole applicant for the utilization facility licenses and will operate the plant upon completion. Prime contractors and principal consultants are identified in Sections 1.4.2, through 1.4.5.

The Applicant has been responsible for the design and construction of, and currently operates, eight multi-unit fossil fuel power plants and one 2-unit nuclear power plant. Additionally, two large multi-unit hydroelectric generating plants, one of which is a pumped-storage plant, and several diesel engine and combustion turbine-driven generator installations have also been designed, constructed, and are currently being operated by the Applicant.

The Applicant also has an ownership interest in two operating fossil fuel plants and one operating nuclear power plant. These plants provide capacity and energy to the Applicant's system but are not operated by the Applicant.

These facilities, which had a net capacity of 8,197,600 KWe at the end of 1977, constitute the Applicant's electric generating system.

The Applicant has been active in the development of atomic energy for electric generation for many years. In 1952 it became a charter member of the Dow Chemical-Detroit Edison Nuclear Power Development Project, which subsequently became Atomic Power Development Associates, Inc. This organization designed and developed a fast breeder power reactor for the Atomic Energy Commission's Power Demonstration Program. The Applicant also took part in the formation of Power Reactor Development Company, which was organized to finance, construct, own, and operate the fast breeder reactor designed by Atomic Power Development Associates, Inc., for the Enrico Fermi Atomic Power Station.

The Applicant's engineers have had experience in many phases of nuclear projects including: assignments to Atomic Power Development Associates, Inc. for design and development of core and fuel elements, shielding design, coordination of research at various levels on the metallurgical and chemical aspects of fuel elements; shift supervisor duties and preoperational duties, including preparation of plant operation manuals, at the Enrico Fermi Atomic Power Station; assignment to Power Reactor Development Company for coordination of control instrumentation and electrical features; assignment to the Nautilus nuclear submarine project for field engineering and mechanical operations during startup and initial operation; assignment to the nuclear reactor at Shippingport, Pennsylvania, for training and operational duties; assignment to the Knolls Atomic Power Laboratory for participation in prototype design of a sodium boiler for a submarine reactor; construction, startup, operation, and decommissioning of PBAPS Unit 1, a 40,000 KWe capacity unit employing an HTGR; and construction, startup, operation, and maintenance of PBAPS Units 2 and 3, each unit consisting of a BWR having an original rated core thermal power of 3293 KWt and producing a corresponding net electrical output of 1065 MWe.

1.4.2 ARCHITECT-ENGINEER AND CONSTRUCTOR

The Applicant has retained Bechtel Power Corporation and Bechtel Construction, Inc. to provide architectural, engineering, construction, and startup services for LGS. In addition, Bechtel is responsible for procurement of equipment other than the NSSS, turbine-generators, and certain

other major components that have been purchased by the Applicant. Bechtel has been continuously engaged in engineering and construction activities since 1898. A review of recent tabulations of nuclear units in the continental United States that are planned, under construction, or in operation, indicates that Bechtel is responsible for the engineering design of approximately 60 of these units and, in addition, is charged with responsibility for construction of over 40 units. Bechtel is, therefore, eminently qualified to provide the required services for station design, equipment procurement, construction, and startup.

1.4.3 NUCLEAR STEAM SUPPLY SYSTEM SUPPLIER

GE has the contract to design, fabricate, and deliver the boiling water-type NSSS and nuclear fuel for LGS, as well as to provide technical direction for installation and startup of these systems. GE has been engaged in the development, design, construction, and operation of boiling water reactors since 1955. A review of recent tabulations of nuclear units in the United States that are planned, under construction, or in operation, reveals that approximately 65 of these units employ GE BWRs. Thus, GE has substantial experience, knowledge, and capability to design, manufacture, and furnish technical assistance for the installation and startup of the LGS NSSS.

1.4.4 TURBINE-GENERATOR SUPPLIER

GE was the original contractor to design, fabricate, and deliver the turbine-generators for LGS, as well as to provide technical assistance for installation and startup of this equipment. GE has a long history in the application of turbine-generators to nuclear power stations dating back to 1955. Over 100 of the nuclear units planned, under construction, or in operation in the United States employ GE turbine-generators. GE is, therefore, well qualified to design, fabricate, and deliver the turbine-generators for LGS, and to provide technical assistance for the installation and startup of this equipment. Siemens Power Corporation has the contract to design, fabricate and install the retrofit high pressure and low pressure turbines. Like GE, Siemens is well qualified to perform this work.

1.4.5 CONSULTANTS

The licensee has engaged consultants to provide information and recommendations in a number of specialized fields. Principal consultants include:

a. Gilbert Associates: siting

b. Dames & Moore: geology, seismology, groundwater hydrology

c. Meteorological Evaluation Services, Inc.: meteorology

d. Buchart-Horn: archeology

e. MPR Associates, Inc.: quality assurance

f. C. L. Hosler: cooling tower studies

g. Radiation Management Corporation: aquatic and terrestrial biology, and radioactive releases and their effects

h. Nuclear Associates International Corp: core analysis

i. Kibbe & Associates: nuclear fuel supply

j. Nuclear Energy Services: inservice inspection

k. J. E. Edinger: limnology

l. Hydrocon: Schuylkill River hydrology, radioactive release dispersion analysis

m. Betz-Converse-Murdoch, Inc.: sewage treatment

n. Sanders & Thomas: Schuylkill River soundings, road relocation

o. E. H. Bourquard Associates, Inc: water supply

p. Tippetts-Abbett-McCarthy-Stratton: water supply, hydrology

1.5 REQUIREMENTS FOR FURTHER TECHNICAL INFORMATION

1.5.1 CURRENT DEVELOPMENT PROGRAMS

1.5.1.1 Instrumentation for Vibration of Reactor Intervals

Vibration testing for reactor internals has been performed on virtually all GE BWR plants. At the time of issue of Regulatory Guide 1.20, test programs for compliance were instituted. The first BWR/4 plant of this size, Browns Ferry 1, is considered a prototype design and was instrumented and subjected to both cold and hot, two-phase flow testing to demonstrate that flow-induced vibrations similar to those expected during operation do not cause damage. Subsequent plants that have internals similar to those of the prototypes are tested in compliance with the requirements of Regulatory Guide 1.20 to confirm the adequacy of the design with respect to vibration. Combined with the system for monitoring of vibration within the reactor vessel and its immediate piping, additional equipment is provided to monitor selected rotating machines within the plant in order to provide early warning of excessive machine vibration.

1.5.1.2 Core Spray Distribution

GE has a program underway to study BWR/6 core spray distributions using a combination of single nozzle steam and air tests, single and multiple nozzle analytical models, and full-scale air tests. This methodology was confirmed by a full-scale 30° sector steam test conducted during 1979 and reported in Reference 1.5-1. The NRC has agreed "that the overall empirical/engineering method outlined by GE ... is an acceptable method for verification of the currently assumed core spray distributions which are used to justify conservatisms of the spray cooling heat transfer coefficients in ECCS-LOCA licensing calculations."

For other BWR plants, the NRC believes that "there is a sufficient technical basis to permit continued plant operation and licensing in the interim period while these additional tests and information are being developed. This interim conclusion is based on:

a. The existence of a considerable safety margin between available and required spray flow indicated by preliminary analyses and measurements provided for each size BWR/1 through BWR/5;

b. The relative ease with which ECCS re-analyses could be performed to establish an acceptable power limit in the unlikely event that test results do not support the spray flows currently assumed;

c. The possibility that plants under construction could modify their spray nozzles or aiming pattern to provide a better spray distribution, if future test results indicate the desirability of such changes (particularly applicable to the BWR/6, where the type of preliminary measurements referenced in a. above are not yet available);

d. The existence of counter-current-flow-limiting phenomena in many plants would provide a steam/water layer on top of the core which should force a more even distribution of the core spray;

e. The aforementioned empirical/engineering method is expected to provide timely confirmation of the spray flow margin presently believed to exist."

1.5.1.3 Core Spray and Core Flooding Heat Transfer Effectiveness

Due to the incorporation of an 8x8 fuel rod array with unheated "water rods," tests have been conducted to demonstrate the effectiveness of the ECCS in the new geometry.

These tests are regarded as confirmatory only, since the geometry change is very slight and the "water rods" provide an additional heat sink in the inside of the bundle that improves heat transfer effectiveness.

There are two distinct programs involving the core spray. Testing of the core spray distribution has been accomplished and submitted (Reference 1.5-2). The other program concerns the testing of core spray and core flooding heat transfer effectiveness. The results of testing with stainless steel cladding are reported in Reference 1.5-3. The results of testing using Zircaloy cladding are reported in Reference 1.5-4.

1.5.1.4 Verification of Pressure-Suppression Design

The Mark II pressure-suppression test program was initiated in the fall of 1975 to investigate suppression pool dynamic phenomena. Phase I blowdown tests were completed late in 1975. These tests utilized a single 24 inch diameter (590 mm ID) downcomer that vented into a 7 foot (2.13 meters) inside diameter tank, representative of a single downcomer/pool cell in a typical Mark II suppression pool. The objective of this phase of testing was to quantify pool dynamics phenomena, particularly the effect of wetwell pressurization on pool swell, and the load associated with the low mass flux steam condensation, or chugging. Primary variables were simulated break size, initial vent submergence, and wetwell air space configuration, i.e., vented or closed wetwell. The Phase II tests were generally similar to the Phase I tests, except a 20 inch diameter (489 mm ID) downcomer was used. The Phase I and II tests thus bound the range of vent-to-pool area ratios of all Mark II containments. Although the test objectives were similar during Phases I and II, some changes were made in the Phase II test matrix after review of the Phase I data. For example, since the Phase I test had shown that wetwell configuration was the variable that had the most pronounced effect on pool dynamics, the decision was made to concentrate the testing effort on the closed wetwell configuration, which is characteristic of the Mark II containment.

In place of the open wetwell tests, additional blowdowns were included in the Phase II test matrix in order to investigate the effect of saturated liquid versus saturated steam breaks and the effect of downcomer bracing configuration.

As was the case for the Phase I tests, the primary Phase II variables were simulated break size and initial vent submergence. The Phase III tests investigated the pool temperature sensitivity of pool swell and of the load associated with the chugging phenomenon. Only a single break size and vent submergence were tested, with pool temperature alone being a variable. A significant number of blowdowns were performed to yield a statistically significant data set.

1.5.1.5 Critical Heat Flux Testing

A program for critical heat flux testing was established and was to be similar to that described in Reference 1.5-5. Since that time, however, a new analysis has been performed and the General Electric BWR Thermal Analysis Basis (GETAB) program initiated. The results of that analysis and related testing is described in Reference 1.5-6.

1.5.1.6 Fuel Assembly Structural Testing

Although tests are being conducted to determine the effects of vibration on fuel assembly spacers and to determine the forces to which the assemblies are subjected during shipment, there is no special program at present concentrating on structural testing, and no topical report is anticipated.

1.7 DRAWINGS AND OTHER DETAILED INFORMATION

Table 1.7-1 provides a listing of electrical drawings used in the plant design.

Table 1.7-2 provides a listing of P&ID drawings, with a reference to their former UFSAR figure number where applicable.

Table 1.7-3 provides a listing of control and instrumentation drawings used in the plant design.

Table 1.7-4 provides a listing of miscellaneous drawings, with a reference to their former UFSAR figure number where applicable.

Note: Refer to the corresponding Limerick design drawings and their associated open change documentation for up to date plant design information.

E-69	Sh.1	Single Line Meter & Relay Diagram MCC Load Tab - D234-R-H & D244-R-H - Reactor Area Safeguard MCC 440 V - Unit 2	-
E-69	Sh.2	Single Line Meter & Relay Diagram MCC Load Tab - D234-R-H & D244-R-H - Reactor Area Safeguard MCC 440 V - Unit 2	-
E-70	Sh.1	Schematic Meter & Relay Diagram - 1 Generator, 11 Unit Auxiliary Transformer - Unit 1	-
E-70	Sh.2	Schematic Meter & Relay Diagram - 1 Generator, 11 Unit Auxiliary Transformer - Unit 1	-
E-72	Sh.1	Schematic Meter & Relay Diagram - 2 Generator, 21 Unit Auxiliary Transformer - Unit 2	-
E-72	Sh.2	Schematic Meter & Relay Diagram - 2 Generator, 21 Unit Auxiliary Transformer - Unit 2	-
E-74	Sh.1	Schematic Meter & Relay Diagram - 13.2KV Unit Auxiliary Power System - Unit 1	-
E-75	Sh.1	Schematic Meter & Relay Diagram - 13.2KV Unit Auxiliary Power System - Unit 2	-
E-76	Sh.1	Schematic Meter & Relay Diagram - 13.2KV Station Auxiliary Power System - Unit 1	-
E-77	Sh.1	Schematic Meter & Relay Diagram - 13.2KV Station Auxiliary Power System - Unit 2	-
E-78	Sh.1	Schematic Meter & Relay Diagram - 1 Transformer - Unit 1	-
E-79	Sh.1	Schematic Meter & Relay Diagram - 2 Transformer - Unit 2	-
E-80	Sh.1	Schematic Meter & Relay Diagram - D11 & D12 Safeguard Buses, 4 kV - Unit 1	-
E-81	Sh.1	Schematic Meter & Relay Diagram - D13 & D14 Safeguard Buses, 4 kV - Unit 1	-
E-82	Sh.1	Schematic Meter & Relay Diagram - D21 & D22 Safeguard Buses, 4 kV - Unit 2	-
E-83	Sh.1	Schematic Meter & Relay Diagram - D23 & D24 Safeguard Buses, 4 kV - Unit 2	-
E-84	Sh.1	Schematic Meter & Relay Diagram - 114A, 114B, 114C, 114D, 124A, 124B, 124C, 124D, 214D, 224D, 134D, 234D	-
E-85	Sh.1	Schematic Meter & Relay Diagram - Diesel Generators, 4 kV - Units 1 & 2	-
E-85	Sh.2	Schematic Meter & Relay Diagram - Diesel Generators, 4 kV - Units 1 & 2	-
E-87	Sh.1	Schematic Meter & Relay Diagram - 214A, 214B, 214C, 224A, 224B & 224C Load Centers 440 V - Unit 2	-
E-88	Sh.1	Schematic Meter & Relay Diagram - D114, D214, D314, D414 Safeguard Load Centers 440 V - Unit 1	-
E-89	Sh.1	Schematic Meter & Relay Diagram - D124, D224, D324, D424 Safeguard Load Centers 440 V - Unit 2	-
E-92	Sh.1	Schematic Meter & Relay Diagram - 125/250 V dc System - Units 1 & 2	-
E-92	Sh.2	Schematic Meter & Relay Diagram - 125/250 V dc System - Units 1 & 2	-
E-92	Sh.3	Schematic Meter & Relay Diagram - 125/250 V dc System - Units 1 & 2	-
E-92	Sh.4	Schematic Meter & Relay Diagram - 125V/250V DC System Units 1 & 2	-
E-97	Sh.1	Schematic Meter & Relay Diagram - 2.3 KV Plant Services Power System - Comm	-
		SCHEMATIC BLOCK DIAGRAM - REACTOR SYSTEM	
E-100	Sh.1	Schematic Block Diagram - Steam Leak Detection System - Units 1 & 2	-
E-101	Sh.1	Schematic Block Diagram - Nuclear Steam Supply Shutoff System - Units 1 & 2	-
E-101	Sh.2	Schematic Block Diagram - Nuclear Steam Supply Shutoff System - Units 1 & 2	-
E-101	Sh.3	Schematic Block Diagram - Nuclear Steam Supply Shutoff System - Units 1 & 2	-
E-102	Sh.1	Schematic Block Diagram - RHR System - Units 1 & 2	-

Note: See note in Section 1.7 for drawing considerations.

1.8 CONFORMANCE TO NRC REGULATORY GUIDES

This section provides a brief description of LGS conformance with the guidelines presented in the regulatory guides and provides reference to the UFSAR sections where the LGS design and details of conformance or alternate approaches are discussed.

The conformance information below applies only to the particular guide being addressed and not necessarily to other guides that may be referenced in that guide.

This section also identifies those guides classified as Category 1,2,3 or 4 per Reference 1.11-2, as discussed in Section 1.11.

REGULATORY GUIDE 1.1 Net Positive Suction Head for Emergency Core Cooling and Containment Heat Removal System Pumps (Safety Guide 1)

Rev 0, November 2 1970

LGS is in conformance with this guide as discussed in Sections 5.4.7 and 6.3.2.

(Category 1)

REGULATORY GUIDE 1.2 Thermal Shock to Reactor Pressure Vessels (Safety Guide 2)
Rev 0, November 2 1970

Although not used as a design basis, LGS is evaluated as being in conformance with this guide. Reactor vessel integrity is discussed in Section 5.3.

(Category 1)

REGULATORY GUIDE 1.3 Assumptions Used for Evaluating the Potential Radiological Consequences of a Loss-of-Coolant Accident for Boiling Water Reactors

Rev 2, June 1974

Regulatory Guide 1.3 was used for the original plant design. Regulatory Guide 1.3 is used for the determination of in-plant doses, shielding design and equipment unless such evaluations are re-performed using Alternate Source Terms. The requirements of Regulatory Guide 1.3, as they apply to the determination of control room and off-site radiological consequences for LOCA, are superseded by the requirements of Regulatory Guide 1.183

(Category 1)

REGULATORY GUIDE 1.4 Assumptions Used for Evaluating the Potential Radiological Consequences of a Loss-of-Coolant Accident for Pressurized Water Reactors

Rev 2, June 1974

This guide is for pressurized water reactors and therefore is not applicable to LGS.

REGULATORY GUIDE 1.5 Assumptions Used for Evaluating the Potential Radiological Consequences of a Steam Line Break Accident for Boiling Water Reactors (Safety Guide 5)

Rev 0, March 10 1971

Regulatory Guide 1.5 was used for the original design of LGS. Regulatory Guide 1.5 is used for the determination of in-plant doses, shielding design and equipment unless such evaluations are re-performed using Alternate Source Terms. Regulatory Guide 1.5 steam cloud dispersion methodology is used for the MSLB does assessment for Alternate Source Terms. The requirements of Regulatory Guide 1.5, as they apply to the determination of control room and off-site radiological consequences for a Main Steam Line Break, are superseded by the requirements of Regulatory Guide 1.183.

(Category 1)

REGULATORY GUIDE 1.6	Independence Between Redundant Standby (Onsite) Power Sources and Between Their Distribution Systems (Safety Guide 6)
Rev 0, March 10 1971	

LGS is in conformance with this guide as discussed in Sections 7.1.2.5, 7.6.2.8.2.1.1 and 8.1.6.1.

(Category 1)

REGULATORY GUIDE 1.7	Control of Combustible Gas Concentrations in Containment Following a Loss-of-Coolant Accident
Rev 2, November 1978	

LGS is in conformance with this guide. There is a clarification of quality group requirements of paragraph C.3 for the gas analyzer packages, as discussed in Section 6.2.5.4.

(Category 1)

REGULATORY GUIDE 1.8	Personnel Selection and Training
Rev 1-R, May 1977	

LGS is in conformance with this guide to the extent discussed in Section 12.5.3.5.2, 13.1 and 13.2.

(Category 1)

REGULATORY GUIDE 1.9	Selection of Diesel Generator Set Capacity for Standby Power Supplies (Safety Guide 9)
Rev 2, December 1979	

LGS is in conformance with Revision 0 (3/10/71) of this guide as discussed in Section 8.1.6.1. Revision 1 of this guide was for comment only, and Revision 2 is not applicable to LGS (being for plants whose construction permit applications are docketed after December, 1979).

(Category 1)

REGULATORY GUIDE 1.10	Mechanical (Cadweld) Splices in Reinforcing Bars of Category I Concrete Structures
Rev 1, January 2 1973	

LGS is in conformance with this guide except that there are alternate approaches to paragraphs C.4.a, C.4.b, C.5.a, and C.5.b in that some testing procedures differ but are interpreted to be equally or more stringent than those recommended in the regulatory guide. Details are discussed in Section 3.8.6.

(Category 1)

REGULATORY GUIDE 1.11 Instrument Lines Penetrating Primary Reactor Containment (Safety Guide 11)
Rev 0, March 10, 1971

LGS is in conformance with this guide except that position indication of excess flow check valves is provided locally, rather than in the control room as suggested in Paragraph C.1.c. of the guide. Details are discussed in Sections 6.2.4 and 6.2.6. LGS is in conformance with this guide for the TIP system lines to the extent discussed in Section 6.2.4.

(Category 1)

REGULATORY GUIDE 1.12 Instrumentation for Earthquakes
Rev 2, March 1997

The LGS design is in conformance with this guide as discussed in Section 3.7.4.1.

REGULATORY GUIDE 1.13 Spent Fuel Storage Facility Design Basis
Rev 1, December 1975

This guide applies to LGS on a case-by-case basis. LGS is in conformance with this guide as discussed in Sections 9.1.2 and 9.1.4.

(Category 4)

REGULATORY GUIDE 1.14 Reactor Coolant Pump Flywheel Integrity
Rev 1, August 1975

The subject matter does not apply to LGS as reactor coolant recirculation pumps do not have inertia flywheels.

REGULATORY GUIDE 1.15 Testing of Reinforcing Bars for Category 1 Concrete Structures

Rev 1, December 28, 1972

LGS is in conformance with this guide as discussed in Section 3.8.6.2.

(Category 1)

REGULATORY GUIDE 1.16 Reporting of Operating Information - Appendix A Technical Specifications

Rev 4, August 1975

LGS reporting requirements are established in Chapter 16, Technical Specifications, which were based on NUREG-0123, Revision 2, "Standard Technical Specifications for GE Boiling Water Reactors."

REGULATORY GUIDE 1.17 Protection of Nuclear Power Plants Against Industrial Sabotage

Rev 1, June 1973

LGS is in conformance with this guide to the extent discussed in Section 13.6.

(Category 1)

REGULATORY GUIDE 1.18 Structural Acceptance Test for Concrete Primary Reactor Containments

Rev 1, December 28, 1972

LGS is in conformance with paragraphs C.4 through C.8 & C.13. Alternate approaches are employed for portions of paragraphs C.1, C.2, and C.3 regarding pressure tests, measurement locations, and deflection measurement. The test environment of paragraph C.9 is not considered applicable, and LGS has not utilized the test pressure drop procedures of paragraph C.10. Details are discussed in Section 3.8.1.7.

(Category 1)

REGULATORY GUIDE 1.19 Nondestructive Examination of Primary Containment Liner Welds (Safety Guide 19)

Rev 1, August 11 1972

LGS is in conformance with this guide except that alternate approaches are employed for paragraphs C.1.a (radiographic examination increments) and C.7.a and C.7.b (acceptance standards). Conformance to paragraph C.4 (personnel qualification) is subject to an interpretation. Details are discussed in Sections 3.8.1 and 3.8.2.

(Category 1)

REGULATORY GUIDE 1.20 Comprehensive Vibration Assessment Program for Reactor Internals During Preoperational and Initial Startup Testing

Rev 2, May 1976

LGS's program is evaluated as being in conformance with this guide and is discussed in Section 3.9.2.4 and 14.2.

(Category 1)

REGULATORY GUIDE 1.21 Measuring, Evaluating, and Reporting Radioactivity in Solid Wastes and Releases of Radioactive Materials in Liquid and Gaseous Effluents from Light-Water-Cooled Nuclear Power Plants

Rev 1, June 1974

The LGS process and effluent radiological monitoring and sampling systems are designed to allow conformance to this guide, as discussed in Section 7.7, 11.5 and 12.3. Evaluation and reporting procedures during operation will conform to this guide.

(Category 1)

REGULATORY GUIDE 1.22 Periodic Testing of Protection System Actuation Functions (Safety Guide 22)

Rev 0, February 17 1972

The LGS design is in conformance with this guide as discussed in Sections 7.1.2.5 and 8.1.6.1.

(Category 1)

REGULATORY GUIDE 1.23 Onsite Meteorological Programs (Safety Guide 23)

Rev 0, February 17 1972

The LGS onsite meteorological instrumentation systems met NRC requirements at the time of installation, prior to the issuance of this guide. LGS conforms to the guidelines of Regulatory Guide 1.23, except as discussed in detail in Sections 2.3.2 and 2.3.3.

(Category 1)

REGULATORY GUIDE 1.24 Assumptions Used for Evaluating the Potential Radiological Consequences of a Pressurized Water Reactor Radioactive Gas Storage Tank Failure (Safety Guide 24)

Rev 0, March 23 1972

This guide is for PWRs and therefore does not apply to LGS.

REGULATORY GUIDE 1.25 Assumptions Used for Evaluating the Potential Radiological Consequences of a Fuel Handling Accident in the Fuel Handling and Storage Facility for Boiling and Pressurized Water Reactors (Safety Guide 25)

Rev 0, March 23 1972

Regulatory Guide 1.25 was used for the original design. Regulatory Guide 1.25 is used for the determination of in-plant doses, shielding design and equipment unless such evaluations are re-performed using Alternate Source Terms. The requirements of Regulatory Guide 1.25, as they apply to the determination of control room and off-site radiological consequences for a Fuel Handling Accident, are superseded by the requirements of Regulatory Guide 1.183.

(Category 1)

REGULATORY GUIDE 1.26	Quality Group Classifications and Standards for Water-, Steam-, and Radioactive-Waste-Containing Components of Nuclear Power Plants
Rev 3, February 1976	

LGS is in conformance with this guide except that alternate approaches are used for the CRD hydraulic control units, isolation of certain steam lines, parts of the fuel pool cooling system, diesel generator cooling system, and control structure chilled water system, instrument tubing for "passive" instrumentation, the SLCS storage tanks and accumulator vessels, and the HPCI globe stop-check valves. Details are discussed in Section 3.2.2.

(Category 1)

REGULATORY GUIDE 1.27	Ultimate Heat Sink for Nuclear Power Plants
Rev 2, January 1976	

LGS is in conformance with this guide except that alternate approaches were used to paragraphs C.1, C.1.a, C.1.b, and C.1.c regarding thermal analysis methods and selection of meteorology. The design meteorology is in conformance with Revision 1 of the guide. Details for both Revision 1 and Revision 2 are discussed in Section 9.2.6.6.

(Category 2)

REGULATORY GUIDE 1.28	Quality Assurance Program Requirements (Design and Construction)
Rev 3, August 1985	

At the time of initial licensing, this guide, which endorsed/modified ANSI N45.2 (1977), was not applicable to LGS (being for plants whose construction permit applications are docketed after October 1979); Quality assurance during construction is discussed in the document "LGS Generating Station Units 1 and 2; Summary Description of the Quality Assurance Program for Design and Construction." The LGS QA program during operation will be in conformance with this guide, as discussed in the QATR.

Further, as discussed in a letter of approval from the NRC to Exelon, dated December 24, 2002, Regulatory Guide 1.28, Rev 3 endorses NQA-1-1983. The NRC letter approves Exelon's proposal to update its commitment to quality standards by adopting the guidance of NQA-1-1994. Therefore, N45.2.13-1976, superseded by NQA-1-1983 has been superseded by NQA-1-1994.

(Category 1)

REGULATORY GUIDE 1.29	Seismic Design Classification
Rev 3, September 1978	

LGS is in conformance with this guide except that alternate approaches have been taken for the fuel pool cooling system and isolation of certain steam lines. There are clarifications for certain reactor internals and reactivity control systems. Details are discussed in Section 3.2.1.

(Category 1)

REGULATORY GUIDE 1.30 Quality Assurance Requirements for the Installation, Inspection, and Testing of Instrumentation and Electric Equipment (Safety Guide 30)

Rev 0, August 11 1972

LGS is constructed in accordance with this guide, which endorses/ modifies ANSI N45.2.4 (1972)/IEEE 336 (1971), although the standard is not specifically a part of construction quality assurance procedures as discussed in Section 8.1.6.1.

The commitments to this Regulatory Guide and ANSI N45.2.4 were deleted since they were superseded by Exelon's commitment to ASME NQA-1 1994 subpart 2.4.

(Category 1)

REGULATORY GUIDE 1.31 Control of Ferrite Content in Stainless Steel Weld Metal

Rev 3, April 1978

Revision 3 of this guide is not applicable to LGS (being for plants whose construction permit applications are docketed after October 1, 1978). For the GE scope of supply, Revision 1 of the guide is used as a design basis for LGS, with certain alternate approaches considered to meet the intent of the guide. Details are discussed in Section 5.2.3.4, along with a comparison of Bechtel procedures with Revision 3 of the guide.

REGULATORY GUIDE 1.32 Criteria for Safety-Related Electric Power Systems for Nuclear Power Plants

Rev 2, February 1977

This guide, which endorses/modifies IEEE 308 (1974), is not applicable to LGS (for plants whose construction permit applications are docketed after April 14, 1977). The LGS design is in conformance as discussed in Section 8.1.6.1.

(Category 1)

REGULATORY GUIDE 1.33 Quality Assurance Program Requirements (Operation)

Rev 2, February 1978

LGS is in conformance with this guide, which endorses/modifies ANSI N18.7 (1976), except for certain alternate approaches to the guide and the ANSI standard, as discussed in the QATR.

(Category 1)

REGULATORY GUIDE 1.34 Control of Electroslag Weld Properties

Rev 0, December 28 1972

Electroslag welding was not used on LGS and therefore this guide is not applicable.

REGULATORY GUIDE 1.35	Inservice Inspection of Ungrouted Tendons in Prestressed Concrete Containment Structures
Rev 2, January 1976	

LGS does not have a prestressed concrete containment and therefore this guide does not apply.

REGULATORY GUIDE 1.36	Nonmetallic Thermal Insulation for Austenitic Stainless Steel
Rev 0, February 23 1973	

LGS is in conformance with this guide as discussed in Section 5.2.3.2.

(Category 1)

REGULATORY GUIDE 1.37	Quality Assurance Requirements for Cleaning of Fluid Systems and Associated Components of Water-Cooled Nuclear Power Plants
Rev 0, March 16 1973	

This guide endorses/modifies ANSI N45.2.1 (1973). While this standard is not specifically applied in Bechtel's scope of work, the procedures in use satisfy the intent of the guide as discussed in Section 5.2.3.4. The GE scope of supply is in conformance with this guide as discussed in Sections 4.5.

The commitments to this Regulatory Guide and ANSI N45.2.1 were deleted since they were superseded by Exelon's commitment to ASME NQA-1 1994 subpart 2.1.

(Category 1)

REGULATORY GUIDE 1.38	Quality Assurance Requirements for Packaging, Shipping, Receiving, Storage, and Handling of Items for Water-Cooled Nuclear Power Plants
Rev 2, May 1977	

This guide endorses/modifies ANSI N45.2.2 (1972). The guide/ standard is not specifically utilized during construction, although procedures in use for LGS conform with the intent of the guide. Quality assurance during construction is discussed in the document "LGS Generating Station Units 1 and 2; Summary Description of the Quality Assurance Program for Design and Construction." The GE scope of supply is in conformance with this guide as discussed in NEDO-11209-04A, "Nuclear Energy Business Group Boiling Water Reactor Quality Assurance Program" February, 1980.

The commitments to this Regulatory Guide and ANSI N45.2.2 were deleted since they were superseded by Exelon's commitment to ASME NQA-1 1994 subpart 2.2.

(Category 1)

REGULATORY GUIDE 1.39	Housekeeping Requirements for Water-Cooled Nuclear Power Plants
Rev 2, September 1977	

LGS is in general conformance with this guide, which endorses/ modifies ANSI N45.2.3 (1973), although the ANSI Standard is not specifically a part of construction quality assurance procedures. Quality assurance during construction is discussed in the document "LGS Generating Station Units 1 and 2; Summary Description of the Quality Assurance Program for Design and Construction."

The commitments to this Regulatory Guide and ANSI N45.2.3 were deleted since they were superseded by Exelon's commitment to ASME NQA-1 1994 subpart 2.3.

(Category 1)

REGULATORY GUIDE 1.40 Qualification Tests of Continuous-Duty Motors Installed Inside the Containment of Water-Cooled Nuclear Power Plants

Rev 0, March 16, 1973

Limerick is in conformance with the intent of this guide, which endorses/modifies trial use standard IEEE 334-1971, as discussed in Section 8.1.6.1. The Standard was revised on October 29, 1974, and the method of qualification testing was modified from the trial use version. The in-containment motors at LGS were qualified by testing performed in accordance with the enhanced methods stated in the 1974 version of IEEE Standard 334.

(Category 1)

REGULATORY GUIDE 1.41 Preoperational Testing of Redundant Onsite Electric Power Systems to Verify Proper Load Group Assignments

Rev 0, March 16 1973

LGS is in conformance with this guide as discussed in Sections 8.1.6.1, 8.3.2.2, and 14.2.7.2.

(Category 1)

REGULATORY GUIDE 1.42 Interim Licensing Policy on as Low as Practicable for Gaseous Radioiodine Releases

Withdrawn by the NRC March 22, 1976.

REGULATORY GUIDE 1.43 Control of Stainless Steel Weld Cladding of Low-Alloy Steel Components

Rev 0, May 1973

This guide applies to welding of cladding to low-alloy steels made to coarse grain practice. LGS vessel plate and nozzle forgings are made to fine grain practice and a low heat input process is used. Other components are not clad. Therefore, the guide is not applicable.

(Category 1)

REGULATORY GUIDE 1.44 Control of the Use of Sensitized Stainless Steel

Rev 0, May 1973

For GE scope of supply, this guide is not used as a design basis for LGS and in some instances alternate approaches are used which, however, conform to the intent of this guide. For the Bechtel scope of supply, there is conformance with the guide except for alternate approaches taken for nonsensitization and intergranular corrosion testing. Details are discussed in Section 5.2.3.3.

REGULATORY GUIDE 1.45 Reactor Coolant Pressure Boundary Leakage Detection Systems

Rev 0, May 1973

The LGS design complies with the intent of this regulatory guide. Three diverse methods of detection have been provided. The design bases, limitations, and operation of these systems are discussed in Sections 5.2.5.2.1.3 through 5.2.5.2.1.5. These provisions meet or exceed the recommendations of ANSI/ISA S67.03. Each of the three systems provided for leak detection has readouts and alarms in the main control room in accordance with Regulatory Guide 1.45.

(Category 1)

REGULATORY GUIDE 1.46 Protection Against Pipe Whip Inside Containment

Rev 0, May 1973

For the recirculation system, pipe break locations are selected by alternate criteria which are in accordance with the intent of this guide. For all other systems, the criteria of BTP MEB 3-1 (dated 11/24/75) are used in lieu of the criteria of the regulatory guide. Protection against the effects of postulated pipe ruptures, both inside and outside the primary containment, is discussed in Section 3.6.2.

(Category 1)

REGULATORY GUIDE 1.47 Bypassed and Inoperable Status Indication for Nuclear Power Plant Safety Systems

Rev 0, May 1973

LGS is in conformance with this guide as discussed in Sections 7.1.2.5 and 8.1.6.1.

(Category 1)

REGULATORY GUIDE 1.48 Design Limits and Loading Combinations for Seismic Category I Fluid System Components

Rev 0, May 1973

The design limits and loading combinations for non-NSSS seismic Category I fluid systems is in accordance with this guide, as shown in Section 3.9. The NSSS systems were designed prior to the issuance of this guide and therefore the guide was not a design basis requirement, however, there is general agreement with the guide. A comparison between Regulatory Guide 1.48 and the NSSS design is provided in Section 3.9.3.

(Category 1)

REGULATORY GUIDE 1.49	Power Levels of Nuclear Power Plants
Rev 1, December 1973	

LGS is in conformance with this guide as discussed in Section 15.0.4.

(Category 1)

REGULATORY GUIDE 1.50	Control of Preheat Temperature for Welding of Low-Alloy Steel
Rev 0, May 1973	

For GE scope of supply, the guide was not used as a design basis for LGS and in some cases alternate approaches are employed that satisfy the intent of the guide. For Bechtel scope of supply, alternate approaches are employed for portions of the procedure qualifications and maintenance of preheat temperature beyond completion of welding. Details are discussed in Section 5.2.3.3.

(Category 1)

REGULATORY GUIDE 1.51	Inservice Inspection of ASME Code Class 2 and 3 Nuclear Power Plant Components

Withdrawn by the NRC July 15, 1975.

REGULATORY GUIDE 1.52	Design, Testing, and Maintenance Criteria for Post Accident Engineered Safety Feature Atmosphere Cleanup System Air Filtration and Adsorption Units of Light-Water-Cooled Nuclear Power Plants
Rev 2, March 1978	

The LGS system was designed prior to the original issuance of this guide in 1973, and therefore the guide was not specifically considered in the design. While there is substantial conformance, there are various exceptions and alternate approaches. These, however, are not considered significantly different from the intent of the guide. Details are discussed in Section 6.5.1 and Table 6.5-2. The initial test program will be in conformance except as may be modified by the general statement on regulatory guides in Section 14.2. Testing during operation is discussed in Chapter 16.

(Category 2 for Revision 1)

REGULATORY GUIDE 1.53	Application of the Single Failure Criterion to Nuclear Power Plant Protection Systems
Rev 0, June 1973	

LGS is in conformance with this guide, which endorses/modifies trial use standard IEEE 379 (1972), as discussed in Sections 7.1.2.5 and 8.1.6.1.

(Category 1)

REGULATORY GUIDE 1.54 Quality Assurance Requirements for Protective Coatings Applied to Water-Cooled Nuclear Power Plants

Rev 0, June 1973

This guide endorses/modifies ANSI N101.4 (1972). Non-NSSS practice is in conformance with the guide except that, since there are no Class I Service Level coatings in LGS, a quality assurance program was not applied. Most NSSS equipment for LGS was ordered prior to the issuance of the guide and ANSI N101.4 was not used as a design basis. GE procedures are considered to satisfy the intent of the guide. Details are discussed in Section 6.1.2. During operation, LGS will be in conformance with ASTM D3843-93 with an additional clarification, exception, and requirement as discussed in the QATR.

(Category 1)

REGULATORY GUIDE 1.55 Concrete Placement in Category I Structures

Rev 0, June 1973

LGS is in conformance with this guide except that an alternate approach used for paragraphs C.2 and C.3 regarding the division of responsibilities of "designer" and "constructor" within Bechtel. Details are discussed in Section 3.8.6.2. Also, this guide references ACI 301-72 and ACI 305-72 and LGS is in conformance with ACI 301-66 and ACI 605-59.

(Category 1)

REGULATORY GUIDE 1.56 Maintenance of Water Purity in Boiling Water Reactors

Rev 1, July 1978

The LGS design is in conformance with this guide except for alternate approaches to measurement of deep bed condensate demineralizer flow and methods of determining resin exhaustion for the condensate cleanup system. The condensate cleanup system is discussed in Section 10.4.6. The RWCU system is discussed in Section 5.4.8.
Water purity limits are presented in Chapter 16.

(Category 3)

REGULATORY GUIDE 1.57 Design Limits and Loading Combinations for Metal Primary Reactor Containment System Components

Rev 0, June 1973

LGS is in conformance with this guide, which applies to hatches and other metal components on LGS, with the clarification that the Code Addenda in effect at the time of design were used, rather than the later one cited by the guide. Details are discussed in Section 3.8.2.5.

(Category 1)

REGULATORY GUIDE 1.58 Qualification of Nuclear Power Plant Inspection, Examination, and Testing Personnel

Rev 1, September 1980

This guide endorses/modifies ANSI N45.2.6. QA during construction is discussed in the document "LGS Generating Station Units 1 and 2; Summary Description of the Quality Assurance Program for Design and Construction."

During operation, for NDE personnel, the Company and contractor personnel performing NDE are trained, tested, qualified, or certified in accordance with a company procedure that meets applicable requirements of 10 CFR 50.55a and ASME Section XI with specific exceptions and clarifications as discussed in the QATR.

(Category 1)

REGULATORY GUIDE 1.59 Design Basis Floods for Nuclear Power Plants
Rev 2, August 1977

Although this guide does not apply to LGS (being for construction permit applications docketed after the guide's issuance), LGS is in conformance as discussed in Section 2.4.2.2.

(Category 2)

REGULATORY GUIDE 1.60 Design Response Spectra for Seismic Design of Nuclear Power Plants
Rev 1, December 1973

A letter from J.M. Hendrie (NRC) to R.M. Collins (Bechtel) dated Dec. 21, 1973 stated that this guide is applicable only to plants docketed for construction permit review after April 1, 1973. LGS was docketed prior to this date, and therefore the guide is not applicable. The design response spectra were determined prior to the issuance of this guide and LGS has employed alternate approaches. Details are discussed in Section 3.7.1.1.

REGULATORY GUIDE 1.61 Damping Values for Seismic Design of Nuclear Power Plants
Rev 0, October 1973

A letter from J.M. Hendrie (NRC) to R.M. Collins (Bechtel) dated Dec. 21, 1973 stated that this guide is applicable only to plants docketed for construction permit review after April 1, 1973. LGS was docketed prior to this date and therefore the guide is not applicable. The damping values for both the NSSS and non-NSSS scope were determined prior to the issuance of this guide. For the NSSS design, an alternate approach has been employed that is more conservative than the recommendations of the guide. The non-NSSS design uses values equal to or more conservative than the guides except for the SSE value for welded steel structures. Details are discussed in Section 3.7.1.

(Category 1)

REGULATORY GUIDE 1.62 Manual Initiation of Protective Actions
Rev 0, October 1973

LGS is in conformance with this guide as discussed in Sections 7.1.2.5 and 8.1.6.1.

(Category 1)

REGULATORY GUIDE 1.63 Electric Penetration Assemblies in Containment Structures for Light-Water- Cooled Nuclear Power Plants

Rev 2, July 1978

The LGS electric penetration assemblies were purchased when Revision 0 (10/73) of this guide, which endorses/modifies IEEE 317 (1972), was in effect. The LGS assemblies are in full conformance with this revision of the guide. Revision 2 of the guide, which endorses/modifies IEEE 317 (1976), is not applicable to LGS per its implementation section (being for plants whose construction permit applications are docketed after August 31, 1978). There are several exceptions and clarifications to this revision of the guide as discussed in Section 8.1.6.1.

(Category 2)

REGULATORY GUIDE 1.64 Quality Assurance Requirements for the Design of Nuclear Power Plants

Rev 2, June 1976

This guide, which endorses/modifies ANSI N45.2.11, does not apply to LGS (being for construction permits docketed after July 15, 1976). Quality assurance during construction is discussed in the document "LGS Generating Station Units 1 and 2; Summary Description of the Quality Assurance Program for Design and Construction." LGS will conform during operation, except for certain alternate approaches to paragraph C.2 of the guide regarding design verification, as discussed in the QATR.

(Category 1)

REGULATORY GUIDE 1.65 Materials and Inspections for Reactor Vessel Closure Studs

Rev 0, October 1973

The reactor vessel closure studs were ordered prior to the issuance of this guide and therefore the guide was not used as a design basis for LGS. The LGS design, is in conformance except that alternate approaches were used for Charpy V impact testing of paragraph C.1.B.(2) of the guide and ultrasonic examination procedures of paragraph C.2.b. Material details and use are discussed in Section 5.3.1.11. The cleanliness recommendations of the guide will be followed during operation.

(Category 1)

REGULATORY GUIDE 1.66 Nondestructive Examination of Tubular Products

Withdrawn by NRC September 1977. Discussion of activities prior to that time is provided in Section 5.2.3.3.

REGULATORY GUIDE 1.67 Installation of Overpressure Protection Devices

Rev 0, October 1973

There are no ASME Section III, Class 1, 2 or 3 relief valves employed in the LGS design, to which Code Case 1569 applies, therefore, the subject matter of this guide is not applicable to LGS.

REGULATORY GUIDE 1.68 Initial Test Program for Water-Cooled Reactor Power Plants
Rev 2, August 1978

LGS will be in conformance with this guide as discussed in Section 14.2.7.2.

(Category 1)

REGULATORY GUIDE 1.68.1 Preoperational and Initial Startup Testing of Feedwater and Condensate Systems for Boiling Water Reactor Power Plants
Rev 1, January 1977

LGS will be in conformance with the guide as discussed in Section 14.2.7.2.

(Category 1)

REGULATORY GUIDE 1.68.2 Initial Startup Test Program to Demonstrate Remote Shutdown Capability for Water-Cooled Nuclear Power Plants
Rev 1, July 1978

LGS will be in conformance with the guide.

(Category 3)

REGULATORY GUIDE 1.68.3 Preoperational Testing of Instrument and Control Air Systems
Rev 0, April 1982

LGS will be in conformance with the applicable portions of this guide.

REGULATORY GUIDE 1.69 Concrete Radiation Shields for Nuclear Power Plants
Rev 0, December 1973

LGS did not directly apply this guide, which endorses/modifies ANSI N101.6 (1972). Certain provisions of the guide, including those pertaining to structural aspects of radiation shield design are met by LGS via conformance to concrete standards. LGS concrete standards are discussed in Section 3.8.

(Category 1)

REGULATORY GUIDE 1.70 Standard Format and Content of Safety Analysis Reports for Nuclear Power Plants
Rev 3, November 1978

The LGS FSAR is in conformance with the format and content requirements of this guide.

(Category 1)

REGULATORY GUIDE 1.71 Welder Qualification for Areas of Limited Accessibility

Rev 0, December 1973

GE does not employ this guide as a design basis for LGS and in some cases employs alternate approaches that are evaluated as satisfying the intent of the guide. Details are discussed in Section 5.2.3.4. Bechtel employs alternate approaches to portions of this guide as in Section 5.2.3.4.

(Category 1)

REGULATORY GUIDE 1.72 Spray Pond Piping Made from Fiberglass-Reinforced Thermosetting Resin

Rev 2, November 1978

The LGS spray pond does not use this type of pipe and therefore the guide does not apply.

(Category 1)

REGULATORY GUIDE 1.73 Qualification Tests of Electric Valve Operators Installed Inside the Containment of Nuclear Power Plants

Rev 0, January 1974

This Regulatory Guide is applicable to safety-related valve operators. Limerick safety-related valve operators are in conformance with this guide which endorses/modifies IEEE 382-1972 as discussed in Section 8.1.6.1.

(Category 1)

REGULATORY GUIDE 1.74 Quality Assurance Terms and Definitions

Rev 0, February 1974

Quality assurance during construction is discussed in the document "LGS Generating Station Units 1 and 2; Summary Description of the Quality Assurance Program for Design and Construction." LGS will be in conformance with this guide, which endorses/modifies ANSI N45.2.10 (1973), during operation as discussed in the QATR.

(Category 1)

REGULATORY GUIDE 1.75 Physical Independence of Electric Systems

Rev 2, September 1978

Although this guide, which endorses/modifies IEEE 384 (1974), does not apply to LGS (being for construction permit applications whose SER's are dated after February 1, 1974), the approach was taken to incorporate as much as possible of the guidelines into the partially completed design. There are various alternate approaches and exceptions to the guide and IEEE 384 as discussed in Sections 7.1.2.5 and 8.1.6.1.

(Category 4 for Revision 1)

REGULATORY GUIDE 1.76 Design Basis Tornado for Nuclear Power Plants

Rev 0, April 1974

LGS is in conformance with this guide except that an alternate equivalent approach to paragraph C.1, regarding design basis tornado characteristics, is used. Details are discussed in Sections 2.3.1.2.4 and 3.3.

(Category 4)

REGULATORY GUIDE 1.77 Assumptions Used for Evaluating a Control Rod Ejection Accident for Pressurized Water Reactors

Rev 0, May 1974

This guide is for PWRs and therefore is not applicable to LGS.

REGULATORY GUIDE 1.78 Assumptions for Evaluating the Habitability of a Nuclear Power Plant Control Room During a Postulated Hazardous Chemical Release

Rev 0, June 1974

LGS complies with the intent of this guide. Details are discussed in Sections 2.2.3 and 6.4.

(Category 1)

REGULATORY GUIDE 1.79 Preoperational Testing of Emergency Core Cooling Systems for Pressurized Water Reactors

Rev 1, September 1975

This guide is for PWRs and therefore does not apply to LGS.

REGULATORY GUIDE 1.80 Preoperational Testing of Instrument Air Systems

Rev 0, June 1974

This guide was superseded by Regulatory Guide 1.68.3 in April 1982.

(Category 4)

REGULATORY GUIDE 1.81 Shared Emergency and Shutdown Electric Systems for Multi-Unit Nuclear Power Plants

Rev 1, January 1975

LGS is in conformance with this guide as discussed in Section 8.1.6.1.

(Category 1)

REGULATORY GUIDE 1.82 Water Sources for Long-Term Recirculation Cooling Following a Loss-of-Coolant Accident

Rev 2, May 1996

LGS is in conformance with this guide as discussed in Section 6.2.2.2.

REGULATORY GUIDE 1.83 Inservice Inspection of Pressurized Water Reactor Steam Generator Tubes

Rev 1, July 1975

This guide is for PWRs and therefore is not applicable to LGS.

REGULATORY GUIDE 1.84 Code Case Acceptability - ASME Section III Design and Fabrication

The non-NSSS scope of supply is in accordance with this guide with the exception of the spray pond nozzles which used Code Case N-316 for installation. Approval of code cases for Class 3 equipment is not currently required by 10CFR50.55a. The NSSS scope of supply procedure for meeting the regulatory requirements is to obtain NRC approval for code cases applicable to Class I components only. These cases are discussed in Section 5.2.1.2. Approval of code cases for Class 2 and 3 equipment was not required at the time of the design of LGS, and is not currently required by 10CFR50.55a. Therefore, GE believes that this procedure in conjunction with 10CFR50, Appendix B, and other regulatory requirements provide adequate assurance of quality in the design and fabrication of safety-related equipment.

(Category 1)

REGULATORY GUIDE 1.85 Code Case Acceptability - ASME Section III Materials

The non-NSSS scope of supply is in accordance with this guide except that Code Cases 1330-3 and 1481 were used in the manufacture of the offgas system aftercondensers. In addition, Code Case 1481 was applied to the post-LOCA hydrogen recombiners. Code Case 1330-3 was incorporated into the 1974 edition of the ASME B&PV Code, Section III. Code Case 1481 addresses the use of materials used in equipment operating above 800°F, since the present ASME B&PV Code, Section III is limited in applicability to equipment operating below 800°F. In order for the aftercondensers and recombiners to meet the requirements of the ASME B&PV Code, Code Case 1481 must be applied. The NSSS scope of supply procedure for meeting the regulatory requirements is to obtain NRC approval for code cases applicable to Class I components only. These cases are discussed in Section 5.2.1.2. Approval of code cases for Class 2 and 3 equipment was not required at the time of the design of LGS, and is not currently required to 10CFR50.55a. Therefore, GE believes that this procedure in conjunction with 10CFR50, Appendix B and other regulatory requirements provide adequate assurance of quality in the design and fabrication of safety-related equipment.

With regard to Code Case N242 "Materials Certification, Section III, Division 1, Classes 1, 2, 3, MC and CS Construction," Regulatory Guide 1.85 calls for identification in the FSAR of those components and supports requiring the use of Paragraphs 1.0 through 4.0 of the Code Case. Accordingly, Table 1.8-1, is provided.

(Category 1)

REGULATORY GUIDE 1.86 Termination of Operating Licenses for Nuclear Reactors
Rev 0, June 1974

This guide is not applicable at the operating license stage.

REGULATORY GUIDE 1.87 Guidance for Construction of Class 1 Components in Elevated-Temperature Reactors (Supplement to ASME Section III Code Cases 1592, 1593, 1594, 1595, and 1596)

Rev 1, June 1975

This guide is not applicable to LGS.

(Category 1)

REGULATORY GUIDE 1.88 Collection, Storage, and Maintenance of Nuclear Power Plant, Quality Assurance Records

Rev 2, October 1976

This guide, which endorses/modifies ANSI N45.2.9 (1974), is not applicable to LGS (being for construction permit application submittals after October 1976). Quality assurance during construction is discussed in the document "LGS Generating Station Units 1 and 2; Summary Description of the Quality Assurance Program for Design and Construction." LGS will be in conformance during operation, except for certain alternate approaches to the ANSI Standard regarding correction to documents and storage, as discussed in the QATR.

(Category 1)

REGULATORY GUIDE 1.89 Qualification of Class 1E Equipment for Nuclear Power Plants

Rev 0, November 1974

Regulatory Guide 1.89, Revision 0, does not apply to LGS. LGS equipment requiring qualification was qualified in accordance with NUREG-0588, Category II as described in Sections 8.1.6.1 and 3.11.

(Category 4)

REGULATORY GUIDE 1.90 Inservice Inspection of Prestressed Concrete Containment Structures with Grouted Tendons

Rev 1, August 1977

LGS does not have a prestressed concrete containment and therefore this guide is not applicable.

REGULATORY GUIDE 1.91 Evaluation of Explosions Postulated to Occur on Transportation Routes Near Nuclear Power Plants

Rev 1, February 1978

Although this guide does not apply to LGS (being for plants whose construction permits were docketed after February 24, 1978), LGS is in conformance as discussed in Section 2.2.3.

(Category 2)

REGULATORY GUIDE 1.92 Combining Modal Responses and Spatial Components in Seismic Response Analysis

Rev 1, February 1976

This guide does not apply to LGS (being for plants whose instruction permits were docketed after February, 1976). LGS seismic response analysis methods are discussed in Section 3.7 and 3.9. Refer to Section 3.10.

(Category 1)

REGULATORY GUIDE 1.93 Availability of Electric Power Sources
Rev 0, December 1974

The LGS design is in conformance as discussed in Section 8.2. LGS will conform to this guide during operation as discussed in Chapter 16.

(Category 4)

REGULATORY GUIDE 1.94 Quality Assurance Requirements for Installation, Inspection, and Testing of Structural Concrete and Structural Steel During the Construction Phase of Nuclear Power Plants
Rev 1, April 1976

This guide, which endorses/modifies ANSI N45.25 (1974), is not applicable to LGS (being for plants whose construction permits are docketed after October, 1976). Quality assurance during construction is discussed in the document "LGS Generating Station Units 1 and 2; Summary Description of the Quality Assurance Program for Design and Construction."

The commitments to this Regulatory Guide and ANSI N45.2.5 were deleted since they were superseded by Exelon’s commitment to ASME NQA-1 1994 subpart 2.5.

(Category 1)

REGULATORY GUIDE 1.95 Protection of Nuclear Power Plant Control Room Operators Against an Accidental Chlorine Release
Rev 1, January 1977

This guide is not applicable to LGS (being for plants whose construction permits were docketed after the guide's issuance). The LGS design for protection against accidental chlorine release is discussed in Sections 2.2.3 and 6.4.

(Category 1)

REGULATORY GUIDE 1.96 Design of Main Steam Isolation Valve Leakage Control Systems for Boiling Water Reactor Nuclear Power Plants
Rev 0, May 1975

In 1994, LGS received approval to remove the MSIV-LCS and replace it with the MSIV Leakage Alternate Drain Pathway discussed in Section 6.7

(Category 1)

REGULATORY GUIDE 1.97 Instrumentation for Light-Water-Cooled Nuclear Power Plants to Assess Plant and Environs Conditions During and Following an Accident

Rev 2, December 1980

LGS is in conformance with this guide to the extent discussed in Section 7.5.

(Category 3)

REGULATORY GUIDE 1.98 Assumptions Used for Evaluating the Potential Radiological Consequences of a Radioactive Offgas System Failure in a Boiling Water Reactor

Rev 0, March 1976

LGS is in conformance with this guide except that an alternate approach is used for paragraph C.4.b (dose conversion factors) and there is a clarification to paragraph C.4.a regarding surface body dose rates. Details are discussed in Section 15.0.4.

(Category 1)

REGULATORY GUIDE 1.99 Radiation Embrittlement of Reactor Vessel Materials

Rev 2, May 1988

LGS is in conformance with this guide as discussed in Section 5.3.1.4.

(Category 3)

REGULATORY GUIDE 1.100 Seismic Qualification of Electric Equipment for Nuclear Power Plants

Rev 1, August 1977

This guide which endorses/modifies IEEE 344 (1975) does not apply to LGS (being for plants whose construction permits are docketed after the guide's issuance). LGS seismic qualification of electrical components is discussed in Section 3.10.

(Category 1)

REGULATORY GUIDE 1.101 Emergency Planning for Nuclear Power Plants

Rev 2, October 1981

LGS is in conformance with this guide except for certain alternate approaches discussed in the Emergency Plan.

REGULATORY GUIDE 1.102 Flood Protection for Nuclear Power Plants

Rev 1, September 1976

LGS is in conformance with this guide as discussed in Section 3.4.

(Category 2)

REGULATORY GUIDE 1.103 Post-Tensioned Prestressing Systems for Concrete Reactor Vessels and Containments

Rev 1, October 1976

LGS does not have a prestressed concrete containment and therefore this guide is not applicable.

REGULATORY GUIDE 1.104 Overhead Crane Handling Systems for Nuclear Power Plants

Rev 0, February 1976

This guide was withdrawn by the NRC on August 16, 1979. The LGS reactor enclosure crane was designed and procured prior to the issuance of this guide. For explanatory purposes, a comparison with the guide is given in Section 9.1.5.

(Category 4)

REGULATORY GUIDE 1.105 Instrument Setpoints

Rev 1, November 1976

Although this guide does not apply to LGS except for the RRCS (being for plants whose construction permits applications are docketed after Dec. 15, 1976). LGS will be in conformance during operation as discussed in Section 7.1.2.5 and Chapter 16.

(Category 2)

REGULATORY GUIDE 1.106 Thermal Overload Protection for Electric Motors on Motor-Operated Valves

Rev 1, March 1977

This guide is not applicable to LGS (being for plants whose construction permits are docketed after issuance of the guide). The LGS design is discussed in Section 8.1.6.1.

(Category 1)

REGULATORY GUIDE 1.107 Qualifications for Cement Grouting for Prestressing Tendons in Containment Structures

Rev 1, February 1977

LGS does not have a prestressed concrete containment and therefore this guide is not applicable.

REGULATORY GUIDE 1.108 Periodic Testing of Diesel Generator Units Used as Onsite Electric Power Systems at Nuclear Power Plants

Rev 1, August 1977

Although this guide does not apply to LGS (being for plants whose construction permits are docketed after issuance of the guide), LGS is in conformance. All diesel generator protective trips which are enforced during a LOOP or emergency operation, are annunciated in a group trouble alarm in the main control room and individually in the diesel generator local annunciator panel. An indication of which of the protective trips is activated first is provided on the local annunciator panel to facilitate diagnosis of trouble. The surveillance feature which would indicate the first diesel generator protective trip, is not necessary for the safe and orderly shutdown and for maintaining the

plant in a safe shutdown condition. Periodic testing of the diesel generators is described in Section 8.1.6.1.20. LGS will be in conformance during operation as discussed and clarified in Chapter 16.

(Category 2)

REGULATORY GUIDE 1.109	Calculations of Annual Doses to Man from Routine Releases of Reactor Effluents for the Purpose of Evaluating Compliance with 10CFR50, Appendix I
Rev 1, October 1977	

LGS is in conformance with this guide as discussed in Section 5.2 of the EROL.

(Category 1)

REGULATORY GUIDE 1.110	Cost-Benefit Analysis for Radwaste Systems for Light-Water-Cooled Nuclear Power Reactors
Rev 0, March 1976	

This guide is not applicable to LGS (being for plants whose construction permit applications are docketed after June 4, 1976). This analysis was not performed for LGS.

(Category 1)

REGULATORY GUIDE 1.111	Methods for Estimating Atmospheric Transport and Dispersion of Gaseous Effluents in Routine Releases from Light-Water-Cooled Reactors
Rev 1, July 1977	

LGS is in conformance with this guide except for certain alternate approaches as discussed in Section 2.3.

(Category 1)

REGULATORY GUIDE 1.112	Calculation of Releases of Radioactive Materials in Gaseous and Liquid Effluents from Light-Water-Cooled Power Reactors
Rev 0-R, May 1977	

LGS is in conformance with this guide as discussed in Section 11.1.

(Category 1)

REGULATORY GUIDE 1.113	Estimating Aquatic Dispersion of Effluents from Accidental and Routine Releases for the Purpose of Implementing Appendix I
Rev 1, April 1977	

LGS is in conformance with this guide as discussed in Section 5.2 of the EROL.

(Category 1)

REGULATORY GUIDE 1.114 Guidance on Being Operator at the Controls of a Nuclear Power Plant

Rev 1, November 1976

LGS will be in conformance with the guide.

(Category 3)

REGULATORY GUIDE 1.115 Protection Against Low-Trajectory Turbine Missiles
Rev 1, July 1977

The LGS analysis does not employ the guidelines of paragraph C.4 regarding damage probabilities assuming turbine failure. However, the total probability, calculated using assumptions acceptable to NRC on other projects, is well within the limits. Details are discussed in Section 3.5.1.3.

(Category 2)

REGULATORY GUIDE 1.116 Quality Assurance Requirements for Installation, Inspection, and Testing of Mechanical Equipment and Systems

Rev 0-R, May 1977

This guide endorses/modifies ANSI N45.2.8 (1975). The ANSI standard is not specifically a part of the construction QA program, however, LGS is in general conformance with the guide. Quality assurance during construction is discussed in the document "LGS Generating Station Units 1 and 2; Summary Description of the Quality Assurance Program for Design and Construction."

The commitments to this Regulatory Guide and ANSI N45.2.8 were deleted since they were superseded by Exelon's commitment to ASME NQA-1 1994 subpart 2.8.

(Category 1)

REGULATORY GUIDE 1.117 Tornado Design Classification
Rev 1, April 1978

Although this guide does not apply to LGS (being for plants whose construction permit applications are docketed after May 30, 1978), LGS is in conformance except that an alternate approach is used for protection of the spray pond spray networks. Details are discussed in Section 3.5.1.4.

(Category 2)

REGULATORY GUIDE 1.118 Periodic Testing of Electric Power and Protection Systems
Rev 2, June 1978

This guide, which endorses/modifies IEEE 338 (1977), does not apply to LGS except for the RRCS (being for plants whose construction permit applications are docketed after issuance of the guide). The design for periodic testing of electric power and protection systems is discussed in Sections 8.1.6.1 and 7.1.2.5, respectively.

(Category 1)

REGULATORY GUIDE 1.119 Surveillance Program for New Fuel Assembly Design

Rev 0, June 1976

This guide was withdrawn June 1977.

REGULATORY GUIDE 1.120 Fire Protection Guidelines for Nuclear Power Plants

Rev 1, November 1977

Per the letter transmitting Regulatory Guide 1.120 (Rev 1) LGS will be evaluated against BTP ASB 9.5-1 in lieu of this guide. LGS's conformance to ASB 9.5-1 is discussed in Appendix 9A.

(Category 1)

REGULATORY GUIDE 1.121 Bases for Plugging Degraded PWR Steam Generator Tubes

Rev 0, August 1976

This guide is for PWRs and therefore is not applicable to LGS.

REGULATORY GUIDE 1.122 Development of Floor Design Response Spectra for Seismic Design of Floor-Supported Equipment or Components

Rev 1, February 1978

This guide is not applicable to LGS (being for plants whose construction permit applications are under review after issuance of the guide). LGS floor design response spectra are discussed in Section 3.7.2.3.

(Category 1)

REGULATORY GUIDE 1.123 Quality Assurance Requirements for Control of Procurement of Items and Services for Nuclear Power Plants

Rev 1, July 1977

Historical Information

This guide endorses/modifies ANSI N45.2.13 (1976). Neither the guide nor the ANSI standard are specifically used during construction. Quality assurance during construction is discussed in the document "LGS Generating Station Units 1 and 2; Summary Description of the Quality Assurance Program for Design and Construction." LGS will conform during operation, as discussed and clarified in the QATR.

Regulatory Guide 1.123, Rev 1 has been withdrawn and superseded by Regulatory Guide 1.28, Rev 3, August 1985.

Limerick will conform to Regulatory Guide 1.28, Rev.3, August 1985 during operation, as discussed and clarified in the QATR.

(Category 1)

REGULATORY GUIDE 1.124 Service Limits and Loading Combinations for Class 1 Linear-Type Component Supports

Rev 1, January 1978

This guide does not apply to LGS (being for plants whose construction permit applications are docketed after January 10, 1978). This guide has not been used on LGS, and procedures for the subject matter of this guide are discussed in Section 3.9.

(Category 2)

REGULATORY GUIDE 1.125 Physical Models for Design and Operation of Hydraulic Structures and Systems for Nuclear Power Plants

Rev 1, October 1978

This guide is not applicable to LGS (being for plants whose construction permits are under review after issuance of the guide).

(Category 1)

REGULATORY GUIDE 1.126 An Acceptable Model and Related Statistical Methods for the Analysis of Fuel Densification

Rev 1, March 1978

This guide has not been applied. The fuel densification analysis defined in section 4.2.4.4.11 of NEDE-20944-P, "BWR 4/5 Fuel Design", September 1976 has been found acceptable by the NRC and is applicable to LGS.

(Category 1)

REGULATORY GUIDE 1.127 Inspection of Water-Control Structures Associated with Nuclear Power Plants

Rev 1, March 1978

LGS will be in conformance with this guide during construction of the spray pond. The various investigations and inspections associated with the spray pond are discussed in Sections 2.4 and 2.5. LGS will be in conformance with this guide during operation.

(Category 3)

REGULATORY GUIDE 1.128 Installation Design and Installation of Large Lead Storage Batteries for Nuclear Power Plants

Rev 1, October 1978

This guide is not applicable to LGS (being for plants whose construction permit applications are docketed after December 1, 1977). The LGS design of large lead storage battery facilities is discussed in Section 8.1.6.1 and 8.3.2.

(Category 1)

REGULATORY GUIDE 1.129 Maintenance, Testing, and Replacement of Large Lead Storage Batteries for Nuclear Power Plants

Rev 1, February 2 1978

This guide does not apply to LGS (being for plants whose construction permit applications are docketed after December 1, 1977). However, LGS is in conformance with this guide as described in Section 8.1.6.1. Periodic testing is discussed in Chapter 16 .

(Category 1)

REGULATORY GUIDE 1.130 Design Limits and Loading Combinations for Class 1 Plate-and-Shell-Type Component Supports

Rev 0, July 1977

This guide is not applicable to LGS (being for plants whose construction permit applications are docketed after April 1, 1978). LGS design limits and loading combinations are discussed in Sections 3.9 and 5.4.1.4.

(Category 2)

REGULATORY GUIDE 1.131 Qualification Tests of Electric Cables, Field Splices, and Connections for Light-Water-Cooled Nuclear Power Plants

Rev 0, August 1977

This guide is not applicable to LGS (being for plants whose construction permit applications are docketed after May 1, 1978). LGS qualification tests of electric cables, field splices, and connections are discussed in Section 3.11.

(Category 1)

REGULATORY GUIDE 1.132 Site Investigations for Foundations of Nuclear Power Plants

Rev 1, March 1979

This guide is applicable to LGS only for new investigations conducted after March 30, 1979. No new investigations have been conducted since that time. Site investigations are discussed in Sections 2.4 and 2.5.

(Category 1)

REGULATORY GUIDE 1.133 Loose-Part Detection Program for the Primary System of Light-Water-Cooled Reactors

Rev 1, May 1981

LGS is no longer in conformance with this guide. The Loose-Part Detection Program has been relaxed as discussed inn BWR Owners' Group Licensing Topical Report NEDC-32975P and associated SER.

REGULATORY GUIDE 1.134 Medical Certification and Monitoring of Personnel Requiring Operator Licenses

Rev 2, April 1987

LGS will be in conformance with this guide, which endorses/ modifies ANSI/ANS 3.4-1983, as discussed in Section 13.1.

(Category 1)

REGULATORY GUIDE 1.135 Normal Water Level and Discharge at Nuclear Power Plants

Rev 0, November 1977

This guide is not applicable to LGS (being for plants whose construction permits are docketed after May 1, 1978). The hydrologic analysis for LGS is discussed in Section 2.4.

(Category 1)

REGULATORY GUIDE 1.136 Material for Concrete Containments

Rev 1, October 1978

This guide is not applicable to LGS (being for plants whose construction permit applications are docketed after November 30, 1978). LGS containment material is discussed in Section 3.8.1.

(Category 1)

REGULATORY GUIDE 1.137 Fuel Oil Systems for Standby Diesel Generators

Rev 1, October 1979

This guide endorses/modifies ANSI N195 (1976) and is limited in its applicability to LGS to paragraph C.2, per the letter transmitting Revision 0 of this guide. LGS will conform to paragraph C.2 during operation, except that the fuel oil surveillance test requirements will be as described in the plant Technical Specifications. The design of fuel oil transfer system is discussed in Section 9.5.4.

(Category 2)

REGULATORY GUIDE 1.138 Laboratory Investigations of Soils for Engineering Analysis and Design of Nuclear Power Plants

Rev 0, April 1978

This guide is applicable to LGS only for new investigations conducted after December 1, 1978. No new investigations have been conducted since that time. Site investigations are discussed in Sections 2.4 and 2.5.

(Category 1)

REGULATORY GUIDE 1.139 Guidance for Residual Heat Removal

Rev 0, May 1978

Although the LGS design was completed prior to the issuance of this guide, LGS is in conformance with the intent, subject to clarifications regarding system protection features and pressure relief discussed in Section 5.4.7. LGS will be in conformance with this guide during operation.

(Category 3)

REGULATORY GUIDE 1.140 Design, Testing, and Maintenance Criteria for Normal Ventilation Exhaust System Air Filtration and Adsorption Units of Light-Water-Cooled Nuclear Power Plants

Rev 1, October 1979

This guide is not applicable to LGS per its implementation section. The LGS design was substantially completed prior to the issuance of this guide. For explanatory purposes, a comparison with Revision 1 of the guide is provided in Table 9.4-18.

(Category 1)

REGULATORY GUIDE 1.141 Containment Isolation Provisions for Fluid Systems

Rev 0, April 1978

The LGS containment isolation system was substantially completed prior to the issuance of this guide which endorses/modifies ANSI N271 (1976). LGS is in conformance with the guide except for certain design features of closed systems inside containment, valve leakage control and leak testing. Details are provided in Section 6.2.4.

(Category 2)

REGULATORY GUIDE 1.142 Safety-Related Concrete Structures for Nuclear Power Plants (Other than Reactor Vessels and Containments)

Rev 0, April 1978

This guide, which endorses/modifies ACI 349-76, is not entirely applicable to LGS (being for plants whose construction permit applications are docketed after December 15, 1978). Practices specified in the UFSAR for design and construction of safety related concrete structures bring LGS into compliance with substantial portions of the guide. LGS safety-related concrete structures are discussed in Section 3.8.

(Category 1)

REGULATORY GUIDE 1.143 Design Guidance for Radioactive Waste Management Systems Structures and Components Installed in Light-Water- Cooled Nuclear Power Plants

Rev 1, October 1979

LGS is in conformance with the intent of the guide, subject to the exceptions and clarifications listed in Table 3.2-1, Note 18. The design codes, standards, and quality assurance for radwaste

system piping and components are presented and discussed in Table 3.2-1; design of the radwaste structure is discussed in Section 3.8; radwaste management systems are discussed in Chapter 11.

(Category 1)

REGULATORY GUIDE 1.144 Auditing of Quality Assurance Programs for Nuclear Power Plants

Rev 1, September 1980

This guide endorses/modifies ANSI N45.2.12 (1977). The guide and the ANSI standard are not specifically utilized during construction. Quality assurance during construction is discussed in the document "LGS Generating Station Units 1 and 2; Summary Description of the Quality Assurance Program for Design and Construction."

Regulatory Guide 1.28 superseded commitments to RG 1.144. LGS will comply with Regulatory Guide 1.28 during operation, as described in the QATR.

(Category 1)

REGULATORY GUIDE 1.145 Atmospheric Dispersion Models for Potential Accident Consequence Assessments at Nuclear Power Plants

Rev 1, November 1982

The LGS X/Q values resulting at the EAB and LPZ are calculated using the NRC sponsored computer code PAVAN consistent with the procedures in Regulatory Guide 1.145, as discussed in Section 2.3.

REGULATORY GUIDE 1.146 Qualification of Quality Assurance Program Audit Personnel for Nuclear Power Plants

Rev 0, August 1980

LGS will comply with this guide, which endorses/modifies ANSI N45.2.23 (1978), as described in the QATR.

Regulatory Guide 1.28 superseded commitments to RG 1.146. LGS will comply with Regulatory Guide 1.28 during operation, as described in the QATR.

REGULATORY GUIDE 1.147 Inservice Inspection Code Case Acceptability ASME Section XI Division 1

Latest Revision

LGS conforms with this guide as specified in the Inservice Inspection Program and Inservice Testing documents .

REGULATORY GUIDE 1.148 Functional Specification for Active Valve Assemblies in Systems Important to Safety in Nuclear Power Plants

Rev 0, March 1981

The program (Section 3.9.3.2b) for the initial procurement of LGS valves was developed prior to the issuance of Regulatory Guide 1.148 and therefore does not include such a functional valves

specification. However, the intent of a functional specification has been met by functional requirements in the existing valve specification.

REGULATORY GUIDE 1.150 Ultrasonic Testing of Reactor Vessel Welds During Preservice and Inservice Examinations

Rev 1, February 1983

LGS will be in conformance with Regulatory Guide 1.150 to the extent practicable. The extent of compliance will be submitted with the RPV PSI Report.

REGULATORY GUIDE 1.155 Station Blackout

Rev. 0, August 1988

LGS is in conformance with this guide by virtue of compliance with NUMARC 87-00, November 1987, except where Regulatory Guide 1.155 takes precedence. Compliance is discussed in Section 8.1.6.1.25.

REGULATORY GUIDE 1.166 Pre-earthquake Planning and Immediate Nuclear Power Plant Operator Post-Earthquake Actions

March 1997

This guide provides guidance acceptable to the NRC staff for a timely evaluation after an earthquake of the recorded instrumentation data and for determining whether plant shutdown is required by 10 CFR Part 50.

REGULATORY GUIDE 1.167 Restart of a Nuclear Power Plant Shut Down by a Seismic Event

March 1997

This guide provides guidance acceptable to the NRC staff for performing inspections and tests of nuclear power plant equipment and structures prior to restart of a plant that has been shut down by a seismic event.

REGULATORY GUIDE 1.181 Content of the Updated Final Safety Analysis Report in accordance with 10 CFR 50.71(e)

Rev 0, September 1999

This Guideline endorses NEI 98-03, Revision 1, “Industry Update Guidelines for Final Safety Analysis Reports.”

REGULATORY GUIDE 1.183 Alternative Radiological Source Terms for Evaluating Design Basis Accidents at Nuclear Power Reactors

Rev 0, July 2000

This guideline supersedes Regulatory Guides 1.3, 1.5, and 1.25 for assumptions and methodology for assessing radiological consequences of design basis accidents. Alternative Source Terms (AST) for determination of off-site and control room dose was approved for use at LGS by NRC Safety Evaluation Report dated September 8, 2006. LGS is in conformance with this Regulatory Guide, with exceptions, as discussed in Section 15.0.4.

REGULATORY GUIDE 1.190 Calculational and Dosimetry Methods for Determining Pressure Vessel Neutron Fluence

Rev 0, March 2001

This Guideline was not used as a design basis, which is discussed in Section 4.1.4.5, 4.3.2.8 and 5.3.1.6.2. LGS reactor pressure vessel neutron fluence calculations performed after October 2002 will be in conformance with this guide (Reference 5.3-13).

REGULATORY GUIDE 1.194 Atmospheric Relative Concentrations for Control Room Radiological Habitability Assessments at Nuclear Power Plants

Rev 0, July 2003

The LGS X/Q values resulting at the control room intake are calculated using the NRC sponsored computer code ARCON96, consistent with the procedures in Regulatory Guide 1.194, as discussed in Section 2.3.

Table 1.8-1

COMPONENT IDENTIFICATION FOR CODE CASE N242

VALVE OR SYSTEM	PARTS OR COMPONENTS

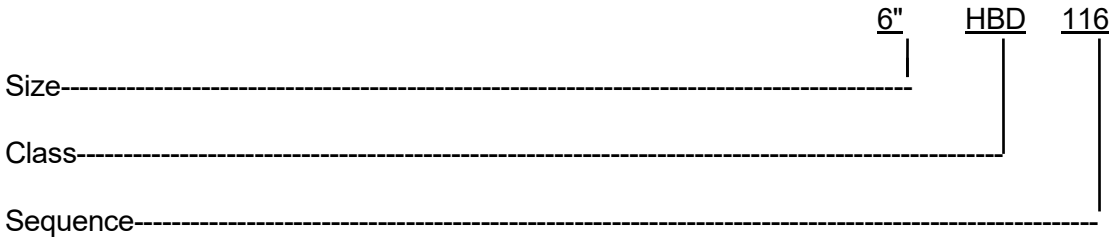
1.9 STANDARD DESIGNS

This section is not applicable to LGS as it is not a standard design plant.

1.10 SYMBOLS AND TERMS

1.10.1 TEXT ACRONYMS

Acronyms used throughout the UFSAR are listed in Table 1.10-1.



1.10.2 LOGIC SYMBOLS

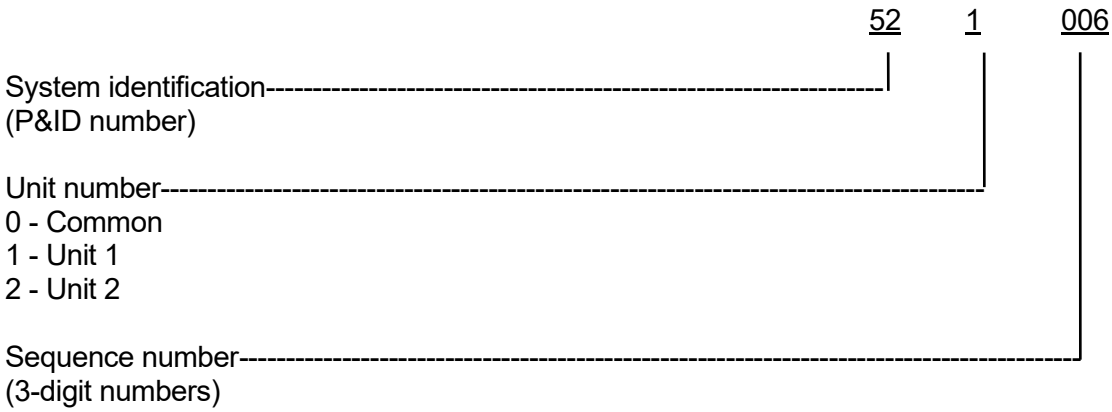
Logic symbols used on FCDs are shown in Figure 1.10-2.

1.10.3 PIPING IDENTIFICATION

Piping is identified by a three-group identifier where the first group is the nominal pipe size in inches; the second is a three-letter group for the pipe class; and the third is a three-digit group sequentially assigned within a pipe class.

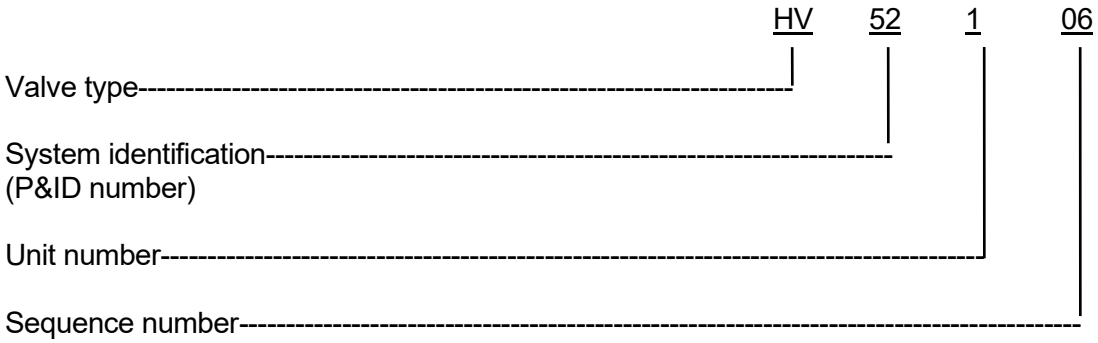
Example:

The three-letter group for the pipe class is described in detail in Table 1.10-2.



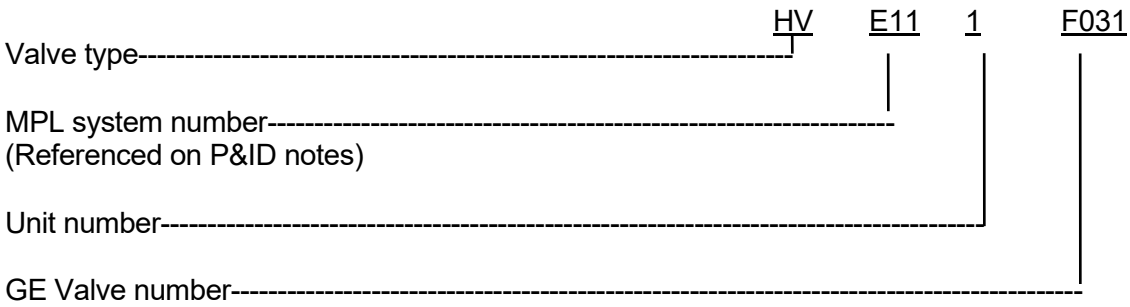
The three-digit sequence number is assigned consecutively to identify specific lines in a pipe class as follows:

Piping common to both units	0-99 and 500-699
Piping for Unit 1	100-199, 300-399, and 700-799
Piping for Unit 2	200-299, 400-499, and 800-899



1.10.4 VALVE IDENTIFICATION

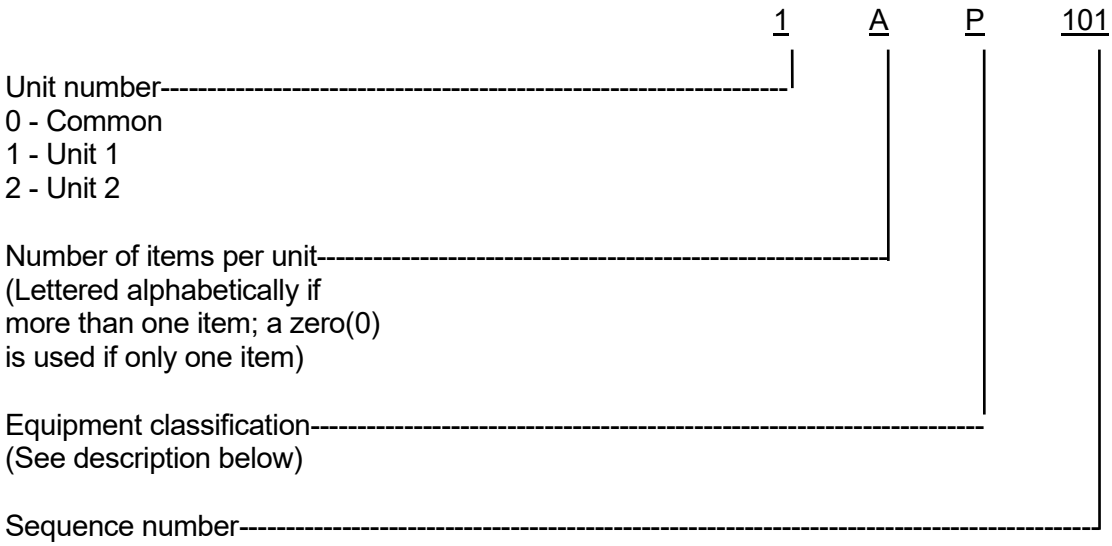
All manual and remotely operated valves have unique identification numbers for tracking purposes. Listed below are the numbering systems used for each group of valves.



Manual valves, except those which have a GE MPL number and those valves supplied by vendors as part of an equipment package and not installed by Bechtel, are identified by the following method:

Remote-operated valves that do not have a GE MPL number are identified by the operator number as follows:

Those valves in GE's MPL are identified by the GE numbering system as follows:



Valve types are indicated in drawing M-00. Valves that are not numbered but are supplied as part of a vendor mounted equipment package are identified in the vendor's operation and maintenance manuals. This is done to avoid duplication in numbering these valves.

1.10.5 EQUIPMENT NUMBERING

Equipment is identified on the P&IDs by a four-group identifier as discussed below.

Example:

Equipment classification is identified by type as follows:

A	13.8, 4.16, and 2.4 kV switchgear
B	440 V load centers and motor control centers
C	Control boards or relay boards
D	Direct current equipment
F	Filters and cleaning equipment
G	Generators (turbine, diesel) and associated equipment
H	Hoists and cranes
K	Air compressors, chiller compressors, process fans, and blowers
L	Lighting, heater, and distribution panels
P	Pumps including drive motors
R	33/220/500 kV switchgear and associated equipment
S	Miscellaneous
T	Tanks and pressure vessels
U	Floor sections
V	Air conditioning units, ventilation fans and exhausters
W	Power receptacles
X	Transformers
Y	Instrument ac equipment
Z	Computer equipment

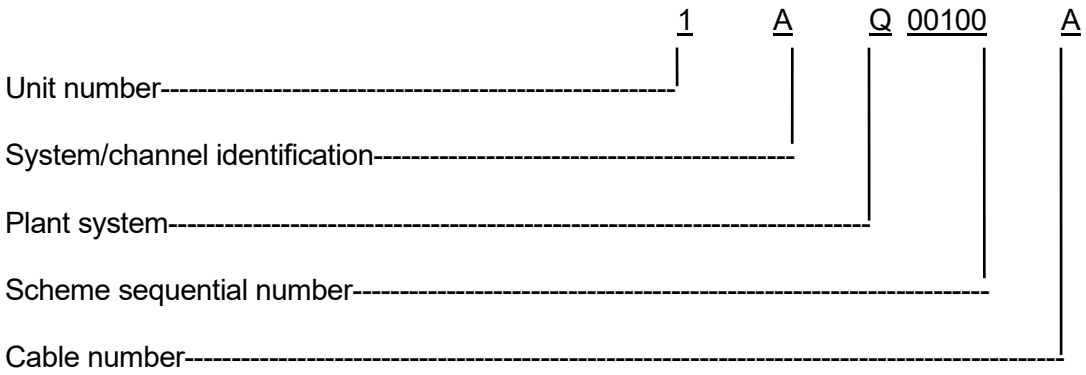
1.10.6 ELECTRICAL COMPONENT IDENTIFICATION

This section describes the methods used to identify electrical equipment locations and to number electrical schemes, cables, and raceways.

1.10.6.1 Equipment Location Numbers

Each piece of electrical equipment is identified by an equipment number as described in Section 1.10.4. To facilitate cable routing from one equipment location to another, a location number is also assigned to each piece of electrical equipment. Generally, the equipment number and equipment location number for a specific piece of electrical equipment are identical. For large pieces of electrical equipment, such as switchgear, load centers, and MCC, which are compartmentalized, the equipment location number consists of the basic equipment number plus additional suffixed information to identify a location within the equipment itself. The following two examples illustrate equipment location numbers:

Example 1: 10X101
Example 2: 10B22403

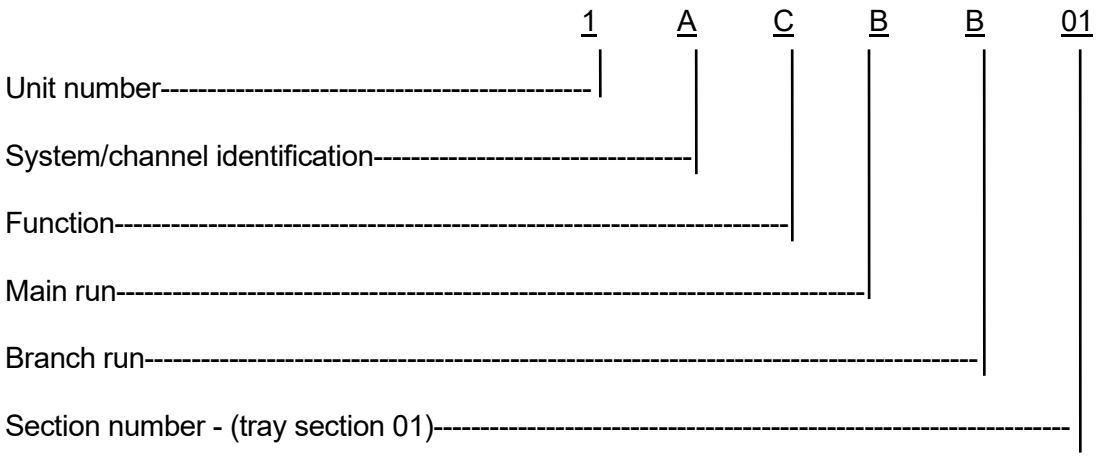


In the first example, the equipment number and equipment location number for transformer 10X101 are identical. In the second example, the basic MCC equipment number 10B224 is suffixed to establish an equipment location number, 10B22403, which identifies a specific cubicle within the MCC.

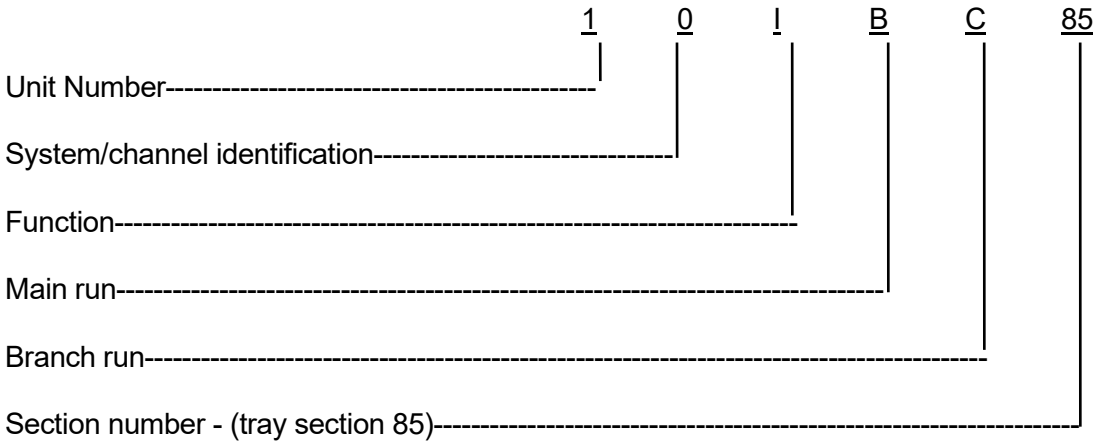
Equipment location numbers are generally assigned to items listed in the circuit and raceway schedules. Accordingly, most electrical equipment related to systems such as lighting, communications, and cathodic protection is not included.

Electrical equipment that is an integral part of mechanical equipment is assigned the same number as the mechanical equipment.

1.10.6.2 Scheme Cable Numbers



Each electrical scheme is identified by a number with up to nine characters. The first character is numeric and refers to the plant unit number for which the scheme is applicable. The second character is alphabetic or numeric and refers to the separation group to which the cable belongs. The third character is alphabetic and classifies the scheme by major plant system. The next six characters are numeric or alphanumeric, and provide a sequential, but arbitrary, identity for each scheme. (The letter designation at the end of the scheme number is the cable number.) Except for cabling associated with the plant lighting, communications, and cathodic protection systems, each cable in the plant is identified by a scheme cable number. Given below is an example of a typical scheme number including the cable number.



1.10.6.3 Raceway Numbers

All electrical cable trays, ducts, conduits, manholes, conduit sleeves, and junction boxes are identified by six-character raceway numbers. The two examples given below illustrate typical raceway numbers for safety-related and nonsafety-related cable trays, respectively.

Safety-related

Nonsafety-related

The following example illustrates a typical conduit number:

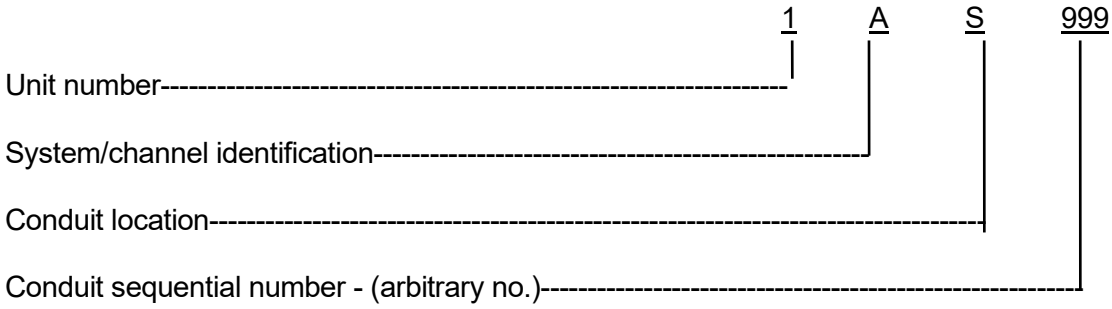


Table 1.10-1

ACRONYMS USED IN UFSAR

AASHTO	American Association of State Highway and Transportation Officials
ABS	absolute summation
AC	alternating current
ACI	American Concrete Association
ACRS	Advisory Committee on Reactor Safeguards
ADS	automatic depressurization system
AE	Architect/Engineer

PIPING AND VALVE CLASS IDENTIFICATION

Pipe and valve classes are designated by a three-letter code. The first letter indicates the primary valve and flange pressure rating; the second letter, the type of material; and the third letter, the code to which the piping is designed.

FIRST LETTER - PRIMARY PRESSURE RATING

C - 1500 psi
D - 900 psi
E - 600 psi
F - 400 psi
G - 300 psi
H - 150 psi
I - 250 psi
J - 125 psi
K - 175 psi
L - 75 psi
M - General use as designated on piping class sheets
N - Sanitary drainage
R - Threaded vents and drains
S - Welded vents and drains
X - Special Rating

SECOND LETTER - MATERIAL

A - Alloy steel
B - Carbon steel
C - Austenitic steel
D - Copper
F - Carbon steel - copper bearing
G - Carbon steel - lined
H - Cast iron
J - Alloy steel
K - PVC
L - Carbon steel - impact test as code requires
M - Duriron
N - Carbon steel - galvanized
P - Bronze
Q - Brass

Table 1.10-2 (Cont'd)

THIRD LETTER - DESIGN CODE

A - Nuclear power plant components, ASME B&PV Code, Sect. III, Class 1
B - Nuclear power plant components, ASME B&PV Code, Sect. III, Class 2
C - Nuclear power plant components, ASME B&PV Code, Sect. III, Class 3
D - Power Piping Code ANSI B31.1.0
F - National Fire Protection Code
G - National Plumbing Code

1.11 RRRC CATEGORY 1, 2, 3, AND 4 MATTERS

1.11.1 DISCUSSION OF CATEGORIES

The Regulatory Requirements Review Committee has characterized the backfitting potential of certain regulatory guides and branch technical positions or other proposed modifications to existing staff positions by placing them in one of three categories (Reference 1.11-1):

a. Category 1 - Clearly forward fit only. No further staff consideration of possible backfitting is required.

b. Category 2 - Further staff consideration of the need for backfitting appears to be required for certain identified items of the regulatory position. These individual issues are such that existing plants need to be evaluated to determine their status with regard to these safety issues in order to determine the need for backfitting.

c. Category 3 - Clearly backfit. Existing plants should be evaluated to determine whether identified items of the regulatory position are resolved in accordance with the guide or by some equivalent alternative.

In addition to the above RRRC categories, there also exists an Office of Nuclear Reactor Regulation (NRC) Category 4 list of those matters not yet reviewed by the RRRC, but which have been deemed by the Director, Office of Nuclear Reactor Regulation, to warrant being addressed and considered in ongoing reviews.

The NRC transmitted a list of Category 2, 3, and 4 matters to the licensee (Reference 1.11-2), and requested that the listed items be considered in the LGS FSAR. Reference 1.11-2 defines these categories as follows:

a. Category 1 - Matters are to be applied in accordance with the implementation section of the published guide.

b. Category 2 - This is a new position whose applicability is to be determined on a case-by-case basis.

c. Category 3 - Conformance or an acceptable alternative is required.

d. Category 4 - Matters are to be treated like Category 2 matters until such time as they are reviewed by the RRRC, and a definite implementation program is developed.

Table 1.11-1 identifies the UFSAR sections containing material relevant to the RRRC and to the NRC categorized matters with the exception of Category 1 (those to be implemented in accordance with the implementation section of the published NRC position) which are outside the scope of this appendix.

The categorization of regulatory guides in the RRRC and NRC lists is given in Section 1.8.

1.12 UNRESOLVED SAFETY ISSUES

1.12.1 INTRODUCTION

The NRC continuously evaluates the safety requirements used in its reviews against new information as it becomes available. Information related to the safety of nuclear power plants comes from a variety of sources including experience from operating reactors; research results; NRC staff and ACRS safety reviews; and vendor, architect-engineer, and utility design reviews. Each time a new concern or safety issue is identified from one or more of these sources, the need for immediate action to ensure safe operation is assessed. This assessment includes consideration of the generic implications of the issue.

In some cases, immediate action is taken to ensure safety, for example, the derating of BWRs as a result of the channel box wear problems in 1975. In other cases, interim measures, such as modifications to operating procedures, may be sufficient to allow further study of the issue before making licensing decisions. In most cases, however, the initial assessment indicates that immediate licensing actions or changes in licensing criteria are not necessary. In any event, further study may be deemed appropriate to make judgments as to whether existing NRC requirements should be modified to address the issue for new plants or if backfitting is appropriate for the long-term operation of plants already under construction or in operation.

These issues are sometimes called generic safety issues because they are related to a particular class or type of nuclear facility rather than to a specific plant. Certain of these issues have been designated as unresolved safety issues (Reference 1.12-1). However, as discussed above, such issues are considered on a generic basis only after the NRC staff has made an initial determination that the safety significance of the issue does not prohibit continued operation or require licensing actions while the longer term generic review is under way.

In 1978, the NRC undertook a review of over 130 generic issues addressed in the NRC program. The review is described in Reference 1.12-2. The report provides the following definition of an unresolved safety issue:

> A USI is a matter affecting a number of nuclear power plants that poses important questions concerning the adequacy of existing safety requirements for which a final resolution has not yet been developed and that involves conditions not likely to be acceptable over the lifetime of the plants it affects.

Furthermore, the report indicates that in applying this definition, matters that pose "important questions concerning the adequacy of existing safety requirements" were judged to be those for which resolution is necessary to (1) compensate for a possible major reduction in the degree of protection of the public health and safety, or (2) provide a potentially significant decrease in the risk to the public health and safety. Quite simply, a USI is potentially significant from a public safety standpoint and its resolution is likely to result in NRC action on the affected plants.

All of the issues addressed in the NRC program were systematically evaluated against this definition as described in Reference 1.12-2. As a result, 17 USIs addressed by 22 tasks in the NRC program were identified. The issues and applicable task numbers are listed below. Progress on these issues was first discussed in the 1978 NRC Annual Report. The number(s) of the generic task(s) (for example, A-1) in the NRC program addressing each issue is indicated in parentheses following the title.

1. Water Hammer (A-1)
2. Asymmetric Blowdown Loads on the Reactor Coolant System (A-2)
3. Pressurized Water Reactor Steam Generator Tube Integrity (A-3, A-4, A-5)
4. BWR Mark I and Mark II Pressure-Suppression Containments (A-6, A-7, A-8, A-39)
5. Anticipated Transients Without Scram (A-9)
6. BWR Nozzle Cracking (A-10)
7. Reactor Vessel Materials Toughness (A-11)
8. Fracture Toughness of Steam Generator and Reactor Coolant Pump Supports (A-12)
9. Systems Interaction in Nuclear Power Plants (A-17)
10. Environmental Qualification of Safety-Related Electrical Equipment (A-24)
11. Reactor Vessel Pressure Transient Protection (A-26)
12. Residual Heat Removal Requirements (A-31)
13. Control of Heavy Loads Near Spent Fuel (A-36)
14. Seismic Design Criteria (A-40)
15. Pipe Cracks at Boiling Water Reactors (A-42)
16. Containment Emergency Sump Reliability (A-43)
17. Station Blackout (A-44)

The NRC has performed an in-depth and systematic review of generic safety concerns identified since January 1979 to determine if any of these issues should be designated as new USIs. The candidate issues originated from concerns identified in Reference 1.12-3, ACRS recommendations, abnormal occurrence reports, and other operating experience. The Commission considered the above information and approved the following four new unresolved safety issues:

1. Shutdown Decay Heat Removal Requirements (A-45)
2. Seismic Qualification of Equipment in Operating Plants (A-46)
3. Safety Implication of Control Systems (A-47)
4. Hydrogen Control Measures and Effects of Hydrogen Burns on Safety Equipment (A-48)

A description of the above process together with a list of the issues considered is presented in Reference 1.12-4. An expanded discussion of each of the new USIs is also contained in Reference 1.12-4.

In addition to the four issues identified above, the Commission approved another issue, A-49, Pressurized Thermal Shock, as a USI in December 1981.

In December, 1987 the NRC issued a compilation of the generic safety issues as NUREG-0933, "A Prioritization of Generic Safety Issues." This compilation includes the USIs and is periodically supplemented to update the status of the safety issues.

1.12.2 APPLICABILITY TO LGS

Seven of the twenty-seven tasks identified with the USIs are not applicable to LGS because they apply to PWRs only. These tasks are A-2, A-3, A-4, A-5, A-12, A-26, and A-49. Also, Tasks A-6 and A-7 only apply to Mark I or Mark III BWR containments. With regard to the remaining eighteen tasks that are applicable to LGS, the NRC staff has issued NUREG reports or rule changes providing its resolution of seventeen of the issues. These issues are listed below.

TASK NUMBER	NUREG REPORT NO. AND TITLE
A-1	NUREG-0927, "Evaluation of Water Hammer in Nuclear Power Plants - Technical Findings Relevant to Unresolved Safety Issue A-1".
	NUREG-0993, "Regulatory Analysis for USI A-1, "Water Hammer".
	NUREG-0800, SRP 3.9.3, 3.9.4, 5.4.6, 5.4.7, 6.3, 9.2.1, 9.2.2, 10.3 and 10.4.7, Various Titles.
A-8	NUREG-0808 "Mark II Containment Pool Dynamic Loads".
	NUREG-0802, "Safety/Relief Valve Quencher Loads: Evaluation for BWR Mark II and III Containments".
	NUREG-0800, SRP 6.2.1.1.c, "Pressure-Suppression Type BWR Containments".
A-9	NUREG-0460, Vol 4, "Anticipated Transients Without Scram for Light-Water Reactors".
	10CFR50.62, Federal Register Notice 49FR2036.
A-10	NUREG-0619, "BWR Feedwater Nozzle and Control Rod Drive Return Line Nozzle Cracking".
A-11	NUREG-0744, Revision 1, "Resolution of the Task A-11 - Reactor Vessel Materials Toughness Safety Issue".
A-17	NUREG-1174, "Evaluation of Systems Interactions in Nuclear Power Plants". NUREG-1229, "Regulatory Analysis for Resolution of USI A-17".

A-24 NUREG-0588, Revision 1, "Interim Staff Position on Environmental Qualification of Safety-Related Electrical Equipment".

NUREG-0800, SRP 3.11, "Environmental Qualification of Mechanical and Electrical Equipment".

10CFR50.49, Federal Register Notice 47FR28363.

A-31 NUREG-0800, SRP 5.4.7 and BTP 5-1, "Residual Heat Removal Systems" (incorporate requirements of USI A-31).

A-36 NUREG-0612, "Control of Heavy Loads at Nuclear Power Plants".

A-39 NUREG-0802, "Safety/Relief Valve-Quencher Loads: Evaluation for BWR Mark II and III Containments".

NUREG-0800, SRP 6.2.1.1.c, "Pressure-Suppression Type BWR Containments".

A-40 NUREG-1233, "Regulatory Analysis for USI A-40".

NUREG-0800, SRP 2.5.2, 3.7.1, 3.7.2 and 3.7.3, Various Titles.

A-42 NUREG-0313, Revision 2, "Technical Report on Material Selection and Processing Guidelines for BWR Coolant Pressure Boundary Piping" (Note: Revision 1 is applicable prior to issuance of NRC Generic Letter 88-01.)

A-43 NUREG-0869, Revision 1, "USI A-43 Regulatory Analysis".

NUREG-0897, Revision 1, "Containment Emergency Sump Performance".

A-44 NUREG-1032, "Evaluation of Station Blackout Accidents at Nuclear Power Plants, Technical Findings Related to Unresolved Safety Issue A-44, Draft Report for Comment".

NUREG-1109, "Regulatory Analysis for the Resolution of Unresolved Safety Issue A-44, Station Blackout, Draft Report for Comment".

10CFR50.63, Federal Register Notice 53FR23215.

A-45 NUREG-1289, "Regulatory and Backfit Analysis for the Resolution of USI A-45".

NUREG-1292, "Shutdown Heat Removal Analysis: Plant Case Studies and Special Issues Summary Report".

A-47 NUREG-1217, "Evaluation of Safety Implications of Control Systems in LWR Nuclear Power Plants".

NUREG-1218, "Regulatory Analysis for Resolution of USI A-47".

A-48 10CFR50.44, Federal Register Notice 46FR58484.

NUREG-1370, "Resolution of Unresolved Safety Issue A-48, "Hydrogen Control Measures and Effects of Hydrogen Burns on Safety Equipment".

The remaining issue applicable to LGS is Seismic Qualification of Equipment in Operating Plants (A-46). It is further discussed below.

1.12.3 DISCUSSIONS OF TASKS AS THEY RELATE TO LGS

This section provides an implementation and status summary of LGS for each of the applicable USIs. This includes the NRC requirements summary of each issue as stated in Generic Letter 89-21 (Request for Information Concerning Status of Implementation of Unresolved Safety Issue Requirements).

A-1 Water Hammer

REQUIREMENTS SUMMARY:

On March 15, 1984, the EDO sent the Commissioners a Policy Issue titled, "Resolution of Unresolved Safety Issue A-1, Water Hammer." In this Policy Issue the staff concluded that the frequency and severity of water hammer occurrences had been significantly reduced through (a) incorporation of design features such as keep-full systems, vacuum breakers, J-tubes, void detection systems and improved venting procedures, (b) proper design of feedwater valves and control systems and (c) increased operator awareness and training. Therefore, the resolution of USI A-1 did not involve any hardware or design changes on existing plants. It did involve SRP changes (forward fits) and a comprehensive set of guidelines and criteria to evaluate and upgrade utility training programs (per TMI Item I.A.2.3.). In addition, the assumption was made that for BWRs with isolation condensers a high reactor vessel water level feedwater pump trip was in place or being installed. This was necessary because calculated values had postulated an isolation condenser failure by water hammer that opened a direct pathway to the environment.

Items to certify:

1. A comprehensive set of guidelines and criteria to evaluate and upgrade utility training programs (per TMI Item I.A.2.3) is in place.

2. BWRs with isolation condensers have installed and operated a high reactor vessel water level feedwater pump trip.

IMPLEMENTATION AND STATUS SUMMARY:

1. TMI Item I.A.2.3 implementation was complete at the time of receipt of the operating license. The LGS training program has been upgraded and subsequently INPO accredited.

2. LGS does not have an isolation condenser.

A-8 Mark II Containment Pool Dynamic Loads

REQUIREMENTS SUMMARY:

The requirement is that the 11 BWRs having the Mark II containment shall meet the requirements of GDC 16, "Containment Design."

As stated in NUREG-0808, "Mark II Containment Program Load Evaluation and Acceptance Criteria", the original design of the Mark II containment system considered only those loads normally associated with DBAs that were known at the time. These included pressure and temperature loads associated with a LOCA, seismic loads, dead loads, jet impingement loads, hydrostatic loads due to water in the suppression chamber, overload pressure test loads, and construction loads. However, since the establishment of the original design criteria, additional loading conditions were identified that must be considered for the pressure-suppression containment system design.

In the course of performing large-scale testing of an advanced design pressure-suppression containment (Mark III), and during in-plant testing of Mark I containments, new suppression pool hydrodynamic loads were identified that had not been included explicitly in the original Mark II containment design basis. These additional loads result from dynamic effects of drywell air and steam being rapidly forced into the suppression pool during a postulated LOCA and from suppression pool response to SRV operation, which is generally associated with plant transient operating conditions. Because these new hydrodynamic loads had not been considered, the NRC staff determined that a detailed reevaluation of the Mark II containment system was required.

The issuance of NUREG-0808, NUREG-0802, and NUREG-0487 documented acceptable methods for calculating the hydrodynamic loads associated with plant transient conditions. Specifically, the loads referenced in these NUREGs, as modified by the acceptance criteria, constituted the resolution of USI A-8. SRP 6.2.1 has been modified to reflect the applicability of these NUREGs to Mark II containment evaluations.

Implementation is believed to be complete for all Mark II BWRs. As part of the licensing process, the staff required that the new calculation methodology defined in the referenced NUREGs be utilized by the applicant before issuance of a full power license.

IMPLEMENTATION AND STATUS SUMMARY:

The Mark II containment pool dynamic loads were addressed in the DAR for LGS (Appendix 3A and 3B) during the initial operating license review. The NRC review is documented in SSER-2, Sections 6.2.1.7 and 6.2.1.8.

A-9 Anticipated Transients Without Scram

The USI was resolved on June 26, 1984 with the publication of a final rule (10CFR50.62), to require improvements in plants to reduce the likelihood of failure of the RPS to shut down the reactor following anticipated transients and to mitigate the consequences of an ATWS event. The rule includes the following design-related requirements: 10CFR50.62(C)(l) - Diverse and Independent Auxiliary Feedwater Initiation and Turbine Trip for All PWRs, 10CFR50.62(C)(2) - Diverse Scram Systems for CE and B&W Reactors, 10CFR50.62(C)(3) - ARI for BWRs, 10CFR50.62(C)(4) - SLCS for BWRs, and 10CFR50.62(C)(5) - Automatic RPT Under Conditions Indicative of an ATWS for BWRs. Information requirements and an implementation schedule are also specified.

IMPLEMENTATION AND STATUS SUMMARY:

LGS has completed implementation of ARI, RPT and adequate SLCS capacity. These were installed prior to fuel load and the Technical Specifications included RPT and SLCS. The SLCS

Technical Specification was revised in June 1989 when minor discrepancies were identified in the original Technical Specification.

A-10 BWR Feedwater Nozzle Cracking

REQUIREMENTS SUMMARY:

Inspections of operating BWRs conducted up to April 1978 revealed cracks in the feedwater nozzles of 20 reactor vessels. It was determined that cracking was due to high-cycle fatigue caused by fluctuations in water temperature within the vessel in the nozzle region. This item was originally identified in NUREG-0371 and was later determined to be a USI.

By letter dated November 13, 1980, D.G. Eisenhut (NRC) provided licensees with a copy of NUREG-0619, "BWR Feedwater Nozzle and Control Rod Drive Return Line Nozzle Cracking." The letter stated that NUREG-0619 provided the resolution of the staffs generic technical activity A-10, a USI, which resulted from the inservice discovery of cracking in feedwater nozzles and CRD return line nozzles. NUREG-0619 describes the technical issues, GE and staff studies and analyses and the staff's positions and requirements. Licensees were required to respond, pursuant to 10CFR50.54(f), that implementation dates indicated in NUREG-0619 would be met.

Generic Letter 81-11 was subsequently issued to provide technical clarification to the November 13, 1980 letter and to clarify that it had been sent to PWR licensees for information only and that no response was required from PWR licensees.

IMPLEMENTATION AND STATUS SUMMARY:

Implementation of NUREG-0619 was reviewed during the initial operating license review. As discussed in the SER, LGS does not have a CRD system return line to the reactor vessel; equalizing valves are installed between the cooling water header and exhaust water header; the flow stabilizer loop is routed to the cooling water header; and both the exhaust header and flow stabilizer loop are stainless steel piping; and are acceptable.

A-11 Reactor Vessel Materials Toughness

Because of the remote possibility of failure of nuclear RPVs designed to the ASME B&PV Code, the design of nuclear facilities does not provide protection against reactor vessel failure. Prevention of reactor vessel failure depends primarily on maintaining the reactor vessel material fracture toughness at levels that will resist brittle fracture during plant operation. At service times and operating conditions typical of current operating plants, reactor vessel fracture roughness properties provide adequate margins of safety against vessel failure; however, as plants accumulate more and more service time, neutron irradiation reduces the material fracture toughness and initial safety margins. This item was originally identified in NUREG-0371 and was later determined to be a USI.

10CFR50, Appendix G required that the charpy upper-shelf energy throughout the life of the vessel be no less than 50 ft-lbs unless it is demonstrated that lower values will provide margins of safety against failure equivalent to those provided by Appendix G of the ASME code. USI A-11 was initiated to address the staff's concern that some vessels were projected to have beltline materials with charpy upper-shelf energy less than 50 ft-lbs.

This USI was resolved in October 1982 with the issuance of NUREG-0744, Revision 1 which was later transmitted to all licensees with Generic Letter 82-26.

NUREG-0744 provides a method for evaluation of reactor vessel materials when their charpy upper-shelf energy are predicted to fall below 50 ft-lbs. Plants will use the prescribed method when analysis of irradiation damage predicts that the charpy upper-shelf energy is below 50 ft-lbs.

IMPLEMENTATION AND STATUS SUMMARY:

Implementation of NUREG-0744 was addressed in the initial operating license review. LGS complies as discussed in SER and SSER-9 Section 5.3.1.2.

A-17 Systems Interaction in Nuclear Power Plants

REQUIREMENTS SUMMARY:

Generic Letter 89-18, dated September 6, 1989, was sent to all power reactor licensees and constitutes the resolution of USI A-17. No licensee actions were required by Generic Letter 89-18.

Generic Letter 89-18 had two enclosures which (1) outlined the bases for the resolution of USI A-17, and (2) provided five general lessons learned from the review of the overall systems interaction issue. It was anticipated that licensees' review of this information would be considered in other programs, such as the "Individual Plant Examination for Severe Accident Vulnerabilities." Specifically, the staff expected that insights concerning water intrusion and flooding from internal sources, provided in the appendix to NUREG-1174, will be considered in the IPE program. Also considered in the USI's resolution was the expectation that licensees would continue to review information on events at operating nuclear power plants in accordance with the requirements of TMI Item I.C.5 of NUREG-0737.

IMPLEMENTATION AND STATUS SUMMARY:

No changes were required for LGS.

I. The IPE for LGS was approved by the NRC by letter dated December 9, 1994.

II. TMI Item I.C.5 of NUREG-0737 is implemented through an Operating Experience Assessment Program as discussed in Section 1.13.

A-24 Qualification of Class 1E Equipment

REQUIREMENTS SUMMARY:

The publishing of NUREG-0588, Revision 1, "Interim Staff Position on Environmental Qualification of Safety-Related Electrical Equipment" in July 1981 completed the staff resolution of Generic Technical Activity A-24, "Qualification of Class 1E Safety-Related Equipment." Part I of the report is the original "For Comment" NUREG-0588 which in conjunction with the DOR Guidelines was endorsed by a Commission Memorandum and Order as the interim position on this subject until "final" positions were established in rule making. On January 21, 1983 the Commission amended its regulations, in 10CFR50.49 (the rule), effective February 22, 1983 to codify existing qualification methods in national standards, regulatory guides, and certain NRC publications including NUREG-0588.

The rule is based on the DOR Guidelines and NUREG-0588, which "provide guidance on (1) how to establish environmental service conditions, (2) how to select methods which are considered appropriate for qualifying the equipment in different areas of the plant, and (3) other areas such as margin, aging, and documentation." NUREG-0588 does not address all areas of qualification; it does supplement, in selected areas, the provisions of the 1971 and 1974 versions of IEEE 323. The rule recognizes previous qualification efforts completed as result of Memorandum and Order CLI-80-20 and also reflects different IEEE 323 versions dependent on the date of the construction permit SER. Therefore, plant specific requirements may vary in accordance with the rule.

In summary, the resolution of A-24 is embodied in 10CFR50.49. A measure of whether each licensee has implemented the resolution of A-24 may therefore be found in the determination of compliance with 10CFR50.49. This was addressed by 72 SERs for operating plants shortly after publication of the rule and subsequently in operating license reviews pursuant to SRP 3.11. This was further addressed by the first round EQ inspections conducted by the Office of Inspection and Enforcement, the Regions, and Nuclear Reactor Regulation.

IMPLEMENTATION AND STATUS SUMMARY:

Environmental qualification of electrical equipment was addressed during the initial operating license review. LGS Unit 1 did not complete the necessary documentation until after the operating license was issued. However, the Unit 1 NPF-27 License Condition 2.C(5) was completed and closed in SSER-4. SSER-9 addressed EQ for LGS Unit 2.

A-31 RHR Shutdown Requirements

This USI was resolved in May 1978 and affected PWRs and BWRs. The USI involved establishment of criteria for the design and operation of system necessary to take a power reactor from normal operating conditions to cold shutdown.

The USI was resolved with the issuance of SRP section 5.4.7. The SRP stated (BTP RSB 5-1) that, for purposes of implementation, plants would be divided into three classes: Class 1 would require full compliance with the BTP for construction permit or PDA applications which were docketed before January 1, 1978. Class 2 required a partial implementation of the BTP for all plants for which construction permit or PDA applications were docketed before January 1, 1978, and for which an operating license issuance was expected on or after January 1, 1979. Class 3 affected all operating reactors and all other plants for which issuance of the operating license was expected before January 1, 1979. The extent to which Class 3 plants would require implementation of the BTP was based on the combined inspection and enforcement and DOR review of related plant features. In general, the outcome of these evaluations were that only plants receiving operating licenses after January 1, 1979 were affected by this USI resolution.

IMPLEMENTATION AND STATUS SUMMARY:

The RHR shutdown requirements for LGS were addressed during the initial operating license review as addressed in SER and SSER-2 Section 5.4.7.

A-36 Control of Heavy Loads, Phases I & II

REQUIREMENTS SUMMARY:

The following is abstracted from NUREG-0612: In nuclear power plants heavy loads may be handled in several plant areas. If these loads were to drop in certain locations in the plant, they may impact spent fuel, fuel in the core, or equipment that may be required to achieve safe shutdown and continue decay heat removal. Task A-36 was established to systematically examine staff licensing criteria and the adequacy of measures in effect at operating plants, and to recommend necessary changes to assure the safe handling of heavy loads. The guidelines proposed include definition of safe load paths, use of load handling procedures, training of crane operators, guidelines on slings and special lifting devices, periodic inspection and maintenance for the crane, as well as various alternatives. The report NUREG-0612 completes Task A-36.

The requirements documents are the Generic Letter dated December 22, 1980 "Control of Heavy Loads" transmitting NUREG-0612 and Generic Letter 85-11 dated June 28, 1985 which stated that implementation of Phase I (guidelines noted above) was sufficient and that Phase II could be implemented by licensees as appropriate. Phase II was to have extended the issue beyond the guidelines noted above to include a showing that either single failure proof handling equipment was not needed or that it had been provided.

IMPLEMENTATION AND STATUS SUMMARY:

The requirements for heavy loads, NUREG-0612, were addressed in the initial operating license review. The licensee completed implementation in accordance with an August 13, 1984 submittal and Unit 1 Operating License NPF-27 License Condition 2.C(19).

See LGS UFSAR Section 3.12 for additional information on the control of heavy loads at LGS.

A-39 Determination of SRV Pool Dynamic Loads and Temperature Limits

REQUIREMENTS SUMMARY:

BWR plants are equipped with SRVs to protect the reactor from overpressurization. Plant operational transients, such as turbine trips, will actuate the SRV. Once the SRV opens, the air column within the partially submerged discharge line is compressed by the high pressure steam released from the reactor. The compressed air discharged into the suppression pool produces high pressure bubbles. Oscillatory expansion and contraction of these bubbles create hydrodynamic loads on the containment structures, piping and equipment inside containment.

NUREG-0802 presents the results of the staff's evaluation of SRV loads. The evaluation, however, is limited to the quencher devices used in Mark II and III containments. With respect to Mark I containments, the SRV acceptance criteria are presented in NUREG-0661, and are dealt with as part of USI A-7 (Mark I Long-Term Program).

SRP 6.2.1.1.C, "Pressure-Suppression Type BWR Containments", addresses the applicable review criteria since all Mark II and III containment designs are understood to have completed their operating license reviews subsequent to resolution of this USI and reflection of the resolution in the SRP.

In conjunction with NUREG-0661, NUREG-0763 and NUREG-0783, the issuance of NUREG-0802 concludes USI A-39.

IMPLEMENTATION AND STATUS SUMMARY:

See A-8.

A-40 Seismic Design Criteria - Short-Term Program

REQUIREMENTS SUMMARY:

USI A-40 was originated in 1977. The basic objectives were (1) to study the seismic design criteria, (2) to quantify the conservatism associated with the criteria and (3) to recommend modifications to SRP if changes are justified. Lawrence Livermore National Laboratory completed the study and published their findings in NUREG/CR-1161 dated May 1980. The report recommended specific changes to the SRP. NRC staff reviewed the report and developed some other changes that would reflect the present state of seismic design practices. The resulting SRP changes were issued for public comments in June 1988, and the final SRP changes are to be published in September 1989.

The major SRP changes as a resolution of USI A-40 consist of (1) clarification of development of site specific spectra, (2) use of single synthetic time history, (3) location of input ground motion for Soil-Structure Interaction, and (4) design of flexible vertical tanks. Except for item (4), all other items do not constitute any additional requirements for current licenses and applications, and thus, no backfits are being required for these items. However, the revised provisions could be used for margin studies and reevaluations or IPE for External Events.

The participant utilities in Seismic Qualification Utility Group agreed to implement the changed criteria for flexible vertical tank for their plants. However, there are four plants (six reactors) where this issue has to be resolved on an individual basis. (These plants are: Callaway 1/2, Wolf Creek, Shearon Harris 1, and Watts Bar 1/2.) The 50.54(f) letters have been sent to the affected utilities.

IMPLEMENTATION AND STATUS SUMMARY:

Seismic qualification was addressed during the initial operating license review. The program is discussed in UFSAR Section 3.10 and was accepted as discussed in the SER, SSER-2, SSER-3, and SSER-9, Section 3.10.

A-42 Pipe Cracks in Boiling Water Reactors

Pipe cracking has occurred in the heat-affected zones of welds in primary system piping in BWRs since mid-1960. These cracks have occurred mainly in Type 304 stainless steel which is the type used in most operating BWRs. The major problem is recognized to be IGSCC of austenitic stainless steel components that have been made susceptible to this failure by being "sensitized," either by postweld heat treatment or by sensitization of a narrow heat- affected zone near welds.

"Safe ends" that have been highly sensitized by furnace heat treatment while attached to vessels during fabrication were very early (late 1960s) found to be susceptible to IGSCC. Most of the furnace sensitized safe ends in older plants have been removed or clad with a protective material and there are only a few BWRs that still have furnace sensitized safe ends in use. Most of these, however, are in smaller diameter lines.

Earlier reported cracks (prior to 1975) occurred primarily in 4 inch diameter recirculation loop bypass lines and in 10 inch diameter core spray lines. Cracking is most often detected during ISI using UT techniques. Some piping cracks have been discovered as a result of primary coolant leaks.

This USI was resolved with the issuance of NUREG-0313, Revision 1 which was transmitted to all holders of BWR operating licenses or construction permits in February 1981 via Generic Letter 81-03. MPA B-05 was established for implementation of the resolution at operating plants.

NUREG-0313, Revision 1 provided the NRC staff's revised acceptable methods for reducing the intergranular stress-corrosion cracking susceptibility of BWR code class 1, 2, and 3 pressure boundary piping of sizes identified above and safe ends. In addition, it provided the requirements for augmented inservice inspection of piping with nonconforming materials.

As a result of further IGSCC degradations in large piping, the staff provided licensees with additional requirements in several NRC communications (i.e., Bulletin 82-03, Bulletin 83-2, Bulletin 84-11). The long-term resolution of IGSCC in BWR piping was provided in NUREG-0313, Revision 2 which was transmitted to all holders of BWR operating licenses via Generic Letter 88-01.

IMPLEMENTATION AND STATUS SUMMARY:

IGSCC was most recently addressed by the licensee in its response to Generic Letter 88-01. For LGS, this response consisted of an FSAR revision (Revision 54, dated October 1988), a Technical Specification revision (which was determined not to be necessary and was withdrawn on April 28, 1989) and an ISI program revision which will be completed and implemented at the next refueling outage for each unit.

A-43 Containment Emergency Sump Reliability

REQUIREMENTS SUMMARY:

An issue existed concerning the availability of adequate recirculation cooling water following a LOCA when long-term recirculation of cooling water from the PWR containment sump, or the BWR RHR system suction intake, must be initiated and maintained to prevent core melt.

The technical concerns evaluation under USI A-43 were: (1) post-LOCA adverse conditions resulting from potential vortex formation and air ingestion and subsequent pump failure, (2) blockage of sump screens with LOCA generated insulation debris causing inadequate NPSH on pumps, and (3) RHR and containment spray pumps inoperability due to possible air, debris, or particulate ingestion on pump seal and bearing systems.

NUREG-0897, Revision 1 presents the results of the staff's technical findings. These findings established a need to revise current licensing guidance on these matters. Regulatory Guide 1.82 (Rev 0) and SRP (NUREG-0800) Section 6.2.2, "Containment Heat Removal Systems" were revised to reflect this new guidance.

This revised guidance applies only to future construction permits, preliminary design approvals, final design approvals, standardized designs, and applications of licenses to manufacture. For operating plants, the staff performed a regulatory analysis to determine if this new guidance should be applied. The results of this analysis was reported in NUREG-0869, Revision 1, "USI A-43 Regulatory Analysis." The staff concluded that the regulatory analysis does not support any new generic requirements for current licensees to perform debris assessments. However, an Information Notice was issued recommending (but not requiring) licensees use the revised guidance to conduct a 10CFR50.59 analysis for future insulation modifications or replacements.

IMPLEMENTATION AND STATUS SUMMARY:

Suppression pool strainer blockage is discussed in UFSAR and SER Sections 6.2.2. Additional actions are being taken for LGS in response to NRC Bulletin 96-03.

A-44 Station Blackout

Station blackout means the loss of offsite ac power to the essential and nonessential electrical buses concurrent with turbine trip and the unavailability of the redundant onsite emergency ac power system. WASH-1400 showed that station blackout could be an important risk contributor, and operating experience has indicated that the reliability of ac power systems might be less than originally anticipated. For these reasons station blackout was designated as a USI in 1980. A proposed rule was published for comment on March 21, 1986. A final rule, 10CFR50.63 "Loss of All Alternating Current Power," was published on June 21, 1988 and became effective on July 21, 1988. Regulatory Guide 1.155 was issued at the same time as the rule and references an industry guidance document NUMARC-8700. In order to comply with the A-44 resolution, licensees are required to:

- maintain onsite emergency ac power supply reliability above a minimum level
- develop procedures and training for recovery from a station blackout
- determine the duration of a station blackout that the plant should be able to withstand
- use an alternate qualified ac power source, if available, to cope with a station blackout
- evaluate the plant's actual capability to withstand and recover from a station blackout
- backfit hardware modifications if necessary to improve coping ability

10CFR50.63(c)(1) of the rule required each licensee to submit a response including the results of their coping analysis within 270 days from issuance of an operating license or the effective date of the rule, whichever is later.

IMPLEMENTATION AND STATUS SUMMARY:

The LGS electrical distribution system met the NRC design criteria prior to development of 10CFR50.63. The simultaneous loss of both offsite and onsite power is considered to be a highly unlikely occurrence.

Long-term operation following a loss of all ac power is limited only by suppression pool heatup and ambient heatup of the HPCI and RCIC pump rooms, where compartment cooling requires ac power, and by dc battery capacity.

The LOOP and SBO incidents are programmed as training exercises during the certification program at the LGS Simulator.

The station blackout event has also been incorporated into simulator requalification programs.

The plant staff have written emergency procedures for the station blackout event.

The licensee submitted the LGS program for implementation of the station blackout rule on April 17, 1989.

A-45 Shutdown Decay Heat Removal Requirements

REQUIREMENTS SUMMARY:

USI A-45 was closed out without any new licensing requirements other than the IPE, as described below. Since all of the significant USI A-45 results have been found to be highly plant specific, the Commission decided it was not appropriate to propose a single generic action to be applied uniformly to all plants.

The Commission is currently implementing the Severe Accident Policy (50FR32138) and will require all plants currently operating or under construction to undergo a systematic examination termed the IPE. The reason for this examination is to identify any plant specific vulnerabilities to severe accidents. The IPE analysis intends to examine and understand the plant emergency procedures, design, operations, maintenance, and surveillance to identify vulnerabilities. The analysis will examine both the decay heat removal system and those systems used for other related functions. For CE plants without power-operated relief valves, the need for a rapid depressurization capability will be addressed in the IPE program.

NRC has decided to subsume A-45 into the IPE program as the most effective way of achieving resolution of specific plant concerns associated with A-45.

IMPLEMENTATION AND STATUS SUMMARY:

The IPE for LGS was approved by the NRC by letter dated December 9, 1994.

A-46 Seismic Qualification of Equipment in Operating Plants

As an outgrowth of the Systematic Evaluation Program, the need was identified for reassessment of design criteria and methods for the seismic qualification of mechanical equipment and electrical equipment. The seismic qualification of the equipment in operating plants must, therefore, be reassessed to ensure the ability to bring the plant to a safe shutdown condition when subject to a seismic event. The objective of this issue was to establish an explicit set of guidelines that could be used to judge the adequacy of the seismic qualification of mechanical and electrical equipment at operating plants in lieu of attempting to backfit current design criteria for new plants.

The resolution of USI A-46 was mainly based on work completed by the Seismic Qualification Utility Group and EPRI using the seismic and test experience data approach and reviewed and endorsed by the Senior Seismic Review and Advisory Panel and the NRC staff. The scope of the review was narrowed down to equipment required to bring each affected plant to hot shutdown and maintain it there for a minimum of 72 hours. A walk-through of each plant is required to inspect equipment in the scope. Evaluation of equipment will include: (a) adequacy of equipment anchorage; (b) functional capability of essential relays; (c) outliers and deficiencies (i.e., equipment with nonstandard configurations); and (d) seismic systems interaction.

The staff issued Generic Letter 87-02 on February 19, 1987, with associated guidance, requiring all affected utilities to perform an evaluation of the seismic adequacy of their plants. The specific requirements and approach for implementation are being developed jointly by the Seismic

Qualification Utility Group and the staff on a generic basis prior to individual member utilities proceeding with plant specific implementation (see discussion below).

IMPLEMENTATION AND STATUS SUMMARY:

Generic Letter 87-02 issued on February 19, 1987 and Supplement No. 1 thereto issued May 22, 1992, do not list Limerick as an USI A-46 Plant and therefore does not apply to Limerick, since seismic qualification was addressed during initial operating licensing review. Seismic/dynamic qualification of safety related electrical and mechanical equipment is discussed in LGS UFSAR Section 3.10 and was accepted as discussed in the SER, SSER-2, SSER-3, and SSER-9.

A-47 Safety Implications of Control Systems

USI A-47 is being closed out with the issuance of Generic Letter 89-19 which was issued September 20, 1989. The Generic Letter states, "The staff has concluded that all PWR plants should provide automatic steam generator overfill protection, all BWR plants should provide automatic reactor vessel overfill protection, and that plant procedures and technical specifications for all plants should include provisions to verify periodically the operability of the overfill protection and to assure that automatic overfill protection is available to mitigate main feedwater overfeed events during reactor power operation. Also, the system design and setpoints should be selected with the objective of minimizing inadvertent trips of the main feedwater system during plant startup, normal operation, and protection system surveillance. The Technical Specifications recommendations are consistent with the criteria and the risk considerations of the Commission Interim Policy Statement on Technical Specification Improvement. In addition, the staff recommends that all BWR recipients reassess and modify, if needed, their operating procedures and operator training to assure that the operators can mitigate reactor vessel overfill events that may occur via the condensate booster pumps during reduced system pressure operation."

The Generic Letter provides requirements that licensees provide NRC with their schedule and commitments within 180 days of the Generic Letter date. The implementation schedule for actions on which commitments are made should be prior to startup after the first refueling outage, but no later than the second refueling outage, beginning 9 months after receipt of the Generic Letter.

IMPLEMENTATION AND STATUS SUMMARY:

The licensee’s response to Generic Letter 89-19 was submitted to the NRC on March 20, 1990 and was supplemented on May 4, 1990.

A-48 Hydrogen Control Measures and Effects of Hydrogen Burns on Safety Equipment

REQUIREMENTS SUMMARY:

USI A-48 arose as a result of the large amount of hydrogen generated and burned within containment during the TMI accident. This issue covers hydrogen control measures for recoverable degraded core accidents for all BWRs and those PWRs with ice condenser containments. Extensive research in this area has led to significant revision of the Commission's hydrogen control regulations, given in 10CFR50.44.

The rule in 10CFR50.44 requiring inerting of BWR Mark I and Mark II containments as a method for hydrogen control was published on December 2, 1981. The BWR Mark I and Mark II reactor containments have operated for a number of years with an inerted atmosphere (by addition of an

inert gas, such as nitrogen) which effectively precludes combustion of any hydrogen generated. USI A-48 with respect to BWR Mark I and II containments is not only resolved but understood to be fully implemented in the affected plants.

The rule for BWRs with Mark III containments and PWRs with ice condenser containments was published on January 25, 1985. The rule required that these plants be provided with a means for controlling the quantity of hydrogen produced but did not specify the control method. In addition, the action plan for USI A-48 provided for plant specific reviews of lead-plants for reactors with Mark III and ice condenser containments. Sequoyah was chosen as the lead-plant for ice condenser containments and Grand Gulf for Mark III containments. Both of the lead-plant licensees chose to install igniter-type systems to burn the hydrogen before it reached threatening concentrations within the containment. Final design igniter systems have been installed not only in both lead plants, Sequoyah and Grand Gulf, but in all other ice condenser and Mark III plants as well. Documentation of the staff's safety evaluations of the final analyses required to be submitted by these licensees by the rule are continuing toward completion in 1989.

Large dry PWR containments were excluded from USI A-48 because they have a greater ability to accommodate the large quantities of hydrogen associated with a recoverable degraded core accident than the smaller MARK I, II, III and ice condenser containments. However, this issue has continued to be considered and in 1989, hydrogen control for large dry PWR containments was identified as a high priority Generic Issue 121. (NUREG-0933). The resolution of Generic Issue 121 is being actively pursued in close coordination with more recent research findings.

The NRC staff has concluded that USI A-48 is resolved as stated in SECY 89-122. If interested, the report should be consulted for further details regarding the relationship of A-48 to other ongoing hydrogen activities.

IMPLEMENTATION AND STATUS SUMMARY:

LGS uses an inerted containment as discussed in Section 6.2.5 (see SER and SSER section 6.2.5). Both units received temporary exemptions from inerting during the initial startup testing program. Both units are now in full compliance .

1.13 TMI-2 RELATED REQUIREMENTS FOR NEW OPERATING LICENSES

1.13.1 NUREG-0737, CLARIFICATION OF THE TMI ACTION PLAN REQUIREMENTS

Following the accident at Three Mile Island Unit 2, the NRC developed the TMI Action Plan, NUREG-0660, to provide a comprehensive and integrated plan for improving the safety of power reactors. NUREG-0737 was issued with an October 31, 1980 letter from D.G. Eisenhut (NRC) to licensees of operating power reactors and applicants for operating licenses forwarding specific TMI-related requirements from NUREG-0660 which have been approved by the NRC for implementation at this time. In this NRC report, these specific requirements comprise a single document which includes additional information about implementation schedules, applicability, method of implementation review by the NRC, submittal dates, and clarification of technical positions. It should be noted that the total set of TMI-related actions have been documented in NUREG-0660, but only those items that the NRC has approved for implementation to date are included in NUREG-0737.

Enclosure 2 to NUREG-0737 lists TMI Action Plan requirements for operating license applicants. Section 1.13.2 itemizes these requirements sequentially according to the NUREG-0737 number. Each item is accompanied by a response and/or reference to a section in the UFSAR that further discusses how the licensee or the LGS design complies with the requirement. These responses were revised periodically as ongoing efforts to address each requirement were completed.

1.13.2 TMI ACTION PLAN REQUIREMENTS FOR APPLICANTS FOR AN OPERATING LICENSE (ENCLOSURE 2 TO NUREG-0737)

- I.A.1.1 SHIFT TECHNICAL ADVISOR

Position

Each applicant shall provide an on-shift technical advisor to the shift supervisor. The STA may serve more than one unit at a multiunit site if qualified to perform the advisor function for the various units.

The STA shall have a bachelor's degree or equivalent in a scientific or engineering discipline and have received specific training in the response and analysis of the plant for transients and accidents. The STA shall also receive training in plant design and layout, including the capabilities of instrumentation and controls and the control room. The applicant shall assign normal duties to the STAs that pertain to the engineering aspects of assuring safe operations of the plant, including the review and evaluation of operating experience.

Clarification

(1) Due to the similarity in the requirements for dedication to safety, training, and onsite location and the desire that the accident assessment function be performed by someone whose normal duties involve review of operating experiences, our preferred position is that the same people perform the accident and operating experience assessment function. The performance of these two functions may be split if it can be demonstrated the persons assigned the accident assessment role are aware, on a current basis, of the work being done by those reviewing operating experience.

(2) To provide assurance that the STA will be dedicated to concern for the safety of the plant, our position has been the STAs must have a clear measure of independence from duties associated with the commercial operation of the plant. This would minimize possible distractions from safety judgments by the demands of commercial operations. We have determined that, while desirable, independence from the operations staff of the plant is not necessary to provide this assurance. It is necessary, however, to clearly emphasize the dedication to safety associated with the STA position both in the STA job description and in the personnel filling this position. It is not acceptable to assign a person who is normally the immediate supervisor of the shift supervisor to STA duties as defined herein.

(3) It is our position that the STA should be available within 10 minutes of being summoned and therefore should be onsite. The onsite STA may be in a duty status for periods of time longer than one shift, and therefore asleep at some times, if the 10 minute availability is assured. It is preferable to locate those doing the operating experience assessment onsite. The desired exposure to the operating plant and contact with the STA (if these functions are to be split) may be able to be accomplished by a group, normally stationed offsite, with frequent onsite presence.

We do not intend, at this time, to specify or advocate a minimum time onsite.

Response

See Section 13.1.2.1.1 for discussion of the STA position. Qualification requirements for STA positions are discussed in Section 13.1.3.1.

- I.A.1.2 SHIFT SUPERVISOR RESPONSIBILITIES

Position

Review the administrative duties of the shift supervisor and delegate functions that detract from or are subordinate to the management responsibility for assuring safe operation of the plant to other personnel not on duty in the control room.

Clarification

(1) The highest level of corporate management of each licensee shall issue and periodically reissue a management directive that emphasizes the primary management responsibility of the shift supervisor for safe operation of the plant under all conditions on his shift and that clearly establishes his command duties.

(2) Plant procedures shall be reviewed to assure that the duties, responsibilities, and authority of the shift supervisor and control room operators are properly defined to effect the establishment of a definite line of command and clear delineation of the command decision authority of the shift supervisor in the control room relative to other plant management personnel. Particular emphasis shall be placed on the following:

(a) The responsibility and authority of the shift supervisor shall be to maintain the broadest perspective of operational conditions affecting the safety of the plant as a matter of highest priority at all times when on duty in the control room. The principle shall be reinforced that the shift supervisor should not become totally

involved in any single operation in times of emergency when multiple operations are required in the control room.

(b) The shift supervisor, until properly relieved, shall remain in the control room at all times during accident situations to direct the activities of control room operators. Persons authorized to relieve the shift supervisor shall be specified.

(c) If the shift supervisor is temporarily absent from the control room during routine operations, a lead control room operator shall be designated to assume the control room command function. These temporary duties, responsibilities, and authority shall be clearly specified.

(3) Training programs for shift supervisors shall emphasize and reinforce the responsibility for safe operation and the management function that the shift supervisor is to provide for assuring safety.

(4) The administrative duties of the shift supervisor shall be reviewed by the senior officer of each utility responsible for plant operations. Administrative functions that detract from or are subordinate to the management responsibility for assuring the safe operation of the plant shall be delegated to other operations personnel not on duty in the control room.

Response

In the assignment of functions to the Shift Manager, consideration is given to aspects such as the need to keep the Shift Manager in control of and aware of plant operational, maintenance, and testing activities which may affect safe operation and the need to prevent administrative duties from detracting from the primary responsibility of assuring safe operation.

A letter was written by S.L. Daltroff (PECo) on December 26, 1979, which defines and emphasizes the primary management responsibility of the Shift Superintendent (now the Shift Manager). Similar to PBAPS, this letter will be promulgated to shift supervision in the form of an administrative procedure.

The letter referenced above also defined the duties of control room operators. The nature of the letter was not only to define and emphasize responsibility but to effect the establishment of a definite line of command. This letter will form the basis for an administrative procedure in which the duties of the control room operator will be defined.

In the administrative procedure covering shift operations, a directive will be written which will specify who can relieve the Shift Manager. It will require only that a member of Shift Supervision bearing an active senior license and qualified as an Emergency Director will have such an authority.

Temporary relief of the Shift Manager will normally be accomplished using the Shift Supervisor. Duties and responsibilities, similar to those of the Shift Manager, will be defined in the administrative procedure covering shift operations. He will be a senior licensed individual having worked side-by-side with the Shift Manager, fully knowledgeable of the Shift Manager's responsibilities and the overall plant status at any given time.

The licensee is engaged in a Management Development Program, which includes management training for shift supervisors. All management training courses include training in such topics as style of management, planning, delegation, communications, motivation, personnel and industrial relations and performance review. In addition, all shift supervision has, or will have prior to startup, completed the Genco II Kepner Tregoe Course in Decision Making. In the future, it is planned that shift supervision will have the opportunity to attend some of the subsequent courses associated both with the Management Development Program and the Kepner Tregoe Program.

The administrative responsibilities for all members of shift supervision are defined in an administrative procedure.

The administrative procedure covering shift operations will define shift supervision's administrative responsibilities. Those which will be retained will be those which are defined in that administrative procedure.

The duties and responsibilities of the Shift Manager during accident/transient conditions will be delineated in both the Emergency Plan and the administrative procedures governing shift operations. The procedures developed from the Emergency Plan will contain detailed responsibilities of the Shift Manager during such conditions.

The STA will hold a staff position in the Operations Group. He reports directly to the Shift Manager on his staff. The STA advises the Shift Manager concerning off-normal events and will make appropriate recommendations regarding corrective and precautionary actions.

See Section 13.1.2.1.1 for further discussion.

- I.A.1.3 SHIFT MANNING

Position

Assure that the necessary number and availability of personnel to man the operations shifts have been designated by the licensee. Administrative procedures should be written to govern the movement of key individuals about the plant to assure that qualified individuals are readily available in the event of an abnormal or emergency situation. This should consider the recommendations on overtime in NUREG-0578. Provisions should be made for an aide to the shift supervisor to assure that, over the long-term, the shift supervisor is free of routine administrative duties.

Clarification

At any time a licensed nuclear unit is being operated in Modes 1-4 for a PWR (power operation, startup, hot standby or hot shutdown, respectively) or in Modes 1-3 for a BWR (power operation, startup, or hot shutdown, respectively), the minimum shift crew shall include two licensed senior reactor operators, one of whom shall be designated as the shift supervisor, two licensed reactor operators, and two unlicensed auxiliary operators. For a multiunit station, depending upon the station configuration, shift staffing may be adjusted to allow credit for licensed senior reactor operators and licensed reactor operators to serve as relief operators on more than one unit; however, these individuals must be properly licensed on each such unit. At all other times, for a unit loaded with fuel, the minimum shift crew shall include one shift supervisor who shall be a

licensed senior reactor operator, one licensed reactor operator, and one unlicensed auxiliary operator.

Adjunct requirements to the shift staffing criteria stated above are as follows:

(1) A shift supervisor with a senior reactor operator's license, who is also a member of the station supervisory staff, shall be onsite at all times when at least one unit is loaded with fuel.

(2) A licensed senior reactor operator shall, at all times, be in the control room from which a reactor is being operated. The shift supervisor may from time to time act as relief operator for the licensed senior reactor operator assigned to the control room.

(3) For any station with more than one reactor containing fuel, the number of licensed senior reactor operators onsite shall, at all times, be at least one more than the number of control rooms from which the reactors are being operated.

(4) In addition to the licensed senior reactor operators specified in (1), (2), and (3) above, for each reactor containing fuel, a licensed reactor operator shall be in the control room at all times.

(5) In addition to the operators specified in (1), (2), (3), and (4) above, for each control room from which a reactor is being operated, an additional licensed reactor operator shall be onsite at all times and available to serve as relief operator for that control room. As noted above, this individual may serve as relief operator for each unit being operated from that control room, provided he holds a current license for each unit.

(6) Auxiliary (nonlicensed) operators shall be properly qualified to support the unit to which assigned.

(7) In addition to the staffing requirements stated above, shift crew assignments during periods of core alterations shall include a licensed senior reactor operator to directly supervise the core alterations. This licensed senior reactor operator may have fuel handling duties but shall not have other concurrent operational duties.

Licensees of operating plants and applicants for operating licenses shall include in their administrative procedures provisions governing required shift staffing and movement of key individuals about the plant. These provisions are required to assure that qualified plant personnel to man the operational shifts are readily available in the event of an abnormal or emergency situation.

The following information regarding fatigue management and work hours controls is historical. The current regulatory requirements are provided by the 10CFR26 Fitness for Duty Programs rule, which became effective on April 30, 2008. Implementation of the amended rule was required by October 1, 2009. Limerick administrative procedure LS-AA-119, "Fatigue Management and Work Hour Limits," was revised and issued to implement requirements for managing fatigue and controlling work hours in accordance with 10CFR26, Subpart I, "Managing Fatigue." The procedure defines the scope of workers that are subject to the fatigue management program and the scope of workers subject to work hour controls. The procedure also includes the 10CFR26 work hours limits.

These administrative procedures shall also set forth a policy, the objective of which is to prevent situations where fatigue could reduce the ability of operating personnel to keep the reactor in a safe condition. The controls established should assure that, to the extent practicable, personnel are not assigned to shift duties while in a fatigued condition that could significantly reduce their mental alertness or their decision making ability. The controls shall apply to the plant staff who perform safety-related functions (e.g., senior reactor operators, reactor operators, auxiliary operators, health physicists, and key maintenance personnel).

IE Circular No. 80-02, "Nuclear Power Plant Staff Work Hours," dated February 1, 1980 discusses the concern of overtime work for members of the plant staff who perform safety-related functions. The guidance contained in IE Circular No. 80-02 was amended by the

July 31, 1980 NRC letter. In turn, the overtime guidance of the July 31, 1980 NRC letter was revised in Section I.A.1.3 of NUREG-0737. The NRC was issued a policy statement which further revises the overtime guidance as stated in NUREG-0737. This guidance is as follows:

Enough plant operating personnel should be employed to maintain adequate shift coverage without routine heavy use of overtime. The objective is to have operating personnel work a nominal 8-hour day, 40-hour week while the plant is operating. However, in the event the unforeseen problems require substantial amounts of overtime to be used, or during extended periods of shutdown for refueling, major maintenance or major plant modifications, on a temporary basis, the following guidelines shall be followed:

a. An individual should not be permitted to work more than 16 hours straight (excluding shift turnover time).

b. An individual should not be permitted to work more than 16 hours in any 24-hour period, nor more than 24 hours in any 48-hour period, nor more than 72 hours in any seven day period (all excluding shift turnover time).

c. A break of at least eight hours should be allowed between work periods (including shift turnover time).

d. Except during extended shutdown periods, the use of overtime should be considered on an individual basis and not for the entire staff on shift.

Recognizing that very unusual circumstances may arise requiring deviation from the above guidelines, such deviation shall be authorized by the plant manager or his deputy, or higher levels of management. The paramount consideration in such authorization shall be that significant reductions in the effectiveness of operating personnel would be highly unlikely. Authorized deviations to the working hour guidelines shall be documented and available for NRC review.

In addition, procedures are encouraged that would allow licensed operators at the controls to be periodically relieved and assigned to other duties away from the control board during their tours of duty.

Operating license applicants shall complete these administrative procedures before fuel loading. Development and implementation of the administrative procedures at operating plants will be reviewed by the Office of Inspection and Enforcement beginning October 1, 1982.

Response

See Section 13.1.2 on shift manning.

The shift operations administrative procedure governs the required shift staffing and movement of key individuals about the plant, in particular the location of control operators and shift supervision.

An administrative procedure contains, working hour restrictions, which are in accord with current regulations at the time of writing.

The same administrative procedure that sets forth policies regarding overtime contains procedures which govern the deviation from overtime restrictions and how deviations will be documented.

The operations shift complement required when refueling operations are scheduled, along with the responsibilities of the refueling shift personnel, are defined in administrative procedures.

The licensee maintains a Nuclear Training Division. This organization compiles specific job requirements for operating people within power plants. For this list of job requirements, qualifying tests are generated. These tests are administered to applicants for promotion, with promotion to the applicable job described being contingent upon a passing grade. This applies to all plant operators including the equipment operator.

- I.A.2.1 IMMEDIATE UPGRADING OF OPERATOR AND SENIOR OPERATOR TRAINING AND QUALIFICATION

Position

Applicants for SRO license shall have 4 years of responsible power plant experience, of which at least 2 years shall be nuclear power plant experience (including 6 months at specific plant) and no more than 2 years shall be academic or related technical training. After fuel loading, applicants shall have 1 year of experience as a licensed operator or equivalent.

Certifications that operator license applicants have learned to operate the controls shall be signed by the highest level of corporate management for plant operation.

Applicants must revise training programs to include training in heat transfer, fluid flow, thermodynamics, and plant transients.

Clarification

Applicants for SRO either come through the operations chain (C operator to B operators to A operator, etc.) or are degree-holding staff engineers who obtain licenses for backup purposes.

In the past, many individuals who came through the operator ranks were administered SRO examinations without first being an operator. This was clearly a poor practice and the letter of March 28, 1980 requires reactor operator experience for SRO applicants.

However, NRC does not wish to discourage staff engineers from becoming licensed SROs. The effort is encouraged because it forces engineers to broaden their knowledge about the plant and its operation.

In addition, in order to attract degree-holding engineers to consider the shift supervisor's job as part of their career development, NRC should provide an alternate path to holding an operator's license for 1 year.

The track followed by a high school graduate (a nondegreed individual) to become an SRO would be 4 years as a control room operator, at least one of which would be as a licensed operator, and participation in an SRO training program that includes 3 months on-shift as an extra person.
The track followed by a degree-holding engineer would be, at a minimum, 2 years of responsible nuclear power plant experience as a staff engineer, participation in an SRO training program equivalent to a cold applicant training program, and 3 months on-shift as an extra person in training for an SRO position.

Holding these positions assures that individuals who will direct the license activities of licensed operators have had the necessary combination of education, training, and actual operating experience prior to assuming a supervisory role at the facility.

The staff realizes that the necessary knowledge and experience can be gained in a variety of ways. Consequently, credit for equivalent experience should be given to applicants for SRO licenses.

Applicants for SRO licenses at a facility may obtain their 1 year operating experience in a licensed capacity (operator or senior operator) at another nuclear power plant. In addition, actual operating experience in a position that is equivalent to a licensed operator or senior operator at military propulsion reactors will be acceptable on a one-for-one basis. Individual applicants must document this experience in their individual applications in sufficient detail so that the staff can make a finding regarding equivalency.

Applicants for SRO licenses who possess a degree in engineering or applicable sciences are deemed to meet the above requirements, provided they meet the requirements set forth in sections A.1.a and A.2 in enclosure in the letter from H.R. Denton (NRC) to all power reactor applicants and licensees, dated March 28, 1980, and have participated in a training program equivalent to that of a cold senior operator applicant.

The NRC has not imposed the 1 year experience requirement on cold applicants for SRO licenses. Cold applicants are to work on a facility not yet in operation; their training programs are designed to supply the equivalent of the experience not available to them.

Response

Applicants for SRO license will have at least 4 years of responsible power plant experience, of which at least 2 years will be nuclear plant experience, including 6 months at the plant and no more than 2 years will be academic or related technical training.

The requirements for certification are implemented in administrative procedures.

The training programs for RO and SRO license will include training in heat transfer, fluid flow, thermodynamics, and plant transients. See Section 13.2.1.1 for further discussion.

- I.A.2.3 ADMINISTRATION OF TRAINING PROGRAMS

Position

Pending accreditation of training institutions, training instructors who teach systems, integrated response, transient and simulator courses shall successfully complete a SRO examination prior to fuel loading and instructors shall attend appropriate retraining programs that address, as a minimum, current operating history, problems and changes to procedure and administrative limitations. In the event an instructor is a licensed SRO, his retraining shall be the SRO requalification program.

Clarification

The above position is a short-term position. In the future, accreditation of training institutions will include review of the procedure for certification of instructors. The certification of instructors may, or may not, include successful completion of an SRO examination.

The purpose of the examination is to provide NRC with reasonable assurance during the interim period that instructors are technically competent.

The requirement is directed to permanent members of training staff who teach the subjects listed above, including members of other organizations who routinely conduct training at the facility. There is no intention to require guest lecturers who are experts in particular subjects (reactor theory, instrumentation, thermodynamics, health physics, chemistry, etc.) to successfully complete an SRO examination. Nor is it intended to require a system expert, such as the instrument and control supervisor teaching the control rod drive system, to sit for an SRO examination.

Response

The requirements for training instructors will be implemented in administration of the training program.

- I.A.3.1 REVISE SCOPE AND CRITERIA FOR LICENSING EXAMINATIONS

Position

Applicants for operator licenses will be required to grant permission to the NRC to inform their facility management regarding the results of examinations.

Contents of the licensed operator requalification program shall be modified to include instruction in heat transfer fluid flow, thermodynamics and mitigation of accidents involving a degraded core.

The criteria for requiring a licensed individual to participate in accelerated requalification shall be modified to be consistent with the new passing grade for issuance of a license.

Requalification programs shall be modified to require specific reactivity control manipulations. Normal control manipulations, such as plant or reactor startups, must be performed. Control manipulations during abnormal or emergency operation shall be walked through and evaluated by a member of the training staff.

An appropriate simulator may be used to satisfy the requirements for control manipulations.

Clarification

The clarification does not alter the staff's position regarding simulator examinations.

The clarification does provide additional preparation time for utility companies and NRC to meet examination requirements as stated. A study is under way to consider how similar a nonidentical simulator should be for a valid examination. In addition, present simulators are fully booked months in advance.

Application of this requirement was stated in June 1, 1980 to applicants where a simulator is located at the facility. Starting October 1, 1981, simulator examinations will be conducted for applicants of facilities that do not have simulators at the site.

NRC simulator examinations normally require 2 to 3 hours. Normally, two applicants are examined during this time period by two examiners.

Utility companies should make the necessary arrangements with an appropriate simulator training center to provide time for these examinations. Preferably these examinations should be scheduled consecutively with the balance of the examination. However, they may be scheduled no sooner than 2 weeks prior to and no later than 2 weeks after the balance of the examination.

Response

The requirements for RO and SRO examinations and requalification programs will be implemented.

- I.B.1.2 EVALUATION OF ORGANIZATION AND MANAGEMENT

Position

Corporate management of the utility-owner of a nuclear power plant shall be sufficiently involved in the operational phase activities, including plant modifications, to assure a continual understanding of plant conditions and safety considerations. Corporate management shall establish safety standards for the operation and maintenance of the nuclear power plant. To these ends, each utility-owner shall establish an organization, parts of which shall be located onsite, to: perform independent review and audits of plant activities; provide technical support to the plant staff for maintenance, modifications, operational problems, and operational analysis; and aid in the establishment of programmatic requirements for plant activities.

The licensee shall establish an integrated organizational arrangement to provide for the overall management of nuclear power plant operations. This organization shall provide for clear management control and effective lines of authority and communication between the

organizational units involved in the management, technical support, and operation of the nuclear unit. The key characteristics of a typical organization arrangement are:

(1) Integration of all necessary functional responsibilities under a single responsible head.

(2) The assignment of responsibility for the safe operation of the nuclear power plant(s) to an upper-level executive position.

Utility management shall establish a group, independent of the plant staff, but assigned onsite, to perform independent reviews of plant operational activities. The main functions of this group will be to evaluate the technical adequacy of all procedures and changes important to the safe operation of the facility and to provide continuing evaluation and assessment of the plant's operating experience and performance.

Response

The licensee's corporate and plant staff organizations for routine operations are described in Sections 17.2 and 13.1. The emergency organization is described in the nuclear emergency plan. Independent review activities are described in Section 13.4

- I.C.1 SHORT-TERM ACCIDENT ANALYSIS AND PROCEDURE REVIEW

Position

In our letters of September 13 and 27, October 10 and 30, and November 9, 1979, we required licensees of operating plants, applicants for operating licenses, and licensees of plants under construction to perform analyses of transients and accidents, prepare emergency procedure guidelines, upgrade emergency procedures, and to conduct operator retraining (see also Item I.A.2.1 of this report). Emergency procedures are required to be consistent with the actions necessary to cope with the transients and accidents analyzed. Analyses of transients and accidents were to be completed in early 1980, and implementation of procedures and retraining were to be completed 3 months after emergency procedure guidelines were established; however, some difficulty in completing these requirements has been experienced. Clarification of the scope of the task and appropriate schedule revisions were included in NUREG-0737, Item I.C.1.

Pending staff approval of the revised analysis and guidelines, the staff will continue the pilot monitoring of emergency procedures described in Item I.C.8 (NUREG-0660). The adequacy of the BWR vendor's guidelines will be identified to each near-term operating licensee during the emergency procedure review.

Response

Emergency operating procedures are developed from the BWROG Emergency Procedure and Severe accident Guidelines (EPG/SAGs). Reference UFSAR Section 15.0.6 for a discussion of these guidelines. The development of the EPGs was based on reanalysis of transients and accidents and inadequate core cooling. The licensed operator training program includes training on the emergency operating procedures.

Additional information has been provided in a letter from V.S. Boyer (PECo) to D.G. Eisenhut (NRC) dated April 15, 1983.

- I.C.2 SHIFT RELIEF AND TURNOVER PROCEDURES

Position

The licensee shall review and revise as necessary the plant procedure for shift and relief turnover to assure the following:

(1) A checklist shall be provided for the oncoming and offgoing control room operators and the oncoming shift supervisor to complete and sign. The following items, as a minimum, shall be included in the checklist:

(a) Assurance that critical plant parameters are within allowable limits (parameters and allowable limits shall be listed on the checklist).

(b) Assurance of the availability and proper alignment of all systems essential to the prevention and mitigation of operational transients and accidents by a check of the control console. What to check and criteria for acceptable status shall be included on the checklist.

(c) Identification systems and components that are in a degraded mode of operation permitted by the Technical Specifications. For such systems and components, the length of time in the degraded mode shall be compared with the Technical Specifications action statement.

(2) Checklists or logs shall be provided for completion by the offgoing and oncoming auxiliary operators and technicians. Such checklists or logs shall include any equipment under maintenance or test that by itself could degrade a system critical to the prevention and mitigation of operational transients and accidents or initiate an operational transient (what to check and criteria for acceptable status shall be included on the checklist); and

(3) A system shall be established to evaluate the effectiveness of the shift and relief turnover procedures (for example, periodic independent verification of system alignments).

Response

The requirements stated in this section will be implemented except for the request to establish separate checklists or logs for use by the offgoing and ongoing equipment operators and maintenance technicians.

A variety of shift turnover checklists or logs, situated in various locations of the plant and under the control of many groups would further hinder the transfer of vital information to the operating shift personnel with primary responsibility for plant operations. A limited number of checklists or logs, centralized in the control room and under the supervision of control room personnel, is essential to effective transfer of information.

Maintenance and testing of equipment vital to safe operation of the plant is performed with the knowledge and approval of the appropriate licensed control room operator. The checklists, status boards, or logs will be utilized to identify any equipment under maintenance or test that by themselves could degrade a system critical to the prevention and mitigation of operational

transients and accidents, or initiate an operational transient. Some of this information will be supplied to the control room operators and supervisors, as appropriate, by the equipment operators and technicians for entry into the checklists and logs. Shift personnel meetings under the direction of shift supervision are normally held shortly after shift turnover. Offgoing equipment operators will normally be relieved at their job locations in the plant. Equipment operators will, when job conditions permit, complete and review an applicable shift turnover checkoff list. If plant operations require that equipment operators conduct shift turnover on the job away from their normal turnover location and no turnover checklist is executed, the person making relief will, at the earliest convenience, report to shift supervision to obtain a supplementary briefing. Examples of activities that could preclude normal turnover include filling the main generator with hydrogen and executing a demineralizer regeneration.

Checklists for oncoming and offgoing control room operators and oncoming shift supervisors to be used during shift turnover will be included in administrative procedure for shift operations.

A checklist for shift turnover to be used by equipment operators will be written and will be included in the shift operations administrative procedure.

Included as part of the shift operations administrative procedure, and specifically in the sections relating to shift turnover, instructions will be communicated to the various levels of shift operating personnel directing that, when deficiencies in the turnover process are noticed primarily by the discovery of information which was not surfaced during the turnover, such deficiencies will be brought to the attention of shift supervision, who will in turn initiate a modification to the turnover checkoff list. This mechanism will ensure that, as job responsibilities change, appropriate modifications will be made to the checklist.

- I.C.3 SHIFT SUPERVISOR RESPONSIBILITIES

This item is included with Section I.A.1.2, Shift Supervisor responsibilities.

Response

This requirement will be implemented.

- I.C.4 CONTROL ROOM ACCESS

Position

The licensee shall make provisions for limiting access to the control room to those individuals responsible for the direct operation of the nuclear power plant (e.g., operations supervisor, shift supervisor, and control room operators), to technical advisors who may be requested or required to support operation, and the predesignated NRC personnel. Provisions shall include the following:

(1) Develop and implement an administrative procedure that establishes the authority and responsibility of the person in charge of the control room to limit access.

(2) Develop and implement procedures that establish a clear line of authority and responsibility in the control room in the event of an emergency. The line of succession for the person in charge of the control room shall be established and limited to persons

possessing a current senior reactor operator's license. The plan shall clearly define the lines of communication and authority for plant management personnel not in direct command of operations, including those who report to stations outside the control room.

Response

An administrative procedure for control room access will be written and will define the authority and responsibility of the Shift Manager, or alternate, to exercise control over control room access. This administrative procedure will provide the Shift Manager, or alternate, with authority to order persons out of the control room if they have gained entrance and were not authorized or if conditions in the control room change to an extent which changes the access requirements.

Administrative procedures establish a clear line of authority and responsibility in the control room for emergency conditions. This will include the line of succession for the person in charge of the control room.

During plant emergencies, lines of communications and authority for the subject plant management personnel will be delineated in the Emergency Plan. This will include those persons reporting to the TSC, EOF, and Press Facility.

- I.C.5 FEEDBACK OF OPERATING EXPERIENCE

Position

Each licensee will review its administrative procedures to assure that operating experience from within and outside the organization is continually provided to operators and other operational personnel and is incorporated in training programs.

Response

The Regulatory Assurance Section is supervised by the Manager, Regulatory Assurance, who reports to the Vice President, LGS and is responsible for ensuring review of operating experience reports that may be directed to the plant by various industry groups and regulatory agencies and for disseminating such reports to the appropriate personnel for review for applicability to LGS and determination of required action.

In addition, the External and Internal Operating Experience (OPEX) program ensures that appropriate events that occur within the Exelon fleet and in the industry are evaluated for similar conditions at the station. To ensure consistency between various plants within the Exelon fleet, a corporate OPEX coordinator provides overall coordination and direction to this program. Mechanisms exist for identifying, screening, and investigating OPEX items. The corporate OPEX coordinator screens OPEX issues. Depending on the OPEX item being investigated, appropriate corporate, station or other qualified personnel evaluate the issue. Corporate actions are identified if required and are tracked for completion within the site action tracking program. Appropriate status reporting and monitoring of OPEX are also performed. The site OPEX coordinator function resides within Regulatory Assurance.

- I.C.6 VERIFY CORRECT PERFORMANCE OF OPERATING ACTIVITIES

Position

It is required (from NUREG-0660) that licensees' procedures be reviewed and revised, as necessary, to assure that an effective system of verifying the correct performance of operating activities is provided as a means of reducing human errors and improving the quality of normal operations. This will reduce the frequency of occurrence of situations that could result in or contribute to accidents. Such a verification system may include automatic system status monitoring, human verification of operations, and maintenance activities independent of the people performing the activity (see NUREG-0585, Recommendation 5), or both.

Response

Plant procedures will describe a system for the control of removal and restoration and alignment of safety-related plant systems or equipment. This system will use a combination of control room indicators, operability testing, or independent verification (subject to radiation exposure limitations), to ensure that equipment is in its correct alignment.

- I.C.7 NSSS VENDOR REVIEW OF PROCEDURES

Position

Obtain NSSS vendor review of power ascension and emergency operating procedures to further verify their adequacy.

Response

This requirement will be implemented.

- I.C.8 PILOT MONITORING OF SELECTED EMERGENCY PROCEDURES FOR NEAR-TERM OPERATING LICENSE APPLICANTS

Position

Correct emergency procedures as necessary based on the NRC audit of selected plant emergency operating procedures (e.g., SBA, loss of feedwater, restart of ESF following a loss of ac power and steam line break).

Response

Information on emergency procedures (NUREG-0737, Item I.C.1) was provided to the NRC in a response (Letter from V.S. Boyer to D.G. Eisenhut dated April 15, 1983) to Generic Letter 82-33, Supplement 1 to NUREG-0737. Emergency operating procedures are developed from the current revision of the BWROG Emergency Procedure Guidelines.

- I.D.1 CONTROL ROOM DESIGN REVIEWS

Position

Licensees and applications for operating licenses are required to conduct a detailed control room design review to identify and correct design deficiencies. This detailed control room design review is expected to take about a year. Those applicants for operating licenses who are unable to

complete this review prior to issuance of a license shall make preliminary assessments of their control rooms to identify significant human factors and instrumentation problems and establish a schedule approved by us for correcting deficiencies. These applicants will be required to complete the more detailed control room reviews on the same schedule as licensees with operating plants.

Clarification

Applicants for operating license who will be unable to complete the detailed control room review prior to issuance of a license are required to perform a preliminary control room design assessment to identify significant human factors problems. Applicants will find it of value to refer to the draft document, NUREG/CR-1580, "Human Engineering Guide to Control Room Evaluation," in performing the preliminary assessment. We will evaluate the applicant's preliminary assessments including the performance by us of onsite reviews/audits. Our onsite review/audit will be on a schedule consistent with applicant licensing needs and will emphasize the following aspects of the control room:

(1) The adequacy of information presented to the operator to reflect plant status for normal operation, anticipated operational occurrences, and accident conditions;

(2) The groupings of displays and the layout of panels;

(3) Improvements in the safety monitoring and human factors enhancement of controls and control displays;

(4) The communications from the control room to points outside the control room, such as the onsite technical support center, remote shutdown panel, offsite telephone lines, and to other areas within the plant for normal and emergency operation.

(5) The use of direct rather than derived signals for the presentation of process and safety information to the operator;

(6) The operability of the plant from the control room with multiple failures of nonsafety-grade and nonseismic systems;

(7) The adequacy of operating procedures and operator training with respect to limitations of instrumentation displays in the control room;

(8) The categorization of alarms, with unique definition of safety alarms;

(9) The physical location of the shift supervisor's office either adjacent to or within the control room complex.

Prior to the onsite review/audit, we will require a copy of the applicant's preliminary assessment and additional information which will be used in formulating the details of the onsite review/audit.

Response

The CRDR effort directed by Item I.D.I and required by Supplement 1 to NUREG-0737 began in 1980 with the licensee's participation in the BWROG CRDR Subcommittee. The subcommittee

produced a BWR Owner's Group Generic CRDR Program which addresses Item 5.1.b of Supplement 1. This generic program was submitted to the NRC for review in August 1981. The review and subsequent discussions between the NRC and representatives of the subcommittee have resulted in a supplement to the review program.

A preliminary review of the LGS control room was conducted using the original design review program in October 1981. At that time, the LGS control room was still in the construction phase, and the formal LGS emergency procedures were not available for the walk-through.

The licensee subsequently developed a program to address the assessment, implementation and verification phases of the LGS CRDR Program. This program was submitted in August 1983 and a report was submitted in June 1984 and supplemented in November 1984 and June 1985.

Basic Requirements Completion Dates:

(Numbering refers to corresponding portions of Section 5 of Supplement 1)

5.1.a) As was the case during the initial review phase, a person competent in human factors engineering as well as persons competent in system design and system operation were included in the assessment phase of the Program. This assessment was completed in April 1984.

5.1.b) A detailed review of the control room has been completed as discussed in current status above. Completion of the review to address the supplemental checklist and those items not included in the preliminary review due to construction status was completed in January 1984.

5.1.c) Assessment of the HEDs was completed in June 1985.

5.1.d) Proposed improvements have been reviewed by the multidisciplinary task force described in 5.1.a to ensure that the proposed change addresses the identified HED and does not create additional HEDs. All changes have been integrated with other control room modifications.

5.2.a) The program plan for completing the CRDR was completed and is outlined below:

i. Completed the generic review program including the supplemental review and the emergency procedure walk- through.

ii. Assessed the identified HEDs and generated recommendations for modification to those HEDs that warrant a change.

iii. Each of the proposed modifications were reviewed to verify that it corrected the HED it was intended to correct and did not create any new unacceptable HEDs. The modifications have been coordinated with the balance of the NUREG-0737 Supplement 1 initiatives.

iv. The NRC conducted an in-progress audit in December 1983.

5.2.b) A summary report was prepared and submitted in June 1984 and supplemented in November 1984 and June 1985. These reports included proposed modifications and their Unit 1 schedules. Unit 2 modifications and schedules were provided in October 1988.

- I.D.2 PLANT SAFETY PARAMETER DISPLAY CONSOLE

Position

Each applicant and licensee shall install a SPDS that will display to operating personnel a minimum set of parameters which define the safety status of the plant. This can be attained through continuous indication of direct and derived variables as necessary to assess plant safety status.

Response

The LGS design includes a PMS. This system is based, in part, on the GE emergency response system described in Reference 1.13-7. The SPDS is a part of this PMS. The SPDS is not safety-related, as discussed in Supplement 1 to NUREG-0737. Sensors, isolators, signal conditioners or other components which provide input to the SPDS are Q-listed if they are part of a safety-related system. The SPDS parameters, a subset of the parameters available in the PMS data base, are based on the Regulatory Guide 1.97 (Rev 2) BWR parameter list. All of the critical safety functions defined in Supplement 1 to NUREG-0737, "Clarification of TMI Action Plan Requirements," for a BWR, are addressed by the PMS process variables.

The parameters included in the SPDS display are based on the entry conditions for the LGS EOPs. As changes and improvements are made to the RPV control and containment control procedures, the system can be modified to reflect these changes. The system has been designed in accordance with the guidance provided in NUREG-0696.

A safety analysis describing the basis on which the selected parameters are sufficient to assess the safety status of each identified function for a wide range of events was transmitted by letter from J.S. Kemper (PECo) to A. Schwencer (NRC) dated September 2, 1983.

The software debugging, validation, testing, and acceptance testing will be completed during the Power Ascension Test Program. The SPDS and Regulatory Guide 1.97 parameter displays will be functional within 30 days after the completion of the 100 hour warranty run at 100% power.

- I.G.1 TRAINING DURING LOW POWER TESTING

Position

We require applicants for a new operating license to define and commit to a special low power testing program approved by NRC to be conducted at power levels no greater than 5% for the purposes of providing meaningful technical information beyond that obtained in the normal startup test program and to provide supplemental training.

Clarification

Chapter 14 of the Final Safety Analysis Report describes the applicant's initial test program. The objectives of the initial test program include both training and the acquisition of technical data. This program has been determined by the staff to be acceptable as reported in Section 14 of this report. However, we require the applicant to perform additional testing and training beyond the requirements of the initial test program.

Response

The BWROG program for compliance with NUREG-0737 Requirement I.G.1 was transmitted to the NRC via letter (BWROG-8120) from D.B. Waters (BWROG) to E.G. Eisenhut (NRC). The generic program described in this document is divided into five sections: I-Preoperational Testing; II-Cold Functional Testing; III-Hot Functional Testing; IV-Startup Testing; and V-Additional Training and Testing. The initial test program for LGS as described in Chapter 14 follows the testing described in the first four sections of the BWROG program. During this program, the licensee expects to perform significant plant transients only once, but with a maximum of licensed personnel in attendance. The LGS unit unique simulator provides an excellent mechanism for training people without affecting the real plant. Repetition of startup tests solely for testing purposes will be done on this simulator. Chapter 14 has been changed to describe the additional testing discussed in section V of the BWROG program.

Additional training is to be included in the certification program on the LGS simulator which shall include total loss of offsite and onsite ac power.

- II.B.1 REACTOR COOLANT SYSTEM VENTS

Position

Each applicant and licensee shall install RCS and reactor vessel head high point vents remotely operated from the control room. Although the purpose of the system is to vent noncondensable gases from the RCS which may inhibit core cooling during natural circulation, the vents must not lead to an unacceptable increase in the probability of a LOCA or a challenge to containment integrity. Since these vents form a part of the reactor coolant pressure boundary, the design of the events shall conform to the requirements of 10CFR50, Appendix A, "General Design Criteria." The vent system shall be designed with sufficient redundancy that assures a low probability of inadvertent or irreversible actuation. Each licensee shall provide the following information concerning the design and operation of the high point vent system:

(1) Submit a description of the design, location, size, and power supply for the vent system along with results of analyses for LOCA initiated by a break in the vent pipe. The results of the analyses should demonstrate compliance with the acceptance criteria of 10CFR50.46.

(2) Submit procedures and supporting analysis for operator use of the vents that also include the information available to the operator for initiating or terminating vent usage.

Clarification

A. General

(1) The important safety function enhanced by this venting capability is core cooling. For events beyond the present design basis, this venting capability will substantially increase the plant's ability to deal with large quantities of noncondensable gas which could interfere with core cooling.

(2) Procedures addressing the use of the RCS vents should define the conditions under which the vents should be used as well as the conditions under which the vents should not be used. The procedures should be directed toward achieving a substantial increase in the plant being able to maintain core cooling without loss of containment integrity for events beyond the design basis. The use of vents for accidents within the normal design basis must not result in a violation of the requirements of 10CFR50.44 or 10CFR50.46.

(3) The size of the RCS vents is not a critical issue. The desired venting capability can be achieved with vents in a fairly broad spectrum of sizes. The criteria for sizing a vent can be developed in several ways. One approach, which may be considered, is to specify a volume of noncondensable gas to be vented and in a specific venting time. For containments particularly vulnerable to failure from large hydrogen releases over a short period of time, the necessity and desirability for contained venting outside the containment must be considered (e.g., into a decay gas collection and storage system).

(4) Where practical, the reactor coolant system vents should be kept smaller than the size corresponding to the definition of LOCA (10CFR50, Appendix A). This will minimize the challenges to the ECCS since the inadvertent opening of a vent smaller than the LOCA definition would not require ECCS actuation, although it may result in leakage beyond technical specification limits. On PWRs, the use of new or existing lines whose smallest orifice is larger than the LOCA definition will require a valve in series with a vent valve that can be closed from the control room to terminate the LOCA that would result if an open vent valve could not be reclosed.

(5) A positive indication of valve position should be provided in the control room.

(6) The reactor coolant vent system shall be operable from the control room.

(7) Since the RCS vent will be part of the RCPB, all requirements for the reactor pressure boundary must be met, and, in addition, sufficient redundancy should be incorporated into the design to minimize the probability of an inadvertent actuation of the system. Administrative procedures may be a viable option to meet the single failure criterion. For vents larger than the LOCA definition, an analysis is required to demonstrate compliance with 10CFR50.46.

(8) The probability of a vent path failing to close, once opened, should be minimized; this is a new requirement. Each vent must have its power supplied from an emergency bus. A single failure within the power and control aspects of the reactor coolant vent system should not prevent isolation of the entire vent system when required. On BWRs, block valves are not required in lines with safety valves that are used for venting.

(9) Vent paths from the primary system to within containment should go to those areas that provide good mixing with containment air.

(10) The reactor coolant vent system (i.e., vent valves, block valves, position indication devices, cable terminations, and piping) shall be seismically and environmentally qualified in accordance with IEEE 344 (1975) as supplemented by Regulatory Guide 1.100, Regulatory Guide 1.92 and SEP 3.92, 3.43, and 3.10. Environmental qualifications are in accordance with the May 23, 1980 Commission Order and Memorandum (CLI-80-21).

(11) Provisions to test for operability of the reactor coolant vent system should be a part of the design. Testing should be performed in accordance with subsection IWV of Section XI of the ASME Code for Category B valves.

(12) It is important that the displays and controls added to the control room as a result of this requirement not increase the potential for operator error. A human factor analysis should be performed taking into consideration:

(a) the use of this information by an operator during both normal and abnormal plant conditions,

(b) integration into emergency procedures,

(c) integration into operator training, and

(d) other alarms during emergency and need for prioritization of alarms.

B. BWR Design Considerations

(1) Since the BWROG has suggested that the present BWR designs have an inherent capability to vent, a question relating to the capability of existing systems arises. The ability of these systems to vent the RCS of noncondensable gas generated during an accident must be demonstrated. Because of differences among the head vent systems for BWRs, each licensee or applicant should address the specific design features of this plant and compare them with the generic venting capability proposed by the BWROG. In addition, the ability of these systems to meet the same requirements as the PWR vent system must be documented.

(2) In addition to RCS venting, each BWR licensee should address the ability to vent other systems, such as the isolation condenser which may be required to maintain adequate core cooling. If the production of a large amount of noncondensable gas would cause the loss of function of such a system, remote venting of that system is required. The qualifications of such a venting system should be the same as that required for PWR venting systems.

Response

The BWROG position on NUREG-0737, Item II.B.1 requirements for RCS vents is contained in D.B. Waters (BWROG) letter to D.G. Eisenhut (NRC) dated April 24, 1981, D.B. Waters (BWROG) letter to D.G. Eisenhut (NRC) dated October 8, 1980, and T.D. Keenan (BWROG) letter to D.G. Eisenhut (NRC) dated October 17, 1979. The licensee concurs with the BWROG conclusion that adequate RCS venting capability is provided by the existing plant design. The following is a description of the existing LGS provisions for RCS venting and an assessment of this capability relative to the NUREG-0737 position and clarification.

Position (1)

LGS is provided with five power-operated, safety-grade SRVs (ADS valves PSV-41-F013E, H, K, M, and S) that would be the primary means of venting noncondensable gases from the RPV following a LOCA. The point of connection of the vent lines to the vessel is such that accumulation of gases above this elevation in the vessel will not inhibit natural circulation cooling of the reactor core. These ADS valves are self-actuating at their set relieving pressure to provide system overpressure protection and can also be actuated automatically or manually from the control room to depressurize the reactor. Operation of the ADS valves requires only safety-grade equipment and controls and does not require any source of offsite or ac power. The valves are controlled by dc power from the safeguard batteries and are pneumatically actuated from individual safety-grade accumulators and a safety-grade nitrogen bottle supply for long-term operation. Additional information regarding the design, qualification, power source, etc., of the SRVs is presented in Sections 5.1, 5.2.2, 6.2, 6.3, 7.3, 9.3.1.3, and 15.

Although the power-operated, safety-grade SRVs discussed above satisfy the NUREG-0737 requirements, the following other means of venting noncondensables from the RPV exist:

a) Nine other SRVs (PSV-41-F013 A-D, F, G, J, L, and N) are provided. These valves are identical to those used for ADS except that they are not equipped for automatic actuation or provided with safety-grade air supplies. They may be individually operated from the control room provided that the normal instrument air supply is available. Normally open reactor head vent line 2"- DBA-108 discharges to main steam line "C", which can then be vented to the suppression pool by opening any of the three SRVs on that line.

b) Normally closed reactor vessel head vent valves (2"-HV-41-F001 and F002) are provided. These motor- operated valves are operable from the control room, provided that the normal power supplies are available. The head vent lines discharge to the drywell equipment drain tank.

c) The main steam-driven HPCI and RCIC system turbines exhaust to the suppression pool. These will function automatically to ensure adequate core cooling, as discussed in Sections 6.3 and 5.4 and, in the process, provide continuous venting of noncondensables to the suppression pool during their operation. The effect of noncondensables in the HPCI and RCIC turbine steam has been analyzed and the results are described in the D.B. Waters (BWROG) letter to D.G. Eisenhut (NRC) dated April 24, 1981.

The effects of inadvertent opening of a SRV or both head vent valves would be the same as a small steam line break. A complete steam line break is part of the plant's design basis, and smaller size breaks have been shown to be of lesser severity. A number of reactor system blowdowns due to SORV have confirmed this. Similarly, a break in any of the systems enumerated above would be less severe than a complete steam line break. Because the results of the complete steam line break analysis have demonstrated compliance with the acceptance criteria of 10CFR50.46, no new analyses are required to show conformance with 10CFR50.46 for vent line failures.

Position (2)

In the development of the BWR EPG, this issue was considered. The EPG regarding reactor vessel level control addresses all contingent actions required to maintain RPV level. These actions include venting for all instances when the accumulation of noncondensables may be of concern. Further discussion of this issue is contained in the D.B. Waters (BWROG) letter to D.G. Eisenhut (NRC) dated April 24, 1981.

Clarification A(1)

The automatic and/or manual operation of the RCS vent paths described above provides effective venting capability to deal with large quantities of noncondensable gas. This venting capability will preclude the possibility of noncondensable gas accumulation interfering with core cooling.

Clarification A(2)

The BWR EPG include provisions for RCS venting for all instances when the accumulation of noncondensables may be of concern. This topic is further discussed in the D.B. Waters (BWROG) letter to D.G. Eisenhut (NRC) dated April 24, 1981. As stated in the response to Position (1), the use of these vent paths or their failure will not result in a violation of the requirements of 10CFR50.46.

An analysis demonstrating that the direct venting of noncondensable gases into the primary containment will not result in violation of combustible gas concentration limits is presented in Section 6.2.5. The gas generation rates assumed in this analysis are in accordance with 10CFR50.44 and Regulatory Guide 1.7.

Clarification A(3)

Because the containments are inerted, and postaccident combustible gas control is maintained by oxygen deficiency, the LGS design is insensitive to the rate or extent of metal-water reaction up to the point where containment pressurization is limiting. This point is substantially beyond the present Regulatory Guide 1.7 design basis as demonstrated by the conservative assessment of this margin provided in Sections 6.2.1.3.4 and 6.2.5.

Further consideration will be given to the impact of combustible gas source terms beyond the present design basis in response to the proposed NRC degraded core rulemakings.

Clarification A(4)

As stated in the response to Position (1), a failure of one of the above vents would result in the equivalent of a small steam line break LOCA.

Clarification A(5)

SRV position indication is provided in the control room by the acoustic monitoring system described in Section 7.6.1.5. Direct position indication is provided in the control room for the HPCI, RCIC, and head vent valves.

Clarification A(6)

Each SRV, HPCI, RCIC, and head vent valve may be individually operated from the control room.

Clarification A(7)

All design requirements for the RCPB have been met in the design of appropriate portions of each vent path described above. Because inadvertent operation of a vent path will cause only a minor plant transient as described in the response to Position (1), redundancy is not felt to be necessary. Compliance with 10CFR50.46 is assured for all events as described in the response to Position (1).

Clarification A(8)

Block valves are not provided on the SRV lines in accordance with the clarification. The isolation provisions for the HPCI and RCIC steam lines will withstand a single active failure. Such provisions are not felt to be necessary for the head vent valves for the reasons discussed in the response to clarification A(7).

Clarification A(9)

The point within primary containment to which noncondensables are vented is not of concern because the containment is inerted and effective mixing is assured. Mixing of gases within the primary containment is discussed in Section 6.2.5.2.3.

Clarification A(10)

The equipment, piping, controls, and position indication associated with the ADS SRV and HPCI vent paths described above have been environmentally qualified in accordance with Commission Order and Memorandum CLI-80-21 and seismically analyzed as described in Chapter 3. Portions of the RCIC and the head vent line required for venting are also designed to withstand seismic accelerations. The RCIC valves are environmentally qualified to achieve containment isolation.

Clarification A(11)

The SRVs and the HPCI and RCIC steam valves are tested in accordance with 10CFR50, Appendix J and the intent of subsection IWV of Section XI of the ASME B&PV Code.

Clarification A(12)

This clarification does not apply because no new equipment is being provided to meet the RCS venting requirements.

Clarification B(1)

The information provided above and in the referenced letters demonstrates that the LGS ADS SRVs meet all of the BWROG implementation criteria and NRC requirements for RCS venting.

Clarification B(2)

The following ECCS are available for maintenance of reactor vessel water level at LGS.

a. HPCI

b. RCIC

c. LPCI

d. CS

None of the operating modes of the above systems require venting other than from the reactor vessel.

LGS is not equipped with isolation condensers.

- II.B.2 PLANT SHIELDING

The information in the position and response is historical and represents the original plant design requirements based on source terms consistent with TID-14844. The application of Alternative Source Terms (AST) per Regulatory Guide 1.183 has resulted in the re-assessment of control room and off-site radiological consequences from design basis accidents. Shielding design remains on the TID-14844 source terms; however, Regulatory Guide 1.183 source terms may be used for re-evaluations.

Position

With the assumption of a postaccident release of radioactivity equivalent to that described in Regulatory Guide 1.3, "Assumptions Used for Evaluating the Potential Radiological Consequences of a Loss-of-Coolant Accident for Boiling Water Reactors," and Regulatory Guide 1.4, "Assumptions Used for Evaluating the Potential Radiological Consequences of a Loss-of-Coolant Accident for Pressurized Water Reactors" (i.e., the equivalent of 50% of the core radioiodine, 100% of the core noble gas inventory, and 1% of the core solids are contained in the primary coolant), each licensee shall perform a radiation and shielding design review of the spaces around systems that may, as a result of an accident, contain highly radioactive materials. The design review should identify the location of vital areas and equipment, such as the control room, radwaste control stations, emergency power supplies, MCCs, and instrument areas, in which personnel occupancy may be unduly limited or safety equipment may be unduly degraded by the radiation fields during postaccident operations of these systems.

Each licensee shall provide for adequate access to vital areas of protection of safety equipment by design changes, increased permanent or temporary shielding, or postaccident procedural controls. The design review shall determine which types of corrective actions are needed for vital areas throughout the facility.

Clarification

The purpose of this item is to ensure that licensees examine their plants to determine what actions can be taken over the short-term to reduce radiation levels and increase the capability of operators to control and mitigate the consequences of an accident. The actions should be taken pending conclusions resulting in the long-term degraded core rulemaking, which may result in a need to consider additional sources.

Any area which will or may require occupancy to permit an operator to aid in the mitigation of or recovery from an accident is designated as a vital area. For purposes of this evaluation, vital areas and equipment are not necessarily the same vital areas or equipment defined in 10CFR73.2 for security purposes. The security center is listed as an area to be considered as potentially vital, since access to this area may be necessary to take action to give access to other areas in the plant.

The control room, TSC, sampling station, and sample analysis area must be included among those areas where access is considered vital after an accident. (Refer to section III.A.1.2 of this report for discussion of the TSC and EOF.) The evaluation to determine the necessary vital areas should also include, but not be limited to, consideration of the post-LOCA hydrogen control system, containment isolation reset control area, manual ECCS alignment area (if any), MCCs, instrument panels, emergency power supplies, security center, and radwaste control panels. Dose rate determinations need not be for these areas if they are determined not to be vital.

As a minimum, necessary modification must be sufficient to provide for vital system operation and for occupancy of the control room, TSC, sampling station, and sample analysis area.

In order to assure that personnel can perform necessary postaccident operations in the vital areas, the following guidance is to be used by licensees to evaluate the adequacy of radiation protection to the operators:

(1) Source Term

The minimum radioactive source term should be equivalent to the source terms recommended in Regulatory Guides 1.3, 1.4, 1.7, "Control of Combustible Gas Concentrations in Containment Following a Loss-of-Coolant Accident," and SRP 15.6.5 with appropriate decay times based on plant design (i.e., assuming the radioactive decay that occurs before fission products can be transported to various systems).

(a) Liquid-Containing Systems: 100% of the core equilibrium noble gas inventory, 50% of the core equilibrium halogen inventory, and 1% of all others are assumed to be mixed in the reactor coolant and liquids recirculated by RHR, HPCI, and LPCI, or the equivalent of these systems. In determining the source term for recirculated, depressurized cooling water, assuming that the water contains no noble gases.

(b) Gas-Containing Systems: 100% of the core equilibrium noble gas inventory and 25% of the core equilibrium halogen activity are assumed to be mixed in the containment atmosphere. For vapor-containing lines connected to the primary system (e.g., BWR steam lines), the concentration of radioactivity shall be determined assuming the activity is contained in the vapor space in the primary coolant system.

(2) Systems Containing the Source

Systems assumed in your analysis to contain high levels of radioactivity in a postaccident situation should include, but not be limited to, containment, RHR system, safety injection systems, chemical and volume control system, containment spray recirculation system, sample lines, gaseous radwaste systems, and SGTS (or equivalent of these systems). If any of these systems or others that could contain high levels of radioactivity were

excluded, you should explain why such systems were excluded. Radiation from leakage of systems located outside of containment need not be considered for this analysis. Leakage measurement and reduction is treated under section III.D.1.1, "Primary Coolant Outside Containment." Liquid waste systems need not be included in this analysis. Modifications to liquid waste systems will be considered after completion of section III.D.1.4, "Radwaste System Design Features To Aid in Accident Recovery and Decontamination."

(3) Dose Rate Criteria

The design dose objectives for personnel in a vital area should be such that the guidelines of GDC 19 will not be exceeded during the course of the accident. GDC 19 requires that adequate radiation protection be provided such that the dose to personnel should not be in excess of 5 rem whole body, or its equivalent to any part of the body for the duration of the accident. When determining the dose to an operator, care must be taken to determine the necessary occupancy times in a specific area. For example, areas requiring continuous occupancy will require much lower dose rates than areas where minimal occupancy is required. Therefore, allowable dose rates will be based upon expected occupancy, as well as the radioactive source terms and shielding. However, in order to provide a general design objective, we are providing the following dose rate criteria with alternatives to be documented on a case-by-case basis. The objectives dose rates are average rates in the area. Local hot spots may exceed the dose rate guidelines. These doses are design objectives and are not to be used to limit access in the event of an accident.

(a) Areas Requiring Continuous Occupancy: <15 mrem/hr (averaged over 30 days). These areas will require full-time occupancy during the course of the accident. The control room and onsite TSC are areas where continuous occupancy will be required. The dose rate for these areas is based on the control room occupancy factors contained in SRP 6.4.

(b) Areas Requiring Infrequent Access: GDC 19. These areas may require access on an irregular basis, not continuous occupancy. Shielding should be provided to allow access at a frequency and duration estimated by the licensee. The plant radiochemical/chemical analysis laboratory, radwaste panel, motor control center, instrumentation locations, and reactor coolant and containment gas sample stations are examples of sites where occupancy may be needed often, but not continuously.

(4) Radiation Qualification of Safety-Related Equipment

The review of safety-related equipment which may be unduly degraded by radiation during postaccident operation of this equipment relates to equipment inside and outside of the primary containment. Radiation source terms calculated to determine environmental qualification of safety-related equipment consider the following:

(a) LOCA events which completely depressurize the primary system should consider releases of the source term (100% noble gases, 50% iodines, and 1% particulates) to the containment atmosphere.

(b) LOCA events in which the primary system may not depressurize should consider the source term (100% noble gases, 50% iodines, and 1% particulates) to remain in the primary coolant. This method is used to determine the qualification doses for equipment in close proximity to recirculating fluid systems inside and outside of containment. Non-LOCA events both inside and outside of containment should use 10% noble gases, 10% iodines, and 0% particulate as a source term. Table 1.13-6 summarizes these considerations.

Response

A. Introduction

The design review of plant radiation and shielding was performed as required by NUREG-0737 Item II.B.2 and is described below. The purpose of the review was to identify potential problem areas and equipment which may require the development of special postaccident procedures, installation of additional permanent or temporary shielding, relocation of components or piping, or requalification of components.

Areas that are vital for postaccident occupancy or operation and all safety-related equipment were evaluated to determine if access and performance of required operator activities or equipment functions might be unduly impaired due to the presence of the postulated radiation source in the selected systems. Systems required or postulated to process highly radioactive fluids or gases outside the containment during postaccident conditions were selected for evaluation. Radiation levels in adjacent plant areas due to contained sources in piping and equipment of these systems were estimated. Airborne sources caused by leakage from the primary containment and systems containing postaccident sources were also included in the evaluation for vital areas as described below.

The identification of vital areas and a summary of the methodology used to determine radiation doses for these areas and to equipment are presented below. Doses to personnel in vital areas and access paths are listed in Tables 1.13-1 and 1.13-2, respectively. The identification of essential equipment, doses to equipment used for qualification purposes, and the results of the review of equipment for the postulated radiation sources are provided in the separate EQR. The results of the shielding design review for vital areas are provided below in Section H.

B. Vital Area Identification

Areas which may require occupancy to permit an operator to aid in the mitigation of or recovery from an accident are designated as vital areas. A review of LGS was made which determined that the following areas should be designated vital areas.

Continuous Occupancy

1) Main Control Room

2) Technical Support Center

3) Operations Support Center

4) Security Center

Infrequent Occupancy

1) Counting Room

2) Radiochemistry laboratory

3) Postaccident sampling station

4) North stack instrument room

5) HVAC panels at el 304'

6) Radwaste control room

7) Diesel generator area

Potential vital areas that are not listed above were excluded for the following reasons. The post-LOCA hydrogen control (recombiner) system and containment isolation valves are all automatic or remotely controlled by the operator in the main control room and require no local access. There is no manual ECCS alignment area at LGS. Instrument panels and MCCs are not included because the control and alignment of essential systems are accomplished from the main control room and require no local action.

Eleven access paths to vital areas were also identified and included in this review.

C. Selection of Systems for Radiation and Shielding Review

A review was made to determine which systems could be required to operate and/or could be expected to contain highly radioactive materials following an accident where substantial core damage has occurred. The results of this review are presented below.

1. CS, HPCI, RCIC, RHR, and Safeguard Piping Fill Systems.

The CS, RHR, HPCI (water side), RCIC (water side), and safeguard piping fill systems would contain suppression pool water being injected to the RCS. Although the HPCI and RCIC systems could also carry condensate, suppression pool water was assumed for this review for conservatism. The steam sides of the HPCI and RCIC systems would operate on reactor steam.

2. RHR System (Shutdown Cooling Mode)

The RHR system recirculates reactor water when it operates in the shutdown cooling mode. Before operation in this mode can be initiated, the reactor must be depressurized to less than 75 psig. This depressurization is expected to remove substantially all of the noble gases released into the reactor water. Following an accident, the HPCI, RCIC, RHR (LPCI mode), and CS systems would inject water into the RCS. This water from the condensate tank and/or the suppression pool

would dilute the reactor water prior to the initiation of shutdown cooling with the RHR system. This review assumed that there are no noble gases in the reactor water in the RHR system for the shutdown cooling mode and that the reactor water is diluted by the suppression pool water volume.

3. CRD System

The operation of the CRD system was reviewed to determine if the scram discharge headers will contain highly radioactive water following an accident. It was determined that they will not. Prior to a scram, the CRD housings contain condensate water delivered by the CRD pumps. When a scram occurs, some of this condensate water from the CRD is discharged to the scram discharge header. After the scram, some condensate and reactor water flows to the scram discharge header until it is completely filled. This takes a matter of seconds. Since the vents and drains in the scram discharge header are isolated by the scram, all discharge flow then stops.

Since it is not reasonable to assume that significant core damage occurs in the first few seconds following a scram, the scram discharge header will contain only a mixture of condensate and preaccident reactor water following this postulated accident.

4. RWCU System

For an accident with resulting core damage, the RWCU system would be isolated and would contain no highly radioactive materials beyond the second isolation valve. On a BWR this system is not needed for RCS venting. It would not be practical to use it for accident recovery after a major accident. It was therefore assumed that this system would not operate with highly contaminated reactor water.

5. Gaseous Radwaste System

For an accident with resulting core damage, it would not be practical to use the gaseous radwaste system for accident recovery. Noble gas isotopes with long lives would cause excessive offsite doses if the gaseous radwaste system was used after a design basis accident. It was therefore assumed that this system would not operate.

6. Postaccident Sampling System

Sampling lines used after an accident would contain primary containment gas, secondary containment gas, reactor coolant (pressurized or depressurized) or suppression pool water, depending on the sampling line take-off location.

7. Containment Atmospheric Control System

The recombiner system and associated H_2-O_2 analyzer lines would recirculate primary containment gas after an accident in order to keep hydrogen and oxygen concentrations at acceptable levels.

8. SGTS and RERS

The SGTS and RERS would collect airborne activity in the secondary containment following an accident. Radioactivity would be collected on the filters and charcoal beds in these systems.

9. Containment

The free volume of the primary containment is assumed to initially contain large amounts of postaccident activity. These sources, as well as those assumed for the suppression pool, are described below. Shine through the drywell and wetwell walls would cause a negligible increase to the secondary containment airborne and piping doses, and therefore was not included in this review.

10. MSIV Leakage Alternate Drain Pathway

Following the accident, the MSIV Leakage Alternate Drain Pathway will be aligned. The sources associated with this pathway are discussed below. Shine through the turbine condenser shield wall is considered negligible and therefore, was not included in this review.

D. Source Release Fractions

The following release fractions were used as a basis for determining the concentrations for the radiation and shielding review:

Source A:	Containment atmosphere:	100% noble gases, 25% halogens
Source B:	Suppression pool liquid:	50% halogens, 1% solids
Source C:	Reactor steam:	100% noble gases, 25% halogens
Source D:	Pressurized reactor coolant:	100% noble gases, 50% halogens, 1% solids

These release fractions were applied to the total curies available for the particular chemical species (i.e., noble gas, halogen, or solid) for an equilibrium fission product inventory for a light-water reactor core.

E. Source Term Models

The assumptions used for release fractions for the radiation and shielding design review are outlined above. These release fractions are, however, only the first step in modeling the source terms for the activity concentrations in the systems under review. The decay time and dilution volume also affect the rationale for the selection of values for these parameters.

1. Decay Time

For conservatism, no decay time credit was taken for the radioactive decay that might occur before fission products would be transported to the various systems.

2. Dilution Volume

The volume used for dilution is important, affecting the calculations of dose rate in a linear fashion. The following dilution volumes were used with the release fractions listed above in Section D to arrive at the final source terms for the shielding reviews.

Source A: Drywell and suppression pool free air volumes.

Source B: The volume of the RCS (based on reactor coolant density at the operating temperature and pressure) plus the suppression pool water volume.

Source C: The total reactor system steam volume.

Source D: The volume of the RCS.

3. Contained Sources and Drywell and Secondary Containment Airborne Sources

In defining the contained sources, accident operating modes were assumed for each system. In defining the limits of the connected piping subject to contamination listed below, normally shut valves were assumed to remain shut.

- CS system - Source B
- HPCI system

  Liquid - Source B

  Steam - Source C (with credit for steam specific activity reduction due to turbine operation).

- RCIC system

  Liquid - Source B
  Steam - Source C (with credit for steam specific activity reduction due to turbine operation).

- RHR system - Source B (all modes)
- Postaccident Sampling Lines

  Gas sample lines - Source A
  Liquid sample lines - Source D

- Containment Atmospheric Control (Recombiner) System - Source A (Drywell free volume only)
- Drywell - Source A
- MSIV Leakage Alternate Drain Pathway – Source C
- SGTS, RERS, and Secondary Containment Activity

The following major assumptions were used to calculate the secondary containment airborne radiation doses and the radiation doses for the SGTS filters and the RERS filters.

a. 100% of the noble gases and 25% of the halogens are available for leakage into the secondary containment.

b. The primary to secondary containment leak rate is 0.5% per day.

c. Airborne activity in the secondary containment is confined to spaces below the refueling floor for normal reactor enclosure/refueling area HVAC alignment. Other alignments have been evaluated to provide additional flexibility during refueling operations.

d. The RERS flow rate is two secondary containment air changes per hour.

e. The SGTS flow rate is one air change per day. (For equipment qualification of equipment in the reactor enclosure, the secondary containment airborne doses and RERS filter doses were conservatively based on an SGTS flow rate of one-half air change per day. This results in a longer holdup time and therefore higher doses. For equipment qualification of the SGTS and equipment in the vicinity, an SGTS flow of one air change per day was used.)

f. The RERS charcoal filter is 95% efficient with respect to halogens.

g. The SGTS charcoal filter is 100% efficient with respect to halogens for filter loading.

h. The activity inventory in the core was based on 1000 days burnup and daughter product formation was not considered. These assumptions, which have off-setting effects, were necessitated by limitations in the computer code used to treat the transport of activity from primary to secondary containment.

i. The capacities of the RERS and SGTS filters are sufficient to sustain cleanup for the duration of the accident.

j. Deleted

4. Airborne Sources for Vital Areas

All the vital areas and access paths are located in the turbine enclosure, radwaste enclosure, control structure, administration building, diesel generator enclosure, TSC, and yard areas. The transport pathway of the airborne sources in these areas consists of leakage from the primary containment to the reactor enclosure, and discharge to the environment via the RERS and the SGTS. The airborne activity discharged then re-enters the buildings through the ventilation intake systems after dilution within the building wake cavity.

The assumptions used in calculating the released airborne activity are the same as those listed in Section 3 above the secondary containment except that an SGTS flow rate of one air change per day and the technical specification minimum filter efficiencies are used to maximize the activity released (i.e. RERS is 95%, and SGTS is 99%, efficient). Also, an assumed 5 gpm systems leakage (at suppression pool activity concentration) to the secondary containment is included in the analysis.

The atmospheric dispersion factors (X/Q), along with their calculation basis, are given in Section 15.10 Section 15.10.2.2 “Control Room Dose Module” includes the main control room, HVAC panels, and the north stack instrument room. The X/Q's for the other vital areas are analyzed using the modified Halitsky X/Q methodology. This methodology is discussed below.

J. Halitsky's efforts summarized in Reference 1.13-1 present the basic equation as follows:

$$X/Q = K/A\bar{u}$$

where:

A = cross-sectional area, M^2 orthogonal to u

$\bar{u}$ = wind speed, m/s

K = isopleth (Concentration coefficient - dimensionless)

It is found in many cases that the above Halitsky equation still provides a reasonable estimate of X/Q. Several correction factors can be applied to this equation to account for situation and plant specific features, such as:

- Stream line flows are used in most wind tunnel tests
- Release points are generally much higher than 10 meters above ground
- Null wind velocity is observed at certain periods of time
- Isothermal temperatures are used in wind tunnel tests
- Buoyancy and jet momentum effects are ignored
- Typical 1 hr field tests account for plume meander effects while 3-5 minute wind tunnel tests do not.

A modified Halitsky X/Q methodology was thus formulated and is presented below.

$$X/Q = \frac{K}{\bar{\bar{u}}} \bullet f_1 \bullet f_2 \bullet f_3 \bullet f_4 \bullet f_5 \bullet f_6 \ (sec/m^3)$$

As a test of the modified Halitsky method, calculated values of X/Q, without using factors f_4 and f_5 due to their uncertainty, were compared to the 1 hour field test X/Q data from Rancho Seco (Reference 1.13-3). Only one X/Q was found to be higher than the calculated value. This was due to an external wake influence caused by wind channeling between the nearby cooling towers. The wind channeling prevented the normal wake turbulence and variation effects over time, which normally spread the plume over a wide area. In most cases the modified Halitsky X/Q was found to be a conservative estimate of the measured X/Q; in some cases it was significantly higher.

The choice of K factors and the suggested modifying factors f_1, f_2, etc, are discussed below.

K factors: The choice of an appropriate K factor from the wind tunnel test data is critical for the X/Q estimate to be valid. Halitsky, in Reference 1.13-1, has several sets of K isopleths for round topped containments (PWRs) and block buildings (BWRs). Multiple building complexes must be simulated by single equivalent structures. The effluent velocity to wind speed ratio of approximately 1 is valid for most power plant systems. Various angles of wind incidence are shown to account for vortexing which could result in worse conditions than a wind normal to the building face. K factors should be estimated for various combinations of wind incidence angle and the appropriate effective building cross-sectional area causing the wake (not just the containment area) to determine the peak value as was done by Walker (Reference 1.13-4).

Wind speed (□): Halitsky's K values are based on wind speeds measured at the top of the containment or building. Therefore, the Reference 1.13-2 five percentile wind speed at a 10 meter height should be adjusted to the actual speed at the top of containment or release point. The five percentile wind speed is adjusted using the formulation presented by Wilson (Reference 1.13-5) as follows:

$$\overline{u}_T = \overline{u}\left(\frac{Z}{Z_{Ref}}\right)$$

where:

$\overline{u}_T$ = wind speed at height Z

Z_{Ref} = 10 meters (five percentile wind speed reference height)

Wind speed change factor (f_1), and Wind direction change factor (f_2): The factor supplied from Reference 1.13-2, shown below, were used.

Time Periods	f_1	f_2
0 - 8 hrs	1	1
8 - 24 hrs	.67	.88

24 - 96 hrs	.50	.75
96 - 720 hrs	.33	.50
720 hrs & on	.25	.33

Wind turbulence effect (f_3): Wilson (Reference 1.13-5) and field tests confirm Halitsky's statement that his K isopleths are a factor of 5 to 10 too conservative due to not accounting for random fluctuations of the wind approaching the building. Therefore, a factor of 0.2 was used for f_3.

Elevated release effect (f_4): Bouwmeester (Reference 1.13-6) indicates that there are up to 10 null wind speed conditions during an hour of data collection. During these periods the effects of jet momentum, plume rise, and buoyancy would result in the radioactive effluent being discharged above the effective wake boundary and thus not entering the wake cavity. A reduction factor of 1 was used.

Time average effects (f_5): Wind speed variations and wind direction meandering effects are not modeled in wind tunnel tests to account for this effect. Reference 1.13-6 indicates the use of the following equation:

$$C_p = C_m \left(\frac{t_p}{t_m}\right)^{-1/2}$$

where:

C_p = prototype concentration

C_m = model concentration

t_p = prototype sampling time

t_m = model equivalent sampling time

Normal wind tunnel data is taken for 3 to 10 minute samples. Thus, for a 1 hour field test, C_p = .22 to .41 C_m and for an 8 hour field test, C_p = .08 to .14 C_m. A value of 0.5 was conservatively assumed for f_5.

Adjustment to top of stack (f_6): To account for wind speed at the top of the stack instead of the Reference 1.13-2 five percentile wind speed at 10 meters height, the factor $f_6 = \bar{u} / \bar{u}_T$ was included. The f_6 value equals 0.66.

The resultant X/Q (sec/m^3) calculated for each of the vital areas except for the main control room, HVAC panels and north stack instrument room (control room X/Q calculated in Section 15.10 was used) are thus shown in Table 1.13-7.

For the MSIV Leakage Alternate Drain Pathway, the F_6 factor is 1.0, since the release point is not an elevated release point.

F. Radiation Dose Calculation

1. Primary and Secondary Containment Doses

The sources described above in Section E were used to estimate doses from the systems included in the radiation and shielding design review. No vital areas are located in the primary or secondary containments, thus the doses described in this section were used for equipment qualification purposes only.

Both gamma and beta post-LOCA doses were calculated for the primary containment. The doses were calculated by assuming that 100% of the core noble gas inventory and 50% of the core halogen inventory are released. These source terms are consistent with those specified in NUREG-0588 and NUREG-0737.

The primary containment airborne dose calculations assumed that 50% of the 50% (i.e. 25%) halogen release from the core plates out instantaneously, as assumed implicitly in Regulatory Guide 1.3 (Rev 2). The airborne doses were calculated assuming source terms diluted by the primary containment (drywell and wetwell) free volume. These assumptions are consistent with those specified in NUREG-0737.

The beta doses and dose rates for qualification of equipment were calculated assuming an infinite cloud geometry. The beta doses and dose rates for qualification of coatings were calculated assuming a semi-infinite cloud geometry.

For components inside primary containment the total integrated gamma doses were calculated by adding the post-LOCA primary containment gamma cloud dose to the 40 year normal operating dose. Dose distance relationships were not used to reduce post-LOCA doses inside primary containment.

Both gamma and beta post-LOCA doses were also calculated for the secondary containment, based on the source terms described above in Section E. For compartments inside the secondary containment, the post-LOCA gamma radiation levels were conservatively determined by adding the maximum piping contact dose in that compartment to the secondary containment gamma cloud dose. The total integrated gamma dose was then determined by adding the post-LOCA integrated dose to the 40 year normal operating integrated dose. The equipment qualification levels for all safety-related electrical components were compared to the applicable calculated dose. For those components initially listed as inadequately qualified, more detailed

calculations were performed, taking into account dose/distance relationships in order to determine more realistic doses. A set of dose/distance curves for each system was developed as part of this effort.

2. Doses in Other Plant Areas for Equipment Qualification

Doses for specified areas outside the secondary containment were also calculated as described below, for equipment qualification purposes. For the SGTS equipment compartment, the post-LOCA gamma dose is the contact dose of the SGTS filters. For the remaining areas, the post-LOCA gamma doses were determined by adding the cloud, filter and piping shine doses from adjacent compartments and the control structure cloud dose, as applicable. These post-LOCA doses were added to the normal operating integrated dose to

determine the total integrated gamma doses. Beta doses outside secondary containment would be negligible for equipment qualification purposes, and therefore they were not calculated.

3. Vital Area and Access Path Doses

Calculations were performed to determine airborne and shine doses from the sources described above in Section E to the vital areas and access paths. These doses were used to determine personnel exposures, using occupancy factors as described below in Section G. For radiation doses due to direct shine, credit was taken for attenuation through the walls and due to distance. For airborne doses, both gamma and beta contributions were included. In the access path airborne dose calculations for the yard area routes, the most conservative X/Q bounding that route was used.

G. Personnel Exposure Limits

The general basis for personnel radiation exposure guidelines was GDC 19. The following additional radiation limit guidelines were used to evaluate occupancy and accessibility of plant vital areas and access paths.

Radiation Exposure Guidelines

Occupancy	Dose Objective
Continuous	≤ Rem for duration
Infrequent	≤ Rem for all activities
Accessway	≤ 10 Rem/hr

These dose objectives are for personnel access only.

Emergency Response Procedures specify the criteria for radiological habitability monitoring to insure the dose objectives are not exceeded. Based on the results of the habitability monitoring personnel in the affected areas may be instructed to don protective devices or limit stay times to maintain the dose objectives.

The dose rate received by personnel in vital areas of continuous occupancy should be <15 mrem/h (average over 30 days). The doses for these areas were determined using the control room occupancy factors contained in SRP 6.4, as discussed in NUREG-0737, i.e., 1.0 for 0-1 day; 0.6 for 1-4 days; and 0.4 for over 4 days.

The dose received by personnel in an infrequent occupancy of vital areas and access paths is determined by taking into account the frequency and duration of the activities anticipated for that area, and is consistent with GDC 19 limits. Average area dose rates are used to determine personnel exposure, although local hot spots may exist.

H. Results of Dose Calculations

1. Environmental Qualification of Equipment

Normal operating radiation doses and conservative post-LOCA gamma and beta doses are provided in the Equipment Qualification Report and its references for all

areas containing safety-related equipment. Equipment was reviewed against these doses or, if necessary, against reduced doses calculated as described above in Section F.1. The results of the review of equipment are provided in the EQR.

2. Personnel Access

The reactor enclosure and refueling floor will be inaccessible after a design basis LOCA. However, this does not present a problem since they do not contain any vital areas requiring operator access. The non-LOCA reactor enclosure will be accessible.

Doses to the vital areas described above in Section B from the sources described above in Section E are provided in Table 1.13-1. The dose objective of Table 1.13-1 are not used to limit access in the event of an accident.

Dose rates for vital area access paths are provided in Table 1.13-2. These access paths are given in Table 1.13-5.

The airborne and direct shine doses must be added together to show the total dose to personnel in the vital areas and access paths.

Peak shine dose rates are provided in Table 1.13-1 along with the integrated doses. The dose rate at any given time for a vital area can be estimated by multiplying the peak dose rate by an appropriate factor which can be determined by using the curves in Figures 1.13-1 and 1.13-2.

Potential problem areas that were identified in the design review of plant shielding are listed in Table 1.13-3, along with the solutions that will be followed for these areas.

I. Conclusion

Areas and safety-related equipment vital for postaccident occupancy or operation were identified, and postaccident doses were calculated in accordance with the requirements of NUREG-0737. Also in Table 1.13-3, potential problem areas were identified, and solutions for these problems were determined. No additional shielding is required as a result of this study.

- II.B.3 POST ACCIDENT SAMPLING

The information in the position and response is historical and represents the original plant design requirements based on source terms consistent with TID-14844. The application of Alternative Source Terms (AST) per Regulatory Guide 1.183 has resulted in the re-assessment of control room and off-site radiological consequences from design basis accidents. See UFSAR Chapter 15 for additional information.

Position

A design and operational review of the reactor coolant and containment atmosphere sampling line systems shall be performed to determine the capability of personnel to promptly obtain (less than 1 hour) a sample under accident conditions without incurring a radiation exposure to any individual in excess of 3 and 18¾ rem to the whole body or extremities, respectively. Accident conditions should assume a Regulatory Guide 1.3, "Assumptions Used for Evaluating the Potential

Radiological Consequences of a Loss-of-Coolant Accident for Boiling Water Reactors," or Regulatory Guide 1.4 "Assumptions Used for Evaluating the Potential Radiological Consequences of a Loss-of-Coolant Accident for Pressurized Water Reactor" release of fission products. If the review indicates that personnel could not promptly and safely obtain samples, additional design features or shielding should be provided to meet the criteria.

A design and operational review of the radiological spectrum analysis facilities shall be performed to determine the capability to promptly quantify (in less than 2 hours) certain radionuclides that are indicators of the degree of core damage. Such radionuclides are noble gases which indicate cladding failure and isotopes which indicate fuel melting. The initial reactor coolant spectrum should correspond to a Regulatory Guide 1.3 or Regulatory Guide 1.4 release. The review should also consider the effects of direct radiation from piping and components in the auxiliary building and possible contamination and direct radiation from airborne effluents. If the review indicates that the analyses required cannot be performed in a prompt manner with existing equipment, then design modifications or equipment procurement shall be undertaken to meet the criteria.

In addition to the radiological analyses, certain chemical analyses are necessary for monitoring reactor conditions. Procedures shall be provided to perform boron and chloride chemical analyses assuming a highly radioactive initial sample (Regulatory Guide 1.3 or Regulatory Guide 1.4 source term). Both analyses shall be capable of being completed promptly (i.e., the boron sample analysis within an hour and the chloride sample analysis within a shift).

Clarification

The following items are clarifications of requirements identified in NUREG-0578, NUREG-0660, or the September 13, 1979, October 30, 1979, September 5, 1980 and October 31, 1980 clarification letters.

(1) The applicant shall have the capability to promptly obtain reactor coolant samples and containment atmosphere samples. The combined time allotted for sampling and analysis should be 3 hours or less from the time a decision is made to take a sample.

(2) The applicant shall establish an onsite radiological and chemical analysis capability to provide, within the 3 hour time frame established above, quantification of the following:

   (a) Certain radionuclides in the reactor coolant and containment atmosphere that may be indicators of the degree of core damage (e.g., noble gases, iodines and cesiums, and nonvolatile isotopes);

   (b) Hydrogen levels in the containment atmosphere;

   (c) Dissolved gases (e.g., hydrogen), chloride (time allotted for analysis subject to discussion below), and boron concentration of liquids; and

   (d) Alternatively, have inline monitoring capabilities to perform all or part of the above analyses.

(3) Reactor coolant and containment atmosphere sampling during postaccident conditions shall not require an isolated auxiliary system (e.g., the letdown system, reactor water cleanup system) to be placed in operation in order to use the sampling system.

(4) Pressurized reactor coolant samples are not required if the applicant can quantify the amount of dissolved gases with unpressurized reactor coolant samples. The measurement of either total dissolved gases or hydrogen gas in reactor coolant samples is considered adequate. Measuring the oxygen concentration is recommended, but is not mandatory.

(5) The time for a chloride analysis to be performed is dependent upon two factors: (a) if the plant's coolant water is seawater or brackish water, and (b) if there is only a single barrier between primary containment systems and the cooling water. Under both of the above conditions, the applicant shall provide for a chloride analysis within 24 hours of the sample being taken. For all other cases, the applicant shall provide for the analysis to be completed within 4 days. The chloride analysis does not have to be done onsite.

(6) The design basis for plant equipment for reactor coolant and containment atmosphere sampling and analysis must assume that it is possible to obtain and analyze a sample without radiation exposures to any individual exceeding GDC 19 (i.e., 5 rem whole body, 75 rem extremities).

(7) If inline monitoring is used for any sampling and analytical capability specified herein, the applicant shall provide backup sampling through grab samples, and shall demonstrate the capability of analyzing the samples. Established planning for analysis at offsite facilities is acceptable. Equipment provided for backup sampling shall be capable of providing at least one sample per day for 7 days following onset of the accident and at least one sample per week until the accident condition no longer exists.

(8) The applicant's radiological and chemical sample analysis capability shall include provisions to:

(a) Identify and quantify the isotopes of the nuclide categories discussed above to levels corresponding to the source terms given in Regulatory Guides 1.3 or Regulatory Guide 1.4 and Regulatory Guide 1.7, "Control of Combustible Gas Concentration in Containment Following a Loss-of-Coolant Accident." Where necessary and practicable, the ability to dilute samples to provide capability for measurement and reduction of personnel exposure should be provided. Sensitivity of onsite liquid sample analysis capability should be such as to permit measurement of nuclide concentration in the range from approximately 1 μCi/g to 10 Ci/g.

(b) Restrict background levels of radiation in the radiological and chemical analysis facility from sources such that the sample analysis will provide results with an acceptably small error (approximately a factor of 2). This can be accomplished through the use of sufficient shielding around samples and outside sources, and by the use of ventilation system design which will control the presence of airborne radioactivity.

(9) Accuracy, range, and sensitivity shall be adequate to provide pertinent data to the operator in order to describe radiological and chemical status of the RCS.

(10) In the design of the postaccident sampling and analysis capability, consideration should be given to the following items:

(a) Provisions for purging sample lines, for reducing plateout in sample lines, for minimizing sample loss or distortion, for preventing blockage of sample lines by loose material in the RCS or containment, for appropriate disposal of the samples, and for flow restrictions to limit reactor coolant loss from a rupture of the sample line. The postaccident reactor coolant and containment atmosphere samples should be representative of the reactor coolant in the core area and the containment atmosphere following a transient or accident. The sample lines should be as short as possible to minimize the volume of fluid to be taken from containment. The residues of sample collection should be returned to containment or to a closed system.

(b) The ventilation exhaust from the sampling station should be filtered with charcoal adsorbers and high efficiency particulate air filters.

(11) If gas chromatography is used for reactor coolant analysis, special provisions (e.g., pressure relief and purging) shall be provided to prevent high pressure argon from entering the reactor coolant.

(12) Applicants should provide a description of the implementation of the position and clarification including pipe and instrumentation drawings, together with either (a) a summary description of procedures for sample collection, sample transfer or transport, and sample analysis, or (b) copies of procedures for sample collection, sample transfer or transport, and sample analysis, in accordance with the proposed review schedule but in no case less than 4 months prior to the issuance of an operating license. A postimplementation review will be performed.

Response

Provisions for postaccident reactor coolant and containment atmosphere sampling and analysis are described in Sections 6.2.5, 7.5.1 and 11.5.5.

Limerick license amendment numbers 166/129 approved the elimination of the requirement to have and maintain the Post Accident Sampling System. The following items were committed to as part of the license amendment numbers 166/129.

1. Limerick has developed contingency plans for obtaining and analyzing highly radioactive samples of reactor coolant, suppression pool, and containment atmosphere. The contingency plans are contained in the Limerick chemistry procedures. Establishment of contingency plans is considered a regulatory commitment.

2. The capability for classifying fuel damage events at the Alert level threshold has been established at a level of core damage associated with radioactivity levels of 300 micro-curies/gm dose equivalent iodine in the primary coolant system. This capability is described in Limerick's emergency plans and emergency plan implementing procedures. The capability for classifying fuel damage is considered a regulatory commitment.

3. Limerick has established the capability to monitor radioactive iodines that have been released offsite to the environs. This capability is described in the emergency plans and emergency plan implementing procedures. The capability to monitor radioactive iodines is considered a regulatory commitment.

The following information contained in the UFSAR regarding the regulatory requirements for post accident sampling is retained for historical purposes.

A grab sample system designed by GE is provided. Radiological spectrum and chemical analysis capabilities have been established to ensure that the appropriate analyses can be performed in a timely manner.

Shielding requirements and source terms used will be consistent with those used for the Design Review of Plant Shielding, discussed under Item no. II.B.2.

- II.B.4 TRAINING FOR MITIGATING CORE DAMAGE

Position

We require that the applicant develop a program to ensure that all operating personnel are trained in the use of installed plant systems to control or mitigate an accident in which the core is severely damaged. They must then implement the training program.

Clarification

STAs and operating personnel from the plant manager through the operations chain to the licensed operators shall receive this training. The training program shall include the following topics:

(1) Incore Instrumentation

(a) Use of fixed or movable incore detectors to determine extent of core damage and geometry changes.

(b) Use of thermocouples in determining peak temperatures; methods for extended range readings; methods for direct readings at terminal junctions.

(2) Excore Nuclear Instrumentation

(a) Use of excore nuclear instrumentation for determination of void formation; void location basis for excore nuclear instrumentation response as a function of core temperatures and density changes.

(3) Vital Instrumentation

(a) Instrumentation response in an accident environment; failure sequence (time to failure, method of failure); indication reliability (actual versus indicated level).

(b) Alternative methods for measuring flows, pressures, levels, and temperatures.

(i) Determination of pressurizer level if all level transmitters fail.

(ii) Determination of letdown flow with a clogged filter (low flow).

(iii) Determination of other RCS parameters if the primary method of measurement has failed.

(4) Primary Chemistry

(a) Expected chemistry results with severe core damage; consequences of transferring small quantities of liquid outside containment; importance of using leak-tight systems.

(b) Expected isotopic breakdown for core damage; for clad damage.

(c) Corrosion effects of extended immersion in primary water; time to failure.

(5) Radiation Monitoring

(a) Response of process and area monitors to severe damage; behavior of detectors when saturated; method for detecting radiation readings by direct measurement at detector output (overranged detector); expected accuracy of detectors at different locations; use of detectors to determine extent of core damage.

(b) Methods of determining dose rate inside containment from measurements taken outside containment.

(6) Gas Generation

(a) Methods of hydrogen generation during an accident; other sources of gas (Xe, Kr); techniques for venting or disposal of noncondensables.

(b) Hydrogen flammability and explosive limit; sources of oxygen in containment or RCS.

Managers and technicians in the instrumentation and control, health physics, and chemistry departments shall receive training commensurate with their responsibilities.

Response

The lesson plan for the training program for mitigating core damage was developed prior to fuel loading, and training completed prior to full power operation. The course outline is presented below.

Core Cooling Mechanics
- Alternate methods of core cooling
- Core spray and core flooding
- Heat removal paths
- Boron precipitation
- Fuel cladding quenching
- Limiting core conditions
- Steam and water cooling

Potentially Damaging Operating Conditions
- Vulnerable plant operating conditions

Core cooling with systems unavailable

Gas/Steam Binding Affecting Core Cooling
- Sources of gas/steam vapor
- Symptoms/effects of gas/steam binding

Recognizing Core Damage
- Data collection, instrumentation, and systems
- Fuel/clad behavior
- Reporting requirements

Core Recriticality
- Reactor Shutdown margin
- Maintaining subcriticality
- SLCS
- Instrumentation response

Hydrogen Hazards During Accidents
- Sources of hydrogen and oxygen
- Hazardous concentrations and reduction
- Gas venting

Monitoring Critical Parameters During Accident Conditions
- Parameter identification
- Instrumentation reliability, accuracy, and failure

Radiation Hazards and Radiation Monitor Response
- Emergency plan implementation
- High radiation areas
- Sampling
- Radiation monitor response and failure

Criteria for Operation and Cooling Mode Selection
- Core cooling procedures
- Core cooling equipment and methods

STAs and operating personnel from the Station Superintendent through the operations chain including the licensed operators receive this training.

Other plant managerial personnel and technicians in the instrumentation and control, health physics, and chemistry groups also receive training commensurate with their responsibilities during accident conditions.

- II.D.1 RELIEF AND SAFETY VALVE TEST REQUIREMENTS

Position

PWR and BWR licensees and applicants shall conduct testing to qualify the RCS relief and safety valves under expected operating conditions for design basis transients and accidents.

Clarification

Licensees and applicants shall determine the expected valve operating conditions through the use of analyses of accidents and anticipated operational occurrences referenced in Regulatory Guide 1.70 (Rev 2). The single failures applied to these analyses shall be chosen so that the dynamic forces on the safety and relief valves are maximized. Test pressures shall be the highest predicted by conventional safety analysis procedures. RCS relief and safety valve qualification shall include qualification of associated control circuitry, piping, and supports, as well as the valves themselves.

(1) Performance Testing of Relief and Safety Valves - The following information must be provided in report form:

(a) Evidence supported by test of safety and relief valve functionability for expected operating and accident (non-ATWS) conditions must be provided to NRC. The testing should demonstrate that the valves will open and reclose under the expected flow conditions.

(b) Since it is not planned to test all valves on all plants, each licensee must submit to NRC a correlation or other evidence to substantiate that the valves tested in the EPRI or other generic test program demonstrate the functionability of as-installed primary relief and safety valves. This correlation must show that the test conditions used are equivalent to expected operating and accident conditions as prescribed in the FSAR. The effect of as-built relief and safety valve discharge piping on valve operability must be accounted for, if it is different from the generic test loop piping.

(c) Test data including criteria for success and failure of valves tested must be provided for NRC staff review and evaluation. These test data should include data that would permit plant specific evaluation of discharge piping and supports that are not directly tested.

(2) Qualification of PWR block valves - Although not specifically listed as a short-term lessons learned requirement in NUREG-0578, qualification of PWR block valves is required by the NRC Task Action Plan NUREG-0660 under task Item II.D.1. It is the understanding of the NRC that testing of several commonly used block valve designs is already included in the generic EPRI PWR safety and relief valve testing program to be completed by July 1, 1981. By means of this letter, NRC is establishing July 1, 1982 as the date for verification of block valve functionability. By July 1, 1982, each PWR licensee, for plants so equipped, should provide evidence supported by test that the block or isolation valves between the pressurizer and each power-operated relief valve can be operated, closed, and opened for all fluid conditions expected under operating and accident conditions.

(3) ATWS Testing - Although ATWS testing need not be completed by July 1, 1981, the test facility should be designed to accommodate ATWS conditions of approximately 3200 to 3500 (Service Level C pressure limit) pounds per square inch and 700°F with sufficient capacity to enable testing of relief and safety valves of the size and type used on operating PWRs.

Response

The licensee participated in the BWROG program to test SRVs. The test program has been successfully completed and is described in Reference 1.13-8. The applicability of the test results to the LGS valves is described in appendix A of Reference 1.13-8.

An engineering evaluation was done to identify the expected operating conditions for SRVs during design basis transients and accidents. This evaluation identified one event for which testing was appropriate. This event, the alternate shutdown cooling mode, is an anticipated operating condition that has been considered in the design analysis (Section 5.4.7.5).

The test results documented in the topical report verify the adequacy of the LGS valve operation and integrity under the expected discharge conditions. The loads on the valve and piping induced by the liquid discharge were shown to be lower than the high pressure steam discharge loads for which the system is designed. The test results also provide flow capacity information to show that sufficient shutdown cooling flow is provided through one or two valves, dependent on reactor and system conditions. Clarification Items (2) and (3) are not applicable to BWRs.

- II.D.3 RELIEF AND SAFETY VALVE POSITION INDICATION

Position

RCS relief and safety valves shall be provided with a positive indication in the control room derived from a reliable valve position detection device or a reliable indication of flow in the discharge pipe.

Clarification

(1) The basic requirement is to provide the operator with unambiguous indications of valve position (open or closed) so that appropriate operator actions can be taken.

(2) The valve position should be indicated in the control room. An alarm should be provided in conjunction with this indication.

(3) The valve position indication may be safety-grade. If the position indication is not safety-grade, a reliable single channel direct indication, powered from a vital instrument bus, may be provided if backup methods of determining valve position are available and are discussed in the emergency procedures as an aid to operator diagnosis of an action.

(4) The valve position indication should be seismically qualified consistent with the component or system to which it is attached.

(5) The position indication should be qualified for its appropriate environment (any transient or accident which would cause the relief or safety valve to lift) and in accordance with Commission Order of May 23, 1980 (CLI-80-21).

(6) It is important that the displays and controls added to the control room as a result of this requirement not increase the potential for operator error. A human factor analysis should be performed taking into consideration:

    (a) the use of this information by an operator during both normal and abnormal plant conditions,

(b) integration into emergency procedures,

(c) integration into operator training, and

(d) other alarms during emergency and need for prioritization of alarms.

Response

An acoustic monitoring system that meets the requirements of NUREG-0737 and Regulatory Guide 1.97 is provided for LGS (Sections 7.6.1.5 and 7.6.2.5). The system is designed to the following general requirements:

a. A reliable, single channel, direct indication system is provided.

b. The individual valve position (OPEN/CLOSED) is displayed in the control room. In conjunction with this indication, a third indication signifies that the individual valve has been open. These lights are located above each SRV control switch. An alarm is provided in the control room to annunciate when any valve is open.

c. The position indications are powered from a highly reliable non-Class 1E power source (Section 8.3.1.1.1).

A diverse means of valve position indication as specified in the EOPs is provided by the redundant safety-grade suppression pool temperature monitoring system. This is powered from a Class 1E power source.

d) All valve position system components are seismically qualified except for the power supply.

e) All valve position system components located in a potentially harsh environment qualified for a LOCA environment.

f) A human factors analysis was performed to integrate this new information into the control room. The individual OPEN/CLOSED/WAS OPEN indication is located above the SRV control switch.

The WAS OPEN indication was added to aid the operator in determining which valve has opened when a relief valve instantaneously opens on high pressure and closes immediately. This indication is also used to aid the operator in sequencing the relief valves when the reactor is manually depressurized.

Additional human factors aspects were considered during the CRDR required by Item I.D.1.

- II.E.1.1 AUXILIARY FEEDWATER SYSTEM EVALUATION

Response

These requirements are not applicable to BWRs.

- II.E 1.2 AUXILIARY FEEDWATER SYSTEM INITIATION AND FLOW

Response

This requirement is not applicable to BWRs.

- II.E.3.1 EMERGENCY POWER FOR PRESSURIZER HEATERS

Position

Consistent with satisfying the requirements of GDC 10, 14, 15, 17, and 20 for the event of LOOP, the following positions shall be implemented.

(1) The pressurizer heater power supply design shall provide the capability to supply, from either the offsite power source or the emergency power source (when offsite power is not available), a predetermined number of pressurizer heaters and associated controls necessary to establish and maintain natural circulation at hot standby conditions. The required heaters and their controls shall be connected to the emergency buses in a manner that will provide redundant power supply capability.

(2) Procedures and training shall be established to make the operator aware of when and how the required pressurizer heaters shall be connected to the emergency buses. If required, the procedures shall identify under what conditions selected emergency loads can be shed from the emergency power source to provide sufficient capacity for the connection of the pressurizer heaters.

(3) The time required to accomplish the connection of the preselected pressurizer heater to the emergency buses shall be consistent with the timely initiation and maintenance of natural circulation conditions.

(4) Pressurizer heater motive and control power interfaces with the emergency buses shall be accomplished through devices that have been qualified in accordance with safety-grade requirements.

Clarification

(1) Redundant heater capacity must be provided, and each redundant heater or group of heaters should have access to only one Class 1E division power supply.

(2) The number of heaters required to have access to each emergency power source is that number required to maintain natural circulation in the hot standby condition.

(3) The power sources need not necessarily have the capacity to provide power to the heaters concurrently with the loads required for LOCA.

(4) Any changeover of the heaters from normal offsite power to emergency onsite power is to be accomplished manually in the control room.

(5) In establishing procedure to manually load the pressurizer heaters onto the emergency power sources, careful consideration must be given to:

(a) which ESF loads may be appropriately shed for a given situation;

(b) reset of the safety injection actuation signal to permit the operation of the heaters; and

(c) instrumentation and criteria for operator use to prevent overloading a diesel generator.

(6) The Class 1E interfaces for main power and control power are to be protected by safety-grade circuit breakers (see also Regulatory Guide 1.75).

(7) Being non-Class 1E loads, the pressurizer heaters must be automatically shed from the emergency power sources upon the occurrence of a safety injection actuation signal (see item 5.b, above).

Response

This requirement is applicable to PWRs only. Because the BWR operates in all modes with both liquid and steam in the RPV, saturation conditions are always maintained irrespective of system pressure. There is no need for emergency power to maintain natural circulation or to keep the system pressurized.

The LGS power-operated MSRVs can be actuated using emergency power and have no block valves. They are described in Section 5.2.2. They are nitrogen-operated valves, with their normal gas supply coming from the PCIG compressors, which are described in Section 9.3.1.3. Standby ac power is available to the PCIG compressors following a LOOP.

The MSRVs are provided with gas accumulators described in Section 5.2.2.4, for reliable short-term operation without PCIG system operation. A safety-grade gas bottle supply system, described in Section 9.3.1.3, is available for long-term MSRV operation.

Safety-grade reactor vessel level indication is provided in the control room in accordance with Regulatory Guide 1.97 (Rev 2). Additional information is provided in Section 7.5.

- II.E.4.1 DEDICATED HYDROGEN CONTROL PENETRATIONS

Position

Plants using external recombiners or purge systems for postaccident combustible gas control of the containment atmosphere should provide containment penetration systems for external recombiner or purge systems that are dedicated to that service only, that meet the redundancy and single failure requirements of GDC 54 and 56 and that are sized to satisfy the flow requirements of the recombiner or purge system.

The procedures for the use of combustible gas control systems following an accident that results in a degraded core and release of radioactivity to the containment must be reviewed and revised, if necessary.

Clarification

(1) An acceptable alternative to the dedicated penetration is a combined design that is single failure proof for containment isolation purposes and single failure proof for operation of the recombiner or purge system.

(2) The dedicated penetration or the combined single failure proof alternative shall be sized such that the flow requirements for the use of the recombiner or purge system are satisfied. The design shall be based on 10CFR50.44 requirements.

(3) Components furnished to satisfy this requirement shall be safety-grade.

(4) Licensees that rely on purge systems as the primary means for controlling combustible gases following a LOCA should be aware of the positions taken in Reference 1.13-9. This proposed rule, published in the Federal Register on October 2, 1980, would require plants that do not now have recombiners to have the capacity to install external recombiners by January 1, 1982. (Installed internal recombiners are an acceptable alternative to the above.)

(5) Containment atmosphere dilution systems are considered to be purge systems for the purpose of implementing the requirements of this TMI Task Action item.

Response

The containment hydrogen recombiner system, described in Sections 6.2.5 and 9.4.5, is used for postaccident combustible gas control. The recombiners are permanently installed external to the primary containment and are remotely operated from the control room. The design of the containment penetrations associated with the hydrogen recombiner system is single failure proof for containment isolation purposes during system operation and single failure proof for operation of the recombiner system.

LGS complies with each of the points of clarification as described below.

(1) The containment isolation arrangement uses a combined type of design which is single failure proof as permitted by this clarification item. The hydrogen recombiner supply and return lines connect to the high volume purge lines outside the primary containment. Each high volume purge line is provided with redundant, normally closed isolation valves installed in series outboard of the connection point with the hydrogen recombiner lines. This redundancy ensures that isolation of the high volume purge lines remains single failure proof during operation of the recombiners. Each supply and return line for the hydrogen recombiners is provided with two, normally closed containment isolation valves in series. Because two valves in series are provided, the failure of an isolation valve in the open position would not jeopardize containment integrity. The provision of two redundant hydrogen recombiner packages ensures that the recombination function can be performed in the event of a failure of an isolation valve in the closed position.

(2) The recombiner supply and return lines have been sized such that the flow requirements of the recombiners are satisfied for the full range of possible containment pressures that may exist during the time period when the recombiners are required to operate.

(3) As discussed in Section 9.4.5.1.3, the hydrogen recombiner packages, their associated piping, and the containment isolation provisions for the recombiner lines and the containment purge lines are designed as safety-related.

(4) LGS does not rely on a purge system as the primary means for controlling combustible gases following a LOCA.

(5) LGS does not use a containment air dilution system for combustion gas control.

- II.E.4.2 CONTAINMENT ISOLATION DEPENDABILITY

Position

(1) Containment isolation system designs shall comply with the recommendations of SRP Section 6.2.4 (i.e., that there be diversity in the parameters sensed for the initiation of containment isolation).

(2) All plant personnel shall give careful consideration to the definition of essential and nonessential systems, identify each system determined to be essential, identify each system determined to be nonessential, describe the basis for selection of each essential system, modify their containment isolation designs accordingly, and report the results of the reevaluation to the NRC.

(3) All nonessential systems shall be automatically isolated by the containment isolation signal.

(4) The design of control systems for automatic containment isolation valves shall be such that resetting the isolation signal will not result in the automatic reopening of containment isolation valves. Reopening of containment isolation valves shall require deliberate operator action.

(5) The containment setpoint pressure that initiates containment isolation for nonessential penetrations must be reduced to the minimum compatible with normal operating conditions.

(6) Containment purge valves that do not satisfy the operability criteria set forth in BTP CSB 6-4 or the Staff Interim Position of October 23, 1979 must be sealed closed as defined in SRP 6.2.4., item II.3.f during operational conditions 1, 2, 3, and 4. Furthermore, these valves must be verified to be closed at least every 31 days.

(7) Containment purge and vent isolation valves must close on a high radiation signal.

Clarification

(1) The reference to SRP 6.2.4 in position 1 is only to the diversity requirements set forth in that document.

(2) For postaccident situations, each nonessential penetration (except instrument lines) is required to have two isolation barriers in series that meet the requirements of GDC 54, 55, 56, and 57, as clarified by SRP Section 6.2.4. Isolation must be performed automatically

(i.e., no credit can be given for operator action). Manual valves must be sealed closed, as defined by SRP Section 6.2.4, to qualify as an isolation barrier. Each automatic isolation valve in a nonessential penetration must receive the diverse isolation signals.

(3) Regulatory Guide 1.141 (Rev 2) will contain guidance on the classification of essential versus nonessential systems and is due to be issued by June 1981. Requirements for operating plants to review their list of essential and nonessential systems will be issued in conjunction with this guide including an appropriate time schedule for completion.

(4) Administrative provisions to close all isolation valves manually before resetting the isolation signals is not an acceptable method of meeting position 4.

(5) Ganged reopening of containment isolation valves is not acceptable. Reopening of isolation valves must be performed on a valve-by-valve basis, or on a line-by-line basis, provided that electrical independence and other single failure criteria continue to be satisfied.

(6) The containment pressure history during normal operation should be used as a basis for arriving at an appropriate minimum pressure setpoint for initiating containment isolation. The pressure setpoint selected should be far enough above the maximum observed (or expected) pressure inside containment during normal operation so that inadvertent containment isolation does not occur during normal operation from instrument drift or fluctuations due to the accuracy of the pressure sensor. A margin of 1 psi above the maximum expected containment pressure should be adequate to account for instrument error. Any proposed values greater than 1 psi will require detailed justification. Applicants for an operating license and operating plant licensees that have operated less than one year should use pressure history data from similar plants that have operated more than one year, if possible, to arrive at a minimum containment setpoint pressure.

(7) Sealed closed purge isolation valves should be under administrative control to assure that they cannot be inadvertently opened. Administrative control includes mechanical devices to seal or lock the valve closed, or to prevent power from being supplied to the valve operator. Checking the valve position light in the control room is an adequate method for verifying every 24 hours that the purge valves are closed.

Response

A description of compliance with each Position and Clarification is provided below.

Position (1), Clarification (1)

The containment isolation system design has been reviewed for compliance with SRP 6.2.4 regarding diversity in the parameters sensed for the initiation of containment isolation. Section 6.2.4 and Table 6.2-17 identify all containment isolation signals provided. There are eleven valves classified as nonessential that do not receive diverse containment isolation signals.

Two valves on the feedwater lines (HV-109A, HV-109B) are normally closed and will be opened only for startup of the feedwater system before the control rods are withdrawn or when performing hydrostatic testing of the RPVs during unit shutdown.

The RCIC vacuum pump discharge line is provided with a stop-check valve (HV-F002) to prevent flow from the containment. A remote manually actuated motor operator ensures the long-term positive closure of the stop-check valve. This arrangement ensures that the essential RCIC pump-turbine will be ready to operate in the event of a reactor vessel isolation occurrence accompanied by loss of feedwater flow.

The recirculation pump cooling water supply and discharge isolation valves (HV-106, HV-107) and the drywell chilled water isolation valves (HV-122, HV-123, HV-128, HV-129) have provisions for remote manual isolation consistent with GDC 57. Closure of these isolation valves is undesirable unless the cooling water lines have failed.

The HPCI and RCIC steam supply line warmup valves (HV-F100, HV-F076, respectively) are provided with appropriate isolation signals to secure the line when system isolation is required. There is no adverse consequence associated with the valve opening or leaking while these systems are in operation.

The main steam drain line isolation valves (HV-F016, F019) are normally closed during power operation. They provide a path from the steam lines to the main condenser for removal of condensation during shutdown and startup periods and during periods of low load. The six automatic isolation signals provided for these valves are the same as those provided for the MSIVs.

The main steam and recirculation loop sample line isolation valves (HV-F084, F085 and HV-F019, F020, respectively) are typically open less than 1 hour per year during normal plant operations. The two isolation signals which are provided for these valves ensure their automatic closure before any fuel damage would occur for all anticipated periods of sample line use.

The RWCU supply line isolation valves (HV-F001, F004) are provided with the following signals to initiate automatic valve closure:

a. Reactor low water level

b. Line break in RWCU
   high flow
   heat exchanger high temperature
   compartment high temperature

c. SLCS operation

These isolation signals are provided to protect the core in case of a possible break in the RWCU, to protect the ion exchange resin from damage due to high temperature, and to prevent the removal of boron by the ion exchange resin.

The RWCU system is described in Section 5.4.8. Closing times of the RWCU isolation valves have been chosen to prevent the reactor vessel water level from falling below the top of active fuel if a break were to occur in any of the RWCU lines. Diverse isolation signals are supplied to isolate the RWCU in the unlikely event of such a line break. The system is intentionally left in service whenever the above isolation signals are not activated to provide continuous purification of a portion of the recirculation flow.

Position (2), Clarification (3)

All systems penetrating containment have been evaluated and identified as either essential or nonessential. Table 6.2-17 provides the results of this evaluation for each line, and Table 6.2-27 provides the basis for the selection of essential/nonessential systems.

Position (3), Clarification (2)

Systems determined to be nonessential are provided with diverse, automatic isolation signals, except as described in the response to Position (1). Manual valves are sealed closed as discussed in Section 6.2.4.3.

Position (4), Clarifications (4), (5)

The control systems for automatic isolation valves are such that resetting the isolation signal will not result in the automatic reopening of these valves. The HPCI and RCIC steam line isolation valves are exceptions as discussed in Section 7.1.2.11. Ganged reopening of containment isolation valves is performed only where the operation of multiple valves is required for system operation. Sample inlet and return valve controls for the drywell radiation monitors and combustible gas analyzers are ganged as described in Sections 6.2.4.3.1.3.2.8 and 6.2.4.3.1.3.2.1. RECW and drywell chilled water valve controls are ganged as described in Sections 6.2.4.3.1.3.2.10 and 6.2.4.3.1.3.2.11.

Position (5), Clarification (6)

The setpoint for the drywell high pressure isolation signal is set at the minimum compatible with normal operation. Section 7.3.1.1.2.4.6 describes the selection of the drywell high pressure setpoint.

Position (6), Clarification (7)

Containment purge valves comply with BTP CSB 6-4 as discussed below and in Sections 9.4.5.1. Two purge isolation valves have closure times greater than 6 seconds (2"-HV-105 and 2"-HV-111 have closure times of 15 seconds). An analysis of the radiological consequences of a LOCA that occurs during purging was performed to justify the line size and the valve closure time used in the purge system. Using the assumptions of BTP CSB 6-4, the resulting doses were a small fraction of the 10CFR100 limits. For local leak rate tests, the leakage rate of the purge isolation valves, combined with the leakage rate for all other penetrations and valves subject to Type B and C tests will be less than 0.60 La, in accordance with 10CFR50, Appendix J.

Position (7)

The containment purge isolation valves isolate on receipt of any one of the following safety-related isolation signals:

a. high drywell pressure

b. reactor low water level

c. reactor enclosure high radiation

d. refueling floor high radiation

In addition to the safety-related isolation signals listed above, the containment purge and vent isolation valves (HV-114, 115, 104, 112, 123, 124, 135, 147, 121, 131, 109) will isolate on receipt of a nonsafety-related north stack effluent high radiation signal (Sections 6.2.4.3 and 11.5).

The setpoint of the isolation signal (approximately 4 μCi/cc) has been selected to ensure valve closure before offsite doses exceed EPA Protective Action Guide Level 2 limits (1 rem whole body/5 rem thyroid). Containment purging will not be undertaken during periods of power operation when this monitor is out of service unless a temporary replacement of equivalent sensitivity is used. Provisions are included in the Technical Specifications for periodic instrument calibrations and channel checks.

An analysis has been performed to demonstrate that the offsite doses that might result if a LOCA were to occur during purging operations would be less than both 10CFR100 and EPA Protection Action Guide limits. This analysis used the assumptions of SRP Section 6.2.4 and BTP CSB 6-4 and assumes a pre-existing spike that results in coolant activity levels in excess of Technical Specification limits. The analysis methodology was in accordance with Reference 1.13-10.

- II.F.1 ACCIDENT MONITORING INSTRUMENTATION

ATTACHMENT 1, Noble Gas Effluent Monitor

Position

The requirements associated with this recommendation should be considered as advanced implementation of certain requirements to be included in a revision to Regulatory Guide 1.97, "Instrumentation to Follow the Course of an Accident," which has already been initiated, and in other Regulatory Guides, which will be promulgated in the near-term.

Noble gas effluent monitors shall be installed with an extended range designed to function during accident conditions as well as during normal operating conditions. Multiple monitors are considered necessary to cover the ranges of interest.

(1) Noble gas effluent monitors with an upper range capacity of 10^5 μCi/cc (Xe-133) are considered to be practical and should be installed in all operating plants.

(2) Noble gas effluent monitoring shall be provided for the total range of concentration extending from normal condition (ALARA) concentrations to a maximum of 10^5 μ/Ci/cc (Xe-133). Multiple monitors are considered to be necessary to cover the ranges of interest. The range capacity of individual monitors should overlap by a factor of 10.

It is important that the displays and controls added to the control room as a result of this requirement not increase the potential for operator error. A human factor analysis should be performed taking into consideration:

(1) The use of this information by an operator during both normal and abnormal plant conditions;

(2) Integration into emergency procedures;

(3) Integration into operator training; and

(4) Other alarms during emergency and need for prioritization of alarms.

Clarification

NUREG-0578, section 2.1.8b provided the basic requirements for this item. Letters dated September 27, 1979 and November 9, 1979, provided clarification and NUREG-0660, Item II.F.1 provided the action plan for additional accident monitoring instrumentation by noble gas effluent radiological monitor requirements. Additional clarification was provided by letters dated September 5, 1980 and October 31, 1980.

By summary clarification, the following guidelines were established:

(1) Applicants shall provide continuous monitoring of high level postaccident releases of radioactive noble gases from the plant. Gaseous effluent monitors shall meet requirements specified in Table 1.13-8. Typical plant effluent pathways to be monitored are also given in the table.

(2) The monitors shall be capable of functioning both during and following an accident. System designs shall accommodate a design basis release and then be capable of following decreasing concentrations of noble gases.

(3) Offline monitors are not required for the PWR secondary side main steam safety valve and dump valve discharge lines. For this application, externally mounted monitors viewing the main steam line upstream of the valves are acceptable with procedures to correct for the low energy gammas the external monitors would not detect. Isotopic identification is not required.

(4) Instrumentation ranges shall overlap to cover the entire range of effluents from normal (ALARA) through accident conditions. The design description shall include the following:

(a) System description, including:

i. instrumentation to be used, including range or sensitivity, energy dependence or response, calibration frequency and technique, and vendor's model number, if applicable;

ii. monitoring locations (or points of sampling), including description of methods used to assure representative measurements and background correction;

iii. location of instrument readout(s) and method of recording, including description of the method or procedure for transmitting or disseminating the information or data;

iv. assurance of the capability to obtain readings at least every 15 minutes during and following an accident; and

v. the source of power to be used.

(b) Description of procedures or calculational methods to be used for converting instrument readings to release rates per unit time, based on exhaust air flow and considering radionuclide spectrum distribution as a function of time after shutdown.

(5) Applicants should have available for review the final design description of the as-built system, including piping and instrument diagrams together with either (a) a description of procedures for system operation and calibration, or (b) copies of procedures for system operation and calibration. Changes to technical specifications will be required. Applicants will submit the above details in accordance with the proposed review schedule, but in no case less than 4 months prior to the issuance of an operating license. A postimplementation review will be performed.

The design description shall include the information provided in Table 1.13-8.

Until final implementation on January 1, 1982, all operating reactors must provide an interim method for quantifying high level releases which meet the requirements of the Table 1.13-8. This method is to serve only as a provisional fix until the accident monitoring instrumentation is installed, calibrated, tested and approved by January 1, 1982. Methods are to be developed to quantify release rates up to 10,000 Ci/sec for noble gases from all potential release points and any other areas that communicate directly with systems which may contain primary coolant or containment gases. Measurements/analysis capabilities of the effluents at the final release point (e.g., stack) should be such

that measurements of individual sources which contribute to the common release point may not be necessary. For noble gases, an acceptable method of meeting the intent of this requirement is to modify the existing monitoring system, such that portable high range survey instruments set in shielded collimators "see" small sections of the sampling lines. The applicant shall provide the following information on its method to quantify gaseous releases of radioactivity from the plant during an accident.

(a) An interim system/method description for noble gas effluents, including:

i. Instrumentation to be used including range or sensitivity, energy dependence, and calibration frequency and technique;

ii. monitoring/sampling locations, including methods to assure representative measurements and background radiation correction;

iii. a description of method to be employed to facilitate access to radiation readings. For January 1, 1981, control room readout is preferred; however, if impractical, in situ readings by an individual with verbal communication with the control room is acceptable based on (iv), below;

iv. capability to obtain radiation readings at least every 15 minutes during an accident; and

v. source of power to be used. If normal alternating current power is used, an alternate backup power supply should be provided. If direct current power is used, the source should be capable of providing continuous readout for 7 consecutive days.

(b) Procedures for conducting all aspects of the measurement/analysis, including:

i. procedures for minimizing occupational exposures;

ii. calculational methods for converting instrument readings to release rates based on exhaust air flow and taking into consideration radionuclide spectrum distribution as function of time after shutdown;

iii. procedures for dissemination of information; and

iv. procedures for calibration.

Response

All reactor enclosure stack releases following an accident will be through the north stack. The wide range accident monitoring subsystem of the north stack effluent monitoring system provides continuous monitoring of postaccident releases of noble gases in accordance with the requirements of Table 1.13-8. The system is described in Sections 7.6 and 11.5.2.2.1, and its piping and instrumentation diagram is provided in drawing M-26. Control room displays provided for this system meet the requirements of Regulatory Guide 1.97 (Rev 2), and are described in Section 7.5. Table 1.13-9 outlines the requirements for an interim method for quantifying releases to be used by operating reactors and therefore is not applicable to LGS. Human factors aspects of TMI Item II.F.1 are considered part of the CRDR required by Item I.D.1.

ATTACHMENT 2, Sampling and Analysis of Plant Effluents

Position

The requirements associated with this recommendation should be considered as advanced implementation of certain requirements to be included in a revision to Regulatory Guide 1.97, "Instrumentation to Follow the Course of an Accident," which has already been initiated, and in other regulatory guides, which will be promulgated in the near-term.

Because iodine gaseous effluent monitors for the accident condition are not considered to be practical at this time, capability for effluent monitoring of radioiodines for the accident condition shall be provided with sampling conducted by adsorption on charcoal or other media, followed by onsite laboratory analysis.

It is important that the displays and controls added to the control room as a result of this requirement not increase the potential for operator error. A human factor analysis should be performed taking into consideration:

(1) The use of this information by an operator during both normal and abnormal plant conditions;

(2) Integration into emergency procedures;

(3) Integration into operator training; and

(4) Other alarms during emergency and need for prioritization of alarms.

Clarification

NUREG-0578, section 3.1.8b provided the basic requirements for this item. Letters dated September 27, 1979 and November 9, 1979, provided clarification, however, NUREG-0660 inadvertently omitted this requirement on the action plan for additional accident monitoring instrumentation by sampling and analysis of plant effluents. Additional clarification was provided by letters dated September 5, 1980 and October 31, 1980.

By summary clarification, the following guidelines were established:

(1) Applicants shall provide continuous sampling of plant gaseous effluent for postaccident releases of radioactive iodines and particulates to meet the requirements of Table 1.13-10. Applicants shall also provide onsite laboratory capabilities to analyze or measure these samples. This requirement should not be construed to prohibit design and development of radioiodine and particulate monitors to provide online sampling and analysis for the accident condition. If gross gamma radiation measurement techniques are used, then provisions shall be made to minimize noble gas interference.

(2) The shielding design basis is given in Table 1.13-10. The sampling system design shall be such that plant personnel could remove samples, replace sampling media and transport the samples to the onsite analysis facility with radiation exposures that are not in excess of GDC 19 of 5 rem whole body exposure and 75 rem to the extremities during the duration of the accident.

(3) The design of the systems for the sampling of particulates and iodines should provide for sample nozzle entry velocities which are approximately isokinetic (same velocity) with expected induct or instack air velocities. For accident conditions, sampling may be complicated by a reduction in stack or vent effluent velocities to below design levels, making it necessary to substantially reduce sampler intake flow rates to achieve the isokinetic condition. Reductions in air flow may well be beyond the capability of available sampler flow controllers to maintain isokinetic conditions; therefore, the staff will accept flow control devices which have the capability of maintaining isokinetic conditions with variations in stack or duct design flow velocity of ±20%. Further departure from the isokinetic condition need not be considered in design. Corrections for an isokinetic sampling conditions, as provided in Appendix C of ANSI 13.1 (1969) may be considered on an ad hoc basis.

(4) Effluent streams which may contain air with entrained water (e.g., air ejector discharge) shall have provisions to ensure that the adsorber is not degraded while providing a representative sample (e.g., heaters).

(5) License applicants should have available for review the final design description of the as-built system, including P&IDs together with either (a) a description of procedures for system operation and calibration, or (b) copies of procedures for system operation and

calibration. Changes to technical specifications will be required. Applicants will submit the above details in accordance with proposed review schedule, but in no case less than 4 months prior to the issuance of an operating license. A postimplementation review will be performed.

Response

Sampling of plant gaseous effluents for postaccident releases of iodines and particulates is provided as part of the wide range accident monitoring subsystem of the north stack effluent radiation monitoring system described in Sections 7.6 and 11.5.2.2.1. The design of onsite laboratory facilities for analysis of these samples is described in Chapter 12. The design of the sampling media and sampling considerations are in conformance with Table 1.13-10. Human factors aspects of TMI Item II.F.1 are considered part of the CRDR required by Item I.D.1.

ATTACHMENT 3, Containment High Range Radiation Monitor

Position

In containment radiation level monitors with a maximum range of 10^8 rad/hr shall be installed. A minimum of two such monitors that are physically separated shall be provided. Monitors shall be developed and qualified to function in an accident environment.

Clarification

(1) Provide two radiation monitor systems in containment which are documented to meet the requirements of Table 1.13-11.

(2) The specification of 10^8 rad/hr in the above position was based on a calculation of postaccident containment radiation levels that include both particulate (beta) and photon (gamma) radiation. A radiation detector that responds to both beta and gamma radiation cannot be qualified to post-LOCA containment environments but gamma-sensitive instruments can be so qualified. In order to follow the course of an accident, a containment monitor that measures only gamma radiation is adequate. The requirement was revised in the October 30, 1979 letter to provide for a photon-only measurement with an upper range of 10^7 R/hr.

(3) The monitors shall be located in containment(s) in a manner as to provide a reasonable assessment of area radiation conditions inside containment. The monitors shall be widely separated so as to provide independent measurements and shall "view" a large fraction of the containment volume. Monitors should not be placed in areas which are protected by massive shielding and should be reasonably accessible for replacement, maintenance, or calibration. Placement high in a reactor building dome is not recommended because of potential maintenance difficulties.

(4) For BWR Mark III containments, two such monitoring systems should be inside both the primary containment (drywell) and the secondary containment.

(5) The monitors are required to respond to gamma photons with energies as low as 60 keV and to provide an essentially flat response for gamma energies between 100 keV and 3 MeV, as specified in Table 1.13-11. Monitors that use thick shielding to increase the

upper range will underestimate postaccident radiation levels in containment by several orders of magnitude because of their insensitivity to low energy gamma and are not acceptable.

Response

The primary containment post-LOCA radiation monitors described in Sections 7.1, 7.6.1, and 11.5.2.3.1 have a maximum range of 1 rad/hr to 10^8 rad/hr and are physically separated. They are designed and qualified to function in an accident environment.

Section 11.5.2.3.1 describes the degree of conformance with Item II.F.1 Attachment 3 and Table 1.13-11. Additional human factors aspects were considered during CRDR required by Item I.D.1.

ATTACHMENT 4, Containment Pressure Monitor

Position

A continuous indication of containment pressure shall be provided in the control room of each operating reactor. Measurement and indication capability shall include three times the design pressure of the containment for concrete, four times the design pressure for steel, and -5 psig for all containments.

Clarification

(1) Design and qualification criteria are outlined in Appendix B of NUREG-0737.

(2) Measurement and indication capability shall extend to 5 pounds per square inch absolute for subatmospheric containments.

(3) Two or more instruments may be used to meet requirements. However, instruments that need to be switched from one scale to another scale to meet the range requirements are not acceptable.

(4) Continuous display and recording of the containment pressure over the specified range in the control room is required.

(5) The accuracy and response time specifications of the pressure monitor shall be provided and justified to be adequate for their intended function.

Response

The containment pressure instrumentation is described in Section 7.5.1. The design and qualification of the instrumentation meets the guidelines of Regulatory Guide 1.97 (Rev 2) and Appendix B of NUREG-0737. The accuracy and maximum response time for the complete recording and indicating monitors conforms to the requirements of ANS 4.5 (1980) paragraphs 6.3.4 and 6.3.5, which is the referenced document of Regulatory Guide 1.97. Additional human factors aspects were considered during CRDR required by Item I.D.1.

ATTACHMENT 5, Containment Water Level Monitor

Position

A continuous indication of containment water level shall be provided in the control room for all plants. A narrow range instrument shall be provided for PWRs and cover the range from the bottom to the top of the containment sump. A wide range instrument shall also be provided for BWRs and shall cover the range from the bottom of the containment to the elevation equivalent to a 600,000 gallon capacity. For BWRs, a wide range instrument shall be provided and cover the range from the bottom to 5 feet above the normal water level of the suppression pool.

Clarification

(1) The containment wide range water level indication channels shall meet the design and qualification criteria as outlined in Appendices B and C. The narrow range channel shall meet the requirements of Regulatory Guide 1.89.

(2) The measurement capability of 600,000 gallons is based on recent plant designs. For older plants with smaller water capacities, licensees may propose deviations from this requirement based on the available water supply capability at their plant.

(3) Narrow range water level monitors are required for all sizes of sumps but are not required in those plants that do not contain sumps inside the containment.

(4) For BWR pressure-suppression containments, the ECCS suction line inlets may be used as a starting reference point for the narrow range and wide range water level monitors, instead of the bottom of the suppression pool.

(5) The accuracy requirements of the water level monitors shall be provided and justified to be adequate for their intended function.

Response

The existing suppression pool water level instrumentation and the compliance with the above position is described in Section 7.5.1 and meets the requirements of Regulatory Guide 1.97 (Rev 2). Additional human factors aspects were considered during CRDR required by Item I.D.1.

ATTACHMENT 6, Containment Hydrogen Monitor

Position

A continuous indication of hydrogen concentration in the containment atmosphere shall be provided in the control room. Measurement capability shall be provided over the range of 0% to 10% hydrogen concentration under both positive and negative ambient pressure.

Clarification

(1) Design and qualification criteria are outlined in Appendix B.

(2) The continuous indication of hydrogen concentration is not required during normal operation. If an indication is not available at all times, continuous indication and recording shall be functioning within 30 minutes of the initiation of safety injection.

(3) The accuracy and placement of the hydrogen monitors shall be provided and justified to be adequate for their intended function.

Response

The existing hydrogen instrumentation and the compliance with the above position is described in Section 7.5.1 and meets the requirements of Regulatory Guide 1.97 (Rev 2). Additional human factors aspects were considered during CRDR required by Item I.D.1.

For Limerick Generating Station, continuous indication and recording will be functioning within 90 minutes of the initiation of safety injection. The basis for this 60 minute extension, is as follows: (1) information provided by the monitors is not immediately required following LOCA, as referenced in the Limerick Hydrogen and Oxygen Generation Analysis, Section 6.2.5.3 of the UFSAR. (2) it is appropriate to delay actions necessary to initiate hydrogen and oxygen monitoring until the immediate actions required of the operating crew, to assure that safety systems are functioning properly and critical safety functions are being accomplished, are complete. This is due to the relative safety significance of ensuring critical safety functions are being accomplished in the initial stages of the accident.

The hydrogen monitors have been downgraded to non-safety related as described in NRC Letter to Exelon Nuclear, Subject: "Limerick Generating Station, Units 1 and 2 Issuance of Amendment Re: Elimination of Requirements for Hydrogen Recombiners and Hydrogen/Oxygen Monitors (TAC Nos. MC2741 and MC2742)," dated 04/13/05. With the elimination of the Design Basis LOCA hydrogen release, hydrogen monitors are no longer required to mitigate DBAs and, therefore, do not meet the definition of safety related. However, because hydrogen monitors are required to diagnose the course of beyond DBAs, each licensee should verify that it has made a regulatory commitment to maintain a hydrogen monitoring system capable of diagnosing beyond DBAs.

The 0% - 10% hydrogen concentration range is discussed in NUREG-0737, from which the Attachment 6, Position and Clarification was obtained. See NUREG-0737 11.F 1, Attachment 6 for more information.

Measurement capability over the range of 0% to 10% hydrogen concentration is acceptable as the High Hydrogen Alarm setpoint (4%) falls within this range. Figures 6.2-42/43 show that the Drywell Hydrogen concentration will only exceed 10%, at least 8 days after a LOCA, with no hydrogen control. With recombiner operation at 150 scfm or a 150 scfm purge, hydrogen levels in the drywell will not exceed 4%. Figures 6.2-42/43 show that the Suppression Pool Hydrogen concentration will not exceed 4% for at least 30 days after a LOCA.

- II.F.2 INSTRUMENTATION FOR DETECTION OF INADEQUATE CORE COOLING

Position

Licensees shall provide a description of any additional instrumentation or controls (primary or backup) proposed for the plant to supplement existing instrumentation (including primary coolant saturation monitors) in order to provide an unambiguous, easy-to-interpret indication of ICC. A description of the functional design requirements for the system shall also be included. A description of the procedures to be used with the proposed equipment, the analysis used in developing these procedures, and a schedule for installing the equipment shall be provided.

Clarification

(1) Design of new instrumentation should provide an unambiguous indication of ICC. This may require new measurements or a synthesis of existing measurements which meet design criteria (item 7).

(2) The evaluation is to include reactor water level indication.

(3) Licensees and applicants are required to provide the necessary design analysis to support the proposed final instrumentation system for ICC and to evaluate the merits of various instruments to monitor water level and to monitor other parameters indicative of core cooling conditions.

(4) The indication of ICC must be unambiguous in that it should have the following properties:

(a) It must indicate the existence of ICC caused by various phenomena (i.e., high void fraction-pumped flow as well as stagnant boil-off); and

(b) It must not erroneously indicate ICC because of the presence of an unrelated phenomenon.

(5) The indication must give advanced warning of the approach of ICC.

(6) The indication must cover the full range from normal operation to complete core uncovery. For example, water level instrumentation may be chosen to provide advanced warning of two-phase level drop to the top of the core and could be supplemented by other indicators such as incore and core-exit thermocouples provided that the indicated temperatures can be correlated to provide indication of the existence of ICC and to infer the extent of core uncovery. Alternatively, full range level instrumentation to the bottom of the core may be employed in conjunction with other diverse indicators such as core-exit thermocouples to preclude misinterpretation due to any inherent deficiencies or inaccuracies in the measurement system selected.

(7) All instrumentation in the final ICC system must be evaluated for conformance to Appendix B of NUREG-0737, "Clarification of TMI Action Plan Requirements," as clarified or modified by the provisions of items 8 and 9 that follow. This is a new requirement.

(8) If a computer is provided to process liquid level signals for display, seismic qualification is not required for the computer and associated hardware beyond the isolator or input buffer at a location accessible for maintenance following an accident. The single failure criteria of item 2, Appendix B, need not apply to the channel beyond the isolation device if it is designed to provide 99% availability with respect to functional capability for liquid level display. The display and associated hardware beyond the isolation device need not be Class 1E, but should be energized from a high reliability power source which is battery backed. The quality assurance provisions cited in Appendix B, item 5, need not apply to this portion of the instrumentation system. This is a new requirement.

(9) Incore thermocouples located at the core-exit or at discrete axial levels of the ICC monitoring system and which are part of the monitoring system should be evaluated for conformity with Attachment 1, "Design and Qualification Criteria for PWR Incore Thermocouples," which is a new requirement.

(10) The types and locations of displays and alarms should be determined by performing a human factors analysis taking into consideration:

(a) the use of this information by an operator during both normal and abnormal plant conditions,

(b) integration into emergency procedures,

(c) integration into operator training, and

(d) other alarms during emergency and need for prioritization of alarms.

Response

The design of LGS does not include the use of incore thermocouples for detection of ICC. The licensee endorses the position of the BWROG that there is no technical basis for requiring incore thermocouples in addition to the existing reactor water level instrumentation. A justification of the adequacy of the existing instrumentation to detect conditions of ICC is provided in section 2.3 of NEDO-24708A. Reactor water level instrumentation which is used to monitor ICC is described and reviewed for conformance to Regulatory Guide 1.97 (Rev 2) in Section 7.5.

- II.G.1 POWER SUPPLIES FOR PRESSURIZER RELIEF VALVES, BLOCK VALVES AND LEVEL INDICATORS

Position

Consistent with satisfying the requirements of GDC 10, 14, 15, 17, and 20 for the event of LOOP, the following positions shall be implemented:

Power supply for pressurizer relief and block valves and pressurizer level indicators -

(1) Motive and control components of the power-operated relief valves shall be capable of being supplied from either the offsite power source or the emergency power source when the offsite power is not available.

(2) Motive and control components associated with the power-operated relief and block valves shall be capable of being supplied from either the offsite power source or the emergency power source when the offsite power is not available.

(3) Motive and control power connections to emergency buses for the power-operated relief valves and their associated block valves shall be through devices that have been qualified in accordance with safety-grade requirements.

(4) The pressurizer level indication instrument channels shall be powered from the vital instrument buses. The buses shall have the capability of being supplied from either the offsite power source or the emergency power source when offsite power is not available.

Clarification

(1) Although the primary concern resulting from lessons learned from the accident at TMI is that the power-operated relief and block valves must be closable, the design should retain, to the extent practical, the capability to also open these valves.

(2) The motive and control power for the block valve should be supplied from an emergency power bus different from the source supplying the power-operated relief valves.

(3) Any changeover of the power-operated relief and block valve motive and control power from the normal offsite power to the emergency onsite power is to be accomplished manually in the control room.

(4) For those designs in which instrument air is needed for operation, the electrical power supply should be required to have the capability to be manually connected to the emergency power sources.

Response

BWRs do not have pressurizer equipment. However, the LGS power-operated MSRVs can be actuated using emergency power and there are no block valves. They are described in Section 5.2.2. The relief valves are nitrogen-operated valves with their normal gas supply coming from the PCIG compressors which are described in Section 9.3.1.3. Standby ac power is available to the PCIG compressors following a LOOP.

The MSRVs are provided with gas accumulators described in Section 5.2.2.4 for reliable short-term operation without PCIG system operation. A safety-grade, gas supply system, described in Section 9.3.1.3, for long-term operation of the MSRVs is used for the ADS.

- II.K.1 IE BULLETINS ON MEASURES TO MITIGATE SMALL BREAK LOCAs AND LOSS OF FEEDWATER ACCIDENTS

- II.K.1.5 ASSURANCE OF PROPER ENGINEERED SAFETY FEATURES FUNCTIONING

Position

Review all safety-related valve positions, positioning requirements, and positive controls to assure that valves remain positioned (open or closed) in a manner to ensure the proper operation of engineered safety features. Also, review related procedures, such as those for maintenance, testing, plant and system startup, and supervisory periodic (e.g., daily/shift checks) surveillance to ensure that such valves are returned to their correct positions following necessary manipulations and are maintained in their proper positions during operational modes.

Response

Valve positioning requirements, positive controls, and test and maintenance procedures associated with ESF systems are addressed in station administrative procedures which have been generated based on the requirements of IE Bulletin 79-08 Item 6. MOVs in safety-related systems are normally maintained in a configuration such as to require the least number of valve automatic movements upon system actuation. The position of manual ECCS valves considered vital to system operability is controlled by the use and documentation of either locks, checklists, or independent verification. Surveillance test procedures for ESF systems include return-to-normal

steps or checklists to ensure that the system is returned to service. Prior to fuel load, all ESF systems were confirmed to be aligned in accordance with approved checklists.

- II.K.1.10 REVIEW AND MODIFY, AS REQUIRED, PROCEDURES FOR REMOVING SAFETY-RELATED SYSTEMS FROM SERVICE (AND RESTORING TO SERVICE) TO ASSURE OPERABILITY STATUS IS KNOWN

Position

Review and modify, as required, procedures for removing safety-related systems from service (and restoring to service) to assure operability status is known.

Response

An administrative procedure addressing the release from service and the return to service of safety-related equipment has been written to address the requirements of IE Bulletin 79-08 Item 8. This procedure, and surveillance test procedures, provide controls to ensure that the status of safety-related system operability is known prior to removal from service and return to service.

- II.K.1.17 TRIP PRESSURIZER LEVEL BISTABLE SO THAT LOW PRESSURE (RATHER THAN PRESSURIZER LOW PRESSURE AND PRESSURIZER LOW LEVEL COINDICENCE) WILL INITIATE SAFETY INJECTION

Position

Trip pressurizer level bistable so that low pressure (rather than pressurizer low pressure and pressurizer low level coincidence) will initiate safety injection.

Response

This requirement is not applicable to LGS which has GE-designed reactors.

- II.K.1.20 PROVIDE PROCEDURES AND TRAINING TO OPERATORS FOR PROMPT MANUAL REACTOR TRIP FOR LOSS OF FEEDWATER, TURBINE TRIP, MAIN STEAM LINE ISOLATION VALVE CLOSURE, LOSS OF OFFSITE POWER, LOSS OF STEAM GENERATOR LEVEL, AND LOW PRESSURIZER LEVEL

Position

Provide procedures and training to operators for prompt manual reactor trip for loss of feedwater, turbine trip, MSIV closure, LOOP, loss of steam generator level, and low pressurizer level.

Response

This requirement is not applicable to LGS.

- II.K.1.21 PROVIDE AUTOMATIC SAFETY-GRADE ANTICIPATORY REACTOR TRIP FOR LOSS OF FEEDWATER, TURBINE TRIP, OR SIGNIFICANT DECREASE IN STEAM GENERATOR LEVEL

Position

Provide automatic safety-grade anticipatory reactor trip for loss of feedwater, turbine trip, or significant decrease in steam generator level.

Response

This requirement is not applicable to LGS.

- II.K.1.22 PROPER FUNCTIONING OF HEAT REMOVAL SYSTEMS

Position

Describe the actions, both automatic and manual, necessary for proper functioning of the auxiliary heat removal systems (e.g., RCIC) that are used when the main feedwater system is not operable. For any manual action necessary, describe in summary form the procedure by which this action is taken in a timely sense.

Response

See Section 5.4.6 and 5.4.7 for discussion of the automatic and manual actions necessary for the proper functioning of heat removal systems when the main feedwater system is not available.

- II.K.1.23 DESCRIBE ALL USES AND TYPES OF REACTOR VESSEL LEVEL INDICATION FOR BOTH AUTOMATIC AND MANUAL INITIATION OF SAFETY SYSTEMS. DESCRIBE OTHER INSTRUMENTATION THAT MIGHT GIVE THE OPERATOR THE SAME INFORMATION ON PLANT STATUS

Position

Describe all uses and types of reactor vessel level indication for both automatic and manual initiation of safety systems. Describe other instrumentation that might give the operator the same information on plant status.

Response

Water level indication and measurement is discussed in Sections 7.2, 7.3, 7.5 and 7.7 and shown in drawing M-42 and Figure 7.7-1.

Automatic initiation of safety systems based on reactor water level is accomplished by the following instrument configurations:

1. RPS - Control rod scram is accomplished by four analog loops arranged in a one-out-of-two-twice logic such that the failure of any one switch or of any one set

of sensing lines will not defeat the safety action. This scheme uses four condensing chamber reference legs and two variable leg sensing lines.

2. PCRVICS - Group I Isolation is accomplished by four analog loops arranged in a one-out-of-two-twice logic such that the failure of any one switch or of any one set of sensing lines will not defeat the safety action. This scheme uses four condensing chamber reference legs and four variable leg sensing lines.

3. ECCS - Initiation of ADS, HPCI, LPCI, Core Spray and diesel generator start is accomplished by four analog loops arranged in a one-out-of-two-twice logic for each of the initiation trip units such that the failure of any one switch or any one set of sensing line will not defeat the safety action. This scheme uses the same sensing lines discussed in the PCRVICS above.

4. ATWS - Initiation of the ATWS functions is accomplished by four analog loops arranged in a one-out-of-two-twice logic such that failure of one switch or set of sensing lines will not defeat the safety action. This scheme uses two condensing chamber reference legs and two variable leg sensing lines. These are different variable lines from those used for the RPS.

   Manual initiation of the safety system based on water level may also be accomplished by use of the following indications: (note: all of the reactor water level instruments in this control room have a common reference zero.)

   a. Three narrow range level indicators and one wide range indicator are installed on the reactor console. The narrow range instruments also feed a signal to a recorder on the reactor console. This scheme employs three condensing chamber reference legs and two variable leg sensing lines. The wide range indicator scheme employs a separate condensing chamber reference leg and variable leg sensing line.

   b. Two postaccident range level indications, in response to Regulatory Guide 1.97, are installed on the ECCS panel. Each indication consist of overlapping wide range and fuel zone indicators. These schemes used two condensing chamber reference legs and four variable leg sensing lines.

   c. This indication is supplemented by the single channel upset range on the reactor panel and shutdown range on the recirculation and RWCU panel. Both of these schemes use the same condensing chamber reference leg and variable leg sensing line.

   d. In addition, all of these indications are fed into the ERFDS (SPDS) computer for display in a temperature compensated reactor water level display.

These instruments are augmented by the other parameters required by Regulatory Guide 1.97 (Rev 2) in the control room. These instruments are addressed in the EOPs to be used by the operator to assess plant conditions. The above water level and supplemental instrumentation was subjected to a human factors review and emergency procedure walk-through prior to fuel load.

- II.K.2 <u>COMMISSION ORDERS ON BABCOCK & WILCOX PLANTS</u>

Response

These requirements are not applicable to LGS.

- II.K.3 FINAL RECOMMENDATIONS OF B&O TASK FORCE

- II.K.3.1 INSTALLATION AND TESTING OF AUTOMATIC PORV ISOLATION SYSTEM

This section is not applicable to LGS.

- II.K.3.2 REPORT ON OVERALL SAFETY EFFECT OF PORV ISOLATION SYSTEM

This section is not applicable to LGS.

- II.K.3.3 FAILURE OF PORV OR SAFETY VALVE TO CLOSE

Position

Assure that any failure of a power-operated relief valve or safety valve to close will be reported to the NRC promptly. All challenges to the power-operated relief valves or safety valves should be documented in the annual report. This requirement is to be met before fuel load.

Response

Procedures for prompt notification of NRC include any failure of a SRV to close as one of the events requiring the shift manager to expeditiously notify the NRC.

- II.K.3.5 AUTOMATIC TRIP OF REACTOR COOLANT PUMPS DURING LOCA

This section is not applicable to LGS.

- II.K.3.7 EVALUATION OF PORV OPENING PROBABILITY DURING OVERPRESSURE TRANSIENT

This section is not applicable to LGS.

- II.K.3.9 PROPORTIONAL INTEGRAL DERIVATIVE CONTROLLER MODIFICATION

This section is not applicable to LGS.

- II.K.3.10 PROPOSED ANTICIPATORY TRIP MODIFICATION

This section is not applicable to LGS.

- II.K.3.11 JUSTIFICATION IN THE USE OF CERTAIN POWER-OPERATED RELIEF VALVES

Response

There are no power-operated relief valves at the LGS. The ADS system employs five SRVs to relieve high pressure in the reactor so that flow from LPCI and/or the CS systems enters the reactor in the event that RCIC and/or the HPCI system cannot maintain the reactor water level. See Sections 5.2.2 and 7.3 for further discussion.

- II.K.3.12 CONFIRM EXISTENCE OF ANTICIPATORY REACTOR TRIP UPON TURBINE TRIP

This section is not applicable to the LGS.

- II.K.3.13 SEPARATION OF HPCI AND RCIC SYSTEM INITIATION LEVELS - ANALYSIS AND IMPLEMENTATION

Position

Currently, the RCIC system and the HPCI system both initiate on the same low water level signal and both isolate on the same high water level signal. The HPCI system will restart on low water level but the RCIC system will not. The RCIC system is a low flow system when compared to the HPCI system. The initiation levels of the HPCI and RCIC system should be separated so that the RCIC system initiates at a higher water level than the HPCI system. Further, the RCIC system initiation logic should be modified so that the RCIC system will restart on low water level. These changes have the potential to reduce the number of challenges to the HPCI system and could result in less stress on the vessel from cold water injection. Analyses should be performed to evaluate these changes. The analyses should be submitted to the NRC staff and changes should be implemented if justified by the analysis.

Response

Analysis performed by the BWROG (NEDO-24951) has concluded that changing the initiation setpoint of HPCI/RCIC is unwarranted. The report recommended a modification to the RCIC circuitry to permit auto-restart of RCIC on low level after a high level trip. Therefore, modifications to the RCIC trip circuitry have been made to delete the high water level turbine trip and to apply this signal to the auto-close circuit of the steam supply valve. This provides automatic operation of the RCIC system to trip at high water level and auto-restart at low water level.

- II.K.3.15 MODIFY BREAK DETECTION LOGIC TO PREVENT SPURIOUS ISOLATION OF HPCI AND RCIC SYSTEMS

Position

The HPCI and RCIC systems use differential pressure sensors on elbow taps in the steam lines to their turbine drives to detect and isolate pipe breaks in the systems. The pipe break detection circuitry has resulted in spurious isolation of the HPCI and RCIC systems due to the pressure spike which accompanies startup of the systems. The pipe break detection circuitry should be modified so that pressure spikes resulting from HPCI and RCIC system initiation will not cause inadvertent system isolation.

Submit sufficient documentation to support a reasonable assurance finding by the NRC that the modifications, as implemented, have resulted in satisfying the concerns expressed in the previous requirements.

Response

The HPCI/RCIC steam line isolation logic has been modified to address the spurious isolation of these systems due to the pressure spike which accompanies startup of them. The modification consists of adding a time delay to the high flow trip logic of HPCI/RCIC. This prevents the instantaneous pressure spike from causing a system isolation.

- II.K.3.16 REDUCTION OF CHALLENGES AND FAILURES OF RELIEF VALVES - FEASIBILITY STUDY AND SYSTEM MODIFICATIONS

Position

The record of relief valve failures to close for all BWRs in the past 3 years of plant operation is approximately 30 in 73 reactor-years (0.41 failures per reactor-year). This has demonstrated that the failure of a relief valve to close would be the most likely cause of a small break LOCA. The high failure rate is the result of a high relief valve challenge rate and a relatively high failure rate per challenge (0.16 failures per challenge). Typically, five valves are challenged in each event. This results in an equivalent failure rate per challenge of 0.03. The challenge and failure rates can be reduced in the following ways:

(1) Additional anticipatory scram on loss of feedwater

(2) Revised relief valve actuation setpoints

(3) Increased ECC flow

(4) Lower operating pressures

(5) Earlier initiation of ECCS

(6) Heat removal through emergency condensers

(7) Offset valve setpoints to open fewer valves per challenge

(8) Installation of additional relief valves with a block or isolation valve feature to eliminate opening of the SRVs, consistent with the ASME Code

(9) Increasing the high steam line flow setpoint for MSIV closure

(10) Lowering the pressure setpoint for MSIV closure

(11) Reducing the testing frequency of the MSIVs

(12) More stringent valve leakage criteria

(13) Early removal of leaking valves.

An investigation of the feasibility and contraindications of reducing challenges to the relief valves by use of the aforementioned methods should be conducted. Other methods should also be included in the feasibility study. Those changes which are shown to reduce relief valve challenges without compromising the performance of the relief valves or other systems should be implemented. Challenges to the relief valves should be reduced substantially (by an order of magnitude).

Clarification

Failure of the power-operated relief valve to reclose during the TMI-2 accident resulted in damage to the reactor core. As a consequence, relief valves in all plants, including BWRs, are being examined with a view toward their possible role in a small break LOCA.

The SRVs are dual-function pilot-operated relief valves that use a spring-actuated pilot for the safety function and an external air diaphragm actuated pilot for the relief function.

The operating history of SRVs has been poor. A new design is used in some plants, but the operational history is too brief to evaluate the effectiveness of the new design. Another way of improving the performance of the valves is to reduce the number of challenges to the valves. This may be done by the methods described above or by other means. The feasibility and contraindications of reducing the number of challenges to the valves by the various methods should be studied. Those changes which are shown to decrease the number of challenges without compromising the performance of the valves or other systems should be implemented.

Response

The licensee endorses the BWROG generic response to Item II.K.3.16 for LGS. This response is described in Reference 1.13-11. The following recommendations from this reference have been implemented at LGS in order to reduce the challenges to relief valves by approximately an order of magnitude:

1) Low water level isolation setpoint (see section 6.3.1.1.1 of Reference 1.13-11). The RPV water level isolation setpoint for MSIV closure is being lowered from Level 2 to Level 1 as part of the ATWS modifications for LGS.

2) Low-low set relief or equivalent manual actions (see section 6.3.1.3.1 of Reference 1.13-11). This recommendation ensures that by following the initial pressurization the pressure will be relieved by one valve alone, and the remaining SRVs will not experience any subsequent actuation. At LGS this will be accomplished manually as directed by the EOPs to manually open SRVs to terminate SRV cycling by reducing RPV pressure to below the lowest SRV safety lift setpoint, in accordance with guidance from the current BWROG EPGs.

3) Reduce MSIV testing frequency (see section 6.3.1.4.4 of Reference 1.13-11). A number of isolation events occur when the MSIV closure tests are being conducted. Reducing the MSIV test frequency would result in a reduction in the number of isolation events. Appropriate reductions have been made to the frequency of testing for the LGS MSIVs.

- II.K.3.17 REPORT ON OUTAGES OF ECCS SYSTEMS LICENSEE REPORT AND PROPOSED TECHNICAL SPECIFICATION CHANGES

Position

Several components of the ECCS are permitted by technical specifications to have substantial outage times (e.g., 72 hours for one diesel generator; 14 days for the HPCI system). In addition, there are no cumulative outage time limitations for ECCS. Licensees should submit a report detailing outage dates and lengths of outages for all ECCS for the last 5 years of operation. The report should also include the causes of the outages (i.e., controller failure, spurious isolation).

Clarification

The present technical specifications contain limits on allowable outage times for ECCS and components. However, there are no cumulative outage time limitations on these same systems. It is possible that ECCS equipment could meet present technical specification requirements but have a high unavailability because of frequent outages within the allowable technical specifications.

The licensees should submit a report detailing outage dates and length of outages for all ECCS for the last 5 years of operation, including causes of the outages. This report will provide the staff with a quantification of historical unreliability due to test and maintenance outages, which will be used to determine if a need exists for cumulative outage requirements in the technical specifications.

Based on the above guidance and clarification, a detailed report should be submitted. The report should contain (1) outage dates and duration of outages; (2) causes of the outage; (3) ECCS or components involved in the outage; and (4) corrective action taken. Tests and maintenance outages should be included in the above listings which are to cover the last 5 years of operation. The licensee should propose changes to improve the availability of ECCS equipment, if needed.

Applicants for an operating license shall establish a plan to meet these requirements.

Response

Starting from the date of commercial operations, for a period of five calendar years for each instance of ECCS unavailability because of component failure, maintenance outage (both forced or planned), or testing, the following information will be collected:

a. Outage date

b. Duration of outage

c. Cause of outage

d. ECCS or component involved

e. Corrective action taken

The above information will be assembled into a report, which will also include a discussion of any changes, proposed or implemented, deemed appropriate, to improve the availability of the ECCS equipment.

- II.K.3.18 MODIFICATION OF ADS LOGIC - FEASIBILITY FOR INCREASED DIVERSITY FOR SOME EVENT SEQUENCES

Position

The ADS actuation logic should be modified to eliminate the need for manual actuation to assure adequate core cooling. A feasibility and risk assessment study is required to determine the optimum approach. One possible scheme that should be considered is ADS actuation on low reactor vessel water level provided no HPCI or high pressure core spray flow exists and a low pressure ECCS is running. This logic would complement, not replace, the existing ADS actuation logic.

Response

Option 4, as outlined in the BWROG Generic Response to NUREG-0737 Item II.K.3.18, has been implemented prior to fuel load. Specifically, modifications were made to add a timer that would bypass the high drywell pressure permissive after a sustained low water level and to add an ADS manual inhibit switch.

- II.K.3.21 RESTART OF CORE SPRAY AND LPCI SYSTEMS

Position

The CS and LPCI system flow may be stopped by the operator. These systems will not restart automatically on loss of water level if an initiation signal is still present. The CS and LPCI system logic should be modified so that these systems will restart if required to assure adequate core cooling. Because this design modification affects several core cooling modes under accident conditions, a preliminary design should be submitted for staff review and approval prior to making the actual modification.

Part a

By January 1, 1981, each licensee shall submit proposed design modifications and supporting analysis which will contain sufficient information to support a reasonable assurance finding by the NRC that the above position is met. The documentation should include as a minimum:

(1) A discussion of the design with respect to the above paragraphs of IEEE 279 (1971);

(2) Support information including system design description, logic diagrams, electrical schematics, piping and instrument diagrams, test procedures and technical specifications

(3) Sufficient documentation to demonstrate that the system, as modified, would not degrade proper system functions.

Part b

Licensee to implement modifications at the next refueling outage following staff approval of the design unless this outage is scheduled within 6 months of the approval date. In this event, modifications will be completed during the following refueling outage.

Response

The licensee endorses the BWROG position for Item II.K.3.21 for LGS. This position was forwarded to the NRC by letter from D.B. Walters (BWROG) to D.G. Eisenhut (NRC) dated December 29, 1980. The conclusion of this position is that automation of the restart of LPCI and CS will result in a net decrease in safety because of the complexity of the logic required. Logic modifications to the LPCI and CS systems are therefore not warranted for LGS.

- II.K.3.22 AUTOMATIC SWITCH-OVER OF RCIC SYSTEM SUCTION - VERIFY PROCEDURES AND MODIFY DESIGN

Position

The RCIC system takes suction from the CST with manual switch-over to the suppression pool when the CST level is low. The switch-over should be made automatically. Until the automatic switch-over is implemented, licensees should verify that clear and cogent procedures exist for the manual switch-over of the RCIC system suction from the CST to the suppression pool.

Response

Modifications have been made to change the RCIC system suction valve logic to automatically switch suction from the CST to the suppression pool on low CST level.

- II.K.3.24 CONFIRM ADEQUACY OF SPACE COOLING FOR HPCI AND RCIC SYSTEMS

Position

Long-term operation of the RCIC and HPCI systems may require space cooling to maintain the pump-room temperatures within allowable limits. Applications should verify the acceptability of the consequences of a complete loss of ac power. The RCIC and HPCI systems should be designed to withstand a complete loss of offsite ac power to their support systems, including coolers, for at least 2 hours.

Response

At LGS, the HPCI and RCIC compartment unit coolers are powered by onsite emergency power and therefore continue to be available during a LOOP. The unit coolers are described in Section 9.4.2.2. The ESW pumps which provide flow to the coolers are also powered from onsite emergency power. Adequate space cooling is therefore assured during a LOOP. There are no other supporting systems that require offsite power such that operation of the HPCI and RCIC systems would be impaired if offsite power should be lost. The current LGS design is therefore acceptable.

- II.K.3.25 EFFECT OF LOSS OF AC POWER ON PUMP SEALS

Position

The licensees should determine, on a plant specific basis, by analysis or experiment, the consequences of a loss of cooling water to the reactor recirculation pump seal coolers. The pump seals should be designed to withstand a complete loss of ac power for at least 2 hours. Adequacy of the seal design should be demonstrated. The results of the evaluation and proposed modifications are due by July 1, 1981. Modifications are to be implemented by January 1, 1982.

Clarification

The intent of this position is to prevent excessive loss of RCS inventory following an anticipated operational occurrence. Loss of ac power for this case is construed to be LOOP. If seal failure is the consequence of loss of cooling water to the reactor coolant pump seal coolers for 2 hours, due to LOOP, one acceptable solution would be to supply emergency power to the component cooling water pump.

Response

At LGS, two systems are available for cooling the recirculation pump seals: the RECW system and the recirculation pump seal purge system. Recirculation pump vendor test data has shown that if either one of these seal cooling systems is operating, seal temperatures will remain within acceptable limits and excessive seal deterioration is not expected to occur.

The primary cooling for the recirculation pump seals is provided by the RECW system which cools the reactor water that flows to the lower seal cavity. After a LOOP, the RECW pumps will be powered by onsite emergency power and will restart automatically. The service water system, which normally provides cooling water to the RECW heat exchangers, will not be available, but cooling water to the heat exchangers can be provided via manual realignment of the ESW system. If the RECW pumps do not restart or are unavailable for some other reason, the ESW can be manually routed directly to the recirculation pump seals for cooling by way of the RECW piping.

Backup cooling is provided by the recirculation pump seal purge system which injects cool water from the CRD system into the lower seal cavity. The CRD pumps are powered from the emergency diesels and can be manually restarted once onsite power is available. Therefore, the CRD pumps provide an alternate method for seal cooling during a LOOP. However, the ability to use CRD may be limited by the requirement to limit the RPV cooldown rate.

Even in the remote case where neither cooling source is reestablished and gross seal degradation occurs, the GE analysis performed under the direction of the BWROG has shown that the maximum coolant loss would be limited to 70 gpm per pump. This loss is small enough to be compensated for by normal or emergency reactor water level controls. It should be noted that since the initial licensing of the LGS Units, an improved seal design, prone to even less leakage in the event of failure, has been installed on the pumps.

Instrumentation for various parameters, including seal cavity pressure, seal staging and drain flows, drywell equipment drain sump pump flow and drywell floor drain sump pump flow is available to the operator to indicate potential seal failure. In addition, gross seal failure may lead to

changes in drywell pressure, temperature, or radioactivity, all of which are monitored and recorded in the control room.

It is therefore concluded that a total loss of recirculation pump seal cooling is not a problem at LGS and modifications are not necessary.

- II.K.3.27 PROVIDE COMMON REFERENCE LEVEL FOR VESSEL LEVEL INSTRUMENTATION

Position

Different reference points of the various reactor vessel water level instruments may cause operator confusion. Therefore, all level instruments should be referenced to the same point. Either the bottom of the vessel or the top of the active fuel are reasonable reference points.

The applicant is to submit documentation by January 1, 1981 and implement action by April 1, 1981.

Response

All reactor vessel water level instruments are referenced to the bottom of the dryer skirt. Section 7.7.1.1.3.1.3 contains additional design information.

- II.K.3.28 VERIFY QUALIFICATION OF ACCUMULATORS ON ADS VALVES

Position

Safety analysis reports claim that air or nitrogen accumulators for the ADS valves are provided with sufficient capacity to cycle the valves open five times at design pressures. GE has also stated that the ECCS are designed to withstand a hostile environment and still perform their function for 100 days following an accident. Licensee and applicant should verify that the accumulators on the ADS valves meet these requirements, even considering normal leakage. If this cannot be demonstrated, the licensee and applicant must show that the accumulator design is still acceptable.

Clarification

The ADS valves, accumulators, and associated equipment and instrumentation must be capable of performing their functions during and following exposure to hostile environments and taking no credit for nonsafety-related equipment or instrumentation. Additionally, air (or nitrogen) leakage through valves must be accounted for in order to assure that enough inventory of compressed air is available to cycle the ADS valves.

Response

The criteria and design basis for short-term ADS valve operation and accumulator capacity is given in Section 5.2.2.4.1. Long-term vessel depressurization capability for the alternate shutdown cooling flow path described in Section 5.4.7.5 is provided by supplying nitrogen to the ADS valves from the safety-grade system described in Section 9.3.1.3.

- II.K.3.30 REVISED SMALL BREAK LOCA METHODS TO SHOW COMPLIANCE WITH 10CFR50, APPENDIX K

Position

The analysis methods used by NSSS vendors and/or fuel suppliers for small break LOCA analysis for compliance with 10CFR50, Appendix K, should be revised, documented, and submitted for NRC approval. The revisions should account for comparisons with experimental data, including data from the LOFT Test and Semiscale Test facilities.

Clarification

As a result of the accident at TMI-2, the Bulletins and Orders Task Force was formed within the Office of Nuclear Reactor Regulation. This task force was charged, in part, to review the analytical predictions of feedwater transients and small break LOCAs for the purpose of assuring the continued safe operation of all operating reactors, including a determination of acceptability of emergency guidelines for operators.

As a result of the task force reviews, a number of concerns were identified regarding the adequacy of certain features of small break LOCA models, particularly the need to confirm specific model features (e.g., condensation heat transfer rates) against applicable experimental data. These concerns, as they applied to each LWR vendor's models, were documented in the task force reports for each LWR vendor. In addition to the modeling concerns identified, the task force also concluded that, in light of the TMI-2 accident, additional systems verification of the small break LOCA model as required by II.4 of 10CFR50, Appendix K, was needed. This included providing predictions of Semiscale Test S-07-10B, LOFT Test (L3-1), and providing experimental verification of the various modes of single-phase and two-phase natural circulation predicted to occur in each vendor's reactor during small break LOCAs.

Based on the cumulative staff requirements for additional small break LOCA model verification, including both integral system and separate effects verification, the staff considered model revision as the appropriate method for reflecting any potential upgrading of the analysis methods.

The purpose of the verification was to provide the necessary assurance that the small break LOCA models were acceptable to calculate the behavior and consequences of small primary system breaks. The staff believes that this assurance can alternatively be provided, as appropriate, by additional justification of the acceptability of present small break LOCA models with regard to specific staff concerns and recent test data. Such justification could supplement or supersede the need for model revision.

The specific staff concerns regarding small break LOCA models are provided in the analysis sections of the Bulletins and Orders Task Force reports for each LWR vendor. These concerns should be reviewed in total by each holder of an approved ECCS model and addressed in the evaluation as appropriate.

The recent tests include the entire Semiscale small break test series and LOFT Test (L3-1) and (L3-2). The staff believes that the present small break LOCA models can be both qualitatively and quantitatively assessed against these tests.

Other separate effects tests (e.g., Oak Ridge National Laboratory core uncovery tests) and future tests, as appropriate, should also be factored into this assessment.

Based on the preceding information, a detailed outline of the proposed program to address this issue should be submitted. In particular, this submittal should identify (1) which areas of the models, if any, the licensee intends to upgrade, (2) which areas the licensee intends to address by further justification of acceptability, (3) test data to be used as part of the overall verification/upgrade effort, and (4) the estimated schedule for performing the necessary work and submitted this information for staff review and approval.

Response

The response to the NRC small break model concerns was provided at a meeting between the NRC and GE on June 18, 1981. Information provided at this meeting showed that, based on the small break test results and sensitivity studies, the existing GE small break LOCA model satisfies the concerns of NUREG-0626 and is in compliance with 10CFR50, Appendix K. Therefore, the GE model is acceptable relative to the concerns of Item II.K.3.30, and no model changes need to be made to satisfy this item.

Documentation of the information provided at the June 18, 1981 meeting was provided via the letter from R.H. Buchholz (GE) to D.G. Eisenhut (NRC), dated June 26, 1981.

- II.K.3.31 PLANT SPECIFIC CALCULATIONS TO SHOW COMPLIANCE WITH 10CFR50.46

Position

Plant specific calculations using NRC approved models for small break LOCAs as described in II.K.3 item 30 to show compliance with 10CFR50.46 should be submitted for NRC approval by all licensees.

Calculations to be submitted by January 1, 1983 or 1 year after staff approval of LOCA analysis models, whichever is later (required only if model changes have been made).

Response

The small break LOCA calculations included in the LGS LOCA analysis are given in Section 6.3.3.7 and Table 6.3-5. The references listed in Section 6.3.6 describe the currently approved 10CFR50, Appendix K methodology used to perform these calculations. Compliance with 10CFR50.46 has previously been established for that methodology. As stated in the June 26, 1981, letter from R.H. Buchholz (GE) to D.G. Eisenhut (NRC), no model changes are needed to satisfy NUREG-0737 Item II.K.3.30; therefore, there is no need to revise the calculations given in Section 6.3.3.7.

The response provided above is historical. The original LOCA analysis has been replaced, and the applicable LOCA analysis is discussed in Section 6.3.3.7.

- II.K.3.44 EVALUATION OF ANTICIPATED TRANSIENTS WITH SINGLE FAILURE TO VERIFY NO FUEL FAILURE

Position

For anticipated transients combined with the worst single failure and assuming proper operator actions, licensees should demonstrate that the core remains covered or provide analysis to show that no significant fuel damage results from core uncovery. Transients which result in a SORV should be included in this category. The results of the evaluation are due January 1, 1981.

Response

The BWROG transmitted a generic response to this requirement by letter dated December 29, 1980, from D.B. Waters (BWROG) to D.G. Eisenhut (NRC). This response contains an evaluation that states the worst case transient with single failure combination for BWR/4 plants is the loss of feedwater event with failure of the HPCI system. A SORV was also considered in addition to the HPCI failure. The results of these studies indicate that the core remains covered during the entire course of the transient either due to RCIC system operation or automatic or manual depressurization permitting low pressure inventory makeup. The operator action assumed in the analysis is to manually depressurize the vessel to permit low pressure injection.

By letter dated November 16, 1981, from J.S. Kemper (PECo) to D.G. Eisenhut (NRC), the licensee verified that the assumptions and initial conditions used in the BWROG generic report are representative of LGS.

- II.K.3.45 EVALUATION OF DEPRESSURIZATION WITH OTHER THAN ADS

Position

Analyses to support depressurization modes other than full actuation of the ADS (e.g., early blowdown with one or two SRVs) should be provided. Slower depressurization would reduce the possibility of exceeding vessel integrity limits by rapid cooldown.

Response

The applicant endorses the BWROG position on Item II.K.3.45 for LGS. This position is presented in Reference 1.13-11 and is summarized below.

An evaluation of alternate modes of depressurization other than full actuation of the ADS was made by the BWROG with regard to the effect of such reduced depressurization rates on core cooling and vessel integrity.

Depressurization by full ADS actuation constitutes a depressurization from about 1050 to 180 psig in approximately 3.3 minutes. The alternate modes of depressurization that were evaluated considered vessel depressurization over the same pressure range (1050 to 180 psig) within two different time periods (6-10 minutes and 15-20 minutes). The cases considered show that no appreciable improvement can be gained by slower depressurization based on core cooling considerations. Because a full ADS blowdown is well within the design basis of the RPV and ADS is properly designed to minimize the threat to core cooling, no change in the depressurization rate is necessary, and no modifications to LGS are needed for this TMI item.

- II.K.3.46 RESPONDING TO MICHELSON CONCERNS

Position

GE should provide a response to the Michelson concerns as they relate to BWRs.

Clarification

GE provided a response to the Michelson concerns as they relate to BWRs by letter dated February 21, 1980. Licensees and applicants should assess applicability and adequacy of this response to their plants.

Response

All of the generic February 21, 1980 GE responses are applicable to LGS Units 1 and 2 and are adequate in terms of a response to the Michelson concerns for LGS.

- III.A.1.1 EMERGENCY PREPAREDNESS, SHORT-TERM

Position

Comply with 10CFR50, Appendix E and Regulatory Guide 1.101, "Emergency Planning for Nuclear Power Plants," and meet the essential elements of NUREG-75/111, "Criteria for Preparation and Evaluation of Radiological Emergency Response Plans and Preparedness in Support of Nuclear Power Plants," or have a favorable finding form the Federal Emergency Management Agency.

Response

Emergency planning is discussed in the Emergency Plan.

- III.A.1.2 UPGRADE EMERGENCY SUPPORT FACILITIES

Position

Establish an interim onsite TSC separate from, but close to, the control room for engineering and management support of reactor operations during an accident. The TSC shall be large enough for the necessary utility personnel and five NRC personnel, have direct display or call-up of plant parameters, and dedicated communication with the control room, emergency operations facility, and the NRC. Provide a description of and a completion schedule for establishing a permanent TSC in accordance with the regulatory position of NUREG-0696, "Functional Criteria for Emergency Response" (February 1981).

Establish an onsite OSC, separate from but with communications to the control room for use by operation support personnel during an accident.

Designate a near-site EOF with communications with the plant to provide evaluation of radiological releases and coordination of all onsite and offsite activities during an accident.

These requirements shall be met before fuel loading.

Response

The three types of emergency response facilities required by Section 8 have been provided for LGS.

The TSC meets all of the requirements of section 8.2.1 and is fully functional.

The OSC meets all of the requirements of section 8.3.1 and is fully functional.

The EOF is located approximately 20 miles from the LGS site. The EOF meets all of the technical requirements of section 8.4.1 and is fully functional.

Staffing of the EOF and the TSC is described in the Emergency Plan.

- III.A.2 EMERGENCY PREPAREDNESS

Position

(1) Each nuclear facility shall upgrade its emergency plan to provide reasonable assurance that adequate protective measures can and will be taken in the event of a radiological emergency. Specific criteria to meet this requirement is delineated in NUREG-0654 (FEMA-REP-1), "Criteria for Preparation and Evaluation of Radiological Emergency Response Plans and Preparation in Support of Nuclear Power Plants."

(2) Perform an emergency response exercise to test the integrated capability and a major portion of the basic elements existing within emergency preparedness plans and organizations.

Response

Emergency planning is discussed in the Emergency Plan.

- III.D.1.1 PRIMARY COOLANT OUTSIDE CONTAINMENT

Position

Applicants shall implement a program to reduce leakage from systems outside containment that would or could contain highly radioactive fluids during a serious transient or accident to as-low-as-practical levels. This program shall include the following:

(1) Immediate leak reduction

(a) Implement all practical leak reduction measures for all systems that could carry radioactive fluid outside of containment.

(b) Measure actual leakage rates with system in operation and report them to the NRC.

(2) Continuing Leak Reduction - Establish and implement a program of preventive maintenance to reduce leakage to as-low-as-practical levels. This program shall include periodic integrated leak tests at intervals not to exceed each refueling cycle.

Clarification

Applicants shall provide a summary description, together with initial leak test results, of their program to reduce leakage from systems outside containment that would or could contain primary coolant or other highly radioactive fluids or gases during or following a serious transient or accident.

(1) Systems that should be leak tested are as follows (any other plant system which has similar functions or postaccident characteristics even through not specified herein, should be included):

(a) RHR,

(b) Containment spray recirculation,

(c) HPCI recirculation,

(d) Containment and primary coolant sampling,

(e) RCIC,

(f) Makeup and letdown (pressurized water reactors only), and

(g) Waste gas (includes headers and cover gas system outside of containment in addition to decay or storage system).

Include a list of systems containing radioactive materials which are excluded from program and provide justification for exclusion.

(2) Testing of gaseous systems should include helium leak detection or equivalent testing methods.

(3) Should consider program to reduce leakage potential release paths due to design and operator deficiencies as discussed in our letter to all operating nuclear power plants regarding North Anna and related incidents, dated October 17, 1979.

Response

A review of all systems designed to handle highly radioactive fluids during or after a serious transient or accident has been performed to ensure that appropriate design features to minimize leakage have been included. System isolation provisions have been reviewed in conjunction with this effort (Section 6.2.7). A leak reduction program for these systems will be implemented prior to and after fuel load to measure actual leakage rates and to identify sources of leakage in order that total leakage may be reduced to as-low-as-practical levels. The leakage reduction program is described in Section 6.2.8.

The October 17, 1979, NRC generic letter regarding radioactive releases to North Anna Unit 1 expanded the scope of NUREG-0737 Item III.D.1.1 to include a review of potential radioactive release pathways that would not be related to the handling of highly radioactive fluids during or after a core damage event. This generic letter required "...that release paths exemplified by the

North Anna Unit 1 incident or similar release paths as identified in IE Circular 79-21 should also be considered."

In response to this request per clarification (3), above, a review has been performed to identify all potential unplanned release paths for radioactive fluids during normal plant operation. As shown in Table 1.13-4, it has been determined that existing design provisions and administrative controls are sufficient to prevent unplanned and unmonitored releases of radioactivity.

During review of IE Bulletin 80-10, all interfaces between normally nonradioactive and radioactive systems were identified. It was determined that design provisions adequately maintain boundaries between nonradioactive/radioactive interfaces (Item 4 in Table 1.13-4). These design provisions include one of the following:

a. Two normally closed valves in series

b. One normally closed valve and one check valve in series

c. Two check valves in series

d. Heat exchanger tube sheets (in most cases, the nonradioactive fluid is maintained at a higher pressure than the radioactive fluid).

In the event that leakage or operator errors (e.g., valve mispositionings or incorrect valve lineups) lead to contamination of a nonradioactive system, the process sampling system and numerous grab sampling points for the following normally nonradioactive systems are provided to support a routine contamination monitoring program:

a. Circulating water

b. RECW

c. TECW

d. Clarified water

e. Makeup demineralizers

f. Drywell chilled water

g. Auxiliary steam (both steam and feedwater)

h. Plant waste water effluent

i. Service water

j. Instrument and service air

In addition to the above sampling provisions, the following systems are monitored for radioactive contamination by the process radiation monitoring system:

a. ESW and RHR service water

b. RECW

c. Service water

In the event that a nonradioactive system is found to be contaminated, corrective action will be taken to prevent leakage to the environment and isolate and repair the source of the contamination.

- III.D.3.3 IMPROVED INPLANT IODINE INSTRUMENTATION UNDER ACCIDENT CONDITIONS

Position

(1) Each licensee shall provide equipment and associated training and procedures for accurately determining the airborne iodine concentration in areas within the facility where plant personnel may be present during an accident.

(2) Each applicant for a fuel loading license to be issued prior to January 1, 1981 shall provide the equipment, training, and procedure necessary to accurately determine the presence of airborne radioiodine in areas within the plant where plant personnel may be present during an accident.

Clarification

Effective monitoring of increasing iodine levels in the buildings under accident conditions must include the use of portable instruments using sample media that will collect iodine selectively over xenon (e.g., silver zeolite) for the following reasons:

(1) The physical size of the auxiliary and/or fuel handling building precludes locating stationary monitoring instrumentation at all areas where airborne iodine concentration data might be required.

(2) Unanticipated isolated "hot spots" may occur in locations where no stationary monitoring instrumentation is located.

(3) Unexpectedly high background radiation levels near stationary monitoring instrumentation after an accident may interfere with filter radiation readings.

(4) The time required to retrieve samples after an accident may result in high personnel exposures if these filters are located in high dose rate areas.

After January 1, 1981, each applicant and licensee shall have the capability to remove the sampling cartridge to a low background, low contamination area for further analysis. Normally, counting rooms in auxiliary buildings will not have sufficiently low backgrounds for such analyses following an accident. In the low background area, the sample should first be purged of any entrapped noble gases using nitrogen gas or clean air free of noble gases. The licensee shall have the capability to measure accurately the iodine concentrations present on these samples under accident conditions. There should be sufficient samplers to sample all vital areas.

For applicants with fuel loading dates prior to January 1, 1981, provide by fuel loading (until January 1, 1981) the capability to accurately detect the presence of iodine in the region of interest following an accident. This can be accomplished by using a portable or cart-mounted iodine sampler with attached SCA. The SCA window should be calibrated to the 365 KeV of I-131 using the SCA. This will give an initial conservative estimate of presence of iodine and can be used to determine if respiratory protection is required. Care must be taken to assure that the counting system is not saturated as a result of too much activity collected on the sampling cartridge.

Response

Sampling methods and procedures have been implemented at LGS which will permit the measurement of in-plant iodine concentrations during accident conditions. A description of this method is as follows:

The sampling method uses portable air samplers with a combination particulate filter and iodine sampling cartridge sampling head. The sampling heads use a glass fiber particulate filter and a CESCO style (2.25" diameter by 1.04" thickness) iodine charcoal cartridge. The cartridge normally used is the CESCO-type charcoal cartridge. When long sampling times are required, a larger capacity charcoal cartridge is available. During emergency conditions, with high xenon or krypton concentrations potentially present, either a silver zeolite or a silver impregnated silica gel adsorber canister will be employed.

Iodine activity on the sample cartridge will be determined by gamma isotopic analysis using a computer based multichannel analyzer with high resolution intrinsic germanium detectors located in the LGS counting room. The counting room is located in the radwaste enclosure at el 217'. An assessment of the NUREG-0737 shielding study indicates that the counting room dose rates and airborne radioactivity concentrations are low enough to permit sample analysis during accident conditions.

Isotopic analysis will permit iodine identification in the presence of xenon and krypton. If the analysis of iodine becomes impossible due to interference (high background) from xenon or krypton, then either silver zeolite cartridges will be used or the charcoal cartridge will be purged with clean bottled nitrogen or breathing air to reduce the interference. If the use of silver zeolite does not sufficiently reduce the xenon or krypton interference, the silver zeolite cartridges will also be purged with clean bottled nitrogen or bottled breathing air available onsite.

The Health Physics technical staff have been trained in the implementation of this postaccident procedure.

- III.D.3.4 CONTROL ROOM HABITABILITY

Position

In accordance with Item III.D.3.4 applicants shall assure that control room operators will be adequately protected against the effects of accidental release of toxic and radioactive gases and that the nuclear power plant can be safely operated or shut down under DBA conditions (GDC 19).

Clarification

(1) All applicants must make a submittal to us regardless of whether or not they met the criteria of the referenced SRP sections. The new clarification specifies that applicants that meet the criteria of the SRP should provide the basis for their conclusion that Section 6.4 of the SRP requirements are met. Applicants may establish this basis by referencing past submittals to us and/or providing new or additional information to supplement past submittals.

(2) All applicants with control rooms that meet the criteria of the following sections of the SRP:

2.2.1-2.2.2	Identification of Potential Hazards in Site Vicinity,
2.2.3	Evaluation of Potential Accidents, and
6.4	Habitability Systems

shall report their findings regarding the specific SRP sections as explained below. References 1.13-12, 1.13-13 and 1.13-14 should be used for guidance.

Applicants shall submit the results of their findings as well as the basis for those findings by January 1, 1981. In providing the basis for the habitability finding, applicants may reference their past submittals. Applicants should, however, ensure that these submittals reflect the current facility design and that the information requested in Table 1.13-12 is provided.

(3) All applicants with control rooms that do not meet the criteria of the above listed references, SRPs, regulatory guides, and other references shall perform the necessary evaluations and identify appropriate modifications.

Each applicant submittal shall include the results of the analyses of control room concentrations from postulated accidental release of toxic gases and control room operator radiation exposures from airborne radioactive material and direct radiation resulting from DBAs. The toxic gas accident analysis should be performed for all potential hazardous chemical releases occurring either on the site or within 5 miles of the plant boundary. Regulatory Guide 1.78 lists the chemicals most commonly encountered in the evaluation of the control room habitability but is not all inclusive.

The DBA radiation source term should be for the LOCA containment leakage and ESF leakage contribution outside containment as described in Section 15.6.5, appendices A and B. In addition, BWR facility evaluations should add any leakage from the MSIVs (i.e, valve steam leakage, valve seat leakage, MSIV Leakage Alternate Drain Pathway release) to the containment leakage and ESF leakage following a LOCA. This should not be construed as altering our recommendations in section D of Regulatory Guide 1.95 (Rev 2) regarding MSIV-LCS. Other DBAs should be reviewed to determine whether they might constitute a more severe control room hazard than the LOCA.

In addition to the accident analysis results, which should either identify the possible need for control room modifications or provide assurance that the habitability systems will operate under all postulated conditions to permit the control room operators to remain in the control room to take appropriate actions required by GDC 19, the applicant should submit sufficient information needed

for an independent evaluation of the adequacy of the habitability systems. Table 1.13-12 lists the information that should be provided along with applicant's evaluation.

Response

The information required for control room habitability evaluation as listed in Table 1.13-12 is provided in Sections 1.2, 2.2, 6.4, and 9.4. LGS complies with all criteria of control room habitability in accordance with Item III.D.3.4.

							Skin : 2.0×10^{-2}	≤30

(1) Occupancy factors used to calculate doses are listed in parentheses for each vital area. SRP 6.4 occupancy factors are for 30 days. For vital areas with 1 hour occupancy, the doses reflect 1 hour occupancy at the maximum postaccident dose rate unless otherwise specified.

(2) Airborne whole body doses are specified for the listed vital areas.

(3) Doses do not include shine from sample source. See Table 11.5-3 .

(4) MCR Dose was calculated assuming zero inleakage through the MCR Doors. This requires installation of a MCR door seal described in section 6.4 and 15.10.

(5) The calculated Airborne Organ dose was approximately 35 rem over 30 days. Emergency Response Procedures specify the criteria for radiological habitability monitoring to insure the dose objectives are not exceeded. Bi the results of the habitability monitoring personnel in the affected areas maybe instructed to don protective devices or limit stay times to maintain the dose objectives.

(6) The stay times assumed for these areas are half of the stay times specified in SRP 6.4.

(7) Doses to personnel traversing the Refuel Floor on route to and then occupying the North Stack Instrument Room would be 2.86 Rem if a LOCA were to occur while the upper layer of the reactor well shield plugs were removed in OPCON 1, 2 and 3. Doses to personnel traversing the turbine enclosure roof to the reactor enclosure roof on route to and from, and while occupying the North Stack Instrument Room would be 2.9 Rem, if a Unit 2 LOCA were to occur, and 3.957 Rem, if a Unit 1 LOCA were to occur, when both layer of the shield plugs are removed in OPCON 3. These lower doses are a result of a more location specific analysis of the travel routes. The 4.8 Rem value remains the bounding value in all other conditions and areas until specific analysis are performed.

(8) The information in this Table is historical and represents original plant design requirements. The application of Alternative Source Terms per Regulatory Guide 1.183, resulted in the recalculation of control room dose. See Chapter 15 for details.

Table 1.13-2

RADIATION DOSES FOR VITAL AREA ACCESS PATHS[1] [2] [5] [7]

Access Path [2]	Transit Time (min.)	Peak Piping and Cloud Shine Dose (Rem)	Peak Airborne Whole Body Dose (Rem)	Sum of Shine Plus Whole Body Dose (Rem)	Peak Airborne Thyroid Dose (Rem)	Peak Airborne Skin Beta Dose (Rem)
A	4	$6x10^{-3}$	$1x10^{-3}$	$7x10^{-3}$	$1.4x10^{-2}$	$9x10^{-4}$
A' (Alternate)	3	$2x10^{-3}$	$1x10^{-3}$	$3x10^{-3}$	$1x10^{-2}$	$7x10^{-4}$
B	2	$3x10^{-3}$	$5x10^{-4}$	$4x10^{-3}$	$7x10^{-3}$	$5x10^{-4}$
C	0.5	$3x10^{-3}$	$8x10^{-4}$	$4x10^{-3}$	$1x10^{-2}$	$7x10^{-4}$
C' (Alternate)	3	$3x10^{-2}$	$5x10^{-3}$	$4x10^{-2}$	$7x10^{-2}$	$5x10^{-3}$
D	2	$2x10^{-1}$[3]	$5x10^{-4}$	$2x10^{-1}$[3]	$7x10^{-3}$	$5x10^{-4}$
D' (Alternate)	4	$5x10^{-3}$[3]	$1x10^{-3}$	$6x10^{-3}$[3]	$1.4x10^{-2}$	$1x10^{-3}$
E	[4]	[4]	[4]	[4]	[4]	[4]
E' (Alternate)	15	$3x10^{-3}$	$2.4x10^{-2}$	$3x10^{-2}$	$3.3x10^{-1}$	$2x10^{-2}$
E''(Alternate)						
Unit 1 LOCA	15	$7.8x10^{-1}$[6]	$2.4x10^{-2}$	$8.0x10^{-1}$	$3.3x10^{-1}$	$2x10^{-2}$
Unit 2 LOCA	15	$2.5x10^{-1}$	$2.4x10^{-2}$	$2.7x10^{-1}$	$3.3x10^{-1}$	$2x10^{-2}$
F	2	$1x10^{-3}$	$4x10^{-3}$	$5x10^{-3}$	$5.1x10^{-2}$	$4x10^{-3}$
F' (Alternate)	0.5	$6x10^{-3}$	$1x10^{-3}$	$7x10^{-3}$	$1.3x10^{-2}$	$9x10^{-4}$

(1) Dose rates for all parts of access paths are $\leq$10 Rem/hour except as noted in Table 1.13-3.

(2) Access paths are described in Table 1.13-5.

(3) Dose rates will increase slightly at time t = 36 hours when the H_2 recombiner starts operating, but doses will still be below the peak values shown in this table.

(4) Path is not accessible. See Table 1.13-3.

(5) The above doses exclude the impact of the MSIV leakage alternate drain pathway. This source is significant only for paths through the Turbine Enclosure. SCBAs may be required for thyroid protection.

(6) This is an increase of 1.057 Rem (total) above the unit 2 LOCA dose due to the shine from the unit 1 drywell head through the reactor building north wall. These doses are based on the lower layer of reactor well shield plugs being removed on one unit in OPCON 3, and both layers of the other unit being installed or have the unit in OPCON 4 or 5.

(7) The information in this Table is historical and represents original plant design requirements based on source terms consistent with TID-14844. The application of Alternative Source Terms per Regulatory Guide 1.183 may be used to determine vital area radiation doses for subsequent evaluations.

Table 1.13-3

SOLUTIONS TO POTENTIAL VITAL AREA ACCESS PROBLEMS[1][2]

Potential Problem Area	Description	Solution	Remarks
Access Path D	The northeast area of the radwaste enclosure at el 217' near the airlock for the reactor enclosure will have radiation levels of 20 R/hr at time t = 0 hours.	It is preferable to use access path D' instead of access path D until the dose rate falls below 10 Rem/hr in the vicinity of the airlock.	From Figure 1.13-1, it can be seen that the dose rate near the airlock will fall below 10 Rem/hr about 2 hours after a DBA. Access path D would be used for access to the radwaste control room, radiochemical laboratory, or counting area from the control room.If access is required before the dose rate for access path D has fallen to acceptable levels, the operators can use access path D' to enter the radwaste control room. However, it is not necessary to prohibit access in the vicinity of the airlock because the radiation levels decay rapidly and are in a localized area with short transit.
Access Path E	The stairway next to the reactor enclosure exhaust stack will have peak radiation levels of 28 R/hr at time t = 4 hours.	Access path E' should be used until the dose rate falls below 10 R/hr in the stairway. If both the upper and lower reactor well shield plugs are removed, then use path E''	The first sample from the north stack instrument room must be taken within 24 hours. Due to the long time required to pass through the stairway in access path E and the extent of the radiation field, access to the north stack instrument room using this stairway is not possible until after time t = 24 hours.
Access Path E'	If both reactor well shield plugs on either Unit are removed, the refueling floor travel path will have radiation levels of 100 R/hr at t = 0 hours.	Access path E'' should be used until the dose rate falls below 10 R/hr on the refueling floor.	Access to the refueling floor will not drop below 10 R/hr until after time t = 9 hrs.

(1) Access paths are described in Table 1.13-5.

(2) This information had not been updated to reflect the current licensing design basis. The information should be used for historical reference only and not to support the design basis of the plant.

Table 1.13-4

POTENTIAL UNPLANNED RELEASE PATHS

System(s)	Boundary	Potential Release Path	Administrative Control
Air Removal and Sealing Steam	HV-07-142, -143, -144, -145, (Normally Closed)	Airborne contamination release (local) if valves left open after equalizing pressures	Operating procedure requires valve closure
Liquid Radwaste Equipment Drain Processing	62-0021 (Normally Closed)	Airborne contamination release (local) if valve is left open	Operating procedure requires valve closure
Control Rod Drive	XV-47-1F180 XV-47-1F181 XV-47-1F010 XV-47-1F011 (All valves fail closed)	Scram discharge header volume release to DRW or equipment drain collection tank	Operating procedure provides precaution notice
Various Nonradioactive Systems	Valves or heat exchanger tube sheets	Potential cross contamination at radioactive/nonradioactive system interfaces	Routine analysis in chemistry surveillance
Plumbing and Drainage	Open area drains and/or equipment drains	Inappropriate use of segregated drain systems	Precaution notices, drain plugs, curbs and/or color-coded labels around drains to identify
Plumbing and Drainage	Open area and/or equipment drains inside reactor	Open drains are a potential path for air flow from enclosure (air supply fan area and refueling floor)	Controlled opening of plugged drains secondary containment, if the ¼ in. wg. negative pressure is interrupted
Liquid Radwaste Collection	Offsite disposal of sump oil	Sump oil is potentially contaminated	Chemistry sample analysis required prior to disposal
Liquid Radwaste and Waste Water	Release of final radwaste batch to cooling tower blowdown (monitored)	Unauthorized release (inadvertent)	Routine surveillance

Table 1.13-5

ACCESS PATH IDENTIFICATION[1]

Table 1.13-5 (Cont'd)[1]

Access Path	Route Description	Reference (Bechtel) Drawings
D' (Alternate to D)	In main control room, proceed to stairs/elevator near Columns N & 20. Continue downstairs to el 217' and the PASS. Exit control structure and proceed west (corridor 352) to turbine enclosure exit (Columns Jb & 5). Exit building and proceed south to the end of the radwaste enclosure, then turn east. Enter radwaste enclosure near Columns 13 & C. Proceed north to vital areas.	8031-M-104, M-103 and M-102
E (Radwaste Enclosure el 217' to North Stack Instrument Room)	Exit the radwaste enclosure at Columns J & 14. Walk east through Unit 1 turbine enclosure to control structure. Walk up stairs at Columns M & 20 to el 332'. Proceed southeast across room to stairs at Columns J & 21.8 next to the north stack. Climb stairs to el 411', north stack instrument room.	8031-M-102, M-103, M-104, M-105 M-124, and M-139
E' (Alternate to E)	Exit the radwaste area at Columns J & 14. Continue east through turbine enclosure into Unit 2 side After entering Unit 2 side, continue east to the Unit 2 reactor enclosure entrance (Column 32). Enter stairs near Columns J & 32 and continue up the stairs to el 352' (refueling floor). Proceed south on refueling floor to the door on the south wall between the two units (Columns 22 & D). Enter door and proceed up ladder to south stack instrument area (el 411'). Cross roof area to north stack instrument room.	8031-M-102, M-103, M-104, M-105, M-106, and M-139
E'' (Alternate to E & E', if both reactor well shield plugs are removed)	Personnel shall use the most dose-efficient pathway to enter the 217' elevation of the control structure. Continue up stairs at Columns M and 20 to elevation 324'. Proceed out onto turbine enclosure roof Take scaffold stairs at Columns Kg and 17.6 to reactor enclosure roof elevation 411', proceed along farthest north point of travel on roof to north stack instrument room WRAM sample area.	8031-M-102, M-103, M-104, M-105, M-106, and M-139
F (Radwaste Enclosure el 217' to Diesel Generator Bays	Proceed south through radwaste enclosure to exit at Columns C & 13. Enter yard and move towards south) entrance of the emergency diesel generator bays. Enter bay area.	8031-M-102
F' (Alternate to F)	Proceed south through radwaste enclosure and exit into yard. Continue northeast towards reactor enclosure. Enter generator bays through the north entrance.	8031-M-102

(1) For the MSIV Leakage Alternate Drain Pathway, the F_6 factor is 1.0, since this release point is not an elevated release point.

(2) This Table is historical. The application of Alternative Source Terms per Regulatory Guide 1.183 resulted in the re-evaluation of X/Q values. See UFSAR Section 2.3.

Table 1.13-8

HIGH-RANGE NOBLE GAS EFFLUENT MONITORS (TABLE II.F.1-1)

REQUIREMENT	-	Capability to detect and measure concentrations of noble fission products in plant gaseous effluents during and following an accident. All potential accident release paths shall be monitored.
PURPOSE	-	To provide the plant operator and emergency planning agencies with information on plant releases of noble gases during and following an accident.

DESIGN BASIS MAXIMUM RANGE

Design range values may be expressed in Xe-133 equivalent values for monitors employing gamma radiation detectors or in microcuries per cubic centimeter (μCi/cc) of air at standard temperature and pressure for monitors employing beta radiation detector (Note: 1R/hr @ 1 ft = 6.7 Ci Xe-133 equivalent for point source). Calibrations with a higher energy source are acceptable. The decay of radionuclide noble gases after an accident (i.e., the distribution of noble gas changes) should be taken into account.

10^5 μCi/cc	-	Undiluted containment exhaust gases (e.g., PWR reactor building purge, BWR drywell purge through the SGTS).
	-	Undiluted PWR condenser air removal system exhaust.
10^4 μCi/cc	-	BWR reactor building (secondary containment) exhaust air.
	-	PWR secondary containment exhaust air.
10^3 μCi/cc	-	Buildings with systems containing primary coolant or primary coolant offgases (e.g., PWR auxiliary buildings, BWR turbine buildings).
	-	PWR steam safety valve discharge, atmospheric steam dump valve discharge.
10^2 μCi/cc	-	Other release points (e.g., radwaste buildings, fuel handling/storage buildings).

Table 1.13-8 (Cont'd)

REDUNDANCY	-	Not required; monitoring the final release point of several discharge inputs is acceptable.
SPECIFICATIONS	-	(None) Sampling design criteria per ANSI N13.1.
POWER SUPPLY	-	Vital instrument bus or dependable backup power supply to normal alternating current.
CALIBRATION	-	Calibrate monitors using gamma detectors to Xe-133 equivalent (1R/hr @ 1 ft = 6.7 Ci Xe-133 equivalent for point source). Calibrate monitors using beta detectors to Sr-90 or similar long-lived beta isotope of at least 0.2 MeV.
DISPLAY	-	Continuous and recording as equivalent Xe-133 concentrations or μCi/cc of actual noble gases.
QUALIFICATION	-	The instruments shall provide sufficiently accurate responses to perform the intended function in the environment to which they will be exposed during accidents.
DESIGN CONSIDERATIONS	-	Offline monitoring is acceptable for all ranges of noble gas concentrations.
	-	Inline (induct) sensors are acceptable for 10^2 μCi/cc to 10^5 μCi/cc noble gases. For less than 10^2 μCi/cc, offline monitoring is recommended.
	-	Upstream filtration (prefiltering to remove radioactive iodines and particulates) is not required; however, design should consider all alternatives with respect to capability to monitor effluents following an accident.
	-	For external mounted monitors (e.g., PWR main steam line, the thickness of the pipe should be taken into account in accounting for low-energy gamma radiation.

Table 1.13-9

INTERIM PROCEDURES FOR QUANTIFYING
HIGH-LEVEL ACCIDENTAL RADIOACTIVITY RELEASES (TABLE II.F.1-2)

Applicants are to implement procedures for estimating noble gas and radioiodine release rates if the existing effluent instrumentation goes off-scale.

Examples of major elements of a highly radioactive effluent release special procedures (noble gas).

- Preselected location to measure radiation from the exhaust air, e.g., exhaust duct or sample line.

- Provide shielding to minimize background interference.

- Use of an installed monitor (preferable) or dedicated portable monitoring (acceptable) to measure the radiation.

- Predetermined calculational method to convert the radiation level to radioactive effluent release rate.

Table 1.13-10

SAMPLING AND ANALYSIS OR MEASUREMENT OF
HIGH-RANGE RADIOIODINE AND PARTICULATE EFFLUENTS
IN GASEOUS EFFLUENT STREAMS (TABLE II.F.1-3)

EQUIPMENT	-	Capability to collect and analyze or measure representative samples of radioactive iodines and particulates in plant gaseous effluents during and following an accident. The capability to sample and analyze for radioiodine and particulate effluents is not required for PWR secondary main steam safety valve and dump valve discharge lines.
PURPOSE	-	To determine quantitative release of radioiodines and particulates for dose calculation and assessment.
DESIGN BASIS SHIELDING ENVELOPE	-	10^2 μCi/cc of gaseous radioiodine and particulates, deposited on sampling media; 30 minutes sampling time, average gamma energy (E) of 0.5 MeV.

SAMPLING MEDIA

- Iodine > 90% effective adsorption for all forms of gaseous iodine.
- Particulates > 90% effective retention for 0.3 micron (μ) diameter particles.

SAMPLING CONSIDERATIONS

- Representative sampling per ANSI N13.1 (1969).
- Entrained moisture in effluent stream should not degrade adsorber.
- Continuous collection required whenever exhaust flow occurs.
- Provisions for limiting occupational dose to personnel incorporated in sampling systems, in sample handling and transport, and in analysis of samples.

Table 1.13-10 (Cont'd)

ANALYSIS
- Design of analytical facilities and preparation of analytical procedures shall consider the design basis sample.
- Highly radioactive samples may not be compatible with generally accepted analytical procedures; in such cases, measurement of emissive gamma radiations and the use of shielding and distance factors should be considered in design.

Table 1.13-11

CONTAINMENT HIGH-RANGE RADIATION MONITOR (TABLE II.F.1-4)

REQUIREMENT -	The capability to detect and measure the radiation level within the reactor containment during and the following an accident.
RANGE -	1 rad/hr to 10^8 rads/hr (beta and gamma) or alternatively 1 R/hr to 10^7 R/hr (gamma only).
RESPONSE -	60 keV to 3 MeV photons, with linear energy response (±20%) for photons of 0.1 MeV to 3 MeV. Instruments must be accurate enough to provide usable information.
REDUNDANT -	A minimum of two physically separated monitors (i.e., monitoring widely separated spaces within containment).
DESIGN AND QUALIFICATION -	Category I instruments as described in Appendix A, except as listed below.
SPECIAL CALIBRATION -	In situ calibration by electronic signal substitution is acceptable for all range decades above 10 R/hr. In situ calibration for at least one decade below 10 R/hr shall be by means of calibrated radiation source. The original laboratory calibration is not an acceptable position due to the possible differences after in situ installation. For high-range calibration, no adequate sources exist, so an alternate was provided.
SPECIAL ENVIRONMENTAL QUALIFICATIONS -	Calibrate and type-test representative specimens of detectors at sufficient points to demonstrate linearity through all scales up to 10^6 R/hr. Prior to initial use, certify calibration of each detector at least one point per decade of range between 1 R/hr and 10^3 R/hr.

Table 1.13-12

INFORMATION REQUIRED FOR CONTROL ROOM HABITABILITY EVALUATION
(TABLE III.D.3.4-1)

(1) Control room mode operation, i.e., pressurization and filter recirculation for radiological accident isolation or chlorine release

(2) Control room characteristics:

- (a) air volume control room
- (b) control room emergency zone (control room, critical files, kitchen, washroom, computer room, etc.)
- (c) control room ventilation system schematic with normal and emergency air flow rates
- (d) infiltration leakage rate
- (e) high efficiency particulate air filter and charcoal absorber efficiencies
- (f) closest distance between containment and air intake
- (g) layout of control room, air intakes, containment building, and chlorine, or other chemical storage facility with dimensions
- (h) control room shielding including radiation streaming from penetrations, doors, ducts, stairways, etc.
- (i) automatic isolation capability-damper closing time, damper leakage and area
- (j) chlorine detectors or toxic gas (local or remote)
- (k) self-contained breathing apparatus availability (number)
- (l) bottled air supply (hours supply)
- (m) emergency food and potable water supply (how many days and how many people)
- (n) control room personnel capacity (normal and emergency)
- (o) potassium iodide drug supply

Table 1.13-12 (Cont'd)

(3) Onsite storage of chlorine and other hazardous chemicals:

- (a) total amount and size of container
- (b) closest distance from control room air intake

(4) Offsite manufacturing, storage, or transportation facilities of hazardous chemicals

- (a) identify facilities within a 5 mile radius
- (b) distance from control room
- (c) quantity of hazardous chemicals in one container
- (d) frequency of hazardous chemical transportation traffic (truck, rail, and barge)

(5) Technical specifications (refer to Standard Technical Specifications)

- (a) chlorine detection system
- (b) control room emergency filtration system including the capability to maintain the control room pressurization at $^1/_8$ inch water gauge, verification of isolation by test signals and damper closure times, and filter testing requirements.

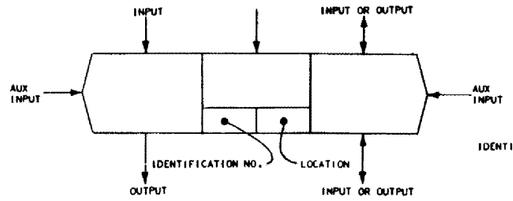
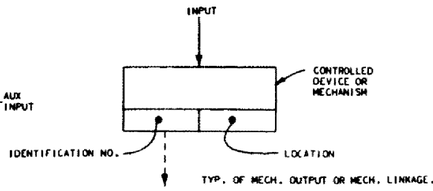
COMMAND BLOCK
THIS BLOCK CAN REPRESENT A SWITCH, VALVE, PROBE, TIMER, OR TRIP CIRCUIT. IT IS NORMALLY THE STARTING POINT OF A FUNCTIONAL SEQUENCE WITH AN OUTPUT ONLY, BUT CAN HAVE INPUT AND AUX. INPUT DEPENDING ON THE TYPE OF DEVICE. THE SAME DEVICE MAY HAVE A NUMBER OF OUTPUTS, BUT EACH FUNCTIONAL SEQUENCE INITIATED SHALL BE SHOWN BY AN INDIVIDUAL BLOCK SHOWING THE SAME IDENTIFICATION NUMBER.

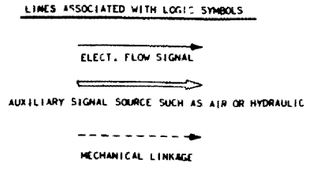


PERMISSIVE CONDITION BLOCK
WHERE THE PERMISSIVE IS A GENERAL CONDITION AND NOT IDENTIFIED WITH A SINGLE DEVICE THE OUTPUTS ENCLOSURE ONLY IS SHOWN



SEAL-IN BLOCK
A SEAL-IN OR LATCHING BLOCK'S FUNCTION IS TO MAINTAIN AN INPUT SIGNAL TO A DEVICE ONCE THE DEVICE HAS BEEN ACTUATED. RESETTING OR INHIBITING A SEAL-IN MAY BE EITHER EXPRESSED OR IMPLIED. IF IMPLIED, THE SEAL-IN WILL BE RESET OR INHIBITED BY INTERRUPTING THE SIGNAL TO THE DEVICE DOWNSTREAM FROM THE POINT WHERE SEAL-IN IS INDICATED. A SEAL-IN SHOWN WITHOUT A RESET DEVICE IMPLIES THAT THE RESET DEVICE IS PART OF, AND LOCATED ON THE NEAREST VALVE OR CONTACTOR. IN ALL OTHER CASES THE RESET DEVICE SHALL BE SHOWN IN CONJUNCTION WITH THE SEAL-IN.

PERMISSIVE DEVICE BLOCK
THIS BLOCK DEFINES A PERMISSIVE FUNCTION WHICH MUST BE SATISFIED TO PERMIT THE SIGNAL FLOW TO PASS TO THE NEXT BLOCK. THIS BLOCK HAS INCOMING, OUTGOING AND MAY HAVE AUXILIARY SIGNALS. THE OUTPUT FROM THIS PERMISSIVE MAY BE SEALED IN.



PERMISSIVE OPERATED BY OTHER DEVICES BLOCK
THIS BLOCK IS A PERMISSIVE OPERATED BY DEVICES SUCH AS VALVE OR PUMP SWITCHGEAR DESIGNATED IN THE INNER BLOCK. THIS COND. OR DEVICE EFFECTS THE OPERATION OF THE FINAL DEVICE. IT HAS ELECT. INPUTS, MECH INPUTS, AUX INPUTS (MECH OR ELEC) AND MECH OR ELECT OUTPUTS. THIS DEVICE IS NORMALLY A VALVE. THIS IS ALSO USED FOR OTHER INPUT/OUTPUT POWER SOURCES SUCH AS AIR OR HYDRAULIC. A SOLENOID PILOT VALVE FOR AN AIR OPERATED VALVE IS AN EXAMPLE OF THIS TYPE DEVICE.

FINAL DEVICE BLOCK
THIS BLOCK CAN BE A RELAY, VALVE, ELECTRO-MECH SW. ETC. NORMALLY IT HAS ONLY INPUTS, BUT CAN HAVE MECH OUTPUTS OR POSITION SWITCH OUTPUTS.

2.3 METEOROLOGY

2.3.1 Regional Climatology
2.3.1.1 General Climate
2.3.1.1.1 Air Masses and Synoptic Features
2.3.1.1.2 General Airflow
2.3.1.1.3 Temperature
2.3.1.1.4 Relative Humidity
2.3.1.1.5 Precipitation
2.3.1.1.6 Relationship Between Synoptic and Local Scale Meteorology
2.3.1.2 Regional Meteorological Conditions for Design and Operating Bases
2.3.1.2.1 Seasonal and Annual Frequencies of Severe Weather Phenomenon
2.3.1.2.2 Maximum Snow Load
2.3.1.2.3 Meteorological Design Basis for the Ultimate Heat Sink
2.3.1.2.4 Design Basis Tornado
2.3.1.2.5 Fastest Mile of Wind

2.3.2 Local Meteorology
2.3.2.1 Normal and Extreme Values of the Meteorological Parameters
2.3.2.1.1 Wind Direction and Speed
2.3.2.1.2 Atmospheric Stability
2.3.2.1.3 Temperature
2.3.2.1.4 Precipitation
2.3.2.1.5 Humidity
2.3.2.1.6 Fog
2.3.2.2 Potential Influence of the Plant and its Facilities on Local Meteorology
2.3.2.2.1 Turbulent Wake Effects From Plant Structures
2.3.2.2.2 Potential Effects of the Waste Heat Dissipation System on the Local Meteorology
2.3.2.3 Topography

2.3.3 Onsite Meteorological Measurements Program
2.3.3.1 Preoperational Meteorological Measurement System (1970-1983)
2.3.3.1.1 Measurements and Instrumentation
2.3.3.1.2 Calibration and Maintenance Procedures
2.3.3.1.3 Data Analysis Procedures
2.3.3.2 Operational Meteorological Measurement System (1983)
2.3.3.2.1 Measurements and Instrumentation
2.3.3.2.2 Calibration and Maintenance Procedures
2.3.3.2.3 Data Analysis Procedures
2.3.3.3 Offsite Meteorological Monitoring Locations
2.3.3.3.1 Philadelphia
2.3.3.3.2 Allentown
2.3.3.3.3 Peach Bottom Atomic Power Station

2.3.4 Short-Term (Accident) Diffusion Estimates
2.3.4.1 Objective
2.3.4.2 Calculations

TABLE OF CONTENTS (cont'd)

2.3.4.2.1 Calculation of X/Q Values at the EAB and LPZ
2.3.4.2.2 Determination of Max Sector and Overall 5% Site X/Q Values
2.3.4.2.2.1 Maximum Sector X/Q
2.3.4.2.2.2 5% Overall Site X/Q
2.3.4.2.3 Meteorological Input
2.3.4.2.4 Building Wake Correction
2.3.4.2.5 Short Term X/Q Modeling Results

2.3.5 Long-Term (Routine) Diffusion Estimates
2.3.5.1 Meteorological Input
2.3.5.2 Plume Rise
2.3.5.3 Diffusion Model
2.3.5.3.1 Source Configuration
2.3.5.3.2 Terrain Corrections
2.3.5.3.3 Atmospheric Stability
2.3.5.3.4 Dispersion Coefficients
2.3.5.3.5 Recirculation Correction Factors

2.3.6 References

2.4 HYDROLOGIC ENGINEERING

2.4.1 Hydrologic Description
2.4.1.1 Site and Facilities
2.4.1.2 Hydrosphere
2.4.1.2.1 Hydrologic Characteristics
2.4.1.2.2 Existing and Proposed Water-Control Structures
2.4.1.2.3 Surface Water Users Whose Intakes Could Be Adversely Affected by the Accidental Release of Contaminants

2.4.2 Floods
2.4.2.1 Flood History
2.4.2.2 Flood Design Considerations
2.4.2.3 Effects of Local Intense Precipitation
2.4.2.3.1 Drainage from Cooling Tower Area
2.4.2.3.2 Drainage From Spray Pond Area
2.4.2.3.3 Drainage from Power Plant Complex Area
2.4.2.3.4 Roof Loads on Safety-Related Structures That Are Due to PMP Onsite
2.4.2.3.5 PMF in Possum Hollow Run
2.4.2.3.6 Summary of Results - Local Intense Precipitation

2.4.3 Probable Maximum Flood on Steams and Rivers
2.4.3.1 Probable Maximum Precipitation
2.4.3.2 Precipitation Losses
2.4.3.3 Runoff and Stream Course Models
2.4.3.4 Probable Maximum Flood Flow
2.4.3.5 Water Level Determinations
2.4.3.5.1 Data Availability
2.4.3.5.2 Historical Floods
2.4.3.5.3 Water Level Determination up to 356,000 cfs

TABLE OF CONTENTS (cont'd)

2.4.3.5.4 Water Level Determination for Flows Above 356,000 cfs
2.4.3.6 Coincident Wind-Wave Activity

2.4.4 Potential Dam Failures, Seismically Induced
2.4.4.1 Dam Failure Permutations
2.4.4.2 Unsteady Flow Analysis of Potential Dam Failures
2.4.4.3 Water Level at Plant Site
2.4.4.3.1 Maximum Computed Water Surface and Wave Effects
2.4.4.3.2 Recapitulation of Conservative Steps in Dam Break Analysis

2.4.5 Probable Maximum Surge and Seiche Flooding

2.4.6 Probable Maximum Tsunami Flooding

2.4.7 Ice Effects

2.4.8 Cooling Water Canals and Reservoirs
2.4.8.1 General Description of the Spray Pond
2.4.8.2 Hydrologic Design Bases
2.4.8.2.1 Design Basis Flood Level
2.4.8.2.2 Safe Shutdown and Operating Basis Earthquakes
2.4.8.3 Low Level Outlet Facilities

2.4.9 Channel Diversions

2.4.10 Flooding Protection Requirements

2.4.11 Low Water Considerations

2.4.12 Dispersion, Dilution, and Travel Times of Accidental Releases of Liquid Effluents in Surface Waters

2.4.13 Groundwater
2.4.13.1 Description and Onsite Use
2.4.13.1.1 Groundwater Aquifer
2.4.13.1.2 Aquifer Recharge and Discharge
2.4.13.1.3 Onsite Use of Groundwater
2.4.13.2 Sources
2.4.13.2.1 Regional Use of Groundwater
2.4.13.2.2 Use of Groundwater in the Vicinity of the Site
2.4.13.2.3 Projected Future Use of Groundwater
2.4.13.2.4 Water Levels and Groundwater Movement
2.4.13.2.5 Aquifer Parameters
2.4.13.2.6 Reversibility of Groundwater Flow
2.4.13.2.7 Water Quality
2.4.13.3 Accident Effects
2.4.13.3.1 Groundwater Movement
2.4.13.3.2 Analytical Model for Radionuclide Migration
2.4.13.3.3 Radionuclide Ion Velocity and Travel Time
2.4.13.3.4 Dispersivity (Dispersion Constant)

TABLE OF CONTENTS (cont'd)

2.4.13.3.5 Results of Analysis
2.4.13.4 Monitoring and Safeguard Requirements
2.4.13.5 Design Bases for Subsurface Hydrostatic Loading

2.4.14 Technical Specification and Emergency Operation Requirements

2.4.15 References

2.5 GEOLOGY AND SEISMOLOGY

2.5.1 Basic Geologic and Seismic Data
2.5.1.1 Regional Geology
2.5.1.1.1 Regional Physiography and Geomorphology
2.5.1.1.2 Regional Stratigraphy
2.5.1.1.3 Regional Geologic Structure
2.5.1.1.4 Geologic History

2.5.1.2 Site Geology
2.5.1.2.1 General
2.5.1.2.2 Physiography
2.5.1.2.3 Stratigraphy
2.5.1.2.4 Structure
2.5.1.2.5 Fracture Zones in the Site Area
2.5.1.2.6 Site Geologic History
2.5.1.2.7 Engineering Geology Evaluation
2.5.1.2.8 Site Groundwater Conditions

2.5.2 Vibratory Ground Motion
2.5.2.1 Seismicity
2.5.2.1.1 Regional Seismicity
2.5.2.1.2 Local Seismicity
2.5.2.2 Geologic Structures and Tectonic Activity
2.5.2.2.1 Regional Geologic Setting
2.5.2.2.2 Regional Tectonic Provinces
2.5.2.2.3 Regional Tectonic Structures
2.5.2.3 Correlation of Earthquake Activity with Geologic Structures or Tectonic Provinces
2.5.2.3.1 Tectonic Models Relating Seismicity to Geologic Structure
2.5.2.4 Maximum Earthquake Potential
2.5.2.5 Seismic Wave Transmission Characteristic of the Site
2.5.2.6 Safe Shutdown Earthquake
2.5.2.7 Operating Basis Earthquake

2.5.3 Surface Faulting
2.5.3.1 Geologic Conditions of the Site
2.5.3.2 Evidence of Fault Offset
2.5.3.2.1 Geologic Structures in the LGS Site Excavation
2.5.3.3 Earthquakes Associated with Capable Faults
2.5.3.4 Investigation of Capable Faults
2.5.3.5 Correlation of Epicenters with Capable Faults

TABLE OF CONTENTS (cont'd)

2.5.3.6 Descriptions of Capable Faults
2.5.3.7 Zone Requiring Detailed Fault Investigation
2.5.3.8 Results of Faulting Investigation

2.5.4 Stability of Subsurface Materials and Foundations
2.5.4.1 Geologic Features
2.5.4.2 Properties of Subsurface Materials
2.5.4.2.1 Properties of Foundation Rocks
2.5.4.2.2 Properties of Foundation Soils

2.5.4.3 Exploration
2.5.4.4 Geophysical Surveys
2.5.4.4.1 Seismic Refraction Survey
2.5.4.4.2 Shear-Wave Velocity Survey
2.5.4.4.3 Up-Hole Velocity Survey
2.5.4.4.4 Micromotion Measurements
2.5.4.5 Excavations and Backfill
2.5.4.5.1 Main Power Block and Cooling Tower Excavation
2.5.4.5.2 Diesel Generator Enclosure Excavation
2.5.4.5.3 Spray Pond Excavation, Slope Protection and Liner Construction
2.5.4.5.4 Fills - General
2.5.4.5.5 Miscellaneous Category I Facilities - Excavation and Backfill
2.5.4.6 Groundwater Conditions
2.5.4.6.1 Spray Pond Seepage Analysis
2.5.4.6.2 Dewatering During Construction
2.5.4.6.3 Groundwater Monitoring
2.5.4.7 Response of Soil and Rock to Dynamic Loading
2.5.4.7.1 Response of Soil Along Pipelines
2.5.4.8 Liquefaction Potential
2.5.4.9 Earthquake Design Basis
2.5.4.10 Static Stability
2.5.4.10.1 Static Stability of Safety-Related Structures on Rock
2.5.4.10.2 Static Stability of Safety-Related Structures on Soil
2.5.4.11 Design Criteria
2.5.4.11.1 Design Criteria For Safety-Related Structures on Rock
2.5.4.11.2 Design Criteria For Safety-Related Structures on Soil
2.5.4.12 Techniques to Improve Subsurface Conditions
2.5.4.12.1 Treatment of Fracture Zones and Clay Seams - Main Power Block Area
2.5.4.12.2 Treatment of Fracture Zones and Clay Seams - Spray Pond and Other Areas
2.5.4.13 Subsurface Instrumentation

2.5.5 Stability of Slopes
2.5.5.1 Slope Characteristics
2.5.5.1.1 Geologic Conditions
2.5.5.1.2 Exploration - Emergency Spray Pond
2.5.5.1.3 Laboratory Testing of Soils
2.5.5.2 Design Criteria and Analyses
2.5.5.2.1 Stability of Rock Slope
2.5.5.2.2 Design Criteria for Soil Slopes

TABLE OF CONTENTS (cont'd)

2.5.5.2.3 Methods of Slope Stability Analyses
2.5.5.2.4 Design Parameters
2.5.5.2.5 End of Construction Under Static Conditions
2.5.5.2.6 Rapid Drawdown Under Static Conditions
2.5.5.2.7 Long-Term Stability Under Static Conditions
2.5.5.2.8 Long-Term Stability Under Seismic Conditions
2.5.5.3 Logs of Borings
2.5.5.4 Compacted Fill
2.5.5.4.1 Soil-Bentonite Liner and Soil Cover
2.5.5.4.2 Riprap and Riprap Bedding
2.5.5.4.3 Construction
2.5.5.4.4 Seepage Test
2.5.5.5 Dikes

2.5.6 References

CHAPTER 2 - SITE CHARACTERISTICS

LIST OF TABLES

TABLE	TITLE
2.1-1	Population Distribution, 0-10 Miles, 1970
2.1-2	Population Distribution, 0-10 Miles, 1980
2.1-3	Population Distribution, 0-10 Miles, 1985
2.1-4	Population Distribution, 0-10 Miles, 1990
2.1-5	Population Distribution, 0-10 Miles, 2000
2.1-6	Population Distribution, 0-10 Miles, 2010
2.1-7	Population Distribution, 0-10 Miles, 2020
2.1-8	Population Distribution, 10-50 Miles, 1970
2.1-9	Population Distribution, 10-50 Miles, 1980
2.1-10	Population Distribution, 10-50 Miles, 1985
2.1-11	Population Distribution, 10-50 Miles, 1990
2.1-12	Population Distribution, 10-50 Miles, 2000
2.1-13	Population Distribution, 10-50 Miles, 2010
2.1-14	Population Distribution, 10-50 Miles, 2020
2.1-15	Sources of Projected Populations
2.1-16	Bureau of Census Populations of Counties Within 50 Miles of the Site
2.1-17	Industries Within 5 Miles of the Site
2.1-18	Comparative Cumulative Populations for 1985
2.1-19	Comparative Cumulative Populations for 2020
2.2-1	Hooker Chemical Company
2.2-2	Pipelines Within 5 Miles of the Site
2.2-3	Airports Within 10 Miles of the Site

LIST OF TABLES (cont'd)

TABLE	TITLE
2.2-4	Airways Within 10 Miles of the Site
2.2-5	Onsite Chemical Storage
2.2-6	Deleted
2.2-7	Summary of Peak Positive Reflected Pressures Resulting from Railroad and Natural Gas Pipeline Explosion
2.3.1-1	Comparison of Annual Wind Direction Frequency Distribution
2.3.1-2	Mean Monthly Temperature Comparison
2.3.1-3	Comparison of Mean Morning and Afternoon Relative Humidity
2.3.1-4	Distribution of Precipitation, Philadelphia International Airport
2.3.1-5	Distribution of Precipitation, Allentown Airport
2.3.1-6	Mean Number of Thunderstorm Days per Year in the LGS Vicinity
2.3.1-7	LGS Design Basis Tornado Parameters
2.3.1-8	LGS Vertical Profile of the 100 Year Recurrence Interval Fastest Mile of Wind
2.3.1-9	Summary of Hurricanes and Tropical Storms Affecting the LGS Vicinity Between 1963 and 1980
2.3.2-1	LGS Percent Data Recovery for Meteorological Sensors
2.3.2-2	LGS Comparison of Annual Wind Direction Frequency Distributions, Weather Station No. 1
2.3.2-3	LGS Monthly Average Wind Speeds, Weather Station No. 1
2.3.2-4	LGS Comparison of Annual Wind Direction Frequency Distributions, Weather Station No. 1
2.3.2-5	LGS Comparison of Annual Wind Direction Frequency Distributions, Weather Station No. 2
2.3.2-6	LGS Comparison of Annual Wind Direction Frequency Distributions from Equivalent MSL Heights
2.3.2-7	LGS Comparison of Annual Wind Direction Frequency Distributions Low Level Sensors
2.3.2-8	LGS Comparison of Monthly Average Wind Speeds

LIST OF TABLES (cont'd)

TABLE	TITLE
2.3.2-9	Comparison of Wind Speed Frequency Distributions
2.3.2-10	LGS Annual Frequency Distribution of Brookhaven Turbulence Classes, Weather Station No. 1
2.3.2-11	LGS Annual Frequency Distribution of Pasquill Stability Classes by NRC Lapse Rate Criteria, Weather Station No. 1
2.3.2-12	LGS Annual Frequency Distribution of Brookhaven Turbulence Classes
2.3.2-13	LGS Annual Frequency Distribution of Pasquill Stability Classes by NRC Lapse Rate Criteria
2.3.2-14	Brookhaven National Laboratory Turbulence Classification
2.3.2-15	LGS Mean Morning and Afternoon Mixing Heights
2.3.2-16	LGS Temperature Means and Extremes, Weather Station No. 1
2.3.2-17	Comparison of Monthly Mean Temperatures, LGS versus Philadelphia
2.3.2-18	Comparison of Monthly Mean Temperatures, LGS versus Allentown
2.3.2-19	LGS Monthly Precipitation Distribution, Weather Station No. 1
2.3.2-20	Comparison of Monthly Mean Precipitation, LGS versus Philadelphia
2.3.2-21	Comparison of Monthly Mean Precipitation, LGS versus Allentown
2.3.2-22	Comparison of Mean Morning and Afternoon Relative Humidity
2.3.2-23	Comparison of Frequency Distributions of Daily Average Relative Humidity Values
2.3.2-24	Comparison of Annual Frequency Distributions of Hourly Relative Humidity Values
2.3.2-25	Mean Number of Days with Heavy Fog
2.3.2-26	Offsite Elevation versus Distance from LGS Vents
2.3.2-27	LGS Joint Frequency Distribution of Calm Hours, 1972-1976, Weather Station No. 1, 30 ft Level
2.3.2-28	LGS Joint Frequency Distribution of Calm Hours, 1972-1976, Weather Station No. 1, 175 ft Level

LIST OF TABLES (cont'd)

TABLE	TITLE
2.3.2-29	LGS Joint Frequency Distribution of Calm Hours, 1972-1976, Weather Station No. 1, 270 ft Level
2.3.2-30	LGS Joint Frequency Distribution of Calm Hours, 4/72-3/73, Weather Station No. 2, 30 ft Level
2.3.2-31	LGS Joint Frequency Distribution of Calm Hours, 4/72-3/73, Weather Station No. 2, 159 ft Level
2.3.2-32	LGS Joint Frequency Distribution of Calm Hours, 4/72-3/73, Weather Station No. 2, 304 ft Level
2.3.2-33	LGS Joint Frequency Distribution of Calm Hours, 1/75-12/76, Satellite Tower, 32 ft Level
2.3.3-1	Instrument Elevations, Preoperational Meteorological Measurement System (1970-1983)
2.3.3-2	Preoperational Meteorological Measurement System (1970-1983) Sensor and System Specifications and Accuracies
2.3.3-3	LGS Percent of Hours with Calm Winds
2.3.3-4	Station Locations - Philadelphia
2.3.3-5	Station Locations - Allentown
2.3.3-6	Instrument Elevations, Operational Meteorological Measurement System (1983)
2.3.3-7	Operational Meteorological Measurement System (1983) Sensor and System Specifications and Accuracies
2.3.4-1	Joint Frequency Distribution
2.3.4-2	Lapse Rate Wind Distributions
2.3.4-3	LGS Effective Probability Levels
2.3.4-4	Summary of the North and South Stacks Maximum Sector and 5% Overall Site Limit X/Q Values at the EAB and LPZ for Regulatory Post-Accident Time Periods
2.3.4-5	LGS Stability and Wind Speed Distributions
2.3.5-1	Historical Annual X/Q - Uncorrected
2.3.5-2	LGS Vent Parameters

LIST OF TABLES (cont'd)

TABLE	TITLE
2.4-1	Access Openings in Safety-Related Structures
2.4-2	Minor Dams Upstream of LGS Site
2.4-3	Dam Failure Investigation: Characteristics of Major Upstream Dams
2.4-4	Domestic Water Users on Schuylkill River Downstream of LGS Site
2.4-5	Industrial Water Users on Schuylkill River Downstream of LGS Site
2.4-6	Major Floods at Selected Stations on Schuylkill River
2.4-7	Probable Maximum Precipitation at LGS Site
2.4-8	Summary of Run-off from Local Intense Precipitation
2.4-9	Surface Water Gauging Stations Upstream from LGS Site
2.4-10	Observed and Estimated Water Surface Elevations of Schuylkill River at LGS Site
2.4-11	Derived Values of Manning's (n) for Schuylkill River Main Channel
2.4-12	Computation of Convergence in Backwater Study
2.4-13	Conveyance, Slope, and Stage for Selected Discharges above 356,000 cfs at LGS Site
2.4-14	Chemical Analysis of Groundwater in the Brunswick Lithofacies in Montgomery County, Pennsylvania
2.4-15	Public Groundwater Supplies
2.4-16	Private Groundwater Users in the Vicinity of the Site
2.4-17	Observation Well Construction Data
2.4-18	Permeability Data
2.4-19	Chemical Analysis of Groundwater from Wells in the Brunswick Lithofacies at the LGS Site
2.4-20	Accidental Spill Analysis Parameters
2.4-21	Summary of Groundwater Level Measurements Used to Establish Design Bases for Hydrostatic Loading
2.4-22	Parameters Used in Rational Formula and Kirpich's Formula

LIST OF TABLES (cont'd)

TABLE	TITLE
2.4-23	Drainage Flow Path Cross-Sectional Data
2.5-1	Modified Mercalli Intensity Scale of 1931
2.5-2	Earthquakes with Epicenters Within Approximately 200 Miles of the Site
2.5-3	Unconfined Compression Tests on Rock Samples
2.5-4	Summary of Engineering Properties of In Situ Soil
2.5-5	Summary of Design Parameters of Soils and Soil-Bentonite Mixtures
2.5-6	Soil Test Results Summary (Spray Pond Test Pits)
2.5-7	Results of Stability Analysis (2H:1V Rock Slope -Spray Pond)
2.5-8	Earthquakes With Epicenters Within Approximately 50 Miles of the Site
2.5-9	Design Parameters of Safety-Related Structures
2.5-10	Soil-Response Study: Summary of Parameters and Results
2.5-11	Representative Engineering Properties of Sound Foundation Rock
2.5-12	Static Moduli of Foundation Rock
2.5-13	Sonic Tests on Intact Cores

CHAPTER 2 - SITE CHARACTERISTICS

LIST OF FIGURES

FIGURE	TITLE
2.1-1	Site Location Map
2.1-2	General Site Area Map
2.1-3	Site Plan
2.1-4	Principal Facility Structures Plot Plan and Normal Release Points for Effluent
2.1-5	Population Distribution Grid, 0-10 Miles
2.1-6	Population Distribution Grid, 10-50 Miles
2.1-7	Low Population Zone
2.2-1	Transportation Routes and Pipelines
2.2-2	Industries Within the LPZ
2.2-3	Airports and Airway Routes
2.2-4	ARCO and Columbia Gas Pipelines
2.3.1-1	Tangential Velocity Distribution
2.3.1-2	Derivation of Design Tornado Wind Velocity
2.3.2-1	LGS versus Philadelphia Wind Direction Percentage
2.3.2-2	LGS versus Allentown Wind Direction Percentage
2.3.2-3	LGS versus Peach Bottom Wind Direction Percentage
2.3.2-4	Philadelphia Wind Direction Percentage
2.3.2-5	Allentown versus Allentown Wind Direction Percentage at 20 and 270 feet
2.3.2-6	Typical Light Wind Traces
2.3.3-1	Location of Meteorological Instruments
2.3.3-2	Elevations of Meteorological Instruments at LGS Site

LIST OF FIGURES (cont'd)

FIGURE	TITLE
2.3.4-1	Cumulative Probability Distribution of X/Q for the Exclusion Boundary
2.3.4-2	Cumulative Probability Distribution of X/Q for the LPZ Boundary
2.3.4-3	Accident X/Q Value for Release Periods Greater Than 2 Hours at the Exclusion Area Boundary
2.3.4-4	Accident X/Q Value for Release Periods Greater Than 2 Hours at the LPZ Boundary
2.3.5-1	Comparisons of Annual X/Q Values Using 175' Level with ESE Sector Wind
2.4-1	Site Plan
2.4-2	Schuylkill River Basin Water Use
2.4-3	Schuylkill River Dams Upstream from LGS Site
2.4-4	Intense Storm Site Runoff Pattern: General Plan
2.4-5	Intense Storm Site Runoff Pattern: Spray Pond and Cooling Tower Areas
2.4-6	Intense Storm Site Runoff Pattern: Sections and Details (3 sheets)
2.4-7	Schuylkill River Discharge Rating Curve at LGS Site
2.4-8	Schuylkill River Basin
2.4-9	Schuylkill River High-Water Profile: Flood of June 22, 1972
2.4-10	Schuylkill River Flood Frequency at Pottstown, PA
2.4-11	Schuylkill River Below Pottstown, PA, Backwater Section Location
2.4-12	Computed Water Surface Profile at LGS Site
2.4-13	Relation Between Friction Slope and Discharge of Schuylkill River at LGS Site
2.4-14	Floods Due to Dam Failure: River Profile and Dam Location Map
2.4-15	Observation Wells and Potentiometric Contours of Water Table: May 25, 1979 and May 31, 1988
2.4-16	Public Groundwater Suppliers Within 20 Miles of the Site
2.4-17	Groundwater Users Within One Mile of the Site

LIST OF FIGURES (cont'd)

FIGURE	TITLE
2.4-18	Hydrographs of Observation Wells (Spray Pond Area and Power Block Area)
2.4-19	Daily Precipitation & Elevation of Water in Observation Wells, Power Block Area
2.4-20	Total Monthly Precipitation: 36 Month Monitoring Period
2.4-21	Cross-Section of Schuylkill River at Hypothetical Dam Site (Looking Upstream)
2.4-22	Cross-Section of Schuylkill River at LGS (Looking Upstream)
2.4-23	Cross-Section of Schuylkill River near Birdsboro (Looking Upstream)
2.4-24	Cross-Section of Representative Prismatic Channel
2.5-1	Physiographic Divisions
2.5-2	Regional Geology
2.5-3	Regional Geologic Section
2.5-4	Regional Stratigraphic Column
2.5-5	Regional Tectonic Map
2.5-6	Geology of the Limerick-Pottstown Area
2.5-7	Bouguer Gravity Anomaly Map
2.5-8	Aeromagnetic Intensity in the Limerick-Pottstown Region
2.5-9	Top of Rock Contours
2.5-10	Geologic Section
2.5-11	Geologic Section
2.5-12	Stratigraphic Section, Site and Vicinity
2.5-13	Geologic Map and Supplemental Photographs A through F, Power Block Excavation
2.5-14	Significant Earthquake Epicenters (1737 through January 1982) and Regional Tectonic Map
2.5-15	Earthquake Epicenters Within 25 Miles of Site

CHAPTER 2 - SITE CHARACTERISTICS

2.1 GEOGRAPHY AND DEMOGRAPHY

2.1.1 SITE LOCATION AND DESCRIPTION

2.1.1.1 Specification of Location

Limerick Generating Station is located in southeastern Pennsylvania on the Schuylkill River, about 1.7 miles southeast of the limits of the Borough of Pottstown and about 20.7 miles northwest of the Philadelphia city limits. The Schuylkill River passes through the site, separating the western portion located in East Coventry Township, Chester County, from the eastern portion located in Limerick Township and Pottsgrove Township, Montgomery County, Pennsylvania. Figure 2.1-1 identifies the general location of the LGS site, and Figure 2.1-2 shows the immediate environs within 5 miles of the site.

The Universal Transverse Mercator coordinates of the LGS Unit 1 reactor are 4,452,582.462 meters north and 449,984.170 meters east, Zone 18T. The corresponding Greenwich coordinates for Unit 1 are 40°13'26.67" north latitude and 75°35'16.27" west longitude. The Unit 2 reactor is located at 4,452,528.462 meters north and 450,033.548 meters east, Zone 18T of the Transverse Mercator Coordinate System with corresponding 40°13'26.64" north latitude and 75°35'14.15" west longitude coordinates.

2.1.1.2 Site Area

The land portion of the site consists of 595 acres, as shown in Figure 2.1-3. The property within the site boundary is owned by the licensee except as noted below. The site boundary is shown in Figure 2.1-3. The licensee owns additional property adjacent to the site on which the nuclear training center is located. This property is not considered part of the site. As shown in Figure 2.1-3, the site is traversed by several public roads, a railroad right-of-way and the Schuylkill River. These areas, including the island in the river, are considered public passageways and not part of the site property.

The site is located in gently rolling countryside, traversed by numerous valleys containing small streams which empty into the Schuylkill River. On the eastern bank of the Schuylkill River the terrain rises from just under el 110' MSL (mean sea level) at the river, to approximately el 300' MSL toward the east, which is the highest ground on the site boundary. Two parallel streams, Possum Hollow Run and Brooke Evans Creek, cut through the site in wooded valleys, running southwest into the Schuylkill River. The grade in the area of the reactor and turbine enclosures is about el 217 feet MSL. On the western bank of the river, the terrain is relatively flat, rising only about 50 feet from the shore to the western edge of the site. One small stream flows southeastward through the site to the Schuylkill River.

The locations of principal station structures are shown in Figure 2.1-4. In addition, the Limerick Energy Information Center is located on the site property. The information center, owned and operated by the licensee, is open to the public during specified hours. Admission to the information center is controlled by the licensee.

A nuclear training center consisting of a simulator, laboratories and classrooms is located on the licensee property adjacent to the site. This facility is operated and controlled by the licensee.

2.1.1.3 Boundaries for Establishing Effluent Release Limits

The boundary line of the restricted area, as defined in pre-1994 10CFR20, is identical to the site boundary line shown in Figure 2.1-3. The land area within the boundary lines is owned by the licensee. Control of public passageways is discussed in Section 2.1.2.1 and 2.1.3.3.

There are no permanent residences within the restricted area.

Station effluent release points are shown in Figure 2.1-4.

2.1.2 Exclusion Area Authority And Control

2.1.2.1 Authority

The exclusion area for LGS, shown in Figure 2.1-3, is defined as the area encompassed by a radius of 2500 feet from the center of each reactor unit. The property within the exclusion area is either owned or controlled by the licensee. Following fuel load, residence within the exclusion area will be prohibited in conformance with 10CFR100.

The Controlled Areas, as defined in the post-1994 10CFR20 Regulation, may be established within the Site Boundary line outside the Restricted Area. LGS has no Controlled Areas because of the Restricted Area boundary extends all the way out to the Site Boundary line.

As shown in Figure 2.1-3, the exclusion area is traversed by several public roads, a Conrail right-of-way, and the Schuylkill River. These areas, including the island in the river, are considered public passageways and not part of the site property. Arrangements for control of public access to these areas in the event of an emergency are discussed in Section 2.1.2.3.

There are no outstanding mineral rights within the exclusion area.

2.1.2.2 Control of Activities Unrelated to Plant Operation

Activities unrelated to plant operation that occur within the exclusion area, aside from transit through the area, are those associated with the Limerick Energy Information Center, located approximately 1500 feet from the plant along Longview Road and Frick's Lock. About 6,000 people are expected to visit the Information Center each year. The number of visitors to the center seldom exceeds 100 at any one time. Evacuation of these people is discussed in the Emergency Plan.

2.1.2.3 Arrangements for Traffic Control on Public Passageways

Arrangements have been made with the Pennsylvania State Police to control public access to the exclusion area in the event of an emergency.

Arrangements have been made with Conrail to control rail traffic through the exclusion area in the event of an emergency.

Letters of agreement between the licensee and the State Police are referenced in the Emergency Plan.

2.1.2.4 Abandonment or Relocation of Roads

Prior to station construction, Longview Road traversed the site in a southerly direction from the juncture of Sanatoga Road and Possum Hollow Road to the railroad right-of-way on the eastern bank of the Schuylkill River. This portion of Longview Road, approximately 6000 feet, was abandoned and relocated to the eastern edge of the LGS site on a portion of roadway formerly known as Lozark Road. New sections of the roadway were constructed to realign Longview Road and Lozark Road between Keen Road and the existing paving on Longview Road South of Brook Evans Creek. Both Longview and Lozark Roads are township roads.

2.1.3 POPULATION DISTRIBUTION

2.1.3.1 Population Within 10 Miles

The population distributions within 10 miles, as a function of distance and direction, for the decades 1970 through 2020 and for the year 1985 are listed in Tables 2.1-1 through 2.1-7. The 1970 and 1980 data are taken from actual census data; the other years are taken from projections (Table 2.1-15). The 1985 projections are considered to be representative of the population near the year of initial station operation, and the 2020 projections represent population near the end of station operation. These projections are based on 1980 census data. The 1980 data shows that population has decreased. A map, keyed to Tables 2.1-1 through 2.1-7, is provided in Figure 2.1-5.

The population distribution within 10 miles is based upon the number of households obtained from a 1980 meter count of PECO Energy Co.'s residential customer billing file, and upon a 1980 meter count of Metropolitan Edison Company's billing file. A factor of 2.88 persons per residential meter in PECo territory and a factor of 2.70 persons per residential meter for the Metropolitan Edison Company territory were used to convert the meter count into population.

Projected populations were determined by using county projection factors obtained from state agencies. Where information was not available to 2020, the licensee extended the available information through that year. Table 2.1-15 lists the sources of population information.

Population for the year 1985 was estimated by the licensee by interpolation of data between 1980 and 1990. Projections for the years 2010 and 2020 were made by increasing projections for the year 2000 at a rate of 20% per 10 year period.

2.1.3.2 Population Between 10 and 50 Miles

Population distribution between 10 and 50 miles for the decades 1970 through 2020 and for the year 1985 are listed in Tables 2.1-8 through 2.1-14. The 1970 and 1980 data are taken from actual census data; the other years are based on projections (Table 2.1-15). A map, keyed to Tables 2.1-8 through 2.1-14, is provided in Figure 2.1-6.

Projected populations were determined by using county projection factors obtained from state agencies. Where information was not available to 2020, the licensee extended the available information through that year. Table 2.1-15 lists the sources of population information.

Population changes for 1950 through 1980 in the counties within 50 miles of the station are indicated in Table 2.1-16.

2.1.3.3 Transient Population

The transient population in the site area is classified as daily or seasonal. The daily transients result from the influx of employees to local business and industrial facilities. Local industries, and their location and employment, are listed in Table 2.1-17. The only industries with a significant daily transient population are Mrs. Smith's Pie Company, Sircom Knitting Company, and Crouse Company.

A 1976 creel survey of people fishing the Schuylkill River within 3.1 miles of the station showed that 96% lived within 6.2 miles of the river and thus do not comprise a transient population. These data also projected 1980 fishing pressure within 3.1 miles of the station at 8800 angler hours for the principal fishing months of May through September. The average time spent fishing was 3.5 hours from shore and 4.7 hours by boat. Less than 20% of the fishing pressure came from boats. Based on these data and data collected in a 1980 creel survey conducted as part of the LGS preoperational program, an average of 1100 boaters per year could be expected to use the Schuylkill River within 10 miles of the station, most of which would occur below Vincent Dam (3.3 miles below the station).

2.1.3.4 Low Population Zone

The LPZ established for LGS, in accordance with 10CFR100, consists of the area within a radius of 1.27 miles (2043 meters). The LPZ and the estimated population within the LPZ are shown in Figure 2.1-7. Population estimates are based on the 1980 meter count.

There are no schools, parks, hospitals, prisons, or public beaches within the LPZ. Industrial facilities within the LPZ include Occidental Chemical Corporation, Amerind-MacKessie, Inc, Mahr Printing, Inc, Structural Foam, Inc, Eastern Warehouse, Inc, and Pottstown Trap Rock Quarries, Inc. The locations of these facilities are shown in Figure 2.2-2, and the number of employees at each location is listed in Table 2.1-17.

Other facilities, located outside of the LPZ, that may require special consideration include the following:

a. Pottstown Memorial Medical Center, with approximately 400 patients and 840 employees. The hospital is located 1.8 miles northwest of the station.

b. Graterford Prison, an 1800 inmate maximum security State Prison. The prison is located approximately 8.3 miles from the station.

c. The Montgomery County Geriatric Center, a 600 patient care facility, is located 5.1 miles from the station.

2.1.3.5 Population Center

The nearest population center, as defined in 10CFR100, is Pottstown Borough, which had a 1980 population of 22,729. The nearest boundary of the borough is 1.7 miles northwest of the station, and is outside the LPZ as defined in Section 2.1.3.4. The transient population in the immediate area does not influence the selection of the population center. The population of the borough is projected to reach 28,195 by 1983, and 46,653 by the year 2020. Based on 1980 census information, these population estimates are probably conservative. The population density in 1970 was estimated to be 5282 persons per square mile, and is expected to grow to 5874 by 1983 and to 9719 by 2020 based on state projections that used 1970 census information. Based on the 1980 census, the population density is estimated to be 4735 persons per square mile in 1980.

2.1.3.6 Population Density

Table 2.1-18 provides a comparison of cumulative population projected for 1985, representative of the initial year of operation, with a cumulative population resulting from a uniform population density of 500 people per square mile in all directions from the plant. Table 2.1-19 provides a comparison of cumulative population projected for 2020, the assumed final year of operation, with a cumulative population resulting from a uniform population density of 1000 people per square mile.

2.2 NEARBY INDUSTRIAL, TRANSPORTATION, AND MILITARY FACILITIES

2.2.1 LOCATIONS AND ROUTES

The major transportation routes located within 5 miles of the site include the following:

a. U.S. Route 422, an east-west highway passing approximately 1½ miles north of the site;

b. Pennsylvania Route 100, a north-south highway passing approximately 4 miles west of the site;

c. Pennsylvania Route 724, a southeast-northwest highway passing approximately 1 mile southwest of the site;

d. The Consolidated Rail Corporation (ConRail) line (formerly Reading Company) passing through the site along the east bank of the Schuylkill River. The line is comprised of two tracks, and has a rail spur serving the station; and

e. The ConRail line (formerly Penn Central Railroad) running north-south, and passing along the western boundary of the site.

These transportation routes are shown on Figure 2.2-1.

Oil and natural gas pipelines located within five miles of the site are shown in Figures 2.2-1 and 2.2-4 and Table 2.2-2, and are described in Section 2.2.2.3.

There is one quarry, Pottstown Trap Rock Quarry Inc, located about 0.8 miles from the site. Operations at the quarry consist of blasting, crushing, grading, and storing lightweight rock. The location of the quarry is shown on Figure 2.2-2.

Industries located within 5 miles of the site are listed in Table 2.1-17. A further discussion is provided in Section 2.2.2.1. The locations and description of airports are provided in Section 2.2.2.5.

There are no military installations within 5 miles of the site.

2.2.2 DESCRIPTIONS

2.2.2.1 Description of Facilities

Industries within 5 miles of LGS, with ten or more employees, are listed in Table 2.1-17. The number of employees, products, and locations are listed for each establishment.

The industry nearest the site is the Pottstown Trap Rock Quarry, Inc. Operations at the quarry include the detonation of explosives in the process of quarrying stone. However, the use of explosives is infrequent, and only enough explosives are brought to the quarry for one particular application. There are no explosives stored on the quarry site. The maximum quantity of explosives detonated at the quarry at any time was 11,700 pounds in 20 delays at 585 lb/delay. Explosives are transported to the quarry by the blaster by truck via Route 422, Evergreen Road and Sanatoga Road. Other industries located within 1.3 miles of LGS include Hooker Chemical Company, Mahr Printing, Inc., Eastern Warehouses, Inc., Amerind-MacKissic, Inc., and Structural

Foam, Inc. The location of these industries is shown on Figure 2.2-2. Occidental Chemical Corporation is the only establishment near LGS which has significant quantities of hazardous materials stored onsite.

2.2.2.2 Descriptions of Products and Materials

Hazardous materials stored near LGS consist of those stored by Occidental Chemical Corporation (These are listed in Table 2.2-1). Explosives and hazardous materials may be transported on the highways and railroads. Explosives and hazardous materials are discussed in Sections 2.2.3.1.1 and 2.2.3.1.3, respectively.

2.2.2.3 Pipelines

As shown in Figures 2.2-1 and 2.2-4, there is a natural gas pipeline adjacent to the site, consisting of two separate pipes, operated by the Columbia Gas Transmission Company, and an oil and gasoline pipeline operated by Sunoco within the site area. The closest distances of approach of these lines to the plant safety-related structures are:

	Sunoco (ft)	Columbia Gas(ft)
Reactor Enclosure, Unit 1	1775.0	3650.0
Reactor Enclosure, Unit 2	1625.0	3487.5
Diesel Generator Enclosure, Unit 1	1837.5	3662.5
Diesel Generator Enclosure, Unit 2	1675.0	3510.0
Spray Pond Pump Structure	1962.5	3600.0

Other pipelines within 5 miles of LGS are operated by PECO Energy, Buckeye Partners, Texas Eastern Transmission Corp. Pipe sizes, age, operating pressure, etc., are listed in Table 2.2-2. At the present time, there are no plans to utilize these pipelines to transport products different than those currently transported.

2.2.2.4 Waterways

There is no commercial traffic on the Schuylkill River in the vicinity of the site, due to the presence of downstream dams. Some small pleasure boating does occur in warmer weather. This, however, is relatively minor.

2.2.2.5 Airports

All landing fields within 10 miles of the site are listed in Table 2.2-3. These include 5 public use facilities and 10 private facilities. Four public use airports lie within 5 miles of the LGS site. The aircraft crash probability analysis from operations at airports and airways, including Pottstown Municipal and Pottstown-Limerick Airports, using the procedures of SRP section 3.5.1.6, is provided in Section 3.5.1.6.

Pottstown Municipal Airport lies about 5 miles northwest of the site, and is the only municipal airport within 5 miles. The 1968 National Airport Plan classed it as a general utility airport, one which can handle general aviation craft, except transports and jets. Pottstown Municipal Airport has no scheduled airline service, but serves a charter service, flying school, and privately owned

aircraft. The airport runway is hard-surfaced, 2700 feet long, and has a heading of 250°. A line extending from the runway to the east, along the runway's axis, would pass about 3.3 miles from the site boundary at its point of closest approach. Approximately 53 aircraft are based at the airport, and estimated movements are 16,000 annually.

The New Hanover Airport, about 5 miles north of the site, has a sod runway, 3450 feet long, at a heading of 270°. The airport has no scheduled service, but serves skydiving operations and privately owned aircraft. Skydiving is the primary activity, with peak movements taking place on weekends, weather permitting. Approximately 70% of the aircraft using the airport are single-engine and 30% are twin-engine. The total number of movements is about 2500 annually.

The Sunset Landing Strip, about 5 miles northeast of the site, has a sod runway 1550 feet long, at a heading of 270°. The airport has no scheduled service. Private flights are estimated at 12 per day, weather permitting.

The Pottstown-Limerick Airport, located at Limerick Center, lies about 2 miles northeast of the site. It has a hard-surfaced runway (10-28) 3412 feet long, at a heading of 280° and a sod strip (3-21) 2167 feet long. Currently, there are a total of about 30,000 aircraft movements annually, most involving runway 10-28. There are approximately 60 aircraft based at the airport, of which 40 are single-engine craft, 11 are twin-engine, and 9 are rotary-wing. Ninety-nine percent of the movements involve VFR operations. IFR approaches are presently made from the north, with an FAA-approved approach to Pottstown VOR. The present approach minimums are 649 AGL or 960 MSL. Instructions for a missed approach to runway 21 indicate a left-hand turn to the east away from the site. This facility is owned by Exelon Corporation and leased to the airport operators. The terms of the lease limit fixed-wing aircraft to a maximum weight of 13,500 pounds. The length of the runway precludes any heavier fixed-wing aircraft from using this facility. There are currently no existing terminal navigational facilities.

The Perkiomen Valley Airport is a hard-surfaced landing strip with no scheduled airline service, but supporting a charter service, flying school, and privately owned aircraft. The runway is 3000 feet long, and has a heading of 270°. About 80 aircraft are based at this airport. Movements are estimated to be 7000 for all aircraft annually.

The Pottstown VOR is located 1.3 miles east of the site. This radio range serves as a hub for several VOR airways used for commercial aircraft flights. These airways extend for 4 miles on each side of their center lines. The Pottstown VOR is the main departure route from Philadelphia International Airport for flights going north and northwest, but due to traffic patterns it is not used for arrivals. By the time these departures reach the Pottstown VOR, the flights have reached an altitude of 7000 feet. The Federal airways passing within 10 miles of the site are listed in Table 2.2-4. FAA annual flight estimates include 20,440 flights using the Pottstown VOR 320° radially, no flights along V143, and 8,395 flights along V29/V147.

In addition to the landing fields discussed above, there is a heliport at the LGS site. The landing pad is located east of the Unit 2 cooling tower, 1,250 feet from the nearest safety-related structure. The approach/takeoff flight path has a heading of 350°/170°, and does not pass over any safety-related structures. The approach/takeoff glide angle is no greater than 30° from vertical. The flight frequency is no more than 156 landings and 156 takeoffs per year.

2.2.2.6 Projections of Industrial Growth

Industry within 5 miles of the LGS site is clustered along the Schuylkill River, adjacent to rail lines and along major transportation arteries. The construction of the Schuylkill Expressway extension and planned improvements to the Pennsylvania Route 724 are expected to spur industrial development in these areas. At the intersection of the Schuylkill Expressway with the Collegeville-Trappe Route 422 bypass, a 1000 acre industrial park is planned. This area, when fully developed could employ 16,000 persons, assuming that 80% of the land would be developed at an average employee density of 20 persons per acre. New industrial areas are also planned near Route 724 in Spring City, East Coventry Township, and west of Pottstown Landing.

Pottstown Borough, in light of 1960-1970 population trends, may have reached a point of development saturation. Therefore, no significant increase in industry is anticipated in this area.

2.2.3 EVALUATION OF POTENTIAL ACCIDENTS

This section provides an evaluation of potential accidents in nearby transportation and industrial facilities, to determine what events need to be considered in the plant design. A description of design features to mitigate such events is also provided.

2.2.3.1 Determination of Design Basis Events

2.2.3.1.1 Explosions

Explosions can potentially occur due to accidents on the nearby railway line, highways, or pipelines, as identified in Section 2.2.2. There are no industrial activities involving explosive storage near the site.

The evaluation of potential railway explosions has been performed in conformance with Regulatory Guide 1.91 methodology. The maximum railway explosion is taken as one corresponding to 56 tons of TNT, which is equivalent to the explosion of a boxcar containing a full load of palletized explosives or a tank car containing liquefied petroleum gas.

The frequency of boxcars, derived from a Bechtel study of hazardous materials that passed through the exclusion area during the period from March 1969 through May 1969, amounted to 1800 cars (i.e., 7200 cars per year). There were only 11 cars (i.e., 44 cars per year) that carried explosives.

The explosives are shipped in multiple boxcar shipments per train. However, no more than two carloads of explosives have been shipped at any one time. Normally, only one carload is shipped at any one time.

The safety-related structures of LGS are designed and constructed to withstand the effects of the design basis railroad explosion with no damage, and would be unaffected by any change in explosive shipment frequency.

Selection of a 56 ton maximum TNT explosion model is conservative for the reasons given below. Information on explosives given below have been excerpted from the Bechtel Design Basis Railroad Accident Study. Additional information on the shipment of explosives through 1983 was obtained from ConRail, the American Association of Railroads, and the U.S. Department of Transportation.

Fifty ton box cars have been the most common size car used for shipping high explosives in the past. However, military shippers of high explosives prefer increased usage of 70 ton cars. The use of 100 ton cars has been infrequent and generally limited to items that move in large trainload shipments, such as unfused artillery shells. Such cars are not loaded to capacity due to interior space limitations. In addition, the characteristics of commodities carried further limits the explosive power contained within the cars. For example, artillery shells normally contain only 20% to 30% by weight of explosive.

Thus, an 80 ton load (assuming 20% weight for cases and packing) of shells would contain 24 tons of explosive. Applying a TNT equivalence factor of 1.35 (for composition B) and a 10% muffling factor yields an explosion equivalent to 29 tons of TNT. Thus, 100 ton cars do not provide the limiting case; the LGS explosion magnitude model is adequate and conservative.

Explosive loadings consist of shells, bombs, bulk explosives, demolition blocks, etc. Demolition blocks provide the greatest concentration of explosive power in a car. Shells, bombs, etc, provide smaller concentrations of explosive power due to the heavy weight of casing (50% to 80% of the weight of the munition).

Composition C3 explosive, in the form of M5 demolition blocks, provides the greatest concentration of explosive power in a car. This explosive is more destructive than TNT, having a relative effectiveness factor of 1.34 when compared with TNT. More powerful explosives were eliminated from consideration because they are shipped in less-than-carload lots.

Military and commercial loading practices rather than accident history set the upper limit on the quantity of explosive considered. Car weight and volume capacities limit the maximum load. M5 demolition blocks are placed in boxes, loaded on pallets, and then blocked inside the rail car. Twenty-four blocks are loaded in a box, 24 boxes are loaded on a pallet, and 56 to 68 pallets are loaded into a rail car. An aisle 20 inches wide is down the center of the car, and a 45 inch to 50 inch wide aisle connects the doors. A maximum of 44 tons of composition C3 can be placed in the car.

Forty-four tons of composition C3 is equivalent in explosive power to 59 tons of TNT. Application of a 10% muffling factor (i.e., absorption of explosive power by boxes, air space, and car structure) yields an explosion equivalent to 53 tons of TNT.

The discussion above corroborates the selection of a 56 ton TNT model as an upper limit on the design explosion. Consideration of the history of actual explosions confirms that the model is conservative. There is no evidence that an entire carload of explosives has completely detonated during the study period. There is evidence that the explosives will burn or partially detonate and scatter remaining car contents. At Tobar, Nevada and at Lewis, Indiana, some low and high order explosives occurred in the same car. Experts of the Bureau of Mines and the Army claim that the detonation of a carload is possible, but can only be assured if the explosive is detonated with the aid of blasting caps.

For the above reasons, it is considered that the maximum explosion of a rail car carrying explosives would be equal to or less than the 56 ton model used in the explosion and average reflected overpressure analysis for LGS.

The peak positive reflected pressures for which the critical structural elements of the safety-related structures were analyzed are given in Table 2.2-7. Missile generation from such an explosion is also postulated and is discussed in Section 3.5.

The effects of a release of 64 tons of propane from a ruptured railroad tank car and subsequent detonation of the gaseous cloud which could occur at a distance of 1100 feet from the nearest portion of the Unit 1 reactor enclosure have also been evaluated. Such an explosion could produce a peak reflected overpressure of approximately 9 to 10 psi on the upper two-thirds of the north, west, or south walls of the reactor enclosure. Lower portions of the reactor enclosure and other safety-related structures nearby are protected from the explosion by the geometry of the topography between the river, the railroad grade, and the reactor enclosure. Such an explosion would take place at either railroad grade level or river level, due to the higher density of propane compared to air, especially after the gas has cooled during expansion from the liquid to gas phase. The shock wave of such an explosion exerts an overpressure for a duration of 2 to 10 milliseconds (Reference 2.2-15).

A structural analysis of the upper two-thirds of the reactor enclosure has demonstrated that the enclosure can sustain the load without being damaged. A statistical analysis of the probability of an LPG tank car release and explosion was also performed based on methods described in Regulatory Guide 1.91 (Rev 1). This method utilized specific information on the number of LPG shipments past the LGS site. Credit was also taken for the fact that most LPG incidents occur in industrial installations or rail yards rather than on mainline track. The result of this analysis indicates a probability of approximately $5x10^{-9}$ for an LPG tank car release and explosion within a distance that could impact the LGS facility with an overpressure of 1 psi or greater. In 1981, according to Conrail, there were 1315 movements of LPG tank cars on the rail line that passes by LGS.

Explosions can also occur on nearby highways. However, since the railway is closer to the plant and truck cargo capacity is less than that of rail cars, the effects of a railroad explosion would be more severe than an explosion occurring on the highways.

An evaluation was conducted to determine the acceptability of the transportation route for the delivery of hydrogen gas via tube trailers to the Hydrogen Water Chemistry tube trailer facility located outside the protected area of LGS. The evaluation follows the Regulatory Guide 1.91, which provides guidance for providing safe separation distances between transportation routes, that may carry potentially explosive cargo, and safety related structures. The method for determining acceptable separation distance, determines the level of risk of damage due to the potential explosion of the cargo . Regulatory Guide 1.91 provides guidance for determining an acceptable level of risk. Based on industry data and site specific characteristics, the results of the risk evaluation indicated that the exposure rate is less than the value specified by Regulatory Guide 1.91. The transportation route for hydrogen gas delivery reflects an exposure rate that is of a sufficiently low risk of damage to nearby structures.

The potential also exists for the rupture of one of several nearby pipelines and the subsequent explosion of a gas or vapor cloud. The worst case overpressure due to a pipeline accident would involve the 20 inch Columbia Gas Transmission Company pipeline carrying natural gas.

Previous evaluations (Reference 2.2-2) indicate that natural gas will not detonate in unconfined spaces. However, to evaluate potential impacts, the detonation of a natural gas cloud from a rupture of the larger of the two Columbia gas pipelines gas been postulated. A detonable gas-air mixture approximately 4 times the requirement of Regulatory Guide 1.91 (Rev 1) is conservatively used to develop the explosive pressures for structural assessment. It has the equivalent explosive charge of 347 tons of TNT. Furthermore, the detonation is assumed to occur at an elevation varying from ground to 500 ft above ground to maximize the overpressures on the safety-related structures. In addition, the detonation is also assumed to occur anywhere along a line 2300 feet

downwind of and parallel to the route of the natural gas pipeline. This was done to maximize the explosion overpressures on each of the safety-related structures. The peak positive reflected pressures for which the critical structural elements of the safety-related structures were analyzed are given in Table 2.2-7.

The Sunoco petroleum products pipeline is assumed to carry gasoline, which has the highest volatility and explosive power of the products carried in the line. The gasoline vapor concentration from the pipeline rupture and spill is postulated to reach the explosive limit (Reference 2.2-3) and has a TNT-equivalent energy of 2.6 tons. The centroid of the explosion is assumed to be along the Possum Hollow Run streambed. The distance to a safety-related structure from the point in the streambed which allows maximum exposure is 800 ft measured from the Unit 2 reactor enclosure. The peak positive reflected pressure at the wall is 1.9 psi, and less than this value at the roof. This is the maximum overpressure from the gasoline explosion on the safety-related structures. The methodology used in calculating the overpressures in based on Reference 2.2-1.

As an example, the peak positive reflected pressure at the southwest corner of the Unit 1 diesel generator building at grade level (el 217') is computed as follows:

R_G = Radial distance from charge = 624 ft

W = Charge weight = 56 tons = 112,000 lb
(from page 4-8 of Reference 2.2-1)

Z_G = Scaled ground distance = $R/(W)^{1/3}$

= $624/(112{,}000)^{1/3}$ = 12.95 $ft/lb^{1/3}$

P_{50} = Peak positive incident pressure = 6.0 psi

α = Angle of incidence = 49°20'
(from page 4-5 of Reference 2.2-1)

$C_{r\alpha}$ = Reflected pressure coefficient = 2.8

P_r = Peak positive reflected pressure = $C_{r\alpha}\, P_{50}$

= 2.8 x 6.0 = 16.8 psi

Because different locations of a wall will experience different peak positive reflected pressures, a critical element of a building wall is analyzed for the average of peak positive reflected pressures at the top and bottom of the wall element.

A low rate of leakage from the Sunoco pipeline would likely be detected within one hour by the flow auditing and measurement procedures used at the pump stations along the pipeline. However, if such a leak were to occur and go undetected for a period of several hours, and if the pipeline transported gasoline (the most volatile substance carried), and if the leak were to be located in the vicinity of Possum Hollow Run, it can be anticipated that the gasoline would run into Possum Hollow Run and then flow downstream toward and into the Schuylkill River. Gasoline, with a density of approximately 0.75 compared to water, would form a thin monomolecular layer on the surface of the water flowing in Possum Hollow Run. No large accumulations or pooling would occur.

The worst situation for this type of release would be on a day during which ambient temperatures remain high because the evaporation rate of gasoline is more rapid at higher temperatures. For any gasoline spill, the lighter fraction components, notably butane, evaporate rapidly, while the heavier components such as naphthene evaporate more slowly. A summertime spill of a quantity of gasoline would evaporate completely within about 24 hours, but a wintertime spill could take a week or more to evaporate completely.

If ignition were to occur, the fire would likely spread over the stream surface to all locations where the gasoline had reached, but excluding portions of the gasoline film that had become disconnected from the ignited portions by such means as flows over small waterfalls or by flows through pipes. After ignition, it can be expected that the ensuing fire could be fairly large in surface area along the creek surface, but would be of short duration. Because the gasoline is assumed to be of small initial quantity, continuous evaporation would occur, and there would be only a small amount of gasoline at any given point along the streambed due to the tendency of gasoline to form a thin surface film over water.

A double-ended rupture of the pipeline would be detected within seconds, and pumping would be terminated promptly. In the unlikely event that there was a complete rupture of the pipe and it went undetected for several hours, the severity of such an occurrence would be approximately the same as that described above for a gasoline spill where it was assumed that the contents of the pipeline between two adjacent high points of bank were spilled into Possum Hollow Run. This would amount to approximately 5000 gallons of gasoline distributed along the creek bed, with an ensuing explosion 800 feet from the plant, and a resulting overpressure of 1.9 psi.

The results of an explosion of gasoline vapor from a long-term continuous release of gasoline are assumed to be similar because gasoline released to the creek bed would be carried downstream into the Schuylkill River and would continue away from the plant.

The Sunoco pipeline is an 8 inch line having a pumping capacity of about 1000 barrels per hour. A 1 hour release of gasoline would therefore amount of 42,000 gallons. The standing capacity of the creek bed (the quantity of fluid that would remain in the creek bed in pools if inflow were stopped) between the point where the pipeline crosses and its juncture with the Schuylkill River is small, so that a flow of gasoline at 42,000 gallons per hour, or 700 gallons per minute, would be expected to drain to the river quickly.

In the analysis of a gasoline spill, a point of detonation was used of 800 feet from the closest Category I structure, occurring at a wide point in the streambed where the path to the reactor complex is relatively unimpeded by terrain. The bed of Possum Hollow Run passes closer to Category I structures, as follows:

Unit 2 Diesel generator	512.5 ft
Unit 2 Reactor enclosure	562.5 ft
Turbine-generator building	637.5 ft
Unit 1 Diesel generator	600.0 ft
Unit 1 Reactor enclosure	662.5 ft

Possum Hollow Run, at these closer points, flows through a fairly steep-walled ravine, which would serve to deflect and significantly lessen the effects of an explosion. For this reason, the 800 ft distance selected is conservative.

Missile generation from the Columbia or the Sunoco pipeline explosion would be less severe than from the railroad explosion because such a postulated explosion would take place in a cloud away from the postulated missile sources.

For the overall structural design and assessment of the critical structural elements of a safety-related structure, the highest values of the peak positive reflected pressures for walls and roofs are selected from the railroad, Columbia pipelines, and Sunoco pipeline. The structural adequacy of the critical elements is evaluated against a ductility ratio of 3.0. All such safety-related structures have been determined to be fully capable of withstanding these overpressures with no adverse effects.

2.2.3.1.2 Flammable Vapor Clouds

A pipeline rupture may occur in which the resulting vapor cloud burns rapidly (deflagrates) rather than detonates. Analyses that estimate the effects (radiant heat load) of such an event are discussed below for the Sunoco gasoline pipeline. Other types of fires are discussed later in Section 2.2.3.1.4.

The same Sunoco pipeline rupture discussed previously is assumed here. In this case, the available gasoline vapor is assumed to deflagrate. Worst case meteorological conditions were assumed, using Pasquill 'F' stability and 1 m/s wind speeds. Any other less stable category or higher wind speed would increase dilution of the gas or vapor cloud, and thus decrease the effect on the reactor enclosure. The resulting fire is calculated to produce a radiant heat load of 85 Btu/ft^2-hr (Reference 2.2-5) at the Unit 2 reactor enclosure for a short time. This level would produce a slight warming of the surface concrete. By comparison, a flat surface in the sun at midday receives solar radiation at approximately 50 to 60 Btu/ft^2-hr.

In analyzing deflagration of natural gas released from a rupture of the Columbia Gas Transmission Company pipeline, it is assumed that the larger of the two lines (20") ruptures at the point where the pipeline passes closest to the Unit 2 reactor (approximately 3000 feet). It is further assumed to be a double-ended rupture (complete separation of the pipe at the point of rupture).

A portion of the cloud downwind within flammable limits is assumed to ignite and deflagrate. The radiant heat load at the Unit 2 reactor enclosure is calculated to be about 70 Btu/ft^2-hr (Reference 2.2-5) for a short time. This level would cause a slight warming of the outer layer of concrete.

2.2.3.1.3 Exposure to Hazardous Chemical Releases

Exposure of control room personnel to hazardous chemical vapors could potentially result from an accident involving a chemical spill. Such spills could occur on the rail line, one of several highways close by, nearby industrial facilities, or from onsite chemical storage. A chemical is considered a potential hazard if it is stored or transported nearby in such quantities that its concentration at the control room air intake following a spill could exceed the toxic incapacitation concentration. Acceptable toxic incapacitation levels were based on compliance with the Regulatory Guide 1.78 requirement of 2 minutes for operator protective action NIOSH and OSHA exposure limits, and ACGIH concentration criteria.

Potential chemical hazards were identified by first compiling a list of toxic chemicals that could pose a vapor hazard based on Regulatory Guide 1.78, NUREG-0570, and other sources. Surveys were conducted to determine which of these are actually stored or shipped within 5 miles of the Limerick Generating Station (LGS) site, with what frequency, and in what quantities. For each of the identified hazards, chemical properties, the information in the Superfund Amendments and Reauthorization Act (SARA) Tier II filings, and survey responses are used to screen out the hazard or determine that further analysis is required. Toxic gas detection systems are not credited in this survey.

From R.G. 1.78, chemicals screened out by meeting any of the following criteria:

- First Screen:

  a. Chemical quantity contained in the largest storage container is less than 100 lb.

  b. Chemical is a liquid at l00°F and has a vapor pressure less than or equal to 10 torr (10 mmHg).

  c. Chemical shipment frequency is less than 10 total shipments per year for truck traffic, 30 per year for rail traffic, or 50 per year for barge traffic.

- Second Screen:

  d. Chemical quantity contained in largest storage container is less than that allowed as defined in R.G. 1.78 Table C-2.

Additionally, chemicals screen out if another instance of the same chemical in the survey is bounding both in terms of distance and mass.

For the railroads, Norfolk Southern (NS) and Eastern Berks Gateway (EBG) /Berks County Authority rail lines provided information on which of these are shipped. The EBG railroad did not have any hazardous commodity shipments through all of 2016 and nine months of 2017. The commodities shipped by NS did not provide shipment quantity per railcar. The railcar cargo load of 230,000 lb was used for the screening analysis. Because the nearest approach of the NS line is less than 0.3 mi from LGS, Regulatory Guide 1. 78 directed to evaluate all hazardous chemicals present in weights greater than 100 lb within 0.3 miles ofthe control room in a detailed control room analysis.

Montgomery and Chester County are the only counties that have stationary facilities within

five miles of LGS. Both Montgomery and Chester County provided the SARA Tier II filings for the potentially hazardous chemicals stored within five miles of LGS in the county. In the Montgomery County, the Pottstown Wastewater Treatment Plant was identified with the largest single container capacity for chlorine on site and Dana Driveshaft Products, LLC identified that the largest single container capacity for propane on site. In the Chester County, the North Coventry Municipal Authority and Pennsylvania American Water Shady Lane Plant identified to have water treatment chemicals including chlorine.

The evaluation of chemical hazards transported by truck only considers those chemicals known to be stored or shipped within the five-mile radius of LGS based on the stationary facility surveys. The quantity of a given chemical in a truck shipment is considered to be the highest amount of the chemical listed for the stationary facilities. However, the size of a single truck shipment is limited to 55,000 lb, which is the available payload capability. The transported chemicals are evaluated as being shipped on the major roadway nearest to LGS. U.S. Route 422 is the bounding major roadway within five miles of LGS. The nearest approach of U.S. 422 to LGS is 1.22 miles. Those chemicals which screen out in the first screening analysis also screen out for the roadway evaluation. Those that do not screen out in the first screening are analyzed with the secondary screening methodology for truck transportation in addition to stationary storage out for the roadway evaluation. Those that do not screen out in the first screening are analyzed with the secondary screening methodology for truck transportation in addition to stationary storage for the stationary facilities.

Pipelines carrying potentially hazardous chemicals within five miles of LGS are identified using the National Pipeline Mapping System (NPMS). Pipe sizes, approximate age, operating pressure, etc., are listed in Table 2.2-2 and shown on Figure 2.2-1.

The analysis assumed complete release of the contents of a single container or tank. The control room habitability analyses performed follows methodology for toxic chemical release and atmospheric dispersion as described in Regulatory Guide 1. 78 and NUREG-0570. These methodologies are implemented in the analysis software. The analysis software performs worst case deterministic hazard analysis cases consistent with Regulatory Guide 1. 78 methodology using LGS specific inputs. If the worstcase analysis results are unsatisfactory, the software performs numerous release and dispersion calculations using randomly sampled inputs to determine the conditional probability that a release will result in unacceptable consequences. These Monte Carlo simulation results are used to evaluate the likelihood of unacceptable results for comparison with the Regulatory Guide 1.78 probabilistic acceptance criterion.

The control room concentrations were determined using the following control room parameters:

a. Control room envelope volume of 126,000 ft^3, as defined in Section 6.4.2.1.

b. 2100 cfm of incoming/outgoing air, based on the design outside air flow rate supplied by the normal control room HVAC system, as described in Sections 6.4.3.1 and 9.4 .1.1.

c. [redacted]

d. In leakage rate of 0.25 air changes per hour, during isolation, as discussed in Section 6.4.2 .3. However, the normal mode of operation with 2100 cfm of outside air is modeled throughout the transient.

e. The analysis does not credit any automatic detection of toxic chemicals or isolation of the control room in response to chemical detection. The use of a breathing apparatus within two minutes of nasal detection is credited.

Sodium Hypochlorite is used in water treatment in LGS for chlorination. It is stored in large quantities locations listed on Table 2 2-5. Sodium Hypochlorite was also evaluated in the analysis.

The analysis determined that the concentration of the chemical will not reach Immediately dangerous to life or health (IDLH) levels in the control room, or the operators can effectively detect and isolate the control room in case of the toxic chemical release, or the release events of the chemical has low probability of 10-5 occurrences per reactor year. The automatic chemical detection systems were not credited in the analysis. Although not credited in the analysis, switching the control room air from normal mode to the chlorine/toxic gas isolation mode is recommended upon nasal detection of a chemical to slow the accumulation of hazardous gases in the control room. When the hazard has cleared the area, returning to normal mode will help clear residual chemicals from the control room. The following chemicals are acceptable with credit for nasal detection and operator donning of a self-contained breathing apparatus (SCBA) within two minutes of detection. Operators should be trained in nasal detection and the use of SCBA as described in Regulatory Guide 1.78: R-142b, Acetone, Butane, Butyl Acrylate, Chlorine, Ethyl Acrylate, Heptane, Hydrochloric Acid, Isobutane, Methanol, Propanol, Methyl Methacrylate Monomer, Natural Gas, Nitric Acid, Propane (Odorized), Styrene, Toluene, Tripropylene, Chlorine Dioxide.

To ensure adequate protection of control room personnel, control room operators will be trained and periodically tested on their ability to put on breathing apparatus within 2 minutes after nasal detection of the toxic chemical detection including chlorine or initiation of the toxic chemical alarm. Subsequently, the operators will manually isolate the control room as described in Section 6.4.3.2.3.

If chlorine is detected with the control room HVAC system initially in the radiation isolation mode (as described in Section 6.4.3.2.2), manual action can be taken to realign the system to the chlorine isolation mode. Analysis of this event assumes that the system remains in the radiation isolation mode with 525 cfm of outside air being mixed with recirculated control room air for a total of 3,000 cfm being passed through the charcoal adsorber filter trains, and that the filter has no effect on removal of chlorine. The results of the analysis indicate that, with the control room HVAC system in the radiation isolation mode, the necessity for automatic chlorine isolation is not required to satisfy General Design Criterion (GDC) 19 of 10CFR50 of Appendix A, and that the control room operators would have sufficient time to don breathing apparatus after nasal detection of the chlorine occurs (as shown in Table 2.2-6).

Once it is confirmed that the isolation is not the result of elevated chlorine or toxic gas concentrations, the operators may remove their breathing apparatus. This action is based upon an evaluation of the chlorine and toxic gas accidents with the control room in the chlorine isolation mode prior to the chlorine or toxic gas accident. This evaluation determined that the control room operator would have sufficient time (more than 2 minutes) to don breathing apparatus after odor detection of the toxic substance.

The LGS toxic chemical analysis complies with the intent of Regulatory Guide 1.78.

2.2.3.1.4 Fires

In addition to the flammable vapor clouds discussed earlier, fire hazards may also exist due to a burning tank car on the railroad, a fire subsequent to a ruptured pipeline, or a nearby forest/brush fire. Potential adverse effects of such fires are radiant heat load on plant structures and smoke generation.

To estimate the effects of a railroad fire, an accident is hypothesized in which a railroad tank car derails, ruptures, and releases a cargo of 62 tons of liquified propane. A 62 ton car is typically the largest size used for propane, and from a fire standpoint liquified propane represents one of the most severe materials transported by rail. The site of the hypothetical derailment is the closest point of approach to the Unit 1 reactor enclosure, about 600 feet. The tank car propane is assumed to be released into the drainage ditch alongside the eastern side of the right-of-way, where it pools and is subsequently ignited. The vapor pressure of liquid propane is sufficiently high at ambient conditions that there will be an adequate supply of gaseous propane for ignition, after which the fire is self-propagating. The fire duration is assumed to be 20 minutes, based on experience with this material.

Assuming 19,600 Btu per pound of propane and 62 tons being consumed in 20 minutes, the radiant heat load on the reactor enclosure may be calculated using the relationship (Reference 2.2-5):

$$D = (FQ/12.57K)^{1/2} \qquad \text{(EQ. 2.2-1)}$$

where:

D = distance, feet

F = fraction of heat that is radiant

Q = heat release, Btu/hr

K = radiation load, Btu/ft^2-hr

The result of this calculation indicates a radiant heat load of approximately 500 Btu/ft^2-hr for 20 minutes at the Unit 1 reactor enclosure. This compares to a solar heat load for a flat surface at midday of 50-60 Btu/ft^2-hr. The smoke effects of such a fire would be negligible. This accident represents the worst case radiant heat event. Other possible fires that result in more severe smoke generation are described below.

Rupture of the ARCO pipeline at Possum Hollow Run while carrying diesel fuel or home heating oil, which represents the worst case from a smoke generation standpoint, results in the release of approximately 5000 gallons (120 barrels) distributed over the streambed downstream toward the Schuylkill River. An open burning pool of oil produces 1.5-10 kilograms per second of particulates (smoke) for each 1000 barrels per hour of fuel consumed (Reference 2.2-5). The 5000 gallons is assumed to be completely burned in a short time (about 10 minutes). Assuming an average burn release of about 5 kilograms of particulates per second over the 600 meter length from the

streambed pipeline crossing to the first downstream bridge, concentrations of particulates at the reactor enclosure are approximately 2.60 grams of particulates per cubic meter. The radiant heat effects of such a fire are negligible.

A brush and forest fire in the vicinity of the LGS site releases 210 kilograms of particulates per hectare (Reference 2.2-7). Assuming a normal fire rate of 40 acres per hour along the southeast bank of Possum Hollow Run, the smoke concentration at the reactor enclosure, 800 feet from the fire center, is approximately 0.6 grams per cubic meter.

The design provisions available if smoke reaches the control room ventilation are described in Section 2.2.3.2.

2.2.3.1.5 Collisions with the Intake Structure

The Schuylkill River is not used as a navigable waterway for anything other than small recreational boats. Moreover, the ultimate heat sink is the spray pond, so that damage to the intake structure does not impair safe shutdown capability.

2.2.3.1.6 Liquid Spills

Petroleum floating on the Schuylkill River surface could approach the intake structure due to a spill upstream. The intake is under water, so oil is excluded from entry into the intake line. The severest possible condition occurs at the design low water condition, with the water surface at 104' MSL. The water intake is still submerged 1 foot at this level. As noted above, the intake structure is not safety-related.

2.2.3.2 Effects of Design Basis Events

From the foregoing discussion, the following design basis events are identified, along with their potential effects:

a. Railroad, Columbia natural gas pipeline, and ARCO pipeline explosion - overpressurization and missile generation

b. Toxic chemical spill - hazardous control room concentrations

c. Propane tank car fire - radiant heat load on structures

d. ARCO pipeline fire - smoke in control room

The following design provisions or considerations account for these events:

a. Railroad, Columbia natural gas pipeline, and ARCO pipeline explosion

    1. Blast - safety-related structures are designed to withstand the resulting overpressurization due to an explosion as discussed in Section 2.2.3.1.1.

    2. Missiles - safety-related structures are designed to withstand the impact of blast-generated missiles, as identified and discussed in Section 3.5.

b. Toxic Chemical Spill

1. Control Room - detection and isolation capability is provided for the 6 chemicals identified as constituting a hazard, as discussed in Section 6.4.

2. Diesel Generators - The manufacturer of the emergency diesel generators has determined that the chemicals identified in Tables 2.2-5 and 2.2-6, when present in concentrations and for time spans calculated using the methodology described in Section 2.2.3.1.3, would have no adverse effects on diesel generator operation.

c. Propane tank car fire - the radiant heat load from such a fire is evaluated as having no adverse effect on safety-related structures. The bulk of the heat load would be absorbed by the precast panels on the face of the structures, which do not serve a safety function.

d. ARCO pipeline fire - smoke detectors in the control room intake alarm, and the operator can manually isolate the control room ventilation system, as discussed in Section 9.4.1.

2.3 METEOROLOGY

2.3.1 REGIONAL CLIMATOLOGY

The regional climatology in the vicinity of the LGS site has been analyzed using long-term data from the nearby NWS stations at the Philadelphia and Allentown, Pennsylvania airports. These data are available in several summarized forms (References 2.3.1-1 through 2.3.1-4) from the National Climatic Center. The LGS site is located about midway between Philadelphia and Allentown with respect to both elevation above MSL and geographic location. Though Reading, Pennsylvania is the NWS station closest to the site, it was removed from service in 1969. Climatic summaries from Philadelphia and Allentown indicate that some extremes of record have occurred since 1969, which would not be included in any Reading summaries.

The Site Meteorological Tower data is reviewed and compared on a periodic basis to the meteorological data from Pottstown - Limerick Airport to verify data consistency.

2.3.1.1 General Climate

2.3.1.1.1 Air Masses and Synoptic Features

The general climate of the LGS site is best described as humid continental. The region is dominated by continental air masses in winter, and by alternating continental and maritime tropical air masses in the summer. The site is near the track of most eastwardly moving low pressure systems which are brought from the interior of the U.S. by the prevailing westerlies. This generally produces a change in the prevailing weather system every three or four days. Coastal storms from the Atlantic Ocean can affect the site, causing heavy rains and severe flooding in the most extreme instances.

2.3.1.1.2 General Airflow

The prevailing winds in the region of the LGS site are from the west. Table 2.3.1-1 compares the long-term annual wind distributions from Philadelphia and Allentown. While there are slight differences, the overall flow patterns are similar. Seasonal variations are evident, with the prevailing wind at both stations shifting to the WSW and SW in the summer months and to the WNW and NW during the winter. Annual average wind speeds are between 9 mph and 10 mph at both stations, but the frequency of measured calms (8%) is much larger at Allentown.

2.3.1.1.3 Temperature

Temperatures in the region of the LGS site rarely exceed 100°F or drop below 0°F. Mean monthly temperatures from Philadelphia and Allentown are given in Table 2.3.1-2. The average temperatures at Allentown are approximately 3°F cooler than Philadelphia, but at times the difference may be as great as 10°F or 15°F. This difference can be attributed almost entirely to local differences at the two NWS stations. Temperatures at Allentown are measured at el 391' MSL, while those at Philadelphia are obtained at el 9' MSL, near the modifying influence of the Delaware Bay. Temperatures in the vicinity of the site should fall somewhere between those at Allentown and Philadelphia.

2.3.1.1.4 Relative Humidity

Mean morning and afternoon values of relative humidity from Philadelphia and Allentown are summarized by month in Table 2.3.1-3. The 7:00 am and 1:00 pm values from each station were selected as being representative of typical morning and afternoon conditions, respectively. As the table indicates, both stations recorded the highest morning values in September and the lowest afternoon values in April. Though Allentown indicates consistently higher values of relative humidity, the differences are small.

2.3.1.1.5 Precipitation

The LGS site receives a moderate amount of precipitation, which is well distributed throughout the year. The precipitation distributions at Philadelphia and Allentown are summarized in Tables 2.3.1-4 and 2.3.1-5, respectively. Both stations indicate slightly more precipitation during the summer months. The only significant difference between the two locations is in the mean annual accumulation of snow and sleet, with Allentown receiving approximately 11 inches more per year. This is not unexpected considering the greater elevation and the inland location of Allentown.

2.3.1.1.6 Relationship Between Synoptic and Local Scale Meteorology

The LGS site is situated in an inland region of rolling terrain where one would expect little local modification of synoptic scale weather systems. There are no large bodies of water near the site, and the Schuylkill River is much too small to significantly affect the local conditions. There is a slight channeling effect at low elevations in the river valley.

2.3.1.2 Regional Meteorological Conditions for Design and Operating Bases

2.3.1.2.1 Seasonal and Annual Frequencies of Severe Weather Phenomenon

2.3.1.2.1.1 Hurricanes

Hurricanes are relatively rare at an inland site such as LGS. These storms usually affect the inland regions of the mid-Atlantic states while moving in a path parallel to the coastline, or after coming ashore in the southern states. In the period from 1901 through 1963, only two hurricanes came ashore in the mid-Atlantic coastal region extending from Virginia to New Jersey. There have been 14 hurricanes and tropical storms that have affected the LGS region between 1963 and 1980 (Reference 2.3.1-22). The primary effect from these storms was increased precipitation that occurred after these storms moved inland and began to dissipate. A summary of the peak winds and precipitation totals in the LGS region from these storms is shown in Table 2.3.1-9. The maximum wind speed resulting from a tropical storm in the region was a fastest mile value of 38 mph recorded at Philadelphia during tropical storm Doria (1971). During the 13 year period from 1955 through 1967, Pautz (Reference 2.3.1-6) reports 69 storms in Pennsylvania where surface winds exceeded 74 mph. There were no wind speeds in the site vicinity in excess of 74 mph between 1967 and 1980. The fastest mile of wind recorded at the regional NWS stations was 57 mph at Philadelphia on June 23, 1969. The highest hourly average wind speed recorded at the LGS site since the beginning of the meteorological monitoring program in 1972 was 50 mph on December 2, 1974 at the 270 foot level on Tower 1. While 74 mph is the wind speed criteria used to designate a hurricane, this total reflects winds resulting from both tropical and extratropical storms.

The potentially heavy rains which can result from a hurricane or a decaying tropical storm as it moves inland are a more serious consideration than strong winds in the LGS area. Doria also produced a 24 hour precipitation total of 4.77 inches. The maximum precipitation measured onsite

during 24 hours from a tropical storm was 5.57 inches during the dissipation stage of Hurricane Agnes (1972). Hurricane Agnes caused severe flooding in June of 1972, leaving 8 inches of rain over most of central and southern Pennsylvania. As much as 19 inches of rain fell during hurricane Agnes in western Schuylkill County, approximately 40 miles northwest of the site.

2.3.1.2.1.2 Tornadoes

Summaries prepared by Pearson (Reference 2.3.1-7) indicate that there were 75 tornadoes within a 50 mile radius of the LGS site in the period 1950 through 1976. This data base has since been updated, indicating that 10 additional tornadoes occurred in the 1° latitude-longitude square surrounding the site in the period 1977-1981. The tornado occurring closest to the LGS site during this period was approximately 13 nautical miles WNW on September 5, 1979. There is also an unconfirmed report (Reference 2.3.1-23) of a small tornado touching down in the immediate Pottstown, Pennsylvania vicinity on May 20, 1982. The most severe occurred on March 22, 1955, 17 miles south of the site. This tornado had a path area of 1.2 square miles, with peak winds estimated to be in excess of 150 mph. The tornado reported closest to the site occurred on June 8, 1961, approximately 6 miles to the east. Peak winds from this storm were estimated to be in excess of 110 mph.

Using the statistical methods of Thom (Reference 2.3.1-8), the tornado probability has been computed for the LGS site. This analysis has been based on 32 years (1950-1981) of data from the National Severe Storms Forecast Center, during which 37 tornadoes were reported in the 1° latitude-longitude square surrounding the site. This produces an annual frequency of 1.16 tornadoes per year.

This data base contains information on all tornadoes that have been reported since 1950, and includes information such as latitude and longitude of the tornado starting and stopping points, path width, path length, and tornado intensity. Of these tornadoes, 32 had measured path lengths and widths, which produce a mean path area of 0.342 square miles. Using Thom's formula, this produces a strike probability for any point within the 1° square of once every 9179 years.

2.3.1.2.1.3 Thunderstorms and Lightning

Thunderstorms are a seasonal phenomenon in the region of the LGS site. Philadelphia and Allentown report 27 and 32 thunderstorm days per year respectively, with 90% of these occurring between the months of April and September. The monthly distribution of thunderstorm days is shown in Table 2.3.1-6. Direct observation of lightning strikes is not a routine function at any of the standard observing stations. However, Uman (Reference 2.3.1-9) has developed a statistic which indicates that the number of lightning flashes (cloud to ground) per square mile per year is equal to between 0.05 and 0.8 times the number of thunderstorm days per year. A conservative estimate of the number of lightning strikes per year in the square mile containing the LGS site is 26.

2.3.1.2.1.4 Hail

Hail storms are a relatively rare phenomenon in the LGS site area. Pautz (Reference 2.3.1-6) reports that there were 57 occurrences of hail in the state of Pennsylvania in the 13 year period from 1955 through 1967. This converts to approximately four hail storms per year. However, hail frequency is not uniform throughout the state. Baldwin (Reference 2.3.1-10) and Changnon (Reference 2.3.1-11) both report an annual frequency of one to two hail storms per year in the eastern region of the state. Changnon indicates that these storms are most likely to occur in the late spring.

Storm data (Reference 2.3.1-12) from the period 1972 through 1976 indicate there were thirteen hail storms in Montgomery and the surrounding counties. An examination of severe weather reports in Reference 2.3.1-24 shows that in the period 1977 through mid-1982 the average number of hail storms has remained at about two storms per year. However, there is a considerable amount of variation from year to year. In 1977, there were six hail storms in the LGS region, while none were reported in 1981. The most severe of these occurred in Schuylkill County on July 29, 1974, where egg-sized hail was reported.

2.3.1.2.1.5 Ice Storms and Freezing Rain

A survey by Bennett (Reference 2.3.1-13) indicates that ice or freezing rain may occur up to three to four times per year in the LGS site region. An analysis of local climatic data from the Philadelphia (Reference 2.3.1-1) and Allentown (Reference 2.3.1-2) NWS stations for a later five year (1977-1981) period shows that freezing rain occurs approximately two days per year in Philadelphia and five days per year at Allentown. Considering the more inland and northerly location of Allentown as compared to Philadelphia, this difference is not unexpected. The fact that the LGS site is also inland and about midway between the two NWS offices in terms of latitude makes the previous estimate of three to four storms per year reasonable. However, glaze accumulations greater than 0.25 inches would be expected only once per year. In the 5 year period from 1972 through 1976, eight cases of freezing rain were reported in the site area.

The NWS stations also make observations of another type of frozen precipitation known as ice pellets. However, unlike freezing rain, ice pellets are frozen before reaching the ground and do not form a glaze, but rather bounce on impact in a way similar to hailstones. The Philadelphia and Allentown NWS stations averaged 7 and 8 days per year respectively when ice pellets were observed during the 5 year (1977-1981) period. However, many of these were isolated observations in conjunction with other types of precipitation and could not categorically be called ice storms.

2.3.1.2.1.6 High Air Pollution Potential

Episodes of limited atmospheric dispersion in the U.S. have been studied by Holzworth (Reference 2.3.1-14) in terms of urban and area source problems. Holzworth has estimated a total of 25 forecast days of high potential for air pollution in a 5 year period in the vicinity of the site. Using a pressure gradient technique to define stagnating conditions, Korshover (Reference 2.3.1-15) found 175 stagnation days in the vicinity of the site during the 40 year period from 1936 through 1975. This converts to 4.4 stagnation days per year, which agrees well with Holzworth's estimate.

Subsequent work by Korshover (Reference 2.3.1-25) has identified 31 additional stagnation days in the period 1976-1981. This also results in an average of 4.4 days per year, which is consistent with Korshover's earlier analysis.

2.3.1.2.2 Maximum Snow Load

The weight on the ground of the 100 year mean recurrence interval snowpack at the LGS site is 25 psf. This value was obtained from estimates by the American National Standards Institute (Reference 2.3.1-16) which are based on the work of Thom (Reference 2.3.1-17). The extreme snow load may be estimated by adding the weight of the 48 hour probable maximum winter precipitation (assumed to occur as snow) to the weight of the 100 year snowpack. From the work of Riedel et al (Reference 2.3.1-18) the 48 hour probable maximum winter precipitation is estimated

to have a water equivalent of 15.0 inches, which has a ground force of 78 psf. Therefore, the extreme snow load on the ground at the LGS site is estimated to be 103 psf.

It should be emphasized that this estimate is unrealistically conservative and is presented only for structure design purposes. The 48 hour probable maximum precipitation is based upon theoretical considerations, not measured values. The assumption that the entire amount falls as snow leads to an estimate of 150 inches of snow in 48 hours, using the standard 10:1 conversion ratio. This is more than double the maximum annual snow accumulation at the Philadelphia, Reading, or Allentown NWS stations in the past 40 years of record. The snowstorm of March 19, 1958 through March 21, 1958, is generally regarded as the worst snowstorm on record for snow load accumulation in the LGS area. This was due to the large snow accumulations and the extremely high water content (20% by volume) of the snow (Reference 2.3.1-19). The maximum water content measured in the site area during this storm was 4.43 inches at Coatesville, Pennsylvania.

2.3.1.2.3 Meteorological Design Basis for the Ultimate Heat Sink

The design basis meteorology for the UHS (spray pond) is discussed in Section 9.2.6.

2.3.1.2.4 Design Basis Tornado

The design basis tornado parameters at the LGS site are presented in Table 2.3.1-7. These parameters were finalized prior to the issuance of Regulatory Guide 1.76 (Reference 2.3.1-20) and are not identical to those listed in the guide for Region I, however they are considered to be equivalently conservative. While the translational speed listed is lower than that of the guide, the rotational speed is higher, and the sum of the two is the same as that of the guide. The lower value of rate of pressure drop is conservative since it implies a longer duration of the pressure load, resulting in a larger dynamic load factor. A value for radius of maximum rotational speed is not specified since it is not required in designing structures to withstand the design basis tornado.

The rotational wind speed of 300 mph used in the analysis of plant design adequacy for tornado resistance (Section 3.3.2.1) was determined from Figure 2.3.1-1. For the LGS reactor enclosure, the design basis tornado (300 mph rotational wind speed plus 60 mph translational velocity) imposes an average wind loading of 220 mph, as determined from the area under the curve of the middle graph of Figure 2.3.1-2. Therefore, 300 mph is taken as a conservative wind speed applied uniformly over the entire structure surface, as shown in Figure 2.3.1-2. Because this rotational wind speed is higher than the value listed in Regulatory Guide 1.76, the analysis is conservative compared to an analysis using the Regulatory Guide 1.76 parameters.

2.3.1.2.5 Fastest Mile of Wind

The 100 year recurrence interval fastest mile of wind to be expected at the LGS site is 82 mph. This value is obtained from the work of Thom (Reference 2.3.1-21), and is valid 30 feet above the ground. Table 2.3.1-8 shows the vertical distribution of the fastest mile of wind, computed using the common power law, in the form:

$$U_z = U_{30}\left(\frac{z}{30}\right)^b \qquad \text{(EQ. 2.3-1)}$$

where:

U_z = wind speed at height z

U_{30} = wind speed at 30 feet

b = stability dependent exponent

Thom indicates that a value for b of 1/7 is appropriate for high wind speeds in rolling rural terrain such as that at LGS.

The design basis wind velocity and associated parameters are discussed in Section 3.3.1.1.

2.3.2 LOCAL METEOROLOGY

Local meteorological data have been collected at the LGS site since January 1972. The analysis of this local meteorology has been based upon five years of site data collected at Weather Station No. 1, from January, 1972 through December, 1976. This is the primary onsite meteorological installation, and is located on high ground (base el 250' MSL) approximately 3000 feet NNW of the reactor-turbine enclosure.

A second meteorological tower, installed at Weather Station No. 2, is located in the Schuylkill River Valley (base el 121' MSL) approximately 3000 feet SSW of Tower 1, to allow comparison of the meteorological conditions in the shallow river valley with those on the adjacent hill. One year of data from April, 1972 through March, 1973 has been selected for this comparison, as it represents the best 1 year cycle of concurrent data recovery between Weather Stations No. 1 and 2.

In addition, two years of data were obtained between January, 1975 and December, 1976 from a light wind sensor on the Satellite Meteorological Tower. This tower is located on the east side of the valley floor in a position to detect any downslope or drainage flow. The exact locations of all weather stations and instruments used in the analyses are shown in Figures 2.3.3-1 and 2.3.3-2. Data recovery from all instruments for each of the time periods summarized in the analyses is shown in Table 2.3.2-1.

2.3.2.1 Normal and Extreme Values of The Meteorological Parameters

(MES was one of the meteorological consultants for licensee during the preoperational phase, 1970-1983. The reference to MES as the meteorological consultant for the licensee is considered historical information.)

2.3.2.1.1 Wind Direction and Speed

The wind measurements at LGS are unique in terms of both the locations and elevations of the sensors. The middle-level and upper-level sensors on Tower 2, at Weather Station No. 2, are located at the same elevations above mean sea level as the lower and middle level sensors on Tower 1, at Weather Station No. 1, though their elevations above grade differ. As can be seen in Figure 2.3.3-2, the 159 foot level on Tower 2 and the 30 foot level on Tower 1 are both located el 280' MSL. For the purposes of this analysis, this MSL height has been designated as "level one". The 304 foot level on Tower 2 and the 175 foot level on Tower 1 are both located el 425' MSL. This elevation has been designated as "level two" in the subsequent analysis.

Distributions of wind speed and direction by atmospheric stability class are listed in Reference 2.3.2-23. Wind directions have been grouped into 22.5° sectors. Atmospheric stability has been classified using both the Brookhaven turbulence classes of Singer and Smith (Reference 2.3.2-1)

and the Pasquill stability classes as defined by the lapse rate criteria in Regulatory Guide 1.23 (Reference 2.3.2-2). Joint frequency distributions of wind speed and direction by atmospheric stability class are provided in Reference 2.3.2-23. Two copies of this report were transmitted to the NRC by letter from E.J. Bradley (PECo) to D.G. Eisenhut (NRC) dated July 27, 1981. An hour-by-hour listing of hourly averaged parameters on magnetic tape was transmitted to the NRC by letter from J.S. Kemper (PECo) to D.G. Eisenhut (NRC), dated August 7, 1981.

2.3.2.1.1.1 Five Year Climatology of Wind Direction and Speed

Annual wind direction distributions from all levels at Tower 1 are summarized for the 5 year period, January 1972 to December 1976 in Table 2.3.2-2. The distribution is essentially the same at all levels, with the WNW and NW sectors being predominant. Wind directions are more or less evenly distributed among the remaining sectors. Seasonal variations at Tower 1 are small, but a slight increase in the frequency of south winds is evident at all levels during the summer months.

Monthly average wind speeds from Tower 1 are summarized in Table 2.3.2-3. The highest monthly average wind speeds occur in early spring, while lower speeds predominate during the summer months. The higher wind speeds measured at Tower 1 usually occur with wind directions from the predominant sectors. The maximum hourly average wind speed measured during the 5 year period was 50 mph on December 2, 1974. This was the result of a low pressure system moving up the Atlantic coast.

MES is the meteorological consultant for the licensee. MES chart reading procedures state that wind speed shall be read as an hourly average. In the case of calm winds, this would be an hourly average of 0 mph.

During the 5 year period (1972-1976) of record, chart reading procedures for wind directions during calm hours changed. Calm hours during the period 1972-1975 were assigned a direction of 777, indicating the trace was uninterpretable. However, examination of the charts from this period indicated that in most cases a direction could be obtained, and that despite the limitations of such a procedure, it was preferable to an arbitrary assignment of direction for a given calm hour. Accordingly, the chart reading procedures were changed, and beginning January 1, 1976, a direction was read for each calm hour.

When calm hours were entered into the joint frequency distributions, those calm hours with uninterpretable directions were distributed uniformly among the directional sectors. Those calm hours with valid directions were put into the sector indicated by that direction. All calm hours were arbitrarily classified as stable and were entered into Class F in the lapse rate distributions.

Tables 2.3.2-27 through 2.3.2-33 contain distributions of calm hours from Tower 1, Tower 2, and the Satellite Tower. In each case the distribution of calm hours which were included in the Class F, 0-3 mph category of each wind rose are compared with the distribution of calms according to the Regulatory Guide 1.111 technique.

Because calm hours were arbitrarily placed in Class F in the earlier wind roses, it was possible for a calm hour with a missing delta temperature to be entered into the distribution. For this reason, the total number of calms in the Regulatory Guide 1.111 type distribution does not match the earlier totals.

Regulatory Guide 1.111 states that calms should be defined as hourly average wind speeds below the starting speed of the vane or anemometer. The starting threshold of the Bendix six-bladed Aerovane is 1.8 mph. However, it is a well-known fact that once a propeller is set in motion, it can

operate at speeds below the starting threshold. Unpublished tests conducted by Brookhaven National Laboratory at the New York University wind tunnel during the 1950s showed that the stopping threshold of the six-bladed Aerovane was roughly 1 ft/sec (0.7 mph) lower than the starting threshold. This indicates that hourly averages of 1 mph are possible.

In addition, MES chart readers are trained to distinguish a calm wind trace from a 1 mph trace based on an analysis of both the speed and direction traces. Figure 2.3.2-6 shows typical light wind speed traces, and an example of the differentiation between calm and 1 mph wind speeds. The hours ending at 6 am and 7 am are calm wind traces, evidenced not only by a 0 mph wind speed, but also by a "boxy" directional trace. However, during the hour ending at 8 am and continuing into the following hour, both the speed and direction traces have become active, with speeds fluctuating between 0 mph and 2 mph. Both of these hours would be read as 1 mph.

The primary reason that calm hours were included in a 0-3 mph wind rose grouping rather than a separate class was to provide compatibility with MES dispersion models. However, it should be noted that Regulatory Guide 1.111 does not specifically say that calms should be assigned "as a separate wind speed class."

2.3.2.1.1.2 The Effect of Terrain on Wind Direction and Wind Speed

In order to assess the influence of the Schuylkill River Valley on the low level wind flow, a 1 year comparison was made between wind measurements at Tower 1, located above the river valley, and Tower 2, located on the valley floor. Wind data from the Satellite Tower were also included in this comparison when appropriate. Though the satellite wind data are from a time period not concurrent with the other towers, these data do provide further insight into the valley circulation and are therefore included.

Annual wind direction distributions from Towers 1 and 2 for the period April, 1972 through March, 1973 are shown in Tables 2.3.2-4 and 2.3.2-5. The 1 year wind direction distribution at Tower 1 is very similar to the 5 year distribution previously presented in Table 2.3.2-2. The wind direction distribution at Tower 2 is somewhat more complex, with the distribution at the 30 foot level showing a preference for those directional sectors parallel to the river valley. Table 2.3.2-6 compares the wind direction distributions from Tower 1 and 2 along the equivalent mean sea level heights, "level one" and "level two." The directional distributions on each of these levels are nearly identical, indicating that winds at the middle and upper levels on Tower 2 are not affected by the underlying valley terrain.

A comparison of the wind direction distributions from the 30 foot sensors on Towers 1 and 2 for the 1 year period is shown in Table 2.3.2-7. The 2 year satellite tower wind distribution is also included for comparison. An increase in the wind directions centered about the NNW and SSE sectors, the orientation of the Schuylkill River Valley, is evident when the 30 foot directional distributions from Tower 2 and the Satellite Tower are compared with the low level directional distribution at Tower 1, situated above the river valley. This effect is most prevalent during low wind speed and stable atmospheric conditions during the summer months.

A comparison of monthly average wind speeds from Tower 1, Tower 2, and the satellite tower is shown in Table 2.3.2-8. Average speeds at Tower 1 are very similar to the 5 year wind speed record summarized in Table 2.3.2-3. Higher average winds occur in the spring, and lower wind speeds predominate in the summer months. A comparison of monthly average wind speeds along level one and level two shows that small differences exist between towers along each level, but they are usually less than 1 mph. It should be noted that there is a preference for lower wind

speeds at the low level sensors located in the river valley. Both Tower 2's 30 foot and the Satellite Tower's 30 foot wind speeds are significantly lower than the 30 foot wind speeds measured above the valley at Tower 1. This is reflected in the comparison of monthly average wind speeds shown in Table 2.3.2-8, as well as in the percentage of calm hours. The Tower 2's 30 foot sensor reported 21.5% calm, comparing well with the more sensitive Satellite Tower anemometer which reported 17.5% calm. In contrast the 30 foot sensor on Tower 1 above the river valley reported only 8.1% calm.

This comparison of low level wind speeds, along with the previously discussed comparison of low level wind directions, clearly indicates that the wind measurements obtained on the satellite tower are similar to those obtained at the 30 foot level on Tower 2, and that the satellite tower is representative of the low level wind flow in the Schuylkill River Valley.

2.3.2.1.1.3 Wind Direction Persistence

Wind direction persistence at the LGS site has been analyzed using a technique which determines the number of consecutive hours the wind direction remains in the same 22.5° sector. This analysis is performed with a sliding technique, using each hour as the starting point in determining persistence. The results, which appear in Reference 2.3.2-23, were derived by tabulating the number of times the wind direction, at each level, remains in the same sector for periods of 6, 12, 24, 36, and 48 hours.

The 5 year annual summary of Tower 1 wind direction persistence indicates that the highest frequency of persistent winds occurs in the predominate (WNW) sector. Examination of the monthly distributions indicates that the most persistent winds occurred during the months of June and August.

Wind direction persistence during the 1 year period of concurrent data from Towers 1 and 2 is also summarized in Reference 2.3.2-23. Comparison of the annual distributions between the two towers shows that wind directions were more persistent at Tower 2 than at Tower 1. The 30 foot distribution at Tower 2 shows the most persistent winds in the NW and NNW sectors, which parallel the river valley.

The monthly summaries for this 1 year period indicate that the most persistent winds occurred during January, not during the summer as one might expect. Examination of hourly meteorological data and synoptic charts indicates that these winds were caused by a strong gradient flow from a slow-moving low pressure system rather than any micrometeorological phenomenon.

2.3.2.1.1.4 Climatological Representativeness of the LGS Wind Data

In order to assess the representativeness of the LGS wind data, the 5 year Tower 1, 270 foot wind distribution has been compared with distributions from the Philadelphia and Allentown NWS stations, and from the PBAPS Meteorological Tower. While the Philadelphia and Allentown data are not derived from the exact same time as the LGS data, they are the most concurrent summaries available from the National Climatic Center.

The distance and directional orientations of these stations from the LGS site are listed below.

Station	Distance and Orientation

	from LGS
Philadelphia	31 miles SE
Allentown	31 miles N
PBAPS	48 miles SW

The annual wind direction distributions from Philadelphia (Reference 2.3.2-3), Allentown (Reference 2.3.2-4), and PBAPS are compared with LGS in Figures 2.3.2-1 through 2.3.2-3. These comparisons indicate that both Philadelphia and Allentown have a larger frequency of winds from the SW direction than LGS. The predominant winds at Philadelphia and Allentown are from the SW and WSW respectively, as compared to a predominant WNW wind at LGS. These distributions are similar in all nonpredominant sectors.

The comparison between the LGS 270 foot and PBAPS 320 foot distributions shows a much closer agreement. This is to be expected since PBAPS is the only station of those compared with a sufficient sensor elevation to be free of local effects.

Due to the large discrepancy in sensor elevation and surface roughness between LGS and the NWS stations, PBAPS is the only site with which meaningful wind speed comparisons can be made. A comparison of these two locations in Table 2.3.2-9 shows that the wind speed frequency distributions are almost identical. The LGS 270 foot sensor has a mean wind speed of 10.4 mph, compared to 10.6 mph at the PBAPS 320 foot sensor.

An evaluation of the climatological representativeness of the time period in which the site data was obtained may be made from a comparison of the concurrent short-term data from the NWS stations with their long-term records. Ten year wind directional distributions from Philadelphia (Reference 2.3.2-5) and Allentown (Reference 2.3.2-6) are compared with the short-term records from each station in Figures 2.3.2-4 and 2.3.2-5. The long-term and short-term records at Allentown are essentially identical. However, some differences are evident in the long-term and short-term Philadelphia comparison.

Several changes in both sensor elevation and location were made at Philadelphia between 1951 and 1960, which could account for some of the differences in the directional distributions.

2.3.2.1.2 Atmospheric Stability

2.3.2.1.2.1 Stability Class Breakdowns

Monthly and annual summaries of atmospheric stability have been incorporated into the wind roses previously discussed in Section 2.3.2.1.1. Annual breakdowns of atmospheric stability classes for the 5 year record at Tower 1, and the 1 year comparison of Towers 1 and 2 are summarized in Tables 2.3.2-12 and 2.3.2-13.

The Brookhaven turbulence classes have been determined using the method of Singer and Smith (Reference 2.3.2-1), which is based upon the short-term fluctuations of the Aerovane wind direction trace. The uppermost Aerovane on each tower, the 270 foot sensor on Tower 1, and the 304 foot sensor on Tower 2 were used to determine the turbulence class. The specific criteria used to define each turbulence class are given in Table 2.3.2-14. The Pasquill stability classes were determined using the temperature lapse rate criteria of Regulatory Guide 1.23 (Reference 2.3.2-2). Lapse rates were measured over the full height interval and between the middle and low levels of each tower.

In the 5 year record at Tower 1, there are distinct differences between the two stability classification systems. The Brookhaven system classifies over 55% of the hours as unstable, compared to approximately 12% unstable, as determined by delta temperature measurements over the full tower height. The lapse rate system predicts approximately 27% more neutral hours and 19% more stable hours than the Brookhaven system. When lapse rates over the lower portion of Tower 1 are used, the number of unstable hours (according to the NRC system) increases slightly, primarily at the expense of neutral hours. The frequency of stable hours as determined by lapse rate criteria remains about the same, regardless of which height interval on the tower is used.

When the stability class breakdowns from Towers 1 and 2 are compared for the April, 1972 through March, 1973 period, the same basic differences between the Brookhaven and NRC systems are evident. There are also significant differences between the two towers within each classification system.

When the Brookhaven stability breakdowns from the two towers are compared in Table 2.3.2-12, Tower 2 reports approximately 10% more unstable hours. This can be attributed primarily to the fact that the 304 foot Aerovane on Tower 2 is located 95 feet lower in reference to surrounding terrain than the 270 foot sensor on Tower 1, and is subject to increased turbulence due to surface friction.

A difference between Towers 1 and 2 is also seen in Table 2.3.2-13 when the Pasquill stability classes are contrasted. Regardless of which height interval is considered, Tower 2 categorizes over 65% of the hours as stable. This is an increase of approximately 15% as compared to Tower 1 for the same time period.

2.3.2.1.2.2 Temperature Inversion Persistence

Monthly and annual summaries of temperature inversion persistence at the LGS site are provided in Reference 2.3.2-23. A temperature lapse rate of greater than 0°C/100m has been used to define inversion conditions. Strong inversions with a lapse rate greater than 1.5°C/100m (Pasquill classes F and G) have also been tabulated.

The most persistent inversion during the five years of measurements at Tower 1 occurred from 2100 August 24, 1974 through 0800 August 26, 1974. This inversion lasted for 36 consecutive hours, and was associated with a large high pressure system which descended from Canada. Winds at the site during this time were variable coming from the SW through NNE direction. The second most persistent inversion lasted 29 hours, and was associated with a Canadian high pressure system which moved through the site area on July 16, 1974 and July 17, 1974.

The most persistent inversions found during the 5 year record usually occurred between the months of August and December.

A comparison of inversion persistence at Towers 1 and 2 for the period April, 1972 through March, 1973 shows that the inversions in the river valley at Tower 2 are more persistent. This comparison also shows that the more persistent inversions occur in the latter half of the year. In 1972 they were confined primarily to the period August through October.

2.3.2.1.2.3 Monthly Mixing Heights

No measurements of mixing height have been made at the LGS site. The nearest NWS upper air station is at Kennedy Airport in New York City. The use of Kennedy data at LGS would be unrealistic. Therefore, in the absence of measurements, the mean seasonal morning and afternoon mixing heights reported by Holzworth (Reference 2.3.2-7) are shown in Table 2.3.2-15. These data have been extracted from the plots in the Holzworth report, and are the best approximations available for mixing heights at LGS.

2.3.2.1.3 Temperature

Ambient dry-bulb temperatures at the LGS site have been summarized in Table 2.3.2-16 and in Reference 2.3.2-23.

The monthly means and extremes of temperature recorded at Weather Station No. 1 are shown in Table 2.3.2-16. The maximum hourly temperature measured at the site was 96.2°F on August 28, 1973. The minimum observed temperature was 0.7°F on January 16, 1972.

2.3.2.1.3.1 Climatological Representativeness of LGS Temperature Data

Monthly mean temperatures from LGS are compared with the concurrent and long-term records from the Philadelphia and Allentown NWS stations in Tables 2.3.2-17 and 2.3.2-18. Both comparisons indicate that 1972 through 1976 was a normal period in terms of temperature. Both NWS stations show little deviation from the long-term record. Temperatures at Allentown are usually slightly cooler than those at Philadelphia, while temperatures at LGS usually fall in between the values from the two NWS stations.

2.3.2.1.4 Precipitation

Precipitation from the LGS site has been summarized in Table 2.3.2-19 and in Reference 2.3.2-23.

As Table 2.3.2-19 indicates, the monthly variation of precipitation at the site is small. The annual mean precipitation measured during the 5 years of record was 59.57 inches. The maximum hourly precipitation (2.25 inches) was recorded during hurricane Agnes in June, 1972. The maximum monthly total (14.23 inches) was in November, 1972, as a result of several moderate rainfalls.

Wind roses, by precipitation rate class, indicate a predominately east to northeasterly flow at the site during precipitation hours. This does not vary seasonally or by precipitation rate class.

Precipitation rate distributions and precipitation intensity versus duration summaries in Reference 2.3.2-23 indicate that the majority of the precipitation at the site has an intensity of $\leq$0.05 in/hr. However, hourly totals exceeding 1 inch were recorded nine times during the 5 year record; and continuous rainfalls of >0.10 in/hr have been observed for up to 12 hours.

2.3.2.1.4.1 Climatological Representativeness of LGS Precipitation Data

Monthly average precipitation values from LGS are compared with the concurrent and long-term records from the Philadelphia and Allentown NWS stations in Tables 2.3.2-20 and 2.3.2-21. These comparisons indicate that even though the 1972 through 1976 period was characterized by abnormally high precipitation amounts, significantly higher precipitation totals were recorded at the site when compared to the NWS stations.

2.3.2.1.5 Humidity

Relative and absolute humidity, dew point temperature, and wet-bulb temperature from Weather Station No. 1 are summarized in Reference 2.3.2-23.

The annual frequency distribution of relative humidity shown in Reference 2.3.2-23 is skewed toward the higher humidities, with the 90% through 100% grouping containing approximately 30% of the total hours. A seasonal trend is evident in the monthly frequency distributions of relative humidity shown in Reference 2.3.2-23, as conditions of high relative humidity (90% through 100%) are more common in the summer and fall months.

The annual frequency distribution of absolute humidity from Weather Station No. 1 is shown in Reference 2.3.2-23. Absolute humidity is expressed in grams of water vapor per cubic meter of air. The maximum frequency is in the 3.01-4.00 g/m^3 category, but the values are quite evenly distributed. There is also a large seasonal variation in absolute humidity as Reference 2.3.2-23 shows. This is expected as the ability of dry air to hold water vapor is temperature-dependent.

The annual frequency distribution of dew point temperatures from the site is shown in Reference 2.3.2-23. The largest frequency of hours occurs in the 60.0°F to 64.9°F category, but the distribution is quite even between 20°F and 65°F. The seasonal trend in dew point temperatures is self-evident.

Cumulative frequency distributions of wet-bulb temperature from the site are given for the annual and monthly cases in Reference 2.3.2-23. Due to the unusually long period of record at the site (5 years), the cumulative frequency distributions of wet-bulb temperature have been computed using onsite data rather than the Philadelphia or Allentown NWS data.

2.3.2.1.5.1 Climatological Representativeness of Humidity Data

Because of its sensitivity to changes in temperature and elevation, relative humidity data from site to site are difficult to compare. Some idea of the climatological representativeness of the LGS data can be seen in Table 2.3.2-22, where mean morning (7 am) and afternoon (1 pm) values of relative humidity from Philadelphia, Allentown, and LGS are compared. As the table shows, in most months the mean values from the three sites are within a few percent of each other. LGS and Allentown are the most similar, with Philadelphia usually a few percent lower, especially in the morning.

Another indication of the climatological representativeness of the LGS relative humidity data can be seen from the summaries of daily average relative humidity given in Section 9.2.6.

In this analysis, two and one-half years (January 1972 through June 1974) of LGS daily average relative humidity data were compared with the concurrent and long-term (34 years) records from Philadelphia. These daily average relative humidity data are summarized in the frequency distribution in Table 2.3.2-23. This table shows that LGS has a higher frequency of days in the 90% through 100% range, and that the concurrent data are representative of long-term conditions at the site. A comparison of frequency distributions of hourly relative humidity values between LGS and Philadelphia is shown in Table 2.3.2-24. This comparison also indicates that LGS has a larger frequency of high relative humidity values.

2.3.2.1.6 Fog

No measurements of natural fog or visibility have been made at the site. However, an approximation of the fog and visibility characteristics of the site can be obtained from the Philadelphia and Allentown National Weather Service data. Table 2.3.2-25 compares the mean

number of days with heavy fog at these two stations. Heavy fog is defined as fog causing visibility to decrease to ¼ mile or less.

This comparison shows surprisingly little difference between the two sites, with Philadelphia averaging 25 days of heavy fog per year, compared to 29 for Allentown. It is reasonable to assume that a similar frequency of heavy fog would be found at LGS.

2.3.2.2 Potential Influence of the Plant and Its Facilities on Local Meteorology

A recent EPRI study by Laurmann (Reference 2.3.2-8) has concluded that although quantitative predictions of the meteorological effects resulting from power plant operation cannot be made, evidence and theory indicate that plants of conventional size (up to 4000 MWe) rarely produce noticeable weather changes. The minor effects on the local meteorology which might occur may be divided into two distinct categories: those attributable to the turbulent wakes associated with the plant structures, and those attributable to the waste heat dissipation system.

2.3.2.2.1 Turbulent Wake Effects From Plant Structures

As part of the technical support for the tall stack regulations in the 1977 Clean Air Act Amendments, the EPA has published a comprehensive review and literature search (Reference 2.3.2-9) on the aerodynamic effects caused by building structures. The consensus of this review is that a structure produces a cavity of increased turbulence on its leeward side, 1.5 building heights deep and persist for approximately five building heights downwind. Based upon these criteria, it is estimated that the turbine-reactor enclosure complex produces a turbulent wake on its leeward side, extending 300 feet vertically and persisting 1000 feet downwind.

Halitsky (Reference 2.3.2-10) has shown through wind tunnel tests that the turbulent effects produced by rounded structures are not as large or severe as those produced by sharp-edged buildings. This is consistent with the results of a combined wind tunnel/field measurement study conducted by Smith and Mirabella (Reference 2.3.2-11) on the cooling tower induced wake at the SMUD Rancho Seco Plant. Their results indicate that the cooling towers produce a turbulent wake only when wind speeds exceed 2 m/sec. They estimate that the wake would be 1.5 structure heights deep, and would persist for 2-3 tower diameters downwind. According to these criteria, the maximum wake produced by two LGS cooling towers would be a turbulent region extending 750 feet vertically and persisting 3400 feet downwind.

2.3.2.2.1.1 Effect of the Turbulent Wake on the Gaseous Reactor Effluent

The primary effect of the structurally induced wakes on the reactor effluent is to bring the effluent plume to the ground more quickly, and to increase the dispersion rate. These factors are accounted for in the diffusion calculations presented in Sections 2.3.4 and 2.3.5.

2.3.2.2.1.2 Effect of the Turbulent Wake on the Meteorological Measurements at Tower 1

The turbulent wake produced by the turbine-reactor enclosure complex is not large enough to affect Tower 1. However, Tower 1 is only 2200 feet from the cooling towers, and is in their turbulent wake during a small percentage of the time. The wake is not expected to have any effect upon mean wind directions or speeds at Tower 1. However, when wind directions are between 135° and 165°, turbulence class readings may be shifted toward a more unstable classification. The 5 year turbulence class wind rose provided in Reference 2.3.2-23 shows that wind speeds >2 m/sec with directions between 135° and 165° occur during 5.3% of the time. However, over half (3.0%) of these hours are already classified as unstable due to natural turbulence. (Note: the 5

year data set represents a period prior to any cooling tower construction). Thus only 2.3% of the total hours might be changed from a stable or neutral to a more unstable classification.

2.3.2.2.2 Potential Effects of the Waste Heat Dissipation System on the Local Meteorology

2.3.2.2.2.1 Natural Draft Cooling Towers

During the early 1970s a large number of publications appeared in open literature speculating upon the atmospheric effects attributable to natural draft cooling towers. As Carson (Reference 2.3.2-12) has pointed out, all too often these studies have predicted atmospheric effects that do not in fact occur. Recently, data from field studies have become available. These studies indicate that while the potential for some minor atmospheric effects resulting from cooling tower operation does exist, the magnitude of these effects is much less than that indicated by earlier theoretical evaluations.

2.3.2.2.2.1.1 Ambient Temperature

Operation of the cooling towers has no effect on the ambient temperatures in the LGS area. Field studies reported by Kramer et al (Reference 2.3.2-13) and Brennan et al (Reference 2.3.2-14) have shown that the cooling tower plumes rise to heights well above the tower tops. Therefore, the cooling towers should have no measurable effects upon the mean surface temperature.

2.3.2.2.2.1.2 Relative Humidity

Observational studies have shown that no changes in the ground level relative humidity should be expected as a result of natural draft cooling tower operation. In a study of a 2000 MW, 8 tower complex in England, Spurr (Reference 2.3.2-15) found no differences in the ground level relative humidity upwind or downwind of the plant.

2.3.2.2.2.1.3 Fog

The cooling tower induced environmental effect most often mentioned is ground level fogging. Observations at natural draft cooling tower installations both in the U.S. (Reference 2.3.2-13) and in Europe (Reference 2.3.2-15) indicate that the visible plume rarely, if ever, intersects the ground surface causing fog. Hosler (Reference 2.3.2-16) reports one observation of the visible cooling tower plume intersecting the ground at the Keystone plant in western Pennsylvania. However, the cooling towers at Keystone are much shorter than those at LGS, making them more susceptible to downwash and subsequent fog problems. The added tower height at LGS, along with a larger exit diameter, should ensure a sufficient rise to prevent downwashing.

2.3.2.2.2.1.4 Solar Radiation

The cooling towers do have the potential to cause slight decreases in the amount of solar radiation received at the site due to plume shadowing. Seeman (Reference 2.3.2-17) has conducted a study at a 1500 MW fossil fuel plant in Europe, and found that a 35% reduction in total radiation (total radiation = solar radiation + whole sky radiation) is possible at the point of maximum shadowing by a visible plume on a clear day. On a cloudy day, the maximum shadowing effect is a 20% reduction in total radiation for short periods of time. Due to the variability in wind direction, the plume moves horizontally and does not remain over any one point for long periods of time, thus giving the same effect as a passing small cumulus cloud. However, Ryznar (Reference 2.3.2-18) has measured increases in solar radiation due to the reflection from the side of the visible plume.

An empirical method for providing climatological estimates of visible plume rise and persistence has been described by Brennen et al (Reference 2.3.2-14). This technique uses one year of Philadelphia International Airport upper air soundings as input and shows that the majority of the long plumes conducive to shadowing occur on days when natural clouds are already present, and (during the winter) when agricultural considerations are minor.

The updraft of heat and water vapor in a natural draft cooling tower can, under the proper conditions, produces cumulus clouds or augments already existing cloud decks. This phenomenon has been documented by both Smith (Reference 2.3.2-19) and Spurr (Reference 2.3.2-15); but it can be expected to occur only when conditions favor natural cloud formation.

2.3.2.2.2.1.5 Precipitation Modification

Observations of precipitation falling from natural draft plumes are very limited. Kramer et al (Reference 2.3.2-20) have documented one observation of light rain falling from a natural draft plume, and several observations of light snowfall. Though it may be possible for a cooling tower to modify the precipitation pattern immediately downwind of the tower, it would not significantly alter the total precipitation in the region, as the water vapor emissions from the towers are small compared to natural fluxes (Reference 2.3.2-12).

During the winter of 1975-1976, Kramer et al (Reference 2.3.2-21) observed light snow from several different cooling towers on ten separate days. This effect was found only during stable atmospheric conditions, with temperatures below 10°F at the height of the plume centerline. In the one year summary of Philadelphia upper air soundings on 22 days, for short periods, the temperature criteria necessary for snowfall were met. This should not be interpreted as a prediction of snowfall frequency. There are several other variables such as atmospheric stability, blowdown water chemistry, drift eliminator condition, and condensation nuclei availability which play a role in snowfall formation. The height to which the plume rises is such that in most cases the snow crystals would sublimate before reaching the ground. There is also a strong likelihood that downslope motion to the east would tend to prevent any depth of cloud development with westerly flow.

Additional precipitation may also come from the cooling tower in the form of drift droplets, though the amounts are very small. Drift deposition at LGS has been evaluated using the model of Hosler, Pena, and Pena (Reference 2.3.2-22). This model indicates that most of the drift deposited from the towers will be in the form of liquid drops, with the amount deposited decreasing with distance from the towers. The annual precipitation increase has been evaluated at the site boundary in each sector. The maximum annual increase in precipitation was 0.253 inches at the ESE site boundary. This is less than 1% of the annual total of natural precipitation reported in Section 2.3.2.1.

2.3.2.2.2.1.6 Atmospheric Stability

In addition to the wake-induced turbulence discussed in Section 2.3.2.2.1, there will also be increased turbulence in the visible cooling tower plume itself directly downwind of an evaporating plume. If the gaseous reactor effluent were entrained into the cooling tower plume, the only effect would be increased rise and dispersion of the effluent, and therefore lower ground level concentrations.

2.3.2.2.2.2 Emergency Spray Pond

The UHS at LGS is a spray pond. During routine operations this pond will not be heated, and water temperatures will fluctuate in response to ambient meteorological conditions in the same manner as any natural pond of the same size. This should produce no adverse impact to the local meteorology.

2.3.2.3 Topography

The topography of the LGS site is described in Section 2.1.1. The topography of the region surrounding the site, out to a distance of 50 miles, is summarized in Table 2.3.2-26 which lists the offsite terrain elevation (in feet above MSL) versus distance from a point midway between the LGS vents. The value listed is the maximum elevation on or outside the site boundary which occurs within each of the sixteen 22.5° sectors at the distance listed.

These terrain elevations were obtained from USGS maps.

2.3.3 ONSITE METEOROLOGICAL MEASUREMENTS PROGRAM

The onsite meteorological measurements program at the LGS site began on December 10, 1970 with preliminary wind measurements taken from a six-bladed Aerovane located 30 feet above grade on a temporary pole. Wind speed and direction data were continuously collected at the temporary pole until December 28, 1971 when it was removed from service. Prior to the sensor removal, the onsite meteorological measurements program was expanded on December 10, 1971 with the installation of Weather Station No. 1 near the temporary pole location. The main tower (Tower 1) extending about 281 feet above grade (el 250' MSL) was erected on high ground, NW of the reactor locations. Wind speed, wind direction, and temperature from three elevations are continuously recorded. Instrument elevations are listed in Table 2.3.3-1. Additional onsite measurements of horizontal and vertical wind direction fluctuations, relative humidity, barometric pressure, and precipitation complete the observation at Weather Station No. 1.

In order to evaluate the effects of the shallow Schuylkill River Valley, the onsite meteorological measurements program was again expanded on December 28, 1971 with the installation of a second weather station. Weather Station No. 2 is located across the Schuylkill River from the main tower and is onsite in an open field having a base elevation close to that of the valley floor. Tower 2 at this location, extends 314 feet above grade (el 121' MSL). Wind speed, wind direction, and temperature from three elevations are continuously recorded. Tower 2 was established to provide supplementary site data on the temperature profile in the valley during the preoperational period. This tower was instrumented at MSL elevations coincident with those of Tower 1 in order to compare meteorological conditions over the valley with those over the adjacent low hills. The locations and relationships between the various wind and temperature instruments are shown in Figures 2.3.3-1 and 2.3.3-2.

The overlapping arrangement of the facilities, which allows a comparison of wind and temperature measurements from each tower at two corresponding levels, produces a complete picture of wind flow and lapse rates from the valley bottom to a point about 270 feet above the higher terrain.

To determine the typical flow over the river and adjacent low terrain, a satellite to Weather Station No. 1 was established and data collection began on November 20, 1974. The sensors are located 32 feet above grade (el 106' MSL) and are capable of continuously measuring wind speed and wind direction.

In 1983, the complete system was upgraded to comply with the criteria of Regulatory Guide 1.23 (Rev 1) and NUREG-0654. Data from each of the meteorological locations is transmitted to the control room where it is logged by a data-logger. The data is also transmitted to the TSC as input to the RMMS (Section 11.5.6).

2.3.3.1 Preoperational Meteorological Measurement System (1970-1983)

This meteorological system was used to obtain measurements as described in Table 2.3.3-1.

2.3.3.1.1 Measurements and Instrumentation

2.3.3.1.1.1 Siting

As shown in Figures 2.3.3-1 and 2.3.3-2, the main meteorological weather tower (Tower 1) located at Weather Station No. 1 is a 280 foot tower situated approximately 3000 feet NW of the LGS structure vents. Tower 1 is also located approximately 2000 feet NNW of the center of the Unit 1 cooling tower location and approximately 2400 feet NW of the center of the Unit 2 cooling tower location. Grade elevation at Weather Station No. 1 is el 250' MSL.

The wind instruments on Tower 1 are mounted on retractable booms extending upwind 10'-0" west of the tower. Each face of the triangular tower is 3'-6" wide. The temperature sensors are located in aspirators and are 2'-0" inches from the tower. Weather Station No. 1 has a base surface made of yardstone. The relative humidity sensor is located in a standard U.S. Weather Bureau-type shelter 5 feet above grade and the surface beneath the instrument shelter is wood.

Meteorological weather tower (Tower 2) located at Weather Station No. 2 is a 310 foot tower situated approximately 2100 feet west of the LGS structure vents. Tower 2 is also located approximately 1950 feet WSW of the center of the Unit 1 cooling tower location, and approximately 2600 feet WSW of the center of the Unit 2 cooling tower location.

The wind instruments on Tower 2 are mounted on retractable booms extending upwind 10'-0" WNW of the tower. Each face of the triangular tower is 3'-6" inches wide. The temperature sensors are located in aspirators and are 2'-0" from the tower. Tower 2 has a base surface made of yardstone.

2.3.3.1.1.2 Instrumentation and Performance Specifications

The instrumentation systems installed on the LGS site were designed to meet the NRC requirements at the time of installation and they generally meet those of Regulatory Guide 1.23. Any deviations from Regulatory Guide 1.23 are described in the following subsections.

The manufacturers' specifications and accuracies for the sensors and associated equipment are given in Table 2.3.3-2. Deviation from paragraph C4 of Regulatory Guide 1.23 regarding the system accuracies is discussed and justified in the following sections on each type of measurement.

2.3.3.1.1.3 Wind speed

The Bendix Aerovane Wind Transmitter, Model 120, measures wind speed by means of a six-bladed rotor coupled to the armature of a tachometer magneto located in the nose of the instrument.

The output voltage is directly proportional to the impeller rotation speed and, therefore, is a function of wind speed. This Aerovane system is used on Towers 1 and 2 at LGS.

As shown on Table 2.3.3-2, some of the instruments do not meet the required starting speeds. This presents no problem because real calm conditions with absolutely no air motion are extremely rare at most sites. Measured calms can be far more frequent, depending on the threshold speed of the instrument used.

At LGS, the number of calm hours recorded on the six-bladed Aerovane is shown in Table 2.3.3-3. All levels of both Towers 1 and 2 are instrumented with these six-bladed sensors. The 175 foot instrument at Tower 1 is at the elevation representative of vent releases. With only 1.7% calm hours, a more sensitive instrument could not produce any significant improvement. The 30 foot level of Tower 2 does have a high percentage of calm hours due to its valley location. With this in mind, light wind instruments meeting the recommendations of Regulatory Guide 1.23 were installed in the valley on the satellite tower. As shown in Table 2.3.3-3, the light wind sensor also produces a large (17.5%) number of calm hours. Experience with both types of instruments indicates that the continued durability and accuracy of the six-bladed Aerovane far outweighs the advantage of the slightly lower threshold speed offered by the light wind instruments. Regulatory Guide 1.23 also specified 90% data recovery, which is considered equally important.

The satellite tower uses a Bendix-Friez 3-cup anemometer, P/N 2416914, to determine wind speed. The 3-cup anemometer has cone-shaped cups formed of 0.010 inch thickness aluminum. The cup wheel is attached to a stainless steel shaft which rotates, via coupling, the tachometer generator. The output voltage is directly proportional to the speed of rotation and, therefore, is a function of wind speed.

2.3.3.1.1.4 Wind Direction

The Bendix Aerovane Wind Transmitter, Model 120, measures wind direction by coupling a streamlined vane to a type 1HG synchro. This synchro electrically transmits the position of the vane and, therefore, the wind direction to the recorder.

The satellite tower uses a Bendix-Friez Wind Vane, P/N 2416970, to determine wind direction. This wind vane is very light and sensitive having a low moment of inertia. Changes in azimuth angle are transmitted, via coupling, to a synchro. The signal output from this synchro is directly proportional to the angular position of the vane and, therefore, wind direction is transmitted to a synchro in the recorder.

2.3.3.1.1.5 Temperature

The ambient temperature-measuring system uses Leeds and Northrup 100 ohm copper thermohm sensors (resistance thermometers). These thermohms are accurate to ±0.2°F across the range of -10°F to 110°F. The detectors use four lead wires, two of which are connected to a constant current source and the other two lead wires are connected, via electronic amplifiers to an analog recorder. Contained in the constant current loop is the copper measuring coil, whose resistance varies with temperature, causing the voltage drop across the coil to change proportionally. This voltage drop is then sensed by the measuring loop of a null balance potentiometer having a scale calibrated in degrees fahrenheit.

2.3.3.1.1.6 Temperature Difference

The temperature difference sensors at the site are identical to the ambient temperature sensors, except for the selection of matched sets. These sets have an accuracy of ±0.1°F across a -12°F to 12°F temperature difference range. The reference thermohm (el 26') is connected (opposite in polarity) to both upper elevation thermohms. The two voltage drops (one from each set) are algebraically added, and the resulting output is equivalent to the temperature difference reading.

Both the ambient temperature and delta temperature sensors are located in a Teledyne/Geotech aspirated thermal radiation shield, Model 327. This is to ensure the measurement of ambient temperature and temperature gradients substantially independent of solar, atmospheric, and terrestrial thermal radiation.

2.3.3.1.1.7 Relative Humidity

The Bendix Hygrothermograph, Model 594, is used at and around the site to determine both relative humidity and ambient air temperature.

The relative humidity portion of the instrument consists of a hair-type humidity-responsive element, a lever system, and a cylindrical chart. The accuracy of the humidity unit is ±5% which includes the temperature effects to which the instrument may be subjected.

The temperature-responsive unit consists of a Bourdon tube, a lever system and a cylindrical chart (same cylinder used for humidity). The accuracy of the hygrothermograph temperature unit is ±1°F.

Regulatory Guide 1.23 suggests that at sites where there may be an increase in atmospheric moisture content (i.e., cooling towers) dew point or humidity should be measured on the tower. The results of published field studies (References 2.3.3-1 through 2.3.3-4) prove conclusively that the only changes in atmospheric moisture characteristics which may be experienced from cooling tower operation would occur at the plume elevation, not at the ground level. The results of approximately 400 flight test observations indicate that the cooling tower plumes would rise clear of the ground and have no effect on the low level moisture characteristics. For dew point or humidity measurements to have any relevance to cooling tower effects, they must be obtained at elevations ranging from approximately 1000 feet to 5000 feet above ground, which is not possible on a continuous basis. Since there is little or no potential for fogging or icing conditions resulting from the cooling towers, there is no need for a dew point measurement at the 10 meter level on the tower.

2.3.3.1.2 Calibration and Maintenance Procedures

2.3.3.1.2.1 Calibration

All sensors and related equipment are calibrated according to written procedures designed to ensure adherence to Regulatory Guide 1.23 guidelines for accuracy. Calibrations occur at least every six months, with component checks and adjustments performed when required.

All meters and other equipment used in calibrations are, in turn, calibrated at scheduled intervals. All instruments used in calibrations are traceable to the NBS.

2.3.3.1.2.2 Maintenance

Inspection and maintenance of all equipment is accomplished in accordance with procedures in the instrument manufacturer's manuals. This inspection occurs at least once a week by qualified technicians capable of performing the maintenance, if required. The results of the inspections and maintenance performed are kept in a log at the site. The information contained in this log is also transmitted to the environmental engineering section and meteorological consultant.

In the event that the required maintenance could effect the instruments calibration, another calibration is performed prior to returning the instrument to service.

2.3.3.1.2.3 Data Output and Recording Systems

All meteorological outputs, at this time, are recorded by analog systems. The charts from these systems are sent on a weekly basis to the meteorological consultant, MES located in Amityville, New York, for inspection to detect discrepancies or evidence of malfunction and data analysis.

The analog recording systems for the weather towers are enclosed in a structure with thermostatically controlled temperature.

2.3.3.1.3 Data Analysis Procedures

2.3.3.1.3.1 Data Quality Control

All data are subject to a quality check by MES. These analog charts are inspected for the following items:

a. Verification of log sheets versus actual charts received

b. Time continuity

c. Instrument malfunction

d. Inking problems

e. Directional switching problems

f. Negative speeds

g. Missing data

An evaluation of system performance is made monthly. The percentage of data recovery for LGS weather station instrumentation is shown from 1972 through 1976 in Section 2.3.2.

2.3.3.1.3.2 Data Reduction

All readings that are taken from the strip-charts represent hourly averages (except where noted).

Data are reduced into the different categories as follows:

Wind

a. Wind speed: hourly average speed. Negative speeds are recorded as read.

b. Wind direction: hourly average direction

c. Span: The span is read from the same portion used to obtain the average direction. Span is defined as the width of the direction trace excluding any abnormal spikes. Maximum span read is 360°.

d. Gustiness: The gustiness is read from the same portion of the chart used to obtain the average direction. Gustiness and its characteristics are described in Reference 2.3.3-5.

Temperature and Humidity

a. Hygrothermographs: All relative humidity and temperature readings taken from a hygrothermograph are instantaneous readings on the hour.

b. Ambient temperature: Recorded on a strip-chart; hourly average temperature manually recorded.

c. Delta temperature: Recorded on a strip-chart; hourly average temperature manually recorded.

2.3.3.1.3.3 Analyses

The hourly data obtained (as described) have been compiled into the series of summary tables described in Section 2.3.2. These data are used as inputs to the computation of the X/Q estimates described in Sections 2.3.4 and 2.3.5.

2.3.3.2 Operational Meteorological Measurement System (1983)

The meteorological measurement system has been upgraded to comply with Regulatory Guide 1.23 (Second Proposed Rev 1). The meteorological monitoring system at LGS complies with the criteria in Regulatory Guides 1.101, 1.97, and 1.21 and NUREG-0654 (Rev 1). The signals from the sensors are digitized and transmitted to the control room and the TSC. Meteorological data can be reviewed at the EOF through the EPDS computer. The satellite tower has been retired from service. Data from this tower was redundant to data already being obtained at the 30' level on Tower 2. The satellite tower is not part of the operational meteorological measurement system. Table 2.3.3-6 is a list of the meteorological measurements made by the system.

2.3.3.2.1 Measurements and Instrumentation

2.3.3.2.1.1 Siting

As shown in Figures 2.3.3-1 and 2.3.3-2, Tower 1 located at Weather Station No. 1 is a 280 foot tower situated approximately 3000 feet NW of the LGS structure vents. Tower 1 is also located approximately 2000 feet NNW of the center of the Unit 1 cooling tower location and approximately 2400 feet NW of the center of the Unit 2 cooling tower location. Grade elevation at Weather Station No. 1 is el 250' MSL.

The wind instruments on Tower 1 are mounted on retractable booms extending upwind 10'-0" west of the tower. Each face of the triangular tower is 3'-6" wide. The temperature sensors are located in aspirators and are 2'-0" from the tower. Weather Station No. 1 has a base surface made of yardstone. A dew point sensor is located on the temperature aspirator at the el 26'.

Tower 2 located at Weather Station No. 2 is a 310 foot tower situated approximately 2100 feet west of the LGS structure vents. Tower 2 is also located approximately 1950 feet WSW of the center of the Unit 1 cooling tower location, and approximately 2600 feet WSW of the center of the Unit 2 cooling tower location.

The wind instruments on Tower 2 are mounted on retractable booms extending upwind 10'-0" WNW of the tower. Each face of the triangular tower is 3'-6" wide. The temperature sensors are located in aspirators and are 2'-0" inches from the tower. The dew point sensor is located on the temperature aspirator at el 26'. Tower 2 has a base surface made of yardstone.

There are two (2) areas were the operational monitoring system does not meet the criteria of Regulatory Guide 1.23. One instance is in the proximity of Tower 1 to the two natural draft cooling towers. The other is the proximity of Tower 2 to multiple transmission poles.

The proposed Revision 1 of Regulatory Guide 1.23 states that the tower:

> "should be located in an area where natural or manmade obstructions....would have little or no influence on the meteorological measurements. The tower should be at least 10 obstruction heights away from the obstruction (Reference 2.3.3-8)."

A review of the Regulatory Guide 1.23 siting criteria shows that they are not applicable to the site for several reasons.

a. The reference quoted as supporting the 10 obstruction heights criteria (Reference 2.3.3-6) did not explicitly specify 10 heights, but rather said that 5 to 10 building heights should separate meteorological sensors and adjacent buildings. Hilficker went on to qualify his criteria as being applicable "most directly to cubicle obstructions", which the natural draft cooling towers clearly are not.

b. Strict application of the 10 obstruction height criteria would mean that, for any plant with a natural draft cooling tower, the meteorological tower would have to be located approximately 1 mile away from the immediate plant vicinity. For the site with local terrain effects (e.g. hills, river valley), this would provide data that would be of questionable representativeness. In addition, placing the tower at this distance would put it beyond the site boundary and control of plant security.

c. It is a well-known fact that the downwind influence of the wake caused by a hyperbolic natural draft cooling towers is a function of the tower diameter, not the tower height. This was shown by Smith and Mirabella (Reference 2.3.2-11) with wind tunnel tests at the SMUD Rancho Seco Plant and field studies at the TVA Paradise Plant. They concluded that, when wind speeds exceeded 2 m/sec, the cooling tower wake could extend to a downwind distance of 2 to 3 tower diameters, with a vertical extent of up to 1.5 tower heights. The 2 to 3 tower diameter criteria has also been confirmed by McLaren (Reference 2.3.3-7).

   Based on these criteria, Section 2.3.2.2.1 states that "the maximum wake produced by two LGS cooling towers would be a turbulent region extending 750 feet vertically and persisting 3400 feet downwind."

   This is a conservative estimate based on the maximum width of a two cooling tower complex rather than the individual tower dimensions.

Because the LGS cooling towers are located less than 2000 feet from Tower 1, there may be times when the meteorological tower is in the cooling tower wake. How often the meteorological tower might be in the cooling tower wake and how this will affect the ability of the plant to meet the objectives of Regulatory Guides 1.101, 1.97, and 1.21 is discussed below.

1. Frequency of Wake Effects

   Tower 1 is in a location that is predominantly upwind of the cooling tower complex. Winds must come from directions between 135° and 165° and be in excess of 2 m/sec for the meteorological tower to experience possible wake effects. At the 30 foot level of Tower 1, this would be 4.56% of the total hours, and at the 175 foot level, 6.64%.

2. Consequences of Wake Effects

   If the meteorological tower is in the cooling tower wake, the only real consequence is that the increased turbulence may cause the atmosphere to appear to be one class more unstable within the wake region. This was found during wind tunnel tests of the AEP Mountaineer Plant (Reference 2.3.3-8) as well as in the Rancho Seco field tests conducted by Start et al. (Reference 2.3.3-9).

   In the Rancho Seco field tests, a meteorological tower was located approximately 660 feet from the cooling tower complex, with wind instruments at heights of 4, 16, and 46 meters. A statistical study was conducted comparing turbulence data (sigma theta) from those hours when the meteorological tower was experiencing uninterrupted flow. The results showed the expected increase in turbulence in the cooling tower wake, but found significant increases only at the 16 meter level. No significant effects were found at the 46 meter level, indicating that the turbulent effect decreases with elevation due to the hyperbolic shape of the cooling towers.

   Of the 4.56% of this time when wake effects were possible at the 30 foot level of Tower 1, 3.23% are already unstable, indicating that a significant shift in stability from stable to neutral or neutral to unstable might be possible only 1.33% of the time. At the 175 foot level, only 2.73% of the hours might undergo such a stability change. However, a change at this level seems less likely based on the Rancho Seco results.

3. Implications for Regulatory Guide 1.101 and 1.97 Objectives

   The primary emphasis of these two guides for meteorology is to provide data for emergency response purposes. The cooling tower wake will have no effect on the average wind direction and speed, and therefore no effect on estimates of the airborne effluent trajectory or speed. The possible shift of stability class may affect the modeled effluent concentrations, but because of the small frequency of occurrence and the uncertainty associated with other model input parameters, this is a minor consideration.

4. Implications for Regulatory Guide 1.21 Objectives

For the routine 10CFR50, Appendix I X/Q calculations required by Regulatory Guide 1.21, the cooling tower wake should have no appreciable effect on the calculated concentrations. These calculations will be based on data from the 175 foot level of Tower 1 and will use the sector average version of the Gaussian plume model with joint frequency distributions of wind and stability data as meteorological input. Because almost no effect is expected from the wake at the 175 foot level, this will not affect the calculated concentrations. However, even if wake effects were present, it is unlikely they would cause noticeable differences in this type of calculation.

d. Two transmission line poles are located approximately 239 feet and 310 feet in proximity to the Tower 2. The transmission line poles are 105 feet in height. To comply with the regulatory guide Tower 2 would need to be 1050 feet away from the poles. An evaluation on the disturbance of meteorological conditions at the effective Tower 2 sensor heights was performed. The evaluation concluded the following:

- Wind speed at the 30 foot elevation would be impacted. An estimated 8% decrease from the -12 to 042 degree sectors and 15% from the 098 to 128 degree sectors. Applying this wind reduction to the ten (10) year speed averages, the reduction would affect the measurements by 4.99% and 2.11 %, respectively. Wind speed data from the 30 foot elevation is not used for Emergency Plan or Offsite Dose Calculations.
- Wind direction at the 30 foot elevation would show an undetermined increase in the turbulence factor. Wind direction data from the 30 foot elevation is not used for Emergency Plan or Offsite Dose Calculations.
- No impact to temperature at the 30, 159, or 304 foot elevations.
- No impact to the wind speed at the 159 or 304 foot elevations.
- Negligible or no impact to wind direction and the wind turbulence factors at the 159 and 304 foot elevations.

The preceding discussions have shown that, while cooling tower wake effects at Tower 1 are possible, the frequency of occurrence is extremely low and should not interfere with the functions and objectives described in Regulatory Guides 1.101, 1.97, and 1.21. The obstruction height question should also be weighed against the other siting criteria of Regulatory Guide 1.23.

Specifically, Regulatory Guide 1.23 also states that the primary meteorological tower should be representative of the meteorological characteristics of the region of effluent release, should not be located in a prevailing downwind direction of the heat dissipation system, and should be at a base elevation close to the finished plant grade.

It is concluded that the present Tower 1 location represents the best possible compromise of the siting criteria. Tower 1 is upwind of the plant, at a location close to plant grade, and representative of dispersion conditions on the plateau on which the plant is built.

In addition, Tower 2's siting with the additional transmission pole obstructions is acceptable, given the fact there is negligible to no impact to the meteorological conditions as observed on the required instrumentation in use by the Emergency Plan
and Offsite Dose Calculation Manual.

2.3.3.2.1.2 Instrumentation and Performance Specifications

The instrumentation systems installed on the LGS site were designed to meet the requirements of Regulatory Guide 1.23 (proposed Rev 1).

The accuracies for the sensors and associated equipment are given in Table 2.3.3-7.

2.3.3.2.1.3 through 2.3.3.2.1.9 DELETED

2.3.3.2.1.10 Data Communication and Display

Data from Tower 1 and from Tower 2 will be logged by a data-logger in the control room and input to the PMS in the TSC. Towers 1 and 2 interface to the control room by means of independent communication lines.

Data from this system will be presented to the control room on a CRT display. Data from this system will be presented to the EOF through the EPDS system. The meteorological data is also used by the Class A model for accident dose assessment.

2.3.3.2.2 Calibration and Maintenance Procedures

Calibration and data collection of the meteorological system are controlled by procedures that are responsive to the appropriate portions of the Quality Assurance Program described in Section 17.2.

2.3.3.2.2.1 Calibration

All sensors and related equipment are calibrated according to written procedures designed to ensure adherence to Regulatory Guide 1.23 (proposed Rev 1) guidelines for accuracy. Calibrations occur according to the requirements of the ODCM, with component checks and adjustments performed when required.

All meters and other equipment used in calibrations are, in turn, calibrated at scheduled intervals. All instruments used in calibrations are traceable to the NIST.

2.3.3.2.2.2 Maintenance

Inspection and maintenance of equipment is accomplished in accordance with station procedures and meteorological vendor procedures. The maintenance of the system is documented in the site work process and vendor reports.

In the event that the required maintenance could effect the instruments calibration, another calibration is performed prior to returning the instrument to service.

2.3.3.2.2.3 Data Output and Recording Systems

All meteorological outputs are recorded by an on site data-logger and the PMS system. The data from the systems are sent on a weekly basis to a meteorological consultant, for inspection to detect discrepancies or evidence of malfunction and data analysis.

The data-logger and PMS Computer systems for the weather towers are enclosed in a structure with thermostatically controlled temperature.

2.3.3.2.3 Data Analysis Procedures

2.3.3.2.3.1 Data Quality Control

The consultant prepares a meteorological data summary, formatted as joint frequency distribution tables of wind speed and wind direction, to satisfy NRC reporting requirements per Regulatory Guide 1.21.

All data are subject to a quality check by the consultant. Digital data is reviewed to detect any malfunctions.

An evaluation of system performance is made monthly to ensure that data recovery is satisfactory.

2.3.3.2.3.2 Data Reduction

Analog chart samples are reduced and compared with the corresponding digital data to ensure both systems are functioning properly.

Temperature and Dew Point (Data Logger)

a. Dew Point: hourly average dew point temperature.

b. Ambient temperature: hourly average temperature.

c. Delta temperature: hourly average temperature.

d. Precipitation: each discrete step represents 0.01 inches of liquid water. The number of steps are added to obtain the total precipitation for the hour.

2.3.3.3 Offsite Meteorological Monitoring Locations

The LGS meteorological data from the preoperational period have been compared with offsite data from the Philadelphia and Allentown, Pennsylvania NWS stations and with the data from PBAPS. Whenever possible LGS parameters were compared with concurrent data from the regional stations to assess their similarity, as well as with the longer term records from the regional stations to assess the climatological representativeness of the time period during which the LGS site data were obtained.

The following are brief descriptions of the offsite measurement locations:

2.3.3.3.1 Philadelphia

The Philadelphia NWS station is presently located at the Philadelphia International Airport, approximately 31 miles SE of the LGS site. The airport is located on the southern edge of the city, bordered on its SE side by the Delaware River. The area is relatively flat, with no appreciable terrain roughness to influence the data.

The Philadelphia NWS meteorological sensors have been moved several times during the period of record used in the long-term comparisons. In 1960, the NWS established standard elevations for all meteorological sensors, and the instrument locations have remained unchanged since that time. A complete history of the sensor locations at the Philadelphia NWS station is shown in Table 2.3.3-4.

2.3.3.3.2 Allentown

The Allentown NWS station is located approximately 31 miles north of the LGS site at the Lehigh Valley International Airport. The station is 5 miles NE of the city of Allentown in the Lehigh River Valley.

The river valley is surrounded by rolling terrain and numerous small streams, but there are also some larger terrain features in the area. Blue Mountain is a ridge located 12 miles north of Allentown, ranging between 1000-1800 feet high. South Mountain, ranging between 500-1000 feet high, is located on the southern edge of Allentown. However, neither of these two mountains is close enough to the Allentown NWS station to have any direct effect on the local meteorology. The Allentown NWS meteorological sensors have been moved between various elevations and locations during the period of record used in the long-term comparisons, but were moved to the standard NWS elevations in 1965, and have remained unchanged since that time. The complete history of the sensor locations and elevations is shown in Table 2.3.3-5.

2.3.3.3.3 Peach Bottom Atomic Power Station

Weather Station No. 2 at the PBAPS is located approximately 48 miles southeast of the LGS site. The PBAPS is located in the Susquehanna River Valley, but Weather Station No. 2 is a 320 foot tower situated on a hill overlooking the valley. The 320 foot wind sensor at Weather Station No. 2 is at an elevation comparable to the upper-level LGS wind sensors, and therefore provides a useful check of the representativeness of the meteorology.

2.3.4 SHORT-TERM (ACCIDENT) DIFFUSION ESTIMATES

2.3.4.1 Objective

Estimates of atmospheric diffusion (X/Q) are made at the exclusion area boundary (731 m) and the outer boundary of the LPZ (2043 m). These estimates are made for periods of 2, 8, and 16 hours, and for 3 and 26 days following a postulated accident. The NRC recommended section-dependent model (PAVAN) in Reference 2.3.4-1 is used.

2.3.4.2 Calculations

2.3.4.2.1 Calculation of X/Q values at the EAB and LPZ

X/*Q* values at the EAB and LPZ were calculated in accordance with Regulatory Guide 1.145. For ground-level releases, calculation for the 2 hours following the accident were based on the following equations:

$$X/Q = \frac{1}{\bar{U}_{10}\,(\pi\sigma_y\sigma_z + A/2)} \qquad (2.3\text{-}2)$$

$$X/Q = \frac{1}{\bar{U}_{10}\,(3\pi\sigma_y\sigma_z)} \qquad (2.3\text{-}3)$$

$$X/Q = \frac{1}{\bar{U}_{10}\,\pi\Sigma_y\sigma_z} \qquad (2.3\text{-}4)$$

where:

X/Q is relative concentration, in sec/m^3.

π is 3.14159.

$\bar{U}_{10}$ is wind speed at 10 meters above plant grade, in m/sec.

σ_y is lateral plume spread, in m, a function of atmospheric stability and distance.

σ_z is vertical plume spread, in m, a function of atmospheric stability and distance.

Σ_y is lateral plume spread with meander and building wake effects (in meters), a function of atmospheric stability, wind speed, and distance [for distances of 800 m or less, $\Sigma_y = M\sigma_y$, where M is determined from Reg. Guide 1.145 Fig. 3; for distances greater then 800 m, $\Sigma_y = (M\text{-}1)\ \sigma_{y\ 800m} + \sigma_y$].

A is the smallest vertical-plane cross-sectional area of the reactor building, in m^2. (Other structures or a directional consideration may be justified when appropriate.)

Plume meander is only considered during neutral (D) or stable (E, F, or G) atmospheric stability conditions. For such, the higher of the values resulting from Equations 2.3-2 and 2.3-3 is compared to the value of Equation 2.3-4 for meander, and the lower value is selected. For all other conditions (stability classes A, B, or C), meander is not considered and the highest *X*/*Q* value of equations 2.3-2 and 2.3-3 is selected.

The *X*/*Q* values calculated at the EAB based on meteorological data representing a 1hour average are assumed to apply for the entire 2-hour period.

2.3.4.2.2 Determination of Max Sector and Overall 5% Site *X*/*Q* Values

2.3.4.2.2.1 Maximum Sector *X*/*Q*

To determine the maximum sector *X*/*Q* value at the EAB, a cumulative frequency probability distribution (probabilities of a given *X*/*Q* value being exceeded in that sector during the total time) is constructed for each of the 16 sectors using the *X*/*Q* values calculated for each hour of data. This probability is then plotted versus the *X*/*Q* values and a smooth curve is drawn to form an upper bound of the computed points. For each of the 16 curves, the *X*/*Q* value that is exceeded 0.5 percent of the total hours is selected and designated as the sector *X*/*Q* value. The highest of the 16 sector *X*/*Q* values is the maximum sector *X*/*Q.*

Determination of the LPZ maximum sector *X*/*Q* is based on a logarithmic interpolation between the 2-hour sector *X*/*Q* and the annual average *X*/*Q* for the same sector. For each time period, the highest of these 16 sector *X*/*Q* values is identified as the maximum sector *X*/*Q* value. The maximum sector *X*/*Q* values will, in most cases, occur in the same sector. If they do not occur in the same sector, all 16 sets of values will be used in dose assessment requiring time-integrated concentration considerations. The set that results in the highest time-integrated dose within a sector is considered the maximum sector *X*/*Q.*

2.3.4.2.2.2 5% Overall Site *X*/*Q*

The 5% overall site *X*/*Q* value for the EAB and LPZ is determined by constructing an

overall cumulative probability distribution for all directions. *X*/*Q* versus the probability of being exceeded is then plotted and an upper bound curve is drawn. From this curve, the 2-hour *X*/*Q* value that is exceeded 5% of the time is found. The 5% overall site *X*/*Q* at the LPZ for intermediate time periods is determined by logarithmic interpolation of the maximum of the 16 annual average *X*/*Q* values and the 5% 2-hour *X*/*Q* values.

2.3.4.2.3 Meteorological Input

Meteorological data from LGS Weather Station No. 1 taken from January, 1996 through December, 2000, is used in the diffusion calculations. Joint stability class and wind occurrence distributions are computed based on using wind speed and direction from the 30 foot level and temperature difference from the 266-26 foot height interval. The lapse rate, wind speed, and wind direction categories are consistent with the recommendations of Regulatory Guide 1.23 (Reference 2.3.4-3).

The meteorological database was prepared for use in PAVAN by transforming the five years (i.e., 1996-2000) of hourly meteorological tower data observations into a joint wind speed-wind direction-stability class occurrence frequency distribution as shown in Table 2.3.4-1. In accordance with Regulatory Guide 1.145 (Reference 2.3.4-2), atmospheric stability class was determined by vertical temperature difference between the release height and the 10-m level, and wind direction was distributed into 16 - 22.5° sectors.

Seven (7) wind speed categories were defined according to Regulatory Guide 1.23 (Reference 2.3.4-3) with the first category identified as "calm. " The higher of the starting speeds of the wind vane and anemometer (i.e., 0.50 mph) was used as the threshold for calm winds, per Regulatory Guide 1.145, Section 1.1. A midpoint was also assumed between each of the Regulatory Guide 1.23 wind speed categories, Nos. 2-6, as to be inclusive of all wind speeds. The wind speed categories have therefore been defined as follows:

Category No.	Regulatory Guide 1.23 Speed Interval (mph)	PAVAN-Assumed Speed Interval (mph)
1 (Calm)	0 to < 1	0 to <0.50
2	1 to 3	>=0.50 to <3.5
3	4 to 7	>=3.5 to <7.5
4	8 to 12	>=7.5 to <12.5
5	13 to 18	>=12.5 to <18.5
6	19 to 24	>=18.5 to <24
7	> 24	>= 24

In the equations shown in Section 2.3.4.2.1, it should be noted that wind speed appears as a factor in the denominator. This causes obvious difficulties in making calculations for periods of calm. The procedures used by PAVAN to assign a direction to each calm period according to the directional distribution for the lowest wind-speed class. This is done separately for the calms in each stability class.

2.3.4.2.4 Building Wake Correction

A building wake correction of 5851 m^2 is equal to the Reactor Enclosure's combined vertical cross sectional area. A correction value of 2500 m^2 is used for one Reactor Enclosure

2.3.4.2.5 Short-Term *X/Q* Modeling Results

Atmospheric diffusion estimates developed for use in evaluating accidents are summarized in Table 2.3.4-4 for the above-mentioned periods following the accident. This table includes estimates for the maximum sector and overall 5% site *X/Q*.

2.3.5 LONG-TERM (ROUTINE) DIFFUSION ESTIMATES

Radionuclides will be routinely emitted to the atmosphere from three locations at LGS. The source vents include the Turbine Enclosure, Unit 1 Reactor Enclosure, and Unit 2 Reactor Enclosure. Diffusion estimates may be based on a single source originating from one point located midway between the three vent locations or based on each individual location independently.

Estimates of annual average X/Q are performed for receptor locations out to 50 miles in each directional sector. These historical values are presented in Table 2.3.5-1.

2.3.5.1 Meteorological Input

Meteorological data taken at Tower No. 1 from January 1972 through December 1976 are used in calculating the long term diffusion estimates.

Routine releases from LGS will be released through the two reactor enclosure vents and the turbine enclosure vent. These vents are all located at an elevation (el 416' MSL) only 9 ft below the 175 ft instrumentation level at Weather Station No. 1. Winds from the 175 ft level were used to calculate the annual X/Q values shown in Table 2.3.5-1. The maximum value of 6.291×10^{-7} is found at the site boundary (762 m) in the ESE sector. The spacing in this portion of the calculational grid is sufficiently dense to assure that the maximum offsite X/Q value has been calculated.

Distributions of wind speed and direction are computed for 22.5° sectors using the wind speed groups suggested in Regulatory Guide 1.23 (Reference 2.3.5-2). The 5 year 175 foot wind distribution used as input for the diffusion calculations is provided in Reference 2.3.2-23.

All calm hours have been distributed equally among the 16 directional sectors. With the exception of the 0-3 mph and 24+ mph groups, the median speed from each wind speed grouping is used. A speed of 1.61 mph (0.72 m/sec) is used as the median for the 0-3 mph group resulting from the guidance in Regulatory Guide 1.111 (Reference 2.3.5-3) that calm hours be assigned a speed of 0.1 m/sec, if the sensor does not conform with the minimum starting speed criteria of Regulatory Guide 1.23. A speed of 27 mph is used to represent the 24+ mph group.

The diffusion model utilized is described in Section 2.3.5.3.

2.3.5.2 Plume Rise

The volumetric flow rate from the LGS reactor enclosure vents will not vary seasonally. However, the volumetric flow rate from the turbine enclosure vent will vary from a summer maximum of 307 m^3/sec to a winter minimum of 147 m^3/sec, with an annual average of 216 m^3/sec. To calculate plume rise, one set of composite vent parameters was derived by appropriately weighing the diameter and exit velocity of each vent according to its volumetric flow rate. The individual vent parameters along with the derived composite vent parameters used in the plume rise calculations are listed in Table 2.3.5-2.

The Briggs (Reference 2.3.5-7) momentum plume rise equations, in the form expressed by Sagendorf and Goll (Reference 2.3.5-8), are used.

2.3.5.3 Diffusion Model

The sector average version of the Gaussian plume equation, as expressed in Regulatory Guide 1.111 is used for all X/Q calculations. The basic equation is as follows:

$$\frac{X}{Q} = \frac{360f}{\phi\pi^{3/2}2^{1/2}xu_e(\sigma_z^2 + \frac{CA}{\pi})^{1/2}} e^{-\left[(h - z_{corr})/\sigma_z\right]^2}$$

(EQ.2.3.-3)

where:

X	=	Concentration at receptor point (curies/meter^3)
Q	=	Emission rate (curies/sec) - assumed to be 1 curie/sec for these calculations
ϕ	=	Sector width - assumed to be 22.5° for these calculations
x	=	Distance of receptor point (meters)
u_e	=	Effective wind speed applicable to stack height, h, (meters/sec)
h	=	Effective stack height from Briggs equations (meters)
σ_z	=	Vertical standard deviation of the plume at distance, x, (meters)
σ_x	=	Lateral standard deviation of the plume at distance, x, (meters)
f	=	Frequency of occurrence of wind speed and stability combination (dimensionless)
Z_{corr}	=	The terrain correction
CA	=	The area of an obstacle (A) times a shape factor to take account of the details of the flow around the obstacle.
360	=	Number of degrees in a circle .
π	=	3.14

2.3.5.3.1 Source Configuration

The entrainment functions of Regulatory Guide 1.111 are used to determine the portion of the effluent plume entrained into the turbine-reactor enclosure wake. However, the effective height of the entrained portion of the plume is never allowed to decrease below 10 meters. Therefore, the building wake term (CA) was set equal to zero, in accordance with the guidance in Regulatory Guide 1.111 that this term be used only when the effective plume height is equal to zero.

2.3.5.3.2 Terrain Corrections

Individual terrain corrections are applied at each receptor. In order to model the LGS vents in the most realistic manner possible, terrain heights relative to the normal elevation of the Schuylkill River (33.5 m MSL) are used, and are allowed to decrease with distance within the first 1000 m. With the exception of those receptor points within the first 1000 m, the terrain correction applied to any particular receptor is the highest terrain between the source and a point up to, but not including, the next downwind receptor. These corrections are subtracted from the calculated effective plume height. A minimum effective height of 10 m is assumed when the terrain elevation exceeds the calculated plume height. The actual terrain elevations in each direction sector are given in Section 2.3.2.

2.3.5.3.3 Atmospheric Stability

Atmospheric stability classes are determined using the Brookhaven Turbulence Class system developed by Singer and Smith (Reference 2.3.5-5). This system, which has been previously defined in Table 2.3.2-14, is based upon the short-term fluctuations of the wind direction trace.

The long-term diffusion estimates for LGS were based upon the Smith-Singer vertical dispersion parameters and the Brookhaven Turbulence Class system because this system is more appropriate for the release and terrain characteristics of the LGS site than the Regulatory Guide 1.111 parameters.

A. Vertical Dispersion Curves

Regulatory Guide 1.111 specifies that the Pasquill-Gifford or P-G dispersion coefficients be used for long-term dispersion estimates. However, there are several sound reasons for using the Brookhaven (Smith-Singer) coefficients instead:

1. Surface Roughness

The P-G dispersion coefficients were developed primarily from the Prairie Grass diffusion experiments at O'Neill, Nebraska. The Prairie Grass data were collected in extremely flat, smooth terrain with a roughness length, z_o, of 3 cm. In contrast, the Brookhaven coefficients were developed in an area of scrub pines and oaks, with a roughness length of 1 meter. The LGS region, characterized by a combination of buildings, open fields and trees, is much more similar to Brookhaven than to O'Neill, Nebraska.

2. Release Elevation

The Prairie Grass experiments consisted of a series of ground level SO_2 releases, with concentrations measured at downwind distances of up to 800 meters. Extrapolation of these curves to distances beyond one kilometer is based on limited observations. The Brookhaven dispersion coefficients, on the other hand, are based on both elevated and low level releases. The standard curves published by Smith (Reference 2.3.5-10) in the ASME Guide were derived from plumes released at 108 meters and tracked for more than 50 km. In addition, a second set of unpublished dispersion coefficients were developed from low level releases, as shown in Section 2.3.5.3.4.

The entrainment coefficients from Regulatory Guide 1.111 specify that the LGS plume will be elevated 84% of the time. In these cases, the standard Brookhaven coefficients were used. For the remaining 16% of the time, the low level coefficients were used.

The 1977 AMS workshop on stability classification schemes and sigma curves (Reference 2.3.5-9) clearly supported the use of the Brookhaven curves in preference to the P-G curves where elevated sources in rolling terrain are involved:

> "For elevated sources, the "Brookhaven" curves (M.E. Smith, 1968) are an appropriate choice when δz is less than the effective source height. These curves are based on average concentration measurements from a passive source at an elevation of 108 m. They differ from the Pasquill-Gifford and Turner curves both because the measurement site was surrounded by a much rougher surface, mostly forests, from which Z_o equals approximately 1 m."

3. Averaging Time

The Prairie Grass project consisted of short duration field experiments, with the P-G horizontal coefficient representing 3 minute averages, and the vertical coefficients 10 minute averages. In contrast, all of the Brookhaven data from which the dispersion curves were derived were hourly averages.

4. Validation

While model validation is a somewhat nebulous and controversial area, attempts have been made to verify the appropriateness of the more commonly used dispersion coefficients with field data. A recent study by Weil (Reference 2.3.5-11) at the coal-fired Dickerson power plant in Maryland found that when using the Gaussian plume model with the Brookhaven dispersion coefficients, predicted concentrations were within a factor of two during 73% of the cases analyzed. Conversely, the P-G coefficients at times resulted in orders of magnitude disagreement between predicted and measured concentrations.

The Dickerson Plant releases a buoyant plume from stacks approximately 400 feet tall, so the analogy with LGS is not clear-cut. However, the results indicate that the Brookhaven curves are preferable.

B. Stability Class Determination

Because the Brookhaven dispersion coefficients are used in the LGS analysis, it is reasonable and consistent to use the Brookhaven stability classification system as well. The two were developed together and are part of a cohesive system.

Furthermore, although the classification system based on delta temperature is recommended by NRC, the ΔT method has been criticized by the scientific community. It seems clear that the system produces an inordinately high percentage of neutral hours, and several recent workshops and publications have recommended that the system be changed. Several of these suggestions are worth reiterating:

1. Weber et al (Reference 2.3.5-12) conducted a regression analysis comparing several stability classification schemes with vertical dispersion data from the Prairie

Grass, Green Glow, and National Reactor Testing Station experiments. The results from this study showed that during unstable conditions, delta temperature did not correlate at all with the measured concentrations. In stable conditions, delta temperature compared favorably with the other stability classification systems, but the authors cautioned that a strict correlation should only be found for delta temperature measured in the surface layer (<10 meters) and that there was no reason to expect correlation at higher levels.

2. AMS Workshop - At the 1977 AMS workshop on stability classification schemes and sigma curves, there were lengthy discussions of the various methods available to classify stability. The workshop recommended that the standard deviation of the horizontal wind direction fluctuations, sigma theta, be used to estimate horizontal diffusion rates, and that dimensionless ratios of temperature lapse rate and wind speed be used to specify vertical turbulence. The workshop also said that there is little physical justification for the current practice of estimating vertical diffusion based on temperature lapse rate data alone.

   It seems contradictory that the NRC has referenced the report from this workshop in the proposed Revision 1 of Regulatory Guide 1.23, yet ignored some of these fundamental recommendations.

3. Gifford (Reference 2.3.5-13), in a memo to the ACRS regarding the proposed Revision 1 of Regulatory Guide 1.23, reiterates his objection to the use of delta temperature. Gifford states:

   > "My main objection (a long-standing one) to the draft is that it continues to recommend the so-called ΔT method (or $\Delta\theta$ method) as the primary means of determining σ_y and σ_z (p 6, lines 12 & 13). The problems involved, and limitations of this methodology are clearly set out in the American Meteorological Society workshop report on the subject, reference 1 in the proposed revision. This reference (Bulletin AMS 58 , p 1306) states "There is little physical justification for the currently widespread practice of approximating S'" (the stability factor) "by - $\Delta\theta$ alone....in stable conditions the effects of topography....may equally invalidate - $\Delta\theta$ and S' as determinants of σ_z". The reference goes on to stress problems of determining σ_z in other types of conditions (i.e. unstable, daytime) and stresses the poor state of our observational knowledge at present. Finally, problems of the $\Delta\theta$ method (p 1309) are discussed in detail, pointing out the desirability of a more physically based indicator such as the bulk Richardson number S'; and also the problem of measuring $\Delta\theta/\Delta Z$ in a meaningfully shallow layer with present requirements for siting the upper temperature sensor (60 m) is pointed out."

   Clearly, the ΔT method is not entirely palatable to the scientific community, and there is little doubt that the Brookhaven system is at least as good an indicator of stability. Particularly for the LGS site and source elevations, the Brookhaven system offers some distinct advantages. The Brookhaven classes are based on the "gustiness" or short-term fluctuations of wind direction trace averaged over an hour and are a physical representation of the horizontal turbulence of the wind flow. In addition, the Brookhaven system determines the atmospheric stability in the region

of the actual effluent release, which was another of the AMS workshop recommendations.

Regulatory Guide 1.111 states that wind speeds representative of the vent release elevation should be used for long-term dispersion estimates. Accordingly, wind data from the 175 ft level of Tower 1 were used for the LGS annual X/Q calculations. This instrument is within 9' MSL of the LGS vent elevation. For the elevation portion of the mixed mode release, wind speeds were not corrected for source elevation. However, for the low level portion of the mixed mode release, speeds were adjusted by standard power law techniques to the 10 meter level.

Figure 2.3.5-1 shows a comparison of the annual X/Q values from Table 2.3.5-1, which were computed using Brookhaven dispersion coefficients. These values represented by the dashed line are from a similar calculation with ΔT stability and the P-G dispersion coefficients of Regulatory Guide 1.111. The comparison shows that the Brookhaven coefficients were more sensitive to terrain elevation because the lower portion of the mixed code release is set at 10 meters in the BNL model, as compared to a ground level release in the Regulatory Guide 1.111 model. Otherwise, the values are quite similar.

2.3.5.3.4 Dispersion Coefficients

Expressions for calculation of the vertical dispersion coefficients, σ_z. for each turbulence class, have been defined by Singer and Smith (Reference 2.3.5-6) and are as follows:

		Very Unstable	Unstable	Neutral	Stable
σ_z	Source Higher Than 50 Meters	$0.40x^{.907}$	$0.33x^{.859}$	$0.22x^{.776}$	$0.06x^{.709}$
σ_z	Source Lower Than 50 Meters	$0.29x^{.907}$	$0.25x^{.859}$	$0.19x^{.776}$	$0.08x^{.709}$

where:

σ_z = Vertical dispersion coefficient, meters

x = Distance downwind, meters

The σ curves were originally derived for the BNL site, where the terrain is slightly flatter than LGS, but the vegetation and small-scale roughness are quite similar. These expressions for the turbulent diffusion parameters are generally accepted, and have been recommended by Hanna et al (Reference 2.3.5-9) as the preferred system for elevated releases. The entrainment coefficients of Regulatory Guide 1.111, combined with the Tower 1, 175 foot wind speed distribution, indicate that the LGS plume is classified as elevated 84% of the time.

2.3.5.3.5 Recirculation Correction Factors

Regulatory Guide 1.111 specifies that the local meteorology be examined to determine the extent of the temporal and spacial variations in the local circulation, and their effect upon the long-term diffusion estimates. Comparisons between Towers 1 and 2 in Section 2.3.2 indicate that there is little variation in the local meteorology surrounding the LGS site. The Schuylkill River Valley is too shallow to have a major effect on the local circulation. The only significant difference between the two towers is that wind speeds are slightly lower near the valley floor.

Previous submittals (References 2.3.5-1 and 2.3.5-4) summarizing wind recirculation effects at PBAPS (located approximately 48 miles SW of LGS) have shown, through a puff-trajectory analysis, that the reactor effluent rarely returns to the site area. Based upon these two studies, it has been concluded that recirculation correction factors are not warranted at LGS.

BROOKHAVEN NATIONAL LABORATORY
TURBULENCE CLASSIFICATION

Turbulence Class	Brookhaven National Laboratory Classification[1]	Description of Wind Trace
I - Extremely Unstable	A	Fluctuations of the wind direction during the course of 1 hour exceed 90 degrees.
II - Unstable	B_1	Fluctuations are confined to a lower limit of 15° and an upper limit of 45°.
III - Very Unstable	B_2	Trace is similar to I and II, but the upper and lower limits are 90 and 45°.
IV - Neutral	C	The lower limit of the fluctuations is 15°, and no upper limit is imposed. The case is distinguished by an unbroken solid core, through which a straight line can be drawn for the entire hour, without touching "open space" on the chart.
V - Stable	D	The trace approximates a line, and short-term fluctuations do not exceed 15°. Direction may vary gradually over a wide angle during the hour.

2.4 HYDROLOGIC ENGINEERING

2.4.1 HYDROLOGIC DESCRIPTION

2.4.1.1 Site and Facilities

LGS is located in southeastern Pennsylvania on the Schuylkill River, about 1.7 miles southeast of the limits of the Borough of Pottstown and about 20.7 miles northwest of the Philadelphia city limits. The Schuylkill River passes through the site and separates the western portion, which is located in East Coventry Township, Chester County, from the eastern portion, which is partly in Limerick Township and partly in Lower Pottsgrove Township, both in Montgomery County, Pennsylvania. All of the major plant structures are located in Limerick Township. The location of the site and major plant structures with respect to the surrounding topography is shown in Figure 2.4-1.

The natural ground elevations vary from 110 feet MSL at the Schuylkill River to 280 feet MSL at the highest site elevation. The access elevations of major safety-related structures are listed in Table 2.4-1. Safety-related structures are shown in Figure 3.8-58. Because the topography of the site is such that storm water will flow away from safety-related equipment and structures, site grading is not considered safety-related.

Schuylkill River flooding and flooding that is due to the PMP falling on the plant area are discussed in Sections 2.4.2 and 2.4.3.

2.4.1.2 Hydrosphere

2.4.1.2.1 Hydrologic Characteristics

The plant site is located on the east bank of the Schuylkill River at latitude 40° 13' 3" N, longitude 75° 35' 15" W, approximately 5.5 river miles downstream from Pottstown, Pennsylvania. The drainage area at this point is 1168 square miles, with river bed elevations ranging from about 105 feet MSL at the site to about 1750 feet MSL near the headwaters.

The watershed of the Schuylkill River (Figure 2.4-2) lies entirely in southeastern Pennsylvania. The basin is about 80 miles long by 25 miles wide and encompasses an area of 1909 square miles above its confluence with the Delaware River at Philadelphia. The principal towns and cities along the course of the river are Pottsville, Reading, Pottstown, Phoenixville, Norristown, Conshohocken, and Philadelphia.

To determine the discharge characteristics at the site, it is assumed that the flows at Pottstown and at the site are identical, since the drainage area at the site is less than 2% greater than that at the Pottstown gauging station.

The dominant hydrologic feature in the area is the Schuylkill River, which furnishes part of the project's water requirements and receives its effluents. The principal uses of the Schuylkill River are municipal and industrial water supply. The river is also used for recreational fishing and boating.

In the vicinity of the site, the Schuylkill is a meandering stream of quite gentle slope (2-2½ feet/mile), flanked by floodplains that consist of about 10% built-up areas, 30% thick forest growth, and 60% cultivated or fallow fields.

In about 1947, a massive cleanup project was started on the Schuylkill to remove the silt and debris deposited in the channel by many years of coal mining operations upstream. Physical features (stilling basins, dredged material, impounding basins, and initial channel dredging) were essentially completed by the end of 1950. Maintenance dredging will continue on an as-needed basis whenever the desilting pools become one-half full.

As for future developments along this portion of the river, no additional construction is planned downstream of the plant site, other than the project's own cooling water pumping station. Because of the width of the river at this point, the new pumping station would have no significant effect on the flood levels. Some channel improvement is planned for a 2 mile stretch of the river at Pottstown for small craft navigability and flood crest reduction, but this will have no effect on the flood levels at the plant site.

The extreme instantaneous and average daily flows of record at the Pottstown gauging station are:

	Flow (cfs)	Date
Minimum (instantaneous)	87	August 13, 1930
Average	1,793	October 1926- September 1969
Maximum (instantaneous)	95,900	June 1972

As discussed in Section 2.4.3, the PMF on the Schuylkill River is conservatively estimated at 500,000 cfs, using Appendix B of Regulatory Guide 1.59 (Rev 2). The corresponding stage is estimated at el 174'. If it is also assumed that Ontelaunee Dam would fail under a maximum probable flood condition, the resulting stage would be increased to el 181', without wind.

2.4.1.2.2 Existing and Proposed Water-Control Structures

Figure 2.4-3 shows the location of 23 small dams upstream of LGS. Heights, volumes, and drainage areas are given in Table 2.4-2. None of these dams are close enough and large enough to threaten LGS in event of failure.

There are three significant water-control structures upstream of LGS that are either in existence or in planning at the present time. They are the Ontelaunee, Blue Marsh, and Maiden Creek dams. Their locations are also given in Figure 2.4-3, and their general design characteristics are summarized in Table 2.4-3 and discussed in detail in Section 2.4.4. Ontelaunee Dam is owned by the city of Reading and is used for water supply and recreation. Blue Marsh Dam is a federally owned structure constructed (1979) by the U.S. Army Corps of Engineers. Plans for construction of Maiden Creek Dam, an authorized U.S. Army Corps of Engineers project, have been indefinitely deferred and the project is considered inactive at this time.

In Section 2.4.4, it is shown that a flood wave resulting from the failure of these three dams would result in a maximum transient water level of 201 feet, if the simultaneous crest of the Schuylkill River's SPF is assumed. The 1% wave from a 40 mph wind would have a run-up of less than 6.4 feet, so that the maximum instantaneous water surface from the combined event would theoretically be el 207'. However, conservative approaches used throughout the estimation procedure ensure that, in fact, the actual maximum water surface that is due to such an event would certainly be less

than el 207'. About 3.3 miles downstream of the plant site lies Vincent Dam - an older, free overflow, rock-filled timber crib structure about 12 feet high, with a crest elevation of 103.5 feet. The dam is used now for water supply (1.5 million gallons per day) by Home Water Company and is also used as a sediment trap and recreation pool. Since the thalweg of the Schuylkill is at el 102' to el 104' in the vicinity of the pumping station, there may be a small backwater effect at LGS. However, the Schuylkill River pumping station is not a safety-related facility, so that loss of tail-water due to a failure of Vincent Dam does not impair safety-related water supplies.

2.4.1.2.3 Surface Water Users Whose Intakes Could Be Adversely Affected by the Accidental Release of Contaminants

Figure 2.4-2 shows the location of surface water users on the Schuylkill River between the site and the river mouth in Philadelphia. Domestic users, as classified by the Delaware River Basin Commission (Reference 2.4-1), are listed in Table 2.4-4, together with 1971 actual use and consumptive use details of individual entitlements. Similar information is presented in Table 2.4-5 for industrial users. Groundwater users are discussed in Section 2.4.13.2.

2.4.2 FLOODS

2.4.2.1 Flood History

Flood history is discussed in detail in Section 2.4.3.5.2. Table 2.4-6 shows peak recorded flows at several stations in the Schuylkill Basin. Historically, the greatest recorded flood at Pottstown was due to Hurricane Agnes in 1972; however, according to Philadelphia records, there may have been greater floods before the beginning of the Pottstown record. None of the historic floods on the Schuylkill River (Section 2.4.3.5.2) was caused by ice jams or landslides. Surges, seiches, and tsunamis are not relevant to the LGS site. The consequences of the failures of upstream dams are discussed in Section 2.4.4.

2.4.2.2 Flood Design Considerations

The DBFL with respect to the Schuylkill River is conservatively estimated at el 207'. This stage is derived from an SPF, combined with the wave crests from three simultaneous dam breaks and the 1% wave run-up generated by a 40 mph wind. Without the wave, the maximum level is estimated at el 201'. The three dams are Ontelaunee, Blue Marsh, and Maiden Creek (in the early planning stage). The derivation of this flood is discussed in Section 2.4.4.

The lowest grade level entrance to any safety-related structure is at el 217', which is 10 feet above the DBFL. Therefore, Schuylkill River floods cannot affect any of the safety-related facilities.

The Schuylkill River PMF is conservatively estimated at 500,000 cfs, based on Appendix B of Regulatory Guide 1.59 (Rev 2). When combined with a simultaneous dam break flood wave due to a PMF-induced failure of Ontelaunee Dam, the highest stage obtained at LGS was el 181' (without wind-wave). This is well below the stage obtained from the multiple dam break, as given above. The Schuylkill River PMF is discussed in detail in Section 2.4.3.

The water surface (el 201') resulting from the dam break analysis is transient. It is estimated that the time required for the dam break flood wave at the river cross-section at LGS to rise above and subside back to the SPF elevation (152 feet) is approximately 7.5 hours. The length of time for which the flood wave will be above el 177' and el 195' would be about 4.5 and 2 hours, respectively.

The shortest distance from the el 201' (dam break flood elevation without wave run-up) contour to the nearest safety-related structure inland (diesel oil storage tanks) is about 126 feet. The foundation of these structures is at el 194'. For flood waters to reach these structures, percolation through the embankment would have to occur. An analysis of the percolation was made using the following equation, assuming that Darcy's law is valid and that flow is one-dimensional:

$$\bar{b}\,\frac{\partial^2 b}{\partial x^2} + \frac{\partial z}{\partial x}\cdot\frac{\partial b}{\partial x} = \frac{n}{k}\cdot\frac{\partial b}{\partial t} \qquad \text{(EQ.2.4-1)}$$

where:

$b(x,t)$ = saturated thickness

$\bar{b}$ = average saturated thickness

k = hydraulic conductivity

n = porosity

$z(x)$ = elevation of base of porous medium

Subject to the following conditions:

$b(0,t) = H_o$

$b(x,0) = 0$

where:

H_o = the available head at $x = 0$

It can be shown that the solution to the above equation can be written in the form:

$$b = \frac{H_o}{2}\, e^{-2cx} \cdot \operatorname{erfc}\left[\frac{x}{2\alpha\sqrt{t}} - \frac{c}{\alpha}\sqrt{t}\right] + \operatorname{erfc}\left[\frac{x}{2\alpha\sqrt{t}} + \frac{c}{\alpha}\sqrt{t}\right] \qquad \text{(EQ. 2.4-2)}$$

where:

$$\alpha^2 = \frac{k\bar{b}}{n}$$

$$c = \frac{a}{2\bar{b}}$$

a = slope of the base of the porous medium

The base of the porous medium (base of embankment material) was assumed to rise linearly from el 170' at the toe of the embankment to el 194' at the tanks. The results of the analysis indicate that, if a conservative permeability of $5x10^4$ ft/yr is assumed and if the flood crest remains at el 202' (Section 2.4.3 shows maximum flood elevation of 201 feet) for a duration of two hours, groundwater would not be above el 194' anywhere within 80 feet of the tanks. Therefore the dam break flood wave would not affect hydrostatic pressures on the foundations of safety-related structures.

2.4.2.3 Effects of Local Intense Precipitation

The latest updated estimate (1976) of point (10 square miles) PMP was obtained from the NOAA (Reference 2.4-2). In the updating, which was subsequent to Hurricane Agnes, relatively small increases were made compared to pre-Agnes PMP estimates from Reference 2.4-3. The updated values are given in Table 2.4-7.

As explained later, the impact of the onsite PMP was analyzed by dividing the site area into smaller subareas. For this purpose, the 72 hour PMP was divided into 6 hour increments using the distribution given in Reference 2.4-2. The 6 hour PMP was divided into 1 hour increments using the U.S. Army Corps of Engineers distribution for standard project storms (Reference 2.4-4). These distributions are shown in Table 2.4-7. The 1 hour PMP was further subdivided into 5, 10, and 15 minute increments using the distribution given in Reference 2.4-29.

To estimate the peak run-off from each subarea, the rational formula was conservatively used:

$$Q = CIA \qquad \text{(EQ. 2.4-3)}$$

where:

Q = peak flow rate in cfs

C = run-off coefficient

I = rain fall intensity in inches/hour corresponding to a duration equal to the time of concentration, and

A = area in acres.

The run-off coefficient, C, was conservatively assumed to be 1. Kirpich's formula (Reference 2.4-34) was used to estimate the times of concentration for different subareas.

To obtain conservative results, the following assumptions were used in the analysis:

a. The site drainage system was assumed to be completely blocked.

b. It was assumed that storage due to ponding did not attenuate the outflow rate from any of these subareas.

c. Rating curves for flow over embankments or roadways were developed using the following equation for critical flow, based on the principle of minimum specific energy (Reference 2.4-33):

$$Q = (gA^3/\alpha\, T)^{1/2} \qquad \text{(EQ. 2.4-4)}$$

where:

Q = discharge in cfs

g = gravitational constant; 32.2 ft/sec^2

A = cross-sectional area, ft^2

T = top width of section, ft

α = energy coefficient, conservatively assumed to be 1.38, based on the ratio of broad-crested to sharp-crested weir coefficients

d. For simplicity, the rating curve for CP-1 was developed using the following weir equation (Reference 2.4-33)

$$Q = CLH^{3/2} \qquad \text{(EQ. 2.4-5)}$$

where:

Q = discharge in cfs

L = crest length, 35 feet

H = height of water above crest, ft

C = weir coefficient, conservatively assumed to be 2.63

As shown in Figures 2.4-4 and 2.4-5, the plant site is divided into three main functional areas:

a. The turbine-reactor complex area, at el 217'

b. The cooling tower area, at el 257' to el 265'

c. The spray pond area

The cooling tower area is the highest of the three main functional areas and is located to the north of the turbine-reactor complex area. The spray pond is located north of the cooling tower area but is separated from it by approximately 300 feet. The intervening land rises (Figure 2.4-5) to a hilltop at el 285', about 800 feet east of the north-south plant centerline (E4000). Run-off from this hilltop would be directed partly to the cooling tower area; partly to the spray pond area; partly to Possum Hollow Run; partly to the turbine-reactor complex area; and partly to Sanatoga Creek. Sanatoga Creek is not shown on Figures 2.4-4 or 2.4-5. It is located north of the spray pond area and drains to the Schuylkill River upstream of the plant site. Figure 2.4-11 shows the confluence of Sanatoga Creek with the Schuylkill River near Sanatoga.

Run-off from the three main functional areas drains toward several low points, which in turn drain away from the site. Numerous local drains and small surface ditches have been provided in the site drainage system to facilitate the drainage of normal storm run-off. However, as noted above, for the investigation of onsite PMP, none of these drainage facilities is assumed to function, except for the open-channel portion of a ditch draining the cooling tower area. Otherwise, all flow is assumed to be surface flow, over land or over roadway. All drain pipes and culverts are assumed plugged.

The impact of a PMF in the Possum Hollow Run, which passes along the eastern and southern sides of the site area, is examined in Section 2.4.2.3.5. The impact of a PMF in the Sanatoga Creek is discussed in the following paragraph.

Sanatoga Creek drains an area of less than 10 square miles. With respect to the plant site, the nearest point on the creek is approximately 1400 feet upstream of its confluence with the Schuylkill River. At this location, the thalweg of the creek is approximately at el 127'. As shown in Figure 2.4-4, the spray pond is located mostly within the Sanatoga Creek Basin. The cooling towers are located on a ridge that rises in an ENE direction and separates them from the spray pond area. The same ridge forms the drainage boundary between Sanatoga Creek and Possum Hollow Run and isolates the turbine-reactor area from Sanatoga Creek. The lowest elevation in the vicinity of the spray pond is el 240', and the crest of the spray pond spillway is at el 251'. The SPF elevation of the Schuylkill River near its confluence with the Sanatoga Creek is estimated to be 155 feet. It is inconceivable that the water surface elevation in Sanatoga Creek, with backwater that is due to a concurrent SPF in the Schuylkill River, would rise higher than el 240', which is 113 feet above the creek thalweg and 85 feet above the SPF elevation of Schuylkill River. For reasons given in Section 2.4.3.5, it is considered unlikely that a PMF on the Schuylkill River would coincide with a PMF on the Sanatoga Creek. Therefore, it was concluded that a PMF in Sanatoga Creek would not endanger safety-related structures, and further detailed analysis was not considered necessary.

The following sections describe flow-routing assumptions, drainage areas, and the water surface elevations resulting from a PMP on the site area. Table 2.4-22 summarizes the drainage characteristics, probable maximum rainfall intensity for the critical duration and the resulting peak discharge for each of the subareas.

2.4.2.3.1 Drainage from Cooling Tower Area

As shown in Figure 2.4-5, the cooling tower area and nearby natural topography are divided into three drainage areas, designated as DA-2, DA-3, and DA-4.

Area Designation	Area (Acres)	Peak Discharge (cfs)
DA-2	25.0	620

DA-3	4.5	151
DA-4	20.8	550

2.4.2.3.1.1 Drainage Area DA-2

The run-off from DA-2 collects in part at the road junction at el 258.8', located at the northern central part of the cooling tower area. This point is designated as CP-1 (collection point-1) on detail 3 in Figure 2.4-6. From CP-1, the run-off drains westward along the roadway and the adjacent ditch and picks up run-off from the remainder of DA-2. Finally, the entire run-off from DA-2 passes through a low point in the roadway (CP-2) and enters a ravine that drains to the Schuylkill River (detail 4 in Figure 2.4-6). To the south of CP-2, the access roadway, which partly encircles the Unit 1 cooling tower, rises to a high point that forms the boundary between DA-2 and DA-3.

The most important aspect of drainage from DA-2 is the height to which water is ponded against the roadway fill that spans the distance between the two cooling towers on their south flank. This fill has a nominal top of el 264'. As long as run-off from DA-2 follows the route described and does not overtop this roadway fill, it need not be added to the flows entering the turbine-reactor complex area.

To estimate the maximum water depth against this embankment, it is conservatively assumed that all the run-off from DA-2 collects at CP-1 and passes through critical depth over a conservatively assumed effective flow width of 35 feet. Critical depth must occur at this point, since flow into the ditch downstream is supercritical. This is shown in section E-E' on detail 3 in Figure 2.4-6 which shows the assumed effective width and the discharge rating curve for CP-1. The discharge rating curve was developed using a weir coefficient of 2.63.

The water surface elevations at CP-1 and along the roadway embankment are shown on section A-A' in Figure 2.4-6. The effective width of 35 feet was selected arbitrarily to approximately correspond to the width of the main stream entering the ditch. However, flow would spread to a larger width of approximately 100 feet, as shown in detail 3 and section E-E' of Figure 2.4-6. Consequently, the maximum water surface elevation is less than the estimated value of el 262.7', which is based on an effective flow width of 35 feet. As shown on Section A-A' in Figure 2.4-6 and on Section C-C' in Figure 2.4-6, downstream of CP-1, the flow enters a ditch (supercritical flow with a normal depth of 4.4 feet) and then backs up over the roadway at CP-2 to a depth sufficient to pass the peak flow of 620 cfs.

To compute the resulting water surface elevation at CP-2, a rating curve was prepared for Section D-D' using the method based on the principle of minimum specific energy presented in Section 2.4.2.3. It is shown in Figure 2.4-6. Using the D-D' rating curve, the water surface elevation at CP-2, corresponding to a discharge of 620 cfs, is estimated as el 245.5'. This is well below CP-1 (el 258.8'). Consideration of backwater effects demonstrates that the critical section at CP-1 is not submerged due to the flow depth at CP-2. A high point in the cooling tower access road just west of the Unit 1 cooling tower separates DA-2 from DA-3. The high point in the adjacent drainage ditch is at el 245.0'. Since the maximum water level at CP-2 was found to be el 245.5', some spillover from DA-2 to DA-3 would occur at this point. A rating curve was developed for the ditch section which acts as a control for any possible spill from DA-2 to DA-3. A water surface elevation of 245.5 feet resulted in a spill of less than 5 cfs. For purposes of estimating water levels this was considered to be negligible when compared to the DA-2 flood peak of 620 cfs and DA-3 flood peak of 151 cfs.

2.4.2.3.1.2 Drainage Area DA-3

As shown in Figure 2.4-5, DA-3 comprises the southwest part of the cooling tower area. It drains generally into the western half of the turbine-reactor complex area, both down the roadway and down the south face of the slopes of the access roadway embankment. DA-3 includes natural ground and the roadway to the 220 kV switchyard, but not the switchyard itself, which is sloped generally south to drain toward the Schuylkill River. A peak flow of 151 cfs is generated from DA-3. The disposition of this discharge is discussed in Section 2.4.2.3.3 with the turbine-reactor complex area.

2.4.2.3.1.3 Drainage Area DA-4

Like DA-3, this area also drains directly to the turbine-reactor complex area on the eastern side of the plant centerline. However, it includes a relatively larger proportion of natural catchment, most of which is on the east of the cooling tower excavation area. The handling of the peak discharge from this area, 550 cfs, is discussed in Section 2.4.2.3.3.

2.4.2.3.2 Drainage from Spray Pond Area

The spray pond drainage area, shown as DA-1 in Figure 2.4-5, includes the spray pond itself and the cut slope areas draining toward it, as well as two small pieces of natural topography that drain toward the cut slopes (one on the NW and the other on the SE perimeter). The total drainage area is 17.2 acres. Drainage is to the pond itself, which has a normal operating level of el 251' and a 60 foot wide spillway set at el 252' (shown as CP-5 on Figure 2.4-5). This spillway drains to a natural channel, across a road embankment, and then northward to Sanatoga Creek.

The spray pond spillway is designed to pass a routed PMF (48 hour storm) preceded by an SPF assumed equal to one-half the PMF ordinates. No infiltration is assumed. The pond is assumed to be at normal water surface at the beginning of the storm. A 30 minute routing period is used, with a flood routing computer program adapted from the U. S. Army Corps of Engineers program for hydrograph combining and routing. Precipitation increments for the most critical six hours of the storm are arranged as follows:

Period (30 min)	Precipitation (% of 6 hr)	Period (30 min)	Precipitation (% of 6 hr)
1	5	7	27
2	5	8	8
3	6	9	7
4	7	10	6
5	7	11	6
6	11	12	5

The remainder of the storm is distributed in accordance with Reference 2.4-4.

The pond is filled to a maximum of el 252.5' at the beginning of the 28th hour. The spillway discharges the surcharge above el 252' before the beginning of the second storm. The second flood peaks at a maximum mean inflow of 251 cfs, with a corresponding maximum outflow of 194 cfs and a maximum water surface of el 253'.

Further details for the pond are given in Section 2.4.8.

2.4.2.3.3 Drainage from Power Plant Complex Area

The finished floor elevation of relevant safety-related structures at the power plant complex area (power block) is el 217'. The plant coordinate line (E4000) divides the power block approximately in half, with the divide at el 217'. Drainage is generally away from the structures. The present site drainage condition was determined from the Limerick Site Master Plan, and various walkdowns.

Jersey barriers have been strategically placed along sections of the perimeter fence for security reasons. In the safety evaluation, the jersey barriers are assumed to block the drainage flow, and thus forming boundaries for the drainage areas. Some potential flow outlets along the south-west boundary of the site have been blocked, or partially blocked, by the jersey barriers. In addition, jersey barriers placed between the Technical Support Center and the Warehouse (see Figure 2.4-6) form a portion of the boundary separating the drainage areas DA-5 and DA-6.

The boundary separating drainage areas DA-5 and DA-6 runs along the jersey barriers, from the Technical Support Center to the Warehouse (see Figure 2.4-6). The boundary then runs along the southern edge of the Turbine Building, up to the centerline of the power block. The remaining southern portion of the boundary runs south along the centerline of the power block. For drainage area DA-5, the northern boundary is the plant access road which separates drainage area DA-3 and DA-5; and the western and southern boundaries are along the plant south-west security fence. For drainage area DA-6, the eastern boundary is the outside edge of the plant access road; the northern boundary is the service road which separates drainage areas DA-6 and DA-4; and the southern boundary is the service road adjacent to the southern side of the power plant complex.

The total drainage areas and peak flows from DA-5 and DA-6 were estimated to be as follows:

Area Designation	Area (acres)	Peak Flow (cfs)
DA-5	14.9	369
DA-6	11.6	242

The surface water flow paths around the power block shown on Figure 2.4-6 have been limited in order to provide additional space for lay-down or storage areas. The locations of the critical cross-sections and flow outlets are shown in Figure 2.4-6, while the widths and average bottom elevations for each of the cross-sections and flow outlets are summarized in Table 2.4-23.

Within drainage area DA-5, the important features are the yard and roads, the power plant structures, the refueling water tank dike, and various buildings (especially the ones erected along the security fence right-of-way on the southwest side of DA-5). The yard and road elevations encompassed by the security fence vary from about el 212' to el 217'. The roads entering the power plant structures have crowns set at el 217' or lower. These are sloped to drain away from the structures.

The area assumed for DA-5 includes, conservatively, the roof area of the power block and the area bounded by the condensate storage tank and the resulting water tank dike. The tank dike crest is at el 223', approximately 7 feet above grade. The tank dike, therefore, would contain much more than the 40 inches of rainfall resulting from the 72 hour PMP.

The path of the surface water flow in DA-5 will begin with inflow from DA-3 and a portion of DA-4, through the northern boundary of DA-5. Run-off from DA-5, combined with the inflow, will flow along

the paths shown in Figure 2.4-6, west of the power block, and exit area DA-5 through the outlets along the perimeter fence on the south-west side of the power plant complex. In the safety evaluation, jersey barriers were assumed to block some the outlets along the south-west boundary of DA-5.

Within drainage area DA-6, important features are the yard and roads, and the parking lot around the Site Management Building, shown in Figure 2.4-6.

The surface water flow in DA-6 will begin with inflow from DA-4 along the northern boundary, as shown on Figure 2.4-6. The run-off from DA-6, combined with the inflow, will flow through the parking lot, and exit DA-6 through the outlet on the eastern side of the site, between the Site Management Building and the Warehouse and Procurement Building, as shown in Figure 2.4-6.

The rational formula was used to estimate peak run-off rates at collection points CP-3 and CP-4 (see Figure 2.4-4), which are 446 cfs and 555 cfs, respectively. Flooding calculations were performed assuming critical flow at the outlets, and a Mannings “n” equal to 0.022. These calculations yield maximum water surface elevations of 218.1 feet at CP-3, and 218.1 feet at CP-4. Backwater calculations performed for the flow path located north of the Turbine Building (shown on Figure 2.4-6) yielded a maximum water surface elevation of 218.6 feet along the northern edge of the Turbine Building.

The results of the peak run-off rates and peak water levels for the present condition at the power block are summarized in Table 2.4-8.

An engineering evaluation of the site drainage conditions determined that the only potentially adverse affect is that flood water due to the local intense precipitation (PMP) event or the postulated cooling tower basin failure (PCTBF) could enter the turbine enclosure for a limited period of time. At certain site locations, the PCTBF event results in higher flood levels than the PMP event, but the PMP event is the bounding event due to the longer duration of the event. Consequently, measures are taken to limit the possible flow of flood water from the turbine enclosure into the control enclosure where the safety-related chilled water system is located at el 200’. These measures include controlling openings in the lower portion of the turbine enclosure walls, relying on flood control features within the turbine building, and by limiting the flow of water through the turbine enclosure doors by providing additional curbs and barriers inside the turbine enclosure and by administratively controlling the opening of certain doors. As a result of these measures, flooding into the control enclosure due to the present site drainage condition results in control enclosure flood level below the elevation of the safety-related chilled water system.

Furthermore, administrative controls have been implemented to ensure that future changes in site conditions, affecting flood water run-off, will receive engineering evaluation and approval prior to implementation.

2.4.2.3.4 Roof Loads on Safety-Related Structures That Are Due to PMP Onsite

In the previous analysis of surface drainage, it is assumed that all roof drainage overflows to the ground and then to the various control points. If all roof drains and scuppers are blocked, water could pond on the roofs of some safety-related structures to a depth controlled by the height of the roof parapets. The highest parapet on any safety-related structure is less than the maximum 24 hour PMP of 34.4 inches. Assuming that some accumulation and overflowing occur, the maximum water depth could equal the height of the parapet plus a small amount of head providing flow over the parapet. The design roof load due to PMP for all the safety-related structures (Section 3.2) is equivalent to this maximum water depth.

2.4.2.3.5 PMF in Possum Hollow Run

Possum Hollow Run has a drainage area of 1.3 square miles. It rises approximately 2.5 miles northeast of the site and flows southwesterly, entering the Schuylkill River through a gorge along the south side of LGS.

To assess the flood hazard to the LGS site posed by Possum Hollow Run PMF, the PMF is assumed to occur in Possum Hollow Run at the same time that an SPF is occurring in the Schuylkill River. The Schuylkill River SPF is assumed to be 50% of the PMF, or 250,000 cfs, which results in a Schuylkill River stage of el 152'.

It is unlikely that a PMF on the Schuylkill River would be coincident with the PMF on the Possum Hollow Run. A PMF on the Possum Hollow Run (drainage area = 1.3 square miles) is caused by a local intense thunderstorm, while a PMF on the Schuylkill River (drainage area = 1170 square miles) is due to a basin-wide PMP storm system whose center lies well upstream of LGS. The two storms would have different characteristics, and the joint probability that they produce peak runoffs at LGS at the same time is very low.

Using the slope-area method, a rating curve was developed for the Possum Hollow Run. For this purpose, a typical cross-section is taken at the point where the el 152' contour crosses the stream. The bed slope of the Possum Hollow Run is 0.02. Based on field inspections and comparison with photographs of streams with known (n) values (References 2.4-6 and 2.4-33), a Manning's (n) value of 0.05 is assumed.

A PMF hydrograph was developed for the Possum Hollow Run using the procedure outlined in Reference 2.4-6. The 6 hour PMP (Table 2.4-7) is divided into one-half hour increments, following the distribution used for the spray pond (Section 2.4.2.3.2). The resulting hydrograph peak is 3840 cfs, and the base is 15.5 hours.

Using the rating curve developed for the Possum Hollow Run, the water surface elevation corresponding to a PMF discharge of 3840 cfs is estimated to be 159 ft. The corresponding normal depth, velocity, and Froude number are 7.0 ft, 8.6 ft/sec, and 0.76, respectively.

As stated earlier, the SPF elevation in the Schuylkill River is 152 feet MSL. The bed elevation of the Possum Hollow Run at its confluence with the Schuylkill River is 105 feet MSL. Therefore, at the time of the SPF, the flood water of the Schuylkill River enters the Possum Hollow Run up to a point where its thalweg is at el 152'. This point is about 2400 feet upstream of the confluence of the Possum Hollow Run with the Schuylkill River. The PMF on the Possum Hollow Run is superimposed on the SPF in the Schuylkill River. It is conservatively assumed that in this backwater reach of 2400

feet the cross-sectional area of the Possum Hollow Run below el 152' is ineffective, and the entire PMF flow passes through the remaining cross-sectional area. This results in a water surface elevation of 159 feet at a section 2400 feet upstream of the confluence. This flood level is about 57 feet below the plant bench. Upstream of this section, the Possum Hollow Run is separated from the plant by high ground that is more than 60 feet above the bed of the Possum Hollow Run. It is not credible that the PMF of the Possum Hollow Run (3840 cfs) causes a water depth of 60 feet or more.

Therefore, it is concluded that the PMF in the Possum Hollow Run coincident with the SPF in the Schuylkill River would not flood any safety-related structure at LGS.

2.4.2.3.6 Summary of Results - Local Intense Precipitation

Table 2.4-8 summarizes the results of local intense precipitation investigations at the associated collection points and drainage areas. These investigations show that water levels are either below the access elevations of the safety-related structures or evaluated to be acceptable as shown in Section 2.4.2.3.3.

The Possum Hollow PMF is treated apart from the onsite local intense precipitation. A maximum PMF discharge of 3840 cfs was calculated. An SPF occurring simultaneously in the Schuylkill River produces a backwater effect, but conservative estimates indicate that the water surface elevation would be well below the plant grade el 216.5'.

2.4.3 PROBABLE MAXIMUM FLOOD ON STREAMS AND RIVERS

The PSAR included a PMF developed by the U.S. Army Corps of Engineers for Pottstown, adjusted to the site by the ratio of drainage areas. This PMF was estimated at 356,000 cfs, with a stage at the plant site of 158 feet. After the PSAR was prepared, Hurricane Agnes occurred (1972). In 1975 the PSAR was update to reflect the effect of Hurricane Agnes. At that time there was no reason to change the PMF. But later the NWS revised the values of PMP for the basin. Another significant change occurred with respect to upstream dams. Construction began on Blue Marsh Dam, and Maiden Creek Dam became an authorized project, whereas at the time of the PSAR, construction on Blue Marsh had not started, and Maiden Creek was not expected to be authorized. These changes combined to require a new flood analysis.

Since the LGS PSAR was prepared, Regulatory Guide 1.59 (Rev 1 and Rev 2) were issued, giving the option of using either detailed flood routing studies (Appendix A) or enveloping maps for determining peak PMF flows (Appendix B). The latter method is simpler, but more conservative, giving a value of 500,000 cfs as compared with the PSAR estimate of 356,000 cfs (both before adjustment for a dam break). The Appendix B method was selected for this report because it is conservative and indicates a "dry-site" condition during the PMF, with a large margin of safety.

PMFs were computed for the Schuylkill River at LGS and for Possum Hollow Run. The computations show that the maximum resulting stage in the Schuylkill River is el 181'. The maximum stage that is due to a PMF in Possum Hollow Run was not computed, but was found to be less than el 186' at a point nearly due east of the turbine-reactor area complex. The PMF for the Schuylkill River is covered in this section. The PMF for Possum Hollow Run is discussed in Section 2.4.2.3.5.

2.4.3.1 Probable Maximum Precipitation

This section is not applicable because the PMF is estimated in accordance with Appendix B of Regulatory Guide 1.59.

2.4.3.2 Precipitation Losses

This section is not applicable because the PMF is estimated in accordance with Appendix B of Regulatory Guide 1.59.

2.4.3.3 Run-Off and Stream Course Models

This section is not applicable because the PMF is estimated in accordance with Appendix B of Regulatory Guide 1.59.

2.4.3.4 Probable Maximum Flood Flow

From Appendix B of Regulatory Guide 1.59, the PMF for the Schuylkill River at the LGS site, corresponding to a drainage area of 1170 square miles, is 500,000 cfs.

The design flood for Ontelaunee Dam is 41,000 cfs. The PMF inflow to Maiden Creek Dam (which may be built at the headwater of Lake Ontelaunee) has been estimated by the U.S. Army Corps of Engineers at 118,000 cfs, with a spillway peak outflow at 92,000 cfs.

Blue Marsh Dam was designed by the U.S. Army Corps of Engineers to pass a PMF without failure. Under current authorization plans, the U.S. Army Corps of Engineers plans to design the Maiden Creek Dam spillway for the PMF. Both of these projects attenuate their PMF inflow peaks considerably. For Blue Marsh, the attenuation is from 128,600 to 74,800 cfs, and for Maiden Creek, it is from 118,000 to 92,000 cfs. In the analysis of flooding that is due to a dam break, it is conservatively assumed that no attenuation occurred during the PMF passages through either Blue Marsh or Maiden Creek Dam.

The flood stage at the LGS site for a 500,000 cfs PMF peak is el 174', not accounting for a hypothesized failure of Ontelaunee Dam (Section 2.4.3.5). To assess stages produced by the flood wave caused by the PMF-induced failure of Ontelaunee Dam, the results of a study of dam failure permutations are used. The method of analysis used in this study is the same as described in Section 2.4.4.2 (References 2.4-23 and 2.4-24). One of the permutations in this study postulates the failure of Blue Marsh Dam superimposed on the SPF in the Schuylkill River. This results in a water surface elevation of 177 feet at LGS. The flood wave caused by the failure of Ontelaunee Dam is superimposed on the above condition, resulting in a water surface elevation of 184 feet at LGS. Thus, the rise in water surface elevation that is due to the failure of Ontelaunee Dam is 7 feet.

The assumption is made that a failure of Ontelaunee Dam also produces an incremental increase in stages of 7 feet at LGS. Thus, the water surface elevation for the PMF plus a failure of Ontelaunee, is estimated as el 174' + 7' = 181'. This elevation (el 181') is 19.7 feet lower than the water surface elevation (el 201') caused by the hypothesized seismically induced failure of three major dams upstream of LGS (Section 2.4.4.2).

Therefore, the latter elevation governs plant safety, and a more refined analysis for the water surface elevation caused by the PMF combined with the failure of Ontelaunee Dam is not warranted.

2.4.3.5 Water Level Determinations

A discharge rating curve for the Schuylkill River near the project site (Figure 2.4-7) was developed using observed flood levels, computer backwater studies, and slope-area methods. The procedure that was used is discussed in the following sections.

2.4.3.5.1 Data Availability

Stream flow data are available in USGS publications (References 2.4-7 through 2.4-11). Within the basin and upstream of the plant site, 22 gauging stations have been operated, with 11 presently active. The stations are listed in Table 2.4-9, and their locations are indicated on Figure 2.4-8. Additional data are contained in References 2.4-12, 2.4-13, and 2.4-14. Data on river and flood profiles are available from the Commonwealth of Pennsylvania, U.S. Army Corps of Engineers, and USGS, in addition to a special high-water mark survey commissioned by the licensee in 1972 (Figure 2.4-9).

2.4.3.5.2 Historical Floods

Flood-producing storms in this area are normally associated with tropical disturbances. Although flooding from snowmelt occurs annually, snowmelt run-off usually has not been associated with major historic floods. Peak stages and discharges published by the USGS and the U.S. Army Corps of Engineers for the major historic floods are given in Table 2.4-6 for several stations on the Schuylkill River. At Pottstown, the 1902 flood, with a peak discharge of 53,900 cfs, was the highest known until June, 1972. However, the Reading and Philadelphia data indicate that the 1902 flood was very likely exceeded in 1850 and 1869 and may have been exceeded in 1757 and 1839.

In June, 1972, Hurricane Agnes produced the flood of record on many Pennsylvania streams. The flow at Pottstown has been evaluated as 95,900 cfs by the USGS (Reference 2.4-15). Figure 2.4-10 shows the flood frequency curve for the Schuylkill River at Pottstown. This curve is based on composite regional flood discharge relationships given in Reference 2.4-16. It is not expected that the 1972 flood alters these regional relationships.

2.4.3.5.3 Water Level Determinations up to 356,000 cfs

Table 2.4-10 gives the values from which the rating curve, shown in Figure 2.4-7, was drawn. For flows above 20,000 cfs, bridge clogging is assumed (Section 2.4.3.5.3.5).

After completion of the studies that resulted in the rating curve shown in Figure 2.4-7, Hurricane Agnes produced the flood of record at Pottstown, 95,900 cfs. Some seven hours before the flood's peak, an oil lagoon at Pottstown was overtopped by the flood waters, producing a slick along the river that left oil marks for a considerable distance downstream (Reference 2.4-17).

Figure 2.4-9 shows the results of a special survey commissioned by the licensee in July, 1972 to determine high-water marks between Sanatoga (1.4 miles upstream from the plant) and Cromby (8.6 miles downstream). All readings were taken along the east side of the Schuylkill River and reflect the top of the oil marks where they were visible.

If an upper envelope of that portion of the profile near the site is taken as indicative of the actual high water, it appears that the 1972 flood rose to about el 131'. In addition, there appears to have been almost no clogging of the bridges during this flood.

The rating curve (Figure 2.4-7) indicates a water level at about el 134.3' for a flow of 95,900 cfs. This is 3.3 feet higher than el 131' given by the flood level survey shown in Figure 2.4-9. The assumption of bridge clogging (Section 2.4.3.5.3.5) accounts for about 2 feet of the difference. The rating curve is apparently conservative when used for estimating water level for a given discharge.

2.4.3.5.3.1 Methods of Computation

The geometry of the channel near the site is taken from a survey made in 1969. Normal uniform flows are assumed for the low flows, and an approximate roughness is obtained using the average water surface slope shown in Reference 2.4-18. These low-stage computations were checked by field observations in December, 1969.

The flood levels for flows from 20,000 to 356,000 cfs are obtained using an adaptation of the U.S. Army Corps of Engineers Standard Step Backwater Program (Reference 2.4-19). Flood levels for flows above 356,000 cfs are discussed in Section 2.4.3.5.4. The program employs a computing method similar to method 1 in Reference 2.4-20. Whenever data are insufficient, conservative estimates are made. The computations consider the 14.1 miles of river between Pottstown (5.5 miles upstream from the site) and the village of Cromby (8.6 miles below the site).

2.4.3.5.3.2 Topographic Data

Figure 2.4-11 shows the locations of cross-sections used in the backwater studies. Data are obtained from four sources:

a. Commonwealth of Pennsylvania cross-sections taken in 1967 for the vicinity of Pottstown (river stations 3680+00 through 3810+00)

b. U.S. Army Corps of Engineers cross-sections taken in 1969 in the same reach to supplement the commonwealth sections

c. USGS topographic sheets revised in 1968, Pottstown and Phoenixville 7.5 minute quadrangles (10 foot contours) for the sections downstream of river station 3810+00

d. Specific surveys made for these studies in 1969 and 1970 by the licensee of all bridges between Pottstown and Vincent Dam and of the river bottom close to the site

The only modifications made to existing topographic data consist of assuming that impounding basins along the river are full of dredged material. For the sections taken from the topographic maps, approximate bottom elevations are developed using information contained in the 1950 report to the Commonwealth of Pennsylvania by the Schuylkill River project engineers (Reference 2.4-18). The surveyed cross-sections indicate that the main channel could be represented as having a horizontal bottom two feet above the thalweg elevation. This approximation is extended to the main channel portions of the unsurveyed sections, if they are assumed to be rectangular in section with their base elevations two feet above the thalwegs shown in the 1950 report.

Lengths of reach for both the main and overbank sections are scaled from the USGS topographic maps.

USGS aerial photographs taken in mid-1968 are used to determine floodplain character for roughness evaluation. Floodplain use culture undoubtedly changes from time to time and place to place, but it is assumed that the net effect of such changes is to keep the floodplain roughness approximately constant.

2.4.3.5.3.3 Selection of Observed Flood Profile

Roughness coefficients for a natural stream are best determined by a trial-and-error process of matching observed high-water profiles with those obtained from backwater computations using various roughness coefficients.

Flood profile information is not available for the 53,900 cfs flood of February, 1902.

Several flood marks are available from the USGS and the U.S. Army Corps of Engineers (Reference 2.4-21) for the 50,800 cfs flood of May, 1942 but were collected before the river restoration project was completed in 1950. Changes to the river, the installation of the impounding basins and dredging, have been sufficient to significantly alter the hydraulic characteristics of the river and floodplain.

The largest flood between 1950 and the time that the rating curve was computed occurred in August, 1955, with a peak of 42,300 cfs. The flood level at the USGS gauge on the Hanover Street Bridge in Pottstown was obtained from Reference 2.4-10, and other flood marks from Reference 2.4-21. These data are as follows:

OBSERVED MAXIMUM WATER LEVELS, 1955

Location	Flood Level (ft)
Pottstown Hanover St. Bridge Station	135.84
S. Pottstown Madison (Keim) St. Bridge	133.55
Linfield Highway Bridge	120.03
Spring City Highway Bridge	105.97

See Section 2.4.3.5.3 for a discussion of the 1972 flood.

2.4.3.5.3.4 Derivation of Manning's (n)

In 1969, the Philadelphia District Office, U.S. Army Corps of Engineers, performed backwater studies in connection with a proposed channel improvement project near Pottstown. The following values of Manning's (n) were apparently used by the U.S. Army Corps of Engineering in their 1969 study:

Natural main channel (before improvement)	0.042
Built-up areas	0.062
Fields (cultivated and fallow)	0.062

Wooded areas	0.078

Aerial photographs support the values 0.062 and 0.078 as reasonable for overbank roughness, considering the types of culture along the river. Because of lack of sufficient definition of observed profiles, it was decided to adopt those values for overbank flows and to use main channel roughness coefficients that result in a surface profile matching the observed 1955 flood levels.

Conversation with a witness to the 1955 flood at Pottstown revealed that only small flotsam was involved and that most probably no clogging occurred at any of the bridges. Thus, the bridge openings were considered clear in the calculations performed to evaluate (n). Table 2.4-11 compares the computed and observed values of water levels and gives the (n) values developed for each reach.

The increase in computed roughness going downstream could be caused by actual discharge increases along the 11½ mile reach, or it could reflect the attenuation of the flood wave as it moved downstream. These, however, are probably of minor importance, and the increase in (n) is probably due to an increasing lack of definition of the physical description of the channel.

It should be noted that a weighted mean of the calculated values agrees well with that used by the U.S. Army Corps of Engineers (0.041 versus 0.042). In terms of flood elevations at the site, it is conservative to use large roughness factors downstream of the project site.

Additional conservatism is introduced by assuming the (n) value to be constant for all flow stages.

2.4.3.5.3.5 Bridge Clogging

The following assumptions are made regarding clogging at the various bridges: openings in handrails and trusses are assumed to be fully clogged; bridge openings flanked by woods are assumed 50% clogged; and main channel openings are taken as 20% clogged. In the 1955 flood, as noted above, the bridges did not become clogged with debris. However, in a flood such as the PMF, large debris would be common, and the bridges could be subject to clogging. Because the bridges are over a mile downstream and well submerged during extreme floods, the net effect of clogging is approximately a 2 foot increase in water level at the site.

2.4.3.5.3.6 Selection of Starting Water Surfaces

To obtain proper convergence, it is necessary to extend the computations to Cromby, 8.6 miles downstream of the project site. At this downstream location, the slope-area method is used to obtain an approximate water level. A typical cross-section and the average slope observed during the 1955 flood are used for this. It is assumed that the true water surface at this location falls between the two elevations bounding a 25% and around the computed conveyance ($AR^{2/3}/n$). Table 2.4-12 shows the convergences obtained in the various runs made in this study.

2.4.3.5.3.7 Flood Discharges Studied

The lower portion of the curve in Figure 2.4-7 was developed from several computed water levels. The results in Table 2.4-10 have already been noted, but some discussion of the flood quantities is in order.

a. The average annual flood discharge, 21,000 cfs is based on 42 years of data at the USGS gauge at Pottstown.

b. The average annual flood at Pottstown, 28,000 cfs is computed from regional data presented by the USGS in Water Supply Paper 1672.

c. The second highest flow of record, 53,900 cfs is at Pottstown.

d. The 100 year flood, 99,000 cfs is computed from the regional data in Water Supply Paper 1672.

e. An arbitrary discharge used to obtain 200,000 cfs is better definition of the rating curve.

f. When the PSAR was prepared, 356,000 cfs was the original modified U.S. Army Corps of Engineers estimate of the PMF. In this report, the PMF is estimated at 500,000 cfs, using the more conservative estimating procedure given in Appendix B of Regulatory Guide 1.59. The calculation of levels for the 356,000 cfs flow with the backwater program provided an additional point for graphic extension of the rating curve.

Figure 2.4-12 shows the computed water surface profiles for these floods for the reach between Sanatoga Highway Bridge and Linfield Railroad Bridge. These two points are approximately 4500 feet upstream and 7500 feet downstream from the site, respectively.

2.4.3.5.4 Water Level Determination for Flows Above 356,000 cfs

The discharge rating curve shown in Figure 2.4-7 is extended to above the 356,000 cfs flow (el 158') using the approximate but conservative method described in this section.

The variation of friction slope with discharge in the backwater studies is plotted in Figure 2.4-13. The actual conveyance provided at the depth obtained in the backwater studies is estimated from the formula:

$$K = 1.486\ (AR^{2/3})n^{-1} \qquad \text{(EQ. 2.4-4)}$$

where:

K = conveyance

A = flow area

R = hydraulic mean depth

n^{-1} = coefficient of roughness

The friction slope is computed from the formula:

$$S_f = (Q/K)^2 \qquad \text{EQ. 2.4-5)}$$

where:

S_f = the friction slope

Q = the discharge

K = the conveyance of the river at the LGS site.

This is done for each of the six discharges used to construct the rating curve at and below 356,000 cfs (Table 2.4-10)

In Figure 2.4-13, the points obtained in the backwater study are indicated with circles. As discharge increases from 21,000 to 28,000 cfs, there is essentially no change in friction slope. However, as discharge then changes to 53,000 cfs, there is a sharp decrease in friction slope; this continues to 99,000 cfs, which seems to be at or near a minimum friction slope; as discharge increases beyond 99,000 cfs, the friction slope increases. The minimum slope obtained here, however, is not the same as the minimum slope of uniform flow, critical slope. All the flows considered are well into the subcritical range, being M1-type backwater curves. Differentiating Equation 2.4-5 with respect to (Q), the following equation is obtained:

$$\frac{\Delta s}{\Delta Q} = \frac{2\overline{Q}\Delta K}{K^3}\left[\frac{\overline{K}}{\Delta K} - \frac{\overline{Q}}{\Delta Q}\right] \qquad \text{(EQ. 2.4-6)}$$

This equation shows that if the ratio $Q/\Delta Q$ is larger (smaller) than $K/\Delta K$ in a certain range of depth, there is a corresponding decrease (increase) in slope and an increase in discharge. Thus, the shape of slope-discharge relation (Figure 2.4-13) is a consequence of the backwater starting elevations and the consequent variation of conveyance with depth at LGS.

There appears to be a trend toward an asymptote of S = 0.00038 as (Q) increases beyond 356,000 cfs. However, without additional backwater computations to confirm this trend, its extrapolation would be questionable. To be conservative with respect to depth, a decreasing slope versus discharge relation was chosen instead of the apparent asymptotic value. The relationship chosen is the best straight-line fit-by-eye to the six points in Figure 2.4-13.

At extreme flood stages above el 158' at the LGS site, the left bank (facing downstream) curves away from the river alignment northeasterly, toward Possum Hollow Run. When the stage of the river rises above this level, this side of the cross-section is less effective in carrying discharge, because of local separation of flow in the bend. A conservative extension of the rating curve is made by neglecting a portion of the left side of the stream (looking downstream) in computing cross-sectional area. A plot of the LGS cross-section looking upstream is given in Figure 2.4-14 and shows the area used in computing conveyance above el 158'.

The slope-discharge relation of Figure 2.4-13 is used to determine the required conveyance and associated stages, as given in Table 2.4-13.

The conservative nature of this extension is shown by comparing the conveyances required at 356,000 cfs. The backwater data for 356,000 cfs yield a friction slope of 0.000366, with a required conveyance (K) of 356,000 $(0.000366)^{-½}$ = $18.6x10^6$ cfs. The straight-line relation in Figure 2.4-13 indicates a slope of 0.00028, which gives a conveyance requirement of K = 356,000 $(0.00028)^{-½}$ = $21.3x10^6$ cfs. This is 14% higher than the conveyance actually required, based on the backwater study, and indicates a correspondingly higher stage at LGS. While the stage for 356,000 cfs is based on the backwater study (el 158'), this comparison demonstrates the conservative nature of the straight-line relation shown in Figure 2.4-13 when used in extending Figure 2.4-7 above el 158'.

The required stage given in Table 2.4-13 is determined from a stage conveyance curve, Stage = f(K), in which the conveyance K is determined from Equation 2.4-4.

In this case, a weighted (n) value was computed for a water surface of el 135' based on 0.042 for the channel and 0.07 for the overbank area. The weighted value obtained is n = 0.063, and this value is used for all depths. For computing the area and hydraulic radius above el 158', the cross-section portion noted above on the left bank is omitted.

The final stage relation is shown in Figure 2.4-7. The conservative nature of the extension above el 158' (356,000 cfs) is clearly shown by the change in slope of the curve at that point. If the straight-line stage-discharge relation that prevails below el 158' is extrapolated, it gives a lower stage for the same discharge. The extended stage rating curve should give conservative estimates of stage at LGS for all discharges covered. This rating curve is not applicable to dam break waves. The stage and discharge during the passage of such waves are discussed in Section 2.4.4. The calculations for the above rating curve are based on the assumption that the river channel carries steady, gradually varied flow with the origin of the backwater curve at Cromby.

2.4.3.6 Coincident Wind-Wave Activity

The water surface obtained with the PMF without wind is less than that obtained with the SPF and a multiple dam break, as discussed in Section 2.4.4. Since that case is more critical, the discussion of wind-wave activity is omitted here (see Section 2.4.4.3 for a discussion of wind-wave activity under the more adverse dam break case).

2.4.4 POTENTIAL DAM FAILURES, SEISMICALLY INDUCED

The reservoirs in the Schuylkill Basin upstream of LGS can be classified as being either minor or major with respect to a seismically induced failure.

Table 2.4-2 is a list of minor dams that are either too small or too remote to cause significant flooding at LGS in the event of their seismic failure. The table indicates that these are all less than 100 feet high and less than 4000 acre-feet in volume. Except for three Schuylkill River dams, their drainage areas are all less than 16 square miles. Their locations are shown in Figure 2.4-3.

Table 2.4-3 lists three major dams whose seismic failure could, under certain circumstances, generate significant waves in the LGS reach of the Schuylkill River. These structures are discussed further, and their various failure permutations are considered here in detail.

Ontelaunee Dam has a storage volume of 11,900 acre-feet and a height of 52 feet. It is principally of concern because it is located immediately below the site of another and larger dam that is authorized for future construction by the U.S. Army Corps of Engineers - Maiden Creek Dam. Maiden Creek

Dam will be situated 5 miles upstream of Ontelaunee Dam and will have a volume of 114,000 acre-feet, of which 38,000 acre-feet will be dedicated to flood control storage; the maximum height will be 110 feet.

Blue Marsh Dam, completed in 1979, is about 35 miles upstream of LGS on Tulpehocken Creek. This U.S. Army Corps of Engineers' project has a total storage of 50,000 acre-feet, of which a minimum of 22,900 acre-feet is dedicated for flood storage; the maximum height is 96 feet.

Figure 2.4-14 presents a location map and a schematic profile relating Ontelaunee, Maiden Creek, and Blue Marsh dams in elevation to LGS. All three dams have, or will have, uncontrolled open spillways.

Felix Dam is a recreation dam on the Schuylkill River in the city of Reading, which is downstream of the Maiden Creek confluence. The pool has a volume of 1470 acre-feet, and the dam is a 24 foot high rock-filled timber crib overflow structure, with a spillway el 237.5' MSL. This dam will be drowned out (or will be previously destroyed) by the SPF, and the flood wave resulting from its failure therefore need not be added to the flood waves from the failure of the Ontelaunee and Maiden Creek dams upstream.

Appendix A of Regulatory Guide 1.59 suggests that an acceptable combination of run-off floods and seismic events would be the SSE with a 25 year flood and the OBE with a standard project flood. The OBE has a design acceleration of 0.075 g horizontal and 0.050 g vertical. The SSE has a design acceleration of 0.15 g horizontal and 0.10 g vertical.

On Blue Marsh Dam, the U.S. Army Corps of Engineers provides for horizontal design accelerations of 0.05 g for concrete structures and 0.10 g for the embankment; no provision is made for a vertical acceleration component. Plans for completing final design and for construction of Maiden Creek Dam, also a U.S. Army Corps of Engineers project, has been indefinitely deferred; the U.S. Army Corps of Engineers presumably would apply its Blue Marsh seismic design values to Maiden Creek Dam.

There is no indication that Ontelaunee Dam, an earth-fill and masonry spillway structure complete in 1934 and now owned by the City of Reading, has any specific design provision for seismic loadings.

The U.S. Army Corps of Engineers design accelerations do not clearly fall into either the OBE or the SSE design category. On the one hand, the embankment horizontal design acceleration exceeds the OBE horizontal design value, but on the other hand the concrete structure horizontal design value is less than the OBE. In addition, no provision is included for vertical design acceleration. While the U.S. Army Corps of Engineers dam designs embody a considerable resistance to seismic failure, the amount of damage accompanying either an OBE or SSE is difficult to assess without a detailed seismic analysis of those structures. Therefore, for the purpose of this report, the two U.S. Army Corps of Engineers dams and the Ontelaunee Dam are all considered as nonseismic Category I structures. Their total instantaneous failure is considered simultaneously with the LGS SPF, which thus corresponds to an OBE design failure condition. This simplification negates the need for study of the SSE combined with a 25 year flood, since that case is simply the same total seismic failure, but with a lesser coexisting flood.

2.4.4.1 Dam Failure Permutations

If a major seismic failure occurred at the future Maiden Creek Dam, a domino-type failure would be likely at Ontelaunee because of the limited spillway capacity. Moreover, these two dams will be approximately 5 miles apart, and Blue Marsh Dam on Tulpehocken Creek is only 6.7 miles from Ontelaunee; thus a seismic event severe enough to cause failure in any one of these could cause severe damage to the other two. Therefore, a multiple failure analysis is considered in which all three structures are considered to fail in such a way that their peaks arrive at LGS simultaneously.

The failure, seismic or otherwise, of any of the six Schuylkill River navigation dams downstream of LGS would not affect safety-related water supplies, since safety-related water supplies do not rely on the Schuylkill River.

Regulatory Guide 1.59 (Rev 2) specifies that the appropriate SPF at the dam should be coincident with the dam failure in the OBE case and that the flood control pool should be filled. This specification is equalled or exceeded in the analysis at all reservoirs, as indicated in Table 2.4-3. The SPF peak flow for LGS of 250,000 cfs is estimated at 50% of the PMF, using the conservative criteria in Appendix B of Regulatory Guide 1.59 (Rev 2) for determining the PMF.

Landslides induced by seismic action could block the river, causing dam break type waves downstream when water pressure builds up and breaches the slide material. However, topographic considerations alone appear to preclude any hazard to the plant from landslide-induced waves. The Allegheny Mountains lie over 40 miles upstream from the site. Any landslides across the river in that area might temporarily back up water that could later breach the slide; however, by the time the flood wave appeared at LGS, it would be greatly attenuated. Below the Allegheny Mountains, in the Great Valley above Reading and the Triassic Lowland below Reading, the river's meander floodplain is typically 3000-5000 feet wide. Blockage of this wide channel by a landslide is not conceivable. The topography on both sides of the floodplain is generally gentle, but with some steeper hills occurring, particularly on the south side of the floodplain, between the site and Reading; however, a study of the USGS 1:24,000 maps indicates that, except at Reading, none of these appear to have the volume required to block the river.

At Reading, there are several steep hills on both sides of the river. Of these, the closest to the river and the steepest is Neversink Mountain, on the north side (Figure 2.4-14). The river is 200 feet wide and has no floodplain at this point. If Neversink Mountain were to collapse and block the river, with the slide subsequently breached by the river, water could back up to el 255' before spillage occurs over Poplar Neck, a long ridge on the south bank. The river bottom here is at about el 170'; therefore, the maximum depth of the water backup would be 85 feet, after which it would spill over Poplar Neck. The resulting wave could not produce a water surface elevation at LGS that would endanger the plant. The joint occurrence of a wave at LGS from a Neversink Mountain slide and a failure of one or more upstream dams is an event much less likely than is required by Regulatory Guide 1.59. The peak flow rate that is due to simultaneous failure of the three dams, Maiden Creek, Ontelaunee, and Blue Marsh, is conservatively estimated at 762,000 cfs. When superimposed on the SPF flow of 250,000 cfs, the combined event results in a total flow rate of 1,012,000 cfs.

2.4.4.2 Unsteady Flow Analysis of Potential Dam Failures

The dam break problem has been discussed in the literature for various idealized cases. The most generalized and convenient approach developed to date is by Sakkas (Reference 2.4-23) as most recently described by Sakkas and Strelkoff (Reference 2.4-24). With this method, cognizance is

given to channel friction and volume of the flood wave. However, it was derived by dry-bed conditions and requires consideration of a uniform prismatic channel downstream.

In Reference 2.4-23, dimensionless graphs are given that are determined by numerical integration of the equations for unsteady flow, using the method of characteristics. A wide variety of combinations of dam height, channel slope, and cross-sections is analyzed so that the various graphs permit an analysis of many practical dam failure situations. Channel geometry is assumed as prismatic, and procedures are given in Reference 2.4-23 for deriving the constants characterizing the channel cross-section, yielding a relation between the cross-section width B and the depth Y. This relation is given by:

$$\overline{B} = \overline{CY^m} \qquad \text{(EQ. 2.4-7)}$$

where:

$\overline{B}$ = the width at depth $\overline{Y}$

$\overline{C}$ and m = constants derived from the cross-section properties.

To determine the constants C and m, it is necessary to have the values of two pairs of B's and Y's (say B_o, Y_o, and B_1,Y_1) of this representative cross-section. Thus paired B's and Y's were obtained by taking the geometric mean of paired b's and y's at three actual river cross-sections using:

$$B_\circ = \left(\pi_{i=1}^{3}\ b_{\circ_i}\right)^{1/3}$$

$$Y_\circ = \left(\pi^{3}_{i=1}\ y_{\circ_i}\right)^{1/3}$$

and

$$B_1 = \left(\pi_{i=1}^{3}\ b_{1_i}\right)^{1/3}$$

$$Y_1 = \left(\pi_{i=1}^{3}\ y_{1_i}\right)^{1/3}$$

in which (i) denotes the individual of the three river cross-sections, at the hypothetical dam, the LGS site, and near Birdsboro, respectively. Because these paired b's and y's determine the (C) and (m) values and thus characterize the shape of the representative cross-section, they are called "paired characteristic breadth and depth dimensions".

Reference 2.4-23 gives dimensionless curves of the time of arrival of the wave front, the flood depth, and its time of arrival as a function of the distance downstream, empirical cross-section constants (C) and (m), and the initial Froude number (F) at the dam:

$$C = \overline{C}\ \overline{Y}_{\circ}^{(m-1)}, \quad F = \frac{\overline{V}_{\circ}}{\left(\overline{gY_{\circ}}\right)^{1/2}}$$

where:

$$\overline{V}_{\circ} = 1.486 \left(\frac{\overline{R}_{\circ}^{2/3} S^{1/2}}{n} \right)$$

$\overline{R}_{\circ}$ = The hydraulic radius at the instant of failure

$\overline{Y}_{\circ}$ = the initial depth at the dam

$\overline{g}$ = acceleration of gravity

S = channel slope

$\overline{n}$ = Manning's friction coefficient for channel downstream

Symbols with bars over the top are dimensioned variables, and symbols without the bar are dimensionless, following Sakkas' notation.

For the assumptions specified, the results of the Sakkas procedure are considered reasonably accurate. However, adapting the general model to a particular situation and then superposing multiple dam failures requires careful consideration and interpretation to obtain conservative estimates of incremental and total flood depth. A set of simplified surrogate regimes is assumed whose cumulative effect on flood depth certainly is greater than the depth in the actual hydraulic regime that would prevail in such an event. This conservatism is justified only because of the LGS location high above the Schuylkill River.

To incorporate the prismatic channel assumption, it is necessary to adopt a single representative channel cross-section between the failed dam and the site. The river section at a dam is typically narrow, whereas the river floodplain below tends to be wider. In the Schuylkill River and its tributaries, the basic valley is U-shaped or V-shaped; i.e., there are no relatively wide floodplains in the reaches between the dams and LGS, and the main stream channel does not vary greatly in basic geometry, particularly under the initial condition of the SPF. Under these conditions an approximation of a constant prismatic section is considered realistic.

A single representative cross-section is defined by taking the geometric mean of two, paired characteristic breadth and depth dimensions at three cross-sections: one at the hypothetical dam described later; one at LGS; and one at a section of the Schuylkill River located about 1 mile upstream of the town of Birdsboro, or about 15 miles upstream of LGS. These three cross-sections are presented in Figures 2.4-21, 2.4-22 and 2.4-23 respectively. Figure 2.4-24 is the defined representative cross-section. The geometric mean section is then used for estimating the effect of a particular dam break.

The results given by the Sakkas procedure apply to a flood wave progressing down an initially dry-bed. To approximate this condition in the analysis, the channel slope and the geometry of the two downstream sections are set before a mean section is determined. They allow for the existence of the SPF and any stage increments from previous dam breaks. In effect, the peak of the SPF is "frozen" at 250,000 cfs at LGS for the time that the peak of a dam break flood wave is enroute to LGS. Conservatism is embedded in this approach, since an earthquake of multiple dam break failure

magnitude is more likely to be a single massive event dispensing flood waves from each dam at the same time, rather than timed so that their peaks would be additive at LGS, simultaneously with the crest of the SPF.

Since Maiden Creek and Ontelaunee dams are located on the same stream within 5 miles of each other, the SPF peak at Ontelaunee is estimated from that at Maiden Creek, using the ratio of drainage areas. This gives the SPF peak at Ontelaunee as 58,400 cfs. If it is conservatively assumed that there is no attenuation that is due to the storage in Ontelaunee reservoir above the spillway crest (el 294'), the SPF peak of 58,400 cfs discharges at a reservoir elevation of 304.2 feet. It is estimated that, at this elevation, the volume of water impounded behind Ontelaunee Dam would be 29,000 acre-feet.

Based on the information available from the U.S. Army Corps of Engineers, the volumes of water stored in Maiden Creek and Blue Marsh reservoirs under SPF conditions are estimated as 130,000 and 76,700 acre-feet, respectively. Thus, the total storage of the three dams combined together is 235,700 acre-feet.

To obtain a conservative water surface elevation that is due to simultaneous failure of the three dams, it is assumed that the total volume of water (235,700 acre-feet) would be stored upstream of a hypothetical dam located near Reading, approximately 30 miles upstream of LGS and 5 miles downstream of Blue Marsh Dam. As the hypothetical dam is downstream of the three real dams, the channel storage assumed available for attenuation of a flood wave released from the hypothetical dam would be smaller than actual. This results in a higher, and therefore conservative, estimate of the water surface elevation at LGS.

The area-capacity characteristics of the hypothetical dam are assumed to be the same as at Blue Marsh Dam, which is the nearest upstream dam. Actually, the channel section at the location of the hypothetical dam would be wider than that at Blue Marsh, and so the above assumption provides conservative estimates of the water surface elevation corresponding to a given storage. By this assumption, the water surface elevation in the hypothetical reservoir for the combined storage of 235,700 acre-feet is estimated to be 333.5 feet. The river bed elevation at this location is 213 feet. Thus the depth of impoundment of the hypothetical dam at the instant of the postulated failure was 120.5 feet.

Using a slope-area method and assuming uniform flow conditions, the water surface elevations corresponding to the SPF at Birdsboro and LGS are estimated to be 188 feet and 152 feet, respectively. To simulate pre-existing SPF conditions in the river, cross-sections at Birdsboro and LGS are assumed to be represented by the portions of the flow sections above the SPF elevations. For the cross-section just downstream of the hypothetical dam, dry channel conditions are assumed. With the Sakkas method, it is conservative to ignore any water in the channel immediately downstream of a failing dam because a deeper than actual reservoir storage results. As stated earlier, to use Sakkas' dimensionless charts, a representative prismatic section for the routing reach from the hypothetical dam to LGS is obtained by taking the geometric mean of the characteristic breadth and depth of the river sections at the hypothetical dam (above dry-bed), at Birdsboro (above SPF elevation), and at LGS (above SPF elevation).

To be conservative, the channel slope between the hypothetical dam and LGS is computed using the dry-bed elevation at the hypothetical dam site and the SPF elevation at LGS. The actual channel slope during SPF conditions is steeper than that used.

To obtain a representative value of the coefficient of roughness, (n), for the river reach between the hypothetical dam and LGS, weighted average values are computed for the sections at Birdsboro and LGS using the equation (Reference 2.4-33):

$$n = \left[\frac{AR^{2/3}}{\sum_{i=1}^{2} \left(\frac{A_i R_i^{2/3}}{n_i} \right)} \right] \qquad \text{(EQ. 2.4-8)}$$

where:

A	=	total flow area
R	=	hydraulic mean depth for the entire section
A_1, R_1	=	flow area and hydraulic mean depth for the channel section
A_2, R_2	=	flow area and hydraulic mean depth for overbank flow
n_1, n_2	=	coefficients of roughness for the channel and overbank sections

For the section at the hypothetical dam site, where dry-bed conditions are assumed, a value of n = 0.062 is used for the entire section. This value is recommended for floodplains with light-to-medium brush and trees (Reference 2.4-33) and conservatively represents the conditions at the hypothetical dam section. For the sections at Birdsboro and LGS, where the dam break flood wave is superimposed on the SPF, a value of 0.062 is used for the overbanks, and a conservative value of 0.03 is used for the interface between the water surface at SPF and the dam break flood wave. The arithmetic average of the (n) values for the three sections was assumed to be applicable for the entire reach.

Using Sakkas' curves (Reference 2.4-23), the maximum flood depth that is due to the dam break is determined at the downstream section at LGS. The calculated depth thus determined is a depth in the derived geometric mean cross-section. To relate the computed depth to the actual section, conveyance relations are used. Using the derived properties of the geometric section (C and m), the area is given by:

$$A = (CY^{m+1})(m+1)^{-1} \qquad \text{(EQ. 2.4-9)}$$

From this, the conveyance (Equation 2.4-4) required in both the geometric section and the natural section can be calculated. Using the stage conveyance characteristics of the natural river section above the SPF elevation at LGS, the water surface elevation that gives incremental conveyance (above SPF elevation) equal to that corresponding to the calculated depth in the geometric mean cross-section is computed. This results in a water surface elevation of 201 feet at LGS.

2.4.4.3 Water Level at Plant Site

2.4.4.3.1 Maximum Computed Water Surface and Wave Effects

This section describes the effect of wind-waves on the maximum water surface (el 201') estimated at LGS that is due to the dam break condition described in the previous section.

The dam break waves are transients and do not contain enough volume to cover the entire Schuylkill Valley above LGS to the computed maximum depth at LGS. However, for an approximate wind-wave analysis, the following conditions are assumed; the water surface at LGS is el 201', and wind velocity is 40 mph.

Fetch is based on a map study of a level pool upstream at el 201' At this water surface elevation, the ridges and the two bends between Pottstown and the site are submerged. This permits a roughly rectangular fetch of 31,000 feet average length and a width of 4,500 feet, on a bearing of about N 72° W. The centerline of the rectangle intersects a ridge about a mile west of the village of Stowe. It is conservative to assume a rectangular fetch area, which according to Reference 2.4-25 gives a fetch effectiveness ratio of 0.18 and an effective fetch of 2.65 miles. Using Reference 2.4-25, these parameters yield a significant wave H_sV (33% frequency) of 3.8 feet, with a period of 3.9 seconds and a length of 78 feet. The maximum wave (1% frequency) is estimated as $1.67H_s = (1.67)(3.8) = 6.4$ feet.

At the LGS site bench, the maximum water surface without wind action, el 201', intersects a sloped-fill surface to the windward (west) side of the plant (Figure 2.4-4). The fill surface has an average slope of 1 vertical to 2 horizontal. The toe of the slope varies between el 170' and el 200'. The top of the fill varies from el 213' at the northwest end (adjacent to the switchyard bench), to el 216' on the south side of the plant, where the top of the fill curves toward the east. From the top of this fill, the ground rises gently on a long flat slope to the roadway at el 215' to el 217', which encircles the west side of the turbine-reactor area complex. The roadway's low part (el 215') is 90-350 feet from the top of the slope. The fill material is broken rock and fines, with sizes up to 24-30 inches. For computing wave run-up, this material can be considered as graded riprap. To compute run-up, curves given in figures 7-19 of Reference 2.4-25 are used, which are for a 1:2 slope. However, the wave from the maximum fetch direction is not perpendicular to the 1:2 slope surface, but intersects it at an angle of about 64° from normal. This results in an effective slope normal to the wave of about 1:4.5, so that actual run-up is less than computed.

Run-up (R) from the significant (33%) wave and the maximum wave (1%) is calculated from Reference 2.4-25 as follows:

Wave	H_o=Height (ft)	H_o/gT^2	R/H_o	R (ft)	Max el Run-up (ft)
Significant	3.8	0.0078	1.3	4.9	206
Maximum	6.4	0.013	1.0	6.4	207

Thus, the highest water surface elevation at LGS that is due to the most severe dam break permutation coincident with wave activity induced by a 40 mph wind would be 207 feet. This is 10 feet below the plant grade (el 217') and 8 feet below the roadway (el 215') .

2.4.4.3.2 Recapitulation of Conservative Steps in Dam Break Analysis

The computed water surface elevations (with and without waves) resulting from the dam break analysis are the result of a compounding of conservative assumptions.

The series of conservative steps used to compute the water surface are listed below.

a. The SPF is estimated at 50% of PMF, as determined from Appendix B of Regulatory Guide 1.59 (Rev 2). The PMF, as estimated by this procedure, has a peak of 500,000 cfs (unadjusted for dam breaks), whereas the peak PMF computed by conventional methods in the PSAR was 356,000 cfs, approximately 30% less. The SPF peak at 50% of the Appendix B PMF, or 250,000 cfs, is thus also conservative. Conservatism is further confirmed by a published U.S. Army Corps of Engineers estimate (Reference 2.4-26) of 128,000 cfs for the SPF at Pottstown; adjusted to the site, this would be 131,000 cfs, 52% of the SPF given by Appendix B of Regulatory Guide 1.59 (Rev 2).

b. The effective cross-sectional area used at LGS omitted part of the left overbank area (looking downstream) to conservatively allow for local flow separation produced by the river bend.

c. The earth-fill dams should not fail instantaneously as is assumed.

d. A dry channel is assumed downstream of the hypothetical dam, resulting by a larger effective reservoir depth by using Reference 2.4-23.

e. The concept of the hypothetical dam implies seismic failures of the three real dams generated at different times, corresponding to three different travel times to LGS. This is an improbable series of selectively destructive tremors. It is more likely that a single catastrophic tremor would be involved in a multiple dam failure, with the resulting flood waves arriving at LGS at different times.

f. The actual channel slope in the river reach from the hypothetical dam to LGS is steeper than the slope used in the analysis. This results in a higher water surface elevation at LGS, computed by Sakkas' procedure.

Since all of these assumptions are conservative, it is concluded that the maximum stages computed with and without waves are well above the stages that a precise analysis would indicate. It is finally concluded that the most severe seismic dam break permutation of the three dams, Blue Marsh, Ontelaunee, and Maiden Creek, would not endanger safety-related structures. The simplified analysis is justifiable because the plant area is high above the Schuylkill River.

2.4.5 PROBABLE MAXIMUM SURGE AND SEICHE FLOODING

This section is not applicable to LGS.

2.4.6 PROBABLE MAXIMUM TSUNAMI FLOODING

This section is not applicable to LGS.

2.4.7 ICE EFFECTS

This section is not applicable to LGS. Spray pond icing is discussed in Section 9.2.6.

2.4.8 COOLING WATER CANALS AND RESERVOIRS

In this section, only the hydrologic engineering aspects of the spray pond components of the UHS are covered. There are no canals in the cooling water system. The spray pond serves as the UHS for the RHRSW system and the ESW system after a possible accident. The pumps of the two systems take water from the spray pond, and circulate it through coolers and heat exchangers. The warm water is returned to the spray pond through a network of spray nozzles. A complete description of the spray pond system is given in Section 9.2.6.

2.4.8.1 General Description of the Spray Pond

The spray pond is located about 500 feet north of the cooling towers. The bottom of the pond is at el 241' and is composed of a 600x400 foot rectangular midsection, with a semicircle (radius = 200 feet) on each side. The spray pond system is common to both Units 1 and 2. The system consists of a spray pond, uncontrolled emergency spillway, pump structure complex, and associated piping and valves.

As shown in Figure 2.4-5, the spray pond is constructed by excavation only. The slopes of the excavation are 1:1 in rock and 4:1 in soils. Around most of the spray pond, random compacted fill about 3 feet deep overlies the original natural ground, with a bench at the soil-rock interface. The water surface area of the pond at el 251' is approximately 9.9 acres. An additional 7.3 acres of the surrounding area, including roads, cut surfaces, and natural terrain, drains towards the pond. Run-off onto the cut face is normally intercepted by a drainage ditch along the outside edge of a peripheral service road at el 255' and is directed to culverts that discharge to the pond. Along the north edge of the pond, the finished roadway is constructed to el 252' for a distance of 60 feet, with 9% slopes upward at either end to el 255'; this low portion of the roadway is designed to function as the crest of an uncontrolled emergency spillway. Spill is directed to a draw that drains northward into Sanatoga Creek.

2.4.8.2 Hydrologic Design Bases

Derivation of the PMF that forms the basis for the hydrologic design of the spray pond and emergency spillway is discussed in Section 2.4.2.3.2. The emergency spillway is sized so that the design flood will be evacuated safely. The elevation of the roadway around the pond and the slope protection of the pond are dictated by anticipated wave action.

2.4.8.2.1 Design Basis Flood Level

To arrive at a conservative elevation that is due to severe floods, with coincident wind-wave activity in the spray pond, the following cases were analyzed for waves, freeboard, and slope protection, using the procedures given in Reference 2.4-25.

Case	Flood	Still Pond Max Water Surface el (ft)	Maximum Wind (mph)
1	PMF	253.0	40
2	½ PMF (SPF)	252.5	90

Results are as follows:

Case	Significant (33-1/3%) Wave Height (ft)	Maximum (1%) Wave Height (ft)	Maximum Wave Run-up ft	Maximum Wave Run-up el
1	0.8	1.3	1.1	254.1
2	2.0	3.3	2.4	254.9

Based on the above, the DBFL is set at el 253.9'. The roadway surface has been set at el 254', or 0.1 foot higher than the DBFL.

Using criteria in Reference 2.4-25, the minimum riprap stone requirements are: a minimum weight of 7 pounds, a 50 percentile weight of 30 pounds, and a maximum weight of 108 pounds (assuming a stone density of 165 lb/ft^3). The gradation and design of the riprap for the spray pond soil slopes are discussed in Section 2.5.5. The riprap is capable of resisting the wave action and therefore protects the soil slopes. No protection is necessary for rock-cut slopes.

2.4.8.2.2 Safe Shutdown and Operating Basis Earthquakes

According to Regulatory Guide 1.59, the higher of the following two alternative combinations of events is considered to be an adequate design basis for floods that are due to seismic failure of dams:

a. Alternative 1 - 25 year flood coincident with SSE and 2 year extreme wind speed from the critical direction and length of effective fetch

b. Alternative 2 - one-half PMF, coincident with OBE, and 2 year extreme wind speed from the critical direction and length of effective fetch

When routed through the spray pond, the SPF yields a maximum water surface el 252.5'. The 25 year flood yields a maximum water surface el 251.8'. The starting water surface elevation in the spray pond for both these cases is assumed to be the normal operating water surface elevation (el 251'). In the latter case, the entire volume of the 25 year, 24 hour precipitation, without any losses over the contributing drainage area of 17.2 acres, is superimposed on the normal pond el 251'. Because the flood is contained below the spillway crest (el 252'), flood routing computations are not required for this case.

To estimate the height of waves due to earthquakes, the following equation, developed for determining the height of waves generated by a piston-type wave generator (Reference 2.4-31) is used:

$$H = 2s \left[\frac{2 \sinh^2 \frac{(2\pi d)}{L}}{\frac{(2\pi d)}{L} + \left[\sinh \frac{(2\pi d)}{L} \cosh \frac{(2\pi d)}{L} \right]} \right]$$

(EQ. 2.4-10)

where:

H = wave height vertical distance between the wave crest and trough (feet)

s = design displacement (amplitude) caused by the earthquake (feet)

d = initial depth of water (feet)

L = wave length; a function of the period of the design basis earthquake (feet)

From the response spectra of the SSE and OBE, the design displacement (amplitude) and period are estimated to be 6.5 inches and 2.0 seconds for the SSE and 3.0 inches and 2.0 seconds for the OBE, respectively. Conservatively, assuming that a negative wave is generated at the opposite boundary of the spray pond and that the amplitudes of the positive and negative waves are in phase and additive, the maximum possible wave height would be 2H. This results in a maximum water surface elevation H above the still water. The computed values of H and the resulting water surface elevations are tabulated below:

Earthquake	Concurrent Flood	Earthquake Wave (ft) H	Earthquake Wave (ft) 2H	2 Yr Wind Effect (ft)	Max Water Surface el (ft)
OBE	SPF	1.0	2.0	0.25	253.8
SSE	25 year	2.1	4.2	0.25	254.2

Because the spillway crest is at el 252', there would be some splash over the spillway for a short duration. However, water loss due to such splashes would be negligible compared to the total capacity of the spray pond and would not impair the safety-related water supply functions of the pond.

For the design of riprap protection, the wind-generated waves described in Section 2.4.8.2.1 are more critical than the short duration earthquake-induced waves.

For the spray-head pipe supports and the pump structure, hydrodynamic forces due to the OBE and SSE are computed. The forces on the pipe supports are computed using the virtual mass formula, $F = C_m V_\rho a$ (Reference 2.4-30), in which (F) is the hydrodynamic force on a body of submerged volume (V) that is due to an acceleration (a), in a fluid of mass density (ρ). Based on information available in Reference 2.4-30, a value of 1.5 is used for the coefficient (C_m). The resulting forces on the spray-

head pipe supports are 431 lbs and 890 lbs for the OBE and SSE, respectively; the forces are assumed to be applied at mid-depth, el 247.3' and el 247.5', respectively.

For the pump structure, hydrodynamic forces are computed both in the N-S and E-W directions. For the N-S direction, the TVA method (Reference 2.4-31) is used. For the E-W direction, where only part of the structure is exposed to water, the method given by Sarpkaya (Reference 2.4-32) is used. The resulting forces and their points of application are given below:

Earthquake	Direction	Max Force (kips)	Point of Application (ft)
SSE	N-S	144.0	246.2
	E-W	70.0	247.5
OBE	N-S	67.0	246.0
	E-W	34.0	247.5

These hydrodynamic forces on the pipe supports and the pump structure do not include the hydrostatic forces that are due to normal water depth, flood surcharge, or earth pressures, nor do they include dynamic forces that are due to waves.

2.4.8.3 Low Level Outlet Facilities

Evacuation of the normal storage of the spray pond, if needed, is accomplished by using the ESW system and/or RHRSW system pumps to pump water to the cooling tower basins via the cooling tower spray pond intertie line down to the minimum operation level of the pumps, and by other means below that level.

2.4.9 CHANNEL DIVERSIONS

This section is not applicable to LGS.

2.4.10 FLOODING PROTECTION REQUIREMENTS

As discussed in Section 2.4.2.2, the safety-related structures and facilities are secure from flooding. Hence, flooding protection requirements are not necessary.

2.4.11 LOW WATER CONSIDERATIONS

Extreme low flow in streams does not affect the ability of any safety-related facilities to perform adequately, including the UHS, as discussed in Section 9.2.6.

Availability of nonsafety-related water supplies is governed by the Delaware River Basin Commission (DRBC) Docket Decision D-69-210CP. The DRBC also has exclusive jurisdiction over the necessity for and approval of compensating water storage capacity for the LGS. LGS shall operate its nonsafety-related water supply systems in accordance with the terms and conditions imposed by the DRBC.

2.4.12 DISPERSION, DILUTION, AND TRAVEL TIMES OF ACCIDENTAL RELEASES OF LIQUID EFFLUENTS IN SURFACE WATERS

There are no credible accidents that can occur that result in an accidental liquid release of radioactive effluents to surface waters.

The term maximum permissible concentration (MPC) is used in various sections of the UFSAR. The term MPC is reflective of pre-1994 10CFR20, Apprendix B, Table II limits. These limits were used for the original licensing basis of the plant. Current liquid effluent releases are limited to ten-times the Effluent Concentration Limit (ECL) for each isotope specified in post-1994 10CFR20, Appendix B, Table 2, Column 2 (See Radioactive Effluent Release Controls Program required by the Technical Specifications).

The radwaste and reactor enclosures are seismic Category I structures. Each structure has a floor drain collection system to collect any potential liquid spills that may occur and to transfer the liquid to radwaste tanks. The radwaste tanks are located at the lowest elevation in the radwaste enclosure, which has a leak-tight membrane from the floor to el 174' MSL (grade is el 217' MSL). Consequently, any effluents accidentally spilled inside these enclosures are contained and remain isolated from the surface water environment.

In addition, the release of radioactive liquids by the failure of an outside storage tank is not considered credible since the tanks are enclosed by retaining dikes (Section 9.2.7). These dikes are constructed of compacted fill. The dikes and the area between the tanks and the dikes are covered with asphalt pavement. The outside tanks that contain radioactive liquid are the Unit 1 and 2 CSTs, each having a capacity of 200,000 gallons, and the refueling water storage tank, with a capacity of 500,000 gallons.

The Unit 1 CST and the refueling water storage tank are surrounded by a retaining dike. The Unit 2 CST is also surrounded by a retaining dike (Section 9.2.7). These dikes are designed to contain 110% of the contents of the largest tank that they enclose. Therefore, even if the entire contents of the largest of these tanks is spilled, the effluents are contained within the diked area, and do not reach any source of surface water.

The retaining dikes surrounding the outside CSTs are designed in accordance with seismic Category IIA requirements (Section 3.2.1). However, an analysis to determine the potential for contamination of nearby surface waters assuming that both tanks and dikes fail is not necessary for the following reasons:

SRP 15.7.3 indicates that the technical specifications shall limit the contents of outside storage tanks to those levels that will not exceed 10CFR20 concentrations at the nearest potable water supply unless dikes are provided to limit the water released by a tank or associated component failure or overflow. LGS has provided a dike to limit these water releases.

Based on section C.1.p of Regulatory Guide 1.29, the CSTs and surrounding dikes have been classified as seismic Category II and IIA respectively because the airborne doses from a failure of these structures would not exceed 0.5 rem whole body or its equivalent to any part of the body (1.5 rem thyroid in this case). Thyroid doses of 2.1×10^{-3} rem have been calculated at the EAB, based on a 350,000 μCi/sec offgas release rate resulting in the tank inventories of Table 12.2-87, an iodine dose factor of 10, and a 5 percentile X/Q of 2.9×10^{-4}.

Although the retaining dikes are not seismic Category I, they will retain their structural integrity during an SSE event as discussed in Section 2.5.5. In view of this, failure of both tanks and dikes need not

be assumed in determining the potential for contamination of nearby surface waters. An analysis is provided in Section 2.4.13 which assumes a radwaste tank failure only. The analysis indicates that significant periods of decay (over 600 years) will occur before any radioactivity is released via the groundwater pathway if the contents should be absorbed by the ground. Because the primary contributors to the normally expected CST activity are the iodines and several shorter-lived isotopes with half-lives of less than 1 day, and all other isotopes have expected concentrations less than the MPC levels for water in unrestricted areas, doses via any food or drinking water pathways will be well below 10CFR20 limits.

Accidental release of radioactive effluents into the groundwater environment is discussed in Section 2.4.13.3.

In view of the above, detailed analyses regarding the ability of the surface water environment to disperse, dilute, or concentrate accidentally released radioactive effluents are not required.

2.4.13 GROUNDWATER

Investigation of regional and local groundwater conditions indicates that the construction and operation of the LGS has no adverse effects on the groundwater resources in the region and the site.

2.4.13.1 Description and Onsite Use

The site is located in the Triassic Lowland Section of the Piedmont Physiographic Province. The region is characterized by rolling hills and long low ridges and is well drained by numerous tributaries to the Schuylkill River. Precipitation averages about 44 inches per year, and run-off averages about 21 inches per year. The balance represents mainly evaporation and transpiration losses, with minor infiltration.

Groundwater occurs in sedimentary rocks of Triassic-age. The Brunswick lithofacies, the aquifer underlying the LGS site, yield small-to-moderate quantities of water to wells.

The water supply for LGS plant operation is obtained from surface water, and no groundwater use is planned.

2.4.13.1.1 Groundwater Aquifer

Groundwater in the region occurs in sedimentary rocks. The region is underlain by the Newark group of Triassic-age, which includes the Stockton Formation and the overlying Lockatong, Hammer Creek, and Brunswick lithofacies.

The strata are intruded by diabase dikes and sills. Although the other units provide some groundwater in the region, the Brunswick lithofacies are the only aquifer of significance at the LGS site.

The Stockton Formation, which crops out about five miles south of the site, is composed of interbedded sandstone, conglomerate, red shale, and red siltstone and is at too great a depth at the LGS site to be of hydraulic importance. The Hammer Creek conglomerates and sandstones stratigraphically overlie the Stockton in the region but are not present in the site area. The nearest occurrence of the Hammer Creek is a few miles west of the site, in Berks County. The Stockton is overlain south of the site by the Lockatong, a dark gray argillite. The areal distribution of these formations and lithofacies is shown in Figure 2.5-2.

The Brunswick, the aquifer at the site, is composed of red shale, sandstone, and siltstone. Within the Triassic Lowland, as well as in the site region, the Brunswick is the most widespread source of groundwater. The Brunswick is interbedded with thin tongues of Lockatong, and changes in lithology are common.
The dip of the Brunswick and Lockatong strata is to the north and northwest at about 10° to 20°. Several broad synclines and anticlines trending about N 60° W are superimposed on the regional structure. The strata have been cut by many faults, most of which are relatively small. Joint systems are well developed and strike N 20° E to N 50° E and about N 50° W to N 90° W. The joints are mostly vertical, and in some strata are closely spaced.

The Brunswick is composed of very fine-grained rocks. The pore spaces within the rock matrix are very small and offer great resistance to the flow of groundwater. Therefore, permeability that is due to the primary porosity of the Brunswick is small.

Most of the groundwater movement within these rocks follows secondary openings that developed following the deposition of the beds. Some of these openings are fractures that parallel the bedding-planes. They are usually narrow and probably contribute little to the permeability. The most important openings are nearly vertical joint planes; they cross each other at various angles throughout the beds. These joints, where present, provide an interconnected series of channels through which groundwater can flow, giving the material a low to moderate permeability (Reference 2.4-36).

The number and width of secondary openings vary; consequently, the permeability differs from one bed to another. In a series of beds 100 feet thick, there may be only a few beds in which the secondary openings are well developed. These beds range in thickness from a few inches to a few feet; the average thickness is about 2 feet (Reference 2.4-36).

In the Brunswick, the water table is found at shallow depths. Wells that penetrate deep strata in the Brunswick may encounter water under confined conditions. The water table slopes from the topographic divides to discharge areas along streams and rivers. The Brunswick is generally a reliable source of small-to-moderate quantities of groundwater but, yields from wells that penetrate it vary widely because of lateral and vertical variations in lithology, the occurrence of lens-shaped beds, uneven spacing of joints and locally complex structure. Fault zones in the Triassic rocks have been found to be barriers to the flow of groundwater, and wells located near them generally have very low yields. The median yield of drilled municipal and industrial wells is about 110 gpm. Yields in excess of 300 gpm are rare and are obtained from wells that intersect a larger number of water-bearing zones. The median transmissivity of the Brunswick is 1100 gpd/ft (Reference 2.4-36).

Most groundwater in the Brunswick aquifer is a calcium bicarbonate-type, but some of the groundwater, with a total dissolved solids content in excess of 500 ppm, is a calcium sulfate-type (Reference 2.4-36). Water quality data for the Brunswick Lithofacies are presented in Table 2.4-14.

Most water from the aquifer is suitable for domestic and other purposes.

2.4.13.1.2 Aquifer Recharge and Discharge

Recharge to the Brunswick occurs through the soil cover as precipitation percolates down to the water table. The water table generally follows the surface of the land, and groundwater flows from high to low topographic areas.

Poor water quality and low yields in wells deeper than 600 feet indicate little groundwater movement below that depth. Most groundwater movement is prevalent only in the upper portion of the Brunswick, where the fracture density is greatest.

At the site, groundwater moves from the topographic high northeast of the plant structures down gradient to the north and the southwest, where it eventually discharges into the Schuylkill River and Possum Hollow Run (Figure 2.4-15).

2.4.13.1.3 Onsite Use of Groundwater

Water for plant operation is supplied by surface water and is discussed in Section 2.4.

Three wells were developed : Well No. 1 is 310 feet deep, 6 inches in diameter, and yields 50 gpm; Well No. 3 is 585 feet deep, 7-7/8 inches in diameter, and yields 65 gpm; and Well No. 4 is 198 feet deep, 6 inches in diameter, and yields 65 gpm. Note that well No. 4 was decommissioned and is no longer in service for domestic water.

These wells will be utilized as permanent water sources as follows:

- Site well 1, source of chlorinated drinking water.

- Site well 3, water to batch plant water tank and 500,000 gallon backup fire water storage tank.

The operation of the wells has no permanent impact on the groundwater resources of the site area.

2.4.13.2 Sources

Within 20 miles of the site, surface water sources supply most of the public and commercial demand. The Schuylkill River and its tributaries are widely used. However, a number of municipalities and industries, together with many domestic users, utilize groundwater.

2.4.13.2.1 Regional Use of Groundwater

The locations of public water supply systems within 20 miles that use groundwater are shown in Figure 2.4-16. An inventory of the supply systems is presented in Table 2.4-15. Public water systems supply more than 80% of the population in the region (Reference 2.4-37). Groundwater contributes less than 40% of the total amount of public water supplied.

Individual, private wells supply groundwater to slightly less than 20% of the population in the region and generally account for less than 10% of the total water usage (Reference 2.4-37).

2.4.13.2.2 Use of Groundwater in the Vicinity of the Site

An inventory of local groundwater users is presented in Table 2.4-16. Locations of groundwater users within 1 mile of the site are shown on Figure 2.4-17.

Groundwater supplies several homes, farms, and commercial interests in the vicinity of the site. Most of the wells are less than 200 feet deep and yield less than 100 gpm. The largest groundwater user, Publicker Industries, is 1½ miles south of the site and uses 150,000 gpd from three wells in the Brunswick.

Water wells in the site vicinity are either not in the same groundwater basin as the plant (hydrologically separate) or are hydraulically up-gradient of the plant. No wells to which groundwater beneath the plant discharges are present in the area.

2.4.13.2.3 Projected Future Use of Groundwater

Population growth and relocation will create a corresponding need for larger supplies of water in the site region. Much of the increase in water usage will take place in Limerick Township and neighboring townships as suburban development creates new demands for groundwater (Reference 2.4-37). Based on the assumption that the usage in the region reflects the national average, water usage is expected to increase by approximately 1 gcd (gallon per capita per day) each year. By the year 1990, a 12% gcd increase, combined with more than a 30% increase in people served by public water systems, will increase the total amount of water use by approximately 50% (Reference 2.4-37). The increase in the demand for water will be met mostly by public water supply systems, which are developing additional wells to meet part of the demand.

The number of domestic and private wells is not expected to increase significantly, because most new water users will purchase water from water supply companies. By 1990, more than 90% of the population in the region will be supplied by public water suppliers.

Large increases in the use of groundwater in the site area are precluded by the low permeability and limited area of the water-bearing units there.

LGS will have no effect on the future use of groundwater in the region. The plant uses groundwater from site wells 1, 3 and 4 for drinking water and for filling the 500,000 gallon backup fire water storage tank.. The site is hydrologically isolated from all public groundwater supplies and areas of extensive groundwater development.

2.4.13.2.4 Water Levels and Groundwater Movement

Groundwater levels were measured in borings (observation wells) at various locations near the spray pond and power block areas. The observation wells were monitored at regular intervals from June 1973 through August 1975, and from November 1978 through May 1979, to determine the direction of groundwater movement and the elevation of the water table, and to establish structural design criteria for groundwater effects. These wells were subsequently monitored throughout the remaining plant construction period to determine the effect of plant construction on the groundwater movement and levels, and to verify/assure the adequacy of the design criteria used in the design of safety-related plant structures. Figure 2.4-18 shows hydrographs of the observation wells.

2.4.13.2.4.1 Observation Wells

A network of 22 groundwater observation wells were installed at the site at various construction stages to determine the depth to water, and to measure groundwater level fluctuations. The locations of these wells are shown in Figure 2.4-15. The construction data (depth of hole, interval screened, etc.) are presented in Table 2.4-17.

Five observation wells were installed in the planned spray pond area in June 1973, and monthly water level readings commenced. In June 1974, four more wells were installed in the spray pond area and incorporated in the monitoring program. Monitoring was temporarily discontinued between August 1975 and November 1978 because of construction of the spray pond. Observation wells P2, SP20, and SP21 were destroyed by this construction.

In November 1978, water level monitoring was resumed in the remaining six wells near the spray pond area. Furthermore, 10 more observation wells were installed in January 1979, and three more wells were installed in June 1981. Six of the 13 wells are located near the power block area, and the remaining seven wells are located near the spray pond area. Observation wells P1 and P4 were destroyed in 1981 by ongoing construction activities and grading. In addition, observation wells P9, P13, and P15 were abandoned in April 1988, June 1984, and December 1987, respectively.

The recorded water levels in the observation wells between early 1979 and early 1988 are shown on the hydrographs in Figure 2.4-18.

2.4.13.2.4.2 Groundwater Levels

The depth to water in observation wells has ranged from 13-96 feet below ground surface. Recharge to the groundwater beneath the site is primarily from infiltration of precipitation on the ground surface. During the period 1973 through 1975, precipitation was average for the region. Thus, groundwater levels during that period were probably near average.

The potentiometric surface determined from levels measured in May 1979, prior to spray pond construction, is shown in Figure 2.4-15. This indicates the water table east of the planned spray pond was at el 250' and decreased in elevation to less than 130 feet southwest of the power block. Postconstruction water levels reveal the same general configuration, with localized variations probably due to site grading/surface and drainage installation.

Hydrographs of observation wells (Figure 2.4-18) indicate that water levels fluctuate seasonally, with the lowest levels occurring in the fall and early winter, and the highest levels occurring in the spring. In the spray pond area, these records indicate a 17 foot maximum seasonal fluctuation (wells P5 and P6), with most well levels fluctuating less than 12 feet.

Neither average water levels nor water level fluctuations were significantly affected by the filling of the spray pond during October 1982 and November 1982. The only exception to this is the water level in well P17, which currently averages about 10 feet higher than it did prior to pond filling. However, the water level fluctuation in well P17 remains as large as or larger than that recorded prior to pond filling, suggesting there is no hydraulic connection between well P17 and the water in the spray pond which is maintained at a constant level. In any event, measured seepage loss from the entire spray pond was calculated to be only 4.7 gpm (Reference 2.4-43).

Hydrographs of observation wells in the power block area (Figure 2.4-18) exhibit larger water level fluctuations than those in the spray pond area. These fluctuations were closely related to precipitation, as illustrated in Figure 2.4-19. Wells P12 and P15 do not show large fluctuations because the water table is below the screened intervals during low periods. When the water table drops below the screen, the level measured in the well is of the water remaining in the sump, a 5 foot length of casing below the screen. Thus, only the highest water levels reflect the water table (fluctuation peaks) at wells P12 and P15.

During construction, the observation wells in the power block area were adjacent to open trenches or to plant excavations backfilled with relatively permeable materials. Precipitation that collected in the open trenches or that infiltrated the permeable backfill provided abnormal amounts of recharge to the water table. When the open trenches were filled and asphalt or other relatively impermeable layer was placed over these backfilled areas, the water table fluctuation was reduced because of the reduction of infiltration of precipitation (Figure 2.4-18). The surfacing also resulted in large reductions

of average water levels in wells P13 and 14. Figure 2.4-15 shows potentiometric contours of the water table as of May 31, 1988.

2.4.13.2.4.3 Direction of Groundwater Flow

Groundwater in the shale and siltstone strata immediately underlying the site flows in fractures and joints. Exploration at the site suggests the fractures are tight below a depth of 140 feet, indicating little or no movement of groundwater in these units below this depth.

The direction of flow is from topographically high areas to topographically low areas (Figure 2.4-15). Groundwater beneath the plant flows southwesterly toward the Schuylkill River, eventually discharging to the river. North of the plant, a groundwater divide is present beneath the topographic ridge. Groundwater north of the divide flows northward, discharging to tributaries of the Schuylkill River. Because of the low permeability and poor hydraulic connection between beds in the bedrock, the influence of groundwater at the site on the regional hydrology is negligible.

Below the shale and siltstone strata described above, some discontinuous beds of sandstone yielded water to the wells used during construction. Pumping tests using these wells and closely spaced observation wells in the sandstone and the overlying siltstone-shale beds measured the hydraulic interconnection between these units. The results indicate that the connection ranges from very slight to negligible.

2.4.13.2.5 Aquifer Parameters

A pumping test and other permeability tests were performed to evaluate the groundwater hydrology of the site.

For the pumping test, a 6 inch diameter test well, located near the center of the construction area, was installed to a depth of 185 feet. Changes in water level as a result of pumping were measured in 6 observation wells located at various distances (20 feet to 700 feet) from the test well. Using the time-drawdown data from the pumping test, and the Theis nonequilibrium formula, bedrock transmissivity (T) is computed to be 2250 gpd/ft. This value corresponds to an average permeability (K) of 11 gpd/ft^2 (550 ft/yr).

Forty constant head tests were performed in auger holes and boreholes to estimate the permeability at the spray pond. Calculated permeabilities range from 4 ft/yr to 1247 ft/yr and are listed in Table 2.4-18. The average permeabilities for the overburden, the contact zone between the overburden and bedrock, and the bedrock are 3.5 ft/yr, 14 ft/yr, and 214 ft/yr, respectively. The tests indicate that the permeability of the overburden is lower than the bedrock's permeability. The greatest range of permeability values was determined from test data in bedrock. Because of the fractured nature of the bedrock, the permeability depends on the number of fractures the boring intercepts. More than 84% of the permeabilities measured in bedrock are less than 390 ft/yr.

2.4.13.2.6 Reversibility of Groundwater Flow

Seepage from the spray pond may cause a groundwater mound beneath the pond, with minor, local reversals of flow direction. This would increase the groundwater flow to the north and to the Schuylkill River, but the general direction of flow would remain the same. Because the pond will be lined, these changes will be minor.

2.4.13.2.7 Water Quality

Chemical analyses of groundwater are available from wells that penetrate the Brunswick lithofacies in Montgomery County (Table 2.4-14). The median dissolved solids content of samples from these wells is 302 ppm, and the median hardness (as $CaCO_3$) is 218 ppm. Groundwater from the Brunswick is largely of the calcium bicarbonate-type, although water samples having concentrations of dissolved solids greater than 500 ppm are of the calcium sulfate-type. Groundwater from the Brunswick is of good quality for most domestic and municipal uses, although it may need to be treated for hardness.

Water quality information is available from Well Nos. 1, 3, and 4 at the LGS site (Table 2.4-19). Samples were taken from holding tanks rather than from open discharge at the wells, but are considered indicative of the water quality. The water is a calcium sulfate-type, with pH ranging from 7.5 to 8. The water is moderately hard, ranging from 134 ppm to 618 ppm as $CaCO_3$, and contains total dissolved solids ranging from 199 ppm to 1052 ppm.

2.4.13.3 Accident Effects

An accidental spill of radioactive effluents from the radwaste enclosure is hypothesized, and the effect of a spill is analyzed with regard to the nearest offsite source of potable water, the Schuylkill River, 800 feet from the radwaste enclosure. Potentiometric contours shown on Figure 2.4-15 indicate that, in the radwaste enclosure area, groundwater flows southwest toward the Schuylkill River. It is assumed that radionuclides from a spill would percolate directly to the water table in the rock and then move with the groundwater laterally toward the river. The radioactive effluents that would constitute a spill are assumed to originate from the waste sludge tank, which contains the largest source of radioactivity in the enclosure. For conservatism, radioactive effluents are postulated to immediately enter the water table below the radwaste enclosure, and concentrations of radionuclides at that point are assumed to be the same as those in the radwaste tanks. No credit is taken for ion exchange, dispersion, or radioactive decay during percolation to the water table.

In addition to the accidental spill of radioactive effluents from the radwaste enclosure hypothesized as the worst case spill, a feed water line break between the main condensers and the condensate filter demineralizer in the Unit 2 turbine enclosure could contaminate the groundwater supply to site well 4. Site well 4 is utilized as a source of chlorinated water at the site. Site well 4 is on the same side of the groundwater divide as the east side of the Unit 2 turbine enclosure therefore a radioactive spill in the Unit 2 turbine building could enter the ground directly beneath the building. This spill would then enter the groundwater and flow southeast of the groundwater divide approximately 600 feet to site well 4.

2.4.13.3.1 Groundwater Movement

The rate at which the contaminants migrate is no greater than that of the groundwater in which it is carried. Groundwater travel time and direction of flow is controlled by permeability and effective porosity of the bedrock and by the hydraulic gradient of the water table. The average groundwater velocity and the travel time to the river may be calculated using a form of Darcy's Law:

$$\mu = \frac{ki}{n} \qquad \text{(EQ. 2.4-11)}$$

$$t_{gw} = \frac{xn}{ki} \qquad \text{(EQ. 2.4-12)}$$

where:

μ	=	average groundwater velocity (ft/yr)
k	=	permeability (ft/yr)
i	=	hydraulic gradient (ratio)
n	=	effective porosity (ratio)
t_{gw}	=	travel time (yr)
x	=	distance (ft)

A permeability of 390 ft/yr is selected as a conservative estimate of the effective permeability of the underlying materials, based on the 84th percentile of the permeability tests described in Section 2.4.13.2.5. No porosity measurements of site bedrock were performed, but the low permeability indicates that interconnected void spaces are few, resulting in a low effective porosity. An effective porosity of 5% is estimated for the bedrock.

The hydraulic gradient between the radwaste enclosure and the river is calculated as 0.031, based on the hydraulic head difference between the 130 foot elevation potentiometric contour just southwest of the radwaste enclosure (Figure 2.4-15) and the elevation of the river, 105 feet, divided by the distance between the river and the radwaste enclosure, 800 feet, which is assumed to be the flow path.

Using these values for the parameters in the above equations, the computed travel time for groundwater, traveling at an average velocity of 243 ft/yr, to flow from the radwaste enclosure to the river is 3.28 years.

2.4.13.3.2 Analytical Model for Radionuclide Migration

The concentration of contaminants would be reduced during migration in the groundwater by the processes of ion exchange, dispersion, and radioactive decay. The total effect of these processes on the concentrations of the contaminants at the point where they would enter the Schuylkill River was determined by use of an analytical model (Reference 2.4-38). The model accounts for adsorption, one-dimensional longitudinal dispersion, and radioactive decay:

$$C/C_o = \tfrac{1}{2} \exp(-\lambda t) \left[\operatorname{erf}\left(\frac{x - u_i t'}{2\sqrt{D_m t'}} \right) - \operatorname{erf}\left(\frac{x - u_i t}{2\sqrt{D_m t}} \right) \right] \qquad \text{(EQ. 2.4-13)}$$

where:

C	=	final concentration
C_o	=	initial concentration
λ	=	radioactive decay constant = 0.693/radioactive half-life
t	=	time
t'	=	(t-Δt) where Δt is the time necessary for the fluid to flow one pulse width (the length of spill volume)
x	=	distance
u_i	=	average velocity of ion
D_m	=	longitudinal dispersion constant
erf	=	error function: $\text{erf}(x) = \frac{2}{\sqrt{\pi}} \int_0^{x - t^2} e dt$

The waste sludge tank is assumed to be 80% full at the time of the spill. Thus, 10,240 gallons of radioactive effluent is assumed to be released. The spill is considered to enter directly into the groundwater. The volume of bedrock containing the effluent is assumed to be a cube. The length of one side of the cube would be 30 feet, based on an effective porosity of 5%. Of the radionuclides present in the waste sludge tank (Table 11.4-9), Sr-90 and Cs-137 are the most hazardous because of their long half-lives (29 years and 33 years, respectively) and their relatively high concentrations (2.2×10^{-3} μc/ml). Because the concentration of Sr-90 is equal to Cs-137 and Sr-90 is adsorbed less than Cs-137, the movement of Sr-90 is analyzed as the worst case.

2.4.13.3.3 Radionuclide Ion Velocity and Travel Time

The average velocity of Sr-90 in groundwater (U_{ion}) is determined by the relationship (Reference 2.4-39):

$$U_i = \frac{U_w}{1 + \left(\frac{P_b K_d}{n}\right)} \qquad \text{(EQ. 2.4-14)}$$

where:

U_i = average velocity of ion in groundwater (ft/yr)
U_w = average velocity of groundwater (ft/yr)

K_d = distribution coefficient (ion exchange factor)

$$= K_{Ca}^{Sr} \frac{E_x}{C_{Ca}}$$

K_{Ca}^{Sr} = equilibrium constant (ratio)

E_x = cation exchange capacity (mg/gm)

C_{Ca} = calcium (or Ca + Mg) ion concentration in ambient groundwater (meq/ml)

P_b = bulk density of the bedrock (g/ml)

n = porosity (ratio)

Cation exchange capacities were measured for three bedrock samples from the site. The samples were ground into two different size fractions, and cation exchange capacities were determined for the two size fractions according to the Agriculture Handbook No. 60 Method (Reference 2.4-39). Cation exchange capacities for samples including particle sizes ranging from 0.001 mm to 1.39 mm averaged 0.5 meq/g. Samples of particle sizes ranging from 4.01 mm to 38 mm have an average cation exchange capacity of 0.05 meq/g.

A cation exchange capacity of 0.05 meq/g was selected as representative of the materials through which the groundwater moves. The cation exchange capacity of a ground rock sample is inversely related to the particle size. Although no fine particle sizes are included in the 4 mm to 38 mm size fraction, bedrock fractures at the site are partially filled with particle sizes less than 4 mm. Thus, it is probable that exchange capacities are higher than 0.05 meq/g at the site, making the value conservative.

A bulk density of 2.65 g/ml, obtained from the literature (Reference 2.4-40), was selected as representative of the rock at the site.

The equilibrium constant (K_{Ca}^{Sr}) for strontium-calcium systems reported in the literature, ranges between 1.0 and 1.6, depending on the percentage of Sr and Ca of the total cation concentration in solution and the principal clay minerals (Reference 2.4-41). Because reduction in concentration is inversely proportional to the selectivity coefficient, a conservative value of 1.0 was chosen.

Concentrations of dissolved solids in ambient groundwater are given in Table 2.4-19. The highest concentration of Ca in the groundwater samples tested is 178 ppm as $CaC0_3$. This sample has a total hardness of 618 ppm as $CaC0_3$. The concentration of Mg as $CaCo_3$ is equal to the total hardness minus Ca hardness as $CaC0_3$, or 440 ppm. These concentrations are equivalent, as divalent ions, to 0.004 meq/ml Ca^{++} and 0.009 meq/ml Mg^{++}, which is a total of 0.013 meq/ml to compete with Sr-90 for exchange sites.

Using these values for the parameters, and the above described relationships, a distribution coefficient (K_d) of 3.84 ml/gm is determined. According to the calculated velocity of the Sr-90 in groundwater, the ion travels at 1.2 ft/yr and takes 666.6 yrs to travel the 800 feet to the river.

2.4.13.3.4 Dispersivity (Dispersion Constant)

The dispersivity (D_m) can be expressed as a characteristic length. Attempts by researchers have been made to relate the median grain-size (d_{50}) to dispersivity in porous media (Reference 2.4-42).

The jointed and fractured bedrock beneath the site approximates a porous medium over a large representative elementary volume. Thus, the distance between fractures, which in some places is on the order of meters, is a reasonable estimate of dispersivity. However, for conservatism in this analysis, a dispersivity of 4 mm (0.013 ft) was chosen, the grain-size fraction from which the cation exchange capacity was determined.

2.4.13.3.5 Results of Analysis

All of the parameters used for the analysis were selected with a very high degree of conservatism. The parameters are presented in Table 2.4-20. The solution, which accounts for ion adsorption, radioactive decay, and one-dimensional longitudinal dispersion, was obtained for the Sr-90 ion. As discussed previously, the movement of strontium in groundwater is faster than the movement of cesium. Thus, actual cesium concentrations at the river would be much less than those calculated for Sr-90. Other radionuclides in the radwaste tank have short half-lives in comparison to groundwater travel times, and they will decay below MPC levels before reaching the Schuylkill River.

As discussed at the beginning of this section, accidental releases are assumed to spill from the waste sludge tank at the radwaste enclosure directly into the groundwater and flow toward the Schuylkill River. Radionuclides in the contaminated groundwater are considered to be at the same concentration as in the waste sludge tank (Table 11.4-9). The travel time of groundwater from the radwaste enclosure to the river is 3.28 years. Considering the adsorption of the Sr-90 ion, the travel time is 666.6 years. The maximum concentration of Sr-90 and Cs-137 that will arrive at the river is less than 1.34×10^{-10} μCi/ml. This is 10^3 times below MPC concentrations for both Sr-90 and Cs-137. Because of the conservative nature of the input parameters, actual concentrations would probably be lower.

From the analysis, it is evident that should a spill of radioactive effluents from the radwaste enclosure reach the groundwater beneath the LGS site, it would not constitute a health hazard to the potable sources of water in the vicinity. Radionuclides in such a spill would decay sufficiently below MPC concentrations before leaving the site.

For the radioactive spill in the Unit 2 turbine building entering the groundwater, based on a conservative analysis, the only isotope above the 10CFR20 maximum permissible concentration (mpc) released from a feedwater line break is tritium (^3H). The mpc value for tritium (^3H) is 3×10^{-3} μCi/gm. NUREG-0016 indicates that the expected Tritium concentration in the feedwater is 1×10^{-2} uCi/gm. Tritium would not be retarded by absorption into the groundwater and since it has a long half life, radioactive decay would not have an appreciable effect. The equilibrium concentration of tritium at well 4 will be 1.5×10^{-3} μCi/gm (below the 10CFR20 mpc level) one year after the accidental spill.

Using the conservative assumption of a continuous source to model the feedwater line break, concentrations at site well 4 are below the 10CFR20 mpc levels. Ample time exists between the accident and the time that concentrations reach the maximum levels. Therefore, site well 4 can be used following an accident. Furthermore, routine monitoring tests of the wells utilized for drinking

water assures that the continued use of site wells does not compromise the safety of the public or plant employees.

2.4.13.4 Monitoring and Safeguard Requirements

Groundwater levels were measured in borings (observation wells) at various locations (Table 2.4-17) near the spray pond and power block areas. The observation wells were monitored at regular intervals from June 1973 through August 1975, and November 1978 through May 1979 to determine the direction of groundwater movement and the elevation of the water table, and to establish structural design criteria for groundwater effects (Sections 2.4.13.2.4 and 2.4.13.5). These wells were subsequently monitored throughout the remaining plant construction period to determine the effect of plant construction on groundwater movement and level, and to verify/assure the adequacy of the design criteria used for design of safety-related plant structures. The recorded water levels in the wells are shown in the hydrographs in Figure 2.4-18.

Figure 2.4-20 shows the corresponding monthly precipitation, and Table 2.4-21 lists the monthly highest water levels measured at the wells of Figure 2.4-15 during the 36 months of monitoring. Also listed in the table are the estimated maximum water levels and highest levels of record at each well, and the corresponding precipitation during the month of highest level. During the 36 month observation period, the highest observed water level was 4.8 feet below the estimated maximum water level at well P11, and the average difference between the estimated maximum water level and the observed maximum water level is 12 feet.

Water levels continued to be measured monthly in the observation wells between September 1979 and February 1982. Three additional wells were constructed in 1981 (wells P17, P18 and P19) and are shown on Figure 2.4-15. Wells P1 and P4 were destroyed during construction of the spray pond. Monitoring of the wells, up to February 1982, covered a period of 66 months, beginning in June 1973.

The extended monitoring of the observation wells demonstrated that May is an annual period of high water levels. During the period of monitoring the water levels did not exceed the estimated maximum water levels except in well SP22. This occurred in May, 1981 when the water level reached el 247.4' which is 0.1 foot higher than the estimated maximum. This well is located between the cooling towers and the spray pond. A review of the hydrograph of well SP22 (Figure 2.4-18) shows a steady increase in water level beginning in June 1974, when it was installed, to about April 1980. Since April 1980 the level has fluctuated in a manner similar to that of other wells. None of the other observation wells experienced this steady increase in level. They have tended to maintain a steady level, or to slightly decline since installation.

The steady increase in water level at SP22 is attributed to the buildup of a localized groundwater mound that was caused by infiltration of water from construction activities within this area. As construction activities decrease and the surface drains in the area are lined, this localized groundwater mound is expected to slowly dissipate.

This water level monitoring has indicated no changes in the groundwater flow direction. The changes in potentiometric surface throughout major plant construction and site grading/surfacing are within the plant design criteria established in Section 2.4.13.5.

The groundwater monitoring program will be discontinued one year after all major site grading/surfacing is completed because further significant changes in the potentiometric surface are not expected. The network of groundwater observation wells will then be abandoned and sealed.

2.4.13.5 Design Bases for Subsurface Hydrostatic Loading

During the operating life of the plant, the underlying groundwater table is expected to be at approximately the same elevations as shown in Figure 2.4-15. As discussed in Section 2.4.13.2.4.2, fluctuations of the measured levels in most observation wells during the 36 months of monitoring have been less than 12 feet, and the maximum has been 17 feet. The levels indicated on Figure 2.4-15 are near the seasonally high levels of those fluctuations.

Although the period of monitoring covers only 36 months, it is sufficient to establish typical seasonal fluctuations and provide a basis for estimating what may be expected during the operating life of the plant. Thus, the maximum expected groundwater levels are conservatively estimated to be 15 feet above the levels shown in Figure 2.4-15 (these levels were measured in May, when levels are near their maximum). In applying this to the design bases for subsurface hydrostatic loading, a single groundwater level is not applicable to all structures, nor even to individual structures, because of the relatively steep gradient of the water table. It can be seen in Figure 2.4-15 that, from the northeast corner of the turbine building to the southwest corner of the radwaste enclosure, the water table drops relatively uniformly more than 50 feet in elevation. Therefore, for the design bases, two maximum expected water levels are provided for each principal structure: the highest (beneath the northeast corner) and the lowest (beneath the southwest corner).

The maximum expected water levels are:

	Maximum expected water table el (ft)	
Structure	Northeast corner	Southwest corner
Turbine enclosure	205	175
Reactor enclosure	195	175
Radwaste enclosure	180	160

Groundwater contours prepared from water levels measured on May 31, 1988 indicate that the above water levels are conservative. These contours are shown in Figure 2.4-15.

2.4.14 TECHNICAL SPECIFICATION AND EMERGENCY OPERATION REQUIREMENTS

The possibility of adverse hydrologically related events at the LGS site is precluded by the configuration of the site topography.

Consequently, there are no emergency protective measures designed to minimize the water associated impact of adverse hydrologically related events on safety-related facilities. In addition, there is no need for technical specifications for plant shutdown required by accidents resulting from these events. Further discussion is in Sections 2.4.1.1 and 2.4.2.2.

The UHS, as described in Sections 2.4.8 and 9.2.6, has been designed with appropriate consideration to adverse hydrologically related events.

(1) These data were compiled from Reference 2.4-12 and from a tabulation furnished by the Dam Safety Section, Division of Dams and Encroachments, Department of Environmental Resources, Commonwealth of Pennsylvania, P.O. Box 2063, Harrisburg, PA 17120, dated March 1, 1977.

Table 2.4-3

DAM FAILURE INVESTIGATION:
CHARACTERISTICS OF MAJOR UPSTREAM DAMS

CHARACTERISTICS	ONTELAUNEE	MAIDEN CREEK	BLUE MARSH
Date constructed	1926-34	Authorized[2]	1979
Distance upstream LGS (mi)	37	42	35
Stream name	Maiden Creek	Maiden Creek	Tulpehocken
el at base (ft)	253	302	236
el spillway crest (ft)	294	394	307
el top dam (ft)	305	412	332
PMF - peak inflow (cfs)	No Est.	118,000	128,600
PMF - peak outflow (cfs)	No Est.	92,000	74,800
SPF - peak inflow (cfs)	No Est.	49,000	54,300
SPF - peak outflow (cfs)	No Est.	17,500	30,300
SPF - max water surface (ft)	No Est.	397.5	317.5
Volume below spillway (acre-ft)	11,900	114,000	50,000
Spillway capacity (cfs)	41,000	92,000	74,000
Type of dam	Earth fill and masonry gravity spillway	Earth and rock fill	Random fill with impervious core
Assumed water surface elevation at time of failure[1] (ft)	304.2	397.5	317.5
Volume at time of failure (acre-ft)	29,000	130,000	76,700

(1) Used in failure study. Equivalent to water surface required to pass floods greater than or equal to the standard project flood

(2) Construction indefinitely deferred

Table 2.4-4

DOMESTIC WATER USERS ON SCHUYLKILL RIVER

DOWNSTREAM OF LGS SITE

No.	Water User[1]	1971[2] Use	ENTITLEMENT				
			Total	Non-Comsumptive	Comsumptive	Consumptive as a Percentage of Total	Approximate Location (River mi.)[3]
1.	Philadelphia Water Dept., Belmont Water Treatment Plant	5,145.250	7,843.200	7,451.040	392.160	5	10.21 (Belmont)
2.	Philadelphia Water Dept., Queen Lane Water Treatment Plant	(4)	(4)	(4)	(4)	4)	12.61 (Queen Lane)
3.	Keystone Water Co., Norristown Dist.	258.333	510.720	459.648	51.072	10	24.30
4.	Philadelphia Suburban Water Co.	11.650	608.000	528.960	79.040	13	34.40
5.	Phoenixville Borough	144.827	212.800	191.520	21.280	10	35.50
6.	Citizens Utility Home Water Co.	35.649	60.800	54.720	6.080	10	45.70

(1) See Figure 2.4-2 for locations of water users.
(2) Water use is given in 10^6 gallons per month (1 month = 30.4 days).
(3) Measured from the confluence of the Schuylkill River with the Delaware River. Source: DRBC, Trenton N.J., and EPA Region III, Philadelphia, PA.
(4) Data included with Belmont Water Treatment Plant.

Table 2.4-5

INDUSTRIAL WATER USERS ON SCHUYLKILL RIVER
DOWNSTREAM OF LGS SITE[4]

No.	Water User[1]	1971[2] Use	ENTITLEMENT Total	Non-Comsumptive	Comsumptive	Consumptive as a Percentage of Total	River Distance From Station (mi.)[3]

(1) The locations are shown on Figure 2.4-8.

Table 2.4-10

OBSERVED AND ESTIMATED WATER SURFACE ELEVATIONS OF SCHUYLKILL RIVER AT LGS SITE

OCCURRENCE	DISCHARGE (cfs)	WATER SURFACE ELEVATION AT SITE (ft)
Observed 12/5/69	566	105.3
Observed 12/18/69	1,610	106.5
Computed Floods		
Average Annual (Pottstown Records)	21,000	117.4
Average Annual (WSP 1672)	28,000	119.5
Maximum Observed Before 1972	53,900	125.7
100 Year (WSP 1672)	99,000	134.8
Additional Discharge for Rating Curve	200,000	145.0
Additional Discharge for Rating Curve	356,000	158.0

Table 2.4-11

DERIVED VALUES OF MANNING'S (n) FOR SCHUYLKILL RIVER MAIN CHANNEL

LOCATION	WATER LEVEL		MANNING'S (n)	APPROXIMATE REACH LENGTHS (mi)
	Observed	Computed		
Pottstown Hanover St. Bridge	135.84	135.8	0.028	1
S. Pottstown Madison St. Bridge	133.55	133.6	0.036	6
Linfield Highway Bridge	120.03	120.0	0.048	4.7
Spring City Highway Bridge	105.97	106.0[1]	-	-

[1] Assigned starting elevation for computations

Table 2.4-12

COMPUTATION OF CONVERGENCE IN BACKWATER STUDY

DISCHARGE (cfs)	STARTING WATER SURFACE -12½%	STARTING WATER SURFACE +12½%[1]	COMPUTED WATER SURFACE AT SITE -12½%	COMPUTED WATER SURFACE AT SITE +12½%	DIFF (ft)
21,000	95.8	97.6	117.4	117.4	-
28,000	97.8	100.0	119.5	119.5	-
53,900	103.9	106.8	125.7	125.7	-
99,000	111.4	115.3	134.7	134.9	0.2
200,000	123.7	128.9	144.8	145.7	0.9
356,000	137.8	144.5	157.3	159.2	1.9

[1] +12½% refers to assumed channel conveyance $\Sigma\left(\frac{AR^{2/3}}{n}\right)$ compared with the computed requirement at the downstream end of study reach.

SP23[i]	266.9	255.0	255.0	10/74	2.51

[a] Determined by adding 15 feet to May 1979 measured level.
[b] Measurements as of February 1982.
[c] June 1973 to August 1975, November 1978, January 1979 to August 1979.
[d] Well destroyed.
[e] Destroyed prior to May 1979.
[f] Abandoned in June 1984.
[g] Abandoned in December 1987.
[h] Abandoned in April 1988.
[i] Monitoring to be discontinued one year after completion of all major site grading/surfacing.

Table 2.4-22

PARAMETERS USED IN RATIONAL FORMULA AND KIRPICH'S FORMULA

SUBAREA	Area A (acres)	Slope S	Length L (ft)	Time of Concentration Tc		Rainfall Intensity I (in/hr)	Peak Flow Rate Q (cfs)
				Calculated (min)	Adopted (min)		
DA-1	17.2	*	*	*	*	*	251
DA-2	25.0	0.00133	600	13.8	10	24.78	620
DA-3	4.5	0.0398	830	4.8	5	32.16	151
DA-4	20.8	0.019	1200	8.4	8.4	26.37	550
DA-5	14.9	0.0033	900	13.3	10	24.78	369
DA-6	11.6	0.00222	900	15.4	15	20.88	242
CP-1	20.0	0.00133	320	8.4	8.4	26.37	530
CP-2	25.0	0.00133	600	13.8	10	24.78	620
CP-3	12.8	0.0033	900	13.3	10	24.78	446
CP-4	35.6	0.0024	1250	19.2	20.0	18.27	555
CP-5	17.2	**	**	**	**	**	194

Rational Formula Q = CIA

Kirpich's Formula Tc = 0.0078 (L/S) ^ 0.77

* Rational method was not used for subarea DA-1.

** Rational method was not used for collection point CP-5, flow is maximum 30 minute mean inflow to spray pond.

2.5 GEOLOGY AND SEISMOLOGY

In accordance with the criteria provided in 10CFR100 Appendix A, "Seismic and Geologic Siting Criteria for Nuclear Power Plants", and Regulatory Guide 1.70 (Rev 3), this section describes and evaluates the geologic and seismologic conditions for the region around LGS. Foundation conditions are evaluated, and the foundation design is described. The seismic history of the region is examined, and the earthquake design criteria are described.

This section presents the results of the evaluation of the regional and site geology and demonstrates that the evaluation is in sufficient detail to ensure the safe design and operation of the nuclear power facility. Results of the literature study, field studies, foundation exploration, and laboratory test programs are presented. Static and dynamic properties of the foundation materials are described, and design criteria are outlined. Groundwater factors affecting plant construction and operation are discussed. (Groundwater conditions are presented in detail in Section 2.4.13).

Investigations were performed to define the site foundation conditions, and regional and site geologic, geohydrologic, and seismological conditions. These investigations determined the characteristics of the foundation materials and their suitability for supporting the structures, the depth and configuration of the groundwater table, and the characteristic effects of the soil and rock materials on the migration of radioactive solutions, should such solutions come in contact with them. Investigations were also performed to evaluate tectonics, faulting, and seismicity of the area, so that appropriate parameters for seismic design could be selected. Results of fault investigations are discussed in Section 2.5.3 and are presented in detail in a report prepared by Dames and Moore in 1974 (Reference 2.5-1). Site exploration is discussed in detail in Section 2.5.4.

LGS is approximately 3 miles southeast of Pottstown, Pennsylvania, adjacent to the Schuylkill River. It is in the Triassic Lowland section of the Piedmont physiographic province. The area is within the Newark-Gettysburg Basin, which is underlain by red sandstones, shales and siltstones of the Triassic Newark Group. These sedimentary basin deposits are gently tilted and warped, and are cut by diabase dikes and sills and by minor faulting.

Faulting has occurred in association with the major episodes of deformation in the region, and some faulting of the Triassic sediments occurred during Triassic and Jurassic time, over 140 million years ago. Some minor Jura-Triassic faults occur near the site; detailed studies carried out by the licensee show that they are not significant to the construction and operation of the plant.

Earthquake activity in historic time within 200 miles of the site has been moderate. Zones of major earthquakes in the eastern United States are far away, and have not had an appreciable effect at the site. Evaluation of tectonic structures and the historical seismic record indicate a design intensity of VII (Modified Mercalli Scale) is adequately conservative for the site. Intensity VII corresponds to a peak ground acceleration of 0.13 g; for additional conservatism, 0.15 g has been adopted for the SSE.

The principal plant structures are founded on competent bedrock, about 100 feet above the river. Bedrock at the site, which consists of Triassic siltstone, sandstone, and shale, is moderately to closely jointed, and joints are generally vertical to nearly vertical. Two major joint systems are prevalent, striking N 20° to 50° E, and N 50° to 60° W. The bedding strikes approximately east-west and dips 8° to 20° to the north. P-wave velocities in rock in the area of the major plant structures average about 12,000 ft/sec.

Minor faults, inactive since mid-Mesozoic time, occur west and south of the construction area. Fracture zones with a few inches of offset have been encountered in the excavation; however, they can be attributed to Mesozoic events and are not significant to plant structures. Minor clay seams, which occur locally along bedding, and the fracture zones are treated as required where encountered in the foundation excavations.

Soils at the site, predominantly clayey silts, are residual and range in thickness from zero to approximately 40 feet.

The natural groundwater at the site occurs in joints and along bedding. The emergency spray pond, excavated partly in soil and partly in rock, is lined to preclude excess seepage. The pond will not significantly affect groundwater levels beneath the plant structure.

2.5.1 BASIC GEOLOGIC AND SEISMIC DATA

2.5.1.1 Regional Geology

2.5.1.1.1 Regional Physiography and Geomorphology

The site is located in the Triassic Lowland section of the Piedmont physiographic province, as shown on Figure 2.5-1. The Piedmont is bounded on the southeast by the Coastal Plain and on the northwest by a projection of the New England Upland (the Reading Prong) and by the Valley and Ridge province (References 2.5-2 and 2.5-3).

The Valley and Ridge province is characterized by folded Paleozoic sedimentary rocks, which form a series of generally northeast-southwest trending parallel ridges. The Reading Prong of the New England Upland is underlain by Precambrian crystalline rocks. The Coastal Plain is underlain by sedimentary formations of Cretaceous and Tertiary ages.

The northeast-southwest trending Piedmont province is an eroded plateau of low relief and rolling topography. The surface of the plateau slopes gently to the southeast. The Piedmont is divided into an upland and a lowland section. The upland section is underlain by metamorphosed sedimentary and crystalline rocks of Paleozoic and Precambrian age (Reference 2.5-4). The rocks are relatively resistant to erosion, and they support an irregular, hilly surface. The higher hills are capped by Cambrian quartzites and Precambrian crystalline rocks, while broad valleys characterize areas underlain by limestone and calcareous shales. The less rugged lowland section, in which LGS is located, is north and west of the Piedmont uplands and is formed largely on shales and sandstones of Triassic-age. Ridges in the Triassic Lowland trend northeast-southwest along the strike of the more resistant bedrock formations. Higher and more rugged terrain exists where these formations have been intruded by diabase dikes and sills (Reference 2.5-4).

2.5.1.1.2 Regional Stratigraphy

In the region surrounding the site, the rocks exposed at the surface form lithologic belts that correspond to the physiographic provinces and sections. These rocks include crystalline igneous materials, metamorphic sequences, and sedimentary formations. The distribution of the geologic units of the region surrounding the site is shown on Figure 2.5-2. The stratigraphic relationships and thickness of the various formations are shown on Figures 2.5-3 and 2.5-4.

The oldest rocks of the region are of Precambrian age. They occur to the northwest of the site in the Reading Prong, and to the south and southwest in the upland section of the Piedmont and the Blue Ridge. These rocks are highly metamorphosed and faulted and have been intruded by a wide range of igneous materials. The Precambrian rocks, as shown on Figure 2.5-2, have been grouped into a single unit. The principal formations within this unit include the Baltimore and Pickering gneiss, and the Franklin limestone and marble. Other Precambrian rocks include granite gneiss and hornblende gneiss which underlie large areas of the Reading Prong. Gabbroic gneiss and gabbro in the upland section of the Piedmont are also of Precambrian age.

The Glenarm Series is a group of metamorphosed sedimentary rocks. In the region around the site, the Glenarm Series is represented primarily by the Wissahickon Formation which consists of schist and gneiss. In early geologic publications the Glenarm Series was identified as Precambrian because of the high degree of metamorphism of these rocks and their intrusion by igneous materials unknown in recognized Paleozoic formations. However, more recent studies (Reference 2.5-5) which include radiometric age determinations, show the Glenarm Series must be younger than 1100 million years (age of the basement gneiss) and older than 550 million years, the age of intrusives that cut the Wissahickon Formation. The Glenarm Series is therefore either late Precambrian or early Cambrian.

Paleozoic sedimentary rocks are exposed in the Piedmont upland, the Reading Prong, the Valley and Ridge, and the Appalachian Plateau provinces within the region. The occurrence of Paleozoic rocks is shown on Figure 2.5-2. Rocks of early Cambrian age consist primarily of quartzites, while the higher Cambrian and Ordovician formations are characterized by shales, limestones, and dolomites. The quartzites are prominent ridge formers in the Piedmont Upland and occur as outliers on the Precambrian rocks of the Reading Prong. The Upper Cambrian and Ordovician calcareous formations constitute what is known as the valley limestones and occur mainly in the lower-lying areas.

Sandstone, conglomerate, and shale with some limestone begin the Silurian sequence, giving way to carbonate formations in the upper units. The Devonian consists of shale and sandstone, with some limestone in the Middle and Lower Devonian.

The Mississippian rocks are divided into the Pocono Group, which is predominantly conglomerate and sandstone with some shale, and the Mauch Chunk Formation, typically consisting of red shales, but also consisting of sandstone and some limestone.

Sandstone and conglomerate are the predominant rock types of the Pottsville Group, oldest of the Pennsylvanian units in the region. Some coal is present in the Pottsville group, but most of the minable coal in the region occurs in the overlying units, which consist of cyclic deposits of shale, clay, coal, limestone, and sandstone. Similar deposits extend through the Permian; in some areas the deposition was continuous, with no clearly defined boundary between Pennsylvanian and Permian time.

Rocks of Triassic-age are contained in basins that parallel the northeast-southwest structural trend of the region. The Triassic basins of eastern North America occur from Canada to the Carolinas. The site is located in one of these Triassic basins, the Newark-Gettysburg Basin, which extends from the Hudson River across north-central New Jersey, through a portion of southeastern Pennsylvania, and into Maryland (Figure 2.5-38). The basin reaches a maximum width of 32 miles in Bucks County, Pennsylvania, near the Delaware River.

The Triassic rocks characteristically occur as red shales and sandstones, which are locally interbedded with basalt flows and intruded by diabase dikes and sills. The rocks of the Triassic basins have been designated by various authors as the Newark Group.

In the northern (Newark) portion of the Newark-Gettysburg Basin, where the site is located, the Newark Group is divided from oldest to youngest into the Stockton arkosic sandstone, the Lockatong gray shale and argillite, and the Brunswick red shale and sandstone. Of these three units, the Stockton is the only unit that can be classified as a true stratigraphic formation (Reference 2.5-6). The other sedimentary units of this group were deposited more or less contemporaneously, and they interfinger with each other. Since no definite three-dimensional boundaries can be placed on the Lockatong and Brunswick, they have been designated as lithofacies related to the Hammer Creek lithofacies which occurs west of the Schuylkill River.

The outcrop of the Stock Formation is found in a 4 mile wide belt along the southeastern border of the Newark Basin. The outcrop of the formation narrows, and ultimately pinches out to the west, in southern Berks County, Pennsylvania. Another body of the Stock Formation occurs between Center Bridge and Lumberville, along the Delaware River, having been brought to the surface by the Furlong and Flemington faults. The formation extends along the strike about 12 miles southwest of the river, where it is cut off by the Chalfont fault. The rocks of the Stock Formation consist of beds of coarse conglomerate at the bottom, and they range from coarse-to-fine arkosic sandstones to fine-grained sandstones and shales. The source of the sediments of the Stock Formation lay to the south of its present outcrop area. The formation is estimated to be at least 3000 feet thick (Figure 2.5-4). It unconformably overlies Precambrian and Paleozoic rocks to the south, at the margin of the basin. The formation is overlain conformably from east to west successively by the Lockatong, the Brunswick, and, west of the Schuylkill River, the Hammer Creek lithofacies.

The remaining sedimentary rocks of the Newark Group fill the basin from the upper contact of the Stockton Formation to the northern border of the basin. A great alluvial fan, formed by a large Triassic-age river that flowed from the north into the basin, provided the source of these sediments. The sediments of this alluvial fan were distributed to the northeast into the Newark Basin, and to the southwest into the Gettysburg Basin. The Hammer Creek conglomerates and sandstones in southern Berks County and in the northern portions of Lancaster and Chester Counties are the remnants of the main body of this great alluvial fan. The stratigraphic thickness of the Hammer Creek lithofacies is about 15,000 feet (Reference 2.5-6). This thickness is about the same as, or greater than, the combined thickness of the Lockatong and Brunswick lithofacies that occur in the site area.

The main body of the Lockatong lithofacies overlies the Stockton Formation in a belt with a maximum width of four miles. About 15 miles east of the site, this belt has been offset by the Chalfont fault. The Lockatong thins to the west. It passes about five miles to the south of the site, where the outcrop is only one-half mile wide. North of the main body of the Lockatong, tongues of this unit are interbedded with strata of the Brunswick lithofacies. The uppermost continuous member of the Lockatong pinches out approximately three miles east of the site. The next lower, the Sanatoga member, passes just north of the site and becomes discontinuous.

The Lockatong lithofacies consist of gray shales and massive mudstone; it has been classified as an argillite although it is not a low rank metamorphic facies. The rock may be calcareous, may contain carbonaceous horizons, and often contains mud cracks. The Lockatong was deposited in a

shallow lake environment. The maximum stratigraphic thickness of this formation is about 3800 feet (Reference 2.5-6).

The Brunswick lithofacies are more closely related to the Hammer Creek, which occurs west of the Schuylkill River, than to the Lockatong. The Brunswick represents the depositional extension of a great alluvial fan. Thus, the western margins of this formation contain more sand members, whereas to the south and east the strata are typically more shaly. The main body of the Brunswick lithofacies extends from the northern border of the basin to its interfingering contact with the Lockatong to the south. To the west of the Schuylkill River, the Brunswick interfingers with the conglomerates and sandstones of the Hammer Creek. The site is located about five miles east of the interfingering contact of the Brunswick and Hammer Creek.

The Brunswick consists of relatively soft red shales, siltstones, and sandstones. The cementing agent is largely iron oxide derived from the hematite contained in the sediments. In areas where the Brunswick approaches the tongues or the main body of the Lockatong, it is sandier and harder. The stratigraphic thickness of the Brunswick strata is about 7000 feet (Reference 2.5-6).

Along the north border of the basin, the upper Brunswick strata locally consists of coarse fanglomerates derived from minor streams pouring into the basin from the north. As shown on Figure 2.5-2 these broader fanglomerates, as well as the basal conglomerate of the Stockton Formation, appear under the same lithologic symbol as the Hammer Creek.

Two types of igneous rocks occur within the Newark Basin. The majority of these are diabase dikes and sills, which have intruded into the sedimentary sequence. A minor basalt flow has been mapped in the area southwest of Reading, Pennsylvania. Both the basalt flow and the intrusives are of Triassic-age. A large sill to the west of the site was intruded along bedding-plane surfaces in the sedimentary rocks, and locally has "baked" the sediments in a zone up to 500 feet wide. Numerous dikes of Triassic-age cut the basin rocks, as well as the Precambrian and Paleozoic rocks surrounding the basin. The most prominent of these dikes, the Downington Dike, extends from 11 miles southwest of Downingtown, Pennsylvania, through Sanatoga Station, just north of the site, and continues about three miles to the northeast. It occupies a fracture zone, and in places it enters zones of weakness provided by pre-existing faults. The major mineral constituents of the Triassic diabase are augite and labradorite. The diabase intrusions postdate Triassic sedimentation and tectonics, as discussed in the following sections on structural geology and geologic history. Radiometric ages obtained during geologic investigations for LGS (see section 3.2.3 and 3.7.1 of Reference 2.5-1) indicate some of the diabase dikes near the site are probably of Jurassic-age.

Cretaceous sedimentary deposits occur in the Coastal Plain province. These sediments consist of clays and sands, which are moderately to poorly consolidated.

Deposits of Cenozoic age consist of Tertiary sediments and terrace deposits, Quaternary gravels, sandy gravels, glacial drift, and Recent alluvium. Tertiary and Quaternary deposits occur in the Coastal Plain province.

Glacial deposits of Pleistocene age cover large areas of the bedrock surface north of the site, but do not extend into the area adjacent to the site.

2.5.1.1.3 Regional Geologic Structure

The dominant structural feature in the region surrounding the site is the Appalachian Orogenic Belt. This belt is marked by northeast-southwest orientation of the axes and alignment of most of the structural features and stratigraphic contacts. The major structural features of the region are shown on Figure 2.5-5. Figure 2.5-38 is a compilation from the recent literature (References 2.5-10, 2.5-60, 2.5-17, 2.5-112, and 2.5-119) showing faults mapped within and in the vicinity of the Newark-Gettysburg Basin. Major faults and structures within 5 miles of the site are shown in more detail on Figure 2.5-6. A Bouguer gravity anomaly map of the region is shown on Figure 2.5-7, and aeromagnetic intensities for the Limerick-Pottstown area are shown on Figure 2.5-8.

The Paleozoic and Precambrian rocks of the Piedmont Uplands to the south and west of the site, and of the Reading Prong and the Great Valley section to the north, are structurally complex. These strata are intensely folded and faulted. The axes of foliation, and of the major folds involving these rocks, generally strike to the northeast. Precambrian and Lower Paleozoic rocks south of the site are strongly metamorphosed, and they exhibit tightly folded structures superimposed on broader synclinoria and anticlinoria. The Paleozoics to the west, and in particular those to the north of the site, exhibit recumbent folds, with basal truncation or decollement by thrust faults.

The majority of the faults that displace Precambrian and Paleozoic strata are thrust faults. The thrust sheets are relatively thin, and they generally exhibit movement to the northwest. The north-south trending faults at their flanks are tear faults. These faults do not involve Mesozoic or Cenozoic strata. To the west of the site, in the Piedmont Uplands, some of the major thrust faults are transected by Triassic-age diabase dikes that show no displacement. Similar relationships of Triassic dikes crossing Paleozoic faults are found in the Readin Prong area, north of the site. The last movement along these faults probably occurred over 200 million years ago, and certainly no later than 140 million years ago, based on the absence of displacement of the Triassic diabase dikes.

A major postulated fault system of Paleozoic age in the region is the Martic Line of thrust faulting. The Martic Line was introduced in earlier geologic publications (Reference 2.5-7), primarily to account for the fact that the Glenarm Series (thought to be of Precambrian age) overlies sedimentary rocks of known lower Paleozoic age in southern Lancaster County, Pennsylvania. The fault was subsequently drawn for hundreds of miles along the Appalachians as the boundary of the inner and outer Piedmont. Cloos and Hietanen (Reference 2.5-8) prove imbricate thrusting in the type area. Wise (Reference 2.5-9) concluded that the Martic Line is a "complex polygenetic feature made up of distinct segments...." He indicates that the Martic Line is a Paleozoic feature, which may be largely a facies boundary marking the edge of a deeply subsided basin to the southeast. Along this basin margin there has been imbricate thrusting, regional metamorphism, brittle movement of large basement blocks, widespread development of kink bands and joints, and local intense folding. Wise states: "The final event was the injection of basaltic dikes of probable Triassic-age with north to northeast trend across the region."

The geologic map of Pennsylvania (References 2.5-10 and 2.5-60) and the tectonic map of the central and southern Appalachians (References 2.5-11) show Triassic dikes crossing the Martic Line without offset, indicating that no movement has occurred in this zone for at least 140 million years.

The major recognized Paleozoic faults in the region occur to the south and west in the Piedmont Uplands, and to the north in the Reading Prong and Great Valley sections. The Huntington

Valley-Cream Valley and Rosemont faults occur in the Piedmont Uplands, 15 miles south of the site. The major structural features in the Piedmont Uplands west of the site are, from south to north, the Mine Ridge anticline, Brandywine Manor fault, Welch Mountain anticline, and the Elverson thrust fault (Reference 2.5-12). Of these features, the nearest to the site is the Brandywine Manor fault, which lies nine miles to the southwest. None of the major Paleozoic faults has a mapped extension to the east of the Triassic border or into the Newark-Gettysburg Basin.

To the north in the Reading Prong and Great Valley sections, nappe structures exhibited by the strata greatly complicate their interpretation. An interpretation presented for the Valley and Ridge province to the northwest (Reference 2.5-13) is that the Paleozoic rocks have been transported westward along nonoutcropping, low angle, detachment thrust faults. The group of rocks observed in any one locality represents an allochthon, entirely unrelated stratigraphically to the surrounding rocks. This hypothesis is supported by deep bore hole and geophysical data, which indicate that the basement below the relatively thin skin of folded and faulted Paleozoic sedimentary rocks does not reflect connected or similar structures (References 2.5-60, 2.5-30, 2.5-87, and 2.5-89).

Over the past several years additional deep seismic reflection studies have suggested that these various thrust faults conveying the allochthonous slices westward are splays of a deeper, regionally extensive detachment surface or decollement which may be a fundamental tectonic structure of the central and southern Appalachians, extending eastward beneath the Piedmont province and possibly continuing beneath the Coastal Plain and Atlantic shelf (References 2.5-60, 2.5-75, 2.5-76, 2.5-77, 2.5-78, 2.5-88, 2.5-97, 2.5-64, 2.5-94, 2.5-68, 2.5-69, 2.5-121, 2.5-122, and 2.5-82). The seismic profiles from Pennsylvania, Virginia, eastern Tennessee, South Carolina, and Georgia show laterally continuous subhorizontal reflectors ranging in depth from less than 6 km in the Valley and Ridge to more than 11 km beneath the Coastal Plain. Cook (Reference 2.5-79) and Harris and Bayer (Reference 2.5-88) interpret these subsurface reflectors to be elements of a regionally extensive decollement underlain by relatively undeformed, unmetamorphosed, layered Paleozoic sedimentary rocks. The subhorizontal east-sloping decollement presumably accommodated crustal foreshortening associated with continental plate convergence in late Paleozoic time when metamorphic Precambrian and early Paleozoic rocks of the Blue Ridge and Piedmont were thrust to the west and northwest over relatively unmetamorphosed sedimentary rocks of the Valley and Ridge.

The eastern extent of the decollement is still poorly known. The seismic reflection profiles confirm the presence of a decollement from the Valley and Ridge to at least as far as the inner (western) Piedmont where the subsurface reflectors thicken, become discontinuous, and dip steeply to the southeast (References 2.5-75, 2.5-76, 2.5-77, and 2.5-78). In one interpretation, the steeply dipping reflectors mark the root zone of the decollement beneath the outer Piedmont (References 2.5-92, 2.5-93, and 2.5-94). Reflections from the coastal plain and continental shelf, however, suggest that the decollement may extend southeastward to the coast (References 2.5-78, 2.5-88, 2.5-68, 2.5-69, and 2.5-122). In the second interpretation, the steeply dipping reflectors are interpreted as sedimentary deltaic deposits accumulating on the shelf of an autochthonous proto-North American continental margin (Reference 2.5-78). Cook et al (Reference 2.5-78) suggest that the decollement may be rooted offshore where a complex structural configuration is evident on the seismic profiles.

A recent reinterpretation (Reference 2.5-97) of these seismic reflection profiles supports the interpretation by Hatcher and his coworkers (References 2.5-90, 2.5-91, 2.5-92, 2.5-93, and 2.5-94). Based on palinspastic restorations of the crust, they suggest that the decollement is probably rooted beneath the Kings Mountain belt of the Piedmont province. Subhorizontal reflectors farther to the southeast described by Cook et al (Reference 2.5-78) as a decollement

probably represent subhorizontal ultramylonites or layered intrusions related to the internal structure of an accreted island arc (Reference 2.5-97).

Age constraints for displacement on the decollement are not well established. Many investigators believe that the principal displacement occurred during the Alleghenian orogeny and that it is responsible for the thin-skinned fold and thrust deformation of the Valley and Ridge Province, emplacement of the crystalline Blue Ridge and Piedmont rocks as thin, allochthonous sheets, and the extensive metamorphism and plutonism along the eastern margin of the Appalachians (References 2.5-92, 2.5-94, 2.5-64, and 2.5-93). Although principal displacement probably did occur during the Alleghenian, Harris and Bayer (Reference 2.5-88) suggest that the decollement is also long-lived and may have grown intermittently from the late Precambrian to the late Paleozoic. Based on radiometric age dates, paleomagnetic data and geologic field relations, however, Ellwood et al (Reference 2.5-81) believe that a 350 million year old intrusive complex was emplaced through the decollement after major thrusting. The 350 million year old age for the intrusion would thus provide a minimum age for thrusting.

A second conspicuous feature indicated by both deep and shallow seismic reflection profiles across the Appalachian orogen is the presence of upwardly concave reflectors beneath the Piedmont and Coastal Plain. Most of the reflectors are listric into the suspected decollement and may represent late Paleozoic thrust faults, Mesozoic listric normal faults, or both (Reference 2.5-78). In this interpretation, the Brevard zone is a splay off the main decollement (Reference 2.5-77). There is some uncertainty as to whether, and to what extent, late Mesozoic crustal rifting was accommodated by reactivation of these listric faults as normal basin faults. It seems reasonable to presume that at least some Mesozoic basin faults are deep-seated, as evidenced by basaltic magmatic activity, in which case they would displace and disrupt the Paleozoic decollement surface.

A postulated major east-west fault zone, named the Cornwall-Kelvin wrench fault, has been inferred by Drake and Woodward (Reference 2.5-14) on the basis of subsea topography and geophysical surveys and has been postulated to extend through the Triassic Lowland of southeastern Pennsylvania. However, there is neither geological nor geophysical evidence of a westward continuation of this fault into the continent, either at the surface or at depth (Reference 2.5-15).

The strata of the Newark Group, unlike those of the older Paleozoic rocks, are only locally and gently folded. In general, the rocks dip between 5° and 20° to the north and northwest. The Brunswick lithofacies and the upper tongues of the Lockatong are involved in broad cross-folded structures north and east of the site. The Triassic strata are characteristically faulted by normal strike and transverse faults, some of which show considerable lateral displacement. Unlike most of the Paleozoic thrusts, the Triassic faults are high angle gravity faults, with the downthrown side usually to the south.

The faults of Triassic-age have generally not displaced the younger Cretaceous and Cenozoic strata in the Coastal Plain to the southeast. According to a recent compilation (Reference 2.5-134, plate 1; Reference 2.5-135, figure 3), the only instance of a fault which offsets coastal plain strata overlying Triassic sediments within 200 miles of the site is the inferred Brandywine fault zone located 9 miles southeast of Washington, D.C., about 140 miles from the site. Evidence for both the faulting and the presence of Triassic sediments at depth is entirely from subsurface data, including seismic reflection, drill holes and geophysical logging, as reported by Jacobeen (Reference 2.5-98). These data indicate that two northeast striking, southeast dipping en echelon reverse faults offset the top of the Lower Cretaceous Arundel Formation a maximum of about 250 feet. The relation of this faulting to Triassic basin structure, however, is uncertain because both

Triassic sediments and granitic rocks were penetrated by deep drill holes on both sides of the fault zone. (It should be noted that Jacobeen (Reference 2.5-98) states he believes the faults to be unrelated to Mesozoic structures.) Up section, the drill hole data confirm that the Paleocene-Eocene Aquia Formation is monoclinally folded without being offset by faulting. This folding occurred prior to Oligocene erosion and only minor flexuring is displayed in overlying Miocene strata (Reference 2.5-98). Jacobeen concludes that there is no evidence for post-Miocene movement on the Brandywine fault zone.

Mixon and Newell (References 2.5-105, 2.5-106, and 2.5-107) suggest that the Brandywine fault zone may be an extension of faults bordering the Richmond Triassic basin in Virginia, 60 miles farther to the southwest, based on the alignment of both fault zones with a linear gravity anomaly that extends between the two locations. However, evidence to associate the Richmond basin faults with Cretaceous or younger faulting apparently could not be found because neither Mixon and Newell (References 2.5-105, 2.5-106, and 2.5-107) nor Wentworth and Mergner-Keefer (References 2.5-134 and 2.5-135) indicate any offset of coastal plain strata where these strata overlap the Richmond basin faults.

Offshore, reported instances of significant Cenozoic displacements within 200 miles of the site are rare. Hutchinson and Grow (Reference 2.5-96) report offset of the basement-Cretaceous contact of up to 280 feet on a 20 mile long, north-northeast trending fault (New York Bight fault) off the northern New Jersey coast, about 100 miles east of the site. However, evidence for post-Cretaceous offset on the fault is highly ambiguous, due to poor seismic resolution in the shallow section, lack of stratigraphic control, and the upward-decreasing amount of possible offset. Hutchinson and Grow (Reference 2.5-96) state that their data are not sufficient to determine the dip of the fault or whether it is reverse or normal. They conclude the data show "potential offset" in the Tertiary and possible "warpage" of strata they infer to be Quaternary in age.

Another fault zone about 15 miles west of, and parallel to, the Brandywine has been named the Stafford fault zone (References 2.5-105, 2.5-106, and 2.5-107). Surface exposures of the Stafford fault zone show that coastal plain strata are offset along high angle basement faults. Although the Stafford fault zone is not associated with Triassic sediments and has no demonstrable relation to any Triassic basin structure, the relative proximity, similar trend, and presence of reverse sense of displacement in both the Brandywine and the Stafford fault zones suggest they may be structurally related.

The Stafford fault zone consists of four subparallel, en echelon basement faults which offset coastal plain strata. Each fault has a maximum throw of about 150 feet. Two of the faults display reverse throw on high angle, west dipping planes (down-to-coast movement).

On one of these faults (the Fall Hill fault) an exposure near the Stafford-Spotsylvania county line shows a high angle fault contact between basement gneiss and Cretaceous coastal plain sediments. The gneiss projects about 14 inches upward into overlying Plio-Pleistocene fluvial gravels, consistent with reactivated reverse displacement along the fault-plane (Reference 2.5-107, figure 7). On the other hand, such relationships are also consistent with features produced by normal stream erosion, particularly in view of the great contrast in erodability between the gneiss and the Cretaceous sands.

A detailed investigation of the Stafford fault zone, including an extensive drilling and trenching program, was conducted by Dames and Moore for Potomac Electric Power Company (Reference 2.5-113). Tertiary strata were identified above the faulted Cretaceous strata in trenches across one of the four faults (Hazel Run fault). The trenches show that this fault truncates Paleocene-Eocene

strata (Aquia Formation) and is overlain by unfaulted Miocene strata (Calvert Formation) which exhibit only minor flexure not necessarily caused by fault movement. Significantly, all three trenches excavated to the base of the alluvial gravels across the trace of the Fall Hill fault disclosed that the gravels are not offset by the fault, strongly suggesting that the feature described by Mixon and Newell is erosional. Therefore, no unequivocal evidence was found for post-Miocene movement on any of the faults; latest movement could be as early as Paleocene or early Eocene.

A discussion of surface faulting is presented in Section 2.5.3 and was presented in detail in a report by Dames and Moore in 1974 (Reference 2.5-1).

2.5.1.1.4 Geologic History

The geologic history of the region can be traced from the Precambrian; the sediments that were deposited to form the Baltimore and Pickering Gneisses and the Franklin Limestone were subjected to magmatic intrusion, metamorphism, and erosion before the onset of Cambrian time.

In late Precambrian, Cambrian, and early Ordovician time, a thick sequence of sediments accumulated. They were derived from a highland that lay southeast of the region and were deposited in a broad inland sea. During Cambrian and early Ordovician time, thick sequences of sand and calcareous and dolomitic ooze accumulated. In the latter part of Ordovician time, the region was subjected to folding and uplift as a result of the Taconic orogeny. Farther to the northwest, sediments were deposited throughout the remainder of the Paleozoic Era.

The major tectonic events during the Paleozoic era began with the Taconic orogeny during the Middle Ordovician, continued with the Acadian orogeny in late Devonian, and culminated in the Appalachian orogeny at the end of the era. Major folding of the strata occurred predominantly during the Appalachian orogeny. The less competent units in the Middle Cambrian, Upper Ordovician, and Upper Silurian became thrust zones (Reference 2.5-16). Thrusting is discussed in Sections 2.5.1.1.3 and 2.5.1.1.4.1.

From the close of the Paleozoic to the present, the region has remained above sea level, and most of the area has undergone erosion. During the late Triassic, a series of down-warped or down-faulted basins developed in the central portion of the Appalachian Highlands. Streams from the higher areas adjacent to these basins filled them with the alluvial deposits that make up the Triassic sedimentary rocks of the region. After sedimentation ceased in the Newark Basin, the Triassic strata were tilted to the northwest along a synclinal hinge line near the north border of the basin. The faulting and broad folding of the strata occurred during or after the tilting.

The igneous activity in the Triassic occurred in three stages. The first stage was the extrusion of basaltic lava, which occurred during Triassic sedimentation. The second stage was the intrusion of diabase sills. The sills are cut by later Triassic faulting, and therefore they predate the development of the major fracture system of the surrounding rock. The final stage was the intrusion of diabase dikes along the major fractures. Most of the dikes in the region are not faulted and represent the final activity affecting the Triassic strata. Paleomagnetic age dating of these Triassic dikes indicates that they were emplaced between 180 and 140 million years ago. Radiometric dates obtained during geologic investigations for the site are in good agreement, ranging from 151 to 198 million years (see Reference 2.5-1, section 3.7).

During Jurassic and early Cretaceous time, the region underwent a prolonged period of erosion. The ancestral patterns of the present day drainage system of the region probably began during the late Triassic or Jurassic. Early in the Cretaceous, the ocean encroached on the Coastal Plain to

the southeast, and alluvium and marine sands, marls, and clays were deposited. These deposits constitute the unconsolidated Cretaceous and Tertiary sedimentary formations of the Coastal Plain.

There is no record in the eastern United States of any major tectonic event in the interval between Cretaceous time and the present. The region was subjected to broad, gentle periodic warping of the crust.

During the Pleistocene epoch, the maximum advance of the continental glaciers reached as far as the northern portion of the Reading Prong, about 20 miles to the northeast of the site. During periods of glacial melting, the major rivers of the region were choked with great quantities of glacial outwash. These materials were deposited along the valleys of the major streams and remain today as terrace deposits. The glaciated region was north of the Schuylkill River headwaters, and the river was little affected by continental glaciation.

2.5.1.1.4.1 Appalachian Plate-Tectonic History

The geologic history of the region summarized above can be stated in terms of lithospheric plate-tectonic interactions based on the considerable geologic research reported in the current technical literature on Appalachian tectonics (References 2.5-26, 2.5-30, 2.5-75, 2.5-76, 2.5-77, 2.5-78, 2.5-88, 2.5-92, 2.5-93, 2.5-94, 2.5-64, 2.5-97, and 2.5-138).

In the late Precambrian (approximately 820 million years ago) extensional tectonics rifted proto-North America from proto-Africa, proto-Europe and proto-South America (References 2.5-116 and 2.5-117). Various continental fragments were distributed in the expanding proto-Atlantic or "Iapetus" Ocean as the major continents separated (References 2.5-116, 2.5-76, 2.5-77 and 2.5-92). Some major continental fragments include the Avalon and Inner Piedmont-Blue Ridge provinces. During the ensuring plate convergence or contraction of the Iapetus Ocean, several island arcs developed offshore of the continental margin. The Carolina slate belt, for example, is believed to be one of these island arcs subsequently accreted to the margin of North America.

In the southern and central Appalachians, closure of the oceanic basin between North America and the Inner Piedmont-Blue Ridge fragment and subsequent collision of the land masses during the Cambrian and Ordovician is recorded by the Taconic orogeny (480-450 million years ago). The Inner Piedmont-Blue Ridge fragment was accreted to North America by overthrusting (References 2.5-117, 2.5-91, and 2.5-76). Extreme deformation, metamorphism and plutonism in the Inner Piedmont accompanied the orogeny. Six hundred to 500 million year old volcanics on the offshore Carolina slate belt suggest that eastward subduction and development of a volcanic arc on the slate belt accompanied closure of the basin (Reference 2.5-91). In western New England, the Taconic orogeny produced extensive thrust and fold deformation, low grade regional metamorphism, gravity-slide nappe structures, and extensive granodioritic and ultramafic intrusions (References 2.5-26, 2.5-30, and 2.5-133).

Continued closure of the Iapetus Ocean by eastward subduction resulted in the collision of the Carolina slate belt with the Inner Piedmont-Blue Ridge terrain of the southern and central Appalachians during the Acadian orogeny (400-300 million years ago) (Reference 2.5-92). Rocks of the Kings Mountain-Charlotte belt probably represent allochthonous portions of the intervening oceanic crust caught in the collision and obducted onto the margin of North America by overthrusting. The orogeny resulted in additional extensive metamorphism and deformation. The allochthonous Inner Piedmont-Blue Ridge fragment was thrust further westward over the old

continental margin. In the northern Appalachians, extensive high grade regional metamorphism and granitic intrusions accompanied the orogeny.

The last phase of plate convergence along the margin of North America culminated in the continental collision between proto- North America and proto-Africa during the Alleghenian orogeny (300-250 million years ago). Most of the prominent southern and central Appalachian structures and provinces assumed their present configuration in this orogeny. Extensive igneous activity in the eastern Piedmont accompanied the orogeny and large-scale overthrusting deformed the sedimentary rocks in the Valley and Ridge Province (References 2.5-76 and 2.5-78). Thrusting of the Piedmont over the Blue Ridge also created the Brevard zone at this time. In the northern Appalachians, the Alleghenian orogeny is manifest primarily in southeastern New England by folding, low and medium grade local metamorphism and granitic intrusions.

In the Triassic, following the Alleghenian orogeny, extensional tectonics again dismembered a megacontinent (Pangaea). Rifting separated North America from Africa, Europe and South America, forming the present Atlantic Ocean in its wake. Extensional Triassic-Jurassic basins bordered by normal faults (such as the Newark-Gettysburg Basin) were superimposed on the Paleozoic compressional structures. As rifting continued, Cretaceous and Tertiary sediments of the Coastal Plain province accumulated on the trailing eastern margin of North America. The composition of these sediments and their gentle dip away from the Appalachian Mountains implies that the Appalachians have stood as an eroding structural high for over 200 million years (Reference 2.5-84). Although many of the Triassic-Jurassic basins are exposed at the surface in the Piedmont Province, most are buried beneath the Coastal Plain sediments and have been tentatively located on the basis of drill holes (Reference 2.5-98), aeromagnetic and gravity anomalies (Reference 2.5-100), and seismic reflection and refraction profiles (Reference 2.5-81).

In summary, the Appalachians evolved principally by a sequence of plate rifts and collisions during the late Precambrian and Paleozoic eras. Subsequent rifting in late Triassic and early Jurassic time initiated the latest cycle of Atlantic sea floor spreading and produced the present configuration of the continental margin.

2.5.1.2 Site Geology

2.5.1.2.1 General

The site is located approximately 3 miles southeast of Pottstown, Pennsylvania, adjacent to the Schuylkill River, as shown on Figure 2.5-6. The principal plant structures are located on a broad ridge, approximately 100 feet above the river. Bedrock, encountered at shallow depths, consists predominantly of red siltstone, sandstone, and shale of late Triassic-age. The soils are residual, derived from the weathering of the underlying bedrock. Minor Triassic-age faults, inactive since Middle Mesozoic time, occur to the west and south of the construction area (see Sections 2.5.1.1.3 and 2.5.3). Fracture zones with a few inches of offset were encountered in the excavation. However, they are not significant to the plant structures.

2.5.1.2.2 Physiography

The topography of the site area is characterized by broad, gently rolling ridges that are dissected by the entrenched courses of the Schuylkill River and its tributaries. Elevations in the area range from a high of 200-300 feet above sea level on the ridge tops to a low of 100 feet along the Schuylkill River. Higher elevations occur in the more rugged terrain to the north and west of the site.

Topography and drainage of the area are controlled to a large degree by the lithologic and structural characteristics of the bedrock. The ridges generally trend east-west along the strike of the bedrock. The prominent ridge tops are capped by the more resistant rocks: sandstone, argillite, and diabase. Higher order drainage courses trend along the major joint directions. Tributary streams in the area (Sanatoga Creek, Possum Hollow Run, and Brooke Evans Creek) flow along the strike of the bedding or along major joints and fracture zones.

2.5.1.2.3 Stratigraphy

Bedrock at the site includes both the Brunswick and Lockatong lithofacies. Bedding dips toward the north at 8° to 20°. In the power block area, the dip is approximately 10° to 18° to the north. Contours on top of rock are shown on Figure 2.5-9.

Strata of the Brunswick lithofacies underlie most of the area. This rock unit is several thousand feet thick and is basically a reddish-brown siltstone, which grades locally to a shale. Calcite commonly fills joints and bedding-planes in the rock. Sandstone beds interfinger with the siltstones and range from reddish-brown, very fine-grained, silty sandstone to light gray, and medium-to-coarse-grained sandstone. Lateral gradation between sandstones and siltstones is common throughout the area. Geologic sections through the site area are shown on Figures 2.5-10 and 2.5-11. The stratigraphic column at the site is shown on Figure 2.5-12.

The Lockatong lithofacies, represented by the Sanatoga Member, interfinger with the Brunswick in the northern part of the site area. The Sanatoga Member of the Lockatong lithofacies consists of bluish-gray, calcareous argillite, with two distinct beds of black carbonaceous shale. The Sanatoga member occurs in the spray pond area, but does not occur beneath the cooling towers or the main plant structures.

Diabase has been intruded into the sedimentary rocks along major fractures, trending about N 20° to 30° E. The most extensive of these intrusives is the Downingtown Dike, about 1300 feet west of the site. The rocks at the borders of the dikes have been baked to a tough gray hornfels.

For the most part, soils consist of red sandy and clayey silts, with numerous rock fragments derived from the underlying bedrock. Soil thickness ranges from 0-40 feet with an average of 10-15 feet. A typical soil section consists of the following:

0-5 feet	-	Reddish-brown clayey silt
5-10 feet	-	Reddish-brown clayey silt with numerous rock fragments
10-20 feet	-	Highly weathered and fractured rock with some silts and clays

Residual soils overlying the diabase and hornfels are usually thicker and contain fewer rock fragments than the section described above.

Typical flood plain deposits occur along the Schuylkill River. They consist of silt, sand, and gravel that have been transported from upstream areas.

2.5.1.2.4 Structure

The principal structural features and relationships in the site area are shown on Figures 2.5-6 and 2.5-13. The bedrock strata dip to the north at between 8° to 20°. Two major joint directions are

prevalent in the area. Both are nearly vertical; they strike approximately N 20° to 50° E and N 50° to 60° W. Several fracture zones with minor offsets of Jura-Triassic age were encountered in foundation excavations and are described in Section 2.5.1.2.5.

As previously indicated, the site lies within a down-warped Triassic basin. Subsequent to the deposition and consolidation of the basin sediments, the region was uplifted, and the brittle basin materials were broken by numerous small faults and fractures.

Three faults, the Sanatoga, the Brooke Evans, and the Linfield, occur within 2 miles of the site. These faults are shown on Figure 2.5-6 and discussed in Section 2.5.3. The nearest approach of the Sanatoga fault to the reactor enclosure area is 1300 feet to the west. Vertical displacement on the fault is approximately 290 feet, with the downthrown side to the east. The fault-plane is intruded by Triassic diabase, which is part of the Downingtown Dike.

The Brooke Evans Fault passes within 2800 feet to the south of the plant area and trends approximately N 50° E. The apparent vertical displacement is about 350 feet, with the downthrown side to the south.

The Linfield fault is located east of the town of Linfield, about 2 miles southeast of the site. Field investigations in 1974 (Reference 2.5-1) identified five vertical or nearly vertical faults, trending N 40° to 55° E, with apparent vertical offsets of from 1-20 feet.

All three of these faults, the Sanatoga, the Brooke Evans, and the Linfield, are associated with the Jura-Triassic events that occurred 140-200 million years ago (Section 2.5.3.2).

2.5.1.2.5 Fracture Zones in the Site Area

Three fracture zones were encountered during excavation of the main power block. Figure 2.5-13 shows their locations, widths, and attitudes at final foundation grades. None of the zones presents a hazard to the structures. The zones have relatively lower strength than the rock adjacent to them; consequently, they were treated to preclude any unacceptable differential settlement across them. Treatment of these zones is discussed in Section 2.5.4.12.

A fracture zone (Zone A), consisting of discrete fractures about 20 feet apart with hard, relatively unfractured rock between them, was encountered in the Unit 1 foundation excavation, at the south edge of the reactor enclosure. To the northeast, these fractures converge and intersect other fractures, resulting in a zone of closely fractured, partly weathered rock varying in width from 2-7 feet. This zone extends across the northern part of the reactor enclosure foundation and the entire control structure and turbine enclosure foundations (Figure 2.5-13). No offset was observed along this zone. At the south wall of the control structure, most of the fractures in this zone, and essentially all of the weathering, terminated at a bedding-plane (clay seam 1 described later in this section) at about el 158. At this wall, the fracture zone was removed down to the bedding-plane. To the northeast, it was treated, where necessary, by dental excavation, as described in Section 2.5.4.12. Treatment of the zone was not required at the south wall of the Unit 1 reactor enclosure, since the "zone" consists only of narrow, widely spaced fractures with hard unweathered rock between them.

Another fracture zone (Zone B) occurs at the southeast corner of Unit 2 reactor enclosure (Figure 2.5-13). It strikes about N 30° E, is essentially vertical, and contains highly fractured, partly weathered rock in a zone about one foot wide. This zone has about 8-10 inches of apparent

vertical offset, down on the southeast side. Since this fracture zone is vertical and narrow, dental treatment was probably not needed, but was done as a conservative measure, as described in Section 2.5.4.12.

A third zone (Zone C) in the foundation of the Unit 2 turbine enclosure was mapped as a minor fracture zone. Dames and Moore indicate that the zone is similar in character to fracture Zone B, with apparent vertical offsets of up to two feet (Reference 2.5-1, section 2.3.4.3). This zone contains from ¼-4 inches of clay and decomposed rock. Treatment of this zone was not necessary.

Two clay seams were encountered in the plant excavation. They occur along bedding, striking generally northeast-southwest and dipping 10° to 18° northwest. The first seam is near the top of rock south of Unit 1, where it is about 10 inches thick in the south slope of the excavation. The thickness of this zone decreases rapidly down-dip, toward Unit 1, and is generally less than 1½ inches thick under Unit 1; in places it is barely discernible. Clay, where present in the seam, contains numerous hard rock particles of small gravel size. Some shearing is evident along this seam.

The second clay seam is stratigraphically lower than seam 1 and intersects foundation grade in part of Unit 2. This seam occurs along shaly beds, which are relatively softer than the adjacent siltstone. The soft material in seam 2 is usually only about ¼-½ inch thick where exposed in foundations or excavated slopes, and it consists of plastic clay with shaly, sheared rock fragments. Only minor local treatment of these seams was required. The method of treatment is described in Section 2.5.4.12.

Geologic mapping in the spray pond excavation (Figures 2.5-42 and 2.5-43) disclosed only few minor instances of offset along near-vertical joints and fractures. The maximum apparent displacement observed does not exceed 3 inches. These minor offsets observed in the spray pond excavation are consistent with the late Triassic or Jura-Triassic deformational features found elsewhere at the site and in the region around the site. Extensive geologic investigations conducted by Dames and Moore (Reference 2.5-1) have confirmed the noncapability of these deformational features (Section 2.5.3).

Near the western end of the spray pond excavation, a vertical joint trending N 20° E displayed about 1 inch of offset (east side down); the joint was traced a distance of about 100 feet A narrow (2-6 inches wide) east-west zone of closely spaced jointing and fracturing, locally accompanied by more widely spaced jointing, was exposed in the southern part of the pond. It was traced from the western edge of the excavation eastward for a distance of about 600 feet. The maximum observed offset on this feature is no more than 2 inches (south side down); slickensides were not generally apparent but were noted in a few places. These features were examined by an NRC geologist and a geotechnical engineer during their site visit on September 10, 1981. Locally altered and weathered rock within the zone was excavated to sound rock following procedures employed in the main power block excavation (Section 2.5.4.12).

In the rock slope at the eastern end of the spray pond excavation, an east-west fracture zone was exposed that displayed between 2 and 3 inches of total apparent lateral displacement (left-lateral sense) as measured by offsets between matching joints on either side of the fracture. No slickensides were visible along this fracture. The fracture terminated downward at a bed of hard, calcareous siltstone. No trace of the fracture was present on the exposed bedding-plane surface of this underlying siltstone, thus demonstrating the superficial nature of the fracture. Several other

narrow east-west zones of closely spaced fractures were also mapped in the spray pond excavation, none of which showed evidence of offset.

There is little evidence of shearing in the excavation, despite the proximity of the Sanatoga fault to the western end of the spray pond. As investigated and mapped by Dames and Moore (Reference 2.5-1), the Sanatoga fault - Downington dike passes within about 250 feet of the western end of the spray pond. The N 20° E joint with about 1 inch offset noted above strikes parallel to the trend of the Sanatoga fault. The structural investigations conducted by Dames and Moore recognize east-west fracturing and shearing as a secondary but persistent occurrence accompanying the dominant northeast and northwest structural trends. East-west shearing was mapped at the site in a trench excavated across the trace of the Sanatoga fault. Similar shears were also recorded in exposures of the Downington dike south of the site and in road-cuts about 3 miles northeast of the site.

Dames and Moore concluded that lateral shears occur as a numerically minor east-west regional fracture trend which includes both extension fractures and shears. In several cases these joints appear to have resulted from simple shear along northeast-trending fractures (Reference 2.5-1).

2.5.1.2.6 Site Geologic History

The geologic history of the region is discussed in Section 2.5.1.1.4. The Newark-Gettysburg basin, in which the site is located, was formed in two phases (Reference 2.5-17). The first phase consisted of formation of the sedimentary basin, probably by down-warping rather than faulting. The bulk of the intrusives were emplaced late in basin development, but before the end of deposition. The second phase consisted of a deformational period. Faill (Reference 2.5-17) states: "All the deformation appears to have been postdepositional, with the monocline, the folds, and the faults developing contemporaneously.... With few exceptions, faults are not intruded with diabase - in general, the faults offset diabase plutons. This indicates that most of the faulting occurred after the diabase intrusions."

Studies by Dames and Moore (Reference 2.5-1), which include radiometric age dating of the diabase dikes in the vicinity of the site, indicate that the age of the diabase in the site area is 191 ±10 million years. The age of the faulting is uncertain but is considered by the Geology Review Board, a group of authorities on Appalachian geology, to be associated with the Jura-Triassic development of the Newark Basin 140-200 million years ago (Reference 2.5-1).

Reported instances of Triassic basin faults that also offset Cretaceous and Tertiary deposits are quite rare along the Atlantic coastal plain. These rare occurrences are characterized by relatively small displacements compared to those present in known Triassic basins. All such displacements investigated have been found to be at least 500,000 years old, and no proof has been found for post-Miocene movement. These occurrences are considered to be unrelated to the capability of Triassic faults in the site region.

According to a recent compilation (References 2.5-135, plate 1, and 2.5-134, figure 3), the only instance within 200 miles of the site of a fault that offsets coastal plain strata overlying Triassic sediments is the inferred Brandywine fault zone located 9 miles southeast of Washington, D.C., about 140 miles from the site. Evidence for both the faulting and the presence of Triassic sediments at depth is entirely from subsurface data, including seismic reflection, drill holes and geophysical logging, as reported by Jacobeen (Reference 2.5-61). These data indicate that two northeast striking, southeast dipping en echelon reverse faults offset the top of the Lower Cretaceous Arundel Formation a maximum of about 250 feet. The relation of this faulting to

Triassic basin structure, however, is uncertain because both Triassic sediments and granitic rocks were penetrated by deep drill holes on both sides of the fault zone. Jacobeen (Reference 2.5-61) states he believes the faults to be unrelated to mesozoic structure. Up section, the drill hole data confirm that the Paleocene-Eocene Aquia Formation is monoclinally folded without being offset by faulting. This folding occurred prior to Oligocene erosion, and only minor flexuring is displayed in overlying Miocene strata (Reference 2.5-61). Jacobeen concludes that there is no evidence for post-Miocene movement on the Brandywine fault zone.

Mixon and Newell (References 2.5-105, 2.5-106 and 2.5-107) suggest that the Brandywine fault zone may be an extension of faults bordering the Richmond Triassic basin in Virginia, 60 miles to the southwest, based on the alignment of both fault zones with a linear gravity anomaly that extends between the two locations. However, evidence to associate the Richmond basin faults with Cretaceous or younger faulting apparently could not be found because neither Mixon and Newel nor Wentworth and Mergner-Keefer (References 2.5-135 and 2.5-134) indicate any offset of coastal plain strata where these strata overlap the Richmond basin faults.

Another fault zone about 15 miles west of, and parallel to, the Brandywine has been named the Stafford fault zone (References 2.5-105, 2.5-106, 2.5-107 and 2.5-151). Surface exposures of the Stafford fault zone show that coastal plain strata are offset along high angle basement faults.

However, the Stafford fault zone is not associated with Triassic sediments and has no demonstrable relation to any Triassic basin structure at this location. Nevertheless, the relative proximity and similar trend of the Brandywine and the Stafford fault zones suggest they may be structurally interrelated.

The Stafford fault zone consists of four subparallel, en echelon basement faults that offset coastal plain strata. Each fault has a maximum throw of about 150 feet. Two of the faults display reverse throw on high angle, west dipping planes (down-to-coast movement).

On one of these faults (the Fall Hill fault), an exposure near the Stafford-Spotsylvania county line shows a high angle fault contact between basement gneiss and Cretaceous coastal plain sediments. The gneiss projects about 14 inches upward into overlying Plio-Pleistocene fluvial gravels, consistent with reactivated reverse displacement along the fault-plane (Reference 2.5-107). Such relationships are also consistent with features produced by normal stream erosion, particularly in view of the great contrast in erodability between the gneiss and the Cretaceous sands.

A detailed investigation of the Stafford fault zone, including an extensive drilling and trenching program, was conducted by Dames and Moore for Potomac Electric Power Company (Reference 2.5-113). Tertiary strata were identified above the faulted Cretaceous strata in trenches across one of the four faults (Hazel Run fault). The trenches show that this fault truncates Paleocene-Eocene strata (Aquia Formation) and is overlain by unfaulted Miocene strata (Calvert Formation) which exhibit only minor flexure not necessarily caused by fault movement. The Aquia and Calvert Formations were not present in trenches across the remaining faults; instead, these faults are directly overlain by undisturbed Quaternary materials (generally Plio-Pleistocene upland gravels). Along the Fall Hill fault, three trenches were excavated to expose the basal contact of the upland gravels crossing the fault. In all three cases, the upland gravels were not disturbed by faulting. The investigation concluded (Reference 2.5-113) that the minimum age of fault displacement on the Stafford fault zone is at least 500,000 years. Moreover, no unequivocal evidence was found for post-Miocene movement on any of the faults. Absence of post-Miocene movement is also

supported by an investigation by Mixon (Reference 2.5-150), who maps a late Miocene erosional scarp trending across the Stafford fault zone without observable offset.

It is concluded that the indication of Cretaceous and early to middle Tertiary offset above possible Triassic basin faults is a highly exceptional occurrence within the site region and does not warrant the presumption of similar movement on Triassic basin faults in general. Furthermore, detailed investigations of these known exceptional occurrences within the site region have established that their age of latest movement is at least 500,000 years, and is probably Miocene or older. Therefore, these occurrences are considered to be unrelated to the capability of Triassic faults in the site region.

Since late Mesozoic time, the area around the site has been a land mass subject to erosion. Continental glaciation that occurred during the Pleistocene did not extend to the site area. Bedrock at the site is overlain by up to 40 feet of residual soil derived from the bedrock by weathering. These residual soils, which overlie the Sanatoga fault and the Downington Dike without offset, have been dated in studies by Dames and Moore as being of Yarmouthian age, or 500,000-850,000 years before present (Reference 2.5-1, p. 4-17).

Additional discussion related to post-Mesozoic faulting in the site region is provided in Section 2.5.2.3.1.2.

2.5.1.2.7 Engineering Geology Evaluation

Site subsurface exploration is described and discussed in Section 2.5.4.3. Laboratory tests of foundation materials and in situ geophysical tests of the foundation materials are discussed in Sections 2.5.4.2 and 2.5.4.4, respectively. Geologic mapping of the foundation excavations is described in Sections 2.5.1.2.5 and 2.5.4.3. It is concluded from these studies and evaluations that the site geologic and foundation conditions are entirely suitable for plant construction and operation.

2.5.1.2.7.1 Geologic Conditions Under Category I Structures

All seismic Category I plant facilities are founded on bedrock, except part of the spray pond, portions of the underground piping, and electrical ducts, diesel oil tanks, and valve pits, which are founded on weathered rock, natural soil or fills. For more detail, refer to Section 2.5.4.5. The locations of the major Category I facilities are shown on Figure 3.8-58.

The foundation rock at the site consists of reddish-brown siltstone, interbedded and lensing with shale and sandstone. These rocks are part of the Brunswick and Lockatong lithofacies of Triassic-age (Section 2.5.1.2.3). The bedrock strata dip to the north at angles of from 8° to 20°. Several fracture zones with minor offsets were encountered during site excavation; these zones and their treatment are described in Sections 2.5.1.2.5 and 2.5.4.12. All the Category I rock foundations were excavated to unweathered bedrock. Geologic maps and sections of the Category I excavations at the main power block are shown in Figures 2.5-10, 2.5-11, and 2.5-13. Engineering properties of the foundation rock are described in Section 2.5.4.

The natural soils at the site consist of materials derived from the in situ weathering of siltstone, sandstone, and shale. Soil from 0 feet to about 40 feet thick was encountered in the borings at the site. In some parts of the area, the bedrock has not completely broken down into soil, and the soil materials are mixed with weathered, decomposed rock fragments. Weathering decreases with

depth, and grades gradually to fresh rock. The evaluation of the stability of the natural soils at the site is presented in Section 2.5.4.

2.5.1.2.7.2 Landslide Potential

There are no steep or unstable natural rock slopes in the construction area. No old landslides, rock slips, or landslide scars have been noted near plant structures. The natural rock slopes present no hazards to plant structures. Stability of soil slopes is discussed in Section 2.5.5.

2.5.1.2.7.3 Areas of Potential Subsidence, Collapse, or Uplift

Rocks in the area around the site are primarily well-indurated siltstones, sandstones and shales to a depth of several thousand feet. No cavernous or karstic terrain exists in the area. There is no mining or significant fluid withdrawal in the area.

Analyses of precise leveling surveys indicate that some broad crustal warping may be occurring in the area (Reference 2.5-18). If so, it is of a broad, regional nature and does not significantly affect plant structures. Measurements of residual stresses (Reference 2.5-1) using overcoring methods indicate very low stress in the area near the site. It is concluded that available data indicate that uplift or subsidence, either from man's activities or natural geologic conditions, does not have any significant effect on the safe operation of the LGS.

2.5.1.2.7.4 Behavior of Site During Prior Earthquakes

There is no evidence at the site of any effects, such as landslides, fissuring, or subsidence, that could be attributed to prior earthquakes.

Within historical time, the maximum intensity of earthquakes that have occurred near the site was probably V or less. Ground motion at this intensity has no significant effect on the dense soil and well-indurated rock at the site. For additional information on historical seismicity, see Section 2.5.2.1.

2.5.1.2.7.5 Zones of Deformation or Structural Weakness

As reported in the PSAR, the preconstruction investigation defined major joint and fracture systems, minor faults in the area around the site, and indicated the possibility of fracture zones with small offsets within the site area.

During the foundation excavation some fracture zones with small displacements were encountered and were treated as required. Descriptions of the fracture zones are presented in Section 2.5.1.2.5, and their treatment is discussed in Section 2.5.4.12. Figure 2.5-13 shows their locations at final foundation grades, their widths, and their attitudes. None of the zones presents a hazard to plant structures.

2.5.1.2.7.6 Zones of Alteration or Irregular Weathering

Bedrock at the site is overlain by from 0-40 feet of residual soil, developed in situ by the gradual decomposition of the parent rock.

The soil horizon has developed over a long period of time, probably in excess of 500,000 years (Reference 2.5-1, section 4.0). The soil grades gradually into fresh, unweathered rock; no clearly defined boundary between soil and rock exists. Weathering appears to be a function of lithology and fracture spacing. Where the rock is closely jointed or shaly, weathering has progressed more rapidly, and a thicker soil horizon is present. In the fracture zones, weathering extends below the general level of the fresh rock surface. These zones are generally narrow, such as the fracture zones described in Section 2.5.1.2.5, and were treated locally when encountered in foundation excavations.

Within the site area, the narrow zones of irregular, relatively deeper weathering that were encountered in the foundation excavations were treated by standard methods, as described in Section 2.5.4.12, and pose no hazard to the construction and operation of the LGS plant.

2.5.1.2.7.7 Potential for Unstable or Hazardous Rock or Soil Conditions

The bedrock at the site contains no unstable minerals, and the soils derived from this rock are also composed of stable minerals. There are no potentially unstable or hazardous conditions present in the site foundation materials.

2.5.1.2.7.8 Unrelieved Residual Stress In Bedrock

Geologic investigations by Dames and Moore in 1974 (Reference 2.5-1) include several measurements of residual stress in rock, made using overcoring methods. These tests were made in closely jointed rock near the Sanatoga fault and in a boring in Possum Hollow Run southeast of the major plant structures. Of the 15 tests made, only two indicate valid results. Dames and Moore state: "Only the results of test FTa-1 and test ET-1 are considered valid (Reference 2.5-1, page 5-4). They show relatively low stresses: major principal stresses of 450 psi and 950 psi, respectively; and minor principal stresses of 175 psi and 650 psi, respectively. The orientation of the major stresses in the two tests is almost identical; N 75° W and N 85° W, respectively."

The report of the geologic evaluation committee, consisting of Dr. Donald U. Wise, Dr. Carlyle Gray, and Dr. Paul B. Myers (Reference 2.5-1), evaluates the residual stress-field as follows: "The present WNW orientation of compressive stresses in the residual stress measurement differs markedly from the NNE compression which produced the Jura-Triassic faults at the site and nearby folds. The effect is to increase normal stresses across the faults, increasing fractional resistance to movement, and decreasing available space for additional graben displacement."

Calcite is present in vein form along joints and fractures in the site area. Despite the fact that calcite twins easily at low stress levels, calcite twins are rare in the latter stages of the mineralization in the site area. The low stress levels indicated by the calcite correspond well with values measured in situ.

It is concluded that the stress regime at the site is low and stable, and residual stress is not a factor in the safe operation of LGS.

2.5.1.2.7.9 Conclusions and Summary

Consideration of all the engineering geologic factors at the LGS site leads to the conclusion that the site is suitable for constructing and operating the plant. The bedrock in the construction area is competent and provides satisfactory foundation support for all major plant structures.

2.5.1.2.8 Site Groundwater Conditions

This section provides a summary of groundwater conditions at the site. Reference for more detailed information on this subject may be made to Sections 2.4.13 and 2.5.4.6.

LGS will have no effect on the future use of groundwater in the region. The site is hydrologically isolated from public groundwater supplies and areas of extensive groundwater development.

Groundwater at the site occurs in sedimentary rocks of Triassic-age. The Brunswick lithofacies, the formation underlying the plant site, is consolidated rock consisting of bedded sandstone, siltstone and shale. It yields small-to-moderate quantities of water to wells. Most of the groundwater movement within the Brunswick follows secondary openings, the most important of which are nearly vertical joint planes that cross each other at various angles throughout the beds, giving the rock a low to moderate permeability. About 85% of the permeabilities measured in bedrock are less than 390 ft/yr.

Recharge to the Brunswick occurs through the relatively impervious soil cover as precipitation percolates down to the water table. The water table approximately parallels the topographic surface, groundwater flows from high to low topographic areas. Groundwater beneath the plant flows toward the Schuylkill River in a southwesterly direction, eventually discharging to the river. North of the plant, a groundwater divide is present beneath the topographic high that occurs there. Groundwater north of the divide flows northward, discharging to tributaries of the Schuylkill River.

A map of the potentiometric surface at the site determined from levels measured in May, 1979, is shown in Figure 2.4-15. This indicates the groundwater level is at el 250' east of the spray pond, decreasing through the area of the principal plant facilities to about el 120' southwest of the power block enclosure. Fluctuation of water levels in observation wells are illustrated by the hydrographs in Figure 2.4-18, and discussed in Section 2.4.13.

The emergency spray pond, excavated partly in soil and partly in rock, was lined to preclude excess seepage. The pond will not significantly affect groundwater levels beneath the plant (refer to Section 2.5.4.6 for a discussion of groundwater conditions beneath the spray pond).

2.5.2 VIBRATORY GROUND MOTION

This section presents the evaluation of the geologic and seismic conditions in the site region as they affect design for vibratory ground motion. The investigation undertaken for the PSAR includes the following:

a. A study of geologic structure and tectonic history of the site region

b. A review of seismicity of the region, primarily based on a literature search and supplemented by a review of contemporary newspaper accounts

c. An evaluation of seismicity of the region that considers the relationship of historic earthquakes to geologic and tectonic features

d. Field geophysical measurements to determine physical properties of the bedrock at the site

e. Selection of appropriate OBE and SSE

f. Estimation of maximum level of ground motion to be expected at the site due to the occurrence of the OBE and SSE

g. Characterization of seismic design criteria in the form of response spectra and recommended time histories

Detailed descriptions and the results of the geologic and geophysical investigations that provide background information for some of the results discussed in this section are presented in Sections 2.5.1, 2.5.3, and 2.5.4. Information gained after the submittal of the PSAR has been considered and added, and discussion of this information is provided where appropriate in this report.

2.5.2.1 Seismicity

The site is located in a region that has experienced a moderate amount of historic earthquake activity. The record of earthquake occurrence in southeastern Pennsylvania and the surrounding area dates back to the early 1700s. Since this region has had a relatively large and well distributed population since this time, it is probable that any major earthquake activity (defined in this context as intensity greater than or equal to VIII on the Modified Mercalli Scale, Table 2.5-1), would have been reported in local newspapers, private journals, or diaries. No evidence in documentation of this type has been found.

As indicated in the PSAR, zones of major earthquakes in the eastern United States, such as the St. Lawrence River region and the New Madrid, Missouri region, are too far removed from the site, both tectonically and geographically, to have an appreciable effect on the seismic evaluation. Maximum historic intensities at the site from earthquakes in these two active regions are estimated to be about IV or less on the Modified Mercalli Scale. Earthquakes near Charleston, South Carolina in 1886 are the only major earthquakes recorded in the Coastal Plain physiographic province of the eastern United States. These shocks, which had a maximum intensity of about IX, were centered about 550 miles SSW of the site. It is estimated that these shocks were felt in the site area, with an intensity of about III. The more modest local and regional seismicity of the site area is more important to the seismic evaluation of the site area than effects from events in the distant zones of major earthquakes; thus, only seismicity within 200 miles of the site is considered in the discussion below. For the purposes of this discussion the site region is defined as that area within a 200 mile radius.

2.5.2.1.1 Regional Seismicity

The epicenters of earthquakes of maximum intensity IV-V or greater within approximately 200 miles of the site are shown in Figure 2.5-14 and listed in Table 2.5-2. This data set covers the interval from the first historical account in the beginning of the 18th century through January 1982. A total of 131 events are shown and listed. Sixteen of these earthquakes (3 of intensity VI, 10 of intensity V, and 3 of intensity VI-V) occurred after 1967 and thus are an update of the PSAR compilation. A number of additional small pre-1968 earthquakes were found (2 of intensity V-VI, 9 of intensity V, and 18 of intensity IV-V), predominantly from two recent catalogs by Winkler (References 2.5-53 and 2.5-54). Data on post-1967 events have been taken from various publications of the USGS (References 2.5-19, 2.5-20, 2.5-21, and 2.5-55), Bulletins of the Northeastern U.S. Seismic Network (Reference 2.5-56), Bulletins of the Southeastern U.S. Seismic Network (Reference 2.5-57), and supplementary data from a National Geophysical and Solar

Terrestrial Data Center earthquake list (Reference 2.5-58). The new earthquakes do not alter the seismic characterization of the site region implied by pre-1968 seismic history.

The parameters of the Moodus, Connecticut, event of May 16, 1791 have been altered from the data in the PSAR. Although two events are listed in the PSAR, one on May 16th and another on May 18th, no single account describes two large events, two days apart. Rather, two very similar descriptions of a single earthquake, quoted as occurring on these two different dates, are the source of the two events in the PSAR. It is probably confusion over the date of occurrence of this shock that has led to duplication in the original listing. More importantly, the maximum intensity at East Haddam, Connecticut, is anomalous with respect to reports from nearby localities. This observation led Linehan (Reference 2.5-22) to reevaluate the intensity of this earthquake, which he assessed as V-VI. Seismologists from the NOAA, U.S. Department of Commerce, have recommended that the 1791 earthquake be reclassified as intensity VII. This value is conservatively adopted in this report.

Although no modification of the maximum intensity associated with the 1929 Attica, New York earthquake is exercised here, it may be noted in passing that, in a recent study of this event (Reference 2.5-23), a revised intensity of VII has been suggested.

As Table 2.5-2 shows, 59 earthquakes with maximum intensities of IV-V or greater have been reported within 100 miles of the site since the first historical account, at the beginning of the 18th century. Of these shocks, 5 were of intensity VII, 10 were of intensity VI, 40 were of intensity IV-V or V, and 4 were of uncertain intensity. Of the intensity VII earthquakes, the closest to the site was a shock near Wilmington, Delaware in 1871, approximately 30-40 miles from the site. Smaller earthquakes have occurred closer to the site. A series of shocks occurred in the Reading-Sinking Spring area in 1954 and 1955, about 20-25 miles to the west of the site. The largest of these had a maximum intensity of VI. Such smaller shocks are discussed in detail in the section on local seismicity below.

A discussion of the most significant earthquakes in the region follows:

a. Wilmington earthquake of October 9, 1871:

This shock is the largest earthquake originating in or near the Piedmont, and close enough to the site to be of significance in the current report. Little information about this earthquake is available, and it is therefore difficult to accurately locate its epicenter or estimate its maximum intensity. It is believed that the epicenter was located somewhat to the south of Wilmington, Delaware, where the shock was felt with intensity VII. The shock was felt from Chester, Pennsylvania, to the north, to Middletown, Delaware, to the south; and from Salem, New Jersey, to the east, to Oxford, Pennsylvania, to the west. The initial shock was followed by a much smaller aftershock just after midnight on October 10th. A contemporary newspaper account indicates that the shock was felt at Wilmington, "with great distinctness." Buildings were shaken severely, and a number of chimneys in various parts of the city were shaken down. Windows and glass were broken. The shock also was felt strongly and resulted in broken chimneys in the surrounding towns of Oxford, Pennsylvania, and New Castle and Newport, Delaware.

An interesting aspect of this earthquake is the fact that it was accompanied by a very loud sound, as of an explosion. This loud noise, in fact, led to the belief that

the shock was caused by an explosion, probably at the powder mill of the E.I. Dupont deNemours Company, near Wilmington. This possibility was carefully investigated at the time, however, and it was concluded that the shock was due to an earthquake.

b. Wilkes-Barre earthquake of February 21, 1954:

This earthquake and a strong aftershock two days later were probably not of tectonic origin. The shock occurred in an area in Wilkes-Barre, Pennsylvania, which is underlain by coal mines extending to a depth of 400 feet below the ground surface. Wilkes-Barre is about 65 miles north of the site. The affected area was confined to the east side of the Susquehanna River, in a five-block residential area. The effects of this disturbance were locally severe. Occupants fled to the streets. Sidewalks pushed upward with a heaving motion and then collapsed. Hundreds of homes were damaged, ceilings and cellar walls split, and backyard fences were pushed over. Gas and water mains snapped. Methane gas rising from cracks in the earth presented a temporary emergency. The estimated property damage was $1,000,000; however, this figure may be somewhat high.

The second shock, two days later, occurred in the same area. Again, hundreds fled to the streets. Cracks appeared in ceiling, and walls of apartment buildings. Curbs pulled away from sidewalks; street pavements buckled from curb to curb. Additional water and gas mains were broken.

The small affected area of these shocks suggests a very shallow focus and a source mechanism of limited lateral extent. Detailed investigations of the event shortly after it occurred lead to these conclusions: it was closely related to slip along a zone of weakness that exists in the strata (in which coal mining was taking place) along the south side of the affected area, and, whatever the cause-and-effect relationship was between this slip and roughly concurrent failure of coal pillars and partial mine collapse, this event would not have occurred without the previous existence of the coal mine excavations.

c. Earthquake of March 8, 1889:

This shock had its epicenter in southeastern Pennsylvania, probably near York, about 60 miles southwest of the site, where the shock was felt most strongly.

The maximum intensity of the shock was VI. The shock was felt throughout northeastern Maryland, northern Delaware, and southeastern Pennsylvania. The area in which it was felt was roughly elliptical in a NE-SW direction from Trenton, New Jersey, to Hagerstown, Maryland. The shock lasted about ten seconds.

No serious damage was reported. The greatest damage occurred at York, where some chimneys were knocked over and people were badly frightened. A man was thrown from a sofa, and articles were thrown from shelves. The shock was accompanied by a loud rumbling noise. It is interesting to note that there were reports of a "ball of fire" passing over the area at the same time as the shock.

2.5.2.1.2 Local Seismicity

Some minor earthquake activity has occurred in the site vicinity. Seventy-two events within approximately 50 miles of the site are listed in Table 2.5-8 and plotted in Figure 2.5-15. Forty-five of these events have been of less than intensity IV-V (or unassigned) and therefore do not appear in the regional catalog above. Data on the additional events have been taken from various publications of the USGS (References 2.5-19, 2.5-20, 2.5-21, and 2.5-55), Bulletins of the Northeastern U.S. Seismic Network (Reference 2.5-56), Bulletins of the Southeastern U.S. Seismic Network (Reference 2.5-57), Winkler (References 2.5-53 and 2.5-54), and supplementary data from a National Geophysical and Solar Terrestrial Data Center earthquake list (Reference 2.5-58).

The completeness and accuracy of earthquake reporting in the site area is not uniform over the entire period of record. Before instrumental epicenters were reported in the northeastern and southeastern U.S. Seismic Network Bulletins, most earthquake locations were based on sensory and damage reports from area surveys following the earthquake, from newspaper articles, historical journals and publications, and private diaries. No formal location accuracy estimate is attempted for earthquakes occurring before 1975. However, it is believed reasonable to assume that these events are generally located to an accuracy of better than ten to several tens of kilometers. The instrumental locations of earthquakes occurring after 1975 are generally better constrained. The degree of uncertainty in the locations of the small site area events that have occurred after 1975 is about one-half the degree of uncertainty associated with pre-1975 event locations. In addition, the disproportionate number of post-1975 earthquakes indicates an increased earthquake detection capability in the site area. Location uncertainties, and the nonuniformity of location accuracy and event detection capability over the total time period of record, should be recognized in considering the seismicity of the vents listed below and of those shown in Table 2.5-8 and Figure 2.5-15.

Descriptions of the historical seismicity for the Reading-Sinking Spring, Allentown and Philadelphia areas follow. A "detected" event as used in this discussion indicates that the event was felt, heard, or noticed in some way.

a. Reading-Sinking Spring Area Earthquakes: (about 20-25 miles west of the site)

1. May 28 and 29, 1906 - A small shock of reported intensity III was felt on May 28 over an area within about 2-3 miles of Geigerstown. On May 29 a water tank collapsed in New York City, tentatively associated with a IV-V shock in Reading. The occurrence of this latter event is suspect.

2. June 8, 1937 - This shock was very slight, with a possible maximum intensity of III. The epicenter was in the vicinity of Reading. Little information is available.

3. January 7, 1954 - This shock and a series of aftershocks originated in the Sinking Spring area west of Reading. The shock had a maximum intensity of VI. Damage in Sinking Spring consisted of plaster ripped from walls, dishes and bottles tumbled from tables, upset furniture, and slight damage to brick and frame buildings. People were thrown out of bed. In the surrounding communities, many people felt the tremor, homes rocked, furniture toppled, and dishes and lamps rattled. The main shock was followed by many minor aftershocks over a period of a few weeks.

4. January 23, 1954 - An aftershock of maximum intensity III shook a 10 mile square area surrounding Sinking Spring.

5. August 10, 1954 - About 12 tremors, four of "good size," maximum intensity IV, were felt in the Sinking Spring area within a 10 minute period.

6. September 24, 1954 - A series of minor tremors, maximum intensity III, were felt in the Sinking Spring area.

7. January 19, 1955 - A shock of maximum intensity IV occurred in the Sinking Spring Area. The shock was felt from West Reading west to Wernersville; houses vibrated, windows and dishes rattled, and a lamp tumbled to the floor. A noise accompanied the shock. Many felt the shock and were alarmed.

b. Allentown Area Earthquakes:

1. May 31, 1884 - This shock had a maximum intensity of about V. The shock was felt in a small area at Allentown. No damage was reported other than dishes thrown from tables.

2. May 31, 1908 - This shock had a maximum intensity of VI. This shock was felt in all parts of Allentown, in a total area of about 50 square miles, but not in the surrounding communities. The shock lasted about one or two seconds and was accompanied by a low rumbling sound followed by a loud report, as of an explosion. Many people were frightened by the shock. Some were thrown to the ground. Damage consisted of a few fallen chimneys, broken windows, dishes, etc, and other minor building damage.

3. November 23, 1951 - An extremely local shock was reported in the northwest section of Allentown. The maximum intensity of the shock was IV. Many were awakened. It was reported that a bed was moved 6-7 inches. A vase was knocked off a shelf and a pump was put out of order. Reports indicated that the water level in a well used for 25-30 years dropped 60 feet. The shock was accompanied by a low rumbling noise.

4. September 14, 1961 - This shock was centered in the Lehigh Valley, about 5 miles east of Allentown. The maximum intensity of the shock was V. It was felt in a larger area than the foregoing earthquakes; however, no damage was reported. The earthquake was strongest in Allentown, Bethlehem, and surrounding communities where the shock was felt by nearly all and where many were alarmed and awakened. Many were shaken from their beds. Loose bricks fell from a chimney. Buildings shook, loose objects rattled, and thunderous sounds were heard.

c. Philadelphia Area Earthquakes:

1. November 26, 1755 - Detected at Philadelphia.

2. November 22, 1963 - Detected at Delaware County, Pennsylvania.

3. October 13, 1763 - Detected at Philadelphia.

4. October 30, 1763 - Intensity IV-V at New Jersey; IV at Philadelphia; detected at Bensalem, Pennsylvania.

5. November 22, 1777 - Detected at Philadelphia.

6. November 23, 1777 - Detected at Delaware County, Pennsylvania.

7. November 29 and 30, 1783 - For November 29 event at 22:15: intensity IV-V at Philadelphia; IV at New York City and New Haven, Conn.; detected at Hartford, Conn., Boston, Mass., N.H., N.J., and R.I.; shocks also felt at 21:00 and 01:00-02:00 the next morning (November 30) at Philadelphia and New York City.

8. March 17, 1799 - Detected at Philadelphia.

9. March 17, 1800 - Severely felt at Philadelphia.

10. November 29, 1800 - Severely felt at Philadelphia.

11. November 12, 1801 - Detected at Philadelphia.

12. December 8, 1811 - Intensity III at parts of Pennsylvania and Delaware (including Wilmington, DE).

13. November 11 and 14, 1840 - Both had intensity IV at Philadelphia; great and unusual swell on the Delaware River was noted.

14. October 12, 1870 - Intensity III near Wilmington, Delaware.

15. October 9, 1871 - Intensity VII at Wilmington, Delaware. A press report stated chimneys toppled and windows broke. Damage also was reported at New Castle and Oxford. Event was felt in New Jersey (IV-V at Haddonfield; IV at Salem) and Pennsylvania (IV at Philadelphia).

16. August 10, 1877 - Intensity III near Trenton, N.J.

17. September 10, 1877 - Intensity IV-V in the Delaware Valley. Felt from Trenton, N.J. to Philadelphia, over an area 20 miles wide with center near Burlington, N.J.

18. March 25, 1879 - Intensity IV-V in the Delaware Valley, near Dover, Delaware and below Philadelphia. Felt from Chester, Pennsylvania to Salem, N.J., a distance of 30 miles. Felt most strongly on the east side of the Delaware River.

19. October 10, 1892 - Intensity III near Wilmington, Delaware.

20. November 20, 1895 - Intensity IV at Claymont, Delaware and Chester, Pennsylvania; felt at Wilmington, Delaware and Linwood, Pennsylvania.

21. March 17, 1900 - Intensity III near Philadelphia.

22. April 28, 1900 - Intensity III near Philadelphia. Felt at Camden, N.J., southern N.J., and Philadelphia.

23. November 29, 1900 - Intensity III near Philadelphia.

24. February 6, 1909 - Intensity III near Trenton, N.J.

25. January 26, 1921 - Intensity V at Moorestown, N.J. Rumbling noise reported. Felt in Philadelphia. Fissure reported in Burlington.

26. January 24, 1933 - Intensity V near Trenton, N.J. A Sharply felt shock. Pictures thrown from wall at Lakehurst.

27. August 22, 1938 - Intensity V in central New Jersey. Felt throughout central New Jersey, southeastern Pennsylvania, and northern Delaware. Slight damage at Gloucester City and Highstown, N.J., and Ardmore, PA. Four smaller shocks occurred on the 23rd and one on the 27th.

28. November 14, 1939 - Intensity V in Salem County, N.J. Reported felt from Trenton, N.J. to Baltimore, MD., and from Cape May, N.J., to Philadelphia, PA and its adjoining counties. About 6000 square miles were affected. Little or no damage resulted. Intensity V at Deep Water, N.J. where small objects overturned.

29. January 8, 1944 - Felt from Wilmington, Delaware to the southwestern outskirts of Philadelphia. Windows rattled and houses shook.

30. December 27, 1961 - Intensity V near Pennsylvania-New Jersey border. At Bristol and in the northeast portion and suburbs of Philadelphia, buildings shook, dishes rattled, and disturbed objects were observed by many. Police and newspaper offices were swamped with calls from alarmed citizens inquiring about the loud rumbling sounds. Felt by many at Levittown and Langhorne, Pennsylvania and Bordertown and Trenton, New Jersey, where houses shook and creaked, windows and dishes rattled. Felt by several at Burlington.

31. February 28, 1973 - Felt in all or parts of Connecticut, Delaware, Maryland, New Jersey, Pennsylvania, and Virginia. Observers reported cracked plaster at North East and Perryville, MD, and Laurel Springs and Penns Grove, N.J. At Harrisonville, N.J., cinder block basements reportedly cracked. An observer at Palmyra, N.J. reported damage (not described) and that a driveway "dropped 3 inches." At New London, PA, patio, walls, and plaster cracked. "Silent cracks where concrete meets house," loosened rain spouts and cracked plaster were observed by Norristown, PA, residents. At Thornton, PA, pipe connections to a well broke. Two mirrors fell from a wall and shattered at Wallingford, PA. Small objects shifted and fell in several towns in Delaware, New Jersey, and Pennsylvania. Magnitude 3.8.

32. March 2 to May 2, 1980 - Sequence of small earthquakes in the vicinity of Abington, PA. The largest events were on March 5 (magnitude 3.5) and March 11 (magnitude 3.7); both were felt with maximum intensities of IV to V. A small magnitude 3.1 aftershock 13 minutes after the March 5 event was also felt in the Abington area. Bischke (1980) reports that both of the March 5 and 11 events were felt and heard by many people as explosive or low distant rumbling sound. "In one case a plant overturned; in several cases small objects vibrated and shifted slightly on their foundations, plaster cracked and pictures tilted on the walls. In general, windows and dishes rattled, and over half of the people reporting the March 11 event at 1 in the morning were awakened by the earthquake."

33. August 30, 1980 - Event near Medford, N.J.; magnitude 3.0.

The descriptions above discuss all known seismic activity in the Reading-Sinking Spring, Allentown, and Philadelphia areas. As discussed below, none of these seismic activities are associated with any known structures within the context of 10CFR100, Appendix A.

Six events with maximum intensities ranging from II to VI have been tabulated near Reading-Sinking Spring. These occurred between 1906 and 1955 and were located only by sensory reports.

Four shocks of intensities from IV to VI are reported to have occurred in the Allentown area between 1884 and 1961. Only sensory report information constrains the locations of these events.

Estimates of location accuracy for these earthquakes indicate an uncertainty of several miles or more. In addition, small events of this type could easily occur on small dislocations in the earth's crust with no surface representation. Because of their small size and uncertain locations, none of these events are associated with known structures in the context of 10CFR100, Appendix A.

As discussed in Section 2.5.2.3, a number of earthquakes in the site region appear to parallel the NE-SW geologic structural trend in a relatively narrow belt along the axis of the Fall Zone. This belt passes through the Philadelphia area about 30 miles southeast of the site. A total of 33 events and event sequences are noted in this area. These range in size from indeterminate intensity to intensity VII and occurred from 1755 to 1980. For all events before 1973, only sensory report locations are available. For the sequences beginning February 28, 1973 and March 2, 1980, instrumental and intensity report data exist. For a single earthquake on August 30, 1980, only instrumental data was found.

The Philadelphia area earthquakes occurring before the availability of instrumental data are, as with the Allentown and Reading-Sinking Spring events, too poorly located and too small to suggest association with specific known structures in the context of 10CFR100, Appendix A. A similar conclusion is reached for the August 30, 1980 event.

Sbar et al. (Reference 2.5-148) investigated the February 28, 1973 earthquake sequence and speculated that this sequence may have occurred on a northeast continuation of a graben described by Spoljaric (Reference 2.5-149). This continuation coincides with the Fall Zone in the Wilmington, Delaware area. Sbar et al. noted that more accurate locations of earthquakes and extensive mapping of faults are necessary to verify their hypothesis.

Bischke (Reference 2.5-146) investigated the association of the March 2, 1980 sequence with the Huntingdon Valley fault and concluded that the fault should be considered active on the basis of meizoseismal epicenters for several earthquakes of this sequence. Instrumental epicenters lie from several to over ten miles from the Huntingdon Valley fault. Bischke attributes these locations to inadequate instrumental coverage and possible errors in local crustal model velocities. Bischke concludes further that additional study of this fault is warranted.

Although both the 1973 and 1980 sequences have been speculated to occur on specific structures near the Fall Zone in the Philadelphia area, all events of these sequences have been small (less than magnitude 4.0), therefore they are not associated with large source structures. Both sequences have had disparate sensory and instrumental epicenter locations indicating some real uncertainty in the epicenters of these events. Each sequence has been an isolated instance of a cluster of events near a known or postulate structure. For these reasons; it is believed that these earthquakes should not be associated with known structures in the context of 10CFR100, Appendix A. Rather they are seen as part of the historic series of earthquakes near the Fall Zone in the Philadelphia area as noted above.

As discussed below, the April 1982 and March 1980 earthquakes are not correlated with the same structure.

A magnitude of 2.9 earthquake occurred on April 12, 1982 near Burlington, New Jersey. The epicenter was at 40°3.5' N, 74°48.9' W, according to an instrumental location by Lamont-Doherty Geological Observatory. Bischke (Reference 2.5-147) located this event about 6 miles to the west of the instrumental location based on sensory reports. The earthquake was both felt and heard, and many people detected the trembling motion for 5-10 seconds. An intensity of III to IV has been proposed for this event, although intensity V effects were felt locally (Reference 2.5-147).

Bischke (Reference 2.5-147) associates the April 12, 1982 earthquake with the Fall Zone beneath the Delaware River and attributes the failure of the instrumental epicenters to agree with the intensity data to instrumental location errors. This event should not be associated with a particular structure in the context of 10CFR100, Appendix A. Because the March 2, 1980 sequence and the April 12, 1982 event are associated with separate features, it is concluded that they are not correlated.

2.5.2.2 Geologic Structures and Tectonic Activity

2.5.2.2.1 Regional Geologic Setting

The site is located in the Triassic Lowland section of the Piedmont physiographic province of the Appalachian Highlands. The Piedmont is bounded on the southeast by the Atlantic Coastal Plain physiographic province. The Fall Zone, which trends NE-SW approaching within about 30 miles southeast of the site, marks the topographic boundary between the Piedmont and Coastal Plain provinces.

Bedrock in the Piedmont is generally at shallow depth, covered only by a thin veneer of residual soil. In some places, bedrock is exposed. Crystalline Precambrian rocks outcrop to the north and northeast of the site (the Reading Prong) and in a narrow belt parallel to the Fall Zone southeast of the site. The site is located in a down-warped or down-faulted Triassic basin, the Newark Basin, which contains sedimentary rocks, predominantly sandstones and shales. The geologic history of the Piedmont is complex. Major tectonic activity has occurred in the ancient part and many zones of faulting have been identified. Many intrusions are known; for example, the rocks of the Newark

Basin are crossed by numerous dikes and sills, which in some instances have intruded pre-existing faults.

Coastward, the bedrock surface is down-warped to the south and east, with the line of flexure generally within the Fall Zone. In the Coastal Plain, the bedrock is covered by unconsolidated sediments consisting of interbedded silt, sand, and gravel. These sediments form a wedge-shaped mass that thickens toward the southeast. These sediments range in age from Cretaceous to Recent. The down-warping of the bedrock surface of the Coastal Plain has occurred under the weight of accumulating sediments.

There are indications that some down-warp of the coastal plain relative to the Appalachian chain may be occurring today, although no significant crustal warping during Pliocene and Quaternary time is evident in the record of offshore sedimentation (References 2.5-24 and 2.5-25).

North of the site, the Triassic Lowland rocks abut Precambrian crystalline rocks of the Reading Prong, a narrow highland belt separating the Piedmont rocks from the intensely folded Lower Paleozoic rocks of the Great Valley sequence farther north. Westward, Triassic rocks of the Gettysburg Basin lie directly upon recumbent folds and nappes of the Valley and Ridge province.

2.5.2.2.2 Regional Tectonic Provinces

The site lies in a Triassic Lowland section (Newark Basin) of the Appalachian Piedmont tectonic province (Figure 2.5-16). This part of the Appalachian Piedmont in Pennsylvania, New Jersey, and Maryland is typified by the presence of several triassic basins (Culpeper, Gettysburg, and Newark) that have been postorogenically down-warped in the contorted metamorphic and igneous rocks exposed elsewhere in the Piedmont (Figure 2.5-16). Southwest of Reading, Triassic basin sediments of the Piedmont province rest directly on tightly folded and overturned beds of the Northern Valley and Ridge province.

A few miles north of the site, a belt of metamorphosed Precambrian (Grenville) crystalline rock, capped by patches of resistant basal Cambrian quartzite and dolomite, intervenes between the Triassic basin sediments and the slightly metamorphosed, but tightly folded, strata of the Great Valley section of the Northern Valley and Ridge province, here occupied by the Lehigh Valley. This intervening strip of Precambrian rock is the Reading Prong, the southwestern most extension of a distinctive belt of Grenville rocks that forms a series of highlands that can be traced northeastward into western Vermont. Traditionally, the Reading Prong has been viewed as a physiographic and lithologic extension of the crystalline rocks of the New England Appalachians.

Precambrian rocks also occur along South Mountain, southwest of Harrisburg. Here they form the northeastern arm of the Blue Ridge tectonic province, an anticlinorium of late Precambrian metavolcanics (greenstones) and associated Grenville age rocks, enclosing the southwestern flank of the Gettysburg Basin. Grenville rocks may possibly persist in a continuous zone from the Blue Ridge province to the Reading Prong-Hudson Highlands-Green Mountain belt, but if so, the relationships are obscured beneath the Triassic sediments of the Newark and Gettysburg Basins.

Proceeding northwestward from the site, across the folds of the Northern Valley and Ridge province, the folds are at first appressed and complexly faulted in the Great Valley belt but become more open farther northwest, where they assume their classic cylindrical forms. Beyond the Allegheny front (Figure 2.5-16), the folding at once becomes open and subdued, with the strata descending into a broad, gently folded basin or synclinorium. Classically this region of broad, gentle folding is part of the Appalachian Plateaus, though truly undeformed Paleozoic strata lie as much as 100 miles further beyond the Allegheny front.

Southeast of the site, the wedge overlap of Coastal Plain strata on the Piedmont crystalline rocks is about 30 miles distant; beyond, undeformed Lower Cretaceous through Recent sediments of the Atlantic Coastal Plain province thicken uniformly seaward.

The New England part of the Appalachian orogenic belt is an extensive terrain composed predominantly of metamorphic rocks, with lesser amounts of igneous and sedimentary rocks included. Like the rest of the Appalachian orogen, the New England Appalachians (Figure 2.5-16) are characterized by elongated structural systems and tectonic belts; however, the dominant orientation of these features, at least in the southern and western parts of the New England Appalachians, is more nearly north-south than NE-SW, as it is in most of the Appalachians. Recent application of plate-tectonic concepts to New England geology has led to a recognition of several fundamentally distinct crustal units within the New England Appalachians (References 2.5-26, 2.5-27, and 2.5-28). Several investigators have used findings to subdivide the New England Appalachians into tectonic provinces (for example, see Reference 2.5-29. The provinces are not discussed in this report since, for the reasons explained in Section 2.5.2.3, the detailed subdivision of the New England Appalachians is not significant to the LGS site.

2.5.2.2.3 Regional Tectonic Structures

Faulting of Precambrian age undoubtedly exists in the Piedmont, but the rocks of the Piedmont have been so metamorphosed since that time that no significant Precambrian faults are recognizable. Paleozoic faults generally are characterized by thrusting toward the northwest, a reflection of compressional forces imposed during the late Paleozoic (Alleghenian) orogeny, as well as during earlier tectonic events.

These thrusts are especially well displayed in the Northern Valley and Ridge province, just northwest of the Blue Ridge-Reading Prong anticlinoria, where the compressive forces in the sedimentary pile were at a maximum. In the Valley and Ridge provinces, thrusting is believed not to have involved basement rocks; rather, the foreshortening necessitated by the great Valley and Ridge folds is thought to have been taken up by buried ramp thrusts riding over incompetent shale lying on top of the basement rocks (References 2.5-13 and 2.5-30). Highly complex fault patterns are also displayed in the Precambrian rocks of the Blue Ridge and Reading Prong anticlinoria; their appearance attests to the fact that basement rocks were very much involved with thrusting southeast of the Great Valley. Southeastward, in the Appalachian Piedmont, the crystalline rocks have been subjected to multiple deformational and metamorphic episodes the Paleozoic, and many zones of pre-Triassic faulting have been identified.

Recent studies using COCORP (Consortium for Continental Reflection Profiling) seismic reflection data suggest that the entire Blue Ridge and at least part of the Piedmont of the southern and central Appalachians are allochthonous, underlain at several kilometers depth by a regional decollement which was active during the Alleghenian orogeny. This same decollement would extend westward beneath the Valley and Ridge province, where upward-splaying ramp thrusts, listric into the decollement, absorbed the westward translation and crustal foreshortening achieved along the decollement, thereby producing the well-known thrust fault and fold pattern of the Valley and Ridge province.

The closest major mapped fault of Paleozoic age is the Brandywine Manor fault, which approaches within about 9 miles to the southwest of the site. The Huntington Valley-Cream Valley fault (and the related Rosemont fault) approach within about 15 miles to the south of the site. None of the major Paleozoic faults has a mapped extension eastward into the Triassic Newark Basin. These

faults have been completely healed and are inactive. Some major thrust faults are transected by subsequently intruded Triassic-age dikes that show no displacement.

Faults of Triassic-age occur within the Newark Basin (Figures 2.5-2 and 2.5-38). The most significant of these to the east of the site. The Chalfont fault is the closest of these, approaching within about 9 miles to the northeast of the site. Some minor Triassic faults exist closer to the site (Figure 2.5-6). Some of these faults have developed along the major joint systems in the Triassic rocks. In some instances, Triassic-age dikes have intruded along some of these fracture zones, thus indicating their lack of activity since the Triassic (more than 140 million years ago). These minor faults are discussed in Section 2.5.1.2.3.

Faulting younger than Jura-Triassic is reported in a few places in the Coastal Plain. Reported displacements are steeply dipping; reverse motion on northeast-trending planes has occurred in some instances. All such displacements are minor compared to older faulting. Within 200 miles of the site, these faults include the Brandywine fault (140 miles southwest of the site), the Stafford fault system (150 miles southwest of the site), and the New York Bight fault (off the New Jersey coast, about 100 miles east of the site). On none of these is there unequivocal evidence for latest movement younger than Miocene, or possibly no younger than Paleocene or early Eocene (Section 2.5.1.1.3).

A postulated major east-west fault zone, named the Cornwall-Kelvin wrench fault, has been suggested to extend through the Triassic Lowland of southeastern Pennsylvania. The postulation of this fault zone is based on subsea topographic and geophysical surveys. However, there are neither geological nor geophysical bases for projecting this postulated fault zone into the continent.

Two small faults occur in the Newark Basin near the site: the Sanatoga fault, in the northwest portion of the site; and the Brooke-Evans fault, in the southeast portion of the site. The maximum displacement along these faults is about 350 feet. The Sanatoga fault has been intruded by the Triassic-age Downingtown Dike. These faults were investigated by Dames and Moore (Reference 2.5-1) and evaluated by an independent review committee consisting of experts in Appalachian geology. The review committee concluded that these faults are closely related to the well-dated Jura-Triassic dikes injected along them.

Geologic structure is discussed further in Sections 2.5.1.1.3 and 2.5.3.

2.5.2.3 Correlation of Earthquake Activity with Geologic Structures or Tectonic Provinces

As shown in Figure 2.5-14, the trend of epicenters in the site region is generally NE-SW, parallel to the trend of geologic structure in the Appalachian Mountains. As a particular example, within 100 miles of the site there appears to be a pattern of seismicity paralleling geologic structure in a relatively narrow belt, roughly along the axis of the Fall Zone. At distances greater than 100 miles northeast of the site, the seismicity becomes more diffuse and scattered throughout that part of the New England Appalachians within 200 miles of the site. To the southwest of the site, at distances greater than 100 miles, the seismicity is again more diffuse and, moreover, there are fewer events until the Virginia Piedmont is reached just beyond the 200 mile radius. A modest clustering of historic earthquakes occurs here, in the general area of Richmond, Virginia. Finally, both to the southeast and northwest of the Fall Zone, there is scattered earthquake activity within the Coastal Plain and Appalachian physiographic provinces, respectively.

The earthquake activity in northeastern Massachusetts, although well in excess of 200 miles from the site, has been considered. In November 1755, an intensity VIII earthquake occurred offshore

near Cape Ann, at least 300 miles from the site. This is the largest historic earthquake known to have occurred in the New England region. It has been associated variously with the Southeastern or Avalon Platform tectonic province, a Cape Ann-New Hampshire tectonic province (each more than 200 miles from the site) (Reference 2.5-29), an east-west zone of intense thrust and strike-slip faulting (Reference 2.5-31), a northwest trending seismic and plutonic zone (Reference 2.5-32), and a specific plutonic structure (Reference 2.5-33). None of the above alternatives would relate the event to provinces or structures that are closer than 200 miles from the site; therefore, the 1755 Cape Ann event is not significant to the site.

2.5.2.3.1 Tectonic Models Relating Seismicity to Geologic Structure

A number of widely divergent hypotheses have recently been advanced relating seismicity in the Appalachian region to specific geologic structures. Direct field evidence, such as surface faulting or fault-generated topographic features, has not been found. This wide divergence of opinion results because of the limited data base available and because the hypotheses are constructed largely from permissive rather than compelling evidence. These hypotheses have been summarized and evaluated previously by others (Reference 2.5-79).

The hypotheses that have been advanced can be grouped into one of four general mechanisms: (1) reactivation of steep basement faults, (2) decollement reactivation, (3) stress amplification at the margins of mafic and ultramafic intrusions, and (4) subsidence of the continental margin. The following discussion reviews and assesses these hypotheses.

2.5.2.3.1.1 Reactivation of Steep Basement Faults

Steeply dipping, northeast-trending faults exhibiting Cretaceous and Cenozic displacement are present in the Atlantic Coastal Plain. Several authors suggest that the faults are a reactivation of former basement structures and relate historic seismicity to recurrent movement on these faults.

Cretaceous and Cenozoic displacement is indicated from geologic and seismic reflection data for a number of faults, including the Stafford fault zone (References 2.5-110, 2.5-106, and 2.5-107), the Brandywine fault zone (Reference 2.5-98), and the New York Bight fault (Reference 2.5-96) within 200 miles of the site; and south of the 200 mile radius, the Belair fault zone (in Georgia) (References 2.5-114, 2.5-111, and 2.5-115) and the Cooke and Helena Banks faults (onshore and offshore South Carolina, respectively) (References 2.5-68 and 2.5-69). The faults displace strata as young as Eocene or Miocene in age and, in possibly two cases (New York Bight and Stafford faults), as young as Pliocene or early Pleistocene in age. (The interpretation of Plio-Pleistocene movement on the Stafford fault zone discussed in Reference 2.5-107 seems questionable in view of several trenches across the same fault which show no such offset (Section 2.5.1.1.3).) Wentworth and Mergner-Keefer assume these faults have experienced recurrent movement, based on the indication of smaller displacements on them in younger strata.

Zoback and Zoback (Reference 2.5-140) suggest that if these faults are zones of weakness, they may localize stress and cause brittle failure (earthquakes) in the upper crust. Wentworth and Mergner-Keefer (References 2.5-134 and 2.5-135) further suggest that a domain of northeast-trending, specifically reverse faults exists along the east coast, in keeping with the inference by Zoback and Zoback of persistent NW-SE regional compression. They point out that northeast-trending reverse faults in the basement must have been reactivated by compressive stresses. They propose that the reactivated basement structures are most likely to be normal faults associated with Triassic and possibly Precambrian rifting. (It should be noted, however, that evidence for reverse displacement on the Helena Banks fault is quite tenuous, and there is no

indication that the New York Bight fault is reverse. Furthermore, there is no convincing proof of post-Miocene offset on any of the investigated reverse faults.) Mergner-Keefer (References 2.5-134 and 2.5-135) propose that historic seismicity in the eastern U.S., including the 1886 Charleston event, is related to continued reactivation of these reverse faults but that long periods of quiescence and small cumulative offsets make it difficult to recognize surface rupture and to document historic fault activity.

In support of their reactivation hypothesis, Wentworth and Mergner-Keefer infer the existence of a persistent, northwest directed regional compressive stress-field by reference to focal mechanism solutions, and to orientation and sense of displacement of Cretaceous and Cenozoic faults. In particular, they refer to focal mechanism solutions in the Giles County, Virginia seismogenic zone (Reference 2.5-70) and the Newark Basin area (References 2.5-63 and 2.5-119), and selected solutions from the Charleston, South Carolina area (Reference 2.5-131), and conclude that reverse faulting on northeast-trending high angle or subhorizontal faults is the predominant mode of contemporary fault movement.

However, the evidence is not fully supportive of such a regional stress regime. As Stephenson and Pratt (Reference 2.5-127) and Talwani (Reference 2.5-129) note, fault-plane solutions in the southeast imply considerable local variations in stress; for example, the data from Monticello Reservoir in central South Carolina and from Lake Jocassee in northwest South Carolina imply northeast directed compression, as does hydrofacturing and overcoring data at Bad Creek (Reference 2.5-130). At Charleston itself, focal mechanism solutions strongly favor northwest-oriented fault-planes (northeast compression). Tarr et al (Reference 2.5-131) consider that all except three of 16 solutions define relatively well constrained, northwest-oriented faulting, whereas but two solutions, defining a nearly vertical plane loosely constrained between a northwest and an E-NE strike, merely permit inference of northeast-trending faulting. Tarr et al (Reference 2.5-131, p. 1895) in this latter case select the northeast, rather than northwest trend on the basis of evidence (geophysical) unrelated to focal mechanism solutions. The favored indication of northwest-trending structure is corroborated by recent detailed focal plane studies by Talwani (Reference 2.5-129) which imply shallow northwest-oriented, steeply dipping reverse faulting and deep-seated, northeast-oriented strike-slip (but not reverse) faulting.

In summary, the hypothesis of Wentworth and Mergner-Keefer that contemporaneous northwest directed crustal compression causes large eastern U.S. earthquakes by reverse reactivation along steep basement faults has a number of inconsistencies. Among these are:

a. Even with a long recurrence interval of 500,000 to 1 million years and a displacement rate of 0.35-0.5 m per million years on the reactivated faults (Reference 2.5-134), many late Cenozoic displacements should be evident. However, there is little convincing evidence for post-Miocene offset on any of the recognized Cenozoic reverse faults. Consequently, there is little basis for extrapolating continued movement from Miocene to the present time on reverse faults presumed to be present throughout the eastern U.S. Therefore, there is little justification for associating present day seismicity with these faults.

b. Implicit in the model is regional NW-SE directed compression. However, several authors describe either random and weak regional compression (Reference 2.5-83) or NE-SW directed compression (References 2.5-127, 2.5-129, and 2.5-132).

c. To the extent that NW-SE compression in the central and southern Appalachians is postulated to exist based on the premise of indicated northeast-trending

Cretaceous and Cenozoic reverse faults (Reference 2.5-140), this inferred compressive stress direction cannot then serve as evidence to justify postulating the existence of additional, as yet undiscovered reverse faulting (References 2.5-134 and 2.5-135).

d. NW-SE regional compression, required by the model, is not consistent with subsidence known to be occurring in regions along the Atlantic Coast. Subsidence implies a tensional horizontal stress regime with associated normal faults.

e. Composite focal mechanism solutions by Talwani (Reference 2.5-129) suggest that northeast-trending reverse faults are not active in the Charleston area. Instead two clusters of seismicity are present: a shallow cluster (4-8 km) which defines a northwest-trending reverse fault, and a deep cluster (9-13 km) which defines a northeast-trending strike-slip fault. Either the Charleston area is unique or the reactivation model is not regionally applicable. Furthermore, composite fault-plane solutions by Tarr et al (Reference 2.5-131) show two relatively well constrained vertical nodal plane striking northwest. Even if Wentworth and Mergner-Keefer's hypothesis were correct, it does not appear to be applicable to the Charleston area.

f. The present day Charleston seismogenic zone trends northwest (Reference 2.5-131), rather than northeast, and composite focal mechanism solutions suggest that the seismic activity is associated with a northwest-trending structure (References 2.5-129 and 2.5-131). In addition, the extended meizoseismal area of the 1886 earthquake trends northwest (References 2.5-123, 2.5-65, and 2.5-124). Thus, although seismic reflection data show structures trending both northwest and northeast, there is little evidence associating either the 1886 earthquake or recent seismicity to a northeast-trending structure.

One of the few, and certainly one of the best documented, instances of possible relation of seismic activity to tectonic structure involves the Ramapo fault in northern New Jersey (Figure 2.5-38). This activity, detected by seismic network monitoring for microearthquakes (Nuttli magnitude less than 3) appears to be concentrated near the trace of the Ramapo fault and its northern splays east of the Hudson River (Reference 2.5-119). Hypocentral locations of microearthquakes near the fault appear to fall approximately on the downward projection of mapped dips on the Ramapo and associated Paleozoic shear zones (Reference 2.5-119, figure 4). Nodal plane solutions for three microearthquakes positioned close to the fault indicate reverse-slip (Reference 2.5-137, figure 14).

In contrast, macroseismicity shows no obvious tendency to cluster near the Ramapo zone. Historical earthquakes with epicentral locations within at least 25 kilometers of the Ramapo do not exceed intensity VI (Reference 2.5-82, figures 1 and 2). Considering the complete record, many of the microearthquakes recorded by the seismic network (including those with reverse-slip fault-plane solutions) are located at considerable distance from the Ramapo fault system. Further, there have been some earthquakes located close to the Ramapo that have fault-plane solutions indicating reverse-slip on northwest trending, southeast dipping planes (Reference 2.5-82). Thus, the record shows a diffuse scattering of historical epicenters in the region, with a clustering of some, but by no means all, of the detected small earthquakes along the Ramapo.

It is interesting to examine the geologic evidence for offset along the Ramapo. Detailed mapping of the area in the vicinity of the Ramapo, including trenching and examination of drill cores across the Ramapo fault, have revealed no evidence of reactivation along the Ramapo fault surface. In drill hole cores which penetrated the actual fault contact (cataclastic Triassic fanglomerate over

gouge over phyllonitized basement rock), the last recorded displacement is normal; no evidence of reverse reactivation is seen (Reference 2.5-119, figure 7). No instance has been discovered of offset glacially polished surfaces or of offset surficial deposits in natural exposures or in trenches across the trace of the Ramapo fault (Reference 2.5-119, p. 282). Ratcliffe (Reference 2.5-119, p. 281) concludes, "my present feeling is that we have not yet demonstrated either from experiment, theory or empirical observation that the premise restricting seismic activity to surface brittle fracture zones (e.g., Ramapo fault) is at all valid."

2.5.2.3.1.2 Decollement

Recent seismic reflection profiles reveal the presence of a low angle detachment surface or decollement beneath much of the southern and central Appalachians (References 2.5-88, 2.5-76, 2.5-77, 2.5-78, and 2.5-75). The decollement was active primarily during the Alleghenian orogeny when rocks of the Valley and Ridge, Blue Ridge and Piedmont were thrust tens of mile to the west and northwest (Reference 2.5-92). Harris and Bayer (Reference 2.5-88) and Cook and others (Reference 2.5-77) suggest that the decollement may extend from beneath the Valley and Ridge to the continental margin. Recent seismic profiles from the Coastal Plain and continental shelf, although not conclusive (Reference 2.5-97), appear to substantiate this eastward extent (References 2.5-78, 2.5-67, 2.5-68, 2.5-69, 2.5-121, and 2.5-122). The postulated depth of the decollement based on those profiles beneath Charleston, S.C., also agrees well with a seismic velocity discontinuity at about 10 km depth observed by Talwani (Reference 2.5-129).

Several authors suggest that seismicity in the eastern U.S. is caused by reactivation of the decollement (References 2.5-68, 2.5-69, and 2.5-123). The decollement is a fundamental mechanical discontinuity in the crust and if it has not been disrupted by subsequent Mesozoic extensional faults or intrusive complexes, it may be a zone of crustal weakness susceptible to reactivation by properly oriented intraplate stresses. Reactivation would be in either a forward (thrust) sense in response to NW-SE regional compression (Reference 2.5-68) or in a gravity-driven backward sense (References 2.5-123, 2.5-65, and 2.5-124). Large earthquakes such as the Charleston 1886 event would represent displacement or slippage on the decollement.

The decollement reactivation hypothesis as thus proposed may not be incompatible with the reactivation of steep basement faults. Seismic reflection profiles suggest that many high angle faults are listric into the decollement (Reference 2.5-78). Movement on the high angle faults would thus be viewed as second order displacements (but capable of producing earthquakes) accommodating horizontal movement on the decollement (Reference 2.5-68, pp. 121-122). Noting that at least one listric fault appears to project to a Triassic basin border fault, Cook et al (Reference 2.5-78, p. 742), speculate that perhaps the listric thrust (reverse) faults were reactivated during Mesozoic rifting as listric normal faults to produce the Triassic basins.

The following geologic and seismic data are cited as evidence supporting decollement reactivation: (1) the decollement is the most likely fault that could achieve significant differential offset without producing surface displacement. (2) Common to all the focal mechanism solutions supporting displacement on high angle northeast-trending reverse faults (References 2.5-132, 2.5-70, and 2.5-63) is one subhorizontal nodal plane which supports displacement on the decollement. (3) Seismic reflection profiles indicate the structural disruptions and other geometric impediments to reactivation are not present across the decollement (References 2.5-78, 2.5-123, and 2.5-140). (4) Releveling data by Citron and Brown (1979) indicate that vertical crustal movements as far west as the Blue Ridge front may be related to gravity-induced back-slip along the decollement (Reference 2.5-123). The maximum primary stress orientation may be different above and below the decollement supporting a decoupled upper sheet (Reference 2.5-123).

On the other hand, active movement along a decollement appears unlikely for the following reasons:

a. Continuation of the decollement beneath the coastal plain is not certain. The subhorizontal seismic reflectors representing the decollement (Reference 2.5-78) widen, become discontinuous and dip steeply southeastward beneath the outer Piedmont where magnetic and gravity data have been interpreted to suggest a root zone (References 2.5-102, 2.5-92, and 2.5-93). Recent palinspastic restorations of the crust by Iverson and Smithson (Reference 2.5-97) indicate that the decollement is rooted to the east beneath the outer Piedmont and does not extend to the east beneath the Coastal Plain.

b. Although Cook et al (Reference 2.5-78) and Seeber and Armbruster (Reference 2.5-123) suggest that no offsets of the decollement or other geometric impediments to reactivation exist, figure 7 of Reference 2.5-78 seems to show a series of normal faults within the inner Piedmont which displace basement Precambrian Grenville rocks as well as overlying Precambrian and Paleozoic sedimentary rocks beneath of the decollement. If these extensional faults are related to Mesozoic rifting, which they appear to be because they displace Paleozoic strata, then they must also displace the overlying decollement. Ellwood et al (Reference 2.5-81) also cite paleomagnetic data, radiometric age data and geologic relationships indicating that a major, relatively undisplaced intrusive complex has been emplaced through the decollement. Mafic dikes and aulocogens related to Mesozoic rifting (Reference 2.5-117) would also have to be truncated after rifting. It is not probable that gravitational back-slip could overcome these impediments to reactivation, and it is difficult to account for a source of relatively shallow crustal compression of a passive, presumably subsiding continental plate margin.

c. Seismic data from the Giles County, Virginia seismogenic zone are not consistent with decollement reactivation. Hypocentral depths range from 5 km to 25 km (Reference 2.5-70) which places it beneath the decollement in the crystalline basement under the deformed Paleozoic sediments of the Valley and Ridge province.

d. Seeber and Armbruster (Reference 2.5-123) speculate that the stress-field above and below the decollement may differ. Composite focal plane solutions from the Charleston area, however, indicate a consistent orientation of maximum stress across the postulated depth of the decollement suggesting that there is no decoupling of the stress-field (Reference 2.5-129).

e. If gravitational backsliding is responsible for seismicity, then extensional stresses resulting in normal faulting should be evident in the overthrust plate. However, many focal mechanism solutions indicate reverse displacements in the overthrust plates, and geologic and geophysical evidence suggest that some Cenozoic faults in the overthrust plate have reverse displacements (References 2.5-134 and 2.5-135).

f. It does not seem likely that the gravitational force resolved parallel to the postulated, extremely low angle decollement is sufficient to overcome normal frictional shear resistance of rock materials within the decollement.

Deep seismic reflection data (COCORP and other lines) suggest that the central and southern Appalachian system, including at least the Blue Ridge and inner Piedmont provinces, are underlain at depth by a low angle regional thrust, or decollement, resting on relatively unmetamorphosed sedimentary rocks, extending westward beneath the Valley and Ridge province. This decollement was presumably active during the Alleghenian orogeny at the end of the Paleozoic Era; ramp-like displacements branching upward from the decollement produced the well-known thrust sheets of the southern Appalachian Valley and Ridge and were taken up as faulted anticlinal folds in the central Appalachians. The eastern extent, or "root zone", of the decollement is a matter currently in dispute (Section 2.5.1.1.3). The inclination of the decollement plane is flat; profiles (Reference 2.5-78, figure 7, and Reference 2.5-88, figure 5) show it to be a horizontal to subhorizontal surface, broken perhaps by local offsets or minor ramps, but not exceeding about 2½° overall, sloping gradually downward to the east.

This new evidence of a decollement east of the Blue Ridge helps to explain the mechanics of the Alleghenian orogeny. Heretofore it has been difficult to explain the large-scale westward thrusting that produced the Valley and Ridge structures in late Permian or early Triassic time, in the face of so little surface evidence for such thrust faulting, or for a source of compression, in the metamorphosed rocks to the east, which show abundant evidence of only earlier Paleozoic orogenies. On the other hand, its relevance, if any, to current seismicity is unclear. Speculations that gravity-induced backsliding may be occurring on the decollement and thereby causing earthquakes, in particular the Charleston event of 1886 (References 2.5-123 and 2.5-124) seem implausible in view of the extremely low coefficient of friction that would be necessary for gravitational slippage to occur on a subhorizontal plane, even discounting structural and lithologic impediments that would be expected to exist along the decollement surface. Similarly, the inverse hypothesis of a compressional reactivation of the decollement proposed in Reference 2.5-68 to account for events such as Charleston seems improbable. The source of such compression at the edge of a passive, presumably subsiding continental margin acting on a relatively shallow crustal feature is difficult to envision.

The possibility of a continuation of the Alleghenian decollement into the New England Appalachians is not in accordance with recent studies (Reference 2.5-133). Such decollements as may occur there relate to the Taconic orogeny (Reference 2.5-26); these are found along the western and northern margin of New England (References 2.5-133 and 2.5-136), east of Logan's line. Subsequent Acadian orogeny and metamorphism (Reference 2.5-26) have obliterated the regional mechanical significance of such decollements, and there is no evidence of extensive regional Alleghenian thrusting in New England. As pointed out in Reference 2.5-28 and by others since 1975, strike-slip rather than thrust faulting appears to have characterized at least the latter part of late Paleozoic deformation in New England. This deformation is best developed as displayed in eastern New England and as inferred in the Gulf of Maine.

The idea of reverse reactivation of pre-existing NE-SW striking faults generated by inferred, present day NW-SE oriented regional crustal compression has gained popularity with some investigators (References 2.5-140, 2.5-134, and 2.5-135). Early Mesozoic (i.e., Jura-Triassic) faults having this orientation are attractive candidates because they presumably had a deep-seated origin related to continental rifting, but other smaller faults seaward of the edge of the Coastal Plain showing evidence of reverse offset of Cretaceous and younger strata are also considered, provided they have the appropriate NE-SW strike.

It seems somewhat presumptuous to define by inference a regional stress-field on the basis of fault orientation, or even of focal plane mechanism solutions, in the Appalachians. The reason is that

the occurrence of strain release of modern stress would be expected to be constrained by the existing structural planes of rock weakness, regardless of the "real" stress orientation, provided the stress levels are moderate, as seems appropriate for a passive continental margin. Because the structural grain of the Appalachians, which was imposed during Paleozoic orogenies, has a very pronounced and persistent NE-SW orientation, often almost to the exclusion of other trends, earthquakes in the Appalachians occur mostly on NE-SW trending planes. The same problem exists when the argument is turned around to infer the orientation of modern stresses from the trend and sense of displacement of existing faults (for example, faulting of coastal plain strata) because presumably these faults are simply new expressions of old basement faults that have been reactivated. If the faults do not extend to basement, they are of no significance.

Here there is an additional critical problem; namely, the justification for assuming that displacements for which there is no proof of movement over the past several million to several tens of millions of years have any meaningful relationship to modern stresses or seismicity.

In References 2.5-134 and 2.5-135, it states that a northeast- trending reverse fault may have been responsible for the Charleston event of 1886 and cites the inference of existing northwest directed compressive stress in the eastern U.S. from focal plane and fault orientation studies (Reference 2.5-140). They review the evidence indicating Cretaceous and Cenozoic reverse offsets on NE-SW trending faults in the eastern U.S. and propose that such faults should be viewed as potential sources of large earthquakes, such as the Charleston event of 1886. Their conclusion is based on dating different measured displacements on the same or different faults and deriving rate curves, extrapolating continued episodic movement to the present from the most recent documented movement on any of the faults (Reference 2.5-134, figure 5). These rate curves are assumed to represent a hypothetical family of both known and as yet undiscovered NE-SW reverse faults, an assumption Wentworth and Mergner-Keefer consider reasonable in view of the limited area for which such documentation can be obtained.

Critical to the presumption (References 2.5-134 and 2.5-135) of significant potential for present day movement on these hypothetical faults is the age and amount of the most recent offset plotted in their data set because the older and smaller an offset is, the less justification there is in presuming continued activity to the present. They (Reference 2.5-134, figure 5) present only one data point younger than Eocene: namely, an offset measured at an exposure of the Stafford fault system in Virginia. This particular exposure, which occurs along the Fall Hill fault of the Stafford fault system, is diagrammed in a field trip guide by Mixon and Newell (Reference 2.5-107, figure 7). It shows a sharp, 14 inch projection of metamorphic rock (gneiss) upward into overlying upland gravels (late Pliocene to early Pleistocene in age), consistent with the gneiss having moved upward in a reverse sense on a steep, west dipping plane. Below this, the metamorphic rock has been reverse-faulted against Cretaceous alluvial deposits (Potomac Group) with obvious deformation and significant offset. However, the above described offset in the overlying fluvial gravels apparently is accompanied by little or no deformation, in that no shear planes are shown in Reference 2.5-107 extending upward into the gravel along the plane of the fault, and the gravels in the sketch appear structureless or vaguely "draped" across the offset. Thus, it would seem that an equally plausible

explanation for the origin of the "offset" in the gravels is that it is an erosional feature, particularly when one considers the contrast in erodability between the Cretaceous sands and the metamorphic rock, the relatively high energy depositional environment of the gravels, and the presence of angular metamorphic boulders in the gravel (Reference 2.5-107, figure 7).

This alternative explanation is reinforced by the trenching across the Fall Hill fault that was performed by Dames and Moore (Reference 2.5-113). In the three trenches that exposed the base of the Plio-Pleistocene alluvial gravels resting on the trace of the Fall Hill fault, the gravels were plainly not offset across the trace of the fault.

The above evidence calls into question the validity of the single data point younger than Eocene (40 million years) of Wentworth and Mergner-Keefer's rate curve (Reference 2.5-134, figure 4) for reverse fault movement. Therefore, there is no solid evidence for movement younger than Eocene on any of the NW-SE trending faults used by Wentworth and Mergner-Keefer in their analysis. Such faults should not be considered to be capable within the content of the siting criteria.

The basis for presuming that the Charleston seismicity is associated with a northeast-trending structure is also questionable. Although Wentworth and Mergner-Keefer cite the data of Tarr et al (Reference 2.5-131) in support of a northeast structure, Tarr et al include only three of a total of 16 focal mechanism solutions from the Middleton Place-Summerville (i.e., Charleston) area in such a trend; moreover, Tarr et al choose this trend not so much from focal mechanism solutions but from gravity anomalies and inferred fault trends (Reference 2.5-131, p. 1892, 1898). Specifically, Tarr et al state that the three focal mechanism solutions are "consistent with early vertical faulting on a plane striking northwest to E-NE, with one inconsistency... A nearly vertical E-NE striking plane was chosen because of independent geophysical evidence..." (Reference 2.5-131, p. 1892). The other 13 focal mechanism solutions which Tarr et al studied define two alternate, relatively well constrained nodal planes that strike northwest, thus implying a stronger likelihood of northwest-faulting at Charleston, and suggesting the presence of unique structure. This is further corroborated by recent detailed focal plane studies by Talwani (Reference 2.5-129), with no evidence found for northeast-trending reverse faulting. It does define reverse motion along a relatively shallow, steeply dipping northwest-oriented plane and strike-slip motion along a deeper, northeast-trending plane. Therefore the Charleston area, rather than being structurally and tectonically typical for the Coastal Plain and surrounding region, seems more likely to be just the opposite, based on current data and analysis.

2.5.2.3.1.3 Stress Amplification at the Margins of Mafic Plutons

The presence of mafic plutons in certain areas of historical or current seismic activity, such as in the New Madrid area and at certain locations in New England, has been pointed out by a number of observers; whether these plutons have the capacity to localize earthquakes is a matter of considerable conjecture. Investigators have suggested that stress is mechanically concentrated in or near the plutons because of contrasts in elastic moduli with the surrounding country rock (References 2.5-103, 2.5-104, and 2.5-99). They theorize that the stress concentrations may be sufficiently high to result in earthquakes.

According to these stress modeling studies, stress can be concentrated in or near mafic plutons by one of three methods: (1) The instructions are "softer" or less rigid than surrounding rocks because of serpentinization, and deform by creep rather than fracture. Stress is thus concentrated in the more rigid country rock surrounding the intrusion (Reference 2.5-99). (2) The intrusions are "stiffer" or more rigid than the surrounding rocks and stress is concentrated within the intrusion (References 2.5-104). (3) The intrusions are weakened by pervasive fracturing and high pore pressure caused by residual volatiles associated with their origin and emplacement. Stress is therefore concentrated in the more rigid country rock.

McKeown (References 2.5-103 and 2.5-104) studied the association between mafic plutons and seismicity primarily in the New Madrid and Charleston area on the basis of geologic, gravity, aeromagnetic and seismic data. He noted that the trend of nodal planes of many fault-plane solutions coincides with the trend of many mafic dikes. He suggests that earthquakes are controlled by the presence of mafic intrusions and that ancient rift zones may have been the primary control for the location of the intrusions.

References 2.5-132, 2.5-118, 2.5-62, 2.5-128, 2.5-101, 2.5-102, and 2.5-140 also report an empirical spatial association of seismicity and mafic plutons interpreted from surface exposures and shallow source gravity and magnetic anomalies. Tarr and Rhea (Reference 2.5-132) further note that in the broad areas of flat or negative anomalies, seismicity is lacking. They indicate that, although earthquakes in the Piedmont tend to be scattered, those in the Coastal Plain tend to Cluster. They interpret the clustering to result from localized stresses on or near intersecting faults and mafic plutons.

Kane (Reference 2.5-99) speculated that the mafic bodies at Charleston are serpentinized. Analytical modeling by Campbell (Reference 2.5-73) supports Kane's hypothesis as an explanation for the Charleston earthquake. Kane suggests that the lack of seismicity at other geophysically inferred mafic and ultramafic plutons is due to the lack of serpentinization, an insufficiently large or randomly changing stress-field, or inappropriate geometric relations between the intrusive body and stress-field direction.

The stress amplification hypotheses are beset with a number of uncertainties and unknowns due chiefly to insufficient information. Some of the major problems and uncertainties are:

a. In most cases where earthquakes are clearly related to geologic structures, the earthquakes occur along planes or zones of weakness (i.e., faults) rather than in areas of concentrated stress in the neighborhood of relatively rigid bodies.

b. Although some intrusions are spatially associated with seismicity, there are many large and small intrusions (such as the Cortlandt Complex near the Ramapo fault, Reference 2.5-120) which are either not associated with seismicity or have no effect on localizing seismicity.

c. Presently it does not appear feasible to obtain field data in sufficient to test the proposed models.

d. Mafic/ultramafic intrusions are common in zones of crustal rifting. If seismicity is caused by the reactivation of basement structures such as triassic association of seismicity with mafic/ultramafic plutons may be simply a secondary coincidence.

e. The inferred mafic/ultramafic bodies are not necessarily localized intrusions. The mafic body beneath Charleston penetrated by core holes in a Jurassic basalt flow. The flow is laterally continuous beyond the limits of concentrated historic seismicity (References 2.5-78, 2.5-122, and 2.5-68).

2.5.2.3.1.4 Subsidence

Several workers have noted that east coast seismicity may be spatially associated with subsiding embayments on the Cretaceous continental margin and Triassic basin border faults inland from the

continental margin. They suggest that the seismic activity may represent minor adjustments in the crust associated with continued opening of the Atlantic Ocean.

Barosh (Reference 2.5-66) empirically observed the relationship between seismicity and structural depressions. He hypothesizes that current seismicity along the Atlantic seaboard is caused by small-scale vertical movements within pre-existing fracture zones and subsiding embayments. The seismicity, for example, is concentrated along the northeastern margin of the subsiding Southeastern Georgia Embayment.

Following the Triassic-Jurassic extension that resulted in the development of Triassic basins and the Atlantic Ocean, the trailing continental margin has sagged and accumulated a mantling wedge of Cretaceous and Tertiary sediment. Subsidence of the margin may be due to sediment loading (Reference 2.5-126), thermal contraction (Reference 2.5-125), thermally induced phase changes (Reference 2.5-109), or oceanward creep of lower continental crust due to gravity (Reference 2.5-71). Barosh (Reference 2.5-66) suggests that seismicity is localized in those areas along the coast where the lowlands are subsiding over the ancestral margin of the continent.

Subsidence in areas along the Atlantic coast is known to be occurring (Reference 2.5-95). Subsidence as a cause for seismicity, however, is not consistent with several facts and observations:

a. Many focal mechanism solutions indicate reverse displacement on either high angle or low angle faults. Reverse displacement is not consistent with a tensional, subsiding stress regime.

b. Many observed Cenozoic faults in the Coastal Plain have reverse and not normal displacement.

c. The nearly aseismic nature of the offshore region (continental shelf) where subsidence has been greatest argues against subsidence as a primary cause of seismicity.

2.5.2.3.1.5 Conclusion

Although the recent geologic and geophysical data summarized above demonstrate the significant role of compressional and extensional deformation in the evolution of eastern North America, they do not provide consistent evidence that these older deformational structures have been regionally reactivated and pose a widespread, significant potential for damaging earthquakes.

Correlation of Charleston seismicity and the Charleston 1886 earthquake with a steep reverse northeast-trending basement fault is extremely tenuous. Composite fault-plane solutions, hypocentral location patterns and the inferred and measured orientation of the principal maximum stress direction implies a coherent pattern of deformation unique to the Charleston area. Fault planes trend northwest with reverse displacement in the upper crust and trend northeast with strike-slip displacement in the lower crust. The vertical maximum principal stress axis near the surface (Reference 2.5-127) and the deeper northeast-trending maximum principal stress axis (Reference 2.5-129) are not consistent with the northwest- oriented stress axis required by the hypotheses for reactivation of steep basement faults (References 2.5-134 and 2.5-135) or thrust reactivation of the decollement (Reference 2.5-68).

Apparent association of small earthquakes with the Ramapo fault is not reflected by any obvious concentration or association of historical macroseismicity in its vicinity; the widely scattered historical epicenters within at least 25 kilometers of the Ramapo fault do not exceed an intensity of VI (Reference 2.5-82). The Ramapo fault has been intensively studied by drilling, trenching and detailed mapping. No evidence for reactivation of the fault surface has been found, and no instance of surficial offset along the fault, either in natural exposures or in numerous trenches, has been discovered (Reference 2.5-119).

It is concluded that the lack of recent faulting and the modest size of even the largest historic earthquakes within 200 miles of the site and the general scatter and infrequency of reported earthquakes argue against the meaningful association of regional macroseismicity with specific faults.

2.5.2.4 Maximum Earthquake Potential

No earthquake within the 200 mile radius site region has exceeded intensity VII during the historic record for this area, which began in the early 18th century. There have been 6 intensity VII shocks during this period in the site region. Of these, 2 occurred near New York City, in 1737 and 1884, at the edge of the Newark Basin, near the junction of the Piedmont, New England, and Coastal Plain provinces; one occurred near Wilmington, Delaware in 1871, about 35 miles south of the site, near the Piedmont-Coastal Plain boundary; one occurred along the New Jersey coast in 1927, about 80 miles northeast of the site in the Coastal Plain; one occurred near Moodus, Connecticut in 1791, about 180 miles northeast of the site in the New England Upland section of the New England Province;

and one occurred in Wilkes-Barre, Pennsylvania in 1954 in the Folded Appalachians to the N-NW of the site and was almost certainly not related to either tectonic strain accumulation or release, as these terms are normally understood. One additional intensity VII event, which was slightly more than 200 miles from the site, occurred near Richmond, Virginia in 1875, close to the Piedmont-Coastal Plain province boundary. Thus, most of the intensity VII events recorded, and particularly those south of the New England Appalachian-Piedmont Coastal Plain physiographic province junction, have occurred near the Fall Zone. An apparent NE-SW trend of smaller earthquakes occurs along the same zone, although intensity VI and smaller events are scattered throughout the site region.

Considering the historic seismicity of the site region alone, a reasonable interpretation of maximum potential earthquake might be either an intensity VII event along the Fall Zone at its closest approach to the site or an intensity VI event very near the site. Because of the uncertainties involved in associating regional activity with specific structures, however, the maximum potential earthquake is specified as being equivalent to the I_o = VII 1871 Wilmington, Delaware earthquake occurring near the site. This is equivalent to translating the largest historical earthquake that has occurred anywhere within 200 miles of the site.

2.5.2.5 Seismic Wave Transmission Characteristic of the Site

Detailed descriptive data on the foundation material properties appear in Section 2.5.4. All Category I structures are founded on competent bedrock, except some buried structures including portions of underground piping and electrical ducts, diesel oil tanks, and buried valve pits. An analysis was performed to determine the response of the soil column and the effects of the properties used in the analysis are given in Section 2.5.4.2.2, and the results of the analyses are given in Section 2.5.4.7.1.

The seismic wave velocity of the in situ soils and the fill materials, on which the buried structures are founded, are not available. However, because of the shallow foundation soil depth to the competent bedrock and the smooth transition from rock to soil foundation (Figure 2.5-37), LGS Category I underground piping is designed in accordance with the procedure identified in Section 3.7.3.12 for seismic load, assuming the seismic shear-wave velocity of the foundation soil is the same as the competent bedrock. The application of the bedrock seismic wave velocity to the foundation soil material in buried piping analysis is shown in Reference 2.5-53.

The LGS design response spectra, discussed in Section 3.7.1 and Figures 3.7-1 and 3.7-2, are based on data developed from records of previous earthquake activities representing an envelope of motion expected at a sound rock site.

2.5.2.6 Safe Shutdown Earthquake

The SSE is defined in terms of a peak ground acceleration and a design response spectrum. As indicated in Section 2.5.2.4, the site design intensity is VII on the Modified Mercalli Scale. This intensity may be associated with a peak ground acceleration of approximately 0.13 g (References 2.5-34 and 2.5-35). For additional conservatism, a peak acceleration of 0.15 g the design response spectrum shown in Figure 3.7-2 for critical damping values of 0.0%, 0.5%, 2.0%, 5.0%, and 10.0%.

2.5.2.7 Operating Basis Earthquake

The OBE is defined as one-half the peak ground acceleration associated with the SSE, 0.075 g. The design response spectrum is identical in shape to that specified for the SSE. This value (0.075 g) is the high frequency asymptote of the OBE design response spectrum shown in Figure 3.7-1. Curves for the same percent critical damping values appearing in the SSE design response spectrum are shown.

2.5.3 SURFACE FAULTING

2.5.3.1 Geologic Conditions of the Site

LGS is located approximately 3 miles southeast of Pottstown, Pennsylvania, adjacent to the Schuylkill River. It is situated within the western portion of the Newark Basin, which is part of the Triassic Lowland subdivision of the Piedmont physiographic province (Section 2.5.1.1). The Triassic Lowlands represent sedimentary basins that form outcrop patterns broadly parallel to the sinuous, folded Appalachians and extend from Maine to South Carolina. The basins contain rocks of relatively similar gross lithologic types, usually occurring in the same stratigraphic sequence (Reference 2.5-6).

The Newark Basin, together with the contiguous Gettysburg Basin further west, forms the largest of the Triassic basins. This basin extends in a W-SW direction from the Hudson Palisades, near the New Jersey-New York boundary to the Catoctin Mountains, near Frederick, Maryland (Figure 2.5-38). The basin varies in width from 3 miles in its narrowest section to almost 35 miles at its greatest width. The Newark-Gettysburg Basin represents a series of some 18,000-20,000 feet of nonmarine sedimentary rocks with associated basaltic flows, and diabase dikes, sills, and stocks (Figure 2.5-6). For detailed descriptions of the regional geology, see Section 2.5.1.1. Site geologic conditions are described in Section 2.5.1.2.

Several faults of apparently large displacement occur within the Newark Basin. These are the Chalfont and Furlong faults in Pennsylvania, and the Flemington and Hopewell faults in New Jersey. These faults, which are of Triassic-age, result in Paleozoic age rocks being exposed at the surface, indicating at least 10,000 feet of displacement. The orientation and direction of movement of these faults are not known. Although generally considered to be steeply south dipping normal faults (Reference 2.5-36), Sanders (Reference 2.5-37) suggests predominant strike-slip movement, and Faill (Reference 2.5-17) indicates these faults may be high angle reverse faults resulting from intersection of two different axes of monoclinal folding within the basin.

Smaller Triassic faults cross the basin margins and extend well into the surrounding rocks. They usually show less than 3000 feet of displacement. Associated with these faults are local concentrations of smaller faults.

The major fault closest to the site is the Chalfont fault, which passes 9 miles to the northeast (Figure 2.5-2). The maximum throw on this fault is 6500 feet, in Bucks County, Pennsylvania, near Bennetts Corner (Reference 2.5-38). The throw decreases to about 3000 feet at the Montgomery County line and eventually dies out to the northeast of the site. The northeastward branch of the Chalfont fault (at Bennetts Corner) is called the Furlong fault. The fault crosses the Delaware River near Center Bridge, Pennsylvania and continues through New Jersey (where it is called the Flemington fault) to just beyond the north border of the Triassic basin. The maximum throw on the Furlong-Flemington fault is 10,000 feet, with an undetermined amount of right-lateral, strike-slip displacement (Reference 2.5-37). The displacement along the Furlong fault in eastern Pennsylvania is sufficient to offset the entire thickness of the Newark Group and expose the Cambrian rocks on the floor of the basin. Five and one-half miles southeast of the Furlong fault, the east-west trending Buckmanville fault crosses the river and becomes the Hopewell fault of New Jersey. A throw of 15,000 feet has been measured on the Hopewell, with a right-lateral, strike-slip displacement of 12 miles (Reference 2.5-37). Other faults associated with the Furlong-Buckmanville complex and their eastward extensions into New Jersey are, the Holmquist School, Bridge Valley, Pidcock Creek, and Danborough faults. These faults are all normal, with the downthrown side to the south. Some show lateral displacement, and all are strike faults.

Many of the minor faults in the Newark Basin of southeastern Pennsylvania are transverse normal faults. These have developed along the major joint system exhibited by the Triassic strata, and they trend approximately N 30° E. Some of the Triassic dikes have intruded along these fracture zones subsequent to movement along them. The Downingtown Dike is an example of this type of intrusion.

In this report the minor faults that occur in the site area have been named the Sanatoga fault, the Brooke-Evans fault, and the Linfield fault, as shown on Figure 2.5-6. The Sanatoga fault passes within 1300 feet to the west of the reactor location, the Brooke-Evans fault is 2800 feet to the south, and the Linfield fault is 2 miles to the southeast.

Detailed field investigations of faults in the site area were performed by Dames and Moore in 1974 (Reference 2.5-1).

2.5.3.2 Evidence of Fault Offset

As previously indicated, the site lies within a down-warped basin of Triassic-age. Subsequent to the deposition and consolidation of the basin sediments, the region was uplifted, and numerous small faults and fractures were formed.

The Sanatoga fault, shown on Figure 2.5-6, trends approximately N 25° E, becoming discontinuous approximately 2 miles to the north and 1 mile south of the site area. The nearest approach of the fault trace to the reactor area is 1300 feet to the west. Detailed studies by Dames and Moore in 1974 (Reference 2.5-1) indicate vertical displacement on the fault is approximately 290 feet, with the downthrown side to the east. The fault-plane is occupied by a Triassic diabase intrusive, which is part of the Downingtown Dike.

The Brooke-Evans fault passes within 2800 feet to the south of the plant area and trends approximately N 50° E. Slickensides on the fault-plane indicate some lateral movement. Field evidence based on the offset of marker beds indicates that the movement was probably both right-lateral and vertical. The apparent vertical displacement is about 350 feet, with the downthrown side to the south. West of the Schuylkill River, magmatic material from the Downingtown Dike occupies the fault for a short distance. A high concentration of calcium carbonate filling occurs in the fracture zone associated with fault.

A third fault, the Linfield fault, is located east of the town of Linfield about 2 miles southeast of the site. This fault trends N 20° E, with the downthrown side to the west. Displacement on this fault is approximately 130 feet. Field evidence based on slickensides in the fault-plane indicates an undetermined amount of lateral movement. This fault is associated with a diabase dike that occupies a parallel fault approximately 700 feet to the east.

Detailed inspection of rock cores and nearby outcrops disclosed the existence of other very small displacements (maximum less than 2 feet), especially in those areas close to the faults described above. On the basis of detailed stratigraphic correlation in the site area done for the PSAR, it was concluded that the strata between the Brooke-Evans fault to the south and the Sanatoga fault to the north have not been offset by faulting. The rock at the site is moderately-to-well jointed. A statistical analysis of joints by Dames and Moore in the rock cores revealed a higher joint frequency along the northeast trend through the southeastern portion of the construction area, an the PSAR noted that the presence of these abundant joints may be related to an undetected fracture zone. Fracture zones with minor offsets were encountered in the excavation. These are described in Section 2.5.3.2.1.

As noted in the PSAR, the presence of minor faults within the Newark Basin in general, and near the site area in particular, is not surprising, nor is it hazardous to the operation of the plant. As previously discussed, such minor faulting is common throughout the basin. Regional crustal stresses during Mesozoic time resulted in numerous small-scale readjustments and fracturing of the brittle, flat-lying Triassic strata. Small-scale insignificant displacements are likely to be found in any major rock exposure within the basin.

Evidence that confirms the regional inactivity of the Triassic faults includes the following:

a. The regional uplifting forces that induced the basin faulting no longer exist.

b. There is no evidence that faulting has displaced overlying Coastal Plain sediments.

c. Many faults are known to be healed by secondary mineralization.

d. Within the same Triassic rock-type, no fault exhibits surface expression in the form of fault scarps.

These faults were discussed in the PSAR (section 2.5.2.3.4) and were described as inactive for at least the last 140 million years. The PSAR stated: "Perhaps the most conclusive proof of tectonic inactivity near the site is the presence of unfaulted, intact diabase, at least 140 million years old, along the nearby fault planes. The faults near the site have not moved in at least 140 million years and will not move during the life of the proposed facility."

Subsequently, some evidence for possible offset of the diabase was observed, and an extensive geologic study was made by Dames and Moore (Reference 2.5-1) in an attempt to date as closely as possible the age of the faulting in the area.

A committee consisting of Dr. D.U. Wise, University of Massachusetts (Amherst); Dr. C. Gray, Franklin and Marshall College, Lancaster, Pennsylvania; and Dr. P.B. Myers, Lehigh University, Bethlehem, Pennsylvania, was selected to evaluate the study. In evaluating the faults in the area around the site, they state: "The fault and fold patterns are indicative of a Jura-Triassic (150-200 million years) stress system with maximum compression oriented NNE... The present WNW orientation of compressive stresses in the residual stress measurements differs markedly from the NNE compression which produced the Jura-Triassic faults at the site and nearby folds. The effect is to increase normal stresses across the faults, increasing fractional resistance to movement, and decreasing available space for additional graben displacement."

2.5.3.2.1 Geologic Structures in the LGS Site Excavation

The site stratigraphy consists of a sedimentary sequence of red shale, siltstone, and sandstone (Figure 2.5-12). Structural mapping of the excavation at the LGS site shown on Figure 2.5-13, confirms the existence of three fracture zones with small displacements (LGS PSAR, supplement 4, question 2.29).

All three zones are characterized by the following:

a. Two vertical, or subvertical, northeast-trending fractures, in addition to numerous closely spaced smaller fractures

b. Observable vertical stratigraphic offsets (1 inch to 4 feet), which vary along the length of a given shear zone

c. Mineralization of the shear zone or adjacent fractures by calcite, quartz, or fibrous clay (Reference 2.5-1, section 3.4)

d. Subvertical and subhorizontal slickensides, indicating both strike-slip and subsequent dip-slip offsets

A detailed discussion of these shear zones is presented in a 1974 Geologic Report by Dames and Moore (Reference 2.5-1).

The minor faulting and shearing encountered within the site excavation are not unique to the area, and they have the same geometry as and similar mineralization to adjacent larger faults. These larger faults in turn are part of the pervasive fault-fold pattern that reflects an initial northeast-trending regional compressive stress. Extension features (small grabens and dikes) for the most part strike parallel to the compression axis, and dikes sometimes display an en echelon geometry.

As one would expect, the fold axes, together with thrust shear joints in nearby areas, strike normal to the compression.

Upon completion of their 1974 study (Reference 2.5-1), Dames and Moore concluded:

> "The results of this comprehensive investigation indicate that shears exposed in the excavation are not capable by AEC (NRC) definition. It is concluded that movement along the shears could not have occurred later than 500,000 years ago and in all probability, have been inactive since Jura-Triassic time some 150-200 million years ago."

The review committee (Dr. Wise, Dr. Gray, and Dr. Myers) concluded:

> "We believe the small faults discovered in the LGS containment excavation have been thoroughly tied to regional 150-200 million year structural events of this area. The ancient stress-field orientations which caused the faults have been superseded by the present stress-field orientations which tend to lock the faults against further motion. The faults have undeformed or little deformed delicate minerals in them indicating the absence of strong shearing stresses in the containment area since cessation of mineralization, most likely in the same 150-200 million year range. There is no evidence of displacement of any feature as young as the undisturbed upland terrace surface which has a minimum age on the order of a half million years.
>
> We conclude that a very strong circumstantial case has been made on structural ground for the containment faults being on the order of 150-200 million years old. An equally strong geomorphic case has been made precluding any movements in the last half million years.
>
> The committee sees abundant evidence suggesting geologic antiquity of the faults. We have yet to see the first piece of evidence suggesting recent movements. Based on our collective local experience, none of us has seen anything about the faults onsite to indicate they are other than typical small movement features associated with the 150-200 million year old events in the area."

It is concluded that these small faults are not significant to the operation of the power plant.

2.5.3.3 Earthquakes Associated with Capable Faults

There are no capable faults within 5 miles of the site. There have been no earthquakes in historic time with epicentral locations within 10 miles of the site. For correlation of epicenters and geologic structure, see Sections 2.5.2.2 and 2.5.2.3.

2.5.3.4 Investigation of Capable Faults

There are no capable faults within 5 miles of the site. Shear zones encountered in foundation excavations have been mapped in detail (Section 2.5.1.2.5 and Figure 2.5-13). The geologic investigations demonstrate that the small fracture zones encountered during foundation excavation and the faults in the vicinity of the site are associated with the 150-200 million year old events in the area.

2.5.3.5 Correlation of Epicenters with Capable Faults

There are no capable faults within 5 miles of the site. No earthquakes with epicentral locations within 10 miles of the site have occurred in historic time. For regional correlation of epicenters with geologic structures, see Sections 2.5.2.2 and 2.5.2.3.

2.5.3.6 Descriptions of Capable Faults

There are no capable faults in the region around the site extending to within 5 miles of the site. For a description of faults within 5 miles of the site, see Section 2.5.3.2.

2.5.3.7 Zone Requiring Detailed Fault Investigation

As discussed in Section 2.5.1.2, some shear zones with small offsets were encountered during foundation excavation at the site. Structures of this type are not unusual in the region; however, these zones were mapped in detail and photographed as part of the site geologic record (Figure 2.5-13). The detailed geologic investigation included mapping of an area approximately 5 miles in diameter. A review committee was established (Section 2.5.3.2.1), and the results of all investigations were included in a report issued in July 1974 (Reference 2.5-1). The review committee concluded that the shear zones in the foundation excavation at the site and the faults within the area mapped are typical of features associated with 150-200 million year old events in the area (Section 2.5.3.2.1).

2.5.3.8 Results of Faulting Investigation

See Sections 2.5.1.2 and 2.5.3.7; there are no capable faults within 5 miles of LGS.

2.5.4 STABILITY OF SUBSURFACE MATERIALS AND FOUNDATIONS

2.5.4.1 Geologic Features

Bedrock at the site consists of well-indurated Triassic sandstones, siltstones, and shales that extend to a depth of several thousand feet. Bedding dips toward the north at 8° to 20°. Site stratigraphy is presented in Section 2.5.1.2.3. Geologic structure in the site area is presented in Section 2.5.1.2.4. Bedrock is overlain by from 0-40 feet of residual soil, developed in situ by weathering and decomposition of the parent rock. The soil grades into weathered rock, then into fresh, unweathered rock; no clearly defined boundary exists between soil and rock.

During foundation excavation, some fracture zones with small displacements were encountered and were treated locally as required. Descriptions of the fracture zones are presented in section 2.5.1.2.5; their locations at final foundation grades are shown on Figure 2.5-13. Treatment of these fracture zones is discussed in Section 2.5.4.12.

Engineering evaluation of the site geology is discussed in Section 2.5.1.2.7. The bedrock at the site contains no unstable minerals or hazardous conditions. The stress regime within the bedrock materials is low and stable. There are no mines in the site area and no significant fluid withdrawal. The bedrock in the construction area is competent and provides satisfactory foundation support for plant structures.

2.5.4.2 Properties of Subsurface Materials

The principal plant structures are founded on bedrock. The spray pond is excavated partly in soil and partly in rock. All or portions of other facilities not founded on bedrock are founded on natural soil or manmade fills. The locations of the major plant structures are shown on Figure 2.1-3. Results of laboratory tests for foundation and construction materials are presented in References 2.5-39 and 2.5-51, and in Sections 2.5.4.1.2, 2.5.4.2, and 2.5.4.10.

2.5.4.2.1 Properties of Foundation Rocks

The seismic Category 1 reactor and diesel generator enclosures, as well as the turbine and radwaste enclosures, are founded on hard, competent bedrock. The bedrock consists of siltstone, sandstone, and shale of Brunswick lithofacies of Triassic-age. The Brunswick is described in Section 2.5.1.2. The Lockatong lithofacies, represented by the Sanatoga Members, interfinger with the Brunswick in the northern part of the site area. The Sanatoga Member consists of blue-gray calcareous argillite with two distinct beds of black carbonaceous shale. The spray pond is underlain by both the Lockatong and Brunswick lithofacies.

Bedding and jointing patterns are well developed in the foundation rocks. Bedding-plane spacing varies from a few inches to several feet. Bedding-planes strike generally east to west and dip to the north at 8° to 20°. Two major joint systems are prevalent in the area. Both are vertical or nearly vertical; they strike approximately N 20° to 50° E and N 50° to 60° W. Three fracture zones and two minor clay seams along bedding were encountered in the main power block foundation excavations; they are described in Section 2.5.1.2.5. Treatment of these zones is described in Section 2.5.4.12.

Rock quality designation values were measured in a total of 81 boreholes, which include the 200-, 300- and M-series borings completed in 1970, and borings 400 and 401 completed in February 1971 (Figure 2.5-22). In general, rock quality designation values measured on the first core run (5-10 ft) in rock were very low, usually zero; with some exceptions, minimum rock quality designation values increased to approximately 50% or greater after the first 10-30 feet of rock cored. The lower rock quality designation values in the upper 10-30 feet of rock reflect poorer rock quality caused by rock weathering; this weathered material was removed during foundation excavation. The data and analyses discussed below demonstrate that the higher rock quality designation values are associated with the sound, unweathered bedrock that supports the foundations for the principal plant structures.

Because of the gradational nature of the upward transition from sound rock to soil, engineering properties in the zone of rock weathering can be expected to vary from soil-like properties near the top of the zone to properties approaching those of sound rock near the base of the zone. Properties of sound, unweathered foundation rock were determined as follows.

Laboratory tests on 16 core samples, using substantially the same procedure as specified in the subsequently adopted ASTM D2938-71, indicate unconfined compressive strengths ranging from 6370-24, 540 psi with an average of 15,820 psi. Results of these tests are shown in Table 2.5-3. Laboratory sonic tests on intact cores (ASTM D2845-69) (Table 2.5-13) from four borings yield an average compressional velocity of 12,060 fps.

Seismic refraction surveys were performed to determine P-wave and S-wave velocities for site foundation materials. P-wave velocities in rock range from about 7700 fps to 20,000 fps, with an average of about 12,500 fps; locations of refraction lines are shown in Figure 2.5-21. Shear-wave

velocities were determined to be about 6100 fps in a line perpendicular to the strike of the bedding (north-south). A line run approximately parallel to the east-west strike of the bedding measured a shear-wave velocity of 5800 fps. Poisson's ratio is calculated to be about 0.3. The dynamic modulus of elasticity calculated from the seismic data is $3x10^6$ psi. Representative engineering properties of foundation rock are summarized in Table 2.5-11.

Because geophysical test methods were used to establish dynamic design rock properties, it is appropriate to consider a range of dynamic moduli. Accordingly, all LGS available geotechnical data have been evaluated to establish the most appropriate range of dynamic moduli to be considered. This approach is presented below. It was concluded from this evaluation that an appropriate LGS dynamic rock modulus range would be between $2.7x10^6$ and $4.0x10^6$ psi, a range of ±20%. The seismic analysis of the containment structure and reactor control enclosures included the SSE effect as discussed in Section 3.7. These analyses use a Young's dynamic modulus for rock equal to $3.0x10^6$ psi. Additional soil-structure interaction studies were performed for the containment structure and reactor and control enclosures to assess the sensitivity of the structural response to variations in the design basis rock modulus. Modal analyses have demonstrated that for a ±50% range (of the design elastic modulus), variations in structural frequency do not exceed 10% for predominant modes. These results indicate that a reduction in rock modulus to $1.5x10^6$ psi will not produce significant effects on structural response. It is thus concluded that the average dynamic elastic modulus value of $3.0x10^6$ psi is adequate for design.

Examination of the LGS Design Basis Dynamic Rock Modulus

The following actions have been taken to establish an appropriate range of dynamic elastic rock moduli: (1) re-examination of the data on seismic velocities and dynamic moduli of the rock at the site, as given in the Dames and Moore reports and in the PSAR and the FSAR, (2) study of relevant technical literature including the WASH-1301 report (Reference 2.5-155), and (3) discussions with Dr. A.J. Hendron, a recognized authority on rock foundation engineering.

(1) Seismic velocity data and in situ dynamic moduli at the LGS site.

Young's modulus (dynamic) is calculated from either P-wave or shear-wave velocities. Ambraseys and Hendron (Reference 2.5-153) state, "for fairly competent rock masses (V_P greater than 10,000 fps) the compressional wave velocity and an assumed value of Poisson's ratio ranging from 0.27 to 0.35 may be used to evaluate a dynamic Young's modulus for engineering purposes". The average compressional wave velocity in rock at the site is approximately 12,000 fps; therefore, it is appropriate to consider P-wave velocities in computing the dynamic modulus. Accordingly, the dynamic modulus value of $3.0x10^6$ psi for the site has been re-examined considering both P-wave and S-wave velocity data from refraction surveys, and considering up-hole velocities measured in one hole at the site. Also, results of laboratory tests have been re-evaluated to determine sonic velocities of rock cores, at the recommendation of Dr. A.J. Hendron.

Shear-wave velocities were measured along two refraction lines in the power block area (Figure 2.5-21); Dames and Moore (Reference 2.5-154) reported V_s of 6100 fps along strike and 5800 fps parallel to dip direction, for an average of 5950 fps, as described in Table 2.5-11. Poisson's ratio calculated from the average P-wave and S-wave velocities is 0.33. Young's modulus calculated from the average shear-wave velocity and this Poisson's ratio is $3.1x10^6$ psi.

Upper layer P-wave velocities measured across the entire site have approximately the same average value (12,020 fps) as those measured only in the power block area (11,880

fps) but, as expected, the former data set has significantly higher scatter (standard deviation 2,660 fps vs. 930 fps). A test (F-test) for equivalence of variance shows conclusively that the scatter of the P-wave values for the whole site is unrepresentative of the data for the power block area only. Therefore, P-wave data primarily from the power block area have been considered for evaluation and analysis.

Within the power block area, Dames and Moore (Reference 2.5-154) measured P-wave velocities on lines 3E, 4 and 6 (Figure 2.5-21). In addition, seismic P-wave velocities east of the Unit 1 turbine building were recorded along line 3F. Neglecting the higher velocities detected from the more deeply buried rock strata, eight refraction velocities (PSAR figure 2.5.5) yield an average P-wave velocity of 11,880 fps with an unbiased 1 sigma range of 10,950 fps to 12,810 fps. Using the lower end of the range (10,950 fps), and a Poisson's ratio of 0.30 as recommended by Dame and Moore, (E) is calculated to be 2.9×10^6 psi; the upper end of the range corresponds to (E) of 4.0×10^6 psi. With a Poisson's ratio of 0.33 (as indicated by the ratio between average P-wave and S-wave velocities), the range for (E) is 2.7×10^6 to 3.7×10^6 psi.

From the up-hole survey (Dames and Moore, Reference 2.5-154) and PSAR figure 2.5.6, the weighted mean P-wave velocity (weighted by relating velocity of each layer to the relative thickness of that layer) is 11,650 fps, which is in agreement with the profile data. The corresponding (E), with a Poisson's ratio of 0.3, is calculated to be 3.3×10^6 psi.

Sonic tests on cores taken at the site (nine determinations) (Table 2.5-13) have an average P-wave velocity of 12,060 fps. The ratio of average field measured P-wave velocity to laboratory measured P-wave velocity (11,880-12,060 fps) is 0.98. This ratio provides support for the statement provided below in this section that: "The agreement between laboratory and field velocity measurements suggests that the seismic refraction results are representative of sound foundation rock, for otherwise the field measurements would be significantly less than measurements on intact core. Therefore the field seismic velocity data should provide a reasonable quantitative index of the general character of the in situ foundation rock".

(2) Reduction of dynamic modulus for higher strain levels during SSE event

The rigidity of soil decreases significantly with strain; however, this should not be translated directly to rock, particularly to hard rock. For example, the relative reduction of shear modulus for sands ranges from 15% to 35%, depending primarily on void ratio or relative density, as the strain level increases from 10^{-4}% to 10^{-2}% (Figure 2.5-47). The corresponding reduction in rock moduli for a similar increase in strain level would be expected to be significantly less.

A brief search of the literature was made for data on the effect of strain on the rigidity of rock. Also, the maximum strain that would occur in the foundation rock at LGS during the SSE event was computed.

A simple estimate of strain in rock during a seismic event can be obtained by assuming sinusoidal, plane, vertically propagating SH-waves in an elastic, homogeneous whole space. Under these assumptions, maximum shear strain is equal to the maximum SH-wave particle velocity divided by the propagation velocity of the medium. For rock, a peak particle velocity to peak acceleration ratio of 36 inches/second/g has been recommended

(Newmark and Hall, Reference 2.5-155). Using this ratio and the 0.15g SSE for the site, and estimate of about 5.4 in/sec is derived for the SSE ground motion at the site. The site near surface SH-wave propagation velocity is about 6000 ft/sec, so that:

$$\text{STRAIN} = \frac{5.4 \text{ in/sec}}{72{,}000 \text{ in/sec}} = 7.5\times10^{-5} = 7.5\times10^{-3}\%$$

Actual strain at or near ground surface would not be this high because this calculation ignores the zero stress-free and strain-free surface boundary condition.

Strain levels associated with seismic profiling pulses are presumed to be on the order of 10^{-4}%, depending on the shot charge and line spread (e.g., Silver and Seed, Reference 2.5-159). There is little published information quantifying to what extent typical rock materials deviate from linear-elastic behavior at these small strain levels. Raphael and Goodman (Reference 2.5-157), drawing upon rock mechanics studies conducted in France, state that the modulus computed from seismic profiling should be greater than the rock modulus which would pertain during earthquakes, but they provide little information on the specific ratio of E (earthquake) to E (seismic test) to be adopted for varying circumstances.

Schnable et al (Reference 2.5-158) plot shear modulus as a function of strain for rock (Figure 2.5-46). In this context, "rock" is generally considered to be a material with an S-wave propagation velocity of about 2500-3000 ft/sec or higher (Schnable et al, 1971, Reference 2.5-158 and Algermissen and Perkins, 1976, Reference 2.5-152). These authors indicate that the shear modulus should decrease by less than 10% as the shear strain increases from 10^{-4}% to 7.5×10^{-3}%.

A.J. Hendron (personal communication, 1983) stated that a reduction in dynamic modulus - from E (seismic test) to E (earthquake) - is appropriate for rock because strain levels experienced during earthquakes are higher than the strains which are associated with the measurement of seismic velocities. For the site, Hendron favors tying such a reduction to the square of the ratio of field measured seismic velocities to laboratory measured velocities on core samples. Dr. Hendron has developed such a curve from his studies at the Nevada Test Site and other localities; that curve would plot well above the curve shown on Figure 2.5-45. He stated that the amount of reduction for higher strain during a seismic event is significantly less for dynamic conditions than it is for reducing dynamic E to static E, which is the purpose of Figure 2.5-45. On Hendron's revised graph, for example, he stated that the square of the ratio of field-to-laboratory P-wave velocities $(V_F/V_L)^2$ of 0.87 correlates with a reduction in dynamic modulus E_d of about 22% at a strain level of 10^{-3} in/in (Hendron, personal communication, January 1983). Subsequently, Hendron prepared a brief report describing his additional data on variation of propagation velocity with strain and commenting on dynamic Young's Modulus for the site under SSE conditions. Based on the data on rock quality provided to him, it is his judgment that the reduction factor at LGS should be about 0.75 to 0.85.

The following is a summary of the measured seismic velocities at the site and the corresponding values of the dynamic modulus of elasticity computed from them.

P-Wave (from In Situ Field Surveys)

Average velocity - 11,880 fps
Range of velocities (mean ±1 S.D.) = 10,950-12,810 fps

E (Assuming Poisson's ratio = 0.30)
Average - 3.5×10^6 psi
Range - 3.0×10^6 psi to 4.0×10^6 psi
E (Assuming Poisson's ratio = 0.33)
Average - 3.3×10^6 psi
Range - 2.6×10^6 psi to 3.7×10^6 psi

S-Wave (From In Situ Field Surveys)

Average velocity	-	5950 fps
Range	-	5800-6100 fps
E (Average)	-	3.1×10^6 psi (Poisson's ratio of 0.33)
E (Range)	-	3.0×10^6 psi to 3.3×10^6 psi

Sonic Velocity Tests (On Intact Cores in Laboratory)

Average - 12,060 fps
Ratio of field velocity to lab velocity V_F/V_L
= 11,880/12,060 = 0.98

Up-Hole Survey Measurements

Weighted average velocity - 11,680 fps
E (with Poisson's ratio = 0.33) - 3.0×10^6 psi
E (with Poisson's ratio = 0.30) - 3.3×10^6 psi

Maximum Range of E - 2.6×10^6 psi to 4.0×10^6 psi (Range with ±1 S.D. of P-wave and S-wave velocities, and up-hole velocities, using Poisson's ratio of 0.30 and 0.33)

E used for design - 3.0×10^6 psi

(lower 28 percentile of the maximum range).

The seismic velocity data of the foundation rock at the site indicates that the dynamic (E) value used for design (3×10^6 psi) represents the lower portion of the data range. The available data do not justify a range of dynamic moduli of ±50% of the design basis value. Data from Schnable et al (Reference 2.5-158), for example, indicate that a reduction of less than 10%, for rock of undefined quality, is appropriate. Considering the rock quality at the LGS site is indicated by a velocity ratio squared of about 0.87, Hendron recommends a reduction of about 20%. (Actually, the velocity ratio squared of the rock at is about 0.96, based on the few lab velocities measured.)

It is therefore concluded that 3×10^6 psi is an appropriate value for the average dynamic modulus of elasticity of the foundation rock at the site. The range of moduli to be taken into consideration for design should be 2.7×10^6 psi to 4.0×10^6 psi. Additional discussion of seismic refraction survey techniques is given in Section 2.5.4.4; plate bearing tests and static moduli are described in Section 2.5.4.10.

The agreement between laboratory and field velocity measurements suggests that the seismic refraction results are representative of sound foundation rock, for otherwise the field measurements would be significantly less than measurements on intact core. Therefore, the field

seismic velocities should provide a reasonable quantitative index of the general character of the in situ foundation rock. Weathering reduces rock quality typically in the upper 10-30 feet of rock as indicated by reduced rock quality designation values in this zone. The weathered rock grades upward with no well defined contact into residual soil. Therefore, the properties of weathered rock are similar to those of sound rock at the base of the weathered zone and approach those of soil at the top of the zone. Because foundations for the main plant structures including the power block, radwaste, and pumphouse enclosures are carried to unweathered rock, rock weathering is not significant to foundation design for these facilities. Seismic Category I structures founded on weathered rock are buried structures including diesel oil tanks and portions of buried piping and electrical duct banks. In the foundation design of these structures, the bearing pressure allowable for dense natural soil (6,000 psf) is conservatively used, as discussed in Section 2.5.4.10.2.

Nevertheless it was recognized that occasional localized features such as fracture zones or clay seams encountered in the foundation rock would require evaluation as they became exposed. Accordingly, foundation rock was mapped and evaluated for such features by experienced engineering geologists during the course of construction. Measures to improve foundation conditions were carried out at certain areas where potential rock weakness was encountered. Detailed discussion of these measures is provided in Section 2.5.4.12.

2.5.4.2.2 Properties of Foundation Soils

The in situ soils are residual in nature, derived from weathering of siltstone, sandstone, and shale. The properties of these soils were determined by laboratory testing. Testing of the in situ soils at the spray pond was conducted by Geotechnical Engineers, Inc. The complete laboratory test report is given in Reference 2.5-39. The properties of the soils are given in Sections 2.5.4.2.2.1 through 2.5.4.2.2.3 and are summarized in Table 2.5-4.

The properties of the in situ soils other than spray pond were determined by Dames and Moore. The complete laboratory test results are included in Reference 2.5-51. The laboratory testing procedures are given in Reference 2.5-141. The properties of these soils are described in Section 2.5.4.2.2.4 and are summarized in Table 2.5-4.

A compaction test was performed on a sample of the overburden soil to obtain soil compaction characteristics. Sieve tests were performed on representative soil samples to evaluate grain-size distribution. In addition, Atterberg limits were performed on the bulk soil sample used for the compaction test and on other soil samples to evaluate the plasticity characteristics. The locations of borings at the site are shown in Figure 2.5-20.

Seismic Category I structures not founded on competent bedrock include the spray pond and buried structures described below. The manner and conservatism in which soil data were used in the design of the spray pond is discussed in Section 2.5.5. Seismic Category I buried structures include portions of underground piping and electrical duct banks, valve pits, and diesel oil tanks. These buried structures are founded above the high groundwater table and have bearing weight less than the replaced in situ soil. The static stability of the buried structures is discussed in Section 2.5.4.10.1. The seismic inertia effect of buried structures are negligible and the propagating seismic wave effects on buried piping are considered as described in Section 3.7.3.12.

2.5.4.2.2.1 Index Properties of Soils at Spray Pond

The index properties include the following:

a. Visual and laboratory classification of samples - ASTM D2488

b. Mechanical analysis - ASTM D422

c. In situ moisture content and unit weight - ASTM D2216

d. Atterberg limits - ASTM D423 and ASTM D424

e. Specific gravity tests - ASTM D854

The in situ soil of the spray pond includes clayey silt, sandy silt, and silty fine sand, with varying amounts of gravel-sized rock fragments. The predominant soil is clayey silt, classified as ML and CL. The in situ moisture ranges from 11.9 to 38.7%, and averages 21.7%. The specific gravity ranges from 2.70 to 2.80, with an average value of 2.76.

Sieve and hydrometer analyses were performed to determine grain-size distribution according to ASTM D422. The mean grain-size (D_{50}) was found to be in the range of 0.006 mm to 4.4 mm, with an average value of 0.32 mm.

The Atterberg Limits were obtained according to ASTM D423 and ASTM D424. The liquid limit ranges from 27 to 51, with an average value of 37. The plasticity index ranges from 2 to 27, with an average value of 15 (Figure 2.5-17).

2.5.4.2.2.2 Static Shear Strength of In Situ Soils at Spray Pond

Consolidated-undrained triaxial tests were made in which undisturbed specimens were placed in the triaxial chamber and saturated by the back pressure method. After saturation the samples were consolidated isotropically to a consolidation pressure of 1 ksf. Plots are made of deviator stress vs axial strain, induced pore pressure vs axial strain, and stress paths for each test. These plots are included in appendix J of the PSAR. The failure stresses of samples are shown on Figure 2.5-18. From this drawing, the effective friction angle is determined to be 33.5°.

Points plotted on Figure 2.5-18 represent conditions at failure. In general, the failure condition was chosen when the sample reached 20% strain if the shear stress continues to increase. However, if the peak was reached at a lower strain level, the (p-q) point shown on Figure 2.5-18 would represent the stresses at the peak. The point, p = 10.2 and q = 5.2, represents the Test R14 which reached its peak shear stress at 15% strain. The points are plotted in conformance with this criteria.

The undrained shear strength of the material is calculated from the effective stress friction angle and pore pressure parameter (A) at failure using the following relationship (from Reference 2.5-40):

$$g_f = \frac{\bar{P}_\circ \sin \bar{\phi}}{1 + (2A_f - 1) \sin \bar{\phi}} \qquad \text{(EQ. 2.5-1)}$$

where:

g_f = undrained shear strength

$\bar{\phi}$ = effective stress friction angle

A_f = pore pressure parameter (A) at failure

$\bar{P}_o$ = initial mean effective principal stress

For the samples tested, A_f varies from -0.04 to -0.38. Using the conservative assumption of $A_f = 0$ and $\bar{\phi} = 33.5°$, the undrained shear strength is calculated to be 1.2 $\bar{P}_O$.

2.5.4.2.2.3 Dynamic Shear Strength of In Situ Soils at Spray Pond

Stress controlled cyclic triaxial tests were made in which the undisturbed samples were placed in a chamber and saturated using the back pressure method. When saturated, the samples were consolidated isotropically to an effective confining pressure of 2 ksf. After consolidation, the drainage valves were closed, and a symmetrical cyclic deviator stress was applied. The axial deformation, axial load, and pore pressure were measured continuously during the cyclic loading. The cyclic stress ratio plotted against the number of cycles required to cause 5% double amplitude strain is shown on Figure 2.5-19.

The dynamic shear strength of the soil is determined by multiplying the cyclic stress ratio by the effective overburden pressure. The cyclic stress ratio required to cause 5% double amplitude strain in five cycles is determined to be 0.61 (Figure 2.5-19). The selection of 5 cycles simulates the SSE of 0.15 g at the site, based on correlations of equivalent uniform stress cycles and time histories by Seed, et al (Reference 2.5-41).

2.5.4.2.2.4 Properties of In Situ Soils Other Than Spray Pond Area

The properties of soils at the site, other than those discussed in Sections 2.5.4.2.2.1 through 2.5.4.2.2.3, are discussed in the Dames & Moore report (Reference 2.5-51). The results of the tests are described below and are summarized in Table 2.5-4.

The predominant soils at the site consist of red sandy and clayey silts with numerous rock fragments. They are classified as ML. The in situ moisture content measured in accordance with ASTM D2216-61 ranges from 8.3% to 21.3%, and averages 13.4%. The average grain-size distribution, based on the results of sieve analyses, in accordance with ASTM D422-63, were found to be 14% in gravel-size, 27% in sand-size, and 59% silt and clay. The average liquid limit and plasticity index in accordance with ASTM D422-63, based on three tests, were found to be 25 and 8, respectively. The plasticity index was calculated using the results of the liquid limit test in accordance with ASTM D423-66 and plastic limit test in accordance with ASTM D424-59.

A limited number of compression tests were performed to determine the shear strength of the in situ soil. The total shear strength parameters, based on two unconfined compression in accordance with ASTM D2166-66 and two unconsolidated undrained triaxial compression tests in accordance with ASTM D2850-70, were found to be c = 3.0 ksf, and Ø = 18°. The effective shear strength, based on four consolidated drained triaxial compression tests, were found to be $\bar{c} = 0$, and $\bar{\emptyset} = 26.5°$. Procedures given in Reference 2.5-141 were followed in conducting the consolidated drained triaxial compression tests.

No laboratory tests were made to determine the dynamic shear strength of the soil.

2.5.4.2.2.5 Properties of Type I Fill

A description of Type I fill and methods of placement are given in Section 2.5.4.5.4. The static or dynamic properties of this material have not been measured.

A total unit weight of 140 pcf and an at rest coefficient of lateral earth pressure of 0.7 have been assumed for Type I fill. The Type I fill is expected to have properties similar to dense sand and gravel and to have a maximum shear-wave modulus determined by the following expression (Reference 2.5-144):

$$G = 1000\ K_2\ \sigma_m^{1/2}$$

where:

G = maximum shear modulus, psf, at a strain of 10^{-6} in/in

K_2 = 140

σ_m = average stress, psf, and is equal to $\frac{(\sigma_1 + 2\sigma_3)}{3}$

σ_1 = ν H

σ_3 = 0.7 ν H

ν = Unit weight, 140 pcf

H = depth, ft

2.5.4.3 Exploration

The locations of all field explorations are shown in Figures 2.5-20 and 2.5-21. Summary logs of borings are shown in Figure 2.5-22. Soils are classified in accordance with the Unified Soil Classification System. Rock coring was performed with double-tube, NX equipment.

Site drilling began in September and October, 1969 and continued in the spring of 1970 (Borings 1 through 301). Geophysical surveys (Section 2.5.4.4) were performed in the plant area at this time. In the spring of 1971, additional drilling was performed in the area of the Perkiomen Creek pump station. In late 1971 and early 1972, additional drilling was performed in the Schuylkill River pump station area. In 1973 auger holes were drilled in the area of the emergency spray pond, and in 1974 detailed spray pond investigations were completed. The cooling tower foundation exploration was also completed at this time. Most of the main plant foundation was exposed at this time, and some fracture zones were noted (Sections 2.5.1.2.5 and 2.5.4.12). Between April and July, 1974, an extensive geologic study of these zones and the area around the site was completed by Dames and Moore. This study consists of geologic mapping, with some drilling and test trenching near the Sanatoga, Brooke-Evans, and Linfield faults. Site exploration was completed in the fall of 1974. A total of 366 borings and four test pits was completed in the site area for geologic, groundwater, and foundation investigations. In March, 1977, 13 additional test pits were excavated to depths of from 5-11.5 feet, to investigate soils for use in construction of the soil-bentonite liner for the emergency spray pond.

Static water levels were measured in some of the borings drilled on the site. Perforated plastic pipes were installed in some borings to allow future collection of water level data. These borings are denoted on the plot plan (Figure 2.5-20).

A geologic map of the main power block foundations is presented in Figure 2.5-13. Contours on top of rock in the site area are shown on Figure 2.5-9. Geologic profiles are shown on Figures 2.5-10 and 2.5-11.

2.5.4.4 Geophysical Surveys

2.5.4.4.1 Seismic Refraction Survey

Seismic refraction surveys were conducted at the site. A continuous series of seismic lines closely followed the continuous line of borings drilled across the site (Figure 2.5-21). These lines ranged in length from about 400-700 feet, with some overlapping coverage. Two 550 foot refraction lines were performed perpendicular to the major line that traversed the site.

The results of the seismic refraction surveys were used to develop dynamic properties of the foundation materials. Permanent records of the compressional waves generated from the survey were obtained using an Electro-Technical Labs ER75012 seismic timer, which is a 12-trace refraction seismograph. Geophone spacings of 25 feet and 50 feet were used in performing the surveys. Compressional wave velocities (V_p) in rock measured during these studies range from about 7000 fps to 20,000 fps, with an average of approximately 12,500 fps.

2.5.4.4.2 Shear-Wave Velocity Survey

A shear-wave velocity survey was performed to further evaluate dynamic bedrock characteristics. Shear-wave velocities were computed from the records obtained using two Sprengnether 3-component engineering seismographs. Observations were made at distances of between 500 feet and 1000 feet from the shot point, at the locations indicated on Figure 2.5-21. An apparent shear-wave velocity (V_s) of 6100 ft/sec was derived from the line run perpendicular to the rock strike, roughly in a north-south direction. In the second line, which parallels the approximate east-west strike of the bedding-plane, an apparent shear-wave velocity of 5800 ft/sec was measured. Using elastic theory, a Poisson's ratio of about 0.3 can be calculated using these shear-wave velocities and average compressional wave data across the site. Shear-wave data are included in Table 2.5-11.

2.5.4.4.3 Up-Hole Velocity Survey

An up-hole velocity survey was performed in the pump test well at the location shown on Figure 2.5-21. Measurements were obtained using a Porta-Seis refraction seismograph, with small explosive charges as energy sources, and an in-hole cable with 25 foot geophone spacings. Repeated shots were made and the cable was withdrawn in 5 foot increments.

The up-hole velocity survey was made to determine variations in the vertical compressional wave velocity of the underlying rock. Compressional wave velocities (V_p) measured were 7700 fps from depth 110-140 feet, and 12,600 fps from depths 37-110 feet and from 140-187 feet.

2.5.4.4.4 Micromotion Measurements

Measurements of the ambient background motion of the site and its response to natural motion generators, such as wind and tides, give an index of the dynamic properties of the materials

underlying the site. An attempt was made to measure these motions in the proposed plant area using the Dames and Moore microtremor equipment. This equipment is a highly sensitive, electronic, vibration recording device capable of magnification up to 150,000 times, and it is accurate over a frequency range of about 0.4-30 cycles per second. The 3 component micromotion observation was made on the existing ground surface (prior to construction), near the test well used for the up-hole velocity survey, as shown on Figure 2.5-21.

The microtremor records indicate that ambient motions caused by natural background excitations at the site are negligible. There is a suggestion of motion at a period of 0.7-0.8 second, but no apparent predominant ground period; this is a condition common at sites where competent materials are exposed at the surface.

2.5.4.5 Excavations and Backfill

The location, limits of excavation, and type of fills associated with seismic Category I facilities are presented in Figure 2.5-37. Detailed descriptive data concerning these backfills and excavations are discussed below. Procedural controls, such as inspections and tests, exercised during the preparation of foundations for seismic Category I structures are described below and in Section 2.5.5.

The properties of foundation rock at the site (Section 2.5.4.1 and Tables 2.5-3 and 2.5-11) indicate that the rock has adequate strength to resist significant heave at the depths excavated. Further, the moderately well to well developed conjugate sets of vertical joints present at the site, together with subhorizontal bedding-planes, would presumably have provided for prior release of any excessively high in situ stresses, minimizing the potential for rock rebound.

Seismic Category I facilities on soil, such as pipelines and electrical ducts, are largely buried and backfilled facilities, such that the accompanying loads approximate the original in situ conditions. The diesel oil storage tank facility, which is founded on weathered rock, is also a buried and backfilled facility. At the spray pond, the pump house, overflow structure and all pipe supports are to be founded on rock; as discussed in Section 2.5.5.2, factors of safety on the seismic Category I soil slopes are considerably in excess of the minimum acceptable requirements.

In view of these circumstances, specific measures for monitoring foundation rebound and heave were considered but are not considered to be necessary. No instances of foundation rebound or heave were noted during excavation or construction of the facilities.

2.5.4.5.1 Main Power Block and Cooling Tower Excavation

All seismic Category I rock foundations at the main power block are carried to, or well below, unweathered bedrock. These include the reactor enclosures and control room structure. Rock foundations for the turbine and radwaste enclosures, although they are not seismic Category I structures, are prepared according to the same general procedures and criteria used in preparing the seismic Category I rock foundations.

The excavation of rock proceeded by initial ripping of any weathered surficial rock material, followed where necessary by line blasting and presplitting in holes drilled to provide stable slopes. Essentially vertical slopes in unweathered rock proved stable throughout the duration of construction, and no special protective measures were required.

The surface of the excavated foundation rock is scaled to remove loose debris and jetted with water or air to remove loose fragments and to prepare the surface for concrete. Before placement of structural concrete or concrete backfill to design elevation, all seismic Category I foundations for the main power block are inspected by an engineering geologist to verify the suitability of the rock and its proper surface preparation to receive concrete. Geologic mapping of foundation rock in the main power block area is presented in Figure 2.5-13.

Foundations for each of the cooling towers (nonseismic Category I structures) consist of 40 individual pedestals supporting the columns and extending to bedrock. Excavation proceeded by cutting a ring trench and preparing a suitable surface for each pedestal in unweathered or partly weathered bedrock by ripping or blasting as necessary, followed by scaling and jetting.

2.5.4.5.2 Diesel Generator Enclosure Excavation

The plans and sections of the diesel generator enclosure foundations are shown in Figure 3.8-61. The diesel generator enclosures are founded on bedrock; the geological inspection and preparation of the foundation rock are the same as for the main power block.

The spray pond pump structure and spray network pipe supports are seismic Category I and are founded on bedrock. Geological inspection and preparation of the foundation rock for these structures are the same as that for the main power block.

2.5.4.5.3 Spray Pond Excavation, Slope Protection and Liner Construction

The plans and sections of the spray pond showing excavation, slopes, and normal pond level are given in Figures 3.8-56 and 3.8-57. As shown, the spray pond is constructed primarily by excavation. A soil-bentonite liner and a protective soil cover are placed over the entire bottom of the pond and on the soil slopes. The soil cover on the slopes in turn is protected by riprap and riprap bedding. The rock slopes are treated by shotcrete for protection against weathering. Due to a sloping bedrock surface, the bottom of the pond below the soil-bentonite liner is underlain partially by soil and partially by rock. Slopes in soil are excavated at 4 horizontal to 1 vertical; rock slopes are excavated at 1 horizontal to 1 vertical (Section 2.5.5), except for a short transition zone in weathered rock, which is excavated at 2:1.

The soil-bentonite liner, soil cover, riprap bedding and foundation preparation of the spray pond are discussed in detail in Section 2.5.5.

2.5.4.5.4 Fills - General

All fills placed at the site, which are associated with seismic Category I structures (except spray pond), include random fill, select granular backfill, cementitious backfill, and concrete.

Two types of random fill, identified as Type I and Type II, were used for general site grading.

Type I fill was placed in the areas adjacent to the main power block and as backfill over part of the RHR and ESW piping. Type II fill was used for finished grading in the outlying areas, including backfill over part of the safety-related duct banks.

The division line between cut and fill and the limits of Type I and Type II fill within the main power block complex are shown in Figure 2.5-37.

Type I fill consisted of broken rocks and fines obtained from the site excavations and was graded from fine to coarse material with no rock fragments larger than 8 inches in diameter. It was placed in uniform layers of loose lifts with a maximum thickness of 12 inches and was compacted and tested as described below.

Type I fill placed before July 1971 was compacted to 90% of the maximum dry density in accordance with AASHO T180-61, Method D, and was tested in accordance with AASHO T147-54. Type I fill placed thereafter was compacted to 90% of the maximum dry density in accordance with AASHO T180-70, Method D, and was tested in accordance with AASHO T191-61.

Type I fill was compacted by the following approved types of equipment:

a. Sheep-foot roller with minimum weight of 4000 pound per linear foot of drum, operated at a speed of approximately 3 mph.

b. Rubber tire rollers with minimum of 4 pneumatic tire wheels maintaining tire pressure on the ground of between 80-100 psi. The load per wheel may vary from 18,000-25,000 pounds.

c. Vibratory roller with minimum weight of 21,000 pounds, drum diameter approximately 70 inches and length of 78 inches, and minimum centrifugal force of 40,000 pounds, and frequency 1000-1400 vibrations per minute.

d. In confined areas, hand operated equipment was used with a maximum lift of 8 inches.

e. A total of 379 compaction tests were performed before the end of 1982. The minimum frequency for testing Type I fill for compaction was not less than once for each 500 cubic yards placed. Fills failing to meet the compaction requirements were removed, recompacted, and retested.

Type II fill consisted of broken rocks and fines obtained from the site excavations. It was placed uniformly in unconsolidated lifts not exceeding 24 inches in thickness, producing a reasonably well graded mass with a minimum of stratification of fine or coarse materials. The material was uniformly spread over the entire area by bulldozer prior to compaction. The material was moisture-conditioned to attain satisfactory compaction. Type II fill was compacted by the equipment described for Type I fill under general supervision without testing requirements. Granular Type II fill was also compacted by use of a track-type tractor weighing not less than 60,000 pounds and making a minimum of four passes overlapping one-fourth the width of the track on each pass.

Select granular backfill consisted of imported aggregate or screenings. The maximum particle size was ¾ inch, with no more than 10% by weight passing the No. 200 sieve. Select granular backfill was placed in loose lifts with a maximum thickness of 6 inches and was compacted to 95% of the maximum dry density in accordance with AASHO T180-70, Method D. As an alternative to the above material, when cohesionless select backfill was used, it was compacted to 90% of the maximum dry density in accordance with ASTM D2049-69 by the use of both dry and wet methods. In-place select granular backfill was tested in accordance with AASHO T191-61.

The cementitious backfill consisted of a mixture of portland- cement, aggregate, and water. The minimum compressive strength at 28 days was 80 psi. Testing for compressive strength of cementitious backfill using sand as aggregate was in accordance with ASTM C109, ASTM C31, and ASTM C39. Testing for compressive strength of the backfill using coarse aggregate was in accordance with ASTM C31 and ASTM C39.

Slump tests were performed in accordance with ASTM C143. The cementitious backfill was consolidated by use of mechanical vibrating equipment for proper placement.

The concrete backfill consisted of a mixture of portland-cement, aggregates, admixtures, and water. The minimum 28 day compressive strength was 2,000 psi. The standards and specifications that governed the concrete backfill are stated in the following sections:

a.	Section 3.8.6.1.2.2	Mix proportioning
b.	Section 3.8.6.1.4.2	Mixing and delivery
c.	Section 3.8.6.1.4.3	Placing
d.	Section 3.8.6.1.4.4	Consolidation
e.	Section 3.8.6.1.5	Construction testing

Field tests of Type I random fill, select granular backfill, cementitious backfill and concrete backfill used in conjunction with seismic Category I structures, electrical duct banks, manholes, pipelines and valve pits were performed by Quality Control. The test data are available at the site for inspection and review.

2.5.4.5.5 Miscellaneous Category I Facilities - Excavation and Backfill

Seismic Category I facilities not founded on unweathered bedrock include part of the spray pond, portions of the underground piping and electrical ducts, oil tanks, and valve pits. The spray pond is discussed separately in Section 2.5.4.5.3. Portions of these Category I facilities are founded on weathered rock, natural soil, or fills. The fills are discussed in Section 2.5.4.5.4.

Underground piping was installed in trenches excavated to a minimum of 6 inches below the pipe. Soft spots and unsuitable material found at the bottom of the trenches were removed and replaced with select granular backfill, cementitious backfill, or concrete. Select granular backfill, cementitious backfill, or concrete was placed at least 6 inches below and on each side of the pipe to a minimum of 12 inches above the pipe. The remainder of the trench was backfilled with Type I fill, select granular backfill, cementitious backfill, or concrete. All Category I piping was buried with adequate cover for missile protection.

The plans, profiles, and sections showing the detailed relationship of the Category I piping to subsurface soil, fill, and rock materials are shown on Figure 2.5-37.

The diesel oil tanks and Category I electrical ducts were buried with adequate cover for missile protection. The Category I valve pits were buried, except the roof slabs, which are missile and tornado resistent and are exposed above ground. Soft spots and unsuitable material found at the bottom of the excavations for these structures were removed and replaced with cementitious

backfill or concrete. Where overexcavation occurred below these structures, the select granular, cementitious or concrete backfilling materials were used. Cementitious backfill was placed at least 2 feet below and on each side of the diesel oil tanks, to a minimum of 12 inches above the tanks. The remaining backfill to finish grade was placed using select granular backfill. The sides of the valve pits were backfilled with cementitious backfill or Type I fills. The electrical duct banks were completely encased in concrete with a minimum of 3 inches of concrete cover on all four sides. The remaining trench excavation was backfilled to finish grade with Type I or Type II fills. Section 3.8.4.1.6 contains additional discussions on these miscellaneous structures. The plans, profiles, and sections showing the detailed relationship of the Category I electrical duct banks to subsurface soil, fill, and rock materials are shown on Figure 2.5-37.

2.5.4.6 Groundwater Conditions

A detailed groundwater study of the site is presented in Section 2.4.13. Groundwater occurs at the site in the Brunswick lithofacies which consist of bedded siltstone, sandstone, and shale. Groundwater flows primarily through joints, fractures, and other secondary openings in the consolidated rock. The water table is 15-95 feet below land surface at the site. A map of the potentiometric surface, determined from water levels measured in May, 1979, indicate the groundwater levels range from el 250' east of the spray pond to el 120' southwest of the radwaste enclosure. Fluctuation of water levels in observation wells are indicated by the hydrographs in Figure 2.4-18.

Groundwater studies conducted for the spray pond include installation of permanent observation wells and the performance of 41 permeability tests. Permeability values obtained from the field tests at the spray pond are given in Table 2.4-18. The average permeabilities for various materials are as follows:

Material	Permeability (ft/yr)
Overburden	3.5
Contact Zone	14.0
Rock	214

2.5.4.6.1 Spray Pond Seepage Analysis

The spray pond makeup system has sufficient capacity to replace estimated seepage losses during normal operation. Moreover, the total volume of water in the pond itself is sufficient to accommodate estimated seepage during the 30 day transient period throughout which no makeup to the pond is assumed to be available.

Seepage losses from the pond migrate toward the Schuylkill River and to the north, as shown on Figure 2.5-23. As detailed below, estimated seepage losses from an unlined spray pond indicate that seepage from the pond would not adversely affect the safety and performance of the ultimate heat sink, nor significantly effect groundwater levels beneath the site. Nevertheless, a liner is provided.

Estimated seepage losses from an unlined pond were calculated by subtracting the natural, preconstruction groundwater underflow from the total underflow expected after the spray pond is constructed. Flows toward two discharge areas were analyzed separately because of the difference in differential heads. Two methods were used to calculate total underflow using Darcy's

Law: construction and analysis of a flow net, and computation of underflow through a peripheral cross-section.

In the first analysis, a flow net method was used in which a plan flow net was constructed as shown on Figure 2.5-23. Total flow was calculated using the equation (from Reference 2.5-42):

$$Q = \frac{n_s}{n_d} KDH \qquad \text{(EQ. 2.5-2)}$$

where:

- Q = quantity of underflow, ft^3/yr
- n_s = number of stream tubes
- n_d = number of equipotential drops
- K = permeability, ft/yr
- H = differential head, ft
- D = aquifer thickness, ft

The differential head between the spray pond surface and the Schuylkill River is 141 feet. The differential head between the spray pond surface and the northern discharge area at el 200' is 51 feet. An effective aquifer thickness of 140 feet is used because of the decrease in number and size of fractures at that approximate depth as observed in the core holes. A permeability of 200 ft/yr is used as an effective value for the residual soils and bedrock materials (Section 2.4.13.2.5).

Underflows were determined to be 5.3×10^6 ft^3/yr towards the Schuylkill River, and 1.6×10^6 ft^3/yr toward the north, giving a total underflow of 6.9×10^6 ft^3/yr.

The second method of analysis, a cross-sectional area method, uses the following form of Darcy's Law:

$$Q = KIA \qquad \text{(EQ. 2.5-3)}$$

where:

- Q = quantity of underflow, ft^3/yr
- K = permeability, ft/yr
- I = hydraulic gradient (ratio)
- A = cross-sectional area of underflow, ft^2

Using an aquifer thickness of 140 feet, the cross-sectional area through which both natural underflow and seepage from the pond is flowing toward the Schuylkill River is approximately 224,000 ft^2; the cross-sectional area through which water is flowing toward the north is approximately 168,000 ft^2. The hydraulic gradient is approximately 0.1 toward the Schuylkill River

and 0.05 toward the north. The permeability is 200 ft/yr. The rates of underflow determined by this method are 4.5×10^6 ft^3/yr toward the Schuylkill River and 1.7×10^6 ft^3/yr toward the north, giving a total underflow of 6.2×10^6 ft^3/yr.

Preconstruction natural underflow was calculated using equation 2.5-3. The hydraulic gradient (I) was determined from equipotential contours of the groundwater table measured on June 24, 1974, shown on Figure 2.5-23. The hydraulic gradient is 0.08 for flow toward the Schuylkill River, and 0.02 for flow toward the northern discharge area. The cross-sectional areas of natural underflow (A) are based on a saturated aquifer thickness of 110 feet. The permeability (K) is 200 ft/yr, as described above. Based on these parameters, natural underflow beneath the pond is estimated to be 2.74×10^6 ft^3/yr toward the Schuylkill River and 0.54×10^6 ft^3/yr toward the north. Total preconstruction (natural) underflow, then, is estimated to be 3.3×10^6 ft^3/yr, the sum of these flows.

Therefore, the estimated spray pond seepage loss from an unlined pond is:

$(6.9 \times 10^6) - (3.3 \times 10^6) = 3.6 \times 10^6$ ft^3/yr (Flow net method)

or

$(6.2 \times 10^6) - (3.3 \times 10^6) = 2.9 \times 10^6$ ft^3/yr (Cross-sectional area method)

These calculated losses would cause a decline of 0.6-0.7 feet per month in the water level of an unlined spray pond.

In both methods of analysis, the average permeability is assumed to be approximately that of rock (200 ft/yr). Because only 60% of the pond bottom is exposed to rock, and the balance is exposed to residual soils of markedly lower permeabilities, these estimates of total seepage loss from an unlined pond are probably high.

The permeability of the materials exposed within the pond is an important parameter in the seepage analysis. Bedrock, the most permeable material underlying the pond, underlies approximately 60% of the pond. Most of this rock is now covered with concrete which provides foundation and support for the spray pond piping network.

The balance of pond is underlain by overburden and the bedrock-overburden contact zone. As presented in Table 2.4-18, the 33 measured permeabilities of the bedrock (Brunswick Formation) range from 1 ft/yr to 1247 ft/yr, of which the arithmetic mean is 214 ft/yr. The location of wells where tests were performed is shown on Figure 2.4-15. The median value is 71 ft/yr, and fully 90% of the measured permeabilities in rock are less than 500 ft/yr. Only two of the measured permeabilities are more than 1000 ft/yr. The measured permeabilities from eight tests in the overburden and contact zone range from less than 1 ft/yr to 21 ft/yr (Table 2.4-18). The mean value is 7.5 ft/yr and the median is 3 ft/yr.

Section 2.4.13.1.1 points out that most groundwater flow occurs through secondary openings in the rock (fractures and joint), and the higher permeability measurements are attributed to test performed in relatively more fractured zones that are of limited extent. The 200 ft/yr used in the seepage analysis is quite conservative because: 1) it is approximately equal to the arithmetic mean of all rock permeability measurements even though this average is biased by the inclusion of the abnormally high (greater than 1000 ft/yr) permeability measurements; 2) almost half (40%) of the spray pond area is underlain by overburden or contact zone material that has a significantly lower permeability than the bedrock (average value of 7.5 ft/yr). More realistic, although still

conservative, estimates of the average effective permeability of the spray pond area might be 132 ft/yr (60% at 214 ft/yr and 40% at 7.5 ft/yr), or 173 ft/yr (the average of all permeability tests).

The spray pond includes a soil-bentonite liner on the bottom and on soil slopes, and shotcrete on rock slopes. The soil-bentonite liner is one foot thick and has a permeability of less than one ft/yr (Figure 2.5-24 and Section 2.5.5.4). The seepage loss for the lined pond is calculated to be 1.83×10^6 gal/month or 2.94×10^6 ft^3/yr (Section 9.2.6.4). The liner ensures that the actual seepage loss is acceptable by preventing higher rates of seepage through localized fracture zones in the event such conditions were found to exist.

A seepage test was performed to ensure that the design basis seepage rate assumptions were not exceeded. The test results show that, based on weekly measurements of seepage losses over a 23 week period, the average seepage loss for the entire period is between 11% and 21% of the allowable design value, depending on how evaporation losses are measured. This is equivalent to a seepage rate of about 5-9 gpm for the whole pond. Considering possible error contributions from all measurements, the upper limit of this seepage loss is estimated to be approximately 40% of allowable design value, whereas the lower limit is effectively zero. Therefore, the actual seepage loss from the spray pond is well below the allowable design value. Additional information is contained in Section 2.5.5.4.3 and Reference 2.5-145.

2.5.4.6.2 Dewatering During Construction

Groundwater presented no problem during excavation and construction in the main power block area. The water table was below most of the excavation during construction. The rock around the power block has low permeability and did not transmit significant quantities of water into the excavation. Only small amounts of seepage occurred along the walls of the radwaste enclosure excavation during construction.

This same low permeability of foundation rock caused surface run-off to collect in the foundation excavations, especially during periods of construction inactivity. For example, the rock in the excavation was more or less continuously covered with water from early 1972 to late August. In March 1972, water was standing in the excavation to about el 170', inundating the radwaste foundation area and lower parts of the reactor foundations. On July 6, 1972, rain from Hurricane Agnes raised the water level in the excavations to about el 175'; 22 days later, the water level had not noticeably declined. The run-off water was pumped out of the excavation following resumption of construction activities. These conditions further indicate the low permeability of the foundation rock.

A subdrainage system was installed for dewatering of the main power block region during construction. This system will remain permanent following construction to minimize water table height, thereby minimizing hydrostatic loading on subsurface walls. Any lowering of groundwater elevation by the subdrainage system has not been taken into consideration for design of subsurface portions of power block structures. The maximum expected water table elevations, defined in Section 2.4.13.5, were used for design.

2.5.4.6.3 Groundwater Monitoring

The water level in observation wells at the spray pond and power block area were monitored as discussed in Sections 2.4.13.2.4 and 2.4.13.4. The data obtained were used in establishing the potentiometric surface and the direction of groundwater flow. This water level monitoring,

throughout plant construction and site grading/surfacing, has indicated no changes in the groundwater flow direction. Changes in the potentiometric surface are within the plant design criteria for hydrostatic loading. Hence, the hydrologic condition is expected to remain within the design criteria during the operating life of the plant.

2.5.4.7 Response of Soil and Rock to Dynamic Loading

The responses of soil and rock to dynamic and seismic loading conditions are discussed in Section 2.5.2. Further discussion of response characteristics of soil at the spray pond site is contained in Sections 2.5.4.8 and 2.5.5.2. Soil-structure interaction considerations are discussed in Sections 3.7.1.4 and 3.7.2.4.

2.5.4.7.1 Response of Soil Along Pipelines

A soil response study was performed to determine the characteristics of ground motion induced by the SSE. This ground motion is required to evaluate the response of buried seismic Category I piping.

The stratigraphic profile along seismic Category I piping is shown on Figure 2.5-37. The pipe support conditions vary from rock to in situ soil to as much as 24 ft of Type I fill beneath the pipe.

The soil stratigraphy and properties used in the analyses are shown in Table 2.5-10. The assumed properties for Type I fill are given in Section 2.5.4.2.2.5. The shear modulus of the rock is presented in Table 2.5-11.

Soil response studies were performed using the computer program SHAKE, Reference 2.5-143. The design SSE time history with a peak acceleration of 0.159 (Section 3.7.1.2) was input at the surface of the rock. The shear modulus and damping factors were varied with strain as shown on Figures 2.5-40 and 2.5-41, in general accordance with Reference 2.5-144. The results of the analyses along with solutions for higher and lower moduli for Type I fill are given in Table 2.5-10. The results presented include peak acceleration at the level of the pipe, peak particle velocity at the level of the pipe, and natural frequency of the soil column.

2.5.4.8 Liquefaction Potential

The soil at the seismic Category I spray pond was analyzed for liquefaction potential. The soils at other seismic Category I facilities were not analyzed since these soils are not saturated and the potential for becoming saturated is negligible.

The liquefaction potential of soil in the spray pond site was analyzed for a maximum ground acceleration of 0.15 g. Because of the shallow depth of soil, the maximum induced shear stress was calculated assuming that the soil mass behaves as a rigid body, and the average equivalent shear stress was taken as 65% of the maximum induced shear stress (Reference 2.5-43).

The dynamic strength of soil was determined from the cyclic triaxial test results included in appendix J of the PSAR and is shown graphically in Figure 2.5-19. The equivalent number of uniform stress cycles is taken as five.

The soil profile below the pond bottom used in the analysis represents the most critical section. The soil profile includes a 12 inch layer of protective soil cover and a 12 inch layer of soil-bentonite

liner on top of 9 feet of in situ soil. The pond bottom and the bedrock are at el 241' and el 230', respectively.

The average induced shear stress was calculated as follows:

$$\tau_{ave} = 0.65 \frac{\gamma h}{g} a_{max} r_d \qquad \text{(EQ. 2.5-4)}$$

where:

τ_{ave} = average induced shear stress

γ = saturated unit weight of the material. The values used in the analysis were 123.8 pcf, 119.0 pcf, and 126.4 pcf for the soil cover, soil-bentonite liner, and the in situ soil respectively (Table 2.5-5)

h = depth where the induced stress is to be computed

$\frac{a_{max}}{g}$ = 0.15

r_d = correction factor (0.98 to 0.99 for shallow soil profile)

The shear strength was calculated based on the results of cyclic triaxial shear tests and equals $0.37\sigma_o$, which was obtained by multiplying the design cyclic stress ratio of 0.61 (Figure 2.5-19), the effective overburden pressure σ_o, and a correction factor of 0.60 (Reference 2.5-43).

The factor of safety was obtained by dividing the shear strength by the average induced shear stress. Since both the shear strength of the soils and the induced shear stresses are dependent on depth below ground surface, determinations of the factor of safety against liquefaction were made at various depths. The results of this analysis are summarized in Figure 2.5-25. The minimum factor of safety was computed to be 1.9.

2.5.4.9 Earthquake Design Basis

Derivation of the OBE and SSE are discussed in Section 2.5.2. The liquefaction potential and slope stability of the spray pond are analyzed for the SSE event.

2.5.4.10 Static Stability

The reactor enclosures, control structure, diesel generator enclosure, spray pond pump house, spray networks, turbine enclosures, and radwaste enclosure are founded on sound, unweathered bedrock. Seismic Category I facilities not founded completely on unweathered bedrock include the spray pond, underground piping, diesel oil tanks, valve pits and electrical ducts. Portions of these facilities not founded on rock are founded on natural soil and/or manmade fills.

The strength of the unweathered bedrock amply accommodates the loads of the plant, providing highly stable foundation conditions. As measured by seismic refraction surveys in the area of the principal plant structures, compressional wave velocities range from 7000-20,000 fps, averaging about 12,500 fps; shear-wave velocities range between 5800 fps and 6100 fps. An up-hole survey

(Figure 2.5-21) measured a compressional wave velocity of 12,600 fps in the siltstone beneath the site. Unconfined compression test results on rock core samples (Table 2.5-3) range from 460-1760 tons/ft^2, with an average of about 1140 tons/ft^2. Poisson's ratio is calculated to be about 0.3 (Table 2.5-11). Static moduli derived from additional compression tests on rock cores range from 1.2x10^6 psi to 8.3x10^6 psi, averaging 4.1x10^6 psi; compressive strengths range from about 580-2370 tons/ft^2, averaging 1230 tons/ft^2 (Table 2.5-12). Unconfined compressive strength and elastic modulus determinations substantially followed ASTM D2938-71 and ASTM D3148-72, respectively, which were adopted after these tests were completed.

Plate bearing tests (ASTM D1194-57) were run by Dames and Moore at the site (Reference 2.5-50); the results are quite variable. Values of the Secant Modulus of Deformation at first loading, which includes plastic and elastic deformation and also reflects the closing of joints and fractures, ranges from 30,000 psi to 200,000 psi, with an average of 85,000 psi. The Secant Modulus of Elasticity at second loading is much higher, with an average value of 356,667 psi.

A bearing capacity of 30 tons/ft^2 (60 ksf) for static and frequently applied live loads on sound rock is used for design, following recommendations by Dames and Moore (Reference 2.5-51). Actual loads induced by the plant structures founded on bedrock are much less than the allowable bearing pressure of the foundation rock, and they are far below the ultimate bearing capacity. The structural loads produce no significant total or differential settlement of the foundations.

The design lateral earth pressure acting on subsurface walls of seismic Category I structures was computed assuming granular backfill having the properties stated in Section 2.5.4.5.4. The coefficient of earth pressure "at-rest" was used. In addition, the walls were designed for surcharge loadings and dynamic soil pressures as appropriate. The typical pressure diagrams and combinations are shown on Figure 2.5-39.

2.5.4.10.1 Static Stability of Safety-Related Structures on Rock

The following sections contain information regarding static and dynamic lateral earth pressures and groundwater loads on the reactor enclosure, control structure, diesel generator enclosure including pipe tunnel, and spray pond pumphouse, which are all founded on bedrock. Table 2.5-9 includes safety-related structures, dimensions of foundations, approximate bearing elevation, design bearing pressure, and hydrostatic pressure. Seismic Category I structures not founded on rock are discussed in Section 2.5.4.10.2.

2.5.4.10.1.1 Diesel Generator Enclosure Including Pipe Tunnel

The exterior and interior foundation walls of the diesel generator enclosure are founded on bedrock (Figure 3.8-61). The interior walls support the base slab at el 217'. The space between the bedrock and the bottom of the base slab is backfilled with fillcrete. Concrete backfill surrounds all subsurface walls and extends to the rock profile such that there will be no transmissibility of lateral pressures to the walls.

The pipe tunnel is a concrete box section with the base slab founded on bedrock. The north wall lies parallel to the adjacent reactor enclosure wall and is separated by a 1 inch seismic gap. The west and east tunnel walls are separated by 1 inch seismic gaps from the adjacent radwaste enclosure and auxiliary boiler enclosure. The south tunnel wall was designed as a restrained retaining wall to resist the lateral earth pressure due to backfill which has a saturated unit weight of

140 pcf, an at rest earth pressure coefficient of 0.7, a surcharge of 250 psf due to AASHO H-20 truck loading, and a dynamic lateral force due to seismic loading as shown on Figure 2.5-39.

The box section was also designed for the lateral earth pressure resulting from the Cooper E-72 railroad loading, the live load on the roof, and the seismic load.

Because the high-water table elevation is below that of the foundation in the power block region, there are no groundwater loads acting on the foundations of the diesel generator enclosure.

2.5.4.10.1.2 Reactor Enclosure and Control Structure

The reactor enclosure and control structure are separated from the surrounding Type I fill by adjacent structures or pipe tunnels.

The reactor enclosure and control structure are bounded to the north and west by two nonseismic Category I structures (the turbine enclosure and the radwaste enclosure). The south and east sides of the reactor enclosure and control structure are bounded by pipe tunnels. The adjacent structures and pipe tunnels, founded on competent bedrock, extend up to or above plant grade el ±217'. Those subsurface exterior walls of the reactor enclosure and control structure, lower than the foundation grade of adjacent structures, are placed adjacent to excavated rock slope with Class A concrete or fillcrete backfilled between the face of the wall and the face of the rock slope. Because of the conditions described above, lateral earth pressure is not considered in the design of the exterior walls.

The walls of the control structure and reactor enclosure have been designed for a hydrostatic pressure up to el 195', which is the expected maximum water table elevation in this region.

2.5.4.10.1.3 Spray Pond Pumphouse

The foundation mat and walls of the spray pond pumphouse are founded on bedrock (Figure 3.8-62). Exterior walls along the east, west, and south sides are placed adjacent to excavated rock slopes with Class A concrete or fillcrete backfilled between the face of the wall and the face of the rock slope. The exterior wall along the north side extends to the bottom of the spray pond with no embedment. Because of the conditions discussed above, lateral earth pressure is not considered in the design of the exterior walls.

The north wall of the water pit area has been designed to resist hydrostatic pressure (from el 236' to el 267') and lateral seismic loads. The foundation mat has been designed for the same hydrostatic pressure as the north wall in combination with other concurrent loads.

2.5.4.10.1.4 Diesel Oil Tanks

These tanks are located on a base slab founded on weathered rock or cementitious backfill bearing on weathered rock as shown in Figure 2.5-37. The associated valve pits located on top of the tanks are founded on cementitious backfill, which also acts as backfill around the tanks. The cementitious backfill has a minimum compressive strength of 80 psi. The remaining portion is backfilled with select granular fill placed and compacted as discussed in Section 2.5.4.5.4.

Railroad tracks were located on top of select granular fill. The base slab bearing pressure is 5410 psf, which includes all dead and live loads and the Cooper E-80 railroad loading. The bearing

pressure on the foundation of the valve pits, including dead loads and AASHO H-20 truck loading, is 2830 psf. The allowable bearing capacities of the rock and cementitious backfill are not exceeded by these pressures.

The walls of the valve pits are designed to resist lateral loads due to backfill having a saturated unit weight of 140 pcf and an at rest earth pressure coefficient of 0.7, AASHO H-20 truck surcharge, and dynamic lateral loading due to a seismic event. The roofs of the valve pits are adequately designed to resist AASHO H-20 truck loading and tornado depressurization or missile impact. Because the tanks are founded on bedrock or dense natural soil, the amount of settlement is considered to be insignificant.

As an additional protection against flotation, the tanks are adequately tied to the base slab by holddown straps. For this purpose, the tanks are assumed to be submerged completely in water.

2.5.4.10.2 Static Stability of Safety-Related Structures on Soil

The following sections discuss seismic Category I facilities not founded completely on unweathered bedrock. There are no groundwater loads acting on the foundations of the spray pond, underground piping, diesel oil tanks, valve pits, or electrical ducts because the high water table elevation is below these foundations. Table 2.5-9 includes safety-related structures, dimensions of foundations, approximate bearing elevation, design bearing pressure, and hydrostatic pressure.

2.5.4.10.2.1 Spray Pond

The sustained load from the spray pond is less than the weight of overburden removed; therefore, there is an adequate factor of safety against overstressing the underlying soil (Figures 3.8-55, 3.8-56, and 3.8-57). Soil rebound during excavation for the spray pond is insignificant. Section 2.5.5 contains a discussion of slope stability under static and seismic conditions, including the design parameters and test results of soil exploration.

2.5.4.10.2.2 Underground Piping

The method used for installation of underground piping is discussed in Section 2.5.4.5.5. The placement of backfill is discussed in Section 2.5.4.5.4. All buried pipes satisfy the diameter-to-thickness ratio (<300) requirement in accordance with Reference 2.5-52. Therefore, piping deflection due to earth load will not exceed the allowable. In addition, in accordance with table 1 of Reference 2.5-52, deflections due to AASHO HS-20 loading with the minimum required cover of 4 ft are less than the allowable deflections. Process piping located under railroad tracks that are not encased in concrete are approximately 12 ft below-grade. Therefore, the deflection due to Cooper E-80 railroad loading will not exceed the allowable. The more conservative E-80 loading was used in design for required railroad loadings outside of safety-related structures.

2.5.4.10.2.3 Valve Pits

The valve pits for the RHR and ESW piping (Figure 3.8-64), which are not founded directly on bedrock, fall into the following categories:

a. Valve pits founded on concrete backfill with a minimum compressive strength of 2000 psi, which bears on bedrock

b. Valve pits for diesel oil storage tanks shown on Figure 2.5-37 are founded on cementitious backfill with a minimum compressive strength of 80 psi, which bears on weathered rock.

c. One valve pit (located near RHR and ESW piping for Unit 2 as shown in Figure 2.5-37, coordinates N5819.5, E4205.0) is supported on cementitious backfill which bears on natural soil, with minimum bearing capacity of 6000 psf.

The valve pits are designed for AASHO HS-20 truck loading. The maximum calculated pressure under the base slabs is 2440 psf.

The walls of the valve pits are designed to resist lateral loads due to backfill having a saturated unit weight of 140 pcf and an at rest earth pressure coefficient of 0.7, and a surcharge of 250 psf due to AASHO HS-20 truck loading and lateral force increment due to seismic loading as shown on Figure 2.5-39. The roofs of the valve pits are adequately designed to resist AASHO HS-20 truck loading, tornado depressurization or missile impact. Because the valve pits are founded on concrete or cementitious backfill, the amount of settlement is considered to be insignificant.

2.5.4.10.2.4 Electrical Ducts

Electrical ducts are encased in Class A concrete having a minimum design strength of 2000 psi. The ducts are buried a minimum of 4 ft below finished grade with Type I or II fill placed on top and compacted as described in Section 2.5.4.5.4. The duct banks are founded on either bedrock, weathered rock, dense natural soil or compacted Type I fill. Where the bottom of the trenches were overexcavated, they were backfilled under the ducts with a minimum of 6 inches of either select granular, cementitious, or concrete backfill.

Select granular, cementitious, and concrete backfill are described in Section 2.5.4.5.4.

All Class I electrical ducts have a minimum 4 ft of backfill on top, which has been found adequate for Cooper E-80 loading without causing significant settlement or loading of ducts or foundation.

2.5.4.11 Design Criteria

2.5.4.11.1 Design Criteria For Safety-Related Structures on Rock

The plant structures founded on rock are designed for a maximum acceleration of 0.15 g from an occurrence of the SSE event. From consideration of its engineering properties, it is evident that the foundation rock would not be measurably affected by seismic loadings, and negligible additional foundation settlement would accompany these maximum potential dynamic loads. The maximum contemplated total static and dynamic loads are only a fraction of the bearing capacity of the rock, thus ensuring an ample margin of safety.

2.5.4.11.2 Design Criteria For Safety-Related Structures on Soil

The design criteria and methods of design concerning the liquefaction potential of soil at the spray pond are discussed in Section 2.5.4.8. The design criteria and stability analyses of the spray pond slopes are discussed in Section 2.5.5.2.

2.5.4.12 Techniques to Improve Subsurface Conditions

2.5.4.12.1 Treatment of Fracture Zones and Clay Seams - Main Power Block Area

During excavation of the main power block area, three fracture zones and two clay seams were encountered in the foundation rock. The locations of these zones are shown on Figure 2.5-13. The zones are described in Section 2.5.1.2. Treatment of these zones during construction is described below.

2.5.4.12.1.1 Criteria for Treatment of Fracture Zones and Clay Seams

As outlined in the PSAR, the criteria for treatment of the steeply dipping fracture zones are to: excavate soft or excessively fractured material in the zones under footings to a depth below foundation grade that is at least equal to the width of the undesirable material at foundation grade; slope the sides of these excavations so that they become narrower downward; extend this excavation beyond the edges of footings crossing the fracture zones; and replace the excavated material with concrete. This dental treatment is designed to replace the compressible material under footings with a wedge of concrete that transfers vertical loads laterally to the adjacent sound rock on each side of the zone, to confine this adjacent rock, and to reduce unit loads by extending the bearing area beyond the edges of walls and columns.

The criteria for treatment of a clay seam, except under column footings, are to determine the thickness of soft, compressible material in the seam at its intersection with foundation grade and to treat the seam only if the compressive material is ¾ inch or more thick. Under wall footings, treatment consisted of removing the compressible material in the seam and the rock above it, to provide a minimum of 3 feet of sound rock between the bottom of the footing and the seam. The material removed was replaced with concrete. Isolated column footings do not span the intersection of the clay seam with foundation grade; where this situation could occur, the clay seam and all rock above it were removed under the column footing and replaced with concrete so that all of the footing is founded on rock below the seam. Where the clay seam was not treated, compressible material in the seam is thin (¾ inch or less). This material commonly contains hard rock fragments; thus, the total consolidation resulting from it is very slight. Also, the consolidation occurs rapidly after loading and is completed before the structures are finished.

2.5.4.12.1.2 Treatment of Fracture Zone A

The location, attitude, and width of Zone A at final foundation grade are shown on Figure 2.5-13. The zone is described in detail in Section 2.5.1.2. Fracture Zone A trends generally N 40° to 45° E and dips from 70° to vertical.

Zone A is locally over 10 feet wide at ground surface, but narrows rapidly with depth. Weathering along the zone decreases with depth, and the fractures often converge with depth. At foundation grade, weathered, soft material between fracture surfaces is usually thin, or absent entirely. As a result, Zone A usually is minor in extent at foundation grade, and does not normally require treatment under thick, stiff, reinforced footings, since such footings could span over a narrow, steeply dipping zone. It was treated under wall footings of Category I structures, however,in accordance with the criteria presented in the PSAR.

Photo 1 (figure 13A) of Figure 2.5-13 shows a typical section of Fracture Zone A at foundation grade. Photo 2 (figure 13B) of Figure 2.5-13 shows the type of excavation performed for dental concrete placement. Photo 3 (figure 13C) of Figure 2.5-13 shows placement of dental concrete at "Mh" and "N" lines.

2.5.4.12.1.3 Treatment of Fracture Zone B

Fracture Zone B occurs at the southeast corner of Unit 2 reactor enclosure, as shown on Figure 2.5-13. The zone trends N 30° E and is nearly vertical. It contains from 2-10 inches of crushed, weathered rock and plastic clay. The rock on the southeast side of the zone shows an apparent displacement of 8-10 inches downward relative to that on the northwest side. Zone B is treated in the same manner as Zone A. Dental excavation for Zone B at "D" line is shown on Photo 4 (figure 13D) of Figure 2.5-13. Photos 5 and 6 (figures 13E and 13F) of Figure 2.5-13 show Zone B before and after dental excavation for the column footing at the intersection of lines F and 31.9.

Treatment excavation is performed using picks, shovels, and a backhoe with a hydraulic breaker. The excavation is deeper and wider than the actual fracture zone in order to obtain a wedge effect into the zone. This wedge was created as shown on the photographs of Figure 2.5-13. The excavation continues past the column footing in order to increase the bearing area under the footing.

2.5.4.12.1.4 Other Fracture Zones

Another less significant fracture zone was exposed in the excavation between Zones A and B and north of "J" line. Its location and description are shown on Figure 2.5-13. This zone contains from less than 1 inch to a maximum of about 4 inches of soft material, and they are nearly vertical; consequently, they required no special foundation treatment. The adjacent rock is hard and strong, although sometimes closely jointed, and can easily support the loads imposed by the structures. As noted on Figure 2.5-13, this zone shows slight offsets of several inches.

2.5.4.12.1.5 Treatment of Clay Seams

The clay seam in Unit 1, described in Section 2.5.1.2, is hereafter referred to as Seam 1. A second clay seam, hereafter referred to as Seam 2, is stratigraphically lower than Seam 1 and intersects foundation grade in part of Unit 2. These seams occur along shaly beds that are relatively softer than the adjacent hard siltstone. As mentioned in Section 2.5.1.2, there has apparently been some shearing along these seams, since they show slickensides and some crushing.

Seam 1 has a maximum thickness of about 10 inches near the top of rock south of Unit 1, but its thickness decreases rapidly downdip, so that under Unit 1, it is generally less than about 1½ inches thick, and in places, it is barely discernible, Where the seam contains clay, it also usually contains rock fragments.

As described in the PSAR, three large diameter core holes were drilled downdip from the seam's exposure on excavated rock surfaces to verify that the seam continues to become thinner downdip. These holes show the seam to be no more than ¾ inch thick.

Figure 2.5-13 shows the approximate trace of Seam 1 on the excavated rock surface in the radwaste building and in Unit 1. Normal excavation extends below this seam in Unit 2, as the rock tends to break naturally to the seam, and cleanup and foundation preparation removed the seam northward to the "J" line. Thus the trace of the seam is at the toe of the excavated slope near the "J" line.

Under the mat for Unit 1, clay in Seam 1 has a maximum, thickness of less than ½ inch. Where this seam intersects grade, the thin silver of rock above the seam tends to break naturally to the

seam and was removed during the normal foundation preparation. Special treatment for Seam 1 was done in only one area, under the footing for column F-15.5. Here, all the rock above the seam was removed under that footing. Elsewhere, Seam 1 is so thin that no treatment was required.

The second clay seam, Seam 2, occurs along a relatively soft, thin shaly bed that is stratigraphically lower than Seam 1.

Soft material in Seam 2 is usually only about ¼-½ inch thick where exposed in foundations or excavated slopes, and it consists of plastic clay with shaly, sheared rock fragments. Seam 2 was removed under several column footings in Unit 2. At columns F-31.9, H-31.9, F-30.5, and H-30.5, all the rock above Seam 2 was removed (the footings rest on rock below the seam).

2.5.4.12.1.6 Summary and Conclusions on Treatment of Fracture Zones and Clay Seams

The fracture zones, although narrow and steeply dipping, have been conservatively treated to preclude the occurrence of any significant settlements due to these zones. They pose no threat to the stability of slopes after the structures are completed. The stresses that caused the fracture zones, and the other fractures and joints in the foundation rock, no longer exist and have not existed for millions of years. The faults near the site have been inactive for millions of years, as documented in the PSAR and the geologic report prepared by Dames and Moore in 1974 (Reference 2.5-1).

The two thin clayey seams along bedding were carefully evaluated in the foundation rock and they were treated under some column footings. Settlement due to consolidation of clay in untreated seams is negligible, since the clay is so thin. Any consolidation of the clay will have occurred before the structures are completed.

2.5.4.12.2 Treatment of Fracture Zones and Clay Seams - Spray Pond and Other Areas

No special treatment of foundation rock was required at the spray pond. The foundations for the spray pond pumphouse, overflow structure, and spray network pipe supports were excavated to unweathered bedrock.

Two bedding-plane clay seams, generally not exceeding 1 inch in thickness, were encountered one of which trends across the bottom of pond excavation (Figure 2.5-42). Where exposed in the excavations for the spray networks, the seam was excavated below foundation grade whenever it was overlain by less than one or two feet of firm rock. At the eastern spray network (network "B") the seam was slightly thicker and additional overlying rock was removed beneath the pipe support footings (Figure 2.5-42). At the spray pond pumphouse excavation, this seam was not exposed on bearing rock except in the western abutment trench, in which case all rock overlying the seam was removed.

A considerable amount of soil and soft, weathered rock was overexcavated at the western spray network (network "C"), and replaced by up to 14 feet of backfill concrete (section A-2 of Figure 2.5-43). Small amounts of broken or weathered rock were also removed as locally required along minor east-west trending fracture zones (Figure 2.5-42).

The entire bottom of the spray pond whether underlain by soil or rock, and the soil slopes below the elevation of the perimeter service road, are covered with a soil-bentonite liner (Section 2.5.5.4). The spray pond rock-cut slopes are covered with shotcrete. The shotcrete extends below the soil-

bentonite liner to provide a suitable transition zone. A plan and typical sections are shown on Figure 3.8-57.

2.5.4.13 Subsurface Instrumentation

Subsurface instrumentation is not required at the site. Load- bearing safety-related structures are founded on competent bedrock. The properties of the bedrock are presented in Section 2.5.4.2.1. Instrumentation for surveillance of rock foundations was not installed for the reasons described in Section 2.5.4.5.

2.5.5 STABILITY OF SLOPES

Natural slopes at the site are shown on the Site Plan, Figure 2.1-3.

There are no steep or unstable natural rock slopes within the plant boundaries that would have nay adverse effect on the safety-related operation of the LGS plant. Although excavated rock slopes could be cut vertically, the rock would eventually weather and ravel to a flatter slope with time. Therefore, all permanent excavated rock slopes are either cut on a gradient no steeper than 1 horizontal to 1 vertical, or they have engineered backfill placed against them to provide additional stability. The only permanent exposed rock slopes that could affect safety-related structures are those in the spray pond excavation.

The soil slopes considered are the excavated soil slopes in the spray pond. In addition, the dikes surrounding storage tanks are discussed in Section 2.5.5.5.

2.5.5.1 Slope Characteristics

The spray pond was constructed primarily by excavation. The spray pond is designed for the water level to be at el 251' and for the bottom of the pond to be at el 241'. Because of the sloping bedrock surface, the bottom of the pond is located in both soil and rock. The top of the rock is shown on Figure 2.5-9. Cut slopes are 4 horizontal to 1 vertical in soil and generally 1 horizontal to 1 vertical in rock, with a bench at the soil-rock interface. A short section of weathered rock is excavated at 2 horizontal to 1 vertical.

The bottom of the spray pond, excavated in both soil and rock, and soil slopes below the perimeter service road (at el 255') are covered with a 12 inch thick liner of a soil-bentonite mixture (Figure 2.5-24). The liner is protected by a 12 inch thick soil cover to reduce the possibility of the liner drying and cracking and to prevent damage from equipment during construction and maintenance. The design and construction of the soil-bentonite liner and soil cover are discussed in Section 2.5.5.4.1. In order to prevent erosion due to wave action, the liner and soil cover at the soil slopes are protected by a 12 inch thick layer of riprap bedding and an 18 inch thick layer of riprap. The gradation and placement of the riprap and riprap bedding are discussed in Section 2.5.5.4.2. Rock slopes are covered by shotcrete, which extends below the soil-bentonite liner in the bottom of the pond. A plan and typical sections of the slopes are shown on Figures 2.5-48 and 2.5-49.

2.5.5.1.1 Geologic Conditions

Rock at the site consists of well-indurated, gently dipping sandstone, shale, and siltstone of Triassic-age. Bedding dips 8° to 20° to the north, with only minor local variations. Two major joint systems are prevalent in the area. Both are vertical or nearly vertical; they strike approximately N

20° to 50° E and N 50° to 60° W. Three fracture zones and two clay seams were encountered in foundation excavations in the main power block area; they are described in Section 2.5.1.2.5.

Bedrock is overlain by from 0 feet to about 40 feet of residual soil, developed in situ by the gradual decomposition of the parent rock. No clearly defined boundary between soil and rock exists, as the soil grades into fresh, unweathered rock.

The spray pond is underlain mostly by Lockatong lithofacies beds, except at the southeastern and northwestern margins of the pond (Figure 2.5-42). The Lockatong rocks are characterized by black shale and associated fine-grained, variably calcareous beds deposited in a lacustrine or swampy environment, in contrast to the sandier, typically red beds of the Brunswick Formation. Two prominent black shale or claystone beds, neither exceeding about 4 feet in thickness, were exposed and mapped in the spray pond excavation (Figure 2.5-42). These same beds had been recognized and logged from rock cores during the initial 1969-1970 site exploration by Dames and Moore (see log for Boring 150, Figure 2.5-22).

Joints exposed at the spray pond trend northeast and northwest, the former being dominant. A third prominent joint set trending approximately east-west in the Brunswick sandstone beds tends to be more widely spaced and shows irregular fracturing in the Lockatong (Figure 2.5-42). Major north-south jointing is locally prominent near the middle of the excavation (spray network "D"). Generally, any particular joint was found to be confined vertically to a single bed or series of lithologically similar beds.

Only a few minor offsets were noted in the excavation, along near-vertical joints and fractures. They are described in detail in Section 2.5.1.2.5.

Slickensides are locally abundant in the spray pond excavation. They occur almost without exception as dip-slip striations on curved, gently-to-moderately dipping joint surfaces, in beds that overlie claystone or shale units in the Lockatong. Where observable in profile at vertical cuts within the excavation, these curved joint planes wee seen to terminate downward at the contact with the underlying shale. It is therefore concluded that the slickensides arise from slight differential movement related to compaction of the shales during diagenesis and have no tectonic significance. Figure 2.5-42 shows typical occurrences of these slickensides.

2.5.5.1.2 Exploration - Emergency Spray Pond

The exploration for the site is presented in Section 2.5.4.3. Exploration for the emergency spray pond is discussed detail in this section.

2.5.5.1.2.1 General

The exploration for the emergency spray pond was conducted in three phases. The first phase, conducted during May and June, 1973, consisted of 5 NX core holes and 43 auger holes to define the bedrock surface. The second phase, carried out in April and May, 1974, consisted of 25 borings and 4 test pits to obtain undisturbed soil samples in the spray pond area. The third phase, conducted in March, 1977, consisted of 13 test pits to investigate the soils for use in constructing the soil-bentonite liner.

2.5.5.1.2.2 Phase 1 Exploration

Borings in the first phase were made by American Drilling Company of East Providence, Rhode Island. In order to define the bedrock surface, 43 auger holes were drilled in the spray pond area.

The contours of the top of the bedrock are shown on Figure 2.5-9. Five NX core holes were drilled to determine the bedrock lithology, structure, and foundation conditions at the intake structure.

2.5.5.1.2.3 Phase 2 Exploration

The Phase 2 exploratory borings were also made by American Drilling Company. Block samples from test pits were taken by Geotechnical Engineers, Inc. of Winchester, Massachusetts.

Twenty-five borings were made around the perimeter of the spray pond. The locations of these borings are shown on Figure 2.5-26. Both disturbed and undisturbed samples were obtained in all holes. Disturbed samples were obtained using a standard split spoon sampler (ASTM D1486). Undisturbed samples were obtained using Shelby tubes and a Denison sampler equipped with a 3-7/8 inch ID, 24 inch long brass tube liner. Four test pits were dug to obtain undisturbed block samples. Their locations are shown on Figure 2.5-26.

Laboratory testing of soil samples was carried out by Geotechnical Engineers, Inc. All test results are given in a soil testing report from Geotechnical Engineers, Inc (Reference 2.5-39) and they are briefly discussed in Section 2.5.4.2.2.

Figures 2.5-27 through 2.5-29 show typical subsurface cross-sections through the spray pond.

2.5.5.1.2.4 Phase 3 Exploration

Thirteen test pits were excavated at the spray pond site in March, 1977 to investigate the soils for use in constructing the soil-bentonite liner,. The locations of the test pits and the generalized soil profiles are shown on Figure 2.5-30. Bulk samples of soils suitable for constructing the soil-bentonite liner were taken from each of the test pits, except for one pit where suitable soil material was not encountered. A more detailed discussion on exploration and sampling is given in Section 2.5.5.4.1.1.

Laboratory testing of soil samples and soil-bentonite mixtures was carried out by Geotechnical Engineers, Inc. All test results are given in a July, 1977 report on soil-bentonite mixtures that was prepared by Geotechnical Engineers, Inc. (Reference 2.5-44).

2.5.5.1.3 Laboratory Testing of Soils

The results of laboratory testing of undisturbed samples of soil from the spray pond site are presented in Section 2.5.4.2. The results of laboratory testing of soil-bentonite mixtures for the pond lining are presented in Section 2.5.5.4.

2.5.5.2 Design Criteria and Analyses

The design analyses for the spray pond include seepage analyses, liquefaction potential evaluation of the soils in the pond, and stability of the side slopes. The seepage and the liquefaction evaluation are presented in Sections 2.5.4.6 and 2.5.5.8, respectively. The analysis of the stability of the pond side slopes is provided in this section.

2.5.5.2.1 Stability of Rock Slope

Rock slopes at the spray pond are cut no steeper than 1 to 1. The slope in partly weathered rock west of the spray pond pumphouse is at 2H to 1V. Weathered bedrock elsewhere is cut at the

same slope as the soil, 4H to 1V. The height of the 1:1 rock slope varies from zero to about 20 feet. The bench at the top of the 2:1 rock slope is about 13 feet above bottom of pond excavation (11 feet above the top of the soil liner). The location of rock slopes at the spray pond are shown on Figure 2.5-48; Figure 2.5-49 shows representative rock slope profiles.

Stability of rock slopes is influenced primarily by the orientation of bedding attitudes with respect to that of the slope. Bedding dips quite uniformly at about 10° (range 8° to 13°) to the northwest (N 20° W; strike N 70° E). Major joint trends are nearly east-west and NE-SW. Minor or locally prominent joints trend northwest and north-south. The great majority of these joints are nearly vertical.

Major consideration was given to stability of slopes on the south side of the pond, where beds dip uniformly out of the slope at about 10° to 11°. Because the strike of beds is nearly parallel to the slope, potential failure would occur as a sliding block; prominent east-west joints, together with additional joint sets described above, would provide cohesionless release surfaces for the slide. Simple single-plane, two-dimensional static analysis is therefore appropriate. Seismic loading is conservatively represented as the design SSE acceleration (0.15 g) applied to the entire mass of the assumed failure block, parallel to the maximum dip direction. Such a representative overestimates actual earthquake loading of the slopes and is therefore conservative.

1 to 1 Slope East of Spray Pond Pumphouse. Rock along the slope east of the spray pond pumphouse consists of highly competent, indurated (Calcareous) siltstone and fine-grained sandstone (section E of Figure 2.5-49). The entire slope required excavation by blasting; the in situ rock here resisted attempts at removal by heavy, single-toothed ripping equipment. It is likely that its strength exceeds typical values of unweathered foundation rock (Table 2.5-11). Prominent but widely spaced east-west joints, together with relatively thick bedding, resulted in a steplike slope profile; the average width of the steps which form due to breaking along bedding-planes is more than 1 foot. The rock, thoroughly examined for evidence of clayey or shaly interbeds or partings, displays no evidence of these features.

An assessment of the stability of this slope was made by calculating the angle of internal friction required along bedding-planes to achieve stability, assuming no cohesion on these planes. Although the water table, presently well below the bottom of the pond, is not expected to be significantly affected by any seepage from the pond during operation of the plant, the slope behind the pond was conservatively assumed to be saturated (water table at el 251') for purpose of calculation (actually the weight of water in the pond would enhance the stability of the unsaturated slope). During rapid drawdown under static conditions, the water level behind the slope is assumed to remain at that elevation, and the toe is assumed to be undrained. Under assumed maximum seismic loading, a friction angle of only 25° or less would be sufficient to maintain stability at a safety factor of 1.25 if cohesion is assumed to be zero. This value is much lower than any reasonable coefficient of friction to be expected for the strength of bedding in this rock. In addition, significant cohesive strength is present, for otherwise beds could have been excavated by ripping. Based on the above analysis, the slope east of the spray pond pumphouse is considered to be highly stable.

2 to 1 Slope West of the Spray Pond Pumphouse. The rock in the 2 to 1 slope west of the spray pond pumphouse (section F of Figure 2.5-49) is slightly to moderately weathered, most generally in the upper part of the slope. Jointing is generally well developed, parallel to the slope and in NW-SE and NE-SW orientations. At two intervals of strata exposed in the slope, bedding-planes with brown, thin clayey films or partings about one millimeter thick on them occur. (X-ray analysis of

similar brown clay from partings in rock exposed in the spray bank area indicate that kaolin constitutes most of the clay mineral content.) Bedding-planes are not perfectly planar but undulate on the order of several millimeters to several centimeters. The amplitude of these asperities with respect to the thickness of the clay film should impart a relatively high initial coefficient of friction against sliding, but it is difficult to quantify this effect. For stability calculations, initial friction angle was conservatively estimated to be 20° along the bedding-planes; for additional conservatism, the planes were assumed to be cohesionless although some cohesion occurs along the bedding (all detached blocks of rock were removed during cleaning of the slopes). Maximum weight of the sliding mass is calculated by assuming failure at the toe of the slope (el 239', below pond liner), the failure plane extending back under the 4:1 slope in soil above the rock. Factors of safety were computed for the following conditions:

	CONDITION	POND	SLOPE	LOADING
a.	rapid drawdown	empty	saturated	static
b.	operation	full	saturated	seismic
c.	operation	full	drained	seismic

Water table levels and hydrostatic pressures are assumed to be the same as described above for the 1:1 slope. The calculations indicate that if rock bolts were not installed and shotcrete was not applied, a portion of the 2:1 slope would be unstable under rapid drawdown conditions and under seismic loading, provided that all of the numerous conservative assumptions are correct. In general, the weak bedding-planes described are exposed in the middle or upper part of the slope, whereas stability calculations assumed that the weak plane occurs at the toe of the slope.

Two lines of rock bolts were installed in the 2:1 rock slope to stabilize the two bedding-planes prior to placing shotcrete. Bolts were tensioned to 25 kips and spaced an average of 5 feet apart on the slope. A total of 38 rock bolts, 10 feet long, were installed.

The shotcrete on the rock has a significant stabilizing effect against sliding failure on weak bedding-planes because of its bond strength to rock and its shear strength. Slope failure would initiate along a bedding-plane where the plane forms a bench in the overall slope (Figure 2.5-49). The shotcrete will be thickest at this location of the potential site of movement, at the intersection of a vertical rock face and a bench (a leveling course of shotcrete was applied to fill in rock re-entrants and overhangs). It is calculated that about 45 kips force per linear foot of slope would be required to shear the 3000 psi shotcrete, minimum 4 inches thick, assuming shear strength at 600 psi.

Shotcrete bond strength to rock of at least 100 psi or 14 kips per linear foot of slope is calculated to be resisting slope failure where there is a bench width of 1 foot in front of the failure plane; this is somewhat less than the average width measured in the field. It is important to note that the weakest and most prominent bedding-planes consistently form the widest benches in the slope, as would be expected. Good rock-to-shotcrete bond was assured during preparation of the slope for shotcreting by air-water jetting to remove loose and clayey material from the rock surface.

Table 2.5-7 shows the factors of safety against sliding under various conditions, considering the effect of rock bolts, and of rock bolts and shotcrete; the latter is the present condition of the pond. The minimum factor of safety computed for the conservative assumptions made for the stability

analyses is 4.5. If cohesion of only 5 psi is assumed along the failure plane, the minimum factor of safety is increased to over 10.

The weakest bedding-plane in the excavation is at the eastern end of the 2:1 slope. A soft, black seam of clay about 1 inch thick was barely exposed (no more than 2 inches above bottom of pond) at the extreme northwestern corner of the spray pond pumphouse excavation; the plane dips below bottom of the excavation slope in a westward direction along the toe of the slope. Rock surfaces are exceptionally smooth and planar on each side of the seam. The clay fraction is mostly smectite (expandable clay) as determined by x-ray analysis.

Potential slope instability at this location is effectively eliminated by the buttressing provided by the header pipe footing (section G of Figure 2.5-49). The excavation for the footing, approximately 15x15 feet, was extended to hard, competent rock below the soft clay seam. The surface was thoroughly jetted with water and cleaned prior to placement of Class A concrete backfill. The footing and backfill concrete along with the rock below the bottom of the pond act as a buttress against possible sliding by virtue of the bond strength between concrete and competent rock and the passive resistance of the rock against which the Class A concrete was placed. Typical bond strength between concrete and the rock underlying the footing is more than 200 psi. Assuming a bond strength of only 100 psi, the footing affords a resistance of over 3,000 kips against slope failure, not including the frictional effect of load on the footing or the passive resistance of the rock at the north edge of the footing. Furthermore, substantial resistance against sliding is provided by Class A concrete backfill between the edge of the pumphouse excavation and the pumphouse wall (Figure 2.5-48). This concrete backfill, placed against the irregular edge of rock above the clay seam, helps to lock the rock mass in place.

A calculation was made of the force required to stabilize the slope against sliding on the soft clay seam at the extreme eastern end of the 2:1 slope, neglecting the stabilizing effects of the footing and concrete backfills. Assumptions are the same as described above, except that the angle of friction of the clay seam is assumed to be 8°, with cohesion being zero. The section of slope considered is about 35 feet long, the portion where there is less than 2 feet of competent rock covering the plane at the toe of the slope (the shear strength of this rock is not considered in the calculation). Maximum force required to achieve stability is about 12 kips per foot, or a total of approximately 430 kips, compared to the resisting strength of the header pipe footing of over 3000 kips.

On the north side of the spray pond, beds dip into the slope producing an inherently stable slope configuration. The east slope of the pond bedding has a shallow apparent dip out of the slope only in the southeast segment where the competent rock, which required blasting, is exposed. Thus, slope instability along bedding is not a concern in these areas.

Consideration was given to toppling failure of portions of the slopes where vertical joints isolate columns of rock. The shallow angle of the excavated slopes is not conducive to such failure, and the continuous layer of shotcrete and wire mesh ties the rock together and eliminates any concern for failure due to toppling.

2.5.5.2.2 Design Criteria for Soil Slopes

The soil slopes of the spray pond must be stable against sliding under normal conditions and also during and following an SSE event. The minimum acceptable factors of safety are:

End of construction	1.3
Long-term static condition	1.5
Long-term seismic condition	1.1
Rapid drawdown	1.25

The design value used for the maximum horizontal ground acceleration during the SSE is 0.15 g (Section 2.5.2.6).

2.5.5.2.3 Methods of Slope Stability Analyses

The stability of the soil slopes was analyzed by the Simplified Bishop Method (Reference 2.5-45) using the computer program SLOPE (Reference 2.5-46) and by the wedge method of analysis described in the U.S. Navy Design Manual DM-7 (Reference 2.5-47) and in the U.S. Army Corps of Engineers Manual (Reference 2.5-48).

The wedge analysis was used to determine the sliding stability along the interface of the soil-bentonite liner and the in situ soil underneath. The Simplified Bishop method was used to determine the critical arc through the in situ soil and the corresponding factor of safety.

The wedge analysis considers the stability of the mass of soil above the bottom of the soil-bentonite layer, as shown on Figure 2.5-31. The tendency for this mass to move downslope is resisted by the passive earth pressure at the toe of the slope and the total shear strength developed along the bottom of the wedge. The sum of these resisting forces must be greater than the gravitational force that tends to cause downward movement. The factor of safety against sliding is equal to the ratio between the sum of the resisting forces and the gravitational driving force.

The Simplified Bishop method for evaluating the stability of a slope assumes a trial failure arc; the mass above the arc is broken up into a series of vertical slices, and the equilibrium of each of these slices is considered. It is assumed that the forces acting on the sides of any slice have zero resultant in the vertical direction (Reference 2.5-49). A factor of safety is obtained for the assumed trial failure arc by determining the ratio of the resisting forces to the driving forces. These procedures are repeated for various locations of the center of arc and different lengths of radius until a minimum factor of safety is obtained.

The cross-section used in all circular arc analyses is based on the subsurface conditions at the northwest end of the spray pond (Figures 2.5-27 and 2.5-28). This profile was selected because the depth to rock is the greatest and it, therefore, represents the most critical conditions encountered.

2.5.5.2.4 Design Parameters

Design parameters required for the slope stability analysis include those for the in situ soils, compacted soil-bentonite mixture, compacted soils, riprap, and riprap bedding. Detailed discussions of the engineering properties of these materials are presented in various sections: Section 2.5.4.2 for in situ soils; Section 2.5.5.4.1 for compacted soil-bentonite mixture and

compacted soil; and Section 2.5.5.2.4.2 for riprap and riprap bedding. Design parameters are summarized in Table 2.5-5 and given in the subsequent sections under the headings of various types of materials.

2.5.5.2.4.1 In Situ Soil

a. Unit Weight

The total and saturated unit weights of in situ soils were determined in the laboratory; the average values chosen for design analyses are 122 lb/ft^3 and 126.4 lb/ft^3, respectively.

b. Static Shear Strength

Effective shear strength parameters based on the results of consolidated-undrained triaxial tests are $\bar{\phi}$ = 33.5°, and $\bar{c}$ = 0. The undrained shear strength of the material is 1.2 $\bar{P}_o$, where $\bar{P}_o$ is the initial mean effective principal stress (Section 2.5.4.2).

c. Dynamic Shear Strength

The dynamic shear strength of the soil is determined by multiplying the cyclic stress ratio required to cause 5% double amplitude strain in 5 cycles by the average effective confining pressure. This results in a design dynamic shear strength of $0.61\sigma_o$ where σ_o is the effective overburden pressure (Section 2.5.4.2.2.3).

2.5.5.2.4.2 Soil-Bentonite Mixture

a. Unit Weight

The total and saturated unit weights of the soil-bentonite mixture (selected from laboratory test results) are 113 lb/ft^3 and 119 lb/ft^3, respectively. The mixture is compacted at optimum moisture content to 95% of maximum dry density as determined in ASTM D698.

b. Static Shear Strength

The static effective shear strength parameters of the soil-bentonite mixture are based on the results of consolidated-undrained triaxial tests with pore pressure measurements (R). The design values of $\bar{\phi}$ = 29° and $\bar{c}$ = 0 are chosen from the test results shown on Figure 2.5-32, based on the U.S. Army Corps of Engineers recommendation that two-thirds of the test values should exceed the design value (Reference 2.5-48). The undrained shear strength of the mixture is 0.95 $\bar{P}_o$, where $\bar{P}_o$ is the initial mean effective principal stress (Section 2.5.5.4.1.2.3).

c. Dynamic Shear Strength

The dynamic shear strength of the soil-bentonite mixture is based on test results of undrained triaxial tests after cyclic loading ($C\bar{R}$ - $\bar{R}$). The test is described in Section 2.5.5.4.1.2.3, and the results are shown on Figure 2.5-33. The total shear

strength design parameter values $\overline{\phi}$ = 20° and $\overline{c}$ = 225 lb/ft^2 are based on the U.S. Army Corps of Engineers recommendation that two-thirds of the test values should exceed the design value (Reference 2.5-48).

2.5.5.2.4.3 Compacted Soil

The total and saturated unit weights determined from laboratory test results are 120.5 lb/ft^3 and 123.8 lb/ft^3, respectively. The values were determined at 95% of maximum dry density as determined in ASTM D698. The shear strength of compacted soil is assumed to be equal to the shear strength of the in situ soil.

2.5.5.2.4.4 Riprap and Riprap Bedding

A unit weight of 130 lb/ft^3 assumed for both the riprap and the riprap bedding material. The effective angle of internal friction is assumed to be 45° for the riprap and 40° for the riprap bedding.

2.5.5.2.5 End of Construction Under Static Conditions

The stability of the slope at the end of construction was analyzed using a total stress analysis. The in situ soil is divided into sublayers, and the shear strength assigned to each layer determined from the undrained shear strength relationship of q = 1.2 $\overline{P}_o$ (Section 2.5.5.2.4.1), where $\overline{P}_o$ is the effective average stress at the mid-depth of each sublayer. The minimum factor of safety of a circle is found to be 3.8, and the factor of safety of a wedge with a potential sliding surface along the bottom of the liner is found to be 5.7. Both factors of safety are considerably higher than the minimum value of 1.3 required by the design criteria. Figure 2.5-31 shows the sections analyzed and the critical arcs.

2.5.5.2.6 Rapid Drawdown Under Static Conditions

Drawdown is assumed to be instantaneous from the normal pool level (el 251') to the bottom of the pond (el 241'). The stability of effective stress analysis, with $\overline{\phi}$ = 29° and $\overline{c}$ = 0 for the soil-bentonite liner, and $\overline{c}$ = 0 and $\overline{\phi}$ = 33.5° for the in situ soil and compacted soil. The minimum factor of safety of a sliding wedge is found to be 1.7, and the minimum factor of safety for the critical deep-seated circle is found to be 2.1. All factors of safety are higher than the minimum values required by the design criteria. The results are shown on Figure 2.5-31.

2.5.5.2.7 Long-Term Stability Under Static Conditions

The long-term stability of the spray pond slope is calculated using an effective stress analyses. The water level is assumed to have risen to its normal level of el 251' in the pond. The minimum factor of safety is determined using the infinite slope procedure and using effective shear strength parameters of the material. Under static conditions, the factor of safety is given by:

$$F.S. = \frac{\tan \overline{\phi}}{\tan \alpha} \qquad \text{(EQ. 2.5-5)}$$

where:

$\overline{\phi}$ = effective friction angle

α = angle of inclination of the slope

For α = 14° (4 horizontal to 1 vertical), the minimum factor of safety is 2.2 for a potential sliding along the soil-bentonite liner with a $\overline{\phi}$ = 29°. The factor of safety of a wedge with a potential sliding surface through the interface between the soil-bentonite liner and the soil underneath is 2.6, and the minimum factor of safety for a critical circle is 2.4. Both the minimum factors of safety resulting from the infinite slope analyses, and that determined by the sliding wedge and circular arc analysis, are higher than the minimum values required by the design criteria. The results of these analyses are shown on Figure 2.5-31.

2.5.5.2.8 Long-Term Stability Under Seismic Conditions

Two analyses were made for the stability of soil slopes under seismic conditions. A pseudostatic analysis using effective shear strength evaluated the stability of the slope during an earthquake, and a total stress analysis evaluated the stability of the slope immediately after the earthquake.

The pseudostatic method of analysis involves the computation of the minimum factor of safety against sliding either along a circular arc or along a plane surface or series of plane surfaces for a sliding wedge. A horizontal force is added to account for seismic forces. The entire analysis is handled as a static effective stress analysis. The added horizontal force is equal to the total weight of the sliding mass times the seismic coefficient. The total weight of the sliding mass is calculated using the moist unit weight of the soil above the phreatic surface and the saturated unit weight of the soil below the phreatic surface. For this analysis, it is conservatively assumed that the seismic coefficient used equals the design maximum ground acceleration (0.15g).

In the pseudostatic analysis, the strength used for the soil-bentonite mixture is $\overline{\phi}$ = 29° and $\overline{c}$ = 0 (Section 2.5.5.2.4.2), and ϕ = 33.5°, $\overline{c}$ = 0 for the in situ soil (Section 2.5.5.2.4.1). The minimum safety factor obtained is 1.1 for both the circular arc and a sliding wedge through the soil-bentonite lining. All computed safety factors meet the minimum values required by the design criteria. The results are summarized on Figure 2.5-31.

Immediately after an earthquake, the pore pressures built up in the soil and soil-bentonite mixture during the earthquake reach their maximum values. Laboratory tests evaluated the undrained shear strength of both the soil-bentonite mixture and the in situ soil, without permitting any dissipation of pore pressure built up during cyclic stress loading. The total shear strength parameters representing the total strength of the soil-bentonite mixture and the in situ soil at the end of 5 uniform stress cycles are $\overline{\phi}$ = 20°, $\overline{c}$ = 225 lb/ft^2, and $\overline{c}$ = 0.61σ_o respectively (Section 2.5.5.2.4.2 and Section 2.5.5.2.4.1). The minimum factor of safety for the critical circle and for the sliding wedge procedure are 2.3 and 4.3, respectively. Both values are higher than the minimum value of 1.1 required by the design criteria.

2.5.5.3 Logs of Borings

The logs of borings and test pits from the spray pond exploration are presented in Figure 2.5-22. Drilling and sampling procedures are discussed in Sections 2.5.4.3 and 2.5.5.1.2.

2.5.5.4 Compacted Fill

The spray pond is primarily constructed by excavation (Figures 3.8-56 and 3.8-57). However, a soil-bentonite liner is placed on all soil slopes, as well as the pond bottom. The liner in turn is covered by a layer of compacted soil, riprap, and riprap bedding. The development of design and construction procedures for the development of a design mix for the compacted soil-bentonite mixture and the requirements for the compacted soils are covered in Section 2.5.5.4.1. The riprap and riprap bedding are discussed in Section 2.5.5.4.2.

2.5.5.4.1 Soil-Bentonite Liner and Soil Cover

The following sections present the results of the investigations and studies made in designing a soil-bentonite liner for the emergency spray pond. These consist of a soil investigation of the spray pond site, laboratory testing and design of a suitable soil-bentonite mixture, slope stability analyses, and liner design. The following sections also briefly describe the construction procedures for the soil-bentonite liner and soil cover.

The design criteria for the soil-bentonite liner are:

a. The permeability of the soil-bentonite liner is less than 1 ft/yr ($1x10^{-6}$ cm/sec).

b. The liner is protected to prevent drying and cracking, erosion from wave action, damage from equipment during construction and maintenance.

c. The slope of the pond with a liner is stable against sliding under static condition and during an SSE event. The minimum acceptable factors of safety against sliding are given in Section 2.5.5.2.2.

2.5.5.4.1.1 Soil Investigation and Sampling

The purpose of the field exploration program was to investigate the soils to determine their suitability for use in constructing the soil-bentonite liner. Because the pond is constructed by removing more than 10 feet of material, the primary interest was to investigate whether there is sufficient suitable soil for soil-bentonite mixture within the limits of the pond excavation.

Thirteen test pits were made at the site in March 1977. These test pits were dug to depths ranging from 5 feet to 11.5 feet. A layer of sandy, clayey silt, which is suitable for a soil-bentonite liner, was found to be consistently located between the topsoil and the weathered siltstone/shale bedrock in all test pits. The thickness of this layer varies from less than 2 feet at the southeast end of the pond to more than 6 feet near the northwest end. At the northwest corner, the bedrock was not encountered in Test Pits 1 and 13, because the soils are thicker there. It was determined that suitable soil for the soil-bentonite mixture is available in amounts estimated to be about three times the quantity required for the liner.

At the time of the investigation, the site had been covered with approximately 3 feet of shot rock-fill. The area was being used as a lay-down area for plant construction. The locations of the test pits and soil profiles are shown on Figure 2.5-30. Logs of test pits are included in Figure 2.5-22.

Bulk samples of soils suitable for the soil-bentonite liner were taken from each of the test pits except TP-8, where suitable soil material was not encountered. In addition to the bulk samples, jar samples were taken at each test pit to determine the natural moisture content.

2.5.5.4.1.2 Laboratory Testing and Soil-Bentonite Mix Design

All laboratory testing was performed in the laboratory of Geotechnical Engineers, Inc. of Winchester, Massachusetts. Soil samples obtained during the field investigation, along with the bentonite to be used in the tests, were shipped to the laboratory.

The laboratory testing proceeded in three stages. In the first stage, the onsite soils were classified. In the second stage, moisture-density relationships were established for soil-bentonite mixtures, and the bentonite content to meet permeability requirements was determined. In the final stage, the static and dynamic engineering properties were determined for the soil-bentonite mixture at the bentonite content established in the second stage.

The first stage was performed to obtain the index properties of the soil specifically used in testing for the soil-bentonite mix design, rather then using the properties previously obtained at the spray pond site (Section 2.5.4.2.2.1). As can be seen below, the results are similar.

The laboratory test procedures and the results of all tests are summarized in the July, 1977 report prepared by Geotechnical Engineers, Inc. (Reference 2.5-44).

2.5.5.4.1.2.1 Classification of Onsite Soils

Soil samples were classified visually in the laboratory as well as by testing to determine grain-size distribution, natural moisture content, and Atterberg Limits. The test results are summarized in Table 2.5-6.

a. Grain-Size Distribution

Grain-size determinations were made on all bulk samples according to ASTM D422, except that the sample preparation avoided air-drying of fines. During sieving of the moist soil through the ¾ inch sieve and during washing through the No. 200 sieve, only finger pressure was applied to break clay lumps and weak particles. These procedures prevent breakdown of soil particles.

The range of grain-size curves is shown on Figure 2.5-34. The median grain-size (D_{50}) of the soils varies between 0.006 mm and 2.38 mm, with an average of 0.20 mm. The percent by weight passing the No. 200 sieve varies from 41% to 88%, with an average of 71%.

b. In Situ Moisture Content

Moisture contents of all jar and bulk samples were determined in accordance with ASTM D2216. The moisture contents, determined from the samples kept in water-tight jars, are believed to be representative of in situ moisture contents, and are included in Table 2.5-6. The range of in situ moisture contents for the soils varies between 15.0% and 30.7%, with an average of 23.6%.

c. Atterberg Limits

Atterberg Limits were determined for the 12 bulk samples in accordance with ASTM D423 and ASTM D424, except that the soil was not air-dried before testing, and the grooving tool used was of the Casagrande-type. The results are summarized in Table 2.5-6 and are plotted on Figure 2.5-35.

2.5.5.4.1.2.2 Soil-Bentonite Mix Design

Three soils, which represent the entire range of grain-size distribution for onsite soils were selected for the soil-bentonite mixture design. These soils were designated as Soils A, B, and C, and each was obtained by combining two bulk samples. Their grain-size distributions are shown on Figure 2.5-34. Soils A and C represent the finest and the coarsest soils, respectively, in the spray pond area, and Soil B is typical of the soils in the middle of the range. The bentonite used in the tests was a high swelling Wyoming-type bentonite. The bentonite was in granular form before mixing with soil and water (Reference 2.5-44).

a. Compaction Tests

Compaction tests were made on Soils A, B, and C in accordance with ASTM D698. For each soil, the amount of bentonite mixed with the soils varied from 0% to 20% by weight.

The bentonite used in the test was in granular form, with the size of granules ranging from 0.1 mm to 1.0 mm. Mixtures of soil and bentonite before compaction had the appearance of granular soil. No difficulty was experienced during mixing and compacting of soil-bentonite mixtures as the percentage of bentonite was increased, because the moisture was kept at optimum.

Results of the compaction tests are shown on figures 6, 7, and 8 of Reference 2.5-44. As shown on these figures, the maximum dry density decreases as the bentonite content increases, with the maximum dry density dropping about 10% when the bentonite content increases from 0% to 20%. However, the optimum moisture content did not vary significantly (less than 2%) when the bentonite content was varied from 0% to 20%.

b. Permeability Tests

Permeability tests on Soils A, B, and C mixed with 0% to 20% bentonite were performed on compacted specimens in triaxial cells. The specimens had a diameter of approximately 2.8 inches and were about 1.0 inch high. The specimens were prepared at optimum moisture content and compacted to approximately 95% of the maximum dry density determined by ASTM D698. A Harvard Miniature compaction device was used to compact the specimens.

After compaction, each specimen was placed in a triaxial cell and consolidated under an effective confining. All specimens were allowed to saturate and swell before being tested for permeability. Saturation was checked by determining the value of Skempton's "B" parameter (Reference 2.5-40). All specimens were saturated to a "B" parameter of 0.95 or higher. The swelling of the specimens was roughly proportional to the bentonite content. Specimens with 0% to 5% bentonite showed little swelling, while specimens with 20% bentonite swelled as much as 10%.

The results of the permeability tests are shown on Figure 2.5-36. The permeability decreases from greater than 10^{-5} cm/sec to less than 10^{-7} cm/sec when the bentonite content increases from 0% to 20%.

The details of the permeability tests are given in Reference 2.5-44.

c. Selecting Design Mix of Soil and Bentonite Based on the results of permeability tests, a soil-bentonite mixture with 7.5% bentonite content by weight in terms of soil-bentonite mixture is selected for design, i.e., a mix with 7.5% bentonite and 92.5% soil by dry weight. When mixed with water at the optimum moisture content and compacted to 95% of maximum dry density as determined in ASTM D698, the compacted mixture has a permeability of less than 10^{-6} cm/sec (1 ft/yr) (Figure 2.5-36).

2.5.5.4.1.2.3 Engineering Properties Tests

Static and dynamic triaxial tests were conducted to determine the strength characteristics of the design soil-bentonite mixture (Section 2.5.5.4.1.2.2).

Soils A and C, which envelop the range of the grain-size distribution of the onsite soils sample (Figure 2.5-34), were used in making the soil-bentonite specimens for the strength tests. The test specimens were approximately 6.1 inches high and approximately 2.8 inches in diameter.

a. Consolidated-Undrained Triaxial Tests with Pore Pressure Measurements ($\overline{R}$)

Six consolidated-undrained triaxial tests ($\overline{R}$) were performed. Three specimens were mixed with Soil A, and another three with Soil C.

The specimens were consolidated isotropically at effective consolidation pressures of approximately 0.15 tons/ft^2, 0.30 tons/ft^2, and 0.60 tons/ft^2. These consolidation pressures simulate actual field conditions. Specimens were saturated using a back pressure of 10 tons/ft^2 to achieve a "B" parameter of 0.95 or higher (Reference 2.5-44). After saturation, the test specimens were axially loaded in compression, and pore pressures were monitored.

The results of the six $\overline{R}$ tests are summarized on Figure 2.5-32, which shows maximum shear stress at failure versus the mean effective principal stress at failure. From this drawing, the effective friction angle obtained is 29°. Detailed test data and results are presented in table 4 and figures 14 and 15 of Reference 2.5-44.

The undrained shear strength of the soil-bentonite mixture is calculated from the effective stress friction angle and pore pressure parameter A_f at failure, using the same procedure as for the in situ soil (Section 2.5.4.2.2.2). For the samples tested, A_f varies from 0 to -0.25. Using the conservative values of $A_f = 0$ and $\overline{\phi} = 29°$, the undrained shear strength is calculated to be 0.95 $\overline{P}_o$, where $\overline{P}_o$ is the initial mean effective principal stress.

b. Cyclic Loading Followed by Undrained Triaxial Compression with Pore Pressure Measurements ($C\overline{R}$ - $\overline{R}$) Seven $C\overline{R}$-$\overline{R}$ tests were made in which the specimens

were first subjected to cyclic loading, followed by static axial loading under undrained condition. The purpose of this test was to evaluate any reduction of the shear strength of the soil-bentonite mixtures following a seismic event. Three specimens were prepared with Soil A, and four with Soil C.

The consolidation and saturation of the $C\overline{R}\text{-}\overline{R}$ specimens were similar to that described for $\overline{R}$ testing. After saturation, the specimens were subjected to five cycles of sinusoidal cyclic loading, with deviator stresses of approximately 0.015 tons/ft^2, 0.03 tons/ft^2, and 0.06 tons/ft^2. Drainage was not permitted. The selection of five uniform stress cycles simulates the SSE of 0.15 g at the site, based on correlations of equivalent uniform stress cycles and earthquake time histories by Seed, et al (Reference 2.5-41).

The deviator stress during cyclic loading was chosen to be approximately equal to the average shear stress induced during an earthquake, which is approximately equal to one-tenth of the total overburden pressure when the maximum ground acceleration is 0.15 g, that is:

Deviator Stress = average induced shear stress

$$= 0.65 \frac{\nu H_a}{g} \qquad \text{(EQ. 2.5-6)}$$

$$= 0.65 (\nu h)\ 0.15$$

$$= 0.1 (\nu h)$$

Axial deformations and pore pressures were monitored. A typical test record is presented on figure 16 in Reference 2.5-44.

Upon completion of the cycling, time was permitted for pore pressure to equalize throughout the specimens; however, drainage was not permitted. The specimens were then subjected to undrained axial compressive loading. Pore pressures were monitored.

The results of the seven $C\overline{R}\text{-}\overline{R}$ tests are summarized on Figure 2.5-33, which shows maximum shear stress versus the mean principal stress at the end of 5 uniform stress cycles. From this drawing the total dynamic shear strength parameters are calculated to be $\phi = 20°$ and $\overline{c} = 225$ lbs/ft^2. Detailed test data and results are presented in table 5 and on figures 16, 17, and 18 of Reference 2.5-44.

2.5.5.4.1.3 Design Section

Based on the design criteria given in the previous section and the results of seepage and stability analyses (Sections 2.5.4.6 and 2.5.5.2, respectively), a 12 inch soil-bentonite liner with soil and rock protection was adopted as a precaution (Section 2.5.4.6). The section is shown on Figure 2.5-24 and will conform to these additional requirements:

a. The liner is placed on a 4 horizontal to 1 vertical slope.

b. The liner on the slope is protected by soil, riprap and riprap bedding to prevent erosion from wave action, drying and cracking. Design details of riprap and its bedding are given in Section 2.5.5.4.2.

c. Soil cover on the liner on the bottom of the pond is designed to protect the liner from damage by equipment during construction and maintenance.

2.5.5.4.2 Riprap and Riprap Bedding

The riprap and bedding are 18 and 12 inches thick, respectively. The gradation of the riprap and bedding is as follows:

Riprap

Particle Weight (pounds)	Fraction of Total Mix (% by weight)
>500	0
300 – 500	≥25
10 – 300	45 - 75
<10	0 - 25

Riprap Bedding

Sieve Size (U.S. Standard Sieves)	Fraction Passing (% by weight)
2 inch	100
3/4 inch	52 - 100
3/8 inch	36 - 70
No. 4	24 - 50
No. 16	10 - 30
No. 200	0 - 10

The riprap is placed in a manner to insure that the larger rock fragments are uniformly distributed. The smaller rock fragments serve to fill the spaces between the larger rock fragments, resulting in a well-keyed, densely placed, uniform layer of riprap.

Control of riprap placement consists of visual observation of the operation and of the completed product to assure that a dense, rough-surfaced layer of well-keyed and graded rock fragments of the required thickness is provided.

The riprap bedding material is handled and placed in such a manner as to prevent segregation. The moisture content of the material during placement is controlled as required to minimize segregation. A uniform layer of bedding is formed by spreading with a bulldozer.

2.5.5.4.3 Construction

Brief descriptions of materials, foundation preparation, and construction for the soil-bentonite liner and soil cover are given in this section.

The in situ soils from the excavation within the limits of the spray pond are used for the liner and soil cover. The gradation of soils is checked before mixing with bentonite to make sure they are within the range shown on Figure 2.5-34 and that sizes larger than 2 inches are removed. The bentonite is high swelling, Wyoming-type bentonite.

Water used for adjusting the moisture content of the soil-bentonite mixture is clean and free from deleterious substances.

Before placement of the liner, all underlying soil surfaces are prepared by scarifying, moisture conditioning, and compacting as necessary to meet the required density.

The pond bottom is underlain with soil and rock. Where the pond bottom is overexcavated, it is backfilled to the bottom level of the soil-bentonite liner. The soil backfill, as well as soft spots in the in situ soil, underlying the liner will be compacted to 95% of the maximum dry density determined by ASTM D698.

The soil-bentonite mixture is mixed in a central plant to ensure uniformity of the mixture. The mixture is then transported from the mixing plant to the construction site in clean equipment. The soil-bentonite mixture and the soil cover are placed and compacted to 95% of the maximum dry density determined by ASTM D698.

The individual components of the soil-bentonite mixture are tested for conformance with the specification before mixing. The proportions of the mixture are inspected at the mixing plant for conformance to specified proportions. The plant includes metering and feeding equipment that can be calibrated to the required accuracy. During compaction, the density of the liner and soil cover is checked to confirm that the requirements of the specification are met.

2.5.5.4.4 Seepage Test

Upon completion of construction of the spray pond, a seepage test was conducted to verify that the design basis seepage rate of 1.83×10^6 gallons per month would not be exceeded.

Filling of the spray pond began on October 11, 1982, and was completed on November 22, 1982, when the water surface reached el 251.0'. A seepage loss test was conducted for a period of 23 weeks from December 13, 1982 to May 21, 1983. Measurements of seepage loss were determined for each weekly interval. Depending upon the evaporation rate factor considered, the average seepage loss from the pond during this test was calculated to be between 2.1×10^5 gallons per month and 3.8×10^5 gallons per month, or between about 5 gpm and 9 gpm for the entire pond. This is 11% to 21% of the design basis rate. An error factor was developed which considers the accuracy of measurements of pond water level, of flows into and out of the pond, and of precipitation. The maximum error contribution was estimated to be approximately ±22% of the design basis rate. With error contribution, the upper bound of the average seepage loss is approximately 40% of the design value, and the lower bound is close to zero. Therefore, the test demonstrates that actual seepage will not exceed the design basis rate. Details of the seepage test and data analysis are contained in Reference 2.5-145.

2.5.5.5 Dikes

The dikes surrounding the storage tanks as shown on Figure 3.8-58 are not seismic Category I, but are designed in accordance with seismic Category IIA requirements as discussed in Section 2.4.12 and 2.5.4. However, the dikes will be stable under both static and dynamic conditions as discussed below.

a. A cross-section of the dikes is shown in Figure 2.5-44. The dikes are designed to be 4 feet wide at the crest and minimum 6.5 feet high, with side slopes of 2.25

horizontal to 1 vertical. The dikes are supported by Type I (Unit 1) or II (Unit 2) fill, which varies in thickness from a few feet to more than 30 feet. Between the plant fill and bedrock is natural soil with a thickness varying from a few feet to more than 10 feet. Bedrock is therefore at a depth varying from about 10 feet to more than 40 feet below the dikes. The subsurface conditions described above are based on the logs of boring No. 12 at the tank located southwest of Unit 1 and at borings Nos. 4 and 5 at the tank south of Unit 2. Figure 2.5-20 shows the locations of these borings. The logs of the borings are shown on Figure 2.5-22.

The dikes will be compacted to 95% of the maximum density determined by ASTM D698 (Standard Proctor). Shear strengths for the compacted soil in the dikes and the fill supporting the dikes are assumed to be similar to the shear strength for compacted soil at the spray pond (Section 2.5.5.2.4.3); the angle of internal friction is 33.5°. The natural soil below the fill is dense to very dense sandy and clayey silt with rock fragments. Properties of the natural soil have been added to Table 2.5-4 and Section 2.5.4.2.2.4.

The crest and the inside slopes of the dikes will be protected by a bituminous surface.

b. For design, the groundwater level at the tanks is conservatively considered to be 15 feet above the water table contours shown on Figure 2.5-15. This means that it will be at el 145' at the location of the CST southwest of Unit 1 and at el 175' at the location of the CST south of Unit 2. Based on the logs of borings 4, 5, and 12, the design groundwater level will be in the dense natural soil below the bottom of the fill and just above bedrock. Therefore, there will be no water table within the retaining dikes and the fill supporting them so that the fill and dike cannot liquefy.

Because the groundwater level is below the dikes, the infinite slope analysis and the yield acceleration analysis by Seed and Goodman (Reference 2.5-160) are considered appropriate for evaluating the stability of the slopes.

For static conditions, the infinite slope analysis was used to determine the factor of safety of soil slopes:

$$F.S. = \frac{\tan \phi}{\tan i} \qquad \text{(EQ. 2.5-7)}$$

where:

ϕ = friction angle

i = inclination of slope

Therefore, for $\phi = 33.5°$ and $i = \tan^{-1}(1/2.25) = 24°$, the factor of safety under static conditions is found to be 1.5.

For dynamic conditions, the yield acceleration analysis was used. The yield acceleration is defined as the acceleration at which sliding will begin to occur. The yield acceleration coefficient (k_y) is defined as:

$$k_y g = \sin(\phi - i) g$$

where ϕ and i were defined in the previous paragraph. For $\phi = 33.5°$ and $i = 24°$, (k_y) is found to be 0.165. Compared to the SSE of 0.15 g, the factor of safety for the dynamic condition would be

$$F.S. = \frac{0.165}{0.15} = 1.1$$

These stability values are equal to the minimum values required by the design criteria given in Section 2.5.5.2.2.

Therefore, the dike slopes will be stable under both static and dynamic conditions.

The slope of the fill is 2 horizontal to 1 vertical. With an angle of internal friction of 33.5°, the yield acceleration for such a slope is 0.12 g. During an SSE event, the fill slope may revel back to a slope of 2.15 horizontal to 1 vertical. A probable failure surface is shown in Figure 2.5-44. This would mean a loss of about 4.0 feet at the top of a 25 foot high slope. The ravelling will not influence the stability of the retaining dikes because the minimum space between the toe of the dike and the top of the slope of the fill is more than 20 feet (at the southeast corner of Unit 2 dike).

c. Other than the logs of three borings (Nos. 4, 5, and 12) at the locations of the CST, no separate field borings and laboratory test programs were conducted for the evaluation of stability of the dikes. The shear strength ($\phi = 33.5°$) used in the stability analysis mentioned above was assumed, based on data for similar soils from the spray pond compacted to the same degree (Table 2.5-4).

d. The construction procedure for the earth part of the dikes will be similar to that used for the spray pond construction. The main requirements will be as follows:

1. Soil gradation

Sieve Size	% Passing (by weight)
2 inch	100
¾ inch	75 - 100
No. 4	50 - 95
No. 50	35 - 90
No. 200	30 - 85

2. Loose lift thickness

-For machine compaction 8 inches maximum
-For hand compaction 6 inches maximum

3. Compaction

Minimum 95% of the maximum density as determined by ASTM D698, method D.

4. Testing

In-place density tests will be performed and documented with a minimum of one on each lift or 300 cubic yards of soil placed, whichever is the more frequent.

5. Quality Control

The quality control program will contain requirements for surveillance, audits, inspection, testing, and corrective action for nonconforming conditions.

6. Inservice Inspection

The dikes surrounding the storage tanks are passive water-retaining barriers for short-term water retention. The inspection requirements will conform with appropriate portions of Regulatory Guide 1.127 to assure short-term water retention when needed.

Table 2.5-1

MODIFIED MERCALLI INTENSITY SCALE OF 1931

[Abridged]

I.	Not felt, except by a very few under especially favorable circumstances. (I Rossi-Forel scale.)
II.	Felt only by a few persons at rest, especially on upper floors of buildings. Delicately suspended objects may swing. (I to II Rossi-Forel scale.)
III.	Felt quite noticeably indoors, especially on upper floors of buildings, but many people do not recognize it as an earthquake. Standing motor cars may rock slightly. Vibration like passing of truck. Duration estimated. (III Rossi-Forel scale.)
IV.	During the day felt indoors by many, outdoors by few. At night some awakened. Dishes, windows, doors disturbed; walls make cracking sound. Sensation like heavy truck striking building. Standing motor cars rock noticeably. (IV to V Rossi-Forel scale.)
V.	Felt by nearly everyone; many awakened. Some dishes, windows, etc., broken; a few instances of cracked plaster; unstable objects overturned. Disturbance of trees, poles, and other tall objects sometimes noticed. Pendulum clocks may stop. (V to VI Rossi-Forel scale.)
VI.	Felt by all; many frightened and run outdoors. Some heavy furniture moved; a few instances of fallen plaster or damaged chimneys. Damage slight. (VI to VII Rossi-Forel scale.)
VII.	Everybody runs outdoors. Damage negligible in buildings of good design and construction; slight to moderate in well-built ordinary structures; considerable in poorly built or badly designed structures; some chimneys broken. Noticed by persons driving motor cars. (VIII Rossi-Forel scale.)
VIII.	Damage slight in specially designed structures; considerable in ordinary substantial buildings, with partial collapse; great in poorly built structures. Panel walls thrown out of frame structures. Fall of chimneys, factory stacks, columns, monuments, walls. Heavy furniture overturned. Sand and mud ejected in small amounts. Changes in well water. Disturbs persons driving motor cars. (VIII+ to IX Rossi-Forel scale.)

Table 2.5-1 (Cont'd)

IX.	Damage considerable in specially designed structures; well-designed frame structures thrown out of plumb; great in substantial buildings, with partial collapse. Buildings shifted off foundations. Ground cracked conspicuously. Underground pipes broken. (IX+ Rossi-Forel scale.)
X.	Some well-built wooden structures destroyed; most masonry and frame structures destroyed with foundations; ground badly cracked. Rails bent. Landslides considerable from river banks and steep slopes. Shifted sand and mud. Water splashed (slopped) over banks. (X Rossi-Forel scale.)
XI.	Few, if any, (masonry) structures remain standing. Bridges destroyed. Broad fissures in ground. Underground pipe lines completely out of service. Earth slumps and land slips in soft ground. Rails bent greatly.
XII.	Damage total. Waves seen on ground surfaces. Lines of sight and level distorted. Objects thrown upward into the air.

(1) Only earthquakes with intensities greater than IV on the Modified Mercalli Intensity Scale are included in this table.
(2) Intensity based on Modified Mercalli Intensity Scale of 1931.
(3) Calculated using site coordinates of 40.23 N. latitude, 75.58 W. longitude.
(4) This event may not have occurred within 200 miles of the site. Jessopborough may correspond to Jessup Falls in Warren Co., formerly Washington Co. in the 1700s.

SUMMARY OF ENGINEERING PROPERTIES
OF IN SITU SOIL

PROPERTIES	AT SPRAY POND RANGE	AVERAGE
In situ moisture content (%)	11.9 - 38.7	21.7
In situ total unit weight (lb/ft^3)	98.6 - 137.2	122.0
Grain-size distribution:		
Medium grain-size, D_{50} (mm)	0.006 - 4.4	0.32
Percent by weight passing No. 200 sieve	15 - 100	72
Atterberg limits:		
Liquid limit	27 - 51	37
Plasticity index	2 - 27	15
Effective consolidated-undrained shear strength:		
$\bar{C}$ (psf)	-	0
$\bar{\phi}$ (deg)	-	33.5
Undrained shear strength, s (psf)	-	1.2 $\bar{P}_o$ (1)
Dynamic shear strength	-	$0.61\sigma_o$ (2)
Cyclic stress ratio	-	0.61
Standard penetration resistance (blows/ft)	7 - 86	36
Specific gravity	2.70 - 2.80	2.76

Table 2.5-4 (Cont'd)

OTHER THAN AT SPRAY POND SITE

PROPERTIES	RANGE	AVERAGE
In situ Moisture Content (%)	8.3 - 21.3	13.4
In situ Total Unit Weight (pcf)	126.0-140.6	132.8
Grain-Size Distribution		
Gravel (retain on No. 4 sieve)	4.0 - 25.0	14.0
Sand (passing No. 4 and retain on No. 200)	12.0 - 54.0	27.0
Silt/Clay (passing No. 200 sieve)	26.0 - 82.0	59.0
Atterberg Limits		
Liquid Limit	18.0 - 37.0	25.0
Plasticity Index	3.0 - 17.0	8.0
Standard Penetration Resistance (blows/ft)	2 -.98	.42
Total Undrained Shear Strength	c = 3.0 ksf,	$\phi = 18^o$
Effective Shear Strength	$\bar{c} = 0$,	$\bar{\phi} = 26.5^o$

(1) $\bar{P}_o$ = mean effective principal stress, $(\bar{\sigma}_1 + \bar{\sigma}_3)/2$

(2) σ_o = effective overburden pressure

Table 2.5-5

SUMMARY OF DESIGN PARAMETERS OF SOILS
AND SOIL-BENTONITE MIXTURES

PARAMETER	IN SITU SOIL	SOIL COVER[1]	SOIL-BENTONITE LINER[1]
Unit weight (lb/ft^3)			
Total	122.0	120.5	113.0
Saturated	126.4	123.8	119.0
Effective shear strength parameters			
$\overline{c}$ (psf)	0	0	0
$\overline{\phi}$ (deg.)	33.5	33.5	29.0
Undrained shear strength (psf)[2]	1.2 $\overline{P}_o$	1.2 $\overline{P}_o$	0.95 $\overline{P}_o$
Dynamic shear strength[3]	0.61 σ_o	0.61 σ_o	$\phi = 20^o$
			$c = 225\ lb/ft^2$
Permeability (ft/yr)	-	-	1.0

(1) Both soil cover and soil-bentonite liner are compacted to 95% of maximum dry density determined in accordance with ASTM D698.

(2) $\overline{P}_o$ = mean effective principal stress, $(\overline{\sigma}_1 + \overline{\sigma}_3)/2$

(3) σ_o= effective overburden pressure

Table 2.5-7

RESULTS OF STABILITY ANALYSIS
(2H:1V ROCK SLOPE - SPRAY POND)[2]

Water level in Pond	el of Water Table in Slope	Factor of Safety[1] Loading	Minimum Factor of Safety[1] without shotcrete	Minimum with shotcrete
Empty – rapid drawdown	251	static	1.5	5.7
Full - el 251'	251 (saturated slope)	static	>10	>10
Full - el 251'	251 (saturated slope)	SSE	1.5	4.5
Full - el 251'	241 (drained slope)	static	>10	>10
Full - el 251'	241 (drained slope)	SSE	6.0	>10

[1] These minimum factors of safety against sliding include the effect of the rock bolts. Also, the factors apply only to the least stable bedding-planes of the 2:1 rock slope, where failure of such planes would occur at the toe of the slope. The other portions of the 2:1 slope as well as all other rock slopes have factors of safety exceeding the above values.

[2] The applicable slope is shown in profile as section F, Figure 2.5-49.

DESIGN PROPERTIES USED IN ANALYSIS

Unit weight of soi	122 pcf (Table 2.5-5)
Unit weight of roc	152 pcf (Table 2.5-11)
DIP of failure plane	11°
Friction angle □ (along failure plane)	20°
Cohesion C (along failure plane)	0 psi
SSE loading (parallel to failure plane)	15% of total static weight above failure plane

(1) Intensity based on Modified Mercalli Intensity Scale of 1931. Values in parentheses are body wave or code length type magnitudes given for earthquake size comparison.
(2) Calculated using site coordinates of 40.23 N. latitude, 75.58 W. longitude.
(3) This event may not have occurred within 50 miles of the site.
(4) Cohantle may be a misspelling of Cohansey, formerly either Bridgeton or Greenwich, N.J., approximately 60 miles from the site.

Table 2.5-9

DESIGN PARAMETERS OF SAFETY-RELATED STRUCTURES[1][2]

Safety-Related Structure	Basement Dimension	Approx. Bearing Elev.	Static Design Bearing Pressure	Maximum Hydro-static Pressure	Discussion in UFSAR Section
Containment	100'-4" dia.	174'	8.3 ksf	N/A	2.5.4.10.1.2
Reactor Enclosure	326'x137' (Units 1 & 2)	174'	31.4 ksf	1123 psf	2.5.4.10.1.2
Control Structure	132'x62'	178'	31.4 ksf	936 psf	2.5.4.10.1.2
Spray Pond Pumphouse	83'x22'-9" 151'x22'-9"	257'-6" 235'	14.1 ksf	1810 psf	2.5.4.10.1.3
Diesel Generator Enclosure	273'x86' (Units 1 or 2)	190'	22.1 ksf	Above ground-water level	2.5.4.10.1.1
Valve Pit (on soil)	7'x8' (on fill)	198'	2.7 ksf	Above ground-water level	2.5.4.10.2.3
Electrical Duct Bank (portions on soil	± 4' width x variable length	6' Below Grade	2.7 ksf	Above ground-water level	2.5.4.10.2.4
Diesel Oil Storage Tank Foundation	59'x123' (For all tanks)	189'-9"	5.4 ksf	Not req'd for a slab w/no walls	2.5.4.10.1.4

(1) Bearing capacities of rock material = 60 ksf (Table 2.5-11)
(2) Bearing capacities of soil material = 6 ksf (Section 2.5.4.10.2.4)

Table 2.5-10

SOIL-RESPONSE STUDY
SUMMARY OF PARAMETERS AND RESULTS

DESCRIPTPION OF PARAMETERS	CASE A	CASE B	CASE C
STRATIGRAPHY			
Type 1 Fill			
Depth, ft	40	40	40
K_2	140	100	180
Strain level, in/in	10^{-6}	10^{-6}	10^{-6}
Total unit wt, pcf	140	140	140
At rest earth pressure coefficient	0.7	0.7	0.7
Depth, Centerline Pipe, ft	13	13	13
Rock			
Shear modulus, psf	$1700x10^5$	$1700x10^5$	$1700x10^5$
RESPONSE			
Response at Centerline Pipe			
Peak acceleration, g	0.36	0.32	0.36
Peak particle velocity, ft/sec	0.87	0.76	0.83
Frequency of soil column, Hz	5.9	4.8	7.1

Table 2.5-11

REPRESENTATIVE ENGINEERING PROPERTIES
OF SOUND FOUNDATION ROCK[1]

PROPERTY	APPROXIMATE AVERAGE VALUE	RANGE	REFERENCE
Unconfined compressive strength	15,820 psi	6,370 - 24,540 psi	Table 2.5-3
Allowable bearing pressure			
Normal load	420 psi	-	[2]
Normal plus dynamic load	625 psi	-	[2]
Density	152 lbs/ft^3	140 - 162 lbs/ft^3	Table 2.5-3
Compressional wave velocity (refraction)	12,500 fps	7,000 - 20,000 fps	Section 2.5.4.4.1
Shear-wave velocity (refraction)	5,950 fps	5,800 - 6,100 fps	Section 2.5.4.4.2
Poisson's ratio (measured)	0.30	-	[2]
Modulus of elasticity[3] (dynamic)	3.0x10^6 psi	-	-
Modulus of elasticity[2] (static)	6.9x10^5 psi	-	-
Shear modulus[3]	1.2x10^6 psi	-	-

(1) From measurements on unweathered rock in power block area.
(2) Dames and Moore, Foundation Report dated October 5, 1970, and letter from Dames and Moore to PECo dated August 19, 1971.
(3) Calculated from average shear-wave velocity and Poission's ratio given above.

Table 2.5-12

STATIC MODULI OF FOUNDATION ROCK[1]

BORING NUMBER	ELEVATION (ft)	PEAK COMPRESSIVE STRESS (psi)	YOUNG'S MODULUS (E) (psix10^6)
232	193.0	24,810	5.17
271	157.0	8,000	6.67
272	191.0	18,800	4.0

REGIONAL GEOLOGY

FIGURE 2.5-2

EXPLANATION

MESOZOIC — TRIASSIC: Trd diabase dikes and sills, Trg Gettysburg formation (Brunswick equivalent), Trqc quartz pebble conglomerate, Trn New Oxford formation (Stockton equivalent).

PENNSYLVANIAN: IPpp post-Pottsville formations; IPp Pottsville group - sandstone and conglomerate with coal.

MISSISSIPPIAN: Mmc Mauch Chunck formation - shale and sandstone; Mp Pocono group - conglomerate and sandstone.

DEVONIAN: Dck Catskill formation, red sandstones and shales; Dm Marine gray to brown shales, graywackes, and sandstones; Dho Hamilton group, undifferentiated; Doh Oriskany and Helderberg formations, undifferentiated.

SILURIAN: Skw Keyser, Tonoloway and Wills Creek formations, undifferentiated; Sbm Bloomsburg and McKenzie formations, undifferentiated; Sc Clinton group; St Tuscarora formation.

ORDOVICIAN: Central Pennsylvania - Or Reedsville formation, Ocl Curtin formation, Ob Beekmantown group; Great Valley - Om Martinsburg formation, Ohm Hershey and Myerstown formations; Piedmont - Oco Cocalico formation, Oca Conestoga formation.

CAMBRIAN: Cc Conococheague group, undifferentiated; Cr Richland formation, Cms Millbach and Schaeffers-town formations, Cab Snitz Creek and Buffalo Springs formations; Ce Elbrook formation; Clv Leitnsville formation, undifferentiated; Cl Ledger formation, Ck Kinzers formation, Cv Vintage formation, Cah Antietam and Harpers formations; Cch Chickies formation.

PROBABLY LOWER PALEOZOIC: Xpg pegmatite; Xpc Peters Creek schist; Xwc Wissahickon formation, albite-chlorite schist; Xw Wissahickon formation, oligoclase-mica schist; Xc Cockeysville marble; Xsq Setters formation.

PRECAMBRIAN — PRECAMBRIAN: pC undifferentiated; g gabbroic gneiss and gabbro; gd granodiorite; gg graphitic gneiss, gn granite gneiss.

FIGURE 2.5-12

EXPLANATION

- DH-400 — Drill hole to investigate clay seam.
- 85° — Trace of fracture zone on excavated rock surface, showing dip. Dashed where fractures are tight and indistinct, dotted where concealed.
- 15° — Trace of clay seam on excavated rock surface, showing dip. Dashed where exposed in excavated slope.
- 75° — Joint showing attitude.
- Areas where fracture zones were treated.
- [7] — See notes for further descriptions.
- EL.171 — Elevation of excavated surface.
- PL-3 — Plate load test location and reference number.
- 17 — P — Column line designations referenced in text.
- A — A — Geologic sections shown on Figures 2.5-10 and 2.5-11.

Notes:

1. Fracture generally ranges from less than 1/4 inch wide to barely discernible from here toward D line.
2. Less than 1/2 inch of clay and rock fragments along clay seam parallel to bedding.
3. Fractures converge in this area, closely jointed between fractures.
4. Well defined zone of closely spaced, steeply dipping joints within a zone about 6 to 8 ft. wide; Calcite along some joints.
5. Fracture Zone B contains 2 to 10 inches of clay and decomposed rock, with adjacent closely spaced joints in hard unweathered rock. Shows 8 to 10 inches of apparent vertical offset with east side down.
6. Strong, clean joint.
7. Fracture zone 1/4 to 2 inches wide containing soft, decomposed rock. Several inches offset, with west side down. Zone is narrow; no special treatment required.
8. Fracture zone up to 4 inches wide. Adjacent rock closely jointed. Offset 3 to 4 inches with east side down. Zone is narrow; no special treatment required.
9. Vertical slope excavated in rock exposing 1 to 3 soft, clayey 1/2 to 1 inch thick bedding plane seams in 8 to 18 inch clayey siltstone. (Probable continuation of clay seam No. 2.) Excavated downdip until overlain by 2 to 4 feet of hard competent rock.

GEOLOGIC MAP POWER BLOCK EXCAVATION

SHEET 1 OF 2

FIGURE 2.5-13

FIGURE 13A - Fracture Zone A at Mh and N lines
Looking down on the zone. SW is to the left of the photo. The paint outlines the area to be excavated for dental treatment. Note the numerous through-going joints at an acute angle to the fracture zone.

FIGURE 13C - Fracture Zone A at Mh and N lines
Looking SW along strike as dental concrete is being placed in the zone.

FIGURE 13E - Fracture Zone B at Column line 31.9
Looking SW at zone. Clay and decomposed rock are about 10 inches wide here. The paint in the center of the photo marks column line 31.9.

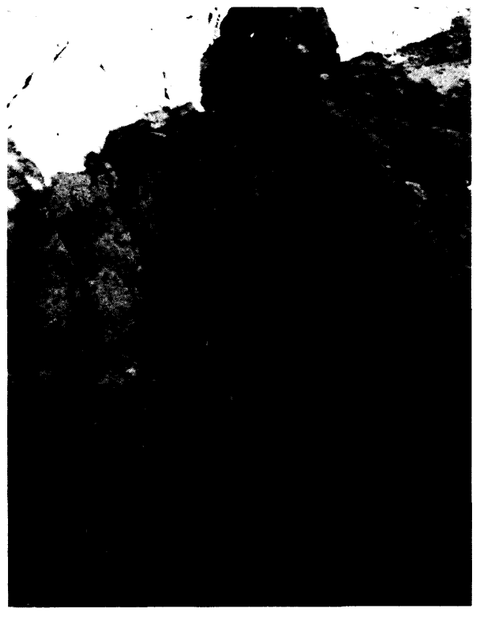

FIGURE 13B - Fracture Zone A at Mh and N lines
Looking NE into the dental excavation, immediately prior placing concrete in it.

FIGURE 13D - Fracture Zone B at D line
Looking SW along the zone after dental excavation into it. Paint in upper left corner of photo mark the "D" line. The scale in the zone is 6 inches long. Note the numerous joints parallel to the zone. The zone here contained a maximum of 2 inches of clayey material and decomposed rock.

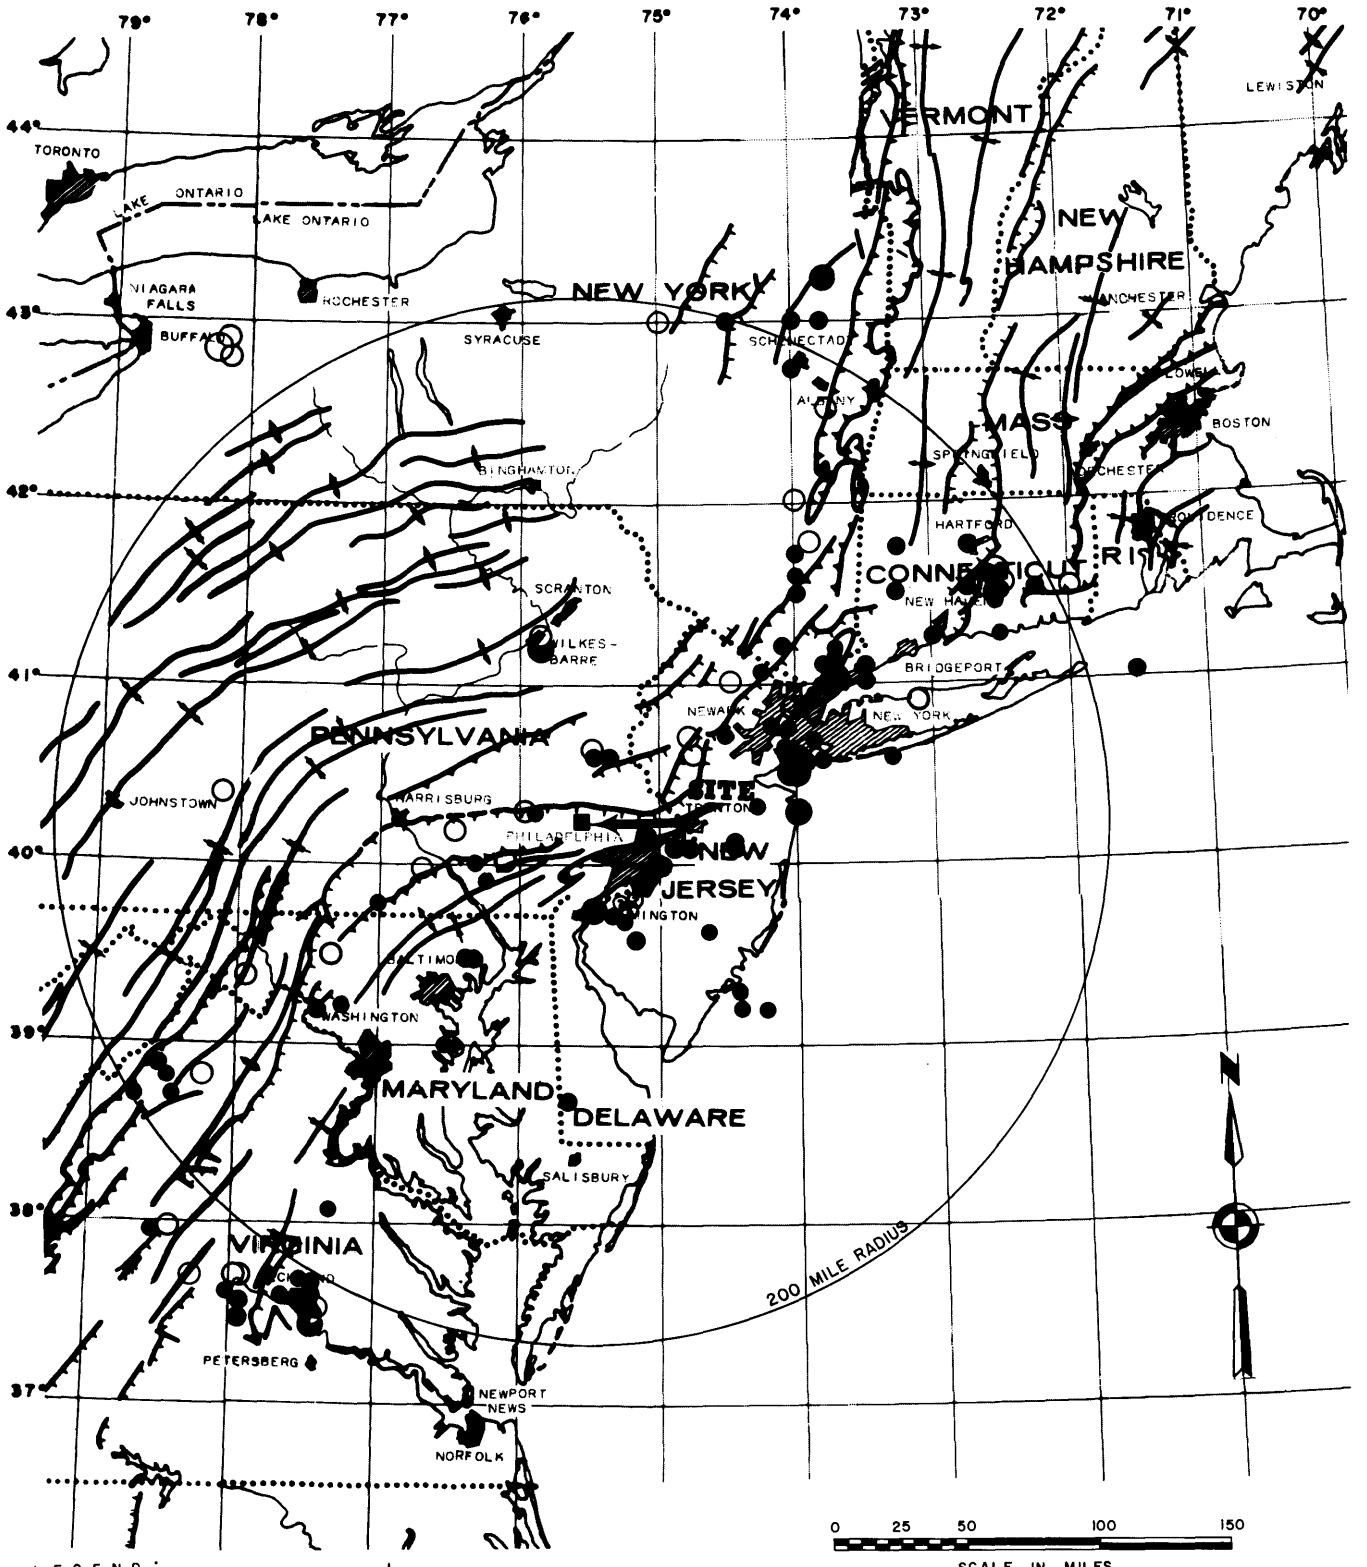

FIGURE 13F - Fracture Zone B at Column Footing F-31.9
Looking SW along the strike of the zone. This area was covered with concrete before it was treated, thus dental excavation was carried through the concrete and into the zone below it. The fracture zone here contained up to 10 inches of clay and soft weathered rock. Scale in the bottom of the excavation is 6 inches long.

EXPLANATION

- Seismic line for determination of compressional wave (Vp) velocities.
- Seismic line for shear wave (Vs) velocity determinations.
- SP ○ Shot point
- Test well used for uphole velocity measurements.

NOTE:

Geophysical surveys performed under technical direction and supervision of Dames and Moore.

WATER LEVEL @ 90½' ON 10-24-69

NOTES:

THE FIGURES IN THE COLUMN LABELLED "BLOW COUNT" INDICATE THE NUMBER OF BLOWS REQUIRED TO ADVANCE EITHER THE DAMES & MOORE SAMPLER OR A STANDARD SPLIT SPOON SAMPLER A DISTANCE OF ONE FOOT INTO THE UNDISTURBED SOIL.

THE DAMES & MOORE SAMPLER IS 3¼" O.D. AND 2½" I.D. THE STANDARD SPLIT SPOON SAMPLER IS 2" O.D. AND 1 3/8" I.D.

DATA RELATIVE TO THE ENERGY USED TO ADVANCE EITHER SAMPLER ARE INDICATED AT THE BOTTOM OF ALL BORINGS DRILLED TO INVESTIGATE THE ENGINEERING PROPERTIES OF THE SOIL. SOIL SAMPLES WERE OBTAINED IN ALL BORINGS NUMBERED 10C AND HIGHER USING A STANDARD SPLIT SPOON SAMPLER ADVANCED BY A 140-LB. HAMMER FALLING 30".

WHEN ROCK WAS CORED, THE FIGURES IN THE COLUMN LABELLED "BLOW COUNT" INDICATE THE PERCENTAGE OF ROCK RECOVERED IN THE CORING RUN, INDICATED TO THE RIGHT OF THESE FIGURES BY HEAVY BLACK LINE.

ELEVATIONS REFER TO U.S.G.S. DATUM.

FOR LOCATIONS, SEE FIGURE 2.5-20.

L-1

Elev. 116

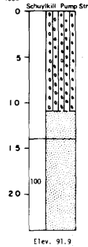
C.R. = 100%

Schuylkill Pump Structure

Elev. 80.8

0.0' - 12.0' SANDY SILT: BROWN, CLAYEY.

12.0' - 15.2' GRADES TO SANDSTONE; WEATHERED.



15.2' - 35.2' SANDSTONE: RED, VERY FINE-GRAINED WITH THIN SHALE PARTINGS. MODERATELY FRACTURED PARALLEL TO GENTLY DIPPING BEDDING. OCCASIONAL VERTICAL JOINTS. AVERAGE CORE LENGTH 8 INCHES.

L-2

Elev. 115.9

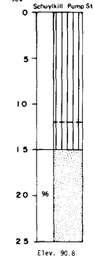
C.R. = 100%

Schuylkill Pump Structure

Elev. 91.9

0.0' - 11.0' SANDY SILT: CLAYEY.

11.0' - 14.0' GRADES TO SANDSTONE, WEATHERED.



14.0' - 24.0' SANDSTONE: RED, VERY FINE-GRAINED, HARD, WITH SHALE PARTINGS. MODERATELY FRACTURED PARALLEL TO BEDDING. ONE VERTICAL JOINT.

L-3

Elev. 115.8

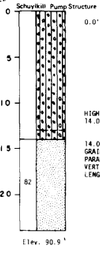
C.R. = 96%

Schuylkill Pump Structure

Elev. 90.8

0.0' - 12.0' CLAYEY SILT

12.0' - 15.0' GRADES TO SHALE AND SILTSTONE: WEATHERED.



15.0' - 25.0' SANDSTONE: VERY FINE-GRAINED, HARD WITH SHALE PARTINGS. MODERATELY JOINTED. AVERAGE CORE LENGTH IS ABOUT 2 INCHES.

L-4

Elev. 114.9

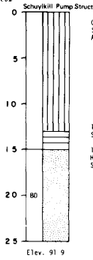
C.R. = 82%

Schuylkill Pump Structure

Elev. 90.9

0.0' - 13.0' SANDY SILT: CLAYEY.

HIGHLY WEATHERED ROCK @ 13.0' - 14.0'.



14.0' - 24.0' SANDSTONE: FINE-GRAINED, HARD, MODERATELY FRACTURED PARALLEL TO BEDDING, OCCASIONAL VERTICAL JOINTS. AVERAGE CORE LENGTH IS ABOUT 4 INCHES.

L-5

Elev. 116.9

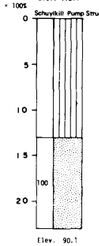
C.R. = 80%

Schuylkill Pump Structure

Elev. 91.9

0.0' - 12.5' SILT: CLAYEY AND SANDY WITH SOME GRAVELS STARTING AT 9'.

12.5' - 15.0' SHALE: WEATHERED, SOFT.



15.0' - 25.0' SANDSTONE: GRAY BROWN, HIGHLY FRACTURED PARALLEL TO BEDDING. SHALE PARTINGS.

L-6

Elev. 113.1

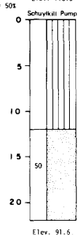
C.R. = 100%

Schuylkill Pump Structure

Elev. 90.1

0.0' - 11.0' CLAYEY SILT

GRADES TO WEATHERED ROCK @ 11.0'.



13.0' - 23.0' SANDSTONE: RED, VERY FINE-GRAINED, HARD, MODERATELY JOINTED. GRADES TO GRAY, MEDIUM GRAINED AT 17'.

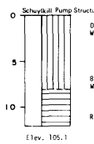
L-7

Elev. 113.6

C.R. = 50%

Schuylkill Pump

Elev. 91.6



0.0' - 12.0' SILT: CLAYEY AND SANDY WITH GRAVEL BELOW 8'

12.0' - 22.0' SANDSTONE: RED HIGHLY WEATHERED, WITH 50% SHALE PARTINGS.

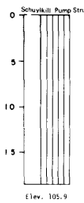
L-8

Elev. 117.1

Schuylkill Pump Structure

Elev. 105.1

0.0' - 8.0' SILT: CLAYEY AND SANDY WITH TRACE OF GRAVEL.



8.0' - 12.0' SHALE: HIGHLY WEATHERED.

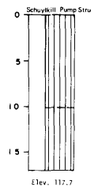
REFUSAL AT 12.0' AUGER HOLE

L-9

Elev. 124.4

Schuylkill Pump Structure

Elev. 105.9



0.0' - 18.5' SILT: SANDY AND CLAYEY WITH OCCASIONAL GRAVEL BELOW 11.0'.

REFUSAL @ 18.5' (AUGER HOLE, NO SAMPLES)

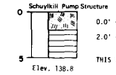
L-10

Elev. 134.7

Schuylkill Pump Structure

Elev. 117.7

0.0' - 10.0' SILT: CLAYEY AND SANDY.



GRADES TO WEATHERED BEDROCK @ 10.0'.

(AUGER HOLE, NO SAMPLES) REFUSAL AT 17.0'.

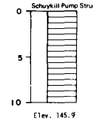
L-11

Elev. 143.8

Schuylkill Pump Structure

Elev. 138.8

0.0' - 2.0' RAILROAD BALLAST



2.0' - 5.0' SHALE: RED

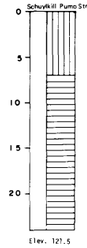
THIS IS A HAND-DUG PIT.

L-12

Elev. 155.9

Schuylkill Pump Structure

Elev. 145.9



0.0' - 10.0' SHALE: BROWN, HIGHLY WEATHERED.

REFUSAL @ 10.0'. (AUGER HOLE, NO SAMPLES)

L-13

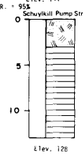
Elev. 145.5

Schuylkill Pump Structure

Elev. 127.5

0.0' - 7.0' CLAYEY SILT

7.0' - 24.0' SHALE: HIGHLY WEATHERED



(AUGER HOLE, NO SAMPLES)

L-14

Elev. 141

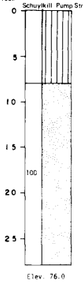
C.R. = 95%

Schuylkill Pump Structure

Elev. 128

0.0' - 3.0 RAILROAD BALLAST

3.0' - 13.0' SHALE: RED, HARD, WITH FINE-GRAINED SANDSTONE PARTINGS.



(AUGER HOLE, NO SAMPLES)

W-1

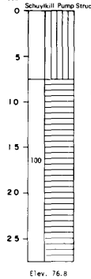
Elev. 104

C.R. = 100%

Schuylkill Pump Structure

Elev. 76.0

0.0' - 8.0' SILT: DENSE, SANDY WITH OCCASIONAL SMALL GRAVEL.



8.0' - 28.0' SANDSTONE: RED, VERY FINE-GRAINED GRADING TO SLIGHTLY COARSER AND GRAY AT 13 FEET; HARD, MODERATELY JOINTED.

W-2

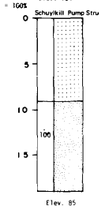
Elev. 104.4

C.R. = 100%

Schuylkill Pump Structure

Elev. 76.8

0.0' - 7.6' SILT: SANDY, DENSE WITH OCCASIONAL SMALL GRAVEL.



7.6' - 27.6' SHALE: RED, THINLY BEDDED, MODERATELY FRACTURED PARALLEL TO NEAR-HORIZONTAL BEDDING.

W-3

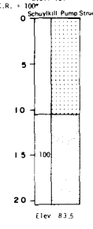
Elev. 104

C.R. = 100%

Schuylkill Pump Structure

Elev. 85

0.0' - 9.0' SAND: SILTY, DENSE, RANDOM GRAVEL.



9.0' - 19.0' SANDSTONE: GRAY TO RED, VERY FINE GRAINED WITH SHALE PARTINGS. HARD, MODERATELY FRACTURED.

W-4

Elev. 104

C.R. = 100%

Schuylkill Pump Structure

Elev. 83.5

0.0' - 10.5' SAND: SILTY, SOME SMALL GRAVEL.

10.5' - 20.5' SANDSTONE: GRAY, HARD WITH RED SHALE PARTINGS. MODERATELY FRACTURED.

W-5

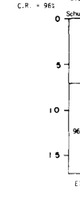
Elev. 104.4

C.R. = 100%

Schuylkill Pump Structure

Elev. 83.9

0.0' - 10.5' SAND: SILTY AND GRAVELLY.



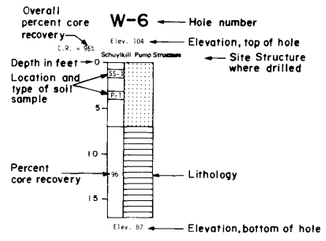
10.5' - 20.5' SANDSTONE: RED, FINE-GRAINED, WITH ZONES OF SHALE; HARD.

W-6

Elev. 104

C.R. = 96%

Schuylkill Pump Structure



Elev. 87

0.0' - 7.0' SAND: SILTY WITH RANDOM SMALL GRAVEL

7.0' - 17.0' SHALE: RED TO GRAY, HARD.

EXPLANATION

- Fill.
- Overburden, undifferentiated.
- Sand.
- Silt; clayey silt (ML).
- Sandy silt (SM).
- Sandy gravel (GM).
- Silt with siltstone fragments or boulders.
- Clay (CL).
- Silty clay, sand and gravel; clayey sand (SC).
- Siltstone.
- Siltstone and soil; siltstone and sandstone.
- Sandstone.
- Shale.

NOTE:

For location of borings, see Figure 2.5-20

NOTES

1. THE STATIC AND DYNAMIC PROPERTIES OF ROCK ARE PRESENTED IN UFSAR SECTIONS 2.5.4.2.1, 2.5.4.4 AND 2.5.4.10. THESE PROPERTIES ARE ALSO COMPILED IN TABLES 2.5-3, 2.5-11, 12 AND 13.
2. THE SOIL PROPERTIES ARE PRESENTED IN UFSAR SECTION 2.5.4.2.2.1 THROUGH 2.5.4.2.2.4.
3. FILLS ARE PRESENTED IN UFSAR SECTION 2.5.4.5.4.
4. SEE FIGURE 2.5-22 FOR LITHOLOGIC LOG OF BORINGS.
5. CONTACT BETWEEN WEATHERED ROCK AND ROCK IS GENERALLY GRADATIONAL OVER 2 TO 5 FEET.

PROFILE OF ELECTRICAL DUCT

PROFILE SHOWN IS FOR UNIT 2
PROFILE FOR UNIT 1 IS SIMILAR

NOTES

1. SEISMIC CATEGORY I ELECTRICAL MANHOLES ARE FOUNDED ON BEDROCK OR ON CLASS A CONCRETE BEARING ON BEDROCK.
2. SEISMIC CATEGORY I ELECTRICAL DUCT BANKS ARE FOUNDED ON BECKROCK, WEATHERED ROCK, DENSE NATURAL SOIL OR TYPE I FILL.
3. CONTACT BETWEEN SOIL AND WEATHERED BEDROCK AND BETWEEN WEATHERED BEDROCK AND BEDROCK ARE GENERALLY GRADATIONAL OVER 2 TO 4 FEET.
4. SEE FIGURE 2.5-22 FOR LITHOLOGIC DESCRIPTION OF BORINGS.

EXPLANATION

Area underlain by Triassic rocks of Newark-Gettysburg Basin.

Mapped Faults (type unspecified).

Boundary of Coastal Plain sediments

Location of geologic section shown in Figure 2.5-3.

Data Sources: Triassic basin and associated faults from Faill(1973) in Pennsylvania and from Olsen(1980) and Ratcliffe(1980) in New Jersey. Other faults in Pennsylvania from Penna. Geol.Survey state geologic map (Map No. 1; 1975, 1980)

SECTION THROUGH EXTERNAL WALL

SOIL AND WATER PRESSURE DIAGRAMS

NOTES:

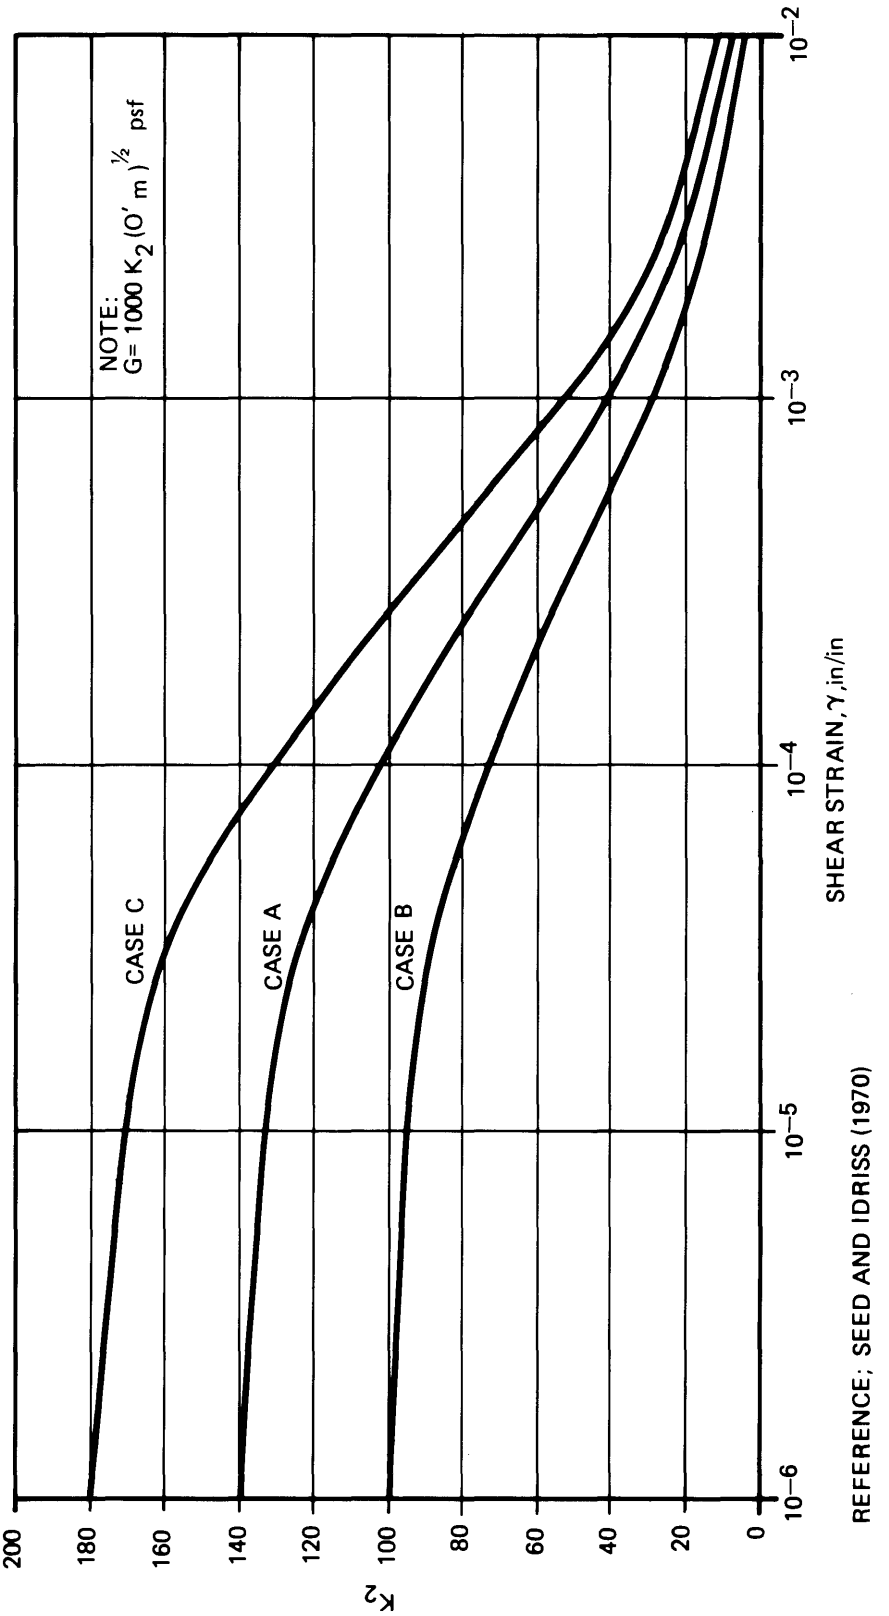
Po1, Po2, Po3 = THRUST RESULTING FROM SOIL IN THE "AT REST" STATE
Pw = THRUST RESULTING FROM HYDROSTATIC PRESSURE
Pou = THRUST RESULTING FROM SURCHARGE PRESSURE
P_{AE1}, P_{AE2} = THRUST RESULTING FROM DYNAMIC ACTION OF SOIL & WATER (SEED-WHITMAN FORMULA, 1970)

$P_{o1} = \frac{1}{2} K_o \gamma_b (H-L)^2$
$P_{o2} = K_o \gamma_b (H-L) L$
$P_{o3} = \frac{1}{2} K_o \gamma' L^2$
$P_w = \frac{1}{2} \gamma_w L^2$
$P_{ou} = K_o q H$
$P_{AE} = \frac{3}{8} \gamma_s H^2 K_h$
$P_{AE1} = 0.3 (1+K_v) K_h \gamma_s H^2$
$P_{AE2} = \frac{1}{2} K_v K_A \gamma_s H^2$
$P_{AE} = gH(1+K_v)0.6K_h + gHK_v$

* Restrained retaining wall assumption used

WHERE:

K_A = STATIC LATERAL ACTIVE EARTH PRESSURE COEFFICIENT
*K_o = COEFFICIENT OF EARTH PRESSURE "AT REST" = 0.70
γ_b = BULK UNIT WEIGHT = 135 p.c.f.
γ' = BUOYANT UNIT WEIGHT = 77.5 p.c.f.
γ_s = SATURATED UNIT WEIGHT = 140 p.c.f.
γ_w = DENSITY OF WATER = 62.5 p.c.f.
q = SURCHARGE PRESSURE = 250 p.c.f.
K_h = HORIZONTAL ACCELERATION/g
0.075 FOR OBE
0.15 FOR SSE



C = COEFFICIENT = 2.0 FOR RIGID WALLS

K_v = VERTICAL ACCELERATION / g
$= \frac{2}{3} K_h$

EXPLANATION

SYMBOLS

- 10° — Strike and dip of bedding.
- 85° — Joints and fractures, showing dip; vertical joint (right); dashed where indistinct.
- 40° / 40° — Dip of slickensided joint plane, showing dip of slickensides. (Note: dip-slip lineation shown.)
- Typ. 70°-90° 1/2'-3' sp. — Representative joint, showing range of dip and joint spacing. (See abbreviations below.)
- Lithologic contact, dashed where indistinct.
- Prominent bedding-plane clay seam.
- Vertical or near-vertical slope in excavation; hachures toward lower side.
- (239) — Denotes elevation of excavated surface at location shown.
- B_1, L_3 — Lithologic units recognized in mapping. (See description at right.)
- Exposure of black shale members of Lockatong Formation.
- A-2 A-2 — Location of Geologic Section (Shown on Figure 2.5-43)

LITHOLOGIC DESCRIPTION

B – Brunswick Formation – Red to brown sandstone, siltstone, minor shale; noncalcareous

B_1 – Brunswick strata below Lockatong units

B_2 – Brunswick strata above Lockatong units

L – Lockatong Formation – Black shale or claystone with associated gray to tan or brown calcareous units

L_1 – Light to medium gray, very hard, fine-grained calcareous sandstone with minor silty limestone; medium bedded. Locally exhibits impressions of dinosaur footprints

L_2 – Black to dark gray, hard, shaly-weathering mudstone or claystone; massive

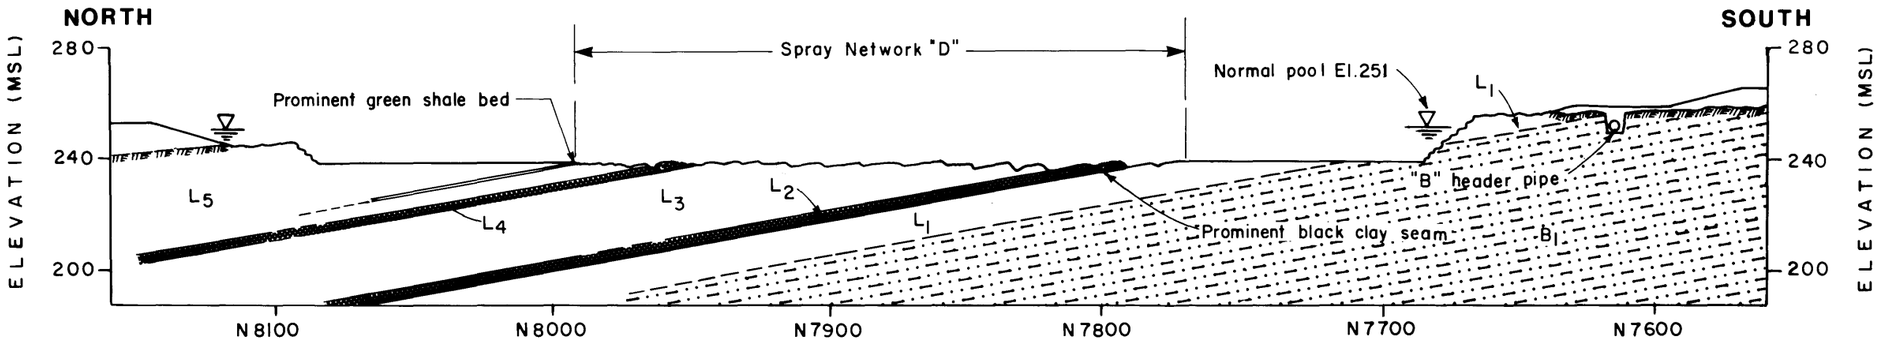
L_3 – Yellow to brown, variably calcareous fine- to very fine-grained silty sandstone, siltstone, minor shale; some greenish weathering members. Mostly thin-bedded

L_4 – Black, highly carbonaceous claystone; in part shaly

L_5 – Lithologically similar to L_3 unit

NOTES:

1. Irregular joints or fractures; generally weathered and oxide-stained, some with clay films. Width is shown where close-spaced fractures form narrow zone.
2. Fracture zone 1/2" to 24" wide; up to 2-1/2" apparent right lateral offset observed; zone terminates downward at L_1-L_2 contact.
3. Numerous curving, gently dipping slickensided joints. Striations show pure dip-slip adjustments.
4. Low-angle joints with slickensides exposed in slope.
5. Prominent shale bed exposed at base of slope (1' to 1-1/2' thick).
6. 2" offset, N. side dn. Fracture zone 2-24" wide, weathered, iron-stained, clay-coated; excavated to firm rock.
7. Fracture zone; fractures dip 70°N to 70°S within zone 6" wide; iron-stained and weathered. No offsets. All soft material excavated to firm rock.
8. Base plan and elevations show excavation configuration prior to placing lining or backfill.



ABBREVIATIONS USED:

typ.: typical or typically; used to indicate joint symbol shown represents a set of numerous repetitive joints
prom.: prominent
sp.: spacing
mult.: multiple; refers to very close-spaced parallel joints observed at western end of pond
weath.: weathered

CHAPTER 3 - DESIGN OF STRUCTURES, COMPONENTS, EQUIPMENT, AND SYSTEMS

TABLE OF CONTENTS

3.1 CONFORMANCE WITH NRC GENERAL DESIGN CRITERIA

3.2 CLASSIFICATION OF STRUCTURES, COMPONENTS, AND SYSTEMS

3.2.1 Seismic Classification
3.2.2 System Quality Group Classifications
3.2.3 Quality Assurance

3.3 WIND AND TORNADO LOADINGS

3.3.1 Wind Loadings
3.3.1.1 Design Wind Velocity
3.3.1.2 Determination of Applied Forces
3.3.2 Tornado Loadings
3.3.2.1 Applicable Design Parameters
3.3.2.2 Determination of Forces on Structures
3.3.2.3 Effect of Failure of Structures or Components Not Designed for Tornado Loadings
3.3.3 References

3.4 WATER LEVEL (FLOOD) DESIGN

3.4.1 Flood Protection
3.4.1.1 Flood Protection Measures for Seismic Category I Structures
3.4.1.2 Permanent Dewatering System

3.4.2 Analytical and Test Procedures

3.5 MISSILE PROTECTION

3.5.1 Missile Selection and Description
3.5.1.1 Internally Generated Missiles (Outside Primary Containment)
3.5.1.1.1 Rotating Component Failure Missiles
3.5.1.1.2 Pressurized Component Failure Missiles
3.5.1.1.3 Gravitationally Generated Missiles
3.5.1.2 Internally Generated Missiles (Inside Containment)
3.5.1.2.1 Rotating Component Failure Missiles
3.5.1.2.2 Pressurized Component Failure Missiles
3.5.1.2.3 Gravitationally Generated Missiles
3.5.1.3 Turbine Missiles
3.5.1.4 Missiles Generated by Natural Phenomena
3.5.1.5 Missiles Generated by Events Near the Site
3.5.1.6 Aircraft Hazards
3.5.1.6.1 Design of Safety-Related Structures

TABLE OF CONTENTS (Cont'd)

3.5.1.6.2 Analysis Method
3.5.1.6.3 Crash Probabilities
3.5.1.6.4 Probability of Aircraft Strike Resulting in Unacceptable Consequences

3.9 MECHANICAL SYSTEMS AND COMPONENTS

3.9.1 Special Topics for Mechanical Components
3.9.1.1 Design Transients
3.9.1.1.1 Control Rod Drive Transients
3.9.1.1.2 CRD Housing and Incore Housing Transients
3.9.1.1.3 Hydraulic Control Unit Transients
3.9.1.1.4 Core Support and Reactor Internals Transients
3.9.1.1.5 Main Steam System Transients
3.9.1.1.6 Recirculation System Transients
3.9.1.1.7 Reactor Assembly Transients
3.9.1.1.8 Main Steam Isolation Valve Transients
3.9.1.1.9 Main Steam Relief Valve Transients
3.9.1.1.10 Recirculation Flow Control Valve Transients
3.9.1.1.11 Recirculation Pump Transients
3.9.1.1.12 Recirculation Gate Valve Transients
3.9.1.2 Computer Programs Used in Analysis
3.9.1.2.1 Reactor Vessel and Internals
3.9.1.2.2 Piping
3.9.1.2.3 Pumps and Motors
3.9.1.2.4 Dynamic Loads Analysis
3.9.1.2.5 Residual Heat Removal Heat Exchangers
3.9.1.2.6 Seismic Category I Items Other than NSSS
3.9.1.2.7 Computer Programs Used for Component Supports
3.9.1.3 Experimental Stress Analysis
3.9.1.3.1 Experimental Stress Analysis of NSSS Seismic Category I Items
3.9.1.3.2 Seismic Category I Items Other than NSSS
3.9.1.4 Considerations for the Evaluation of Faulted Conditions
3.9.1.4.1 Control Rod Drive System Components
3.9.1.4.2 Standard Reactor Internal Components
3.9.1.4.3 Reactor Pressure Vessel Assembly
3.9.1.4.4 Core Support Structure
3.9.1.4.5 Main Steam Isolation, Recirculation Gate, and MSRVs
3.9.1.4.6 Main Steam and Recirculation Piping
3.9.1.4.7 NSSS Pumps, Heat Exchangers, and Turbines
3.9.1.4.8 Control Rod Drive Housing Supports
3.9.1.4.9 Fuel Storage Racks
3.9.1.4.10 Fuel Assembly (Including Channel)
3.9.1.4.11 Refueling Equipment
3.9.1.4.12 Seismic Category I Items Other than NSSS
3.9.2 Dynamic Testing and Analysis

TABLE OF CONTENTS (Cont'd)

3.9.2.1a	Piping Vibration, Thermal Expansion, and Dynamic Effects Testing for NSSS Piping
3.9.2.1a.1	Piping Vibration
3.9.2.1a.2	Thermal Expansion Testing of Main Steam and Recirculation Piping
3.9.2.1a.3	Dynamic Effects Testing of Main Steam and Recirculation Piping
3.9.2.1a.4	Test Evaluation and Acceptance Criteria for Main Steam and Recirculation Piping
3.9.2.1a.5	Corrective Actions for Main Steam and Recirculation Piping
3.9.2.1a.6	Measurement Locations for Main Steam and Recirculation Piping
3.9.2.1b	Piping Vibration, Thermal Expansion, and Dynamic Effects Testing for Non-NSSS Piping
3.9.2.1b.1	Piping Dynamic Transient Tests
3.9.2.1b.2	Piping Steady-State Vibration Testing
3.9.2.2	Dynamic Qualification of Safety-Related Mechanical Equipment
3.9.2.2a	Dynamic Qualification of NSSS Safety-Related Mechanical Equipment
3.9.2.2a.1	Tests and Analysis Criteria Methods
3.9.2.2a.2	Dynamic Qualification of Specific NSSS Mechanical Components
3.9.2.2b	Dynamic Qualification of Non-NSSS Safety-Related Mechanical Equipment
3.9.2.2b.1	Dynamic Qualification
3.9.2.2b.2	Criteria
3.9.2.3	Dynamic Response of Reactor Internals Under Operational Flow Transients and Steady-State Conditions
3.9.2.4	Confirmatory Flow-Induced Vibration Testing of Reactor Internals
3.9.2.5	Dynamic System Analysis of the Reactor Internals Under Faulted Conditions
3.9.2.6	Correlations of Reactor Internals Vibration Tests with the Analytical Results
3.9.3	ASME Code Class 1, 2, and 3 Components, Component Supports, and Core Support Structures
3.9.3.1	Loading Combinations, Design Transients, and Stress Limits
3.9.3.1.1	Plant Conditions
3.9.3.1.2	Reactor Pressure Vessel Assembly
3.9.3.1.3	Main Steam Piping
3.9.3.1.4	Recirculation Loop Piping
3.9.3.1.5	Recirculation System Valves
3.9.3.1.6	Recirculation Pump
3.9.3.1.7	SLCS Tank
3.9.3.1.8	RHR Heat Exchangers
3.9.3.1.9	RCIC Turbine
3.9.3.1.10	RCIC Pump
3.9.3.1.11	ECCS Pump
3.9.3.1.12	SLCS Pump
3.9.3.1.13	MSIVs and MSRVs
3.9.3.1.14	HPCI Turbine
3.9.3.1.15	HPCI Pump
3.9.3.1.16	RWCU System
3.9.3.1.17	Non-NSSS ASME Code Constructed Items
3.9.3.2a	NSSS Pump and Valve Operability Assurance
3.9.3.2a.1	ECCS Pumps
3.9.3.2a.2	SLCS Pump and Motor Assemblies and RCIC Pump Assembly

TABLE OF CONTENTS (Cont'd)

3.9.3.2a.3	RCIC Turbine
3.9.3.2a.4	ECCS Motors
3.9.3.2a.5	HPCI Pump
3.9.3.2a.6	NSSS Valves
3.9.3.2b	Non-NSSS Pump and Valve Operability Assurance
3.9.3.2b.1	Pumps
3.9.3.2b.2	Valves
3.9.3.3	Design and Installation of Pressure Relief Devices
3.9.3.3.1	Main Steam Relief Valves (NSSS)
3.9.3.3.2	Design and Installation Details for Mounting of Pressure Relief Devices in ASME Class 1, 2, and 3 Systems (Non-NSSS)
3.9.3.4	Component Supports Furnished with the NSSS
3.9.3.4.1	Piping
3.9.3.4.2	NSSS Floor-Mounted Equipment (Pumps, Heat Exchangers, and RCIC and HPCI Turbines)
3.9.3.4.3	Supports for ASME Code 1, 2, and 3 Active Components
3.9.3.4.4	RPV Support Skirt
3.9.3.4.5	Bolting Stress Limits (NSSS)
3.9.3.5	Component Supports Not Furnished with the NSSS
3.9.3.5.1	Design Basis
3.9.3.5.2	Snubbers
3.9.3.5.3	Struts
3.9.3.5.4	Bolting Stress Limits (Non-NSSS)
3.9.4	Control Rod Drive System
3.9.4.1	Descriptive Information on CRD System
3.9.4.2	Applicable CRD System Design Specifications
3.9.4.3	Design Loads, Stress Limits, and Allowable Deformation
3.9.4.3.1	CRD Housing Supports
3.9.4.4	CRD Performance Assurance Program
3.9.5	Reactor Pressure Vessel Internals
3.9.5.1	Design Arrangements
3.9.5.1.1	Core Support Structures
3.9.5.2	Design Loading Conditions
3.9.5.2.1	Events to be Evaluated
3.9.5.2.2	Pressure Differential During Rapid Depressurization
3.9.5.2.3	Recirculation Line and Steam Line Break
3.9.5.2.4	Seismic and Hydrodynamic Loads
3.9.5.3	Design Bases
3.9.5.3.1	Safety Design Bases
3.9.5.3.2	Power Generation Design Bases
3.9.5.3.3	Design Loading Categories
3.9.5.3.4	Response of Internals Due to Inside Steam Break Accident
3.9.5.3.5	Stress, Deformation, and Fatigue Limits for ESF Reactor Internals (Except Core Support Structure)
3.9.5.3.6	Stress, Deformation, and Fatigue Limits for Core Support Structure
3.9.6	Inservice Testing of Pumps and Valves
3.9.6.1	Inservice Testing of Pumps
3.9.6.2	Inservice Testing of Valves

TABLE	TITLE
3.6-21	RHR Shutdown Cooling Piping Stress Levels and Pipe Break Data
3.6-22	LPCI Injection Piping Stress Levels and Pipe Break Data
3.6-23	Core Spray Injection Piping Stress Levels and Pipe Break Data
3.6-24	Restraint Data Used in Verification of Recirculation System Pipe Whip Restraint Design
3.6-25	Comparison of PDA and NSC Codes
3.7-1	Critical Damping Values for NSSS Materials
3.7-2	Critical Damping Values for Non-NSSS Materials
3.7-3	Load Combinations and Allowable Responses for Electrical Raceway System
3.7-4	Results of Fatigue Calculations for the Most Limiting BWR/4 Component
3.7-5	Natural Frequencies of Primary Containment Below 33 Hz
3.7-6	Natural Frequencies of the Reactor Enclosure and Control Structure Below 33 Hz
3.7-7	Primary Containment Seismic Inertia Forces, Displacements, and Accelerations (Horizontal Direction)
3.7-8	Primary Containment Seismic Displacements and Accelerations (Vertical Direction)
3.7-9	Primary Containment Shear Forces and Moments
3.7-10	Primary Containment Axial Forces
3.7-11	Reactor Enclosure and Control Structure E-W Inertia Forces, Displacements, and Accelerations
3.7-12	Reactor Enclosure and Control Structure N-S Inertia Forces, Displacements, and Accelerations
3.7-13	Reactor Enclosure and Control Structure Vertical Inertia Forces, Displacements, and Accelerations
3.7-14	Reactor Enclosure and Control Structure E-W Shear Forces and Moments
3.7-15	Reactor Enclosure and Control Structure N-S Shear Forces and Moments

LIST OF TABLES (cont'd)

TABLE	TITLE
3.7-16	Reactor Enclosure and Control Structure Axial Forces
3.7-17	Structure-Foundation Interaction Coefficients
3.7-18	Number of Dynamic Response Cycles Expected During a Seismic Event for NSSS Systems and Components
3.7-19	Fatigue Evaluation Due to Seismic Load
3.7-20	Reactor Enclosure and Control Structure - Seismic Response Comparison of 2-Component ABS Versus 3-Component SRSS Methods
3.7-21	Spray Pond Pumphouse: Frequencies with and without Eccentricities, Global Direction: E-W
3.7-22	Diesel Generator Enclosure: Frequencies with and without Eccentricities, Global Direction: E-W
3.7-23	Reactor Enclosure: Frequencies with and without Eccentricities, Global Direction: E-W
3.7-24	Spray Pond Pumphouse: Comparison of Torsional Moments from Original Design with Values Obtained from 3-D Model with Eccentricity
3.7-25	Diesel Generator Enclosure: Comparison of Torsional Moments from Original Design with Values Obtained from 3-D Model with Eccentricity
3.7-26	Reactor Enclosure: Comparison of Torsional Moments from Original Design with Values Obtained from 3-D Model with Eccentricity
3.7-27	Reactor Enclosure: Comparison of Diesel Shears and Shears Obtained from 3-D Model with Eccentricity
3.8-1	Codes, Standards, Recommendations, and Specifications Used in Design and Construction of Seismic Category I Structures
3.8-2	Load Combinations for Primary Containment Wall, Diaphragm Slab, and Reactor Pedestal
3.8-3	Primary Containment Design Pressure and Temperature Criteria
3.8-4	Load Combinations and Allowable Stresses for ASME Class MC Components
3.8-5	Load Combination for the Reactor Shield Wall
3.8-6	Load Combinations for the Suppression Chamber Columns

LIST OF TABLES (cont'd)

TABLE	TITLE
3.8-7	Load Combinations for the Pipe Whip Restraints and Drywell Platforms
3.8-8	Load Combination for the Seismic Truss
3.8-9	Load Combinations for the Reactor Enclosure
3.8-10	Load Combinations Applicable to Seismic Category I Structures Other Than Primary Containment and Reactor Enclosure
3.8-11	Load Combinations Applicable to Miscellaneous Structural Components of Seismic Category I Structures
3.8-12	Minimum Testing Frequency for Concrete, Concrete Materials, Concrete Masonry, and Masonry Materials
3.8-13	Membrane Force Resultants from "ASHSD" Program
3.8-14	Comparison of Results from "CECAP" Program and Hand Calculations
3.8-15	Comparison of Results from "CE668" Program and Hand Calculations
3.8-16	Comparison of Results from "E0119" Program and Published Results
3.8-17	Comparison of Results from "E0781" Program and Published Results
3.8-18	Parameters Assumed for "FINEL" Program Verification
3.8-19	Comparison of Results from "FINEL" Program and Hand Calculations
3.8-20	Comparison of Containment Load Combinations with SRP 3.8.3
3.8-21	Comparison of Containment Load Combinations with ASME Code, Article CC-3000
3.9-1	Applicable Thermal Transients
3.9-2	Plant Events
3.9-3	List of Computer Programs Used for Non-NSSS Mechanical Systems, Components, and Component Supports
3.9-4	Comparison of ME912 with ME643 and Analytical Results
3.9-5	Comparison Between Sample Problem and Computer Program ME913 Results
3.9-6	Loading Combinations, Stress Limits, and Allowable Stresses

LIST OF TABLES (cont'd)

TABLE	TITLE
3.9-6(a)	Load Combinations and Acceptance Criteria for ASME Class 1, 2, and 3 NSSS Piping, Equipment, and Supports
3.9-6(b)	Reactor Internals and Associated Equipment
3.9-6(c)	RWCU Heat Exchangers
3.9-6(d)	ASME Code Class 1 Main Steam Piping and Pipe-Mounted Equipment - Highest Stress Summary
3.9-6(e)	ASME Code Class 1 Recirculation Piping and Pipe-Mounted Equipment - Highest Stress Summary
3.9-6(f)	RPV and Shroud Support Assembly
3.9-6(g)	Main Steam Safety/Relief Valves (Pilot-Operated) (ASME Section III, 1968, Including Addenda through Summer 1970)
3.9-6(h)	Main Steam Isolation Valve
3.9-6(i)	Recirculation Pump
3.9-6(j)	Reactor Recirculation System Gate Valves, Structural and Mechanical Loading Criteria
3.9-6(k)	HPCI Turbine
3.9-6(l)	SLCS Pump
3.9-6(m)	SLCS Tank
3.9-6(n)	ECCS Pumps
3.9-6(o)	RHR Heat Exchanger
3.9-6(p)	RWCU Pump
3.9-6(q)	RCIC Turbine
3.9-6(r)	RCIC Pump
3.9-6(s)	Reactor Refueling and Servicing Equipment
3.9-6(t)	HPCI Pump
3.9-6(u)	Control Rod Drive (Indicator Tube)

LIST OF TABLES (cont'd)

TABLE	TITLE
3.9-6(v)	CRD Housing

CHAPTER 3 - DESIGN OF STRUCTURES, COMPONENTS, EQUIPMENT, AND SYSTEMS

3.1 CONFORMANCE WITH NRC GENERAL DESIGN CRITERIA

This section discusses the extent to which the design criteria for the plant structures, systems, and components important to safety meet the General Design Criteria for Nuclear Power Plants specified in 10CFR50, Appendix A. For each criterion, a summary is provided to show how the principal design features meet the criterion. The discussion of each criterion also gives the section of the UFSAR where more detailed information is presented to demonstrate compliance with the criterion.

GDC 1 - Quality Standards and Records

> Structures, systems, and components important to safety shall be designed, fabricated, erected, and tested to quality standards commensurate with the importance of the safety functions to be performed. Where generally recognized codes and standards are used, they shall be identified and evaluated to determine their applicability, adequacy, and sufficiency and shall be supplemented or modified as necessary to assure a quality product in keeping with the required safety function. A quality assurance program shall be established and implemented in order to provide adequate assurance that these structures, systems, and components will satisfactorily perform their safety functions. Appropriate records of the design, fabrication, erection, and testing of structures, systems, and components important to safety shall be maintained by or under the control of the nuclear power unit licensee throughout the life of the unit.

Design Evaluation

Structures, systems, and components important to safety are designed, fabricated, erected, tested, and operated under a QA program that satisfies the requirements of 10CFR50, Appendix B. Chapter 17.2 of the UFSAR discusses the QA program during operation, which is designed and implemented to ensure that LGS is tested and operated in conformance with the regulatory requirements and design bases outlined in the license application.

Design requirements and other information regarding implementation of the QA program are described in various sections of the UFSAR. Codes and standards that apply to safety-related, pressure-retaining piping and equipment are discussed in Section 3.2. Building codes and standards are discussed in Section 3.8. Detailed seismic design is outlined in Section 3.7.

Structures, systems, and components are classified with regard to location, service, and relationship to the safety function to be performed. Recognized codes and standards are applied to the equipment in keeping with the appropriate classification. Where codes are not available or where the existing code must be modified, justification is provided in the UFSAR.

Documents and records are available to show objective evidence that the requirements of the QA program have been satisfied. The documentation shows that the required codes, standards, and specifications were observed; specified materials were used; correct procedures were used; qualified personnel performed the work; and inspections and tests verified that finished parts and components meet the applicable specifications. Appropriate records are maintained during the operational life of the plant.

The QA program developed by the licensee and it's contractors satisfies the requirements of GDC 1.

GDC 2 - Design Bases for Protection Against Natural Phenomena

> Structures, systems, and components important to safety shall be designed to withstand the effect of natural phenomena such as earthquakes, tornadoes, hurricanes, floods, tsunami, and seiches without loss of capability to perform their safety functions. The design bases for these structures, systems, and components shall reflect: 1) appropriate consideration of the most severe of the natural phenomena that have been historically reported for the site and surrounding area, with sufficient margin for the limited accuracy, quantity, and period of time in which the historical data have been accumulated, 2) appropriate combinations of the effects of normal and accident conditions with the effects of the natural phenomena, and 3) the importance of the safety functions to be performed.

Design Evaluation

The design basis for protection against natural phenomena is in accordance with GDC 2. Structures, systems, and components important to safety are designed to withstand the effects of natural phenomena such as earthquakes, tornadoes, and floods without loss of the capability to perform required safety functions, with appropriate margin to account for uncertainties in the historical data. The natural phenomena postulated in the design are presented in Sections 2.3, 2.4, and 2.5. The design criteria for the structures, systems, and components affected by each natural phenomenon are presented in Sections 3.2, 3.3, 3.4, 3.5, 3.7, and 3.8. Those combinations of natural phenomena and plant originated accidents that are considered in the design are identified in Sections 3.8, 3.9, 3.10, and 3.11.

GDC 3 - Fire Protection

> Structures, systems, and components important to safety shall be designed and located to minimize, consistent with other safety requirements, the probability and effect of fires and explosions. Noncombustible and heat-resistant materials shall be used wherever practical throughout the unit, particularly in locations such as the containment and control room. Fire detection and fighting systems of appropriate capacity and capability shall be provided and designed to minimize the adverse effects of fires on structures, systems, and components important to safety. Fire fighting systems shall be designed to assure that their rupture or inadvertent operation does not significantly impair the safety capability of these structures, systems, and components.

Design Evaluation

Structures, systems, and components important to safety are designed to minimize the probability and effect of fires and explosions. Noncombustible and heat-resistant materials are used wherever practicable throughout the plant, particularly in the containment, control room, and areas containing engineered safeguards.

Appropriate equipment and facilities for fire protection, including the detection, alarm, and extinguishing of fires, are provided to protect plant equipment and personnel from fire, explosions, and the resultant release of toxic vapors. Automatic and manual types of fire protection equipment are provided.

The fire protection system provides an adequate supply of water to the deluge systems, sprinkler systems, and hose stations located throughout the plant. Two separate Halon extinguishing systems

are provided for the raised flooring in the auxiliary equipment room. Portable fire extinguishers are provided throughout the plant. A detailed description of the fire protection system and its design bases is provided in Section 9.5.1.

Early warning of incipient fires is provided by a fire detection system utilizing smoke detectors and/or heat-responsive devices located in areas of the plant where significant fire potential exists.

The fire protection system is designed, fabricated, and installed in accordance with the requirements of the NFPA, ANI, OSHA, and applicable local codes and regulations as listed in Section 9.5.1.

The fire protection system was inspected and functionally tested prior to plant operation in order to ensure its proper operation. The fire suppression systems are provided with test valves and facilities for periodic testing. All equipment is accessible for periodic inspection.

Although it can be postulated that failure or inadvertent operation of the fire suppression system may incapacitate some safety-related systems or components, such failure or inadvertent operation will not prevent safe shutdown from being achieved through the use of redundant safety-related systems.

Structures, systems, and components important to safety are designed to meet the requirements of GDC 3. Fire protection systems meeting the requirements of GDC 3 are provided.

GDC 4 - Environmental and Missile Design Bases

> Structures, systems, and components important to safety shall be designed to accommodate the effects of and to be compatible with the environmental conditions associated with normal operation, maintenance, testing, and postulated accidents, including LOCAs. These structures, systems, and components shall be appropriately protected against dynamic effects, including the effects of missiles, pipe whipping, and discharging fluids, that may result from equipment failures and from events and conditions outside the nuclear power unit.

Design Evaluation

Structures, systems, and components important to safety are designed to accommodate the effects of and to be compatible with the environmental conditions associated with normal operation, maintenance, testing, and postulated accidents, including the design basis LOCA. These structures, systems, and components are appropriately protected against dynamic effects and discharging fluids that may result from equipment failures. Normal and postulated accident effects and load combinations are given in Sections 3.6, 3.8, 3.9, 3.10, and 3.11.

Special attention has been directed to the effects of pipe movement, jet forces, and missiles within the primary containment. Pipe whip restraints have been provided to the extent practicable (Section 3.6). Primary containment integrity protection is discussed in Section 6.2.1. The structures, systems, and components important to safety are protected from dynamic effects by separating redundant counterparts so that no single event can prevent a required safety action, and by routing and locating these components, to the extent practicable, to avoid potentially hazardous areas. The means used to preserve the independence of redundant counterparts of safety-related systems are discussed in Chapter 6.

Dynamic effects external to the plant, induced by natural phenomena (e.g., tornado-produced missiles), are discussed in Section 3.5. Section 3.11 contains a discussion of design environmental conditions.

Environmental and missile design bases are in accordance with GDC 4.

GDC 5 - Sharing of Structures, Systems, and Components

> Structures, systems, and components important to safety shall not be shared among nuclear power units unless it can be shown that such sharing will not significantly impair their ability to perform their safety functions, including, in the event of an accident in one unit, an orderly shutdown and cooldown of the remaining units.

Design Evaluation

Although LGS Units 1 and 2 share certain structures, systems, and components, sharing them does not significantly impair the performance of their safety functions.

The following safety-related structures are shared between both units:

a. Control enclosure and support subsystems

b. Spray pond pumphouse and support subsystems

c. Spray pond

The safety-related structures are designed to remain functional during and following the most severe natural phenomena. Therefore, sharing these structures does not impair their ability to perform their safety functions.

Seismic Category I structures that house safety-related systems and equipment are discussed in Section 3.8.

The below listed safety systems and subsystems are shared by both units. Refer to the section listed by each system or subsystem for discussion of design criteria for instrumentation. The instrumentation for these systems is available on common panels in the control room and therefore is available to the operators of both units.

SHARED SAFETY SYSTEMS	SECTION
ESW system	7.3.2.11
RHRSW system	7.3.2.12
RHRSW-RMS	7.6.1.1
Control structure support systems	
Habitability, control room isolation subsystem	7.3.2.10
Emergency switchgear and battery room cooling subsystem	7.3.2.15
CECWS	7.3.2.13
AERVS	7.3.2.15
CRV-RMS	7.6.1.1
CREFA-RMS	7.6.1.1
SGTS	7.3.2.7
SGTS-UC	7.3.2.15
RAVE-RMS and REVE-RMS	7.6.1.1
North stack radiation monitoring system	7.6.1.1
Spray pond pumphouse support system	7.3.2.15

The shared systems that are important to safety are discussed below. A more detailed discussion may be found in these referenced sections.

Emergency Service Water System

The ESW system is designed to supply cooling water to safety- related components, including the diesel generators, room coolers and chillers, and the RHR pumps during LOOP and accident conditions. Certain nonessential components can be cooled by the ESW system also, at the operator's option.

The ESW pumps are located in the spray pond pumphouse with the RHRSW pumps. The spray pond pumphouse is designed as seismic Category I. The ESW system consists of two redundant loops, each capable of simultaneously providing 100% of the cooling water required by both Units 1 and 2. The system is designed so that no single active or passive electrical or control component failure or active mechanical component failure can prevent it from achieving its safety-related objective.

For additional discussion, see Section 9.2.2.

RHR Service Water System

The RHRSW system is designed to supply cooling water to the RHR heat exchangers during normal shutdown cooling operations as well as during LOOP and accident conditions.

The RHRSW pumps are located in the spray pond pumphouse with the ESW pumps. The spray pond pumphouse is designed as seismic Category I. The RHRSW system consists of two redundant loops, each supplying one RHR heat exchanger in each unit and capable of simultaneously providing 100% of the cooling water required by both Units 1 and 2. The system is designed so that no single active or passive component failure can prevent it from achieving its safety-related objective.

For additional discussion, see Section 9.2.3.

Ultimate Heat Sink (Spray Pond)

The spray pond provides the water for both the ESW and the RHRSW systems. It is the UHS for both Units 1 and 2. The return lines from the ESW and the RHRSW system are combined, and the total quantity of water from both these systems is discharged through spray networks, which dissipate the heat. There are two redundant return loops. Either one is capable of handling the full flow from the ESW and RHRSW systems when shutting down two units simultaneously.

Each return loop supplies two spray networks. Two of the four networks provide sufficient cooling for the design basis conditions.

The spray pond contains sufficient water to meet the requirements for shutting down one unit if there is an accident and to permit the safe shutdown of the second unit for a period of 30 days without makeup.

For additional discussion, see Section 9.2.6.

Standby Gas Treatment System

The SGTS is designed to maintain both reactor enclosures and refueling area at the required negative pressure when any of these areas are isolated.

The SGTS filter train and fans are located in the control enclosure. The control enclosure is a seismic Category I structure. The SGTS consists of two 100% capacity redundant filter trains and two 100% capacity fans. The system is designed so that no single failure can prevent it from achieving its safety-related objective.

Additional discussion is given in Section 6.5.1.1.

Control Room and Control Structure HVAC Systems

The control room and control structure HVAC systems are designed to maintain the space temperature and pressure in the various areas within the common control structure at their design conditions.

Each system consists of two 100% capacity redundant HVAC units and the system is designed so that a single failure will not prevent the system from achieving its safety-related objective.

Additional discussion is given in Section 9.4.1.

Control Structure Chilled Water System

The CSCWS provides chilled water to maintain stipulated ambient air temperature in various areas inside the common control structure.

The system consists of two 100% capacity redundant chillers and pumps and is designed so that a single failure will not prevent the system from achieving its safety-related objective.

Additional discussion is given in Section 9.2.10.2.

GDC 10 - Reactor Design

> The reactor core and associated coolant, control, and protection systems shall be designed with appropriate margin to assure that specified acceptable fuel design limits are not exceeded during any condition of normal operation, including the effects of anticipated operational occurrences.

Design Evaluation

The reactor core components consist of fuel assemblies, control rods, incore ion chambers, neutron sources, and related items. The mechanical design is based on a conservative application of stress limits, operating experience, and experimental test results.

The core has sufficient heat transfer area and coolant flow to ensure that there is no fuel damage under normal conditions or anticipated operational occurrences. The RPS is designed to monitor certain reactor parameters, sense abnormalities, and shut down the reactor, thereby preventing fuel damage when trip setpoints are exceeded. Trip setpoints are selected according to operating experience and the design bases. There is no case in which the scram-trip setpoints allow the core to exceed the thermal-hydraulic safety limits. Power for the RPS is provided by dc-ac static inverters. Alternate electrical power is available to the RPS buses. The RPS is fail-safe, i.e., scram is initiated on loss of power.

An analysis and evaluation have been made of the effects on core fuel following adverse plant operating conditions. The results of abnormal operational transients are presented in Chapter 15 and show that the MCPR does not fall below the specified limit, thereby satisfying the transient design basis. The conditions assumed in the analysis and the control systems used to accommodate these transients are identified in Chapter 15.

The reactor core and associated coolant, control, and protection systems are designed to ensure that the specified fuel design limits are not exceeded during conditions of normal or abnormal operation and therefore meet the requirements of GDC 10.

h.	Accident analyses	Chapter 15

GDC 11 - Reactor Inherent Protection

> The reactor core and associated coolant systems shall be designed so that, in the power operating range, the net effect of the prompt inherent nuclear feedback characteristics tends to compensate for a rapid increase in reactivity.

Design Evaluation

The reactor core is designed to have a reactivity response that regulates or damps changes in power level and spatial distributions of power production to a level consistent with safe and efficient operation.

The inherent dynamic behavior of the core is characterized in terms of:

a. Fuel temperature or Doppler coefficient

b. Moderator void coefficient

c. Moderator temperature coefficient

The combined effect of these coefficients in the power range is termed the power coefficient.

Doppler reactivity feedback occurs simultaneously with a change in fuel temperature and opposes the power change that caused it. Thus, it contributes to system stability. Since the Doppler reactivity opposes load changes, it is desirable to maintain a large ratio of moderator void coefficient to Doppler coefficient for optimum load-following capability. The BWR has an inherently large moderator-to-Doppler coefficient ratio that permits the use of coolant flow rate for load-following.

In a BWR, the moderator void coefficient is of primary importance during operation at power. Nuclear design is based on the void coefficient inside the fuel channel being negative. The negative void reactivity coefficient provides an inherent negative feedback during power transients. Because of the large negative moderator coefficients of reactivity, the BWR has a number of inherent advantages, such as:

a. Use of coolant flow as opposed to control rods for load-following

b. Inherent self-flattening of the radial power distribution

c. Ease of control

d. Spatial xenon stability

The reactor is designed so that the moderator temperature coefficient is small and positive in the cold condition; however, the overall power reactivity coefficient is negative.

The reactor core and associated coolant system are designed so that, in the power operating range, prompt inherent dynamic behavior tends to compensate for any rapid increase in reactivity in accordance with GDC 11. Referenced sections are as follows:

a.	Nuclear design	Section 4.3
b.	Thermal and hydraulic design	Section 4.4

GDC 12 - Suppression of Reactor Power Oscillations

> The reactor core and associated coolant, control, and protection systems shall be designed to ensure that power oscillations which can result in conditions exceeding specified acceptable fuel design limits are not possible or can be reliably and readily detected and suppressed.

Design Evaluation

The reactor core is designed to ensure that no power oscillation can cause fuel design limits to be exceeded. The power reactivity coefficient is the composite simultaneous effect of the fuel temperature or Doppler coefficient, moderator void coefficient, and moderator temperature coefficient to the change in power level. It is negative and well within the range required for adequate damping of power and spatial xenon disturbances. Operating experience has shown large BWRs to be inherently stable against xenon-induced power instability.

The RPS design and the recirculation pump trip system provide protection from excessive fuel cladding temperatures and protect the nuclear system process barrier from excessive pressures that threaten the integrity of the system. Local abnormalities are sensed, and, if protection system limits are reached, corrective action is initiated through an automatic scram and recirculation pump trip. High reliability of the RPS is achieved through the combination of logic arrangement, trip channel redundancy, power supply redundancy, and physical separation.

The reactor core and associated coolant, control, and protection systems are designed to suppress any power oscillations that could result in exceeding the fuel design limits. These systems ensure that GDC 12 is met. Referenced sections are as follows:

a.	Fuel system design	Section 4.2
b.	Nuclear design	Section 4.3
c.	Thermal and hydraulic design	Section 4.4
d.	Integrity of RCPB	Section 5.2
e.	RPS	Section 7.2
f.	All other instrumentation systems required for safety	Section 7.6
g.	Accident analyses	Chapter 15

GDC 13 - Instrumentation and Control

Instrumentation shall be provided to monitor variables and systems over their anticipated ranges for normal operations, for anticipated operational occurrences, and for accident conditions as appropriate to assure adequate safety, including those variables and systems that can affect the fission process, the integrity of the reactor core, the RCPB, and the containment and its associated systems. Appropriate controls shall be provided to maintain these variables and systems within prescribed operating ranges.

Design Evaluation

Instrumentation is provided to monitor variables and systems over their anticipated ranges for normal operations, for anticipated operational occurrences, and for accident conditions as appropriate to assure adequate safety. Appropriate controls are provided to maintain these variables and systems within prescribed operating ranges. A summary description for each instrumentation and control system is provided in Section 7.1. The instrumentation and controls provided meet the requirements of GDC 13. Referenced sections are as follows:

a.	Reactor Trip System (Reactor Protection System) – Instrumentation And Controls	Section 7.2
b.	ESF Systems	Section 7.3
c.	Systems Required For Safe Shutdown	Section 7.4
d.	Information Systems Important To Safety	Section 7.5
e.	All Other Instrumentation Systems Important To Safety	Section 7.6
f.	Control Systems Not Required For Safety	Section 7.7

GDC 14 - Reactor Coolant Pressure Boundary

The RCPB shall be designed, fabricated, erected, and tested so as to have an extremely low probability of abnormal leakage, of rapidly propagating failure, and of gross rupture.

Design Evaluation

The piping and equipment pressure parts within the RCPB through the outer isolation valves are designed, fabricated, erected, and tested to provide a high degree of integrity throughout the plant lifetime. Section 3.2 classifies the systems and components within the RCPB. The design requirements and codes and standards applied to the quality group ensure a quality product in keeping with the safety functions to be performed.

To minimize the possibility of brittle fracture within the RCPB, the fracture or notch properties and the operating temperature of ferritic materials are controlled to ensure adequate toughness when the system is pressurized to more than 20% of the design pressure. Section 5.2 describes the methods used to control toughness properties. Materials to be impact-tested are tested by the Charpy

V-notch method in accordance with ASME B&PV Code, Section III. The service temperature of these materials is maintained above the NDTT. The fracture toughness temperature requirements of the RCPB materials also apply for the RCPB piping that penetrates the containment.

Piping and equipment pressure parts of the RCPB are assembled and erected by welding unless applicable codes permit flanged or screwed joints. Assembly is according to ANSI B31.7 and ASME Section III. Erection is according to ASME Section III. Welding procedures are employed that produce welds of complete penetration, complete fusion, and freedom from unacceptable defects. All welding procedures, welders, and welding machine operators are qualified in accordance with the requirements of ASME B&PV Code, Section IX for the materials to be welded.

Section 5.2 contains the detailed material and examination requirements for the piping and equipment of the RCPB before and after its assembly and erection. Leakage testing and surveillance is accomplished as described in the evaluation against GDC 30.

The design, fabrication, erection, and testing of the RCPB ensure an extremely low probability of failure or abnormal leakage, thus satisfying the requirements of GDC 14. Referenced sections are as follows:

a.	Design of structures, components, equipment, and systems	Chapter 3
b.	Integrity of RCPB	Section 5.2
c.	Reactor vessel and appurtenances	Section 5.3
d.	Component and subsystem design	Section 5.4
e.	Accident analyses	Chapter 15
f.	QA	Chapter 17

GDC 15 - Reactor Coolant System Design

The RCS and associated auxiliary, control, and protection systems shall be designed with sufficient margin to assure that the design conditions of the reactor coolant pressure boundary are not exceeded during any condition of normal operation, including anticipated operational occurrences.

Design Evaluation

The RCS consists of the reactor vessel and appurtenances, the reactor recirculation system, the pressure relief system, and the main steam and feedwater lines. This system is designed, fabricated, erected, and tested to stringent requirements and appropriate codes and standards that ensure high integrity of the RCPB throughout the plant lifetime. The RCS is designed and fabricated to meet the requirements of the ASME B&PV Code, Section III.

The auxiliary, control, and protection systems associated with the RCS provide sufficient margin to ensure that the design conditions of the RCPB are not exceeded during any condition of normal operation, including anticipated operational occurrences. As described in the evaluation of GDC 13, instrumentation is provided to monitor essential variables to ensure that they are within prescribed operating limits. If the monitored variables exceed their predetermined settings, the auxiliary, control, and protection systems automatically respond to maintain the variables and systems within allowable design limits.

An example of the integrated protective action scheme that provides sufficient margin to ensure that the design conditions of the RCPB are not exceeded is the automatic initiation of the pressure relief system on receipt of an overpressure signal. To accomplish overpressure protection, a number of pressure-operated relief valves are provided that can discharge steam from the nuclear system to the pressure-suppression pool. The pressure relief system also provides for automatic depressurization of the nuclear system if there is a LOCA in which the vessel is not depressurized by the accident. The depressurization of the nuclear system in this situation allows operation of the low pressure ECCS to supply enough cooling water to adequately cool the core. In a similar manner, other auxiliary, control, and protection systems provide assurance that the design conditions of the RCPB are not exceeded during any conditions of normal operation, including anticipated operational occurrences.

The application of appropriate codes, standards, and high quality requirements to the RCS and the design features of its associated auxiliary, control, and protection systems ensure that the requirements of GDC 15 are satisfied.
Referenced sections are as follows:

a.	Integrity of RCPB	Section 5.2
b.	Reactor vessel and appurtenances	Section 5.3
c.	Component and subsystem design	Section 5.4
d.	ECCS	Section 6.3
e.	ESF systems	Section 7.3
f.	Control systems not required for safety	Section 7.7
g.	Accident analyses	Chapter 15

GDC 16 - Containment Design

Reactor containment and associated systems shall be provided to establish an essentially leak-tight barrier against the uncontrolled release of radioactivity to the environment and to assure that the containment design conditions important to safety are not exceeded for as long as postulated accident conditions require.

Design Evaluation

The primary containment system, which includes the drywell and suppression chamber, is designed, fabricated, and erected to accommodate, without failure, the pressures and temperatures resulting from the double-ended rupture or equivalent failure of any coolant pipe within the primary containment. The reactor enclosure encompassing the primary containment provides secondary containment. To provide protection against the consequences of accidents involving the release of radioactive materials from the fuel and nuclear system process barrier, the PCRVICS initiates automatic isolation of appropriate pipelines that penetrate the primary containment whenever monitored variables exceed preselected operational limits. The two containment systems and their associated safety systems are designed and maintained so that offsite doses, which could result from postulated design basis accidents, remain below the values stated in 10CFR50.67 when calculated by the methods of Regulatory Guide 1.183. The referenced sections provide detailed information that demonstrates compliance with GDC 16. Referenced sections are as follows:

a.	Containment systems	Section 6.2
b.	MSIV Leakage Alternate Drain Pathway	Section 6.7
c.	Primary containment ventilation system	Section 9.4.5
d.	Accident analysis	Chapter 15

GDC 17 - Electric Power Systems

An onsite electric power system and an offsite electric power system shall be provided to permit functioning of structures, systems, and components important to safety. The safety function for each system (assuming the other system is not functioning) shall be to provide sufficient capacity and capability to assure that 1) specified acceptable fuel design limits and design conditions of the RCPB are not exceeded as a result of anticipated operational occurrences and 2) the core is cooled and containment integrity and other vital functions are maintained in the event of postulated accidents.

The onsite electric power supplies (including the batteries) and the onsite electric distribution system shall have sufficient independence, redundancy, and testability to perform their safety functions assuming a single failure.

Electric power from the transmission network to the onsite electric distribution system shall be supplied by two physically independent circuits (not necessarily on separate rights of way) designed and located so as to minimize to the extent practical the likelihood of their simultaneous failure under operating and postulated accident and environmental conditions. A switchyard common to both circuits is acceptable. Each of these circuits shall be designed to be available in sufficient time, following a loss of all onsite alternating current power supplies and the other offsite electric power circuit, to assure that specified acceptable fuel design limits and design conditions of the reactor coolant pressure boundary are not exceeded. One of these circuits shall be designed to be available within a few seconds following a LOCA to assure that core cooling, containment integrity, and other vital safety functions are maintained.

Provisions shall be included to minimize the probability of losing electric power from any of the remaining supplies as a result of, or coincident with, the loss of power generated by the nuclear power unit, the loss of power from the transmission network, or the loss of power from the onsite electric power supplies.

Design Evaluation

Two separate offsite power systems that are common to both units and four physically independent, onsite, standby diesel generators per unit, with associated battery systems, are provided to supply adequate power to all the functions important to safety. Either of the two offsite power systems or any three of the four onsite standby diesel generator systems in each unit have sufficient capability to operate safety-related equipment so that specified acceptable fuel design limits and design conditions of the RCPB are not exceeded as a result of anticipated operational occurrences and to cool the reactor core and maintain primary containment integrity and other vital functions if there are postulated accidents. For a further and more detailed discussion on safety-related load distribution on diesel generators, including safety-related equipment common to both units, see Chapter 8.

The two independent offsite power systems supply electric power to the onsite power distribution system via the 220 kV and 500 kV switchyards. The two switchyards are approximately 1.7 miles apart. These two power systems are physically independent and are designed to minimize the possibility of their simultaneous failure under operating and postulated accident and environmental conditions. Each offsite source is capable of supplying all safety-related loads during a LOCA in one unit with a simultaneous safe shutdown of the other unit while maintaining proper voltage regulation.

Each offsite power source can supply all engineered safeguard buses through its associated transformer. Power is available to the safeguard buses from their preferred offsite power source during normal operation and from the alternate offsite power source if the preferred power is unavailable. Each of the offsite power sources is available immediately following a loss of all onsite alternating current power supplies and the other offsite electric power circuit to ensure that fuel design limits and design conditions of the RCPB are not exceeded. The loss of both offsite power sources to a safeguard bus results in the automatic starting and connection of the associated diesel generator. Loads are progressively and sequentially added to prevent generator instabilities. The sequential loading is such that core cooling, containment integrity, and other vital safety functions are maintained.

In addition to the two offsite sources described above, a third offsite source is available from the 33 kV distribution system to supply power to the engineered safeguard loads. This source can be connected to the safeguard buses within 72 hours if there is a loss of one of the two offsite sources or of one of the safeguard transformers.

The onsite safeguard power supplies, including the safeguard batteries and onsite safeguard electric distribution systems, are independent, redundant, and testable, thus ensuring their operability and ability to perform their safety functions, assuming that there is a single failure. For a further and detailed discussion of electric power systems, see Chapter 8.

Onsite and offsite electric power systems are provided in accordance with GDC 17. Provisions are included in the design of the electric power system to minimize the probability of losing electric power from any of the remaining supplies as a result of, or coincident with, the loss of power generated by the nuclear power unit, the loss of power from the transmission network, or the loss of power from the onsite electric power supplies.

GDC 18 - Inspection and Testing of Electric Power Systems

> Electric power systems important to safety shall be designed to permit appropriate periodic inspection and testing of important areas and features, such as wiring, insulation, connections, and switchboards, to assess the continuity of the systems and the condition of their components. The systems shall be designed with a capability to test periodically 1) the operability and functional performance of the components of the systems, such as onsite power sources, relays, switches, and buses, and 2) the operability of the systems as a whole and, under conditions as close to design as practical, the full operational sequence that brings the systems into operation, including operation of applicable portions of the protection system, and the transfer of power among the nuclear power unit, the offsite power system, and the onsite power system.

Design Evaluation

Transmission line protective relaying will be tested on a routine basis. This can be accomplished without removing the transmission lines from service.

The onsite power systems, consisting of the standby diesel generators with their associated switchgear assemblies (supplying power to safety-related equipment) and the associated battery systems, are designed and arranged for periodic testing of each system independently.

Full load testing of each standby diesel generator can be performed while the plant is at power by manually starting each standby generator and by manual synchronization to the normal power

supply. These tests prove the operability of the electric power systems under conditions as close to design as practicable to assess the continuity of these systems and the condition of the components. The inspection and testing of electric power systems, described in Chapters 8 and 16, conform to GDC 18.

GDC 19 - Control Room

A control room shall be provided from which actions can be taken to operate the nuclear power unit safely under normal conditions and to maintain it in a safe condition under accident conditions, including LOCAs. Adequate radiation protection shall be provided to permit access and occupancy of the control room under accident conditions without personnel receiving radiation exposures in excess of 5 rem whole body, or its equivalent to any part of the body, for the duration of the accident.

Equipment at appropriate locations outside the control room shall be provided 1) with a design capability for prompt hot shutdown of the reactor, including necessary instrumentation and controls to maintain the unit in a safe condition during hot shutdown and 2) with a potential capability for subsequent cold shutdown of the reactor through the use of suitable procedures.

Note: The application of Alternative Source Terms in accordance with 10CFR50.67 modified the GDC 19 dose limit from 5 Rem whole body to 5 Rem TEDE.

Design Evaluation

A control room is provided in which appropriate controls and instrumentation are located to permit personnel to operate the unit safely under normal conditions or maintain it in a safe condition under accident conditions. The control room and associated postaccident ventilation systems are designed in accordance with seismic Category I requirements.

The design of the control room permits access and occupancy during a LOCA. Sufficient shielding and ventilation are provided to permit occupancy of the control room for a period of 30 days following the LOCA, without receiving more than a 5 Rem total effective dose equivalent (TEDE). An analysis of exposures within the control room for each of the postulated accidents is presented in Chapter 15.

The capability for prompt hot shutdown of the reactor and the capability for subsequent cold shutdown through suitable procedures from locations outside the control room is provided by the remote shutdown system, if the control room becomes inaccessible. The remote shutdown system has the capability for prompt hot shutdown of the reactor, including necessary instrumentation and controls to maintain the unit in a safe condition during hot shutdown, and subsequent cold shutdown of the reactor. The remote shutdown system panel contains controls for the following equipment:

a. RHR system - The controls for one loop of the RHR system and associated RHRSW system are provided on the remote shutdown panel. The suppression pool cooling and shutdown cooling modes of RHR system operation can be controlled from the remote shutdown panel.

b. RCIC system - All basic RCIC equipment can be controlled from the remote shutdown panel.

c. Reactor recirculation system - The suction valve of one recirculation pump can be controlled from the remote shutdown panel.

d. MSRVs - Three MSRVs can be operated from the remote shutdown panel.

e. Ac power supplies for the above systems can be controlled from the remote shutdown panel.

See Section 7.4 for a further detailed discussion of remote shutdown capabilities. The control room and the remote shutdown panels conform to GDC 19.

GDC 20 - Protection System Functions

> The protection system shall be designed 1) to initiate automatically the operation of appropriate systems, including the reactivity control system, to assure that specified acceptable fuel design limits are not exceeded as a result of anticipated operational occurrences and 2) to sense accident conditions and to initiate the operation of systems and components important to safety.

Design Evaluation

The RPS is designed to provide timely protection against the onset and consequences of conditions that threaten the integrity of the fuel barrier and nuclear system process barrier. Fuel damage is prevented by initiation of an automatic reactor shutdown if monitored nuclear system variables exceed pre-established limits of anticipated operational occurrences. Trip settings are selected and verified to be far enough above or below operating levels to provide proper protection but not be subject to spurious actuation. The RPS includes the sensors, relays, bypass circuitry, and switches that signal the control rod system to shut down the reactor. The shutdowns initiated by neutron monitoring system variables, nuclear system high pressure, turbine stop valve closure, TCV fast closure, and reactor vessel low water level prevent fuel damage following abnormal operational transients. Specifically, these process parameters initiate a shutdown in time to prevent the core from exceeding thermal-hydraulic safety limits during abnormal operational transients. Response by the RPS is prompt, and the total shutdown time is short.

A fully withdrawn control rod (withdrawn to 144 inches) traverses 90% of its full stroke at Technical Specification insertion rates which is sufficient to ensure that acceptable fuel design limits are not exceeded.

In addition to the RPS, which provides for automatic shutdown of the reactor to prevent fuel damage, other portions of the protection systems are provided to sense accident conditions and automatically initiate the operation of other systems and components important to safety. The ECCS and the primary containment and reactor containment isolation control system are initiated automatically following a LOCA to limit the extent of fuel damage and prevent the release of significant amounts of radioactive materials from the fuel and the nuclear system process barrier. The control and instrumentation for the ECCS and the isolation systems are initiated automatically when monitored variables exceed preselected operational limits.

The design of the protection system satisfies the functional requirements as specified in GDC 20. Referenced sections are as follows:

a. Fuel System Design — Section 4.2

b.	ECCS	Section 6.3
c.	Reactor Trip System (Reactor Protection System) – Instrumentation And Controls	Section 7.2
d.	ESF systems	Section 7.3
e.	All Other Instrumentation Systems Important To Safety	Section 7.6
f.	Accident analyses	Chapter 15

GDC 21 - Protection System Reliability and Testability

> The protection system shall be designed for high functional reliability and inservice testability commensurate with the safety functions to be performed. Redundancy and independence designed into the protection system shall be sufficient to assure that 1) no single failure results in loss of the protection function and 2) removal from service of any component or channel does not result in loss of the required minimum redundancy unless the acceptable reliability of operation of the protection system can be otherwise demonstrated. The protection system shall be designed to permit periodic testing of its functioning when the reactor is in operation, including capability to test channels independently to determine failures and losses of redundancy that may have occurred.

Design Evaluation

The protection system is designed for high functional reliability and inservice testability. The protection system design fulfills the single failure criterion by providing redundant channels. No single component failure, intentional bypass, maintenance operation, calibration operation, or test to verify operational availability can impair the ability of the system to perform its intended safety functions. The system design ensures that when a trip setpoint is exceeded there is a high probability of successful completion of the required safety functions. There is sufficient electrical and physical separation between channels and between trip logics monitoring the same variable to prevent environmental factors, electrical transients, and physical events from impairing the ability of the system to respond correctly.

The protection system includes design features that permit inservice testing. This ensures the functional reliability of the system if the monitored variables exceed the corrective action setpoint.

The RPS initiates an automatic reactor shutdown if the monitored plant variables exceed pre-established limits. The RPS consists of two independent trip systems. Each trip system has two trip logics arranged in a one-out-of-two-twice logic, to produce an automatic trip signal.

Both the manual and automatic portions of each trip logic of the RPS can be tested independently during reactor operation. The test verifies the ability to de-energize the scram pilot valve solenoids. Indicating lights verify that the actuator contacts have opened. This capability for a thorough testing program determines if failures or losses of redundancy have occurred. CRD operability can be tested during normal reactor operation. CRD position indicators and the incore neutron detectors are used to verify control rod movement. Each control rod can be withdrawn one notch and then reinserted to the original position without significantly disturbing the reactor system. One control rod is tested

at a time. The control rod mechanism overdrive demonstrates rod-to-drive coupling integrity. Hydraulic supply subsystem pressures can be observed on control room instrumentation. The HCU scram accumulator pressure is monitored and the scram discharge volume level is continuously monitored.

The ESFs are designed to be operable for test purposes during normal operation of the nuclear system. The high functional reliability, redundancy, independence, and inservice testability of the protection system satisfy the requirements specified in GDC 21. Referenced sections are as follows:

a.	Component and subsystem design	Section 5.4
b.	Containment systems	Section 6.2
c.	ECCS	Section 6.3
d.	RPS	Section 7.2
e.	ESF systems	Section 7.3
f.	All other instrumentation systems required for safety	Section 7.6
g.	Accident analyses	Chapter 15

GDC 22 - Protection System Independence

> The protection system shall be designed to assure that the effects of natural phenomena and of normal operating, maintenance, testing, and postulated accident conditions on redundant channels do not result in loss of the protection function, or shall be demonstrated to be acceptable on some other defined basis. Design techniques, such as functional diversity or diversity in component design and principles of operation, shall be used to the extent practical to prevent loss of the protection function.

Design Evaluation

The components of protection systems are designed so that the mechanical and thermal environment resulting from any potential accident condition in which the components are required to function does not interfere with that function. The wiring for the protection system outside the control room is run in rigid metallic conduit or enclosed raceways segregated from all other wiring.

Only one trip actuator logic circuit from each trip system may be run in the same wireway.
The system sensors are electrically and physically separated. In general, redundant sensors have separate process taps. Where common process taps are used, analysis shows that failure of the common process tap will not interfere with the protection function. The wires from duplicate sensors on a common process tap are run in separate wireways.

The RPS is designed to permit maintenance and diagnostic work while the reactor is operating without restricting the plant operation or hindering any safety functions.

The design uses multiple trip logics so that an intentional bypass, maintenance operation, calibration operation, or test will not prevent completion of a protection function when required.

The protection system meets the design requirements for functional and physical independence as specified in GDC 22. Referenced sections are as follows:

a.	Component and subsystem design	Section 5.4
b.	ECCS	Section 6.3
c.	RPS	Section 7.2
d.	ESF system	Section 7.3
e.	All other instrumentation systems required for safety	Section 7.6
f.	Accident analyses	Chapter 15

GDC 23 - Protection System Failure Modes

The protection system shall be designed to fail into a safe state or into a state demonstrated to be acceptable on some other defined basis if conditions such as disconnection of the system, loss of energy (e.g., electric power, instrument air), or postulated adverse environments (e.g., extreme heat or cold, fire, pressure, steam, water, and radiation) are experienced.

Design Evaluation

The RPS and the normally energized portion of the PCRVICS are designed to fail in a safe state on disconnection or loss of energy supply. The rest of the ESFs will not initiate a protection function on disconnection or loss of energy supply. This is acceptable since these systems are designed with more than one independent trip logic, each with its own independent power supply. Disconnection of one of the trip logics or loss of one of the power supplies will not prevent accomplishing a protection function when required. The environmental conditions in which the instrumentation and equipment of the protection system must operate were considered in establishing the component specifications. Instrumentation specifications are based on the worst expected ambient conditions in which the instruments must operate.

The failure modes of the protection system are such that it fails in an acceptable state as required by GDC 23. Referenced sections are as follows:

a.	Environmental design of mechanical and electrical equipment	Section 3.11
b.	RPS	Section 7.2
c.	ESF systems	Section 7.3
d.	All other instrumentation systems required for safety	Section 7.6

GDC 24 - Separation of Protection and Control Systems

The protection system shall be separated from control systems to the extent that failure of any single control system component or channel or failure or removal from service of any single protection system component or channel which is common to the control and protection systems leaves intact a system satisfying all reliability, redundancy, and independence requirements of the protection system. Interconnection of the protection and control systems shall be limited to assure that safety is not significantly impaired.

Design Evaluation

There is separation between the protection system and the control systems. Outputs from the control system components and channels are not used as protection system inputs. The sensors, trip channels, and trip logics of the protection system are not used for automatic control of process systems. Therefore, failure in the controls and instrumentation of process systems cannot induce failure of any portion of the protection system.

For additional details of evaluation of the reactivity control system, see the evaluation for GDC 25.

The protection system is separated from control systems as required in GDC 24. Referenced sections are as follows:

a.	RPS	Section 7.2
b.	ESF systems	Section 7.3
c.	All other instrumentation systems required for safety	Section 7.6

GDC 25 - Protection System Requirements for Reactivity Control Malfunctions

The protection system shall be designed to assure that specified acceptable fuel design limits are not exceeded for any single malfunction of the reactivity control systems, such as accidental withdrawal (not ejection or dropout) of control rods.

Design Evaluation

The RPS provides protection against the onset and consequences of conditions that threaten the integrity of the fuel barrier and the nuclear system process barrier. Any monitored variable that exceeds the scram setpoint initiates an automatic scram and does not prevent the remaining variables from being monitored, and if one channel fails, the remaining portions of the RPS can function.

The reactor manual control system is designed so that no single failure can negate the effectiveness of a reactor scram. The circuitry for the reactor manual control system is completely independent of the circuitry controlling the scram valves. This separation of the scram and normal rod control functions prevents failures in the reactor manual control circuitry from affecting the scram circuitry. Because each control rod is controlled as an individual unit, a failure that results in energizing any of the insert or withdraw solenoid valves can affect only one control rod. The effectiveness of a reactor scram is not impaired by the malfunctioning of any one control rod.

The most serious rod withdrawal errors occur when an out-of-sequence rod is continuously withdrawn while the reactor is just subcritical. The RWM normally prevents the withdrawal of out-of-sequence control rods. If such a continuous rod withdrawal were to occur, the increase in fuel temperature subsequent to scram would not be sufficient to exceed acceptable fuel design limits.

The design of the protection system ensures that specified acceptable fuel design limits are not exceeded for any single malfunction of the reactivity control systems as specified in GDC 25. Referenced sections are as follows:

a.	Fuel mechanical design	Section 4.2
b.	Nuclear design	Section 4.3
c.	Thermal and hydraulic design	Section 4.4
d.	RPS	Section 7.2
e.	All other instrument systems required for safety	Section 7.6
f.	Control systems not required for safety	Section 7.7
g.	Accident analyses	Chapter 15

GDC 26 - Reactivity Control System Redundancy and Capability

> Two independent reactivity control systems of different design principles shall be provided. One of the systems shall use control rods, preferably including a positive means for inserting the rods, and shall be capable of reliably controlling reactivity changes to assure that under conditions of normal operation, including anticipated operational occurrences, and with appropriate margin for malfunctions such as stuck rods, specified acceptable fuel design limits are not exceeded. The second reactivity control system shall be capable of reliably controlling the rate of reactivity changes resulting from planned, normal power changes (including xenon burnout) to assure that acceptable fuel design limits are not exceeded. One of the systems shall be capable of holding the reactor core subcritical under cold conditions.

Design Evaluation

Two independent reactivity control systems using different design principles are provided. The normal method of reactivity control employs control rod assemblies that contain a neutron absorbing material as described in Section 4.2. Control of reactivity is operationally provided by a combination of these movable control rods, burnable poisons, and reactor coolant recirculation system flow. These systems accommodate fuel burnup, load changes, and long-term reactivity changes.

Reactor shutdown by the CRD system is sufficiently rapid to prevent the exceeding of acceptable fuel design limits for normal operation and all abnormal operational transients. The circuitry for manual insertion or withdrawal of control rods is completely independent of the circuitry for reactor scram. Two sources of scram energy (accumulator pressure and reactor vessel pressure) provide the needed scram performance over the entire range of reactor pressure (i.e., from operating conditions to cold shutdown).

The design of the control rod system includes appropriate margin for malfunctions, such as stuck rods, in the highly unlikely event that they do occur. Control rod withdrawal sequences and patterns are selected before operation to achieve optimum core performance and, simultaneously, low individual rod worths. The operating procedures for accomplishing such patterns are supplemented by the RWM, which prevents rod withdrawals yielding a rod worth greater than permitted by the preselected rod withdrawal pattern. An additional design basis of the control rod system requires that the core in its maximum reactivity condition be subcritical with the control rod of the highest worth fully withdrawn and all other rods fully inserted. Because of the carefully planned and regulated rod withdrawal sequence, prompt shutdown of the reactor can be achieved with the insertion of a small number of the many independent control rods. If a reactor scram is necessary, the unlikely occurrence of a limited number of stuck rods does not impair the capability of the control rod system to render the core subcritical.

A SLCS containing a neutron-absorbing sodium pentaborate solution is the independent backup system. This system has the capability to shut the reactor down from full power and maintain it in a subcritical condition at any time during the core life. The reactivity control provided to reduce reactor power from rated power to a shutdown condition with the control rods withdrawn in the power pattern accounts for the reactivity effects of xenon decay, elimination of steam voids, change in water density due to the reduction in water temperature, Doppler effect in uranium, change in neutron leakage from boiling to cold, and change in rod worth as boron affects the neutron migration length.

The redundancy and capabilities of the reactivity control systems satisfy the requirements of GDC 26. Referenced sections are as follows:

a.	Fuel mechanical design	Section 4.2
b.	Reactor trip system	Section 7.2
c.	Systems required for safe shutdown	Section 7.4
d.	Control systems not required for safety	Section 7.7

GDC 27 - Combined Reactivity Control Systems Capability

> The reactivity control systems shall be designed to have a combined capability, in conjunction with poison addition by the ECCS, of reliably controlling reactivity changes to assure that, under postulated accident conditions and with appropriate margin for stuck rods, the capability to cool the core is maintained.

Design Evaluation

There is no credible event applicable to the BWR that requires combined capability of the control rod system and poison additions by SLCS. The primary reactivity control system for the BWR during postulated accident conditions is the control rod system. Abnormalities are sensed, and, if protection system limits are reached, corrective action is initiated through an automatic scram. High integrity of the protection system is achieved through the combination of logic arrangement, trip channel redundancy, power supply redundancy, and physical separation. High reliability of reactor scram is further achieved by separation of scram and manual control circuitry, individual control units for each control rod, and fail-safe design features built into the CRD system. Response by the RPS is prompt, and the total scram time is short.

In operating the reactor, there is a spectrum of possible control rod worths, depending on the reactor state and on the control rod pattern chosen for operation. Control rod withdrawal sequences and patterns are selected to achieve optimum core performance and low individual rod worths. The RWM prevents rod withdrawal other than by a preselected rod withdrawal pattern. This function provides the operator with an effective backup control rod monitoring routine that enforces adherence to established startup, shutdown, and low power level operations. As a result of this carefully planned procedure, prompt shutdown of the reactor can be achieved with scram insertion of fewer than half of the many independent control rods. If accident conditions require a reactor scram, this can be accomplished rapidly with appropriate margin for the unlikely occurrence of malfunctions such as stuck rods.

The reactor core design assists in maintaining the stability of the core under accident conditions as well as during power operation. Reactivity coefficients in the power range that contribute to system stability are: the fuel temperature or Doppler coefficient, moderator void coefficient, and moderator temperature coefficient. The overall power reactivity coefficient is negative and provides a strong negative reactivity feedback under severe power transient conditions.

The design of the reactivity control system ensures reliable control of reactivity under postulated accident conditions with appropriate margin for stuck rods. The capability to cool the core is maintained under all postulated accident conditions. Thus, GDC 27 is satisfied. Referenced sections are as follows:

a.	Fuel mechanical design	Section 4.2
b.	Nuclear design	Section 4.3
c.	Thermal and hydraulic design	Section 4.4
d.	RPS	Section 7.2
e.	All other instrumentation systems required for safety	Section 7.6
f.	Control systems not required for safety	Section 7.7
g.	Accident analyses	Chapter 15

GDC 28 - Reactivity Limits

The reactivity control systems shall be designed with appropriate limits on the potential amount and rate of reactivity increase to assure that the effect of postulated reactivity accidents can neither 1) result in damage to the RCPB greater than limited local yielding nor 2) sufficiently disturb the core, its support structures, or other reactor pressure vessel internals to impair significantly the capability to cool the core. These postulated reactivity accidents shall include consideration of rod ejection (unless prevented by positive means), rod dropout, steam line rupture, changes in reactor coolant temperature and pressure, and cold water addition.

Design Evaluation

The control rod system design incorporates appropriate limits on the potential amount and rate of reactivity increase. Control rod withdrawal sequences and patterns are selected to achieve optimum core performance and low individual rod worths. The RWM prevents withdrawal other than by the preselected rod withdrawal pattern. This function provides the operator with an effective backup control rod monitoring routine that enforces adherence to established startup, shutdown, and low power level operations control rod procedures.

The control rod mechanical design incorporates a hydraulic velocity limiter in the control rod that prevents rapid rod ejection. This engineered safeguard protects against a high reactivity insertion rate by limiting the control rod velocity to less than 5 ft/sec. Normal rod movement is limited to 6 inch increments, and the rod withdrawal rate is limited through the hydraulic valve to 3 in/sec.

The accident analyses in Chapter 15 evaluate in detail postulated reactivity accidents as well as the abnormal operational transients. Analyses are included for rod dropout, steam line rupture, changes in reactor coolant temperature and pressure, and cold water addition. The initial conditions, assumptions, calculational models, sequences of events, and anticipated results of each postulated occurrence are covered in detail. The results of these analyses indicate that none of the postulated reactivity transients or accidents results in damage to the RCPB. In addition, the integrity of the core, its support structures, or other RPV internals is maintained so that the capability to cool the core is not impaired for any of the postulated reactivity accidents described in Chapter 15.

The design features of the reactivity control system, which limit the potential amount and rate of reactivity increase, ensure that GDC 28 is satisfied for all postulated reactivity accidents.

GDC 29 - Protection Against Anticipated Operational Occurrences

The protection and reactivity control systems shall be designed to assure an extremely high probability of accomplishing their safety functions in the event of anticipated operational occurrences.

Design Evaluation

The high functional reliability of the protection and reactivity control systems is achieved through the combination of logic arrangement, redundancy, physical and electrical independence, functional separation, fail-safe design, and inservice testability. These design features are discussed in GDC 21, 22, 23, 24, 25, and 26.

An extremely high probability of correct protection and reactivity control systems response to anticipated operational occurrences is maintained by a thorough program of inservice testing and surveillance. Active components can be tested or removed from service for maintenance during reactor operation without compromising the protection or reactivity control functions. Components important to safety such as CRDs, MSIVs, RHR pumps, etc, are tested during normal reactor operation. Functional testing and calibration schedules are developed using available failure rate data, reliability analyses, and operating experience. These schedules represent an optimization of protection and reactivity control system reliability by considering the reliability effects during individual component testing on the portion of the system not undergoing testing. The capability for inservice testing ensures the high functional reliability of protection and reactivity control systems if a reactor variable exceeds the corrective action setpoint.

The capabilities of the protection and reactivity control systems to perform their safety functions if there are anticipated operational occurrences satisfy the requirements of GDC 29. Referenced sections are as follows:

GDC 30 - Quality of Reactor Coolant Pressure Boundary

Components which are part of the RCPB shall be designed, fabricated, erected, and tested to the highest quality standards practical. Means shall be provided for detecting and, to the extent practical, identifying the location of the source of reactor coolant leakage.

Design Evaluation

By using conservative design practices and detailed quality control procedures, the pressure-retaining components of the RCPB are designed and fabricated to retain their integrity during normal and postulated accident conditions. Accordingly, components that comprise the RCPB are designed, fabricated, erected, and tested in accordance with recognized industry codes and standards listed in Chapter 5. Further product and process quality planning is provided as discussed in the evaluation of GDC 1 to ensure conformance with the applicable codes and standards and to retain appropriate documented evidence verifying compliance. Because the subject matter of this criterion deals with the aspects of the RCPB, further discussion of this subject appears in the response to GDC 14.

Means are provided for detecting reactor coolant leakage. The leak detection system consists of sensors and instruments to detect, annunciate, and, in some cases, isolate the RCPB from potential hazardous leaks before predetermined limits are exceeded. As described in Section 5.2.5, small leaks are detected by temperature and pressure changes, increased frequency of sump pump operation, and measurement of airborne radioactivity in the primary containment atmosphere. In addition to these means of detection, large leaks are detected by flow rates in process lines and changes in reactor water level. The allowable leakage rates are based on the predicted and experimentally determined behavior of cracks in pipes, the ability to make up coolant system leakage, the normally expected background leakage due to equipment design, and the detection capability of the various sensors and instruments. The total leakage rate limit is established so that, in the absence of normal ac power concurrent with a loss of feedwater supply, makeup capabilities are provided by the RCIC system. While the leak detection system provides protection from small leaks, the ECCS network provides protection for the complete range of discharges from ruptured pipes. Thus, protection is provided for the full spectrum of possible discharges. The RCPB and the leak detection system are designed to meet the requirements of GDC 30. Referenced sections are as follows:

a.	Design of structures, components, equipment, and systems	Chapter 3
b.	Integrity of RCPB	Section 5.2
c.	Reactor vessel and appurtenances	Section 5.3
d.	Component and subsystem design	Section 5.4
e.	All other instrumentation systems required for safety	Section 7.6
f.	Accident analyses	Chapter 15

GDC 31 - Fracture Prevention of Reactor Coolant Pressure Boundary

The RCPB shall be designed with sufficient margin to assure that, when stressed under operating, maintenance, testing, and postulated accident conditions, 1) the boundary behaves in a nonbrittle manner and 2) the probability of rapidly propagating fracture is minimized. The design shall reflect consideration of service temperatures and other conditions of the boundary material under operating, maintenance, testing, and postulated accident conditions and the uncertainties in determining 1) material properties, 2) the effects

of irradiation on material properties, 3) residual, steady-state, and transient stresses, and 4) size of flaws.

Design Evaluation

Brittle fracture control of pressure-retaining ferritic materials is provided to ensure protection against nonductile fracture. To minimize the possibility of brittle fracture failure of the RPV, it is designed to meet the requirements of the ASME B&PV Code, Section III.

The NDTT is defined as the temperature below which ferritic steel breaks in a brittle rather than ductile manner. The NDTT increases as a function of neutron exposure at integrated neutron exposures greater than about $1x10^{17}$ nvt with neutrons of energies in excess of 1 MeV. Since the material NDTT dictates the minimum operating temperature at which the reactor vessel can be pressurized, it is desirable to keep the NDTT as low as possible.

The reactor assembly design provides an annular space from the outermost fuel assemblies to the inner surface of the reactor vessel that serves to attenuate the fast neutron flux incident on the reactor vessel wall. This annular volume contains the core shroud, jet pump assemblies, and reactor coolant. Assuming that plant operation is at rated power and the plant has an availability of 100% for the plant lifetime, the neutron fluence at the inner surface of the vessel is not sufficient to appreciably shift the transition temperature. Expected shifts in transition temperature during design life as a result of environmental conditions, such as neutron flux, are considered in the design. Operational limitations assume that NDTT shifts are accounted for in the reactor operation.

The RCPB is designed, maintained, and tested so that adequate assurance is provided that the boundary will behave in a nonbrittle manner throughout the life of the plant. Therefore, the RCPB is in conformance with GDC 31. Referenced sections are as follows:

a.	Design of structures, components, equipment, and systems	Chapter 3
b.	Integrity of RCPB	Section 5.2
c.	Reactor vessel and appurtenances	Section 5.3

GDC 32 - Inspection of Reactor Coolant Pressure Boundary

Components which are part of the RCPB shall be designed to permit 1) periodic inspection and testing of important areas and features to assess their structural and leak-tight integrity and 2) an appropriate material surveillance program for the RPV.

Design Evaluation

The LGS design conforms to GDC 32. The RCPB design meets the requirements of the ASME B&PV Code, Section XI, including Summer 1971 Addenda, which requires access for all mandatory inspections. The design also permits the conduct of a material surveillance program for the RPV. Additional details of these features are in Section 5.2.4.

The reactor recirculation piping and main steam piping are hydrostatically tested with the RPV at a test pressure that is in accordance with ASME Section III.

Vessel material surveillance samples are located within the RPV to enable periodic monitoring of material properties with exposure. The program includes specimens of the base metal, the heat-affected zone within the base metal, and weld metal.

The plant testing and inspection programs ensure that the requirements of GDC 32 are met. Referenced sections are as follows:

a.	Design of structures, components, equipment, and systems	Chapter 3
b.	RCPB	Section 5.2
c.	Reactor vessel and appurtenances	Section 5.3
d.	Component and subsystem design	Section 5.4

GDC 33 - Reactor Coolant Makeup

A system to supply reactor coolant makeup for protection against small breaks in the RCPB shall be provided. The system safety function shall be to assure that specified acceptable fuel design limits are not exceeded as a result of reactor coolant loss due to leakage from the RCPB and rupture of small piping or other small components which are part of the boundary. The system shall be designed to assure that for onsite electric power system operation (assuming offsite power is not available) and for offsite electric power system operation (assuming onsite power is not available) the system safety function can be accomplished using the piping, pumps, and valves used to maintain coolant inventory during normal reactor operation.

Design Evaluation

Means are provided for detecting reactor coolant leakage. The leak detection system consists of sensors and instruments to detect, annunciate, and in some cases isolate the RCPB from potential hazardous leaks before predetermined limits are exceeded. As described in Section 5.2.5, small leaks are detected by temperature and pressure changes, increased frequency of sump pump operation, and the measurement of airborne radioactivity. The allowable leakage rates are based on predicted and experimentally determined behavior of cracks in pipes, the ability to make up coolant system leakage, the normal expected background leakage due to equipment design, and the detection capability of the various sensors and instruments. The total leakage rate limit is established so that,

in the absence of normal ac power concurrent with a loss of feedwater supply, makeup capabilities are provided by the RCIC systems. Thus, protection is provided to ensure that fuel clad temperature limits are not exceeded.

The plant is designed to provide ample reactor coolant makeup for protection against small leaks in the RCPB. The design of these systems meets the requirements of GDC 33. Referenced sections are as follows:

a.	Integrity of RCPB	Section 5.2
b.	ECCS	Section 6.3

c. ESF Systems Section 7.3

GDC 34 - Residual Heat Removal

A system to remove residual heat shall be provided. The system safety function shall be to transfer fission product decay heat and other residual heat from the reactor core at a rate such that specified acceptable fuel design limits and the design conditions of the RCPB are not exceeded.

Suitable redundancy in components and features and suitable interconnections, leak detection, and isolation capabilities shall be provided to assure that for onsite electric power system operation (assuming offsite power is not available) and for offsite electric power system operation (assuming onsite power is not available) the system safety function can be accomplished, assuming a single failure.

Design Evaluation

The RHR system provides the means to:

a. Remove decay heat and residual heat from the nuclear system so that refueling and nuclear system servicing can be performed.

b. Deleted

The major equipment of the RHR system consists of two heat exchangers, four main system pumps, and two service water pumps. The equipment is connected by associated valves and piping, and the controls and instrumentation are provided for proper system operation.

One loop consists of a heat exchanger, two main system pumps, and associated piping, and is located in one area of the reactor enclosure. A redundant loop is located in another area of the reactor enclosure to minimize the possibility of a single physical event causing the loss of the entire system.

Each heat exhanger is alignable to one of two RHR pumps. During cold shutdown and refueling operations, this results in availability of four subsystems of shutdown cooling.

As described in the evaluation for GDC 44, the RHRSW system is used to remove heat from the RHR heat exchanger.

Both RHR loops take suction from a common line coming from the reactor. A failure of either containment isolation valve in this common suction line would therefore prevent use of this flow path. In the event of such a failure, a flow path can be established through the ADS valves (Section 15.2.9).

During cold shutdown and refueling operation conditions when two subsystems of shutdown cooling may be aligned to a common passive heat exchanger and discharge piping, a failure of the associated shutdown cooling discharge valve or check valve will require manual actions to repair the valve to restore flow, or if unsuccessful, may require cooling water flow to be returned through the LPCI injection line.

The systems used for residual heat removal are powered from the safeguard buses. The design of the safeguard buses, as described in the evaluation for GDC 17, assures that residual heat can be removed, assuming a single failure, when onsite electric power is available (assuming offsite power is not available) and when offsite electric power is available (assuming onsite power is not available).

The RHR system is adequate to remove residual heat from the reactor core to ensure that fuel and RCPB design limits are not exceeded. Redundant offsite and onsite electric power systems are provided. The design of the systems used to remove residual heat, including their power supplies, meets the requirements of GDC 34. Referenced sections are as follows:

a.	Component and subsystem design	Section 5.4
b.	ECCS	Section 6.3
c.	ESF systems	Section 7.3
d.	Systems required for safe shutdown	Section 7.4
e.	Onsite power systems	Section 8.3
f.	Water systems	Section 9.2
g.	Accident analyses	Chapter 15

GDC 35 - Emergency Core Cooling

A system to provide abundant emergency core cooling shall be provided. The system safety function shall be to transfer heat from the reactor core following any loss of reactor coolant at a rate such that 1) fuel and clad damage that could interfere with continued effective core cooling is prevented and 2) clad metal-water reaction is limited to negligible amounts.

Suitable redundancy in components and features and suitable interconnections, leak detection, isolation, and containment capabilities shall be provided to assure that for onsite electric power system operation (assuming offsite power is not available) and for offsite electric power system operation (assuming onsite power is not available) the system safety function can be accomplished, assuming a single failure.

Design Evaluation

The ECCS consists of the following: HPCI system; ADS; CS system; and LPCI system (an operating mode of the RHR system). The ECCS is designed to limit fuel cladding temperature over the complete spectrum of possible break sizes in the nuclear system process barrier, including a complete and sudden circumferential rupture of the largest pipe connected to the reactor vessel.

The HPCI system consists of a steam turbine, a constant flow pump, system piping, valves, controls, and instrumentation. The HPCI system is provided to ensure that the reactor core is adequately cooled to prevent excessive fuel clad temperatures for breaks in the nuclear system that do not result in rapid depressurization of the reactor vessel. The HPCI system continues to operate until the reactor vessel pressure is below the pressure at which LPCI operation or CS system operation maintains core cooling. Two sources of water are available, the CST and the suppression pool.

In case the capability of the feedwater pumps, CRD water pumps, and RCIC and HPCI systems is not sufficient to maintain the reactor water level, the ADS functions to reduce the reactor pressure so that flow from the LPCI and the CS systems enters the reactor vessel in time to cool the core and prevent excessive fuel clad temperature. The ADS uses several of the nuclear system pressure relief valves to relieve the high pressure steam to the suppression pool.

Two independent loops are provided as a part of the CS system. Each loop consists of two centrifugal water pumps driven by electric motors, a spray sparger in the reactor vessel above the core, piping and valves to convey water from the suppression pool to the sparger, and the associated controls and instrumentation. In case of low water level in the reactor vessel or high pressure in the drywell, the CS system automatically sprays water onto the top of the fuel assemblies in time and at a sufficient flow rate to cool the core and prevent excessive fuel temperature. The LPCI system starts from the same signals that initiate the CS system and operates independently to achieve the same objective by flooding the reactor vessel.

LPCI and CS operation provide protection to the core if there is a large break in the nuclear system when the feedwater pumps, CRD, RCIC, and the HPCI systems are unable to maintain reactor vessel water level. Protection provided by LPCI and CS also extends to a small break for which the ADS has operated to lower the reactor vessel pressure so that these systems start to provide core cooling.

The results of ECCS performance for the entire spectrum of liquid line breaks are discussed in Section 6.3.

The RHR and CS systems are powered from the safeguard buses. The design of the safeguard buses, as described in the evaluation for GDC 17, assures that emergency core cooling can be provided, assuming a single failure, when onsite electric power is available (assuming offsite power is not available) and when offsite electric power is available (assuming onsite power is not available).

The ECCS provided is adequate to prevent fuel and clad damage that could interfere with effective core cooling and to limit clad metal-water reaction to a negligible amount. Redundant offsite and onsite electric power systems are provided. The design of the ECCS, including its power supplies, meets the requirements of GDC 35. Referenced sections are as follows:

a.	Component and subsystem design	Section 5.4
b.	ECCS	Section 6.3
c.	ESF systems	Section 7.3
d.	Onsite power systems	Section 8.3
e.	Water systems	Section 9.2
f.	Accident analyses	Chapter 15

GDC 36 - Inspection of Emergency Core Cooling System

The ECCS shall be designed to permit appropriate periodic inspection of important components, such as spray rings in the reactor pressure vessel, water injection nozzles, and piping, to assure the integrity and capability of the system.

Design Evaluation

The ECCS discussion in GDC 35 includes inservice inspection considerations.

The CS spargers within the reactor vessel are accessible for remote visual inspection during refueling outages. Removable plugs in the sacrificial shield and/or panels in the insulation provide access for the examination of nozzles from the outside of the vessel. Removable insulation is provided on the ECCS piping out to and including the first isolation valve outside containment. Inspection of the ECCS is in accordance with Section XI of the ASME B&PV Code, or 10 CFR 50.69 Alternative Treatment, when applicable. Refer to Section 6.6.1 for further information.

During plant operations, the pumps, valves, piping, instrumentation, wiring, and other components outside the primary containment can be visually inspected at any time. Components inside the primary containment can be inspected when the drywell is open for access. When the reactor vessel is open for refueling or other purposes, the spargers and other internals can be inspected. Portions of the ECCS that are part of the RCPB are designed to specifications for inservice inspection to detect defects that might affect the cooling performance. The design of the reactor vessel and internals for inservice inspection and the plant testing and inspection program ensures that the requirements of GDC 36 are met. See Section 5.2.4 for further discussion of ECCS inservice inspection.

GDC 37 - Testing of Emergency Core Cooling System

> The ECCS shall be designed to permit appropriate periodic pressure and functional testing to assure 1) the structural and leak-tight integrity of its components, 2) the operability and performance of the active components of the system, and 3) the operability of the system as a whole and, under conditions as close to design as practical, the performance of the full operational sequence that brings the system into operation, including operation of applicable portions of the protection system, the transfer between normal and emergency power sources, and the operation of the associated cooling water system.

Design Evaluation

The ECCS consists of the HPCI system, ADS, LPCI mode of the RHR system, and CS system. Each of these systems is provided with sufficient test connections and isolation valves to permit appropriate periodic pressure testing to ensure the structural and leak-tight integrity of its components.

The HPCI, ADS, LPCI, and CS systems are designed to permit periodic testing to ensure the operability and performance of the active components of each system.

The pumps and valves of these systems are capable of being tested periodically to verify operability. Flow rate tests can be conducted on the CS, LPCI, and HPCI systems.

Each system of the ECCS is capable of being tested under conditions as close to design as practicable to verify the performance of the full operational sequence that brings each system into operation, including the transfer between normal and emergency power sources. The operation of the associated cooling water system is discussed in the evaluation of GDC 46 design conformance. It is concluded that the requirements of GDC 37 are met. Referenced sections are as follows:

a.	Overpressurization protection	Section 5.2
b.	ECCS inspection and testing	Section 6.3
c.	ECCS instrumentation and controls	Section 7.3

d. Standby ac power system Section 8.3

GDC 38 - Containment Heat Removal

A system to remove heat from the reactor containment shall be provided. The system safety function shall be to reduce rapidly, consistent with the functioning of other associated systems, the containment pressure and temperature following any LOCA and to maintain them at acceptably low levels.

Suitable redundancy in components and features and suitable interconnections, leak detection, isolation, and containment capabilities shall be provided to assure that for onsite electric power system operation (assuming offsite power is not available) and for offsite electric power system operation (assuming onsite power is not available) the system safety function can be accomplished, assuming a single failure.

Design Evaluation

If there is a LOCA, the pressure-suppression system rapidly condenses the steam to prevent containment overpressure. The containment feature of pressure-suppression employs two separate compartmented sections of the primary containment: the drywell that houses the nuclear system and the suppression chamber containing a large volume of water. Any increase in pressure in the drywell from a leak in the nuclear system is relieved below the surface of the suppression chamber water pool by connecting vent lines. The pressure buildup in the suppression chamber is equalized with the drywell by a vent line and vacuum breaker arrangement. Cooling systems remove heat from the reactor core, the drywell, and from the water in the suppression chamber during an accident condition; thus, continuous cooling of the primary containment is provided.

Sufficient water is provided in the suppression pool to accommodate the initial energy that can be transiently released into the drywell from a postulated pipe failure.

The suppression chamber is sized to contain this water plus the water displaced from the reactor primary system, together with the free air initially contained in the drywell.

The containment heat removal function is accomplished by the containment cooling mode of the RHR system. This mode consists of the suppression pool cooling subsystem and the containment spray subsystem.

Either or both RHR heat exchangers can be manually activated to remove energy from the containment. The redundancy and capability of the offsite and onsite electrical power systems for the RHR system, discussed in the evaluation against GDC 34, ensure that the system safety function can be accomplished, assuming there is a single failure, for onsite electric power system operation (assuming that offsite power is not available) and for offsite electric power system operation (assuming that onsite power is not available).

The pressure-suppression system is capable of rapid containment pressure and temperature reduction following a LOCA to ensure that the design limits are not exceeded. Redundant offsite and onsite electrical power systems are provided. The design of the containment heat removal system meets the requirements of GDC 38. Referenced sections are as follows:

a. Component and subsystem design Section 5.4

b.	Containment systems	Section 6.2
c.	ECCS	Section 6.3
d.	ESF systems	Section 7.3
e.	Electric power systems	Chapter 8
f.	Auxiliary systems	Chapter 9
g.	Accident analyses	Chapter 15

GDC 39 - Inspection of Containment Heat Removal System

The containment heat removal system shall be designed to permit appropriate periodic inspection of important components, such as torus, sumps, spray nozzles, and piping, to assure the integrity and capability of the system.

Design Evaluation

Provisions are made to facilitate periodic inspections of active components and other important equipment of the containment pressure-reducing systems. During plant operations, the pumps, valves, piping, instrumentation, wiring, and other components outside the primary containment can be periodically visually inspected. Components inside the primary containment can be inspected when the drywell is open for access. The testing frequencies of most components are correlated with the component inspection.

The pressure-suppression chamber is designed to permit appropriate periodic inspection. Space is provided inside the chamber for inspection and maintenance. There are two hatches that permit access to the suppression chamber for inspection.

The containment heat removal system is designed to permit periodic inspection of major components both outside and within the primary containment. This design meets the requirements of GDC 39. Referenced sections are as follows:

a.	Component and subsystem design	Section 5.4
b.	Containment systems	Section 6.2
c.	ECCS	Section 6.3
d.	Water systems	Section 9.2

GDC 40 - Testing of Containment Heat Removal System

The containment heat removal system shall be designed to permit appropriate periodic pressure and functional testing to assure 1) the structural and leak-tight integrity of its components, 2) the operability and performance of the active components of the system, and 3) the operability of the system as a whole and, under conditions as close to the design as practical, the performance of the full operational sequence that brings the system into

operation, including operation of applicable portions of the protection system, the transfer between normal and emergency power sources, and the operation of the associated cooling water system.

Design Evaluation

The containment heat removal function is accomplished by the containment cooling mode of the RHR system. This mode consists of the suppression pool cooling subsystem and containment spray subsystem.

The RHR system is provided with sufficient test connections and isolation valves to permit periodic pressure and flow rate testing.

The pumps and valves of the RHR system can be operated periodically to verify operability. The containment cooling mode is not automatically initiated, but operation of the components can be periodically verified. The operation of associated cooling water systems is discussed in the conformance to GDC 46. It is concluded that the requirements of GDC 40 are met.

GDC 41 - Containment Atmosphere Cleanup

Systems to control fission products, hydrogen, oxygen, and other substances which may be released into the reactor containment shall be provided as necessary to reduce, consistent with the functioning of other associated systems, the concentration and quantity of fission products released to the environment following postulated accidents and to control the concentration of hydrogen or oxygen and other substances in the containment atmosphere following postulated accidents to assure that containment integrity is maintained. Each system shall have suitable redundancy in components and features and suitable interconnections, leak detection, isolation, and containment capabilities to assure that, for onsite electric power system operation (assuming offsite power is not available) and for offsite electric power system operation (assuming onsite power is not available), its safety function can be accomplished, assuming a single failure.

Design Evaluation

Fission products released into the secondary containment following postulated accidents are automatically processed by the RERS and/or the SGTS. Initiation of the SGTS and RERS follows high radiation signals from monitors located in the reactor enclosure exhaust ducts, a high drywell pressure signal, or a low reactor level signal. Initiation of the SGTS follows a high radiation signal from monitors in the refueling area exhaust ducts.

The ability of these systems to remove radioactivity from the process stream is discussed in Section 6.5. The SGTS and RERS are each composed of two trains that are separated physically and electrically so that a single failure does not prevent their function, except as described in Table 6.5-2. The redundancy of these systems is also discussed in Section 6.5.3.

A combustible gas control system consisting of redundant hydrogen recombiners maintains hydrogen and oxygen concentrations below flammable limits following a postulated LOCA. The system continuously processes the primary containment atmosphere following manual initiation. As a backup to the combustible gas control system, the containment atmosphere can be purged through the SGTS filters to the turbine enclosure north vent stack. A detailed description is provided in Section 6.2.5.

The SGTS, RERS, and the combustible gas control system meet the requirements of GDC 41 except as described above.

The containment atmospheric cleanup systems are connected to the safeguard buses. The design of the safeguard buses, as described in the evaluation for GDC 17, ensures that the containment atmospheric cleanup function can be provided, assuming a single failure, when onsite electric power is available (assuming that offsite power is not available) and when offsite electric power is available (assuming that onsite power is not available).

GDC 42 - Inspection of Containment Atmosphere Cleanup Systems

> The containment atmosphere cleanup systems shall be designed to permit appropriate periodic inspection of important components, such as filter frames, ducts, and piping, to assure the integrity and capability of the systems.

Design Evaluation

Inspection of the internal structure of the SGTS and RERS filter banks is facilitated by access doors installed in each unit to allow entry to the unit for visual inspection of structural members and filter faces.

The charcoal beds are provided with removable canisters for taking charcoal samples.

For a further discussion of the SGTS and RERS inspection features, see Section 6.5.

All active components of the combustible gas control system are located externally to the primary containment and are accessible for inspection during normal operation of the plant. For a discussion of inspection, see Section 6.5.

The design of the containment atmosphere cleanup systems meets the requirements of GDC 42.

GDC 43 - Testing of Containment Atmosphere Cleanup Systems

> The containment atmosphere cleanup systems shall be designed to permit appropriate periodic pressure and functional testing to assure 1) the structural and leak-tight integrity of its components, 2) the operability and performance of the active components of the systems such as fans, filters, dampers, and valves, and 3) the operability of the systems as a whole and, under conditions as close to design as practical, the performance of the full operational sequence that brings the system into operation, including operation of applicable portions of the protection system, the transfer between normal and emergency power sources, and the operation of associated systems.

Design Evaluation

Each unit of the SGTS and the RERS is operated periodically to ascertain the operability and performance of the major active components, such as fans, filters, motors, pumps, and valves, as well as the structural integrity of the unit. This test verifies the operability of the system as a whole and the operability of all associated subsystems. See Section 8.3.1 for a discussion of the testing of the auxiliary power system.

The leak-tightness of the HEPA filters is measured by the DOP test. A halogenated hydrocarbon refrigerant system is provided to test the activated charcoal filters. For a further discussion of testing, see Section 6.5. Each loop of the combustible gas control system is designed for periodic pressure and operability testing. For a further discussion of testing, see Section 6.5.

The design of the containment atmosphere cleanup systems meets the requirements of GDC 43.

GDC 44 - Cooling Water
